While datasets such as LAMBADA are an invaluable resource for monitoring high-level progress of LMs in their ability to track discourse entities, such datasets lack the granularity to determine for which contexts LMs can and cannot properly track discourse entities. In this work, we draw inspiration from recent targeted evaluation suites geared at lower linguistic levels (e.g., Marvin and Linzen, 2018; Hu et al., 2020b), and introduce a targeted evaluation suite for tracking of discourse entities in English. In particular, we focus on the interactions between different sentential operators and embedding verbs and indefinite noun phrases (see, e.g., Karttunen 1976 and Section 3); for example, we evaluate whether a language model correctly infers that because a sentence with a negation, such as *Arthur* ***doesn't*** *own a dog*, does not introduce a dis-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 969 - 982
July 10-15, 2022 ©2022 Association for Computational Linguistics

course entity for a dog, further elaborations about such a non-existent dog should be pragmatically odd, and, as such, their probability should be low compared to matched controls.

To evaluate to what extent language models are sensitive to these interactions, we adapt the psycholinguistic assessment of language models paradigm (Futrell et al., 2019) for discourse entity tracking and discuss the methodological challenges that arise with using this paradigm for discourse phenomena. We introduce two expert-created evaluation suites and use them to evaluate GPT-2 and GPT-3 models. We find that while all the models we evaluated show some sensitivity to preceding context, they lack systematicity and are challenged when contexts contain multiple noun phrases.[1]

2 Related Work

The majority of systematic evaluations of autoregressive and masked language models so far have focused on the level of syntax, targeting abilities such as subject-verb agreement (e.g., Linzen et al., 2016; Marvin and Linzen, 2018; Gulordava et al., 2018; Hu et al., 2020b), anaphora agreement and binding constraints (e.g., Marvin and Linzen, 2018; Futrell et al., 2019; Warstadt et al., 2020; Hu et al., 2020a), or filler-gap dependencies (e.g., Wilcox et al., 2018; Chowdhury and Zamparelli, 2018; Da Costa and Chaves, 2020). At higher linguistic levels, Ettinger (2020) compared BERT's (Devlin et al., 2019) behavior on sentences with negation to data from neurolinguistic experiments with humans; Pandia and Ettinger (2021) investigated to what extent pre-trained language models can extract relevant information from the preceding context, both in the presence and in the absence of distractors; and Pandia et al. (2021) investigated whether language models can predict connectives (e.g., *but*) for two given sentences.

More closely related to our work, in the domain of discourse and reference, Upadhye et al. (2020) investigated whether GPT-2 and Transformer-XL (Dai et al., 2019) exhibit similar referential biases in their continuations as humans, i.e., they asked whether models provided with a sentence with two referents are biased similarly as humans when choosing the referent for the next sentence. Kim et al. (2019) used an acceptability judgment task to determine whether contextual LMs correctly distinguish between definite and indefinite noun phrases.

Sorodoc et al. (2020) and Tenney et al. (2019) used probing methods to investigate whether representations of LSTM- and Transfomer-based models contain information about coreference, which also provides some indication of entity tracking abilities. Further, Clark et al. (2019) investigated to what extent attention weights of BERT indicate coreference. These studies found that all evaluated representations contain some information about coreference but not consistently for all entities.

3 Background

English indefinite noun phrases (NPs) of the form *a NOUN* interact with the context in complex ways (see, e.g., Karttunen, 1976; Webber, 1979; Heim, 1982, for more extensive discussions of this phenomenon). In affirmative statements, the indefinite NP generally introduces a new entity to the discourse. However, several sentential operators and clause-embedding verbs modulate this behavior. For example, consider the following contrast between an affirmative and a negated sentence, where # indicates a pragmatically odd continuation:

(1) a. Arthur owns a dog and it follows him everywhere he goes.
b. Arthur doesn't own a dog and # it follows him everywhere he goes.

While in the affirmative sentence, the indefinite NP introduces a novel discourse entity, the negation in (1b) prevents the NP from introducing a new entity. In (1b), it is therefore pragmatically odd to refer back to *a dog* with the pronoun *it*.

The implicative *manage to* and the negative implicative *fail to* in (2a-b) give rise to a similar contrast: The NP under *manage to* introduces a discourse entity, the NP under *fail to* does not.

(2) a. Sue managed to write a book. It was a real page-turner.
b. Sue failed to write a book. # It was a real page-turner.

Indefinite NPs embedded under the factive *know* and the non-factive *doubt* introduce and fail to introduce a discourse entity, respectively:

(3) a. I know that Michael baked a cake. It was delicious.
b. I doubt that Michael baked a cake. # It was delicious.

---

[1] Our evaluation suites along with the results from human experiments and all code for model evaluation is available at `https://github.com/sebschu/discourse-entity-lm`.

Lastly, modals such as *want* also block the introduction of a discourse entity, as shown in (4):

(4) a. Mary got a pet rat and it is very loud at night.
  b. Mary wants to get a pet rat and # it is very loud at night.

While these patterns generally hold, there are exceptions to these rules. For example, in the first sentence in (5), which could be paraphrased as (6), the indefinite scopes over the negation and therefore it is okay to refer back to the mistake.

(5) Mary didn't find a (specific) mistake. It was in the footnote.

(6) There was a (specific) mistake which Mary did not find. It was in the footnote.

However, without additional context, listeners generally do not infer these so-called specific interpretations of sentences with an indefinite NP, so like Karttunen (1976), we will largely ignore these cases throughout the remainder of this paper.

4 Experiments

To what extent are GPT-2 and GPT-3 sensitive to the contrasts that we presented in Section 3? To investigate this question, we adapted the methodology commonly used for syntactic evaluation of language models (e.g., Futrell et al., 2019) and created minimal pairs of contexts that differ in whether they introduce a discourse entity or not. In Experiment 1, we focus on contexts with a single indefinite NP, and in Experiment 2, we focus on sentences with multiple indefinite NPs.

4.1 Experiment 1

Methodology If a language model is sensitive to contexts that differ in whether a discourse entity is introduced or not, we expect the probability of continuations that refer back to the noun phrase in the previous context to be higher when a discourse entity has been introduced than when it has not. Thus, if we have a pair of sentences, such as

(7) a. C_{ref}: John owns a dog.
  b. C_{nonref}: John doesn't own a dog.

and a referential continuation,[2] such as

(8) R: It has a red collar.

then we expect that

$$P(R \mid C_{ref}) > P(R \mid C_{nonref}).$$

However, directly comparing these probabilities may be problematic given that $P(X \mid C_{ref})$ and $P(X \mid C_{nonref})$ are different probability distributions. In theory it could be, for example, that $P(X \mid C_{ref})$ assigns a very high probability to exactly one continuation and therefore its entropy is lower than the entropy of $P(X \mid C_{nonref})$. In this case, it could be that the inequality above does not hold despite the fact that continuations that refer back to the noun phrase in the previous context are ranked higher in the affirmative than in the negated case. To overcome this issue, we make use of a non-referential control continuation, such as N:

(9) N: It is not a big deal.

This continuation no longer refers back to a noun phrase and is therefore a valid continuation for both contexts. Instead of using the inequality above, we thus compare the relative probabilities of the referential and the control continuations:

$$\begin{aligned} &\frac{P(R \mid C_{ref})}{P(R \mid C_{ref}) + P(N \mid C_{ref})} \\ > \; &\frac{P(R \mid C_{nonref})}{P(R \mid C_{nonref}) + P(N \mid C_{nonref})} \end{aligned} \tag{1}$$

These relative probabilities are less sensitive to the entropy of the distribution: If there is a highly likely continuation (that is neither the referential nor the control continuation) for one context but not the other, the model should still assign relatively less probability mass to the referential continuation compared to the control continuation.

Models We evaluate two autoregressive language models,[3] GPT-2 and GPT-3. GPT-2 models were trained on the WebText corpus which contains an estimated 8 billion tokens; GPT-3 models were trained on about 500 billion tokens. For GPT-2,

---

[2] The psycholinguistic assessment of language models paradigm generally focuses on the probability of individual words rather than sequences to evaluate syntactic phenomena. However, considering that the coreference of *it* (or other referential expressions) is modulated by an entire sentence or clause (see the contrast between (8) and (9), which both contain the pronoun *it*), we compare probabilities of sequences.

[3] We selected these autoregressive models instead of masked language models (MLMs) such as BERT (Devlin et al., 2019) because they are more frequently used to generate texts, and discourse abilities such as entity tracking tend to play a more crucial role in generating text than in classification or span extraction tasks for which MLMs are more frequently used.

we evaluate models of four different sizes (GPT-2: 117M parameters, GPT-2 M: 345M, GPT-2 L: 762M, GPT-2 XL: 1.5B) that are available through the HuggingFace Transformers library (Wolf et al., 2020). For GPT-3, we evaluate the largest available model ("davinci") through the OpenAI API which is assumed to have about 175B parameters.[4]

Materials We manually constructed an evaluation set of 16 base contexts and plausible continuations. Each base context contains different nouns and verbs to minimize lexical effects. From these 16 contexts, we constructed four contrasts for each context, as shown in Table 1, which in total yielded 64 items. We chose to manually construct contexts as opposed to generating sentences from a grammar to guarantee semantic and pragmatic well-formedness of contexts and continuations.

Human evaluation As we mentioned in Section 3, the referential continuations are not necessarily pragmatically odd if the indefinite noun phrase in the context is interpreted as a specific noun phrase. We therefore conducted an online experiment on Prolific to verify that native English speakers disprefer the referential continuations when no discourse entity is introduced, as follows. After two practice items, each participant performed two trials with sentences from the evaluation set. On each trial, participants saw a context along with a referential and a non-referential continuation, and they were asked to indicate their preferred continuation by selecting the continuation that "makes more sense" given the context. For each context, we collected preference judgments from 10 participants. The experiment took on average about 2 minutes to complete and participants received \$0.45 in compensation (∼\$14/hr).

Results and discussion Figure 1 shows the proportion of items for which the relative probability of the referential continuation (RRP) is higher for the context that introduces a discourse entity (DEC) than for the context that does not (NDEC), i.e., the proportion of items for which Eq. 1 holds. For three of the four contrasts (*affirmative-negation*, *affirmative-modal*, *managed-failed*) GPT-2 and GPT-3 models exhibited the expected pattern for almost all items in our evaluation set. For the *know-doubt* contrast, however, all models performed approximately at chance, suggesting that the models are not sensitive to this contrast.

Figure 1 also shows the results of the human experiment. Participants preferred the referential continuation more following the DECs than following the NDECs for all items of the *affirmative-negation* and *managed-failed* contrasts. Further, for these two contrasts, participants overwhelmingly selected the referential continuation for the DECs and the non-referential continuation for the NDECs. This result confirms that the stimuli bring about the theoretically expected contrast in humans.

For the *affirmative-modal* and the *know-doubt* contrasts, the results from human participants are less clear-cut. Overall, participants also preferred the referential continuation more in the DECs than in the NDECs. However, for several items, the opposite was the case and the referential continuation was preferred as much or even more in the NDECs than in the DECs. Moreover, unlike in the other two contrasts, participants selected the referential continuation in the NDECs at a high rate.[5]

Considering that the results from the human experiment are not predicted by Karttunen's theory, the model results from the *affirmative-modal* and the *know-doubt* contrast should also be interpreted with caution. However, while the lower proportion of expected relative probabilities in the *know-doubt* condition may suggest that the models are behaving similarly to humans, this is not the case. If one considers the results on an item-by-item basis, they differ from the human results and there is a lot of variability across models such that the five models agree only on less than 33% of items.

In summary, GPT-2 and GPT-3 overall behaved similarly to humans and generally favored the referential continuation more when the preceding sen-

---

[4] The model size of GPT-3 is not publicly available but the EleutherAI project estimated the model size by comparing the performance of the models available through the API to published results: `https://blog.eleuther.ai/gpt3-model-sizes/`.

[5] For contexts with modals, some participants commented that they selected the referential continuation because they assumed that the past tense of the continuation was a grammatical mistake. That is, if the tense had been different, the continuation would have been sensible. For example, for the context *Michael wants to bake a cake* the continuation *and it* ***will be*** *the best thing at the picnic* is acceptable and differs from the continuation that was presented in the experiment, *and it was the best thing at the picnic*, only in its tense.

For contexts with *doubt*, participants frequently seemed to interpret the referential continuation as a reason for the doubt. For example, for the context *I doubt that Carla got a pet rat.*, participants frequently chose the referential continuation *It is very noisy at night.*, presumably because they considered that the rat being noisy made it unlikely that Carla would have got it.

Contrast	Contexts	Referential continuation	Non-referential continuation
affirmative-negation	Michael baked a cake Michael didn't bake a cake	and it was the best thing at the picnic.	and it's not a big deal.
affirmative-modal	Michael baked a cake Michael wants to bake a cake	and it was the best thing at the picnic.	and it's not a big deal.
know-doubt	I know that Michael baked a cake. I doubt that Michael baked a cake.	It was the best thing at the picnic.	It's not a big deal.
managed-failed	Michael managed to bake a cake. Michael failed to bake a cake.	It was the best thing at the picnic.	It's not a big deal.

Table 1: Example contexts and continuations for one base context in Experiment 1.

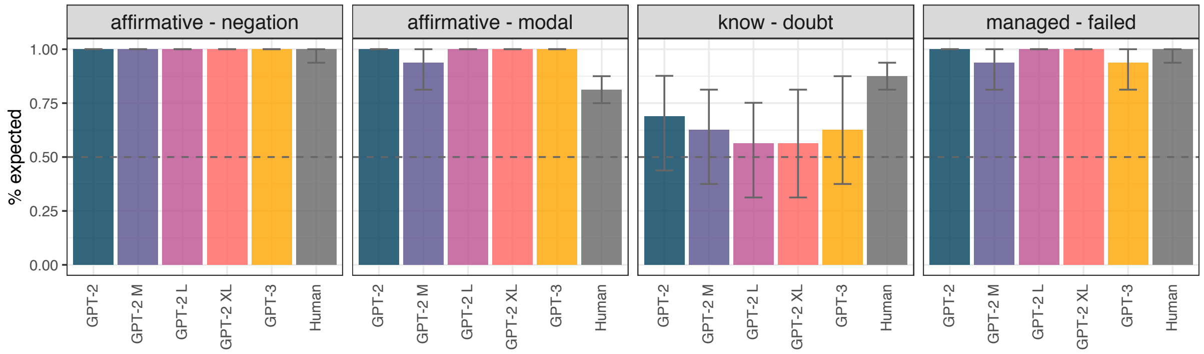

Figure 1: Results from Experiment 1. Each bar indicates the proportion of items for which the relative probability of the referential continuation (RRP) is higher for the context that introduces a discourse entity than for the context that does not, i.e., the expected pattern. Dashed lines indicate chance performance levels, and error bars indicate bootstrapped 95% confidence intervals.

tence introduced a discourse entity. This behavior could be due to at least the following two reasons. It could be that the models indeed correctly combine the sentential operators with the indefinite noun phrase and therefore assign a higher probability to a referential continuation in the DECs. However, it could also be that this result is due to more spurious correlations; for example, it could be that the model learned that clauses with operators such as negation, modals, or negative implicatives are often followed by clauses with a non-referential *it*. In the second experiment, we tease apart these two explanations and further try to overcome the issues with the stimuli that we observed for the *affirmative-modal* and *know-doubt* contrasts.

4.2 Experiment 2

Materials and method We again constructed 16 base contexts that are similar to the ones used in Experiment 1. However, in this experiment, each context contains two indefinite noun phrases with different nouns that are embedded under two different sentential operators. For example, for the *affirmative-negation* contrast, one of the NPs is embedded under negation, such as *a cat* in (10).

(10) John owns a dog but he doesn't own a cat.

In such a context, it is natural to continue with a sentence that refers back to the dog, whereas it is unnatural to refer back to a cat. We therefore compared the models' probability of a sentence that refers back to an entity that has been introduced in the context (11a) to a sentence that refers to an entity that has not been introduced (11b).

(11) a. The dog follows him wherever he goes.
b. # The cat follows him wherever he goes.

On top of these coreferential continuations, we also constructed non-coreferential continuations for contexts such as (10). These continuations contain one of the nouns present in the context but do not refer back to entities in the previous context. For the non-coreferential continuations, models should assign a higher probability to the continuation with a noun for which no discourse entity had been introduced in the context.

(12) a. The cat that he liked had been adopted by someone else.

Context	Coreferential continuations	Non-coreferential continuations
Mary found a shirt at the store but she didn't find a hat.	The shirt/#hat is blue.	The hat/#shirt that she tried on didn't fit.
Mary found a hat at the store but she didn't find a shirt.	The hat/#shirt is blue.	The shirt/#hat that she tried on didn't fit.
Mary didn't find a shirt at the store but she found a hat.	The hat/#shirt is blue.	The shirt/#hat that she tried on didn't fit.
Mary didn't find a hat at the store but she found a shirt.	The shirt/#hat is blue.	The hat/#shirt that she tried on didn't fit.

Table 2: Example contexts and continuations for the *affirmative-negation* contrast for one base context.

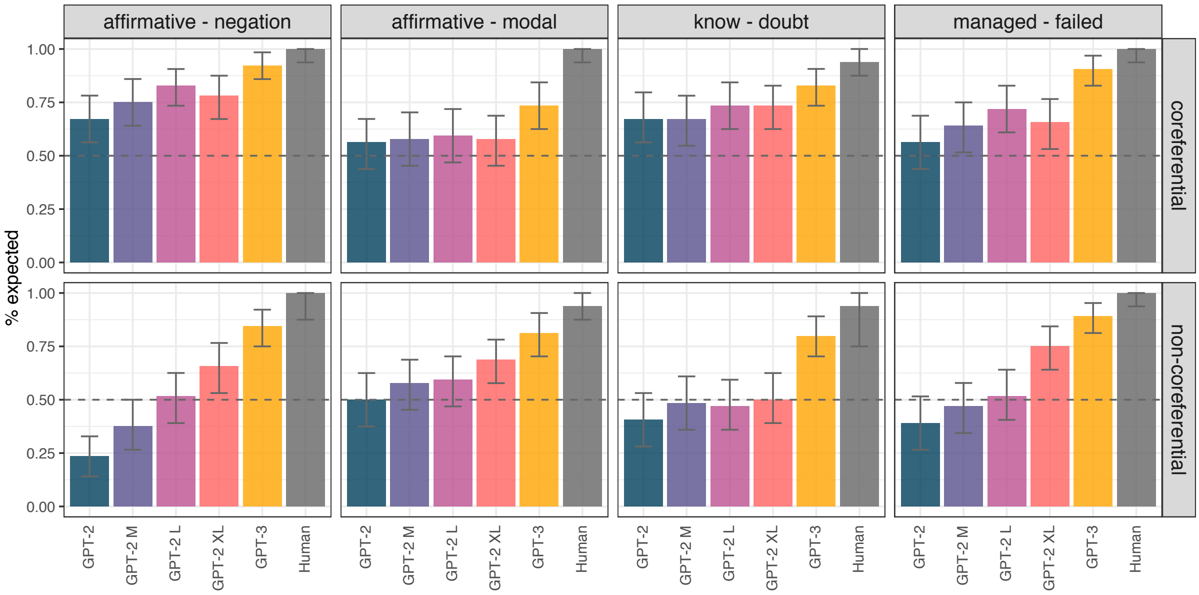

Figure 2: Results from Experiment 2. Dashed lines indicate chance performance levels.

b. # The dog that he liked had been adopted by someone else.

For each of the four contrasts and each base context, we constructed four contexts that crossed the order of the sentential operators and the order of the two nouns used in a context, resulting in 4 contexts per base context and contrast. For each base context, we further constructed two coreferential continuations (one for each noun) and two non-coreferential continuations (one for each noun). In total, this yielded 512 items. Table 2 shows all the contexts and continuations for one base context for the *affirmative-negation* contrast.

Compared to the methods and materials in Experiment 1, this setup has several advantages. First, given that we are comparing two continuations for a fixed context, both continuations come from the same probability distribution and therefore we no longer need a generic control continuation. Second, it is less likely that models can make use of spurious correlations since each context contains two types of sentential operators and, for example, a heuristic of associating negation with non-referential *it* would no longer lead to the expected behavior. Third, given that all continuations are on topic (as opposed to the generic control condition in Experiment 1), humans likely show more consistency in their preferences. Lastly, given that this design allows us to construct stimuli with exactly the same tokens in different orders, we can also assess the systematicity of the model behavior.

We again verified the theoretically predicted preferences in a human experiment.[6]

Results and discussion Figure 2 shows the accuracy of the model and human experiments for the coreferential and non-coreferential continuations. As this figure shows, humans exhibited the theoretically expected behavior for all contrasts for almost all items and chose the coreferential continuation with the noun for which an entity had been introduced in the context, and chose the non-coreferential continuation for the noun for which no entity had been introduced. This suggests that the materials do not exhibit the same shortcomings

---

[6] For practical reasons, we included two items from this experiment in the first human experiment. To rule out interference between similar items, no two items within the same experimental list were derived from the same base context.

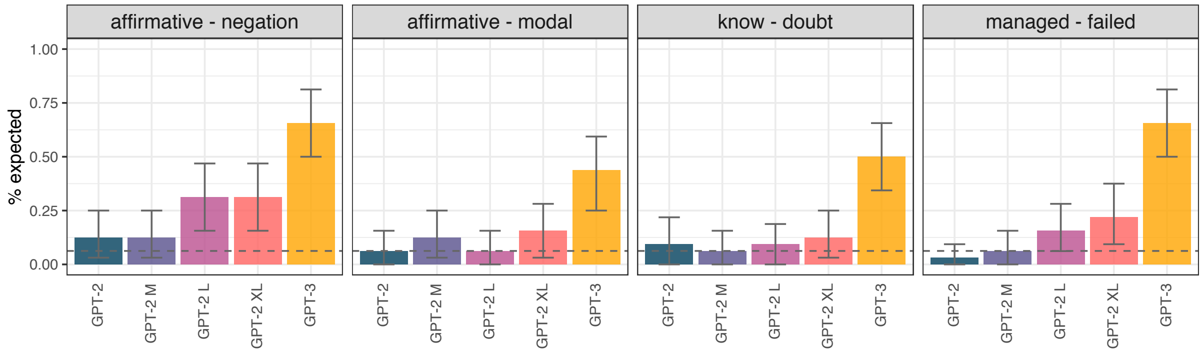

Figure 3: Systematicity of model behavior in Experiment 2. An item counts as correct if all four orders of noun phrases and sentential operators (e.g., *X owns a A but doesn't own a B*; *X owns a B but doesn't own a A*; *X doesn't own a A but owns a B*; and *X doesn't own a B but owns a A*) lead to the correct result. The dashed line indicates chance performance and the error bars indicate bootstrapped 95% confidence intervals.

as in Experiment 1, and that comparisons of models to human behavior are valid for all four contrasts.

If we turn to the model results, there is more variability in performance across models and contrasts. For the coreferential continuations, all models except the smallest GPT-2 model performed above chance for three of the four contrasts. For the *affirmative-modal* contrast, however, only GPT-3 performed significantly above chance. Moreover, all GPT-2 models perform worse for the non-coreferential continuations.

More generally, unlike humans, all models in this experiment performed below ceiling, which suggests that while models exhibit a tendency to choose the right continuation, they do not reliably do so. Further, model size does have an impact on the performance on this task: The smallest GPT-2 model performed consistently worst, and GPT-3 performed consistently best. This dependence on model size is particularly pronounced in the non-coreferential condition: While GPT-3 consistently performed above chance in all contrasts, most smaller models either performed at chance or in some cases, such as the smallest GPT-2 for the items in the *affirmative-negation* contrast, had a bias to select the non-coreferential continuation with the noun that introduced a discourse entity in the context. The lower performance for the non-coreferential continuations is not surprising given that for these examples, a model not only has to correctly infer which noun phrase introduces a discourse entity but additionally that the noun phrase in the continuation does not refer back to anything in the preceding context.

Systematicity As mentioned above, this experimental design also allows us to assess how sensitive the behavior of the different models is to the different orders of sentential operators and nouns in the context. Figure 3 shows the proportion of items for which the model exhibited the expected behavior for all four possible orders. Overall, the performance of all models according to this stricter criterion is much lower than the simple by-item measure highlighting that even the predictions by GPT-3 are sensitive to the exact combination and order of sentential operators and nouns. However, there once again is a clear trend that larger models behave more systematically than smaller ones, suggesting that larger models and models trained on more data learn more stable generalizations. This trend is in part driven by smaller models being less sensitive to the preceding context: The two smallest GPT-2 models assigned the highest probability to the continuation with one of the two nouns independent of the combination of sentential operators and nouns in the context in 52.3% and 43.8% of the cases, respectively. That is, for all four contexts, as shown for one example in Table 2, the smallest GPT-2 model assigned a higher probability to the same continuation independent of which noun phrase introduced a discourse entity more than half of the time. GPT-3, on the other hand, only exhibited this behavior for 7% of the items.

In summary, the results from Experiment 2 suggest that GPT-2 and GPT-3 are less reliable in determining whether an NP introduces a discourse entity when multiple NPs are present. This is in particular true for smaller GPT-2 models but if one considers systematicity, the predictions of GPT-3 are also sensitive to minor changes in the context.

5 Likely Continuations

One drawback of the methodology of the previous two experiments is that we considered only one specific expected and one specific unexpected continuation for each item. Thus, if both the expected and the unexpected continuations are very unlikely according to the LM, we may see poor performance on this task while at the same time, it would be very unlikely that either of the generations is ever sampled from the model. In that case, the evaluations in Experiment 2 may underestimate the models' abilities (Newman et al., 2021) and the results may not be very relevant for practical purposes for which one uses an LM to generate texts. For this reason, we also performed a manual analysis of randomly sampled generations (Aina and Linzen, 2021) from the two largest LMs, GPT-2 XL and GPT-3.

Materials and method We used the contexts from Experiment 2 as prompts for the two LMs and for each context, we sampled a sentence beginning with *the*.[7] For GPT-2 XL, we sampled the continuations using top-40 sampling as in Radford et al. (2019). For GPT-3, we used the default temperature sampling with a temperature of 0.7.

A graduate student in linguistics who was blind to the purpose of this study then annotated each of the continuations for whether it contained referring expressions that likely referred back to a noun phrase in the context as well as which noun phrase(s) (the discourse entity introducing and/or the non-discourse entity introducing NP) were referred back to. To illustrate this, consider the following two generations by GPT-3:

(13) a. Carolyn didn't write a card to her parents but she wrote them a letter. The **letter was long and filled with many details about the cruise.**

b. Chris managed to knit a hat but failed to knit a bag. The **bag is not stuffed.**

In (13a), *the letter* refers back to an entity introduced in the context, whereas in (13b), *the bag* refers back to the NP that does not introduce a discourse entity. If a language model is able to correctly combine sentential operators with indefinite noun phrases, we expect many continuations as in (13a) and no continuations as in (13b).

Model	DE	NDE
GPT-2 XL	43.8	22.3
GPT-3	52.3	21.1

Table 3: Percentage of expressions in model generations that refer back to noun phrases that introduce (DE) or do not introduce a discourse entity (NDE).

Results and discussion Table 3 shows the percentages of expressions in model generations that refer back to noun phrases in the prompt. These results confirm the findings from Experiment 2: Both GPT-2 XL and GPT-3 are to some extent sensitive to the interactions between sentential operators and indefinite NPs as indicated by the higher proportion of expressions referring back to NPs that introduce discourse entities (DE) as compared to referring back to NPs that do not (NDE). At the same time, however, both models produced more than 20% of continuations with expressions that refer back to an NP that did not introduce an entity, which shows that the results from Experiment 2 also apply to likely generations by LMs.

6 General Discussion

In his seminal work in 1976, Karttunen introduced several challenges for natural language understanding systems that aim to track which entities are introduced in a larger discourse. In this work, we evaluated to what extent we made progress on these challenges in the past decades. In two sets of experiments, we found that Transformer-based models are to some extent sensitive to different interactions between sentential operators and indefinite noun phrases. At the same time, however, we found in Experiment 2 that models lack systematicity in their behavior, which suggests that models do not combine indefinite noun phrases and sentential operators as humans do. Further, the analysis of likely continuations showed that this behavior can also be observed in high probability generations.

Learnability of meaning On the one hand, these results provide direct evidence for shortcomings of language models with respect to tracking entities. On the other hand, more broadly, these results also provide interesting data points with regard to the recent debate on whether language models could theoretically mimic human language understanding.

---

[7] As compared to just using the context as a prompt, constraining the continuation to start with *the* led to considerably more continuations with noun phrases referring back to a noun phrase in the context while still putting very few constraints on the overall continuation.

Bender and Koller (2020) recently presented several thought experiments and argued that since LMs are only trained on form and do not have access to meaning or intentions, they can never exhibit human-like language understanding (see also Merrill et al., 2021, for a more formal discussion of this claim). Given that we evaluated the largest available GPT-3 model and still found that the model behavior is inconsistent despite its enormous amount of parameters and training data, our results suggest that at least current language model architectures indeed struggle with human-like understanding. Interestingly though, while the thought experiments by Bender and Koller (2020) focus on lack of world knowledge due to the lack of grounding of language models, our results suggest that additionally, language models fail at learning the meaning of more abstract words such as negation markers or embedding verbs. This is also in line with recent results, which showed that smaller models fail to learn the meaning of negation and discourse connectives. (Ettinger, 2020; Pandia et al., 2021). Lastly, the fact that GPT-2 and GPT-3 have been exposed to orders of magnitude more language data than human learners are and still do not fully succeed at tracking discourse entities underscores that there are differences between how humans and LMs learn.

NLG evaluation We further believe that evaluation suites targeting discourse phenomena, such as the ones presented here, can serve a complementary role to natural language generation (NLG) benchmarks (e.g., Gehrmann et al., 2021) and human studies for evaluating NLG systems. This seems particularly relevant considering that Clark et al. (2021) recently found that untrained crowdworkers, who serve as participants in the majority of human evaluation studies, cannot distinguish between stories written by humans and stories generated by GPT-3. Our experiments, however, show that there is a considerable gap between humans and GPT-3 for basic discourse phenomena, and therefore targeted evaluation suites should be an important measure for tracking progress of NLG models.

Comparison to probing results Recently, Li et al. (2021) developed a probe for investigating whether LM representations provide information about the state of entities at various stages in a larger discourse. This probing method–like the ones presented in this work–also aims to assess entity tracking abilities of pre-trained language models. They considered two sequence-to-sequence models, T5 and BERT, and found that representations from both models can be decoded into entity states with high accuracy. This task may seem more complex than the one used in the experiments above, and T5 and BERT are considerably smaller models than GPT-3, so prima facie, it may be surprising that their results suggest superior discourse abilities than our results. However, there are two important differences in methodology that likely explain this discrepancy. First, the probing classifier was trained on data that was similar to the evaluation data and this setup therefore provided a lot of supervision. Second, the datasets used by Li et al. (2021) were obtained through crowdsourcing or a generation engine and were not constructed as systematically as ours. For these reasons, the probing classifier may have learned spurious correlations between the training and test splits, and the high accuracy on the task may have only in part been driven by entity tracking abilities of LMs.

Potential solutions Considering the still modest performance of GPT-3, it seems unlikely that training models on even more data is going to lead to human-like discourse entity processing by language models. Instead, we consider the following modifications to models to likely lead to more systematic entity tracking. First, there have been some successes in augmenting language models with explicit entity memory representations (e.g., Weston et al., 2014; Sukhbaatar et al., 2015; Rashkin et al., 2020; Cheng and Erk, 2020), and likely such architectural changes could also help in the contexts that we evaluated in this work. Second, considering that the models seem to struggle to learn the meaning of sentential operators, it may be necessary to provide additional supervision, for example using treebanks annotated with meaning representations, such as the Groningen Meaning Bank (Bos et al., 2017). Relatedly, models may also benefit from more grounded learning scenarios. Humans likely differentiate between *Arthur owns a dog* and *Arthur doesn't own a dog* because only in the former case, *a dog* refers to something in the real world and if a model was immersed in more grounded scenarios it would likely be able to infer this difference.

We hope that our evaluation suite will be a valuable resource for assessing progress of future models such as the ones sketched above, and that it will help pave the way for improved discourse entity processing in NLU systems.

Ethics Statement

Risks, limitations, and intended use We consider the main risk of this work that the evaluation suite may be used to make overstating claims about model abilities in the future. In particular, should future models achieve very high or even perfect accuracy on the evaluation suite, then such results may be seen as evidence of human-like abilities of discourse entity processing. We therefore want to emphasize that achieving high accuracy on this evaluation suite is a necessary but not necessarily sufficient requirement for a model to exhibit human-like entity tracking abilities.

Further, it seems likely that models fine-tuned on similar examples would perform a lot better on this evaluation suite, and therefore researchers should only use this dataset for out-of-domain evaluations in which the model has not been trained on similar examples.

Finally, we only evaluated models trained on English data in this work and it is conceivable that entity tracking abilities of models trained on other languages differ from the results reported here.

Human subject experiments As we mentioned in Section 4.1, we recruited crowdworkers from Prolific to validate the experimental stimuli. Participants were based in the US and on average received compensation of about $14/hour, which is almost twice the minimum wage in most states in the US. The experiment has been pre-approved by the New York University IRB, and there were no risks associated with participation.

Acknowledgments

We thank the members of the NYU Computation and Psycholinguistics Lab and the NYU Semantics Group, and the reviewers for their thoughtful feedback. We also thank Alicia Chatten for doing the annotations of the model generations. On Curriculum Learning for Commonsense Reasoning

Adyasha Maharana **Mohit Bansal**
Department of Computer Science
University of North Carolina at Chapel Hill

Abstract

Commonsense reasoning tasks follow a standard paradigm of finetuning pretrained language models on the target task data, where samples are introduced to the model in a random order during training. However, recent research suggests that data order can have a significant impact on the performance of finetuned models for natural language understanding. Hence, we examine the effect of a human-like easy-to-difficult curriculum during finetuning of language models for commonsense reasoning tasks. We use paced curriculum learning to rank data and sample training mini-batches with increasing levels of difficulty from the ranked dataset during finetuning. Further, we investigate the effect of an adaptive curriculum, i.e., the data ranking is dynamically updated during training based on the current state of the learner model. We use a teacher model to measure difficulty of each sample and experiment with three measures based on question answering probability, variability and out-of-distribution. To understand the effectiveness of curriculum learning in various scenarios, we apply it on full model fine-tuning as well as parameter-efficient prompt-tuning settings. Our results show that fixed as well as adaptive curriculum learning significantly improve performance for five commonsense reasoning tasks, i.e., SocialIQA, CosmosQA, CODAH, HellaSwag, WinoGrande in both tuning settings. Further, we find that prioritizing the difficult samples in the tail end of training improves generalization to unseen in-domain data as well as out-of-domain data. Our work provides evidence and encourages research into curriculum learning for commonsense reasoning.[1].

1 Introduction

Curriculum learning (Elman, 1993; Bengio et al., 2009) is an alternative to the typical uniform random sampling of training data and is motivated by the gradual progression of human learning from easier to difficult concepts (see Figure 1). In the machine learning paradigm, a 'teacher' ranks the training samples from easy to difficult and introduces them to the 'learner' in that order. Dodge et al. (2020) show that randomly initialized training data orders can lead to large variance in model performance on the GLUE benchmark (Wang et al., 2018). In light of such evidence, we seek to answer: Does a meaningful data order such as a curriculum based on model confidence or dataset distribution outperform a random data order? Such experiments have been carried out for some NLP tasks like machine translation (Platanios et al., 2019) and natural language understanding (Xu et al., 2020) with positive outcomes. While large pretrained models (PTLMs) have been achieving high performance on such tasks, their commonsense reasoning abilities have been limited. Moreover, the process of commonsense acquisition in humans has been shown to be informative for developing algorithms to accomplish the same in machines (Zhu et al., 2020). Hence, we study the effect of a human-like curricu-

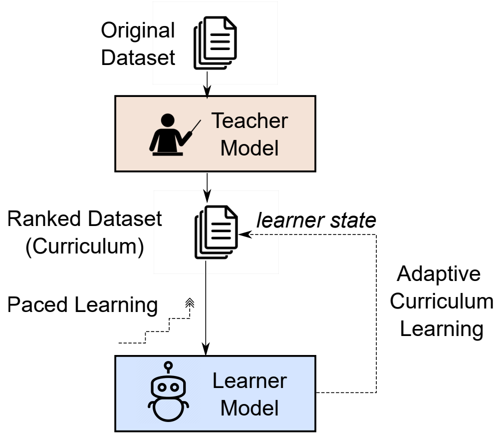

Figure 1: Curriculum Learning. The curriculum of the learner model i.e., the ranked dataset for finetuning is prepared using scores from the teacher model. The ranking remains unchanged in *fixed curriculum learning* whereas the learner state is used as feedback to update the ranking in *adaptive curriculum learning*.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 983 - 992
July 10-15, 2022

lum learning to improve the finetuning of PTLMs for commonsense reasoning tasks.

To impose structure on the data order for sampling training mini-batches, we adopt paced curriculum learning by transfer as proposed in Hacohen and Weinshall (2019). In this method, a pacing function determines the speed at which the ranked data is introduced to the model during training. Ranking of the training dataset is performed using outputs from a pretrained network which has been finetuned on the target dataset using a random training order. We refer to this approach as *fixed curriculum learning*. During human acquisition of skill sets, a student can benefit from a curriculum that is continuously adjusted by the teacher according to the learning progress of the student. Hence, we also investigate *adaptive curriculum learning* for commonsense reasoning tasks. The initial data order imposed by the teacher model is updated at regular intervals during training by taking the learner model's current state into account (Kong et al., 2021). Importantly, we propose to reverse the ranking to a difficulty-to-easy curriculum in ACL, in order to reinforce feedback from the hard-to-learn data points, which has been shown to be beneficial for generalization (Swayamdipta et al., 2020). In order to measure difficulty, we explore three different data-sample informativeness scoring methods i.e. Question Answering Probability (QAP) (Zhang and Bansal, 2019), Energy-based Out-of-Distribution Score (Liu et al., 2020) and Cartography-based Variability (Swayamdipta et al., 2020). Our work is most related to Xu et al. (2020) which splits the training data into N meta-datasets, trains N models for computing the curriculum and follows a heuristically designed training regimen. In contrast, we train a single model for computing the curriculum and use Bayesian optimization (Snoek et al., 2012) to find the best pacing of the curriculum for the target dataset, which is more effective than Xu et al. (2020) as we show in Sec. 5.4, besides being computationally efficient.

We analyze these methods on five commonsense reasoning datasets dealing with various tasks such as reasoning about social interactions (SocialIQA; Sap et al. (2019)), reading comprehension (CosmosQA; Huang et al. (2019)), natural language inference (HellaSwag; Zellers et al. (2019)), pronoun resolution (WinoGrande; Sakaguchi et al. (2020)) and adversarial commonsense (CODAH; Chen et al. (2019)). We explore curriculum learning in full-model finetuning as parameter-efficient tuning and show significant improvements using curriculum learning on each of these datasets. We also demonstrate that curriculum learning prevents the learner model from over-fitting on the training set, which leads to improved generalization to in-domain and out-of-domain data.

2 Related Work

Curriculum learning (CL) is widely used in reinforcement learning (Zaremba and Sutskever, 2014; Matiisen et al., 2019; Graves et al., 2017) and neural machine translation (Platanios et al., 2019; Kocmi and Bojar, 2017; Guo et al., 2020). Sachan and Xing (2018), Penha and Hauff (2020), Xu et al. (2020) and Jafarpour et al. (2021) demonstrate the effectiveness of CL for question generation, information retrieval, natural language understanding and named entity recognition respectively. To the best of our knowledge, we are the first to examine the efficacy of CL for commonsense reasoning.

Various task-specific measures for sample complexity have been proposed in previous works, such as inter-annotator agreement for natural language inference (Laverghetta Jr et al., 2020), sub-graph depth for Abstract Meaning Representation (AMR) structures (Wang et al., 2021a), noise rate in PCA jittering-based data augmentation (Ye et al., 2021), sentence length for sequence modelling (Cirik et al., 2016), and semantic similarity for sentiment analysis (Han and Myaeng, 2017) etc. Wang et al. (2021b) use a neural density estimator to model graph embeddings distribution for the task of graph classification. We use scores based on pretrained models (Zhang and Bansal, 2019; Swayamdipta et al., 2020; Liu et al., 2020) to compute difficulty.

Kong et al. (2021) and Cai et al. (2020) demonstrate that an adaptive curriculum can improve convergence for image classification and neural response generation respectively. We examine adaptive CL for commonsense reasoning.

3 Methods

3.1 Curriculum Learning

Curriculum learning has two axes of variations, i.e., ranking of samples in terms of difficulty, and transitioning of easy to difficult samples during training. Following the transfer method proposed by Weinshall et al. (2018), we use the predictions of a model that has been trained on target dataset (without curriculum learning) in order to rank the synthetic as well as original samples by difficulty (see *Teacher Model* in Fig. 1). We adapt the fixed pacing function (Hacohen and Weinshall, 2019) to implement transition of easy to difficult examples and optimize for hyperparameters of the pacing functions using Bayesian optimization. The pacing function $p_f(i)$ is used to determine a sequence of subsets $X_1, ..., X_m \subseteq X$ of size $|X_i| = p_f(i) * |X|$ from which mini-batches $\{B_i\}$ are sampled uniformly during training. Here, X is the ranked training dataset. The fixed pacing function is comprised of three parameters: (1) starting percentage, (2) increase factor, and (3) step length. The number of training iterations in each step of curriculum learning is defined as step length. The starting percentage decides maximum difficulty of the training samples introduced to the model in first step of curriculum learning. The increase factor is used to exponentially scale up the maximum difficulty at the end of each step. The usage percentage is calculated as $p_f(i) = t * \lambda^{\lfloor i/S \rfloor}$ where t, λ, S and i are the tunable parameters i.e. starting percent, increase factor, step length and current training iteration, resp. Training is initialized by sampling from $t\%$ of the ranked dataset and the usage percentage is re-computed at the end of every S iterations.

3.2 Adaptive Curriculum Learning

When the optimal curriculum for a student is not known in advance, a teacher usually draws up a curriculum based on past teaching experience and then adjusts with the learning progress of the student. Accordingly, Kong et al. (2021) propose initializing the curriculum using the difficulty score obtained from the teacher model and then adapt the score to the current state of the learner model (see Fig. 1). During training, the scores are updated after every L optimization steps. At the $(k+1)$th update, the difficulty score is computed as $\mu_{k+1} = (1-\alpha)\mu_k + \alpha\mu_{cur}$ where μ_{cur}, μ_k and μ_{k+1} are difficulty scores after the current step, the kth and the $(k+1)$th updates respectively. α and L are tunable hyper-parameters. The ranking is *flipped to a difficult-to-easy curriculum* using the updated scores for subsequent training, in order to maximize exposure to difficult samples.

3.3 Difficulty Scoring Functions

Question Answering Probability (QAP). The probability that the teacher model can correctly predict the answer to a question is a measure of model confidence for that particular data sample (Zhang and Bansal, 2019). We propose to use this metric to rank datasets i.e. data samples with high QAP are considered as easy and those with low QAP are treated as difficult examples. Given a model with parameters θ, the QAP μ_i for question-answer pair (x_i, y_i^*) is measured as $\mu_i = p_\theta(y_i^*|x_i)$.

Model Variability. Swayamdipta et al. (2020) propose the model confidence ($\hat{\mu_i}$) and variability ($\hat{\sigma_i}$) measures to identify the effect of data samples on the model's generalization error. Specifically, $\hat{\mu_i} = \frac{1}{E}\sum_{e=1}^{E} p_\theta(y_i^*|x_i)$ and $\hat{\sigma_i} = \sqrt{\frac{\sum_{e=1}^{E}(p_\theta(y_i^*|x_i)-\hat{\mu_i})^2}{E}}$, where E is the number of training epochs. We rank samples in the ascending order of variability i.e. samples with low-variability are ranked as easy.

Energy. Liu et al. (2020) show that the energy score can be reliably used for distinguishing between in- and out-of-distribution (OOD) samples. We use this metric to rank OOD samples as "difficult" and in-distribution samples as "easy" in our curriculum. Energy of a given sample is computed as $E = -T * log \sum_i^K exp^{f_i(x)/T}$ where $f_i(x)$ are the logits for a given sample, taken from the teacher model, and T is the temperature.

4 Experimental Setup

We use a suite of large and small datasets formatted as multiple-choice question answering tasks for our experiments. SocialIQA (Sap et al., 2019), CosmosQA (Huang et al., 2019) and WinoGrande-XL (Sakaguchi et al., 2020) contain upto 60K training samples. Additionally, we use the CODAH dataset (Chen et al., 2019) and also follow the method in Yang et al. (2020) to create HellaSwag-2K (Zellers et al., 2019) for testing our methods in low-resource scenarios. Models are evaluated using the respective task-specific accuracies (see Appendix for dataset statistics). We use pretrained RoBERTa$_{LARGE}$ (Liu et al., 2019) as the teacher as well as learner model in our full-model finetuning experiments. In the first stage, the teacher model is finetuned on randomly sampled training data and used to compute the difficulty scores. Models are also subjected to grid-search based tuning of training hyperparameters in the first stage whenever necessary. In the second stage, we use Bayesian optimization for finding the optimum pacing function parameters for fixed as well as adaptive CL (and use the same training hyperparameters as first stage). For adaptive learning, we set $L = S$ and

optimize for α, t, λ and S parameters. For prefix-tuning experiments, we use GPT2$_{LARGE}$ (Radford et al., 2019) as the PTLM for tuning. See Appendix for dataset statistics and hyperparameter bounds.

5 Results & Analysis

5.1 Main Results

Our experiments with curriculum learning yield upto 2% improvements across five commonsense reasoning tasks using RoBERTa model (see Table 1). Fixed CL results in 1.4%, 0.81% and 0.4% improvement over baseline i.e. no CL (see row 1 in Table 1) for the larger datasets SocialIQA, CosmosQA and WinoGrande respectively. With adaptive CL, the improvements increase to 1.79%, 1.20% and 0.85% respectively. For the smaller datasets, we see similar benefits i.e. 1.7% and 2.5% with fixed CL, and 2.4% and 3.17% with adaptive CL over the baselines of Codah and HellaSwag-2K respectively. These results are obtained using QAP as difficulty score, which is the superior metric for measuring sample difficulty in multiple-choice datasets (see Sec. 5.2). The optimum α values in our experiments are closer to 1.0, which suggests that the initial ranking using teacher model is not quite useful after the first S training steps.

To investigate the effectiveness of curriculum learning, we compare the difficulty scores on the training and validation sets for the teacher vs. learner models. See Figure 4 for a demonstration of the same for HellaSWAG-2K. We observe that the learner model is less confident about the training data implying that there is less overfitting. This results in improved generalization to unseen data in the validation set, and more uniform distribution of QAP scores over the samples. We observe similar trends in other datasets as well (see Appendix for more figures), which suggests that curriculum learning acts as a regularizer during training. In order to further test this hypothesis, we evaluate the out-of-distribution generalization of WinoGrande models by evaluating on the Winograd Schema Challenge (WSC) dataset (Levesque et al., 2012). We observe 0.7% and 2.1% improvement in the performance on WSC using fixed and adaptive CL respectively (see Table 3), indicating that adaptive CL is especially effective at promoting generalization of the trained model. This result also aligns with the finding in Swayamdipta et al. (2020) that hard-to-learn examples play a significant role in learning and generalization.

5.2 Difficulty Metrics

We use three measures of difficulty for ranking the samples in the training data. Results on fixed CL with RoBERTa are shown in Table 2. We see the largest improvements with QAP, similar behavior with variability, and lesser or no improvements with energy. Scatter plot between QAP and variability for SIQA data samples reveals that samples with higher QAP also tend to have lower variance, hence

Method	**MNLI**	**QNLI**	**QQP**	**RTE**	**SST-2**	**MRPC**	**CoLA**	**STS-B**	**Avg.**
BERT$_{LARGE}$	86.7	92.5	91.2	76.1	94.0	91.4	66.1	90.2	83.7
+ CL (Xu et al., 2020)	86.6	92.8	91.8	76.2	94.2	91.9	66.8	90.6	84.1
+ fixed CL (ours)	86.8	93.1	91.8	77.1	94.6	92.3	66.8	91.0	85.6
+ adaptive CL (ours)	87.9	93.5	92.7	77.9	94.6	92.4	66.5	91.8	86.1

Table 4: Results on validation sets of the GLUE dataset using fixed and adaptive CL with BERT$_{LARGE}$.

Method	**SIQA**	**CosQA**	**CDH**	**H2K**
Prefix-tuning	65.39	68.34	73.16	70.24
+ fixed CL	66.18	69.10	75.28	72.58
+ adaptive CL	66.91	69.42	75.56	72.68

Table 5: Results on validation set of commonsense reasoning datasets using prefix-tuning of GPT2 and curriculum learning with QAP as difficulty measure.

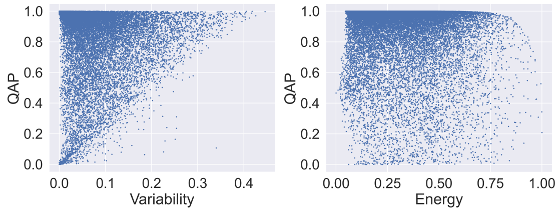

Figure 3: Visualization of scatter plots for QAP vs. Variability (left) and QAP vs. Energy (right) scores from the RoBERTa teacher model for SocialIQA.

SIQA	Cameron gave Casey a drink. He loved helping kids and giving them things. How would Casey feel as a result? [A] very apathetic [B] very grateful [C] somewhat infdifferent
Codah	We organized a bonfire party. I [A] brought marshmallows to toast [B] like to play with fire [C] threw a bucket of water at the bonfire [D] howled like a wolf.

Table 6: Most difficult samples of SIQA and CODAH as ranked by QAP scores. Labels are marked in green.

leading to similar behavior from both metrics in curriculum learning. The energy score fails to yield benefits for CL because the datasets used in our experiments are mostly homogeneous.

5.3 Curriculum Learning for Prefix-Tuning

In the interest of parameter-efficient methods for training PTLMs to perform specialized tasks, we conduct CL experiments for prefix-tuning (Li and Liang, 2021) of GPT2$_{LARGE}$ models on target datasets (see Appendix). We introduce a prefix of length 16 and train a reparameterization network that updates 0.2% of GPT2's parameters for commonsense-based question answering. Results in Table 5 show that CL yields up to 1.5% improvements for smaller datasets and up to 1% improvement on larger datasets, suggesting that CL could be also effective for prompt-tuning settings.

5.4 Curriculum learning for Natural Language Understanding

We evaluate the performance of our proposed curriculum learning methods on conventional NLU tasks i.e. GLUE. In order to facilitate direct comparison to the meta-dataset approach presented in Xu et al. (2020), we train BERT$_{LARGE}$ models with our fixed as well as adaptive curriculum learning methods on all sub-tasks in GLUE (Wang et al., 2018). Results on the validation sets of GLUE are presented in Table 4. Our proposed method outperforms Xu et al. (2020) across all sub-tasks. We see upto 1% improvement on the larger datasets i.e. MNLI, QNLI and QQP. For the smaller GLUE datasets, we observe small improvement margins with curriculum learning approaches, as opposed to the larger improvements for small commonsense reasoning datasets as seen in Table 1.

6 Limitations

Our results are limited to the task of multiple choice question-answering based commonsense reasoning and natural language understanding, but are encouraging and warrant further research into effective adaptive CL methodologies for other NLP tasks. The adaptive curriculum learning method proposed in our paper is expensive for larger datasets since the ranking needs to be recomputed several times during training using the current version of the learner model. Further work is needed to optimize curriculum learning methods for larger datasets like AbductiveNLI (Bhagavatula et al., 2019) and for using larger models like UnifiedQA (Khashabi et al., 2020) for finding the right curriculum.

7 Conclusion

We conduct an empirical analysis of fixed and adaptive curriculum learning (CL) for five commonsense reasoning tasks using pretrained language models (PTLMs). Results show that CL can benefit downstream task performance when introducing a new task to a PTLM, in fully-finetuned as well prompt-tuned settings, and for in-domain as well as out-of-domain data. Our work motivates future research into CL for commonsense reasoning.

A Prefix-Tuning Model

For this scenario, we finetune a GPT2$_{LARGE}$ model for the task of multiple-choice reasoning using prefix-tuning, wherein the weights of pretrained GPT2 are frozen, and only a matrix of prefix embeddings are trained for the target task. Following Li and Liang (2021), we prepend a prefix to the inputs of GPT2 model i.e. $z = [\textsc{Prefix}, x, y]$ where (x, y) is the question-answer input pair. We also a parameterization network to compute the prefix embeddings i.e., $P_\theta = MLP(P_{\theta'})$ where P_θ is the prefix embedding used during inference, $P_{\theta'}$ is a smaller prefix matrix used for reparameterization during training and MLP is the dense layer used as the reparameterization network. We set the prefix length to 16, and the dimensions of $P_{\theta'}$ to 512. The dimensions of P_θ is 1024, according to the hidden size of GPT2$_{LARGE}$. This leads to a total of 0.2% trainable parameters in our prefix-tuning based GPT2 model.

B Experimental Setup

Datasets. We use two large multiple-choice commonsense-based question answering datasets for our experiments i.e. SocialIQA (Sap et al., 2019) and CosmosQA (Huang et al., 2019). Additionally, we also use the CODAH dataset (Chen et al., 2019) folds released in Yang et al. (2019) and follow their method to create HellaSwag-2K (Zellers et al., 2019) for testing our methods on low-resource scenario. All of the above datasets are being for their intended purposes i.e. research only, in our work. All of these datasets are in the English language. Models are evaluated using the respective task-specific accuracies. See Table 9 for dataset statistics.

Models & Hyper-parameters. We use RoBERTa$_{LARGE}$ Liu et al. (2019) as the main PTLM in our experiments. We perform Bayesian optimization for finding the optimum parameters for fixed as well as adaptive CL. For adaptive learning, we set $L = S$ and optimize for α, t, λ and S parameters. All models are also subjected to grid-search based tuning of training hyperparameters.

B.1 Hyperparameter Tuning Bounds

We perform grid-search based optimization for finding the best training hyperparameters for each training scenario and dataset. For curriculum learning based parameters, we first perform bayesian optimization (Snoek et al., 2012) of curriculum learning parameters using the best training hyperparameters for the baseline (non-CL) model. For bayesian optimization, each model is subjected to 15 iterations of optimization with 3 restarts and the tuning is based on accuracy on validation set.

Figure 5: Demonstration of the optimized learning pace of RoBERTa for various datasets. Usage percentage k (y-axis) at training step n (x-axis) refers to the top $k\%$ easiest examples of the ranked dataset.

For the prefix-tuning models, we perform grid-search based tuning of training hyperparameters according to the bounds reported in Table 8 and in addition, up to 10 training epochs.

Abstract

We introduce `DocTime` - a novel temporal dependency graph (TDG) parser that takes as input a text document and produces a temporal dependency graph. It outperforms previous BERT based solutions by a relative 4-8% on three datasets from modeling the problem as a graph-network with path-prediction loss to incorporate longer range dependencies. This work also demonstrates how the TDG graph can be used to improve the downstream tasks of temporal questions answering and NLI by a relative 4-10% with a new framework that incorporates the temporal dependency graph into the self-attention layer of Transformer models (`Time-transformer`). Finally, we develop and evaluate on a new temporal dependency graph dataset for the domain of contractual documents, which has not been previously explored in this setting.

1 Introduction

Understanding the temporal relations between events mentioned in a document is an important natural language task with applications in downstream tasks such as timeline creation (Leeuwenberg and Moens, 2018), time-aware summarization (Noh et al., 2020), temporal question-answering (Ning et al., 2020a), and temporal information extraction (Leeuwenberg and Moens, 2019). This area of research remains important yet challenging due to several limitations such as confounded modalities (eg. events that are certain to happen vs the ones that might happen), event ambiguity (eg. agreeing to terms of a contract vs signing a contract) and need for complete annotation of all event pairs for precise temporal localization (Yao et al., 2020a).

Early work densely annotated all pairs of events to address this problem (Cassidy et al., 2014), but was limited to short passages or adjacent sentences due to the $\binom{n}{2}$ complexity of the task, especially for long documents. Recently this problem formulation was significantly simplified using temporal dependency trees (TDT) (Zhang and Xue, 2019) and temporal dependency graphs (TDG) (Yao et al., 2020a) by only capturing the reference TIMEX or event to build a dependency graph to capture this information. This enabled the development of temporal dependency parsers (Zhang and Xue, 2018a; Ross et al., 2020a) to infer temporal relationships more robustly and efficiently.

We introduce `DocTime` - a state-of-the-art temporal dependency parser that parses document-level text to produce temporal dependency graphs. Unlike previous approaches using contextual features such as BERT(Ross et al., 2020b), our model utilizes a graph network and a novel path prediction loss to reason over long-range multi-hop dependencies while maintaining global consistency of temporal ordering of inter-dependent events.

To validate the utility of `DocTime` and our generated temporal dependency graph, we go one step further than prior work and explore the question of whether temporal dependency graphs are useful for downstream tasks by introducing `Time-Transformer`. It is a framework to incorporate temporal dependency graphs into existing transformer-based architectures without retraining from scratch. We demonstrate the usefulness of our proposed `Time-Transformer` on temporal NLI (Vashishtha et al., 2020) and time-sensitive question answering (Chen et al., 2021) tasks.

Prior work on temporal relationship extraction and temporal dependency parsing have been mostly limited to news (Zhang and Xue, 2019; Yao et al., 2020a; Pustejovsky et al., 2003a), narrative stories (Zhang and Xue, 2018b; Kolomiyets et al., 2012) or clinical notes (Bethard et al., 2016). In addition to experimenting with existing temporal dependency parsing datasets, we introduce a dataset for temporal dependency graphs in a new domain - contractual documents, where temporal reasoning over events has real world legal and monetary implications for users.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics:
Human Language Technologies, pages 993 - 1009
July 10-15, 2022

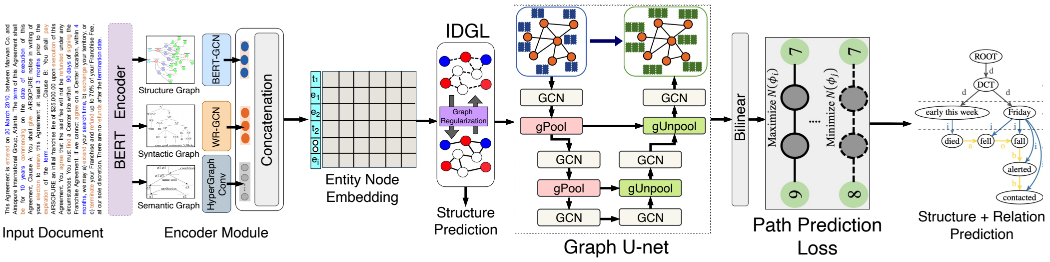

Figure 1: `DocTime` encodes rich token level embeddings from input document using structural, syntactic, and semantic graphs through BERT-GCN, WR-GCN and HyperGraph Conv layers, respectively. Token-level features are concatenated and passed through Iterative Deep Graph Learning (IDGL) to learn a noisy dependency structure over the TIMEX and Event entities. Graph U-net allows the model to incorporate longer range dependencies for predicting the final temporal dependency graph structure and relationships. The model is trained with a novel auxiliary path prediction loss to learn multi-hop connections in TDG.

Our main contributions include:

- A novel document-level temporal dependency parser (`DocTime`) that predicts the temporal dependency graph from text in an end-to-end manner with a novel path prediction loss, which outperforms the current SOTA by a relative 4-8% on three datasets.
- `Time-Transformer`, a novel framework to incorporate Temporal Dependency Graphs into transformer models for downstream tasks without needing to retrain from scratch. Results on natural language inference and question answering with a new self-attention module show a relative 4%-10% improvement.
- Development of new document-level (>1500 words) TDG dataset in the domain of contractual documents (ContractTDG[1]).

2 Related Work

Temporal Dependency Parsing: Previous work has been devoted to pairwise classification of relations between events and time expressions, notably TimeBank (Pustejovsky et al., 2003b) and its extensions like Cassidy et al. (2014) annotated all relations. Pair-wise annotation have multiple problems including polynomial square complexity, global inconsistencies in predictions due to relation transitivity and forced annotation of vague relations (Ning et al., 2018). Prior work focuses on extracting temporal relations between event pairs in the same sentence or adjacent sentences (Goyal and Durrett, 2019; Ning et al., 2019a; Han et al., 2019a,c,b, 2020; Ballesteros et al., 2020; Zhao et al., 2020). TIMERS Mathur et al. (2021a) presented temporal relation extraction in long document.

Temporal Dependency Parsing (TDP): Temporal dependency trees were first proposed by Kolomiyets et al. (2012). (Zhang and Xue, 2018b) provided the the earliest TDT corpus on news data and narrative stories, (Zhang and Xue, 2019) released the first English TDT corpus. Yao et al. (2020a) relaxed the assumption of single reference edge in dependency trees to form the improved TDG. (Zhang and Xue, 2018a) built an end-to-end neural temporal dependency parser using BiLSTM and Ross et al. (2020b) improved it further incorporating BERT. Our approach improves by modeling complex dependencies and introduces a new resource for TDG in contracts.

Linguistically-aware Transformers: Recent works have investigated using linguistic features as a prior for Transformer models. Syntax-bert (Bai et al., 2021a) uses syntactic and constituency dependency on NLI and GLUE benchmarks. Coref-BERT Coreference-Informed Transformer (Liu et al., 2021) performs coreference-aware dialogue summarization. Temporal reasoning about event ordering can find applications in many tasks such as summarization (Noh et al., 2020), question answering (Chen et al., 2021; Ning et al., 2020b; Jin et al., 2020), commonsense reasoning (Qin et al., 2021), and natural language inference (Vashishtha et al., 2020). We propose to use TDG as priors to Transformer models to make them temporally-aware for use in downstream tasks.

3 `DocTime`: Document TDG Parsing

Task Formulation: Let document D be defined as a sequence of n tokens $[x_1, \cdots, x_n]$. The entire document can be seen as sequence of m sentences $[s_1, \cdots, s_m]$. Each document has a set of p events $E = [e_1, \cdots, e_p]$ and q timexes $T = [t_1, \cdots, t_q]$, where $p, q \leq n$. The creation date of the document is represented by timestamp t_{DCT}. Yao

---

[1] `https://github.com/contractTDG/ContractTDG_Dataset`

et al. (2020a) defines a temporal dependency graph (TDG) where each timex node always has a reference timex, which is the most specific narrative time related to the event (Pustejovsky and Stubbs, 2011). If such a narrative time is not available, the timex should be anchored to the DCT. An event node can either have a reference timex or be connected to a reference event, which is an event that provides the most specific temporal location. The task of temporal dependency graph parsing of a text document D results in a dependency graph $G = (C, V)$, where C represents the set of all events, timexes and the document creation date (DCT). V is the set of all edges in the graph, where each edge represents a temporal relationship $\Re$ between corresponding entity node pair $V = \{(t_i, t_j), (e_i, e_j), (e_i, t_j)\} \forall i, j \in C$.

Model Overview: Figure 1 shows an overview of our network architecture for temporal dependency parsing. We first extract token level BERT features from the input document, which are then enriched by three graph networks that encode structural, syntactic, and semantic relationships. This is followed by Iterative Deep Graph Learning over the TIMEX and Event entities to learn an initial dependency structure. This is passed through a Graph U-net to allow the model to incorporate longer range dependencies before predicting the final temporal dependency graph and relationships. The model is also trained with a novel auxiliary path prediction loss.

3.1 Feature Encoding

We leverage the pre-trained BERT language model to obtain the embeddings for each token as follows: $w_1, w_2, \cdots, w_n = \text{BERT}([x_1, x_2, \cdots, x_n])$, where w_i is the embedding of the token x_i. As document sequence lengths can be larger than 512, we use a *sliding window* encoding technique to encode whole documents. We average the embeddings of overlapping tokens of different windows to obtain the final representations. These token representations are enriched with slightly enhanced variants of the structural (G_{str}), syntactic (G_{syn}) and semantic (G_{sem}) graphs utilized by (Mathur et al., 2021b) for document-level temporal relationship extraction. The key differences are the use of BERT-GCN (Lin et al., 2021) to combine contextual and structural graph features, the addition of co-reference relationships to the syntactic graph, and the use of a hypergraph convolution (Bai et al., 2021b) to allow for token level features in the semantic graph . All aspects of these features and the changes are presented in Appendix B.

3.2 Temporal Dependency Prediction

We combine the learned representation for each entity node (timex, event, DCT) by concatenating the node embeddings learned from structural, syntactical and semantic graphs to obtain a D-dimensional feature vector for each of z entities in the document given by $\mathbf{F}(w_i) = g_i^{str} \oplus g_i^{syn} \oplus g_i^{sem}$, where $\oplus$ represents concatenation. We retain only the enriched node embeddings for each word. We then utilize Iterative Deep Graph Learning (IDGL)[2] (Chen et al., 2020) to dynamically learn an initial dependency graph structure from the combined node embeddings. Given a noisy graph input feature matrix $\mathbf{F} \in R^{l*D}$, IDGL produces an implicitly learned graph structure $G^* = \{A^*, \mathbf{F}, \mathcal{F}_l\}$ with a jointly refined corresponding graph node embeddings $\mathbf{F}'$ with adjacency matrix A^* by optimizing with respect to downstream link prediction task $\mathcal{F}_l$ between entity nodes.

3.2.1 Graph U-net For Higher Level Features

The Graph U-net (Gao and Ji, 2019) is a U-shaped graph encoder-decoder architecture containing two down-sampling graph pooling (gPool) layers and two up-sampling graph unpooling (gUnpool) layers with skip connections. gPool layers reduce the size of the graph to encode higher-order features, while the gUnpool layer restores the graph into its higher resolution structure, thereby promoting information exchange between entity pairs through an enlarged receptive field. Each graph pooling and unpooling layer is followed by a GCN layer to implicitly capture the topological information in the input graph. Taking the dynamically learned graph structure G^*, a graph embedding layer converts input node features $\mathbf{F'}$ into low-dimensional representations that are then passed through a graph U-net encoder-decoder $\mho$ to acquire entity-level relation matrix $\mathbf{Y} = \mho(\mathbf{F'})$, $\mathbf{Y} \in R^{l*l*D'}$.

3.2.2 Temporal Dependency Link Prediction and Relation Classification

Given entity adjacency matrix A^* and entity-level relation matrix $\mathbf{Y}$, we use a bilinear function to map them to link and relation probabilities $\mathbf{Z}_l$ and $\mathbf{Z}_r$, respectively. Formally, we have $\mathbf{Z}_l = \sigma(\mathbf{Y} W_l \mathbf{Y} + b_l)$ and $\mathbf{Z}_r = \sigma(A^* W_r A^* + b_r)$, where

---

[2] Implementation: `https://github.com/graph4ai/graph4nlp`

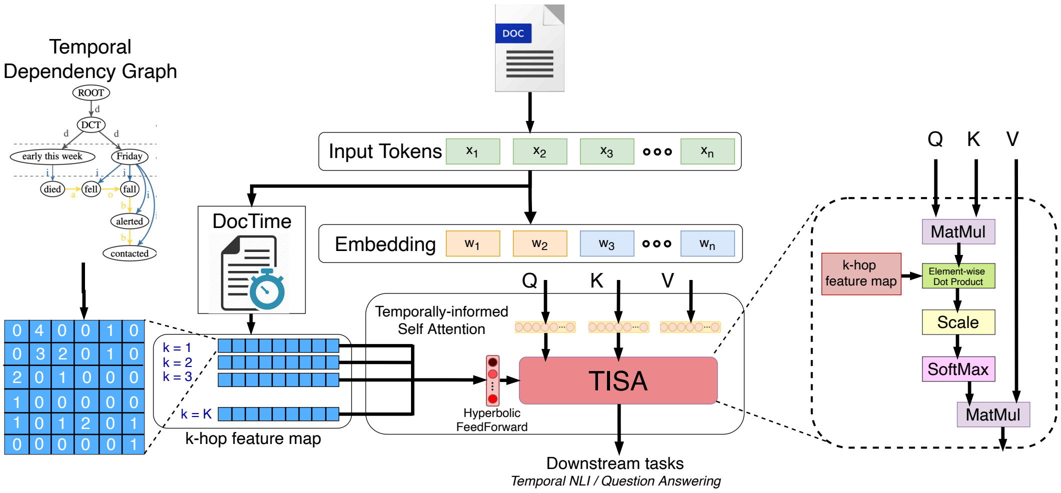

Figure 2: `Time-Transformer` is a variant of pre-trained Transformer models that augments temporal knowledge into the self-attention layer during fine-tuning of the Transformer model on different downstream tasks. Input text is converted into a temporal dependency graph using `DocTime` parser. The graph is then converted into a set of masks that encodes the temporal relationship between each token (i.e. After, Before) using the novel Temporally- informed Self-Attention (TISA). TISA creates K masks to represent the (k)-hop distance between two nodes in TDG for aggregating information across longer ranges in the input. TISA uses hyperbolic feed-forward layer to learn the mask weights.

$W_l, W_r, b_l, b_r \in R^{D'*D'}$ represent learnable parameters. This is followed by a Softmax layer for link prediction and relations classification.

3.3 Training `DocTime`

Path Reconstruction Loss: In a document-level temporal parsing setup, the majority of node pairs may not have any ground truth link or temporal relation. Graph representation learning methods universally model relations between all entity pairs regardless of whether the entity pair has any relationship, leading to dispersion of attention in learning most non-existent edge connections. We propose path reconstruction loss L_{path}, which forces the model to pay more attention to learn entity pairs with relationships rather than ones without relationships. Equation 1 gives the cross entropy loss over all direct edge connection between all pairs of entities, where r^i_j indicates the relation between the entity pair and $P(r^i_j)$ is probability of relation label r. Path reconstruction loss L_{path} modifies the cross entropy loss L_{ce} function as shown in Equation 2 by sampling all n^2 entity pairs and maximizing the probability of the shortest dependency path $\mathscr{N}(\phi)$ between the entity pair nodes. Finally, the path reconstruction loss and the existing classification loss are added as the training objective for `DocTime`, given by $L = L_{path} + L_{ce}$.

$$L_{ce} = -\frac{1}{\sum_{i=0}^{l} N_i} \sum_{i=1}^{l} \sum_{j=1}^{N_i} \{r^i_j \log P(r^i_j) \\ + (1 - r^i_j) \log(1 - P(r^i_j))\} \quad (1)$$

$$L_{path} = -\frac{1}{\sum_{i=0}^{l} N_i} \sum_{i=1}^{l} \sum_{j=1}^{N_i} \{r^i_j \log \mathscr{N}(\phi_i) \\ + (1 - r^i_j) \log(1 - \mathscr{N}(\phi_i))\} \quad (2)$$

Multi-task Training: Dependency link prediction and entity-level relation classification are correlated tasks and reinforce each other. We use multi-task training to optimize both tasks simultaneously using the path prediction cross entropy loss. The final optimization uses a weighted sum of the dependency link prediction loss and entity-level relation classification loss $L = \lambda L_l + (1 - \lambda) L_r$, where the weighting factor λ is a hyperparameter.

4 Time-Transformer

We would also like to understand our temporal dependency parsing can be useful for downstream tasks requiring temporal reasoning. Here we introduce the Time-Transformer, which allow a TDG generated by `DocTime` to be combined with state-of-the-art transformer models for temporal tasks. The Time-Transformer augments the flow of information in a Transformer network via a temporally-informed self-attention mechanism. We first formulate the Time-Transformer architecture in §4 and then construct of temporally-informed attention layers in §4.

Architecture: Time-Transformer was motivated by recent work incorporating syntax (Bai et al., 2021a) or co-reference graphs(Liu et al., 2021) into the transformer architecture to improve downstream tasks. In each case, these approaches encode additional knowledge from the sparse graphs as a masked self attention layer into the transformer. Figure 2 shows the architecture of Time-Transformer incorporating temporal knowledge into the self-attention layer during fine-tuning of the Transformer model. Input text is converted into a temporal dependency graph using `DocTime` parser. The graph is then converted into a set of masks that encodes the temporal relationship between each entity (i.e. After) explained in more detail in the next section: Temporally-informed Self-Attention. The input embedding (token+positional+attention masks) is passed through the Time-Transformer model which modifies the self-attention layer of the standard Transformer architecture with a *temporally-informed self-attention* layer to be fine-tuned on downstream tasks.

TISA: Temporally-informed Self-Attention : The TDG produced by `DocTime` is sparse and to effectively utilize the graph extracted by the temporal dependency parser for longer range temporal relationships, we utilize K self-attention layers that encode the temporal relationship if traversing K hops in the TDG as shown in 2. More formally starting from node A, the minimum number of hops (k) required to reach another node B can be regarded as k-hop distance between A and B, written as k-hop(A, B). We create K masks to represent the (k)-hop distance between two nodes to allow the model to aggregate information across longer ranges in the TDG. Specifically, a mask $M \in \{0, 1, 2, \cdots, r\}^{n \times n}$ denotes if there is a relation between entity i and j, and n is the number of tokens in the input text. The value of the mask is the relationship type for i and j. It is found by inferring the relationship using Allen's interval algebra (Allen, 1983) and is set to 0 if there is no relationship or set to "Overlap" if there is a conflict. We adopt a soft-mask learning strategy to enable the self-attention layer to re-weight the importance of each mask and avoid the problem of vanishing gradient. A hyperbolic feed-forward layer is used to learn the mask weights as research has shown it can avoid distortion of the feature space in graph representations (Ganea et al., 2018). The value of K is a hyperparameter that can be customized according to the nature of input dependency graph.

Training `Time-Transformer`: For each dataset, we optimize the hyper-parameters of `Time-Transformer` through grid search on the validation data. In all our experiments, we limit the maximum value of k-hop to 15. Detailed settings can be found in the appendix.

5 Experiment

5.1 Temporal Graph Parsing Datasets

We train and evaluate `DocTime` on three datasets. First is the **Temporal Dependency Graphs (TDG) dataset** (Yao et al., 2020a) made up of 500 Wikinews articles annotated with document-level temporal dependency graphs. Second is the **Temporal Dependency Trees (TDT) dataset** Zhang and Xue (2019) made from 183 documents derived from TimeBank (Pustejovsky et al., 2003a) annotated with a temporal dependency tree structure. The third dataset we created as part of this paper and is describe in more detail below.

Contract-TDG: Understanding the temporal relationship of events in contracts is an important business problem, where understanding event timelines can have legal and monetary consequences. Previous work on temporal relationships has largely focused on clinical, news or narrative text , whereas to the best of our knowledge the contractual domain has not been explored for this problem. To construct this dataset, we used 100 contracts from the Atticus contracts dataset[3] (Hendrycks et al., 2021), which were sourced from public domain SEC contracts. Due to the multi-page length of these documents, we limited the annotations to the first 1500 words. We did not include definition sections, since they did not contain many events of interest for this task. The documents have a 70-10-20 split for training, validation, and testing.

To obtain the TDG annotations required for our task, we followed the 5 steps procedure outlined by the original TDG dataset in (Yao et al., 2020b): (i) TIMEX Identification (TE), (ii) Identifying reference times for TE, (iii) Event identification, (iv) Identifying reference times for events, (v) Identifying reference events for events. Document Creation

monthly invoices ("Invoices"), which shall set forth in reasonable detail, with such supporting documentation as Recipient may reasonably request with respect to Out-of-Pocket Costs, amounts payable under this Agreement, and (ii) payments pursuant to this Agreement shall be made within fifteen days after the date of receipt of an Invoice by Recipient from Provider. (c) Provider shall allow the Recipient to use [* * *] at no cost, until December 31, 2021 . 2.3 Invoice Disputes. In the event of an Invoice dispute, Recipient shall deliver a written statement to Provider prior to the date payment is due on the disputed Invoice listing all disputed items and providing a reasonably detailed description of each disputed item. Amounts not so disputed shall be deemed accepted and shall be paid , notwithstanding disputes on other items. The Parties shall seek to resolve all such disputes expeditiously and in good faith. Provider shall continue performing the Services in accordance with this Agreement pending resolution of any dispute.

Figure 3: Example of a temporal dependency graph from ContractTDG dataset annotated using Brat Tool.

Dataset	Docs	Timex	Events	Rels
TimeBank (Pustejovsky et al., 2003b)	183	1,414	7,935	6,148
TB-Dense (Cassidy et al., 2014)	36	289	1,729	12,715
MATRES (Ning et al., 2019b)	275	-	1,790	13,577
TDT-Crd (Zhang and Xue, 2019)	183	1,414	2,691	4,105
TDG (Yao et al., 2020a)	500	2,485	14,974	28,350
Contract-TDG) (Ours)	**100**	2354	11,752	12,909

Table 1: Comparison of ContractTDG data statistics to other temporal relation datasets. ContractTDG has fewer documents but comparable number of TIMEX/Events/relations.

Task	TDG (F1)	Contract TDG (F1)
1: TIMEX ID	0.96	0.93
2: TIMEX RT	0.89	0.81
3: Event ID	0.79	0.76
4: RT ID (U)	0.67	0.83
4: RT ID (L)	0.61	0.75
5: RE ID (U)	0.59	0.85
5: RE ID (L)	0.52	0.79

Table 2: Inter-Annotator Agreement (IAA) for the Contract-TDG and TDG dataset. U = structure, L = structure + labels

Times (DCT) were provided as effective dates in the ATTICUS corpus.

Similar to (Yao et al., 2020b) for tasks 1 (TE) and 3 (Event ID), we used the Mechanical Turk platform to obtain two annotations to validate text spans of noisy TIMEXes extracted by HeidelTime software[4] (Strötgen and Gertz, 2013) and verbs that were possible events. Disagreements were resolved by an expert annotator. However, for the reference tasks, we decided against using Mechanical Turk due to the difficulty and length of the contracts as well as the lower agreement faced by the original TDG system for the last two tasks. We instead used the BRAT annotation tool[5] (Stenetorp et al., 2012) with an expert annotator for tasks 2,4, and 5, following the (Yao et al., 2020b) guidelines . ContractTDG is annotated for four temporal relations - after, before, overlaps, and includes.

Table 1 compares the data statistics of the ContractTDG to previous temporal relationship and temporal dependency corpora. Even though this dataset has many fewer documents than the TDG dataset, it has a large number of TIMEX, Events, and Temporal relationships due to the document length. Table 2 reports the F1 IAA metrics for ContractTDG dataset to directly compare to the original TDG dataset. For Tasks 1 and 3 we report IAA F1 for the two crowd sourced worker annotations and for the relationship tagging tasks (2,4,5), we report IAA metrics calculated on the test postion (20% of the data) that was reviewed by two experts. The agreement is slightly lower for the TIMEX/Event identification tasks but higher for the three relationship tasks. We evaluate `DocTime` for dependency structure as well as structure+relation prediction for both development and test splits.

5.2 `Time-Transformer` Experiments for Downstream Tasks

We adopt `Time-Transformer` on BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019a), BigBird (Zaheer et al., 2020a) and FiD (Izacard and Grave, 2021) for evaluation on two downstream tasks in §6.2. We utilized the official checkpoint for each pre-trained language model as provided by respective authors. First, we test `Time-BERT` and `Time-RoBERTa` on Temporal NLI dataset, which consists of 5 sub-datasets (Vashishtha et al., 2020) to study the effect of temporal reasoning for predicting event ordering and duration. Second, we run experiments on the TimeQA dataset (Chen et al., 2021) to evaluate the performance of `Time-BigBird` and `Time-FiD` for the long-document question-answering task. We report Exact Match (EM) and F1 scores as evaluation metrics on dev and test sets of easy and hard versions.

Table 3: Results comparing performance of `DocTime` with baselines and ablative components on TDT, TDG, ContractTDG datasets. We majority and logistic regression baselines from (Zhang and Xue, 2018a). * indicates statistical significance over BERT Ranking Parser (Ross et al., 2020b) ($p \leq 0.005$) under Wilcoxon's Signed Rank test. Darker green represents better F1 performance on ablation studies. Bold denotes the best performing model. `DocTime` improves substantially over all datasets for both dependency structure and structure+relation prediction tasks. The ablation shows that semantic graph features prove to be most beneficial. Our proposed path prediction loss is critical for state-of-the-art performance of `DocTime` model.

6 Results and Analysis

6.1 Temporal Graph Parsing

Performance of `DocTime` w.r.t. baselines: Table 3 compares the performance of `DocTime` against other baseline methods on TDT, TDG and ContractTDG. We also provide a majority baseline ContractTDG to evaluate whether the methods work better than a random label assignment as implemented in (Yao et al., 2020a). We also include the two current SOTA approaches for temporal dependency parsing: The BiLSTM attention-based Neural Ranking Parser proposed by (Zhang and Xue, 2018a) [6] and the BERT Ranking Parser (Ross et al., 2020b) on each dataset . We also report results for a logistic regression baseline proposed by (Zhang and Xue, 2018a). Results in Table 3 show that `DocTime` outperforms both Neural and BERT Ranking Parser by a significant margin on the TDT (2-4%) TDG (5-6%) and ContractTDG (3-4%) datasets. We believe its primarily because they formulate temporal dependency parsing as a ranking task designed to select the best reference event/timex for each node. However, TDG parsing requires the model to be able to reason over multiple dependencies originating from each node while maintaining global consistency of temporal ordering of inter-dependent events. We perform experiments for dependency structure prediction and structure+relation prediction and find that predicting labeled dependency edges is a much more challenging task across all datasets. `DocTime` achieves state-of-the-art performance on all three datasets (see **bold**), and shows that it can successfully handle document-level long-range dependencies in the challenging ContractTDG dataset from the 6-12% relative improvement over the BERT based ranking parser. A more detailed analysis of performance per temporal relationship type can be found in the Appendix, where largest gains are seen for event-event pairs.

Model	UDS-duration	UDS-order	TempEval3	TimeBank-Dense	RED
Majority	50.00	54.52	54.57	50.54	52.51
NBOW (Iyyer et al., 2015)	82.54	54.52	54.57	50.54	52.51
Infersent (Conneau et al., 2017)	92.65	73.22	62.20	68.29	63.47
RoBERTa (Liu et al., 2019b)	94.51	80.17	54.57	94.60	80.59
`Time-RoBERTa (E)`	95.78	82.03	60.66	95.45	82.10
`Time-BERT`	96.01	82.97	61.32	96.08	82.15
`Time-RoBERTa`	**96.67**	**82.98**	**62.50**	**96.33**	**82.50**

Table 4: Accuracy comparison on the Temporal NLI dataset test set. `Time-RoBERTa` fine-tuned by utlizing temporal dependencies extract from `DocTime` model pre-trained on TDG dataset outperform all baselines provided by (Vashishtha et al., 2020)(see **bold**).

Ablation Study of `DocTime`: To assess the contribution of structure and syntactic and semantic graph features, we performed ablation experiments as reported in Table 3 highlighted in red. We also analyzed the effect of different types of training loss. We observe that removing the semantic graph consistently degrades performance, indicating the need for hypergraph learning over temporal arguments and RST features to capture document-level discourse relations. We see that removing structure graph reduced the performance to below the BERT Ranking Parser, as `DocTime` leverages BERT's contextual learning through a structural graph. Syntactic graph adds incremental value to `DocTime` due to its relational learning of syntactic dependencies within each sentence through relational GCN. We evaluated the model performance in case all edges of the TDG are used for one forward pass and call it "Graph Prediction". Training the model by evaluating a single edge in one pass (similar to temporal relation prediction in (Pustejovsky et al., 2003b) is referred to as "Pairwise Prediction". We explore the impact of different training

Table 5: Results comparing F1 score and exact match (EM) performance of Time-BigBird and Time-FiD for QA task on easy and hard sections of TimeQA dataset. We evaluate the Transformer models in 3 settings - fine-tune on TimeQA; fine-tune TriviaQA; and fine-tune on NQ then TimeQA. Green shows improvement due to our proposed Time-Transformer model, while we see degradation due to Euclidean variant of Time-Transformer (E)

losses for the proposed model (Table 3, highlighted in green). Learning DocTime by propagating losses over the entire document graph severely deteriorates model performance as the model has very limited training documents samples (182 for TDT, 400 for TDG, 80 for ContractTDG). Our proposed path prediction loss shows superior performance over pairwise link prediction as it jointly learns the relation label between a pair of nodes as well as the shortest dependency path linking them. As a result, the model can recover from structure prediction errors between nodes by learning an alternative path reconstructed through multi-hop connections.

6.2 Application of Temporal Dependency Parsing for downstream tasks

We train the DocTime model on the TDG corpus, which can be used to infer a temporal dependency graph from raw text samples. We extract events and timexes using CAEVO (Chambers et al., 2014) for all data samples in train,validate, and test. The temporal dependency graph acquired for each document is used as a prior for Time-Transformer to perform downstream tasks.

Performance of Time-Transformer on Temporal NLI: The temporal NLI task requires a model to identify the semantic relationship (entailed, not-entailed) between the context and corresponding hypothesis sentence based on temporal information from text. The temporal dependency graphs extracted using the DocTime trained on the TDG corpus are used as prior for Time-BERT for entailment classification. Table 4 shows the test accuracies of Time-BERT-large, Time-RoBERTa-large and other competitive baselines [(Iyyer et al., 2015),(Conneau et al., 2017)] reported by (Vashishtha et al., 2020). The temporal information prior proposed in Time-Transformer helps the BERT and RoBERTa models perform much better on the NLI task. The accuracy improved by 1.5-2.3 F1 points by applying our framework on the RoBERTa model across the five subsets. We observe the performance gain in the case of the Euclidean version of Time-RoBERTa to be modest as compared to its hyperbolic counterpart.

Performance of Time-Transformer on TimeQA: The TimeQA task focuses on understanding the time scope of facts in the long text followed by answering questions conditioned on the query and the document using implicit temporal information. We then apply the DocTime model output trained on the TDG corpus to the Time-Transformer framework on BigBird and FiD language models for long document question answering task. Following (Chen et al., 2021), we experiment with three variants of pre-trained settings: (1) fine-tuned on the TimeQA training set; (2) fine-tuned on NQ/TriviaQA data (3) fine-tuned on NQ/TriviaQA data and TimeQA.

Table 5 shows the effectiveness of Time-BigBird and Time-FiD in consistently outperforming their corresponding baselines in all three settings. More specifically, we see a realtive gain of 10-14% in F1 and exact match scores (EM) for both easy and hard sections of the dataset. It is impressive to note that the improvements due to the Time-BigBird and Time-FiD models are steady with different pre-training setups with the addition of only a few extra parameters to the baseline model. An important observation here is that the Euclidean versions of Time-BigBird and Time-FiD show persistent performance deterioration across all settings for TimeQA. We attribute this phenomenon to our initial hypothesis behind using hyperbolic operations in the proposed Temporally-informed self attention (TISA) layer. As the text length grows, the complexity of geometric operations increases, leading to vectorial distortions in Euclidean spaces (Ganea et al., 2018). This is remedied by hyperbolic transformations of masked self-attention learning in the proposed Time-Transformer.

Our experiments provide evidence that temporal dependency graphs extracted using DocTime and then utilized as a prior by temporally-

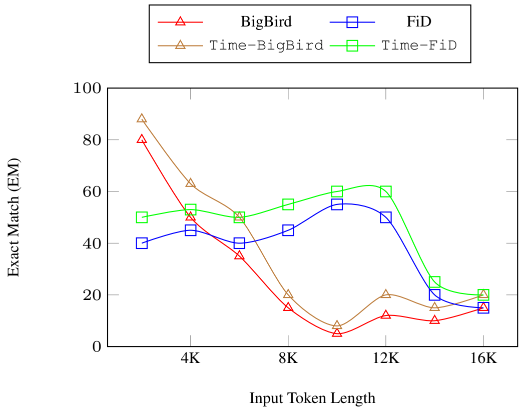

Figure 4: Impact analysis of long-distance dependencies on Transformer models for TimeQA task. Plot shows the exact match (EM) accuracy vs length of input document for hard samples. We use BigBird and FiD fine-tuned on NQ + TimeQA as backbone models. `Time-BigBird` and `Time-FiD` maintain steady improvement over baseline models even with increase in input lengths.

Corpus	**Model**	**Structure + Relation (F1)**			
		te,te	**e,te**	**e,e**	**full**
TD-Graphs	Heuristic	0.82	0.58	0.34	0.51
	Neural Ranking Parser (Zhang and Xue, 2018a)	0.93	0.66	0.58	0.66
	BERT Ranking Parser (Ross et al., 2020b)	0.93	0.74	0.58	0.71
	`DocTime`	**0.96**	**0.75**	**0.72**	**0.77**
Contract-TDG	Heuristic	0.45	0.36	0.18	0.33
	Neural Ranking Parser (Zhang and Xue, 2018a)	0.57	0.45	0.29	0.48
	BERT Ranking Parser (Ross et al., 2020b)	0.70	0.54	0.33	0.61
	`DocTime`	**0.75**	**0.56**	**0.39**	**0.64**

Table 6: Performance (F1 score) of `DocTime` across timex-timex, event-timex and event-event pairs for dependency structure+relation prediction on TDG and ContractTDG datasets. `DocTime` outperforms all baselines on every setting.

informed Transformer architectures such as `Time-Transformer` can improve the performance of several downstream tasks that require temporal reasoning at the sentence-level as well as at the document-level.

Impact of Long-term Dependency on `Time-Transformer` performance: We plot Fig. 4 to understand the capability of Transformer models to handle the long-term dependency in temporal reasoning on the TimeQA dataset. Plot shows the exact match (EM) accuracy vs length of the input document for hard samples. We use BigBird and FiD models fine-tuned on NQ + TimeQA as backbone models. BigBird's performance degrades rapidly as the length increases to over 5000 tokens, while the FiD's performance is quite uniformly distributed across different document lengths due to it's strong capability to deal with long-term dependency. `Time-BigBird` and `Time-FiD` follow a similar trend and maintain steady improvements over their corresponding baseline models with increasing in input lengths.

Space complexity analysis: We choose RoBERTa-base as the base model to analyze the space complexity. Liu et al. (2019b) reported the number of trainable parameters in RoBERTa-Base to be about 123 million. `Time-RoBERTa` introduces an additional 2 million parameters in total due to k-hop mask learning in the TISA layer. Therefore, Time-BERT adds few parameters to the base model without affecting its original space complexity.

Time Complexity analysis: We assume the number of tokens in each sentence to be n and extract k-hop mask matrices from a text document is $O(n^2)$ in the online inference phase. The time complexity of the Transformer embedding lookup layer is $O(n)$. The TISA layer calculates the attention score in $O(KD_q n^2)$ for both QK^T and learns the mask weights using a hyperbolic feedforward layer (MW^M), where D_q is dimension of Q and K is the number of sub-networks. The time complexity of the `Time-BERT` remains the same for small enough value of k ($k \leq 15$ in experiments).

7 Conclusion

We present `DocTime`, a new temporal dependency parsing approach that improves upon previous approaches by integrating longer term temporal information through a graph network with a novel path prediction loss. Additionally, we are able to show how a TDG can be incorporated into Transformer networks with Time-Transformer to improve on down stream tasks for NLI and question answering. Finally we introduce a TDG dataset in a new domain (Contractual documents) to expand research in this temporal reasoning to a new application domain. Future works will aim to explore more ways for integrating temporal dependency graphs into neural architectures across different application domains. In future, we would like to explore temporal event mining to aid various social media applications such as improving hate speech detection (Mathur et al., 2018b; Chopra et al., 2020), analyzing temporality in suicidal ideation detection (Mishra et al., 2019; Mathur et al., 2020) and abuse detection (Gautam et al., 2020; Sawhney et al., 2021). The proposed Time-Transformer can find applications in augmenting financial tasks (Sawhney et al., 2020), affective computing (Mittal et al., 2021), and AI for social good (Mathur et al., 2018a) with temporal common sense reasoning.

A Ethics Statement

We utilize two publicly available datasets - TDT and TDG for evaluating temporal dependency parser. We also curated dataset for TDG on contract documents. We source these contract documents from a publicly available resource - ATTICUS. We repurpose the document in this dataset for our task and provide new annotations. ContractTDG dataset does not violate any privacy as these documents are already in public domain. There is no human bias involved in such documents as they are business contracts filed on the SEC website. These documents do not restrict reuse for academic purposes and any personal information was already redacted before their original release. All documents and our experiments are restricted to English language. Temporal NLI and TimeQA datasets that are publicly available for research purposes. The crowd workers are paid a fair wage. There was no sensitive data involved in the studies.

B Details on Graph Feature Extraction

B.1 Structural Graph Features

The Structural Graph (G_{str}) enriches the token level features with a hierarchical textual structure formed by grouping word tokens into lists of sentences that bind together to form the text document. Prior work has shown that transductive graph learning over G_{str} can help learn the long range word-word dependencies set several sentences apart through hierarchical text modeling (Yao et al., 2019). The directed edges of the Structural Graph encode the following relationships: **(1) Document-Sentence Affiliation**, which connects each document-node to a sentence-node; **(2) Sentence-Word Affiliation**, which joins each sentence node to its constituent word nodes; **(3) Sentence-Sentence Adjacency** and **(4) Word-Word Adjacency**, which preserve sequential ordering for consecutive sentence and word nodes, respectively. For the structural graph, a sentence node embedding s_i is obtained by passing sentences through a pre-trained SentenceBERT model (Reimers and Gurevych, 2019) and the document node embedding D is calculated as the average of all sentence embeddings ($D = \sum_{i=0}^{m} v_i$).

BertGCN (Lin et al., 2021) combines the advantages of both large-scale pre-training and transductive learning. We input the structural graph G_{str} to BertGCN model[7] where each node represents a word, a sentence or the document. BertGCN processes the input node feature matrix sequentially through a Bert model to fine-tune each node to learn local contextual representations. This is followed by passing the learned node feature matrix through two layers of graph convolution to take advantage of global influence propagation through graph edges across multi-hop nodes.

B.2 Syntactic Graph Features

Syntactic cues are useful priors for learning based NLP tasks (Kiperwasser and Ballesteros, 2018). Pre-trained transformer models can capture certain syntactic information implicitly (Hewitt and Manning, 2019) but Jawahar et al. (2019) showed that BERT needs to be trained with deeper layers for handling harder cases involving long-distance dependency information. Moreover, past studies have pointed to the existence of multi-hop coreferring expressions in document-level text due to anaphora and cataphora (Joshi et al., 2020).

G_{syn} is made of separate nodes to represent each constituent word w_i in the document. For each document, there is also a set of co-reference clusters $\{\mathtt{C}_1, \mathtt{C}_2, \cdots, \mathtt{C}_u\}$ referring to the same entities in the graph. We define four types of directed edges in G_{syn} as described below where ξ denotes the set of syntactic dependency arcs inside sentences, $S^r_{w_i}$ denotes root of the sentence in which w_i belongs, and $S_{w_i} \rightarrow S_{w_j}$ represents whether sentences containing words w_i and w_j are adjacent.

$$\varepsilon_{syn}(i,j) = \begin{cases} \text{dependency} & \text{if } (w_i, w_j) \in \xi \\ \text{reversion} & \text{if } (w_j, w_i) \in \xi \\ \text{coreference} & \text{if } w_i, w_j \in \mathtt{C}_u \\ \text{self-loop} & \text{if } i == j \\ \text{root-adjacency} & \text{if } \;\; w_i == S^r_{w_i}, \\ & \;\; \& \; w_j == S^r_{w_j}, \\ & \;\;\; \& \; S_{w_i} \rightarrow S_{w_j} \end{cases} \tag{3}$$

The first two edge types are introduced to allow information flow along and against syntactic arcs between intra-sentential dependency relations to enrich contextually learned embeddings of each word. We connect parse tree roots of adjacent sentences to encode document level long-range syntactic relatedness between sentences. We add an undirected edge between word nodes if both belong to the same co-reference cluster. Inspired by (Kipf and Welling, 2016), self-loop edges are added for better message passing iterations. G_{syn} is instantiated

---

[7] Implementation Used: `https://github.com/ZeroRin/BertGCN`

as a gated variant of Weighted Relational Graph Convolutional Network (WR-GCN) (Zhang et al., 2020) with k-layers. WR-GCN can able to model diverse relations in a heterogeneous graph by treating different types of edges with unequal weights assigned during message passing.

B.3 Semantic Graph Features

Semantic Role Labeling (SRL) parses text sequences to recognize the predicate-argument structure in the sentence to answer *who* did *what* and *when*. Anchoring verb events to their temporal argument spans extracted from semantic parsing helps infer event relationships with their associated time expressions. This can be complemented by discourse features in the form of RST connections can help leverage long-range document-level interactions between phrase units (Bhatia et al., 2015) and identify background-foreground events(Aldawsari et al., 2020) and improve temporal relationship parsing (Mathur et al., 2021b). We utilize Document-level Rhetorical Structure Theory (RST) parser (Shi et al., 2020) to organize contiguous semantic text spans of a document into a hierarchical dependency structure labeled with their rhetorical relations.

G_{sem} consists of individual nodes for each constituent word w_i in the document. Discourse units and temporal arguments may span several word tokens $\{w_1, w_2, \cdots w_k\}$. We add two types of directed edge connections between - (1) event verb predicate - temporal argument edge (ε_t) such that $(w_e \rightarrow \{w_1, w_2, \cdots w_k\} \in \varepsilon_t)$; (2) Rhetorical pair edges (ε_d) labelled by the type of the rhetorical relation $(\{w_1, w_2, \cdots w_i\} \rightarrow \{w_1, w_2, \cdots w_j\} \in \varepsilon_d)$.

$$\varepsilon = \begin{cases} w_e \rightarrow \{w_e, \cdots w_k\} \in \varepsilon_t \\ \{w_1, \cdots w_i\} \rightarrow \{w_1, \cdots w_j\} \in \varepsilon_d \end{cases} \tag{4}$$

The nature of edge connections in G_{sem} extends beyond pairwise interactions as each edge may connect to one or more word nodes. Hence, we formulate the semantic graph as a hypergraph (Feng et al., 2019) where an edge can join an arbitrary number of vertices. We construct $G_{sem} = (\nu, \varepsilon, \mathbf{W})$ where ν is the set of all word nodes w_i, and ε is the subset of hyperedges such that $\varepsilon = \varepsilon_t \cup \varepsilon_d$. Each hyperedge e is assigned a positive weight corresponding to the type of edge relation and is stored in a diagonal matrix $\mathbf{W} \in \Re^{|\varepsilon|x|\varepsilon|}$. The semantic graph is learned using hypergraph convolution layers (Bai et al., 2021b) to obtain discriminative node embeddings for each word node.

C Training Setup

Hyperparameter: Hyper-parameters for `DocTime` were tuned on the respective validation set to find the best configurations for different datasets. We summarize the range of our model's hyper parameters such as: number of hidden layers in WR-GCN/BERT-GCN/HyperGraphGCN $\{1, 2, 3\}$, size of hidden layers in WR-GCN/BERT-GCN/HyperGraphGCN $\{64, 128, 256, 512\}$, BERT embedding size (768), dropout $\delta \in \{0.2, 0.3, 0.4, 0.5.0.6\}$, learning rate $\lambda \in \{1e-5, 1e-4, 1e-3, 1e-2, 1e-1\}$, weight decay $\omega \in \{1e-6, 1e-5, 1e-4, 1e-3\}$, batch size $b \in \{16, 32, 64\}$ and epochs (≤ 100), ϵ-sparsity $\in [0, 1]$, IDGL smoothness ratio=0.5, IDGL sparsity ratio=0.5, IDGL connectivity ratio=0.5, size of hidden layers in Graph U-net $\{64, 128, 256, 512\}$.

Loss Function and Inference: `Time-Transformers` are trained using Cross Entropy loss with Adam optimizer. Across both TempNLI and TimeQA datasets, we found the best results correspond with the use of Adam optimiser set with default values $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e-8$, weight-decay of $5e-4$ and an initial learning rate of 0.001.

`DocTime` uses cross entropy loss for structure prediction. For structure+relation classification, it uses the path prediction loss as defined in Methodology.

Computing Infrastructue: `DocTime` and `Time-Tranformers` are written in PyTorch library and were trained on 4 and 6 Nvidia GeForce RTX 2080 GPU, respectively. **Average Runtime**: `DocTime` takes a maximum of approximately 5 hrs to train once on TDG datasets. `Time-BERT`, `Time-RoBERTa` take 3 hrs to fine-tune on TempNLI. `Time-BigBird`, `Time-FiD` takes 8,12 hours to fine-tune, respectively.

D Hyperparameters

Table 8 show the Training hyperparameters of `DocTime` for TDT, TDG, ContractTDG datasets.

E More Results

Performance across different relation types: We analyze the benefits of `DocTime` for different types of relations in document-level TDG datasets in Table 7. We report F1 scores for structure+relation prediction for timex-timex, event-timex and event-event pairs. We observe a relatively smaller performance gap between the BERT Ranking parser and `DocTime` for event-timex relations. However, `DocTime` shows relatively stronger performance for event-event relations. This phenomenon can be attributed to the fact that both datasets tend to have event-event links between event pairs that are on an average closer in word distance, whereas a higher ratio of event-timex and timex-timex pairs are several sentences apart. `DocTime` can integrate long-range inter-dependencies between entity pairs that are several sentences (or paragraphs in Contract TDG) apart.

FACTPEGASUS: Factuality-Aware Pre-training and Fine-tuning for Abstractive Summarization

David Wan and **Mohit Bansal**
University of North Carolina at Chapel Hill
`{davidwan,mbansal}@cs.unc.edu`

Abstract

We present FACTPEGASUS, an abstractive summarization model that addresses the problem of factuality during pre-training and fine-tuning: (1) We augment the sentence selection strategy of PEGASUS's (Zhang et al., 2020) pre-training objective to create pseudo-summaries that are both important and factual; (2) We introduce three complementary components for fine-tuning. The *corrector* removes hallucinations present in the reference summary, the *contrastor* uses contrastive learning to better differentiate nonfactual summaries from factual ones, and the *connector* bridges the gap between the pre-training and fine-tuning for better transfer of knowledge. Experiments on three downstream tasks demonstrate that FACTPEGASUS substantially improves factuality evaluated by multiple automatic metrics and humans. Our thorough analysis suggests that FACTPEGASUS is more factual than using the original pre-training objective in zero-shot and few-shot settings, retains factual behavior more robustly than strong baselines, and does not rely entirely on becoming more extractive to improve factuality.[1]

1 Introduction

Abstractive summarization aims at generating short summaries that capture the essentials of a long document. Research in this challenging task has made significant progress with the help of large pre-trained models (Lewis et al., 2020; Raffel et al., 2020; Zhang et al., 2020). However, current models suffer from the crucial problem of hallucinations (Maynez et al., 2020), where a summary contains facts or entities not present in the original document. Such unfaithful generation raises the question of whether the models can be trustworthy and used safely for real-world applications. To tackle this problem, many approaches propose post-processing models (Chen et al., 2021; Dong et al., 2020; Liu and Liu, 2021), but such methods are often constrained by external resources to train additional correction or selection models. An alternative line of works focuses on learning factuality directly during fine-tuning by filtering nonfactual training data (Goyal and Durrett, 2021; Nan et al., 2021) or, most recently, incorporating contrastive learning (Cao and Wang, 2021) to encourage generating faithful summaries.

In this work, we propose FACTPEGASUS, a model that addresses the problem of hallucinations for abstractive summarization holistically, by incorporating factuality into the whole training pipeline: We tackle the lack of factuality objective in pre-training and the presence of hallucinations in the downstream dataset during fine-tuning. Current pre-training objectives focus on improving the quality of the generated output in the downstream tasks but often overlook the factuality aspect. Thus, we explore incorporating **factuality into the pre-training objective** of PEGASUS (Zhang et al., 2020) (a state-of-the-art abstractive summarization model). The original objective, gap sentence generation (GSG), transforms any text into a pseudo-summarization dataset by selecting important sentences using ROUGE (Lin, 2004) as output summaries. We explore strategies for combining ROUGE and the factuality metric FactCC (Kryscinski et al., 2020) as the selection criteria, so that the model learns to generate sentences that cover the most important information of the input document as well as remain faithful to it.

Next, we propose three complementary modules that further address factuality problems during fine-tuning: (1) **Corrector** that removes hallucinations existing in reference summaries, allowing training on the full training set without learning unfaithful behaviors; (2) **Contrastor** that encourages the model to better differentiate factual summaries from nonfactual ones by paying attention to the document using contrastive learning; (3) **Connec-**

tor, a special mask-token fine-tuning technique enabled by the GSG-style objective, that simulates the pre-training task during fine-tuning by inserting the mask token into the input document so that the pre-trained model can adapt its knowledge of generating factual summaries directly to the downstream tasks. The connector, corrector, and contrastor address the input, output, and training objective of the downstream task, respectively, and the combination of the components reduces potential confounding problems that cannot be addressed by a single module. We show that the full model improves three factuality metrics, the token and sentence error of DEP Entail (Goyal and Durrett, 2021) and FactCC, on the downstream datasets of XSum (Narayan et al., 2018), WikiHow (Koupaee and Wang, 2018), and Gigaword (Rush et al., 2015). Most notably, FACTPEGASUS outperforms existing factuality-aware summarization models by more than 40% and 34% on XSum for token error and FactCC, respectively. Ablation studies show the usefulness of each of our fine-tuning components as well as the additive gain of combining our complementary modules, and human evaluation confirms that FACTPEGASUS generates significantly more factual summaries over strong baselines.

Finally, we perform a detailed analysis of FACTPEGASUS, which points to several important observations regarding learning and maintaining factuality: (1) **Zero-shot** setting demonstrates the utility of our factuality-aware pre-training objective, as our model outperforms PEGASUS (which uses the original objective) on all three factuality metrics when evaluated directly on the downstream task without any supervised training data. **Few-shot** experiment indicates that even a small number of nonfactual examples can have a strong negative impact on factuality and can nullify much of the gain from factuality pre-training, highlighting the importance of ensuring factuality during fine-tuning. (2) **Factuality dynamics** (Goyal et al., 2022) further shows that FACTPEGASUS exhibits a lesser degree of factuality degradation than what is observed for BART-base. (3) **Factuality vs abstractiveness tradeoff curve** reveals that FACTPEGASUS effectively improves factuality by not simply relying on the increase in extractiveness.

To summarize, our contributions are as follows:

1. We propose a factuality-aware pre-training objective for abstractive summarization and study the effect of different sentence selection strategies on downstream factuality.
2. We introduce three complementary components for improving factuality during fine-tuning that correct hallucinations present in the training set, discourage unfaithful generation during training, and bridge the gap between pre-training and fine-tuning. The full model consistently achieves better factuality scores than strong baselines on three downstream abstractive summarization tasks, confirmed by human evaluation.
3. We conduct thorough factuality analysis and show that FACTPEGASUS generates more factual summaries with no or little supervision, slows down factuality degradation observed for current models, and improves factuality not by becoming more extractive.

2 Related Work

Pre-training Objective for Generation Tasks. Transformer-based models have achieved state-of-the-art performance for abstractive summarization (Devlin et al., 2019; Lewis et al., 2020; Raffel et al., 2020; Zhang et al., 2020). Many such pre-trained models study the effect of useful pre-training objectives, often in the form of masking certain parts of the input. BART (Lewis et al., 2020) randomly masks spans of tokens in the text as input and asks the model to reconstruct the original text. Our work builds on the success of PEGASUS's (Zhang et al., 2020) pre-training objective that closely resembles the downstream summarization task. Their objective selects sentences that best represent the document as the output summary, and masks out the selected sentences in the original text as the input document. We explore various sentence selection strategies to encourage the model to generate summaries that cover the most important information of the document and also remain faithful to it.

Improving Factuality for Summarization. Recent models can achieve highly fluent and coherent abstractive summaries, yet the generated summaries often contain factual errors (Falke et al., 2019; Maynez et al., 2020). Several approaches have addressed this problem, which can be roughly categorized into two types. The first approach proposes post-processing models, that either removes hallucinations in the generated summaries (Cao et al., 2020; Dong et al., 2020), or selects the most factual candidate during beam search (Chen et al., 2021). This approach often requires training additional models and external resources. In an attempt to improve factuality in an end-to-end fashion, Nan et al. (2021) and Goyal and Durrett (2021) explore a useful method of removing nonfactual examples during training, but this only allows the model to be trained on a small portion of the training data.

Recently, contrastive learning (Chopra et al., 2005, CL) has started to gain traction for improving factuality. Popular for representation learning, CL has had great success for vision tasks (Chen et al., 2020) and has also been successfully applied to summarization, where Liu and Liu (2021) improves summary quality by differentiating high-quality summaries from the lower-quality ones. Cao and Wang (2021) extend this idea to improve factuality with various approaches to generate hallucinated summaries as negative examples, showing consistent improvement over existing methods. We similarly incorporate CL as an additional training objective, but we differ from previous works in the choice of anchor and positive sample. Inspired by Lee et al. (2021), who use encoder and decoder output as candidates for CL across multiple text generation tasks, we extend this idea to factuality, i.e., instead of performing CL only between summaries, we perform CL between the document and the summary. This setup encourages the model to generate a faithful summary that pays attention to the document, i.e., the definition of faithfulness.

3 FACTPEGASUS

We describe our training procedure consisting of pre-training with a factuality-aware objective (Section 3.1) and fine-tuning with three complementary modules for improving factuality (Section 3.2).

3.1 Factuality-Aware Pre-training

Recent exploration of good pre-training objectives for abstractive summarization aims at achieving high quality on downstream tasks, often in terms of ROUGE. However, few have analyzed the effect of pre-training objective on factuality. We focus on incorporating this aspect into the pre-training objective of PEGASUS, gap sentence generation (**GSG**), since PEGASUS achieves state-of-the-art performance on the downstream abstractive summarization tasks. The GSG objective transforms text documents into a pseudo-summarization dataset by selecting important sentences as the output summary, which are subsequently masked out in the original text. The best strategy determines the importance by calculating ROUGE-1 between each chosen sentence and the rest of the document. While the original strategy selects sentences that contain the most unigram overlap, there is no guarantee that the selected sentences are faithful to the rest of the document. We provide an illustrative example in Figure 1a, where the original objective selects sentence C due to its high ROUGE-1 score. However, this sentence is not a faithful summary to the rest of the document as the other sentences concern with the fire in Seattle while only sentence C talks about the fire in Denver.

To address this problem, we extend this objective, which we call factual GSG (**factGSG**), where we additionally measure the importance of the sentences according to factuality. We use FactCC (Kryscinski et al., 2020) as the factuality criteria when selecting the summary sentences, as it correlates highly with human factuality judgment (Pagnoni et al., 2021) and is relatively fast to compute. FactCC produces a binary prediction where a score of 1 indicates that the selected sentence is consistent with the rest of the document. Another change in factGSG is the choice of gap sentence ratio, which determines the percentage of sentences in the text that will be selected as the summary. Instead of selecting 30% of the text document as output summary, we only select one sentence, as selecting more sentences will inevitably increase the possibility of hallucinations.

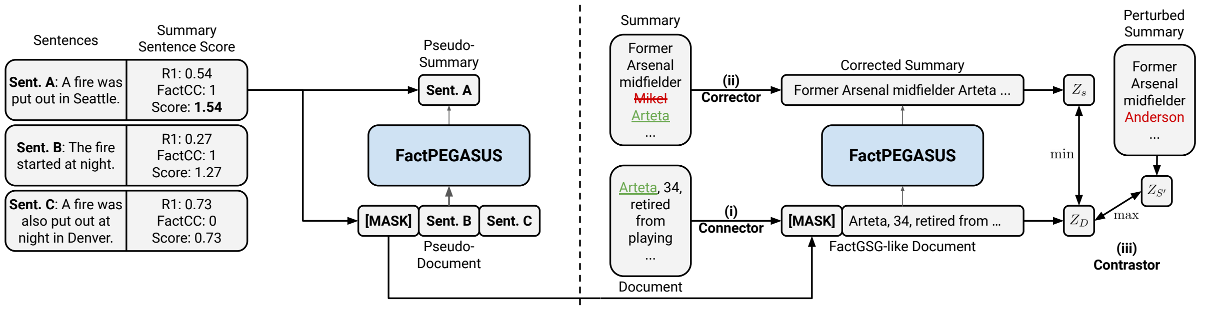
Formally, given a document D of n sentences, $D = \{x_1, x_2, ..., x_n\}$, we select the top-scoring sentence as the output summary, where the score of each sentence x_i is calculated by:

$$s_i = rouge(x_i, D \backslash \{x_i\}) + FactCC(x_i, D \backslash \{x_i\})$$

Going back to the example in Figure 1a, FactCC assigns a score of 0 to the nonfactual sentence C because the fire in Denver is not entailed by the other sentences. This results in sentence A scoring higher than the nonfactual sentence, and thus overcomes the problem in the original objective.

3.2 Factuality-Aware Fine-tuning

Although the typical approach of updating all the model's parameters during fine-tuning adapts well to the downstream task, the model suffers from imitative falsehood (Lin et al., 2021): The model learns to generate similar hallucinations present in the downstream dataset, and even completely forgets its factual behaviors learned during pre-training. This is especially problematic for datasets



(a) Pre-training

(b) Fine-tuning

Figure 1: Illustration of FACTPEGASUS. For pre-training (a), we use the factGSG objective introduced in Section 3.1 that transforms a text document into a pseudo-summarization dataset. We select the pseudo-summary using the combination of ROUGE and FactCC. Here, sentence A is selected as the pseudo-summary, and we mask this sentence in the original text to create the pseudo-document. During fine-tuning (b), the connector (i) simulates the factGSG task by appending the same mask token used in (a) to the input document, so that we have the same setup in both training stages. Then, corrector (ii) removes hallucinations (highlighted in red) from the summary. Finally, contrastive learning in (iii) encourages the model to prefer the corrected summary over the perturbed summary.

like XSum that contains hallucinations on 70% of the summaries (Maynez et al., 2020).

To this end, we present three complementary fine-tuning modules, illustrated in Figure 1b. Each component addresses different parts of the downstream task and collaboratively ensures factuality throughout the fine-tuning stage.

3.2.1 Connector

The GSG objective enables faster and better adaptation during fine-tuning by simulating the downstream task (Zhang et al., 2020). However, there still exists a gap between pre-training and fine-tuning: GSG is a masked sentence prediction task, but downstream summarization does not make use of the mask token. Thus, we simply insert the mask token into the input document of the downstream dataset, so as to simulate what the model expects during pre-training. This can be seen as a form of prompting, which helps us to elicit the factuality knowledge of the pre-trained models. We insert the mask token between sentences, and the best position is determined by evaluating the summarization performance on the validation set. We report the best position of the mask token and discuss the similarity to prompting in Appendix C.

3.2.2 Corrector

The corrector removes hallucinations in the reference summaries so that such examples can be used during training without contributing to the problem of imitative falsehood. We consider summary entities as hallucinating if the text cannot be matched to one of the document entities. We propose three approaches with varying degrees of aggressiveness w.r.t. the removal of hallucinations and the possibility of generating ungrammatical sentences.

Replace: Upon qualitative analysis, we discover that some hallucinated entities in the summary are partially present in the documents. The most prominent example is the use of names, where the summary contains the full name of the person while only the first or last name is mentioned in the document, as shown in Figure 2. Given such observation, we propose a method to find a similar entity with the same NER label in the document and use that to replace the original hallucinated entity in the summary. Although this approach cannot correct hallucinations where similar entities are missing in the document, grammaticality is ensured.

Remove: A more aggressive approach is to remove the hallucinated entities in the training examples. The intuition is that it is often better to not say anything than to say something wrong. We mitigate the problem of creating ungrammatical sentences by removing related words to the removed entities determined by dependency arcs.

Combined: As a middle ground that ensures no hallucinations are present in the reference summaries while being grammatical when possible, we first replace all possible entities and then apply the remove strategy on the remaining ones.

We refer the readers to Appendix-B.1 for the details about hallucination detection, as well as the algorithm and discussion of grammatically for the remove method.

Document	[Arteta]$_{\text{ent}}$, [34]$_{\text{number}}$, retired from playing at [the end of last season]$_{\text{date}}$ ... [Arteta]$_{\text{ent}}$ was seen crying after his final [Arsenal]$_{\text{ent}}$ match... [Guardiola]$_{\text{ent}}$'s first game since succeeding [Manuel Pellegrini]$_{\text{ent}}$ ...
Summary	Former [Arsenal]$_{\text{ent}}$ midfielder [Mikel Arteta]$_{\text{ent}}$ has taken up a coaching role at [Manchester City]$_{\text{ent}}$.
	Corrector
Replace	Former Arsenal midfielder Arteta has taken up a coaching role at Manchester City.
Remove	Former Arsenal midfielder ~~Mikel Arteta~~ has taken up a coaching role ~~at Manchester City~~.
Combined	Former Arsenal midfielder Arteta has taken up a coaching role ~~at Manchester City~~.
	Contrastor
Intrinsic	Former Arsenal midfielder *Manuel Pellegrini* has taken up a coaching role.
Extrinsic	Former Arsenal midfielder *Wenger* has taken up a coaching role.

Figure 2: Example output using different strategies of corrector and contrastor. The first two rows show the original document and summary with highlighted entities and their respective labels (date, number, ent). We mark hallucinated entities in the summaries with red, factual entities in document and summary with green and underlined, and removed entities by the corrector with a ~~strikethrough~~. Perturbed entities by the contrastor are *italicized*.

3.2.3 Contrastor

To better distinguish factual summaries from non-factual ones, we next introduce a contrastive learning objective that encourages the model to prefer factual summaries given the context of the document. We use the document D_i as the anchor and only consider the reference summary S_i as the positive sample. Then, we create a set of nonfactual summaries N_i to form negative pairs following Kryscinski et al. (2020), where we replace factual entities with random entities of the same named entity labels. We experiment with two variants simulating either extrinsic and intrinsic hallucinations. As formulated in Maynez et al. (2020), extrinsic hallucinations refer to entities that are present in the summary but not in the document, whereas intrinsic hallucinations are those that are present in the document but contain inaccurate information or are misplaced. See Appendix B.2 for more details.

We stress that we perform contrastive learning between the document and the summary, similar to Lee et al. (2021), instead of between summaries (Cao and Wang, 2021), as it follows closer to the definition of faithfulness - the summary should be generated within the context of the document.

We use the NT-Xent loss (Chen et al., 2020):

$$l_{D_i,S_i} = -\log \frac{\exp \text{sim}(z_{D_i}, z_{S_i})/\tau}{\sum_{S_j \in N_i \cup \{S_i\}} \exp \text{sim}(z_{D_i}, z_{S_j})/\tau}$$

where z_{D_i}, z_{S_i} and z_{S_j} are representation for D_i, S_i and S_j, respectively. We generate z_D and z_S by performing mean pooling over the last hidden layer of the encoder and decoder output, respectively. $\text{sim}(\cdot,\cdot)$ is the cosine similarity between the representations, and τ is the temperature parameter.

The final loss is calculated by the sum of the cross-entropy loss L_{CE} and the contrastive loss: $L = L_{CE} + \lambda L_{CL}$, where λ is a scalar.

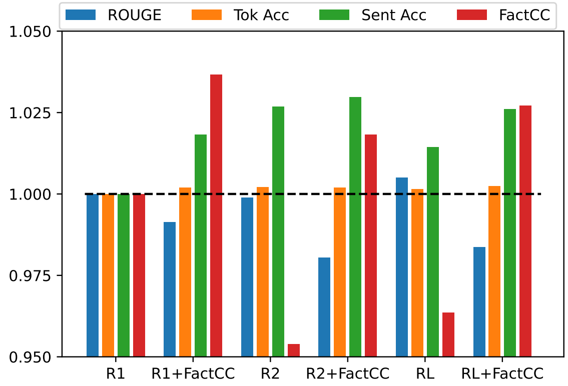


Figure 3: Relative effect using different sentence selection criteria on XSum. Adding FactCC to criteria consistently improves factuality. Full result in Table 10.

4 Experimental Setup

We describe our experimental setup, and refer to Appendix A for more details.

4.1 Datasets and Evaluation Metrics

We pre-train on the C4 dataset (Raffel et al., 2020), and evaluate our pre-trained model on three downstream abstractive summarization datasets: XSum (Narayan et al., 2018), WikiHow (Koupaee and Wang, 2018), and Gigaword (Rush et al., 2015). XSum is the primary dataset for analysis unless otherwise stated, as most of the factuality works for abstractive summarization evaluate on this dataset. Dataset details are presented in Appendix A.1.

We report ROUGE-L (Lin, 2004) to evaluate our generated summaries against the reference. However, we note that this method is not ideal given the presence of hallucinations in the reference summaries (Chen et al., 2021; Maynez et al., 2020): If a more factual model does not produce such hallucinations, the output is scored lower than those that contain the same hallucinations found in the reference.

To evaluate factuality, there have been many proposed automatic metrics (Durmus et al., 2020; Wang et al., 2020; Scialom et al., 2021). We report FactCC (Kryscinski et al., 2020) and DEP-Entail (Goyal and Durrett, 2021), as they are highly correlated with human judgment of factuality (Pagnoni et al., 2021). For DEP-Entail, we report the token-level and sentence-level error. For FactCC, since the model has been trained to evaluate on single sentences, we calculate the average score across all sentences for each summary.

To confirm our observation, we conduct human evaluation asking Amazon Mechanical Turk[2] (AMT) to judge the factuality and informativeness of the summaries. We randomly select 100 documents and ask the annotators to check whether each of the generated summaries is factual and informative. Appendix E provides more details.

4.2 Pre-training and Fine-tuning Setup

For pre-training, we use BART-base's architecture with PEGASUS's SentencePiece (Kudo, 2018) unigram model tokenizer. We first determine the best sentence selection criteria by experimenting with selection criteria that use ROUGE-1, ROUGE-2, and ROUGE-L, as well as combining each with FactCC. To save computation (Lewis et al., 2020; Zhang et al., 2020; Raffel et al., 2020), we pre-train these models on a smaller dataset and fewer training steps. We report the effect of the selection criteria using the normalized ROUGE score and factuality scores over the model that uses ROUGE-1 as the selection criteria. We take the complement of token error and sentence error as token accuracy and sentence accuracy, respectively, to present all metrics where higher is better. Details of pre-training are shown in Appendix A.4.

Finally, We evaluate our pre-trained model on the three downstream tasks. As baselines, we compare our model to BART-base and PEGASUS*, our variant of the PEGASUS-base as there is no publicly available checkpoint. We train PEGASUS* by using the original sentence selection metric (ROUGE-1), and observe higher ROUGE scores on XSum and WikiHow than the ones reported in the original paper. We also compare FactPEGASUS to two summarization models optimized for factuality. DAE (Goyal and Durrett, 2021) uses DEP-Entail to mask out the nonfactual tokens during training, and CLIFF (Cao and Wang, 2021) uses contrastive learning between the reference summaries and automatically generated nonfactual summaries. We apply both methods to BART-base. Details are described in Appendix A.5.

Dataset	Model	RL	tok err↓	sent err↓	FactCC
XS	BART-base	**33.78**	12.38	60.70	23.99

	CLIFF	31.40	10.36	53.14	23.77
	FactPEGASUS	31.17	**6.07**	**38.66**	**34.32**
WH	BART-base	31.81	8.99	45.77	99.09
	PEGASUS*	30.30	9.77	47.28	98.83
	DAE	31.66	4.91*	34.45*	98.87
	CLIFF	**33.82**	13.74	57.42	99.18
	FactPEGASUS	29.33	**7.86**	**42.40**	**99.41**
GW	BART-base	**35.11**	2.29	19.68	55.66
	PEGASUS*	34.74	2.84	22.66	56.43
	DAE	35.57	0.58*	7.54*	59.61
	CLIFF	34.89	**1.72**	**18.45**	58.53
	FactPEGASUS	34.23	2.30	19.32	**60.02**

Table 1: Fine-tuning results on the XSum (XS), WikiHow (WH), and Gigaword (GW) dataset. FactPEGASUS consistently improves factuality metrics for all datasets over the two baseline models, and outperforms existing factuality models on FactCC. The token error and sentence error achieved by DAE (marked with *) is not a fair comparison, because the model optimizes the metric during training.

Model	Factuality	Informativeness
BART-base	24.67	61.33
PEGASUS*	27.33	58.33
DAE	31.99	61.66
CLIFF	29.33	**62.99**
FactPEGASUS	**39.66**	58.67

Table 2: Human evaluation results on XSum. Our model is statistically significantly better ($p < 0.05$) than BART-base, PEGASUS*, and CLIFF, and moderately significantly better than DAE ($p = 0.055$). There is no statistical significance between the informativeness of FactPEGASUS and other models ($p > 0.15$).

5 Result

5.1 Pre-training Sentence Selection Results

Figure 3 shows the effect of different sentence selection criteria. Adding FactCC to all three ROUGE-only criteria consistently improves all factuality metrics at the cost of a small decrease in quality. Overall, the selection strategy of combining ROUGE-1 and FactCC achieves the highest FactCC score out of all strategies while maintaining the smallest relative drop in ROUGE.

---

5.2 Fine-tuning Results

We present our full result on the three downstream tasks in Table 1. While the two baseline models achieve similar factuality scores, FACTPEGASUS consistently improves factuality over the two baselines on all three datasets. The largest improvement can be seen for the XSum dataset, where FACTPEGASUS, compared to BART-base, lowers the token error and sentence error by 51% and 36%, respectively, and increases FactCC by 43% [3] . The same trend but to a lesser degree can also be observed for WikiHow and Gigaword, most notably a 3-point decrease in sentence error for WikiHow and a 2-point increase in FactCC for Gigaword.

Compared to factuality-aware models, FACTPEGASUS achieves the highest FactCC on all tasks. Notably, FACTPEGASUS outperforms DAE by 34% on XSum. In terms of DEP-Entail, FACTPEGASUS outperforms CLIFF on XSum and WikiHow. We note that DAE is trained using the DEP-Entail metric and thus is not a fair comparison.

We note that the ROUGE-L scores for FACTPEGASUS are lower than both baseline models by about 2 points, but we stress that our increase in FactCC is substantially larger than the decrease in ROUGE-L for XSum and Gigaword. The negative relationship between factuality metrics and ROUGE is also reported in prior works (Chen et al., 2021; Kryscinski et al., 2019). For example, fine-tuning BART on a subset of XSum (Goyal and Durrett, 2021) improves factuality at the cost of a 6-point drop in ROUGE-L[4], which is triple the amount of decrease observed for our model.

Human Evaluation results are shown in Table 2. The result agrees with our observation on automatic factuality metrics, as FACTPEGASUS produces significantly more factual summaries than the BART-base, and PEGASUS*, and CLIFF. We achieve moderately significantly better summaries ($p = 0.055$) than DAE. Although, FACTPEGASUS achieves low informativeness, we find no statistical significant difference between our model and other models ($p > 0.15$).

Model	RL	tok err↓	sent err↓	FactCC
factGSG	**32.99**	12.31	59.30	24.94
+ corrector replace	32.48	10.57	55.05	25.06
+ corrector remove	30.37	6.44	39.89	**35.77**
+ corrector combined	31.19	6.10	38.96	33.79
+ contrastor intrinsic	32.14	11.46	57.61	25.26
+ contrastor extrinsic	32.54	11.95	59.10	25.07
+ contrastor + corrector	31.17	6.08	38.92	34.17
FACTPEGASUS	31.17	**6.07**	**38.66**	34.32

Table 3: Fine-tuning ablation on XSum. We present our pre-trained model factGSG fine-tuned without any of our proposed components, and adding different strategies of corrector and contrastor. We then combine the best of the two modules (corrector combined and contrastor intrinsic), and finally add the connector to form the final model, which we copy from Table 1.

Model	RL	tok err↓	sent err↓	FactCC
GSG+mask	23.49	9.04	43.62	24.49
factGSG+mask	**24.23**	**7.69**	**38.88**	**35.14**

Table 4: Zero-shot results when applying the connector to our pre-trained model (factGSG+mask) and PEGASUS*(GSG+mask). FactGSG+mask outperforms GSG+mask on all metrics.

5.3 Fine-tuning Ablation Studies

We present ablation studies of our proposed methods in Table 3. We first compare the performance of different strategies for the corrector and contrastor. For corrector, the level of aggressiveness in correcting hallucinations has a positive relationship with factuality metrics but a negative relationship with ROUGE-L. Although the remove method achieves the highest FactCC score, the combined method further lowers the token and sentence error while achieving relatively high ROUGE-L and FactCC. For contrastor, simulating intrinsic errors, which creates more challenging negative samples, provides better factuality results than simulating extrinsic ones. Finally, we show the additive gain in combining the best corrector and contrastor, as well as adding the connector to form the final model.

We report the same ablation studies for Gigaword and Wikihow in Appendix D.3, and that for PEGASUS* in Appendix D.4.

5.4 Zero-shot and Few-shot Results

With the help of connector proposed in Section 3.2.1, we can explore how knowledge about factuality is transferred to fine-tuning, especially in

---

[3] We also experimented with a more aggressive corrector that can achieve more than 50% increase in FactCC and 59% improvement on sentence error on XSum, but this variant can hurt informativeness. Hence, the results can be tuned depending on the desired tradeoff between factuality and informativeness on the downstream task at hand.

[4] The result is reported in Cao and Wang (2021).

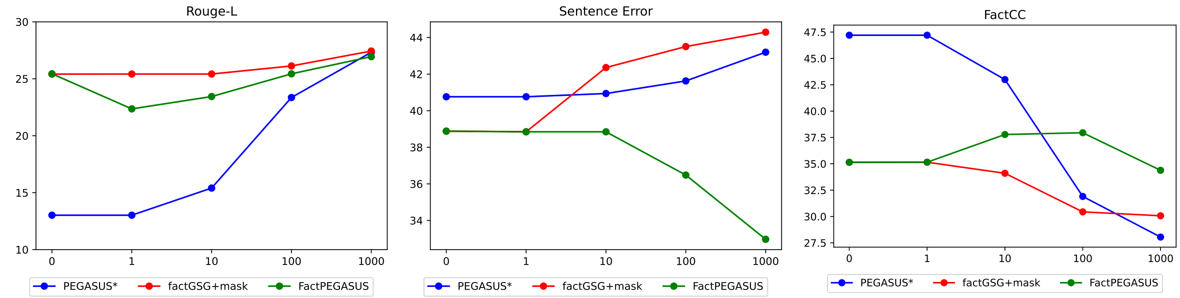

Figure 4: Zero-shot and few-shot results. The lines represent each models's performance when fine-tuned on 0 (zero-shot), 1, 10, 100, and 1000 examples. FACTPEGASUS consistently improves sentence error with more training data. Without the corrector and contrastor, factuality decreases with just 10 examples.

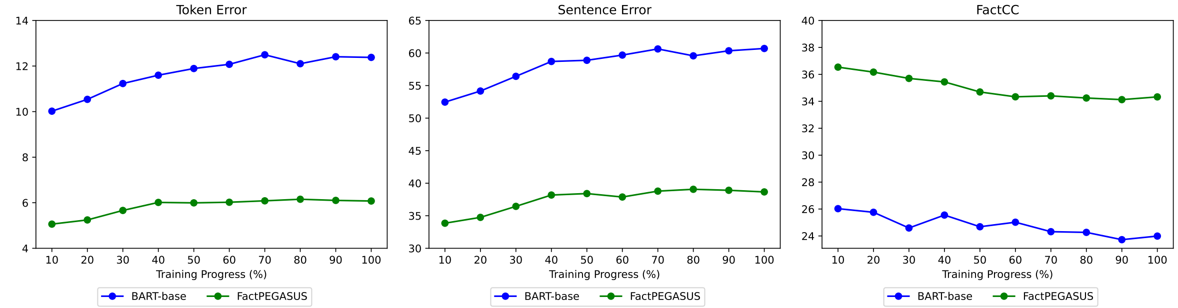

Figure 5: Factuality dynamics result. We show token error, sentence error, and FactCC as training progresses. FACTPEGASUS slows down factuality degradation for all metrics compared to BART-base.

the zero-shot and few-shot settings[5].

Zero-Shot. We apply the mask token to the best position and directly analyze the performance of the models on the test set. To better understand the effectiveness in transferring knowledge about summarization and factuality from the pre-training objective, we apply the connector to our pre-trained model (factGSG+mask) and PEGASUS* (GSG+mask), so that the two models differ only in their pre-training objective. We report the result in Table 4. FactGSG+mask outperforms GSG+mask on all metrics, especially for factuality metrics. Specifically, factGSG+mask lowers the sentence error by 5 points and increases FactCC by about 10 points. This observation confirms that the factGSG objective is more effective at capturing factuality than the original GSG objective.

Few-Shot. We follow a similar setup in Zhang et al. (2020), where we limit the number of training data to 1, 10, 100, and 1,000, and then fine-tune the model up to 2,000 steps with the patience of 10 epochs for early stopping. We select the checkpoint with the best validation performance.

We conduct this experiment by comparing FACTPEGASUS to PEGASUS*, which has been shown for its ability to transfer with as little as 100 training examples (Zhang et al., 2020). In addition, we report the performance of factGSG+mask to understand how the the model is affected without explicitly ensuring factuality (i.e. without corrector and contrastor). As shown in Figure 4, connector allows the model to better make use of the knowledge of pre-training and produces high-quality summaries, as both FACTPEGASUS and factGSG+mask produces a ROUGE-L score comparable to PEGASUS* trained with 1000 examples.

In terms of factuality, we notice that with just 10 examples, PEGASUS* starts to degrade in factuality, which also applies to the factGSG+mask model. However, FACTPEGASUS demonstrates an opposite trajectory: Sentence error decreases with more training data, and FactCC remains about the same score. This indicates that factual behavior is prone to be overwritten when factuality is not ensured explicitly, and thus calls for the importance of the corrector and contrastor.

5.5 Factuality Dynamics during Fine-tuning

To see whether the factuality degradation observed in few-shot experiment also applies to the full fine-

---

[5] Strictly speaking, typical zero-shot and few-shot settings do not allow using the full validation set. However, we use validation results to decide the position of the mask token.

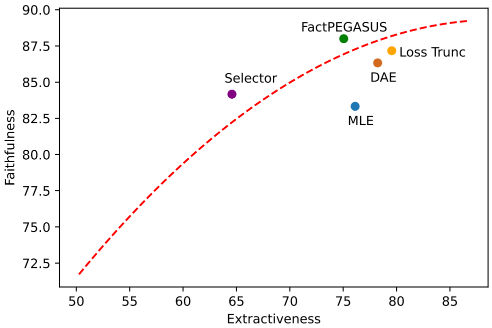

Figure 6: Faithfulness-abstractiveness trade-off curve, shown as the dashed red line, on Gigaword dataset. We plot each model's average faithfulness score evaluated by AMT against its extractiveness level. Our model lies above the graph, performing better than MLE-baseline, DAE (Goyal and Durrett, 2021), and Loss Truncation (Kang and Hashimoto, 2020).

tuning process, we extend our analysis by studying the factuality dynamics, similar to Goyal et al. (2022). The authors observe an increase in sentence errors with the BART model during fine-tuning, and we analyze whether similar factuality degradation occurs for FACTPEGASUS. We save checkpoints of our models every 10% of the total training steps, and evaluate the models on all three factuality metrics. Figure 5 shows the factuality dynamics during fine-tuning. We notice that the degradation occurs for both models but at a different degree. The token and sentence error for BART-base increase by 2 and 8 points, respectively. However, factuality for FACTPEGASUS remains similar, with only an increase of 1 point for token error and 4.8 points for sentence error. The degradation is only about half of what is observed with BART-base, indicating that FACTPEGASUS is better at avoiding learning nonfactual behaviors.

5.6 Factuality vs Abstractiveness Tradeoff

Lastly, we wish to understand whether our proposed method is effectively improving factuality without relying on the increase in extractiveness. To this end, Ladhak et al. (2021) introduces a faithfulness-abstractiveness trade-off curve to measure the faithfulness given the model's extractiveness. The authors kindly provided the same set of examples for Gigaword and AMT template for calculating the faithfulness score.

We show our result on Gigaword in Figure 6. We include the result of their proposed Selector and previous works, including Loss Truncation (Kang and Hashimoto, 2020) and DAE (Goyal and Durrett, 2021). We note that the baseline models increase factuality but mostly due to an increase in extractiveness and thus fall below the curve. In contrast, FACTPEGASUS lies above the line, indicating that we are effectively increasing factuality without relying much on becoming more extractive.

6 Conclusion

In this work, we proposed FACTPEGASUS, a model for abstractive summarization consisting of factuality-aware pre-training and modules for ensuring factuality during fine-tuning. We demonstrated the effectiveness of our model at improving factuality on three downstream abstractive summarization datasets, confirmed by our human evaluation. Our analysis showed that our proposed factuality-aware pre-training objective is effective at capturing knowledge of factuality compared to the original objective and that our fine-tuning modules reduce the factuality degradation observed with current models. We finally showed that improvement in factuality is not solely explained by the increase of extractiveness.

7 Ethical Impact

Our work aims at reducing the risk of generating hallucinations, and even possibly misinformation, for abstractive summarization models so that such models can be used safely for real-world applications. While we demonstrate that we can alleviate this problem, we stress that there is still a long way to go for improving factuality. Thus, we stress that such models should be used with caution for real-world applications.

Acknowledgment

We thank the reviewers for their helpful comments. We also thank Shiyue Zhang and Xiang Zhou for useful discussions and comments on the paper. This work was supported by NSF-CAREER Award 1846185 and NSF-AI Engage Institute DRL-211263.

A More Details on Experimental Setup

A.1 Datasets

Following PEGASUS, we pre-train on the C4 dataset, a large collection of documents from Common Crawl. We evaluate our pre-trained model on three downstream abstractive summarization datasets: XSum, WikiHow, and Gigaword. XSum is a collection of articles from the British Broadcasting Corporation, Gigaword is a large collection of news articles headlines, and WikiHow consists of how-to articles.

We show the dataset statistics for pre-training and fine-tuning in Table 5, where we present the number of examples in the training, validation, and test splits. We also show the number of examples corrected using the replace and remove method. All datasets are from *datasets* (Lhoest et al., 2021).

A.2 Evaluation Metrics

We use the ROUGE package provided by *transformers* (Wolf et al., 2020). We follow the instructions provided by the authors of the factuality metrics to set up and run their code. We report all scores of our models from single runs.

A.3 Training Details

We use *transformers* library for the training script and the checkpoints of the pre-trained models. We use the default setting, including the AdamW optimizer and the linear rate scheduler. We also use mixed precision for both pre-training and fine-tuning the models. We conduct our experiments on the RTX A6000 GPU with 48GB memory and the A100 GPU with 40GB memory. BART-base model has 139M parameters, and PEGASUS* and FACTPEGASUS have 175M parameters.

A.4 Pre-training Setup

Model Architecture. We use the same architecture as BART-base. Specifically, the model has $L = 6$, $H = 768$, $F = 3072$, $A = 12$, where L is the number of layers, H is the hidden size, F is the dimension for feed-forward layer, and A is the number of self-attention heads. We use the SentencePiece (Kudo, 2018) unigram model tokenizer from PEGASUS with a vocabulary size of 96,103.

Sentence Selection Criteria. Before pre-training the full model, we first determine the best sentence selection criteria that produces more factual summaries with comparable quality. We experiment with sentence selection criteria that use ROUGE-1, ROUGE-2, and ROUGE-L, as well as combining each with FactCC. To understand the effect of the pre-training objective on factuality directly, we evaluate the performance on the XSum dataset without applying any of our proposed fine-tuning modules. Following Zhang et al. (2020), we report the models' relative performance to the base model, which only uses ROUGE-1 as the selection criteria. We use the normalized ROUGE F1 scores $\frac{1}{3}(\frac{R1}{R1_{base}} + \frac{R2}{R2_{base}} + \frac{RL}{RL_{base}})$, where $R1_{base}$, $R2_{base}$, and RL_{base} are the ROUGE F1 scores of the base model. We similarly report the factuality metrics by normalizing each score by that of the base model. We take the complement of token error and sentence error as token accuracy and sentence accuracy, respectively, to present all metrics where higher is better.

Similar to previous works (Lewis et al., 2020; Zhang et al., 2020; Raffel et al., 2020) that save computational resources when selecting strategies for pre-training, we pre-train these model on the *realnewslike* subset of the C4 dataset with less steps.

Pre-training Details. We use a learning rate of 1e-4, a weight decay of 0.01, and set the maximum number of input tokens to be 512 and a maximum number of output tokens to be 256. We use a batch size of 256. We pre-train the full model for 750,000 steps with a warm-up of 20,000 steps, and only pre-train the smaller models for the sentence selection criteria experiment for 250,000 steps. Pre-training the smaller models takes 30 hours, and pre-training the full model takes 90 hours.

Calculating FactCC Score. In practice, running FactCC on each sentence-document pair of the pre-training data is expensive. Thus, we opt to only calculate the FactCC score for the top 5 sentences

Dataset	Train	Validation	Test	Corrector	
				Replace	Remove
C4	364,868,892	364,608	-	-	-
realnewslike	13,799,838	13,863	-	-	-
XSum	204,045	11,332	11,334	54,036	152,716
WikiHow	157,252	5,559	5,577	8,077	71,936
Gigaword	3,803,957	178,651	1,951	115,896	1,296,168

Table 5: Dataset Statistics. We show the number of exmaples in each split, as well as the number of training examples changed using the replace and remove strategy of the corrector.

according to the ROUGE score between the sentence and the rest of the document.

A.5 Fine-tuning Setup

For all datasets, we use a label smoothing of 0.1. For decoding, we use a beam size of 6 for all datasets. Task-specific hyper-parameters are shown in Table 6. Fine-tuning on XSum and WikiHow takes 8 hours, and fine-tuning on Gigaword takes 11 hours. Decoding on XSum and Gigaword takes half an hour, while decoding WikiHow takes an hour. We use 5 negative examples for the contrastor and set λ to 5 when calculating the combined loss. We set the temperature τ to 0.05.

For fine-tuning DAE and CLIFF, we follow the authors' instructions and fine-tune BART-base with their respective code and hyper-parameters. For WikiHow and Gigaword, we use the same hyperparameters as above.

B Implementation Details for Corrector and Contrastor

B.1 Corrector

We use spaCy's NER model[6] to find entities in the document and summary. Entities in the summary sentence are considered nonfactual if no matching document entities with the same string are found. We have previously experimented with the additional requirement of matching entity type similar to Kryscinski et al. (2020), but we find that this constraint unintentionally causes some correct entities to be considered hallucinating, leading to unnecessarily less informative summaries when removed.

Given hallucinated entities, we can perform either replace or remove operations. For replace, we find document entities whose words are all contained in the selected entity.

For the remove method, we need to make sure to also remove any related words. We use spaCy's dependency parser to systematically remove those. The algorithm is as follows: We first add all the tokens in the selected hallucinated entity to the list of tokens to remove. Then, we recursively find all parents that contain the dependency relation of *pobj* and *prep* without any other children and add those to the tokens to remove. Finally, we add all children that do not have the label *compound*, *relcl*, and *fixed*. The final set of words will then be removed in the summary sentence.

We qualitatively observe that this approach can cover most of the edge cases that would otherwise result in ungrammatical sentences. Nevertheless, this method is not perfect. We include some sample output with the remove method in Figure 7. The algorithm is good at removing entities and related words, such as prepositions, as illustrated in example 1, 3, and 5. However, we observe that it will create ungrammatical sentences when the hallucinated entity is the subject (example 2), or the object of a transitive verb (example 6).

We leave exploration with the best systematic correction algorithm or models for future work.

B.2 Contrastor

Similar to Kryscinski et al. (2020), we generate hallucinated summaries by performing entity perturbation on the original summaries. We find entity candidates using the NER labels and sort them into three categories: We include MONEY, QUANTITY, and CARDINAL as *number*, DATE and TIME as *date*, and all other labels as *named entities*. We randomly select a factual entity in the summary and replace it with an entity belonging to the same category.

For extrinsic hallucinations, we sample candidates of the same category from the training corpus but exclude those present in the document. For the intrinsic case, we select to consider the entities from the document. The number of negative examples for all tasks is 5.

---

[6] We use the en_core_web_trf model.

Dataset	Learning rate	Num Steps	Warmup	Batch size	Max Input tokens	Max Target tokens
XSum	3e-5	15k	500	256	512	64
WikiHow	3e-5	15k	500	256	512	256
Gigaword	3e-5	50k	2000	256	128	32

Table 6: Hyperparametrs for fine-tuning on the three tasks.

	XSum			WikiHow			Gigaword		
Pos.	R1	R2	RL	R1	R2	RL	R1	R2	RL
1	**32.84**	**11.32**	**25.35**	**21.02**	**4.85**	**4.85**	**26.19**	**9.09**	**22.92**
2	24.10	5.90	18.02	20.65	4.80	14.80	22.89	7.22	20.03

Table 7: ROUGE score on validation set when the mask token is placed at different position. Pos. indicates placing the mask token before the ith sentence. Pos. 1 indicates the beginning of the document.

C Connector Result

This mask-token fine-tuning technique can be seen as a form of prompting, where we elicit our desired faithful abstractive summarization behavior from the pre-trained model directly. Specifically, we consider this as null-prompting (Logan et al., 2021), where using the mask token as the prompt can achieve competitive results with manually engineered prompts. Conveniently, since the mask token during pre-training already serves as a placeholder of where the summary sentence should be generated, it naturally serves as a valid prompt. Figure 1b shows an example of adding the mask token before the first sentence and thus creating a similar setup for pre-training.

We first need to determine the best position of mask token, as discussed in Section 3.2.1, where we insert the mask token before the ith sentence of the document, where $i = 1, 2, ..., 6$, and select the best position that achieves the highest ROUGE score on the dev collection. We report ROUGE score of all positions in Table 7 for the three datasets. Interestingly, we observe that the best mask token position for all datasets is before the first sentence. This agrees with the dataset generation of XSum: the summary is taken from the first sentence of the original article. For Gigaword, there is not a change after the first sentence, since the document only consists of a single sentence.

Model	R1	R2	RL
BART-base	19.75	2.61	12.81
PEGASUS*	18.03	2.65	13.02
FactPEGASUS	**32.97**	**11.42**	**25.41**

Table 8: ROUGE score in zero-shot setting on XSum. We apply the connector to our model. FactPEGASUS outperforms BART base and PEGASUS* on all metrics.

Num Examples	RL	tok err↓	sent err↓	FactCC
0	25.44	7.69	38.88	35.14
1	22.36	7.69	38.85	35.15
10	23.44	7.69	38.85	37.78
100	25.44	**5.15**	36.48	**37.95**
1,000	**27.03**	5.67	**32.97**	34.38

Table 9: Full Result of zero-shot and few-shot experiments.

D Additional Results

D.1 Sentence Selection Criteria Result

We report the full result for the sentence selection criteria in Table 10. Surprisingly, each sentence selection criteria that uses FactCC excels in one specific factuality metric: R1+FactCC is best at FactCC, R2+FactCC is best at sentence error, and RL+FactCC is best for token error.

D.2 Zero-shot and Few-shot

We present additional results of the zero-shot and few-shot experiments here.

Zero-shot We first report the reference-based result of the two baseline models and FactPEGA-

Model	RL	tok err↓	sent err↓	FactCC
R1	29.04	12.31	60.65	23.93
R1+FC	28.99	12.13	59.93	**24.81**
R2	29.08	12.12	59.59	23.67
R2+FC	28.65	12.13	**59.48**	24.37
RL	**29.23**	12.17	60.08	23.06
RL+FC	28.62	**12.10**	59.63	24.58

Table 10: Full result of pre-trained models with different sentence selection criteria shown in Figure 3. We denote the criteria with FactCC with (+FC).

SUS in Table 8. Due to the mismatch of pre-training and fine-tuning, we observe that both baseline models perform much worse than their result when fully trained. However, with the help of the connector, we observe 11.5 ROUGE-1 points increase for our model compared to the baseline models, and almost four times and double the score for ROUGE-2 and ROUGE-L, respectively.

Few-shot We show FACTPEGASUS's full result of the few-shot experiment in Table 9.

D.3 Fine-tuning ablation on Gigaword and WikiHow

We report ablation of each fine-tuning components on Gigaword and Wikihow. The result can be found in Table 11. We observe similar trend as Table 3, where each component improves the performance. For WikiHow and Gigaword, the extrinsic method for contrastive learning perform the best. We think that this is due to the fact that the two tasks do not contain rich entities in the document, and thus require introduction of additional entities from the training corpus.

D.4 Fine-tuning ablation using PEGASUS*

We similarly perform the same ablation using the PEGASUS* model, which we present in Table 12. We observe similar trend as Table 3. We note that using our pre-trained model factGSG achieves better factuality than PEGASUS* in each setting.

E Human Evaluation Detail

To ensure high-quality annotations, we select the workers from the United States and have more than 10,000 number of HITS approved as well as an approval rate greater than 98%. In addition, we also create a qualification test where we rate the factuality of the selected generated summaries. Such examples include cases where some summaries hallucinate the first name of a person, which the workers should mark them as not factual. Only workers with the correct annotation can perform the actual task.

To avoid giving too much text to the workers, we select the most important sentences and replace the less relevant sentences with an ellipsis. For each of the summaries, we select the ten most relevant sentences from the document by cosine similarity of the sentence embedding using SentenceTransformer[7] (Reimers and Gurevych, 2019). We combine and show all the selected relevant sentences from each summary. Since the summaries are similar, we see a large overlap of the relevant sentences.

We give the following prompt, which we modify from Dreyer et al. (2021):

- *consistency/factuality*: Please avoid using general knowledge, and only consider it in the context of the provided document. Select not consistent if facts in the summary are not supported by the document, such as cases like these:
    1. The summary contradicts the information in the document. The summary might say "A fire broke out in Seattle", but a document says it broke out in Portland. Or the summary might say "the Republicans won the election", but the document indicates the Democrats won instead
    2. The summary adds (hallucinates) a fact that is not mentioned anywhere in the document. For example, the summary might say that "A fire broke out at 2 am", but the document doesn't mention the time when the fire broke out.
- *Informativeness*: Please select informative if the summary expresses the main points of the document. Summary should contain relevant and important information and few unimportant details. If you select the summary to be not consistent with the document, please only consider the consistent information when evaluating this category.

The order of the summary is randomly shuffled. Each task consists of three unique workers, where we take the mean as the scores for this document. The final score is the mean factuality score across all documents. The average time for each task is

XSum Example

Article: The Scots started their Six Nations campaign with a thrilling first win over Ireland in four years. They beat France for the first time in 10 years last season at home, but have lost on their past nine trips to Paris. "It is a long time ago since we won there but we understand there is a reason for that," said Laidlaw. "France are a good team and it is a hard place to win. We are under no illusions this week - we need to be on top form to get something out of the game. "We'll need accuracy and we need to be physical and aggressive because the French are big men. But we need to be subtle and clever in our attack. "If we do that, and move France about and play for 80 minutes, I would back our fitness against them. But we obviously need to be in the game right to the death and not let France get any momentum." Media playback is not supported on this device France have not finished in the top half of the Six Nations since 2011, but impressed in narrow defeats by New Zealand and Australia in the autumn, and came close to a shock victory against England at Twickenham in their Six Nations opener. "They have improved massively under [coach] Guy Noves and have not been far away from any team they have played," Laidlaw noted. "They have some really dangerous strike runners throughout the team. "As much as we need to understand why we beat them last year, we need to develop that, be clever and smart and be able to score points." We need to keep doing what we are doing well, keep our skills high and if we do that again this weekend, we are going to put ourselves in a strong position. "The start of the game is massively important, whether it is our kick-off, or or us receiving. It is very important psychologically for them as it is for us. "If we can start the game playing in the right areas of the field for the first 20 minutes and not muck about too much in our own half, hopefully we will put them under pressure and upset the crowd a little bit." Media playback is not supported on this device

Reference: Captain Greg Laidlaw says Scotland must be "subtle and clever" as well as match France physically if they are to secure a first win in Paris since 1999.
Bart-base: Scotland head coach Greig Laidlaw says his side are "under no illusions" when they face France at Twickenham on Saturday.
PEGASUS*: Scotland coach Steve Laidlaw has warned France that they need to be "smart and smart" in their attack if they are to win their first Six Nations game of the season against the French in Paris on Saturday.
CLIFF: Scotland head coach Mark Laidlaw says his side need to be " subtle and clever" in their attack against France in Paris onSaturday.
DAE:Scotland must be " subtle and clever" in their attack when they face France at Twickenham on Saturday, says head coach Gordon Laidlaw.
FactPEGASUS: Scotland captain Laidlaw says his side need to be "subtle and clever" in their attack if they are to beat France.

Gigaword Example

DAE: zoe's ark investigating magistrate prosecutor arrive in abeche
FactPEGASUS: prosecutor arrives in abeche to investigate french association

Figure 8: Example summaries from XSum and Gigaword. Nonfactual components are marked with red.

WikiHow Example

Article: Slide the seats all the way forward and then back to thoroughly vacuum the carpet underneath. Start from the top and work your way down. Dust or dirt that has accumulated up top could fall down; dust or dirt that has accumulated at the bottom will rarely fall up.; , Allow it to sit for a few minutes before blotting dry with a towel. If the stain doesn't come out, repeat. After your final cleaner application, wash the area with a damp sponge and do a final blotting. Make sure to try to get as much dampness from the fabric as possible. Any excessive dampness may promote molding and/or mildew, which does not fall in the definition of detailing a car. Replace with a piece you've cut from a hidden place, such as underneath the seat. Use a water-resistant adhesive to keep it down... Warning: Always ask the owner of the car for permission before doing this step. If you want, have a sample repair that you can show the owner of the car of what the process will look like. If it's done well, this sample will be reassuring. Apply a non-slip dressing so that the driver's feet don't slip and slide while they're trying to do important things like braking. , Use an interior dressing like Armor All to finish it off. If you're not going to use liquids afterward, your detailing brushes should be a super-absorbant material like microfiber cloth, which picks up dust and dirt efficiently. Lightly mist some spray-on vinyl dressing onto the vent grilles to make them look brand new. Cleaning the seats is essential for a good detail. But different seats require different methods. Note that after cleaning, you may have to vacuum out the seats or surrounding area again, as dirt will be loosened up by this process. Cloth interiors: Interiors with nylon or other cloth can be shampooed with a wet-vac extraction machine. Cloth should be adequately dried after extraction has taken place. Leather or vinyl interiors: Interiors with leather or can be cleaned with a leather or vinyl cleaner and then hit softly with a leather brush. Cleaner can be wiped away with a microfiber cloth afterward. If you've cleaned leather seats with product, now's the time to condition them so that the leather looks visually appealing and doesn't dry out or begin to crack. For stronger build-up removal, use 4-ought steel wool on windows. Use plastic cleaner if the gauge cover is made of plastic...

Bart-base: Vacuum the carpet underneath the seats. Blot the stain with a damp sponge. Replace a piece of carpet. Apply a non-slip dressing to the back of the seat. Wipe the seat down with a soft cloth.

PEGASUS*: Vacuum the seats. Blot the area with a damp sponge. Remove any molding and/or mildew. Apply a non-slip dressing to the area. Use a spray-on vinyl dressing to clean the vent grilles. Clean the interior of the car with a leather or vinyl cleaner.

CLIFF: Vacuum the seats and surrounding area. Blot the stain with a damp sponge. Remove a piece of tape from a hidden place. Cover the tape with a non-slip dressing. , Apply an interior dressing to the back of the seat. Apply a vinyl dressing on the vent grilles. Clean the interior of the car with a microfiber cloth. Wash the seats. Condition the leather seats. Use steel wool or plastic cleaner on windows. Brush the wheel rims. Apply tire dressing. Spray degreaser on everything. Apply protectant to the tinted windows. Apply tinting to the glass. Wash and dry the car. Rinse the car thoroughly.

DAE: Vacuum the seats and surrounding area. Blot the area with a damp sponge. Remove a piece of wood from a hidden place. Dress the seats. Wear a non-slip dressing. , Wipe down the vent grilles. Cover the vents.

FACTPEGASUS: Vacuum the carpet under the seats. Wipe the area with a damp sponge. Apply a non-slip dressing to the seat. Wipe down the interior with a spray-on vinyl dressing. Use a leather brush to clean the interior of the car. Use steel wool on windows. Clean the interior

`†wilfred_pigeon@urmc.rochester.edu`, `‡hong_yu@uml.edu`

Abstract

Suicide is an important public health concern and one of the leading causes of death worldwide. Suicidal behaviors, including suicide attempts (SA) and suicide ideations (SI), are leading risk factors for death by suicide. Information related to patients' previous and current SA and SI are frequently documented in the electronic health record (EHR) notes. Accurate detection of such documentation may help improve surveillance and predictions of patients' suicidal behaviors and alert medical professionals for suicide prevention efforts. In this study, we first built **Suic**ide **A**ttempt and Ideatio**n** Events (ScAN) dataset, a subset of the publicly available MIMIC III dataset spanning over $12k+$ EHR notes with $19k+$ annotated SA and SI events information. The annotations also contain attributes such as method of suicide attempt. We also provide a strong baseline model ScANER (**Suic**ide **A**ttempt and Ideatio**n** **E**vents **R**etreiver), a multi-task RoBERTa-based model with a *retrieval module* to extract all the relevant suicidal behavioral evidences from EHR notes of an hospital-stay and, and a *prediction module* to identify the type of suicidal behavior (SA and SI) concluded during the patient's stay at the hospital. ScANER achieved a macro-weighted F1-score of 0.83 for identifying suicidal behavioral evidences and a macro F1-score of 0.78 and 0.60 for classification of SA and SI for the patient's hospital-stay, respectively. ScAN and ScANER are publicly available[1].

1 Introduction

For decades, suicide has been one of the leading causes of death (CBHSQ, 2020). The suicide rate in the United States increased from 10.5 per 100,000 in 1999 to 14.2 in 2018, a 35% increase (Hedegaard et al., 2020). Globally, 740,000 people commit suicide each year. The rates of suicidal behaviors, suicide attempt (SA) and suicide ideation (SI), are much higher (WHO, 2021).

Context:
[*Name*] is a 22 year old male with a history of angry and impulsive behavior who is transferred from an outside hospital s/p Tylenol overdose. [*Name*] reports that he and his girlfriend broke up last Wednesday, and that he subsequently went on an alcohol and cocaine binge lasting from Thursday to Saturday. He has used alcohol and cocaine regularly in the past, but he denies having had a binge of this quantity or duration before. On Saturday night, [**Name**] told his father that he had tried to hang himself at a nearby park, but the rope had broken.

Annotations:
Two instances of suicide attempts are annotated in the paragraph.
1. [*Name*] ... overdose: Annotated for suicide attempt and is assigned 'unsure' category as there is no definite documentation that it is a suicide attempt.
2. On Sat ... broken: This is also annotated for suicide attempt and is assigned the category: 'T71' (asphyxiation, hanging).

Figure 1: An example of *positive* and *unsure* evidence annotations for SA in an EHR note.

A prior study shows that a large proportion of suicide victims sought care well before their death (Kessler et al., 2020). Suicidal behaviors, including SA and SI are recorded by clinicians in electronic health records (EHRs). This knowledge can in turn help clinicians assess risk of suicide and make prevention efforts (Jensen et al., 2012). The diagnostic ICD codes include suicidality codes for both SA and SI. However a study has shown that ICD codes can only capture 3% SI events, while 97% of SI events are described in notes (Anderson et al., 2015). In addition, of patients described with SA in their EHR notes, only 19% had the corresponding ICD codes (Anderson et al., 2015). Therefore, it is important to develop natural language process-

---

[1] The annotations, code and the models are availble at https://github.com/bsinghpratap/ScAN.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1029 - 1040
July 10-15, 2022 ©2022 Association for Computational Linguistics

ing (NLP) approaches to capture such important suicidality information.

Researchers have developed NLP approaches to detect SA and SI from EHR notes (Metzger et al., 2017; Downs et al., 2017; Fernandes et al., 2018; Cusick et al., 2021). These studies either used rule-based approaches (Downs et al., 2017; Fernandes et al., 2018; Cusick et al., 2021) or built the SA and SI identification models on a small set (Metzger et al., 2017) or private set (Bhat and Goldman-Mellor, 2017; Tran et al., 2013; Haerian et al., 2012) of EHR notes. It is also difficult to compare the results of those studies as they varied in EHR data, data curation, as well as NLP models, which were not made available to the public.

In this study, we present ScAN: **S**ui**c**ide **A**ttempt and Ideatio**n** Events Dataset, a publicly available EHR dataset that is a subset of the MIMIC III data (Johnson et al., 2016). ScAN contains $19,690$ expert-annotated SA and SI events with their attributes (e.g., methods for SA) over $12,759$ EHR notes. Specifically, experts annotated suicidality evidence or sentences relevant to SA and SI events during a patient's stay at the healthcare facility, an example of SA annotations is shown in Fig 1. The evidences were put together to assess whether the patient has an SA or SI event.

We also present ScANER (**S**ui**c**ide **A**ttempt and Ideatio**n** **E**vents **R**etriever), a RoBERTa-based NLP model that is built on a multi-task learning framework for retrieving evidences from the EHRs and then predicting a patient's SA or SI event using the complete set of EHR notes from the hospital stay using a multi-head attention model. We focus on the prediction of SA and SI using all the EHR notes during a patient's stay because for the whole duration, multiple EHR notes and note types are generated, including *admission* notes, *nursing* notes, and *discharge summary* notes. Suicidal information are described in multiple notes throughout the stay. For example, a patient was admitted to the hospital with opioid overdose. It was documented initially in the admission note as an SA, but later dismissed as an accident after physician's evaluation. In another example, an opioid overdose admission was first documented as an accident on admission, but later documented to be an SA event after clinical assessment. Both ScAN and ScANER capture SA and SI information at the hospital-stay level. ScANER is able to retrieve suicidal evidences from EHR notes with a macro-weighted F1-score of 0.83 and is able to predict SA and SI with a macro F1-score of 0.78 and 0.60, respectively. Our annotation guidelines, ScAN, and ScANER system will be made publicly available, making ScAN a benchmark EHR dataset for SA and SI events detection. We will release the training and evaluations splits used in this study for benchmarking new models.

2 Related Works

Efforts on detecting SA and SI within EHRs have been explored in recent years. Most work used rule-based or traditional machine learning-based approaches. In one study, experts created handcrafted rules from mentions of suicidality (both SA and SI) and then used the rules to identify suicidality as positive, negative, or unknown in a document (Downs et al., 2017). The rule-based approaches are limited by their scalability. In another study, structured and unstructured EHRs were used to classify at the hospital-stay level as SA, SI, or no mention of suicidal behavior (Metzger et al., 2017). The training data consisted of only 112 SA, 49 SI and 322 unrelated examples. In contrast, ScAN comprises of 697 hospital-stays with more than 19,000 suicidal event examples over 12,759 clinical notes. Only traditional machine learning models such as random forest (Breiman, 2001) were explored. In contrast, ScANER was built on the state-of-the-art self-attention based model.

Hybrid approaches have also been developed to identify SA at the hospital-stay level (Fernandes et al., 2018). In that study, a post-processing heuristic rule-based filter (e.g., removing negated events) was applied to the machine-learning-based classifier (a SVM (Cortes and Vapnik, 1995) classifier) to reduce false positives. Training and evaluation were done also on relatively small datasets (500 for training and 500 for evaluation).

Finally, weakly supervised approaches have been developed to identify SI from EHRs (Cusick et al., 2021). In that study, authors used ICD codes to identify 200 patients with SI and then obtained EHR notes of those patients $(6,588)$. This EHR note dataset was then used as the 'current' SI training data. The remaining 400 patients were labelled as 'potential' SI and their $12,227$ EHRs were also labelled the same. Authors used multiple statistical machine learning models and one deep learning model: convolutional neural network. (Bhat and Goldman-Mellor, 2017) also used feed-forward neural networks to predict suicide attempts over 500k unique patients but the EHR data for this study is not publicly available. (Ji et al., 2020) surveyed multiple studies where the researchers worked on private datasets (Tran et al., 2013; Haerian et al., 2012) for suicide attempt and ideation prediction. Whereas in our study, in contrast to using the ICD codes which has considerable errors, domain experts chart-reviewed a large, publicly available set of EHRs for SI and SA, along with their attributes (e.g., positive or negative SA, SI and the type of self-harm such as asphyxiation and overdose).

3 Dataset

In this section, we introduce ScAN (**S**ui**c**ide **A**ttempt and Ideatio**n** Events Dataset) and describe it's data collection and annotation process. We also discuss some examples from ScAN along with basic dataset statistics.

3.1 Dataset collection

For annotation, we selected the notes from the MIMIC-III (Johnson et al., 2016) dataset, which consists of the de-identified EHR data of patients admitted to the Beth Israel Deaconess Medical Center in Boston, Massachusetts from 2001 to 2012 (Johnson et al., 2016). The data includes notes, diagnostic codes, medical history, demographics, lab measurements among many other record types. We chose MIMIC-III because it is publicly available under a data use agreement and allows clinical studies to be easily reproduced and compared.

The diagnostic ICD codes for the patients are provided at hospital-stay level in MIMIC with admission identification numbers (HADM_ID in MIMIC database). We first filtered the hospital stays that had ICD codes associated with suicide and overdose. This resulted in 697 hospital-stays for 669 unique patients. For each stay, multiple de-identified notes such as nursing notes, physician notes, and discharge summaries are available. For the selected 697 hospital-stays we extracted a total of $12,759$ notes. Each medical note contains multiple sections about a patient such as family and medical history, assessment and plan, and discharge instructions. We extracted different sections from these clinical notes using MedSpaCy's[2] `clinical_sectionizer` and filtered the relevant sections from these clinical notes for annotation. The extensive list of these sections is provided in Appendix A.

3.2 Annotation Process

The aim was to annotate all instances of SA and SI documented in the medical notes as defined by Center of Disease Control and Prevention (CDC) (Hedegaard et al., 2020). The filtered $12,759$ notes were annotated by a trained annotator under the supervision of a senior physician. Each note consisted of instances of SA, SI, both or none. The senior physician randomly annotated 330 notes and had a 100% agreement with the annotator on hospital-stay level annotation and 85% agreement on sentence-level annotations. After adjudication between the senior physician and the annotator, the disagreements were discussed and adjusted by the annotator.

Context:
Tylenol toxicity - Initially treated with NAC protocol. After her history became more clear, it was felt that this was an accidental overdose. Psychiatry was consulted, who agreed there was no evidence of intention to harm. She should be instructed to limit her acetaminophen use in the future to 2gm/day.

Annotation:
1. After ... overdose.: Negative suicide attempt.
2. Psychiatry ... harm: Negative suicide ideation.

Figure 2: An example with *negative* SA and *negative* SI annotations.

Suicide Attempt (SA): The annotator labelled all the sentences with a mention of SA. Some hospital stays could represent multiple types of SA, such as in Fig. 1, where 'tried to hang himself' is labelled as a *positive* SA and 'Tylenol overdose' is labelled as *unsure* since the overdose was never confirmed as an SA event elsewhere in the medical notes of the patient's hospital-stay. The label *unsure* is used when it is not clearly documented if a self-harm was an SA event or not. The *negative* instance, example shown in Fig. 2, is a sentence that confirms that the self-harm, an "accidental overdose", responsible for the patient's hospital-stay is not an SA event. In this work, we only focused on suicidal self-harm and not non-suicidal self-harm (Crosby et al., 2011).

Further sub-categories are also provided for an SA annotation in the form of the ICD label group: a.) T36-T50: Poisoning by drugs, medications

---

[2] https://github.com/medspacy/medspacy

and biological substances b.) T51-T65: Toxic effects on non-medical substances c.) T71: Asphyxiation or suffocation and d.) X71-X83: Drowning, firearm, explosive material, jumping from a high place, crashing motor vehicles, other specified means.

Suicide Ideation (SI): SI is defined as any mention and/or indication of wanting to take one's own life or harm oneself. Similar to SA, any sentence with a mention of SI was labelled within the patient's notes. A SI annotation could be labeled as *positive* or *negative*, an example for each label is shown in Fig. 3.

Context:
She continued to be tearful and extremely upset that she was still alive, and was refusing medications, radiology, and blood draws. She was maintained on a 1:1 sitter and suicide precautions.

Annotation:
1. She cont ..... draws: Positive suicide ideation.

Context:
Pts mental status cleared and was discharged with normal mental status. Psych evaluated pt and did not see any signs of suicidaility. Did not recommend antidepressants.

Annotation:
1. Psych .... suicidaility: Negative suicide ideation.

Figure 3: Examples of *positive* and *negative* SI annotations.

A sentence without SA or SI annotation would be considered as a *neutral-SA* or *neutral-SI* sentence respectively. Sentence level annotations provide more visibility to a medical expert for the hospital-stay level annotation.

3.3 Dataset statistics

ScAN consists of 19, 690 unique evidence annotations for the suicide relevant sections of 12, 759 EHRs of 697 patient hospital-stays. There are a total of 17, 723 annotations for SA events and 1, 967 annotations for SI events. The distribution for both SA and SI events is provided in Table 1.

4 Methodology

In this section, we introduce *ScANER* (**S**ui**c**ide **A**ttempt and Ideatio**n** **E**vents **R**etreiver): a strong baseline model for our dataset. ScANER consists of two sub-modules: (1) An *evidence retriever module* that extracts the evidences related to SA and SI and (2) A *predictor module* that predicts SA or SI label for the patient's hospital-stay using the evidences extracted by the retriever module.

General Statistics	Patients 669	Hospital-stays 697	Notes 12, 759
Suicide Attempt	Positive 14, 815	Negative 170	Unsure 2, 738
Suicide Ideation	Positive 1, 167	Negative 800	

Table 1: Distribution of unique annotations at the patient, hospital-stay and notes level in ScAN.

Evidence	Train	Validation	Test
Yes	9,880	1,803	3,038
No	30,133	4,864	7,836
Suicide Attempt (SA)			
Positive	7,597	1,474	2,433
Negative	136	36	20
Unsure	1,607	216	431
Neutral-SA	30,673	4,941	7,990
Suicide Ideation (SI)			
Positive	928	153	331
Negative	654	107	189
Neutral-SI	38,431	6,407	10,354

Table 2: Distribution of evidences at paragraph level in ScAN for train, validation and test sets. A paragraph was considered an *evidence*, labeled as *Yes*, if it had at least one sentence annotated as SA or SI. A *No* evidence paragraph was both *Neutral-SA* and *Neutral-SI*.

4.1 Evidence Retriever

Problem Formulation: Given an input clinical note, the model extracts the evidences (one or more sentences) related to SA or SI (SA-SI) from the note. This is a binary classification problem where given a text snippet the model predicts whether it has an evidence for SA-SI or not. We learn this task at paragraph level where the input is a set of 20 consecutive sentences because the local surrounding context provides additional important information (Yang et al., 2021; Rawat et al., 2019). A paragraph was labeled as *evidence no*, if all the sentences in that paragraph are *neutral-SA* and *neutral-SI*. If there was at least one SA-SI sentence, it was con-

---

[2] These splits would be released as part of ScAN for benchmarking models.

sidered an *evidence yes*. As the number of non-evidence sentences significantly outsized the evidence sentences, we decided to use an overlapping window of 5 sentences between the paragraphs to build more evidence paragraphs. The distribution of the paragraphs, across all evidence, SA and SI labels for train, validation, and test set is provided in Table 2. We segregated the train and test set such that any patient observed by the *retriever module* during training was not seen in the test set. This is important as there are patients who had multiple hospital-stays in ScAN.

Proposed Model: Transformer (Vaswani et al., 2017) based language models (Devlin et al., 2018; Liu et al., 2019) have shown great performance for a broad range of NLP classification tasks. Hence, to extract the evidence paragraphs we trained a RoBERTa (Liu et al., 2019) based model. It has been previously shown that the domain-adapted versions of the pre-trained language models, such as clinicalBERT (Alsentzer et al., 2019) or BioBERT (Lee et al., 2020), work better than their base versions. So, we further pre-trained the RoBERTa-base model over the MIMIC dataset to create a clinical version of RoBERTa model, hereby referenced as medRoBERTa. During our initial exploration, we experimented with clinicalBERT and BioBERT but found that medRoBERTa consistently outperformed both models. medRoBERTa achieved an overall F1-score of 0.88 whereas both clinicalBERT and BioBERT achieved an overall F1-score of 0.85. Our hospital-level SA and SI predictor would work with any encoder-based evidence retriever model.

Multi-task Learning: We trained medRoBERTa in a multi-task learning setting where along with learning the evidence classification task, the model also learns two auxiliary tasks: (a.) Identifying the label for SA between *positive*, *negative*, *unsure* and *neutral-SA* and, (b.) Identifying the label for SI between *positive*, *negative* and *neutral-SI*. The training loss ($L(\theta)$) for our evidence retriever model was formulated as:

$$L(\theta) = L_{evi} + \alpha * L_{SA} + \beta * L_{SI} \qquad (1)$$

Where L_{evi} is the negative log likelihood loss for evidence classification, L_{SA} and L_{SI} are SA and SI prediction losses respectively, and α and β are the weights for the auxiliary tasks' losses. The distribution of labels across all the three tasks is highly skewed, hence, we applied the following techniques to learn an efficient and robust model.

Suicide Attempt	Positive	Neg_Unsure	Neutral-SA
Train	377	54	1,381
Val	50	10	189
Test	91	19	326
Suicide Ideation	Positive	Negative	Neutral-SI
Train	377	214	1,521
Val	45	28	208
Test	44	35	357

Table 3: Distribution of SA and SI at hospital-stay level in training, validation and testing set.

- Weighted log loss was used in both main task and auxiliary tasks. The total loss for each task was calculated as the weighted sum of loss according to the *label* of the input paragraph. Log weighing helps smooth the weights for highly unbalanced classes. The weight for each class was calculated using:

$$w_{l,t} = \begin{cases} 1.0 & \text{if}(w_{l,t} < 1.0) \\ log(\gamma * N_t / N_{l,t}) & \end{cases}$$

  Where N_t is the count of all training paragraphs for the task t and $N_{l,t}$ is the count of paragraphs with label l for the task t and $w_{l,t}$ is the calculated weight for those paragraphs. We tuned γ as a hyper-parameter. All training hyper-parameters for our best model are provided in Appendix B.

- We also employed different sampling techniques (Youssef, 1999), up and down sampling, to help our model learn from an imbalanced dataset. After sweeping for different sampling combinations as hyper-parameters, we found that down-sampling the *no*-evidence paragraphs by 10% resulted in the best performance.

- The *negative* label of SA is severely under-represented in ScAN making it difficult for the model to learn useful patterns from such instances, refer Table 2. After discussion with the experts, we decided to group the instances of *negative* and *unsure* together and label them as *neg_unsure* because for both groups the general psych outcome is to let the patient leave after the hospital-stay as there is no solid evidence defining whether the self-harm was a SA event.

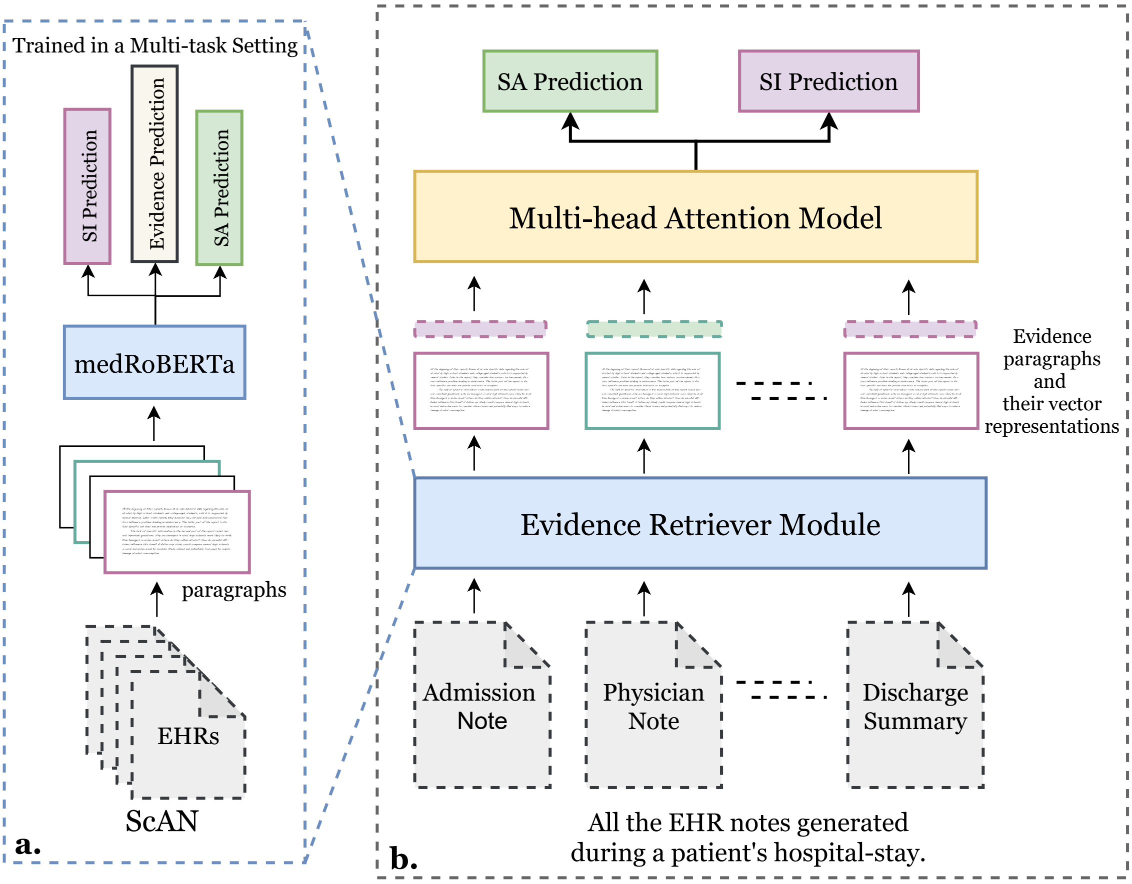

Figure 4: ScANER (**Suic**ide **A**ttempt and Ideatio**n** **E**vents **R**etreiver) consists of two sub-modules: (a.) Evidence retriever module extracts evidence paragraphs from all EHR notes. We trained the module using all annotated paragraphs from ScAN. (b.) Prediction module predicts the SA and SI label for a patient using the evidence paragraphs extracted by the *retriever module* from EHR notes during the patient's hospital-stay.

4.2 Hospital-stay level SA and SI Predictor

Problem Formulation Given all the clinical notes of a patient during the the hospital stay, the model predicts the label for SA (*positive*, *neg_unsure* and *neutral-SA*) and SI (*positive*, *negative* and *neutral-SI*). The *prediction module* uses the evidence paragraphs extracted by the *retriever module*.

Robust Finetuning The retriever module is not perfect and can extract false positives. This results in extracting irrelevant paragraphs, with evidence label *No*, along with evidence paragraphs for a hospital-stay with SA or SI and extracting irrelevant paragraphs as evidences for a hospital-stay with both SA and SI marked as *neutral*. To tackle such situations and train a robust model, we applied three techniques:

- For a hospital-stay with a non-*neutral* label for SA or SI, during training we added some noise in the form of irrelevant paragraphs (a paragraph with no SA or SI annotation) from the notes to the set of actual evidence paragraphs for the input. An irrelevant paragraph from a clinical note was sampled with a probability of 0.05. This forced the predictor module to learn effectively even with noisy inputs.
- For a *neutral* hospital-stay with no evidence paragraphs, we randomly chose X unique irrelevant paragraphs from the notes. X was sampled from the distribution of number of evidence paragraphs of the non-*neutral* hospital-stays. This prevented the leaking of any information to the prediction module during training by keeping the distribution of number of input paragraphs the same across *neutral* and non-*neutral* instances.
- Since these hospital-stays were extracted using the ICD codes related to suicide and overdose, the data is quite skewed with only 102 *neutral* events from a total of 697 hospital-stays. Whereas in a real-world scenario, *neutral* hospital-stays would be much higher than non-*neutral* ones. Hence, to facilitate a bal-

anced learning of the predictor module we introduced $1,800$ *neutral* hospital-stays from the MIMIC dataset. The distribution for SA and SI at hospital-stay level is provided in Table 3.

Proposed Model The paragraphs extracted using the *retriever module* for a patient's hospital-stay were provided as an input to the predictor module. We used a multi-head attention model to predict the SA and SI label for a hospital-stay as self-attention based models have proved to be quite effective for a lot of prediction tasks in machine learning (Devlin et al., 2018; Cao et al., 2020; Hoogi et al., 2019).

We encoded the extracted paragraphs ($[p_1, p_2 .... p_n]$) using the retriever module, medRoBERTa, to get a vector representation of 768 dimensions for each of the paragraphs ($[v_1, v_2 ... v_n]$). Training the *retriever module* on auxiliary tasks of predicting SA and SI helped align these paragraph representations for SA and SI prediction. Then, we added a prediction vector (v_0) along with all the vector representations of the paragraphs to get $\mathcal{V} = [v_0, v_1, v_2 ... v_n]$. We passed $\mathcal{V}$ through our multi-head attention model to get the hidden representations $\mathcal{H} = [h_0, h_1 ... h_n]$. We then passed h_0 through a SA inference layer and SI inference layer to predict the labels. During the whole training process, the weights of the retriever module were frozen whereas v_0 was a learnable vector initialised as an embedding in the multi-head attention model. We used a separate v_0 prediction vector so that it could retain the information from all the other paragraph representations for hospital-stay level prediction similar to how `[CLS]` is utilized in different transformer-based models for sequence prediction (Devlin et al., 2018; Liu et al., 2019). We tuned the number of layers and number of attention heads of our prediction module as hyper-parameters and achieved the best performance using a 2-layer and 3-attention head model. Our complete ScANER model is illustrated in Fig 4.

5 Results and Discussion

Since the labels for both the retriever and prediction task are imbalanced, we used macro-weighted precision, recall, and F1-score to evaluate the overall performance of our models. Macro-weighted metrics provide better model insights across all labels.

Evidence Retriever Performance Our multi-task learning model achieved a F1-score of 0.83 for extracting positive evidence paragraphs and an F1-score of 0.88 overall. The retriever model has higher recall than precision for the positive evidence paragraphs ($0.87 > 0.79$), SA ($0.74 > 0.71$), and SI ($0.62 > 0.46$) events, as shown in Table 4. In healthcare, there is an incentive to maximize recall over precision (Watson and McKinstry, 2009). As mentioned in §4.2, ScANER was trained with added noisy paragraphs and is therefore robust to the extracted evidence paragraphs if they contain some false positives.

The *retriever module* achieves an overall F1-score of 0.63 for SA prediction and 0.64 for SI prediction at paragraph-level. The performance for positive SA and SI evidence is much higher than the performance for *neg_unsure* SA and *negative* SI. We looked at the confusion matrices for SA and SI paragraph-level prediction and found that largely ScANER made mistakes between *positive* and *neg_unsure* labels for SA prediction and between *positive* and *negative* labels for SI prediction (refer Appendix C). The poor performance in SA for *neg_unsure* evidence prediction is mainly due to data sparsity where the *neg_unsure* cases are only 1743; in contrast, the positive cases are 4-fold higher. Similarly, for SI the *positive* cases are 1.4 times higher than the *negative* cases.

Hospital-stay level Prediction Performance Our multi-head attention model is able to achieve an overall macro F1-score of 0.78 for SA prediction and 0.60 for SI prediction, as shown in Table 5. For SA, the *prediction module* achieves a recall of 0.93 for the positive label. After analysing the confusion matrix, the model largely predicts a *positive* label for the visits with *neg_unsure* label, as shown in Table 6. The poor performance for *neg_unsure* is largely because of its small representation in the training set of ScAN, 54 negative cases as compared to 377 positive and $1,381$ neutral instances. In our future work, we plan to expand ScAN with more instances of *negative* SA events.

For SI, the prediction module achieves an overall F1-score of 0.60 with a precision of 0.63 and recall of 0.66. The model has a high recall for *neutral-SI* and *positive* but the *positive* label has a low precision of 0.49. After analysing the test set, we observed that a lot of patient hospital-stays with *negative* labels are getting wrongly predicted as *positive*, as shown in Table 6. After doing error

Paragraph Evidence Prediction				*Paragraph SA Prediction*				*Paragraph SI Prediction*			
Evidence	P	R	F	Labels	P	R	F	Labels	P	R	F
Yes	0.79	0.87	0.83	Positive	0.71	0.74	0.73	Positive	0.46	0.62	0.53
No	0.95	0.91	0.93	Neg_Unsure	0.19	0.26	0.22	Negative	0.38	0.46	0.42
-	-	-	-	Neutral-SA	0.95	0.92	0.93	Neutral-SI	0.98	0.99	0.98
Overall	0.87	0.89	0.88	Overall	0.62	0.64	0.63	Overall	0.61	0.69	0.64

P: Precision, R: Recall and F: F1-score.

Table 4: Paragraph level performance of the *evidence retriever module*. The overall evaluation metrics (precision, recall and F1-score) are macro-weighted. Evidence prediction is the main task whereas SA and SI prediction are auxiliary tasks and help the model align the vector representations of the paragraphs for the *hospital-stay level suicidal behavior prediction*.

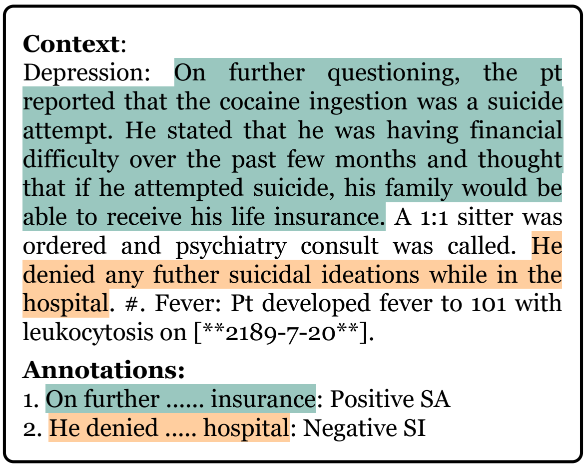
Hospital-stay SA Prediction			
Labels	Precision	Recall	F1-score
Positive	0.81	0.93	0.87
Neg_Unsure	0.48	0.58	0.52
Neutral-SA	0.98	0.93	0.96
Overall	0.76	0.81	0.78
Hospital-stay SI Prediction			
Labels	Precision	Recall	F1-score
Positive	0.49	0.93	0.65
Negative	0.40	0.11	0.18
Neutral-SI	0.99	0.95	0.97
Overall	0.63	0.66	0.60

Table 5: Hospital-stay level SA and SI prediction performance of ScANER.

Hospital-stay SA Prediction			
	Positive	Neg_Unsure	Neutral-SA
Positive	85	4	2
Neg_Unsure	5	11	3
Neutral-SA	15	8	303
Hospital-stay SI Prediction			
	Positive	Negative	Neutral-SI
Positive	41	2	1
Negative	27	4	4
Neutral-SI	15	4	338

Table 6: Confusion matrices for SA and SI prediction at hospital-stay level.

analysis for hospital-stays with *negative* labels, we observed that a lot of extracted evidence paragraphs contain information that suggests that the patient had SI before the SA but does not have SI anymore during the hospital-stay. As shown in the example in Fig 5, the past SI is an explanation for the SA but then the patient does not have any further SI during the hospital-stay. This suggests that period assertions for these annotations are quite important and we aim to add period assertion property in our future work by further annotating ScAN.



Context:
Depression: On further questioning, the pt reported that the cocaine ingestion was a suicide attempt. He stated that he was having financial difficulty over the past few months and thought that if he attempted suicide, his family would be able to receive his life insurance. A 1:1 sitter was ordered and psychiatry consult was called. He denied any futher suicidal ideations while in the hospital. #. Fever: Pt developed fever to 101 with leukocytosis on [**2189-7-20**].

Annotations:
1. On further ...... insurance: Positive SA
2. He denied ..... hospital: Negative SI

Figure 5: An instance for which ScANER incorrectly predicted a *negative* hospital-level SI as *positive*.

6 Conclusion

In this paper, we introduce ScAN: a publicly available suicide attempt (SA) and ideation (SI) events dataset that consists of $12,759$ EHR notes with $19,960$ unique evidence annotations for suicidal behavior. To our knowledge, this is the largest and publicly available dataset for SA and SI, an important resource for suicidal behaviors research. We also provide a strong RoBERTa baseline model for the dataset: ScANER (SA and SI retriever) which consists of two sub-modules: (a.) an *evidence retriever module* that extracts all the relevant evidence paragraphs from the patient's notes and (b.) a *prediction module* that evaluates the extracted evidence paragraphs and predicts the SA and SI event label for the patient's stay at the hospital. ScAN and ScANER could help extract suicidal behavior in patients for suicide surveillance and predictions, leading to potentially early intervention and prevention efforts by medical professionals.

A Selected Clinical Sections

The sections selected for annotations after using `clinical_sectionizer` are enumerated below:

1. Allergy
2. Case Management
3. Consult
4. Discharge Summary
5. Family history
6. General
7. HIV Screening
8. Labs and Studies
9. Medication
10. Nursing
11. Nursing/other
12. Nutrition
13. Observation and Plan
14. Past Medical History
15. Patient Instructions
16. Physical Exam
17. Physician
18. Present Illness
19. Problem List
20. Radiology
21. Rehab Services
22. Respiratory
23. Sexual and Social History
24. Social Work

B Hyper-parameter Settings

All the hyper-parameter settings for both modules of ScANER are provided in Table 7.

Evidence Retriever Module			
Learning Rate 2e-5	Warmup steps 2,000	Optimizer Adam	Adam ϵ 1e-8
γ 2.5	α 1.1	β 1.5	
Hospital Stay SA-SI Prediction Module			
Attention Heads 3	Attention Layers 2	Learning Rate 1e-3	Warmup steps 1,200
Optimizer Adam	Adam ϵ 1e-8		

Table 7: Hyper-parameter setting for both retriever and prediction module of ScANER.

C Confusion matrices

The confusion matrices for SA and SI prediction at paragraph level is provided in Table 8.

Paragraph SA Prediction			
	Positive	Neg_Unsure	Neutral-SA
Positive	1,804	285	344
Neg_Unsure	253	118	80
Neutral-SA	472	204	7,314
Paragraph SI Prediction			
	Positive	Negative	Neutral-SI
Positive	206	69	56
Negative	71	87	31
Neutral-SI	170	73	10,111

Table 8: Confusion matrices for the predictions on the test set of evidence retriever.

Socially Aware Bias Measurements for Hindi Language Representations

Abstract

Trigger warning: This paper contains examples of stereotypes and other harms that could be offensive and triggering to individuals.

Language representations are efficient tools used across NLP applications, but they are strife with encoded societal biases. These biases are studied extensively, but with a primary focus on English language representations and biases common in the context of Western society. In this work, we investigate biases present in Hindi language representations with focuses on caste and religion-associated biases. We demonstrate how biases are unique to specific language representations based on the history and culture of the region they are widely spoken in, and how the same societal bias (such as binary gender-associated biases) is encoded by different words and text spans across languages. The discoveries of our work highlight the necessity of culture awareness and linguistic artifacts when modeling language representations, in order to better understand the encoded biases.

1 Introduction

Language models and representations (Pennington et al., 2014; Bojanowski et al., 2017; Devlin et al., 2019) are commonly used across the world in a variety of applications including machine translation (Kunchukuttan et al., 2017), information retrieval (Rao and Devi, 2018), chatbots (Bhagwat et al., 2019), sentiment classification (Kumar et al., 2019) and more. However, it is also known that these representations capture and propagate societal biases including gender (Bolukbasi et al., 2016), race (Caliskan et al., 2017), (Manzini et al., 2019), and nationality (Dev and Phillips, 2019) related stereotypes. This bias is present across representations for different languages. Each language reflects the culture and history of regions they are used popularly in, and as we go from one language to another, the notion of bias, and the types of societal biases change accordingly. This key difference however, is not reflected in the effort made towards detecting, identifying, and mitigating biases in language representations, with the majority of efforts predominantly in English language and in the context of Western society (Bolukbasi et al., 2016; Nangia et al., 2020). Some recent work tackle the challenges of societal biases in language representations coming from various cultures and languages such as Arabic, French, Spanish, Chinese, and German (Lauscher et al., 2020; Chávez Mulsa and Spanakis, 2020; Kurpicz-Briki, 2020; Zhou et al., 2019; Zhao et al., 2020; Liang et al., 2020). Additionally, Ghosh et al. (2021) and Sambasivan et al. (2020) explore biases and algorithmic fairness concerning non-western contexts in machine learning and Pujari et al. (2019) focus on fairness in language technologies for Indic society by investigating binary gender associated bias in Hindi language representations. However, it is unclear if the representations capture other biases that are *distinct* to the Indian society and can cause harm, such as caste and religion related biases.

In this work, we make three main contributions: (i) with a careful study of the social and cultural composition of the Indian society, we highlight and devise measures to detect and quantify different societal biases present in Hindi language representations, and show gender, caste and religion bias in the language; (ii) we discuss the gendered nature of Hindi and the implications it has on the bias detection techniques for gender bias, highlighting the importance of leveraging linguistic knowledge when developing bias detection methods; and (iii) we demonstrate how the translation of word lists or one-to-one mapping of bias measures across languages is insufficient to detect biases meaningfully, indicating how bias measurement methods cannot be directly adapted from one language to another. Even when detecting the same societal types of

July 10-15, 2022

biases in a different language, translations of the words from English into the target language whose representations are being evaluated, does not suffice as the words may not exist, nor be commonly used or associated with the same sentiment or bias. Sentiments (good, bad, evil, etc) can also be encoded by distinct sets of objects and words (see Sec. 3 for discussion).

All these discoveries call for socio-cultural awareness, and attention to the differences in language structure, the changes of grammars, etc., in multilingual fairness studies. We hope this work can shed lights for future studies in these directions[1].

2 Language and Culture Considerations

The perception and interpretation of biases are sensitive to societal construct, socio-cultural structures, and historical compositions of different regions of the world (Cheung and Chan, 2007). Since languages are culture and region-specific, there is a requirement to study the socio-cultural differences when trying to understand the biases and potential harms of language representations globally. Consider the example of the Hindi language where along with gender bias (Amutha, 2017), other biases like the ones based on caste and religion are also pervasive. Caste is unique to the culture in the Indian peninsula and is not usually considered when analyzing biases in languages in Western studies but remnants of caste based stereotypes are still prolific in the modern hindi literature (Gupta, 2021). Similarly, region and culture-specific biases also are present with respect to religion, occupation, or location (Thorat and Newman, 2007). Additionally, there are several key linguistic differences between English and Hindi languages such as pronouns which in Hindi do not indicate gender unlike in English. Instead, gender may be indicated by adjectives or verbs (Section 2.1), thus requiring distinct strategies for gender bias detection. Further, the word order in Hindi is distinct from that of English, and is similar to Japanese, Korean, Mongolian and Turkish[2]. Unlike English, which has fixed word order, Hindi does not has fixed word order.

2.1 Gender in Hindi

The syntactical use of gender in Hindi is layered and distinct from English (Hall, 2002) in different ways. These differences are reflected in the structure and composition of text, and is essential when interpreting the ways biases are likely to be encoded.

`Gendered verbs`: Verbs in Hindi can be gendered depending upon the tense of the sentence. In case of past tense and the perfect tenses which are built upon the past tense, the gender of the verb is determined by the gender of the subject. For example, 'went' is 'gaya' if male and 'gayi' if female.

`Gendered Adjectives`: Adjectives in Hindi can also be gendered. However, not all adjectives change form according to the gender of the subject. For example, the adjective 'gharelu' (Domestic) in Hindi is used the same whether a man is domestic or a woman is domestic, but adjectives like 'good' is 'achha' if male and 'acchhi' if female.

`Gendered titles`: Some titles for entities in Hindi can be gendered. For example: 'teacher' is 'adhyapak' if male and 'adhyapika' if female.

`Gendered inanimate nouns`: Instantiations of grammatical gender for inanimate nouns when used in a sentence is an important aspect of Hindi language. Note that these instantiations also depend upon the dialect spoken (Hall, 2002). The word 'dahi' (yogurt) is assigned feminine forms of verbs and adjectives in western dialects and masculine forms in Eastern dialects of Hindi.

2.2 Caste, Religion, and Occupation Biases

Historically, discrimination based on attributes of caste, religion, and occupation has been prominent in India (Banerjee and Knight, 1985; Deshpande, 2010). While illegal, some of these biases are still common and as a result, language resources reflect the same. Caste is a form of social stratification unique to Hinduism and Indian society. It involves the concept of hereditary transmission of the style of life in terms of occupation, status, and social interaction, and is commonly associated strongly with last names of persons[3]. Consequently, it is associated with strong biases pertaining to purity, goodness, intelligence, etc. of individuals, which is reflected commonly in Hindi corpora. Despite being a secular nation, due to historical clashes, there are biases in India against the relatively minority religious population practicing Islam as opposed

---

[2] Word order refers to positioning of subject, verb, and object in a sentence.

[3] https://en.wikipedia.org/wiki/Caste

to the majority religion of Hinduism. These biases are associated with perceptions (good, bad, evil, etc.) of the different populations. Although biases against other religions are also present, we especially focus upon Islam and Hinduism since these are the most prominent. Like caste, some last names are highly associated with religion in India, and can serve as a proxy for studying the bias. In addition to these biases, the gaps between rural and urban India in terms of the education and poverty has led to a discrepancy of perception (positive versus negative) between urban and rural occupations.

3 Measuring Biases in Hindi language Representations

To quantify bias in English embeddings, Caliskan et al. (2017) propose the Word Embedding Association Test (WEAT), which measures the stereotypical association between two sets of target concepts and attributes (See Appendix B), where a larger WEAT score indicates a larger bias. May et al. (2019) propose SEAT (Sentence Embedding Association Test) for measuring bias in sentence encoders. Similar to word lists for WEAT tests, SEAT comprises of sentences in which each sentence is is a semantically neutral template which are completed with target words related to protected attributes and associated stereotypes. This puts focus on target words on which bias is to be measured.

3.1 Gender Bias

For evaluating binary gender-associated bias, we create WEAT tests (Caliskan et al., 2017) in two ways in Hindi, by creating (i) *Translated* word lists, and (ii) *Language-Specific* word lists.

For the *Translated*[4] test, we directly translate each individual word in each test for career & family, arts & mathematics and arts & sciences tests in (Caliskan et al., 2017). Note that direct translations of some words like 'Shakespeare' and 'NASA' in Arts and Science lists, are not accurate, have ambiguous spellings, or are not populus in the literature. Also, some words from English like 'cousin' do not have a corresponding word in Hindi. Next, we develop a set of socially-aware *Language-specific* tests, where we curate word lists (both attribute and target) (Appendix C) based on popular word usage in Hindi and their associations, and word frequencies in Hindi Wikipedia text.

Table 1 highlights how translated sets capture lesser bias as compared to the WEAT tests specifically created for Hindi. In particular, the WEAT translated test for binary gender and science versus arts captures significantly low bias, unlike what is prevalent in the society as well as associated text and representations (Khadilkar et al., 2021; Madaan et al., 2018; Pundir and Singh, 2019). This, in turn, emphasizes the importance of creating language-specific tests.

For the WEAT Hindi test set, we create another test to quantify gender bias across neutral adjectives, based on societal biases in Indic society (Gundugurti et al., 2015). Appendix C lists all word sets used in each WEAT test. Further, in Section 2.1, we see that there are four specific gendered word groups in Hindi, all of which are meaningfully gendered and important to be encoded and retained in our representations. For each such group, we construct an independent "Meaningful Encoding (ME)" WEAT test (Dev et al., 2021a) (see word lists in Appendix C). A Meaningful Encoding WEAT test uses attribute lists of words having meaningful gendered information (like gendered verbs) which should be captured by representations. The importance of this is two-fold: (i) it allows us to verify if meaningful gendered information is encoded in our representations, and (ii) compare with biased associations (measured by WEAT) to gauge the overall magnitude of bias versus information about an attribute captured by our embeddings.

In Table 2 we observe that for 300 dimensional Hindi GloVe embeddings (Kumar et al., 2020), significant bias is observed using the three WEAT tests (*Language-Specific*) for binary gender and adjectives, science v/s arts, and maths v/s arts. Each score is over 1.00, and similar valued to WEAT tests for meaningful information encoding (ME scores in Table 2), which highlights how the magnitude of bias encoded is high. Of the four meaningful information encodings, the weakest association is seen among gendered entities, owing to how prone they are to ambiguous usage across different regions (Section 2.1).

To develop SEAT tests in Hindi, similar to (May et al., 2019), we construct a list of sentence templates and fits each target word from a WEAT target list to construct SEAT target lists for each part of the speech category. We used the Hindi translations of the semantically neutral templates provided in (May et al., 2019). However, we remove some am-

Attribute	Description	WEAT (GloVe)		SEAT (GloVe)	
		Translated	Lang-Specific	Translated	Lang-Specific
Gender	maths, arts vs male, female	0.94 (0.02)	**1.12 (0.01)**	0.87 (0.00)	**1.14 (0.00)**
	science, arts vs male, female	0.27 (0.31)	**1.13 (0.02)**	0.18 (0.17)	**1.03 (0.00)**
Caste	adjectives vs caste	0.72 (0.00)	**1.52 (0.00)**	0.74 (0.00)	**1.40 (0.00)**
Religion	adjectives vs religion terms	1.05 (0.00)	**1.28 (0.01)**	1.04 (0.00)	**1.20 (0.00)**
	adjectives vs lastnames	0.93 (0.00)	**1.55 (0.00)**	0.95 (0.00)	**1.41 (0.00)**
Occupation	adjectives vs urban, rural occupations	-0.08 (0.59)	**1.58 (0.00)**	-0.13 (0.88)	**1.42 (0.00)**

Table 1: WEAT and SEAT bias measurements (with p-values in parentheses) for tests with translated versus language-specific word lists. Highlighted values point towards the observation that more bias is captured in language-specific curated word lists.

biguous translations and we add other templates based on colloquial usage (Appendix D) and word lists created for WEAT (Appendix C). We conduct SEAT tests upon 300 dimensional Hindi GloVe embeddings and Hindi ELMo (Kumar et al., 2020).

Table 2 demonstrates that for GloVe, the SEAT scores report significant bias for all tests, while for ELMo, the bias is mainly measured in tests with binary gender and adjectives. From Table 1 we note that the *Language-Specific* word lists record higher amounts of bias than the translated test.This highlights the significance of constructing the word lists in WEAT tests while keeping language and cultural considerations in mind.

3.2 Caste Bias

To evaluate Hindi representations for caste bias, we build two WEAT tests and two corresponding SEAT tests using the last names that are statistically more associated with stereotypically lower and upper castes. For lower castes, we randomly sample lower caste names from the list of scheduled castes provided by the Department of Social Justice and Empowerment in India (Appendix C). Our first test is based upon detecting biased association of occupations with 'upper' castes (the upper strata of castes) and 'lower' castes. Note that, some caste names mean certain occupations themselves in Hindi language. For example 'kumhar' means both a lower caste and the occupation of pottery. We ensure that target word lists have no ambiguous entities. Another WEAT test we build is based upon positive and negative adjectives association with caste names. For the *Translated* version, we take Hindi translations of words from Caliskan et al. (2017) for detecting racial bias. For *Language-specific* test we curate a new word list of adjectives (Appendix C) based on words used popularly as positive or negative in Hindi (Thorat and Newman, 2007).

Table 2 highlights that there is significant caste related perception bias. For both WEAT and SEAT tests, the measured biases are over 1.2 for GloVe embeddings. The results in Table 1 compare the *Translated* and *Language-Specific* adjective word lists. For WEAT test, the bias measured by *Translated* word lists are less than half of that measured by *Language-Specific* word lists, emphasizing the importance of creating socially-aware *Language-Specific* word lists which correlate better with the society and culture the language is associated with.

3.3 Religion Bias

We construct two WEAT and two SEAT tests to detect religion associated biases in Hindi embeddings. Our first test is based upon associating positive and negative adjectives to religious entities. One attribute list consists of Hindu religious entities and one consists of Muslim religious entities. In our second test, we associate adjectives with lastnames. This stems from the distinct last names commonly used by the two populations (see Appendix C). Similar to Caste bias detection, we experiment with the *Translated* and *Language-Specific* adjective lists. Further, we evaluate if religious information which is correctly associated is learnt by the representations (for example, mosque being the place of worship in Islam should be associated with it in representations). For this, we create a meaningful encoding (ME) test for religious information (see word lists in Appendix).

In Table 2 we see using the WEAT and SEAT scores for 300-dimensional GloVe embeddings that significant religious bias with respect to the positive and negative perception is detected. Table 1 compares the measured bias in case of *Translated* and *Language-Specific* adjective word lists, with the latter capturing significantly larger bias.

3.4 Rural v/s Urban Occupation Bias

Besides, we detect bias in urban and rural occupations, which is prevalent in Indic society - with

Attribute		**Description**	**WEAT**	**SEAT**	
			GloVe	**GloVe**	**ELMo**
Gender	BM	maths, arts vs male, female	1.12 (0.01)	1.14 (0.00)	0.17
		science, arts vs male, female	1.13 (0.01)	1.03 (0.00)	0.14
		adjectives vs male, female	1.21 (0.02)	1.19 (0.00)	1.37
	ME	*gendered verbs vs male, female*	*1.87 (0.00)*	*1.84 (0.00)*	*1.66*
		gendered adjectives vs male, female	*1.70 (0.00)*	*1.63 (0.00)*	*1.78*
		gendered entities vs male, female	*1.14 (0.01)*	*1.12 (0.00)*	*1.77*
		gendered titles vs male, female	*1.92 (0.00)*	*1.86 (0.00)*	*1.64*
Caste	BM	occupations vs caste	1.44 (0.00)	1.26 (0.00)	0.89
		adjectives vs caste	1.52 (0.00)	1.40 (0.00)	0.48
Religion	BM	adjectives vs religion terms	1.28 (0.01)	1.20 (0.00)	0.75
		adjectives vs lastnames	1.55 (0.00)	1.41 (0.00)	1.02
	ME	*religious entities vs religion*	*1.75 (0.00)*	*1.69 (0.00)*	*1.23*
Occupation	BM	adjectives vs urban, rural occupations	1.58 (0.00)	1.42 (0.00)	1.12

Table 2: Bias measurements (with p-values in parentheses) for gender, caste, religion and occupation bias. These results are for *Language-Specific* word lists; BM: Bias Measuring test, ME: Meaningful Encoding test.

urban occupations seen as better, richer, more desirable, and even of a higher social status. We construct WEAT and SEAT tests where the attribute list consists of lists of urban occupations and rural occupations and the target lists consisted of polarized adjectives (Appendix C).

Table 2 illustrates with WEAT and SEAT scores the biased associations of perception between urban and rural occupations. For both GloVe and ELMo embeddings, we observe significant (> 1.0) bias with the WEAT test, highlighting the presence of occupation associated bias.

4 Conclusion

Biases are inherently complex as are their encodings in language representations. Their detection needs to take into account a multitude of factors - the language and its grammar, the regions it is spoken in, as well as the history and culture of the region. We demonstrate here how a predetermined set of biases and a peripheral evaluation consisting of a narrow perspective of how biases manifest themselves is not sufficient to achieve fair representations across the globe.

Our work is limited by the scarcity of robust language models in Hindi language, as well as dedicated word lists for different language tasks in Hindi language. Hence, a number of extrinsic tests and experiments for bias evaluation could not be performed to evaluate bias more extensively. We thus focus here only on intrinsic measurements of bias which may not be correlated with bias expressed in downstream tasks (Goldfarb-Tarrant et al., 2019; Cao et al., 2022). We leave investigations regarding the same to future work. Furthermore, we acknowledge that our analysis of gender associated biases is limited to binary gender and our intrinsic evaluations require discrete categorizations (Dev et al., 2021b; Antoniak and Mimno, 2021). Finally, despite the limitations, we believe our work lays down some fundamentals with respect to evaluating biases across languages and associated cultures.

Broader Impact

Language models, with their widespread applications impact people across the world. This makes it imperative that associated harms be understood not just for the Western world and with a focus on English language models, but also across languages and cultures. With this work, we highlight the importance of social and cultural awareness for the same. Bias detection methods need this cultural expertise and can then be followed by adapted mitigation methods (some possible adapted methods discussed in Appendix E). With this work, we demonstrate how translations of words is not sufficient for capturing biases across languages, and thus highlight the need for development of strategies with specific languages and cultures in mind.

Appendix

A Limitations

As acknowledged in the paper, our work is severely limited by the scarcity of language models, dedicated word lists, and language tasks for Hindi language. A number of tests and experiments could not be performed to evaluate bias more extensively. Furthermore, the lack of established language tasks and datasets in Hindi made it difficult to analyze the extrinsic bias in downstream tasks. Although this limits our evaluations of bias in this work, with more work like this and development of more language tools for Hindi, this can be overcome. We further emphasize that while we have evaluated some biases, these are not the only biases present in the Indian society or Hindi language. We merely provide evaluations for some that are strongly present in the literature and thus in the language representations as well.

Since this work highlights various biases and the words commonly associated with it, it can potentially be triggering to persons. However, it is important to study these biases and their impact on language tools in order to mitigate their effect.

B WEAT

Let X and Y be equal-sized sets of target concept embeddings and let A and B be sets of attribute embeddings. Let $cos(a, b)$ denote the cosine similarity between vectors a and b. The test statistic is a difference between sums over the respective target concepts,

$$s(X, Y, A, B) = \sum_{x \in X} s(x, A, B) - \sum_{y \in Y} s(y, A, B) \tag{1}$$

where the quantity, $s(w, A, B)$ is calculated using cosine similarity as follows:

$$s(w, A, B) = \frac{\sum_{a \in A} cos(w, a)}{|A|} - \frac{\sum_{b \in B} cos(w, b)}{|B|} \tag{2}$$

The amount of bias in WEAT is analyzed by effect size d calculated as:

$$d = \frac{mean_{x \in X} s(x, A, B) - mean_{y \in Y} s(y, A, B)}{stddev_{w \in X \cup Y} s(w, A, B)} \tag{3}$$

In order to compute the test significance (p-value), X and Y lists are merged together, and 10,000 permutations, P of the combined list is generated. For the i-th list in P, it is split in new pairs of X_i and Y_i lists. Then the test statistic equation is used to calculate the p-value in the following way:

$$p = \frac{\sum_{i \in P} [s(X_i, Y_i, A, B)] > s(X, Y, A, B)]}{|P|} \tag{4}$$

C WEAT word lists

In our bias detection methods using WEAT, we constructed WEAT tests for Gender, Caste, Religion and Occupation (Rural v/s Urban occupations) biases. Since the direct translations of word lists from (Caliskan et al., 2017) did not provide us with any significant evidence of bias, we constructed the word lists ourselves based upon popular Hindi words usage. Refer to Table 7 for the word lists used to detect gender bias. We obtain the science, maths, gendered words, gendered adjectives and occupations from online Hindi resources. We refer to Wikipedia for glossary of Hinduism entities and Islamic entities. For the list of castes, we refer to the list of scheduled castes provided by the Department of Social Justice and Empowerment in India. For the lastnames we refer to the popular Islamic lastnames and Hindu lastnames provided by online resources.

In addition to the bias measurement (BM), tests, we also provide meaningful encoding. (ME) tests used to capture meaningful gendered information in Hindi.

Table 8, Table 9 and Table 10 provides the word lists used in the measurement of caste, religion and occupation biases respectively.

D SEAT

We define a list of semantically neutral sentence templates for each part of speech type of words as follows:

- Hindi-SEAT-name: 'yeha _ hai', 'veha _ hai', 'vahan _ hai', 'yahan _ hai', '_ yahan hai', '_ vahan hai', 'iska naam _ hai', 'uska naam _ h'
- Hindi-SEAT-common-nouns: 'yeha _ hai', 'veha _ hai', 'vahan _ hai', 'yahan _ hai', '_ yahan hai', '_ vahan hai', 'vo _ hai', 'ye _ hai'
- Hindi-SEAT-verbs: 'yeha _ hai', 'veha _ hai', 'vo _ hai', 'ye _ hai', 'vahan _ hai', 'yahan _ hai'

- Hindi-SEAT-adjectives: ‘yeha _ hai’, ‘veha _ hai’, ‘vo _ hai’, ‘ye _ hai’

In other words, if the target word is adjective, we use Hindi-SEAT-adjective list of semantically bleached sentences with each WEAT target word.

E Debiasing

There have been notable advances towards debiasing embeddings along the direction of gender bias. Both Bolukbasi et al. (2016) and Dev and Phillips (2019) propose using linear projection to debias word embeddings, but the former in addition also equalizes word pairs about the attribute (e.g., gender) axis.

Although we tried and adapted several existing methods for debiasing, we could not evaluate the performance of the debiasing methods on the extrinsic tasks. This is because of the scarcity of reliable Hindi language datasets, which made any form of notable inferences harder. In addition, the deep learning models were already underperforming on these Hindi datasets.

In this work we use the more general approach of linear projection as it can be adapted to several biases apart from gender.

In the method of linear projection, all words $w \in W$ are debiased to w' by being projected orthogonally to the identified bias vector v_B.

$$w' = w - \langle w, v_B \rangle v_B \tag{5}$$

In case of hard debiasing, we required list of equalizing pairs and list of words to not debias in Hindi. However, direct translation of the word lists to Hindi did not always make sense. Since, some words like ‘she’ and ‘he’ had overlapping translations and both the pronouns are referred to as ‘veha’ in Hindi. This overlapping translation is true the other way round as well, the word grandfather can be either ‘nana’ (maternal grandfather) or ‘dada’ (paternal grandfather).

For languages with grammatical gender, Zhou et al. (2019) proposed to determine semantic gender direction. To obtain the semantic gender direction (d_s), the grammatical gender component (d_g) in the computed gender direction (obtained from PCA over gendered word pairs, d_{PCA}) to make the semantic gender direction orthogonal to grammatical gender.

$$d_s = d_{PCA} - \langle d_{PCA}, d_g \rangle d_g \tag{6}$$

We use this orthogonalized gender direction to perform linear debiasing. We refer to this method as LPSG (Linear Projection with Semantic Gender).

E.1 Debiasing Binary Gender

The first step in debiasing using linear projection is to identify a bias subspace/vector. We experiment with different settings to identify the gender vector in Hindi, including (i) a single gender specific word pair direction of $\{\vec{naari} - \vec{nar}\}$, (ii) PCA over a list of paired gender specific words (in the form $\{\vec{m_i} - \vec{f_i}\}$). For more results with other gender directions, refer to the Appendix. Also, the word lists used in the experiment are provided in Appendix E.

For hard debiasing, we considered two types of gender definition word lists. In one list we included only the gender definitional pairs translated to Hindi from the original English lists (after some modifications to remove ambiguous translations). In another experiment, we added pairs of gendered verbs to the list as well.

Hindi is a language having grammatical gender. As introduced in Section 2.1, we have 4 special gender directions along which we want to preserve the information. The direction for gendered verbs (d_v), adjectives (d_a), titles (d_t) and entities (d_e) were calculated by conducting PCA over the word lists (App E). For LPSG method, we provide results of orthogonalizing the semantic gender with respect to verbs and adjectives directions. In another experiment, we orthogonalize the semantic gender with respect to all the 4 directions.

Table 3 demonstrates how different gender subspaces affect the WEAT effect sizes in both bias measuring and information retention tests. Note that the single direction of $\{\vec{naari} - \vec{nar}\}$ was able to debias the best upon the math and arts test. Pairwise PCA over gendered words debiased the science and arts test quite significantly with an effect size of only 0.001 after debiasing. Hard debiasing is not able to debias the first two tests in the WEAT setting, however, it reduces the effect sizes in case of SEAT (see Table 4). In both WEAT and SEAT tests for neutral adjectives vs gendered words, hard debiasing performs best against any other methods. Although hard debiasing works competitively, it comes with the downside that it does not retain the gendered information in our information retention (IR) tests. Both of the LPSG variants were able to debias competitively while at the same time were best in retaining the gendered information of IR tests.

E.2 Debiasing Caste

Similar to debiasing gender, for caste we first begin with determining the caste direction with a two words, one stereotypically considered upper caste and one lower: $\{gha\vec{s}iya - pa\vec{n}dit\}$. We also try with the direction $\{gha\vec{s}iya - de\vec{s}ai\}$. Since castes do not occur in pairs, a set of word pairs cannot be meaningfully constructed as done with binary gender in English (Bolukbasi et al., 2016). Hence, we compose lists of stereotypically upper and lower castes, and conduct PCA over the combined list to obtain the vector of caste bias. Refer to Appendix E for the word lists used in the experiment. In Table 5 we can observe that the linear debiasing using the single direction of $\{gha\vec{s}iya - de\vec{s}ai\}$ is unable to debias competitively when compared with the other two methods. Note that the single direction of $\{gha\vec{s}iya - pa\vec{n}dit\}$ is able to debias better than PCA over list of caste names.

E.3 Debiasing Religion

In order to mitigate religious biases in Hindi, we acknowledge how in Indian culture, the religion of a person is generally identifiable by their last names. We thus, utilize last names to determine the direction of bias. We use both (i) a single set of common last names $\{ach\vec{a}rya - na\vec{s}ir\}$, and (ii) a set of hindu and muslim entities.

Another religion direction is calculated by combining word lists of Hindu and Muslim lastnames and then conducting PCA over them, we call this religion bias direction as d_{last}. The words lists are provided in Appendix E.

In Hindi language, various religious entities are inherently associated with a particular religion, for example, "Bible is to Christianity as Bhagwad Gita is to Hinduism" is not bias. To accomodate for such cases, we again take motivation from (Zhou et al., 2019) to obtain a direction d_{ent} from the entities word lists (Appendix E) and keep the religion direction calculation calculated by Hindu and Muslim lastnames d_{last}, orthogonal to it.

$$d'_{last} = d_{last} - \langle d_{last}, d_{ent} \rangle d_{ent} \tag{7}$$

We believe that if we debias words using d'_{last} as bias direction, we should be able to preserve the knowledge of religion information retention test and debias competitively.

In Table 6, we see that linear debiasing by conducting PCA over a list of religious entities is not able to debias much in any of the tests. The same could be observed for linear debiasing using single set of common last names $\{ach\vec{a}rya - na\vec{s}ir\}$. However, if we linear debias by PCA over a list of lastnames, we are able to debias significantly. Although the Information Retention WEAT effect size is less than the previous methods, they did not even affect the religion bias which is our primary goal. Zhou's variant for religion debias performs well since it is able to debias competitively as well as retains greater amount of necessary religion information. Refer to Appendix C for the word lists used in the test.

Abstract

We propose a simple yet effective way to generate pun sentences that does not require any training on existing puns. Our approach is inspired by humor theories that ambiguity comes from the context rather than the pun word itself. Given a pair of definitions of a pun word,[1] our model first produces a list of related concepts through a reverse dictionary to identify unambiguous words to represent the pun and the alternative senses. We then utilize one-shot GPT3 to generate context words and then generate puns incorporating context words from both senses. Human evaluation shows that our method successfully generates puns 52% of the time, outperforming well crafted baselines and the state-of-the-art models by a large margin.

1 Introduction

Computational humor has garnered interest in the NLP community (Petrović and Matthews, 2013; Miller et al., 2017; Zou and Lu, 2019; Garimella et al., 2020; Yang et al., 2020). In this paper, we tackle the problem of generating homographic puns (Miller et al., 2017): two or more meanings of a word form an intended humorous effect. For example, the three puns listed in Figure 1 exploit two contrasting meanings of the word *sentence*: 1) a grammatical string of words and 2) the punishment by a court assigned to a guilty person.

Sense 1 Definition	a string of words that is complete in itself, typically containing a subject and predicate
Sense 2 Definition	(criminal law) a final judgment of guilty in a criminal case and the punishment that is imposed
Ours 1	The sentence is ungrammatical. The jury didn't hear it.
Ours 2	I'm sorry I said the sentence was too long but punishments are endless.
Human	The Judge has got a stutter. Looks like I am not getting a sentence.

Figure 1: An illustration of homographic puns. The target pun word *'sentence'* and the two sense definitions are given as input. To make the target word interpretable in both senses, we propose to include context words (highlighted in blue and pink) related to both senses.

Due to the lack of sizeable training data, existing approaches are heavy-weighted in order to *not* rely on pun sentences for training. For example, (Yu et al., 2018) train a constrained neural language model (Mou et al., 2015) from a general text corpus and then use a joint decoding algorithm to promote puns. He et al. (2019) propose a local-global surprisal principle, and Luo et al. (2019) leverage the Generative Adversarial Nets (Goodfellow et al., 2014) to encourage ambiguity of the outputs via reinforcement learning. We, on the other hand, propose a simple yet effective way to tackle this problem: *encouraging ambiguity by incorporating context words related to each sense*.

Inspired by humor theories (Attardo, 2010), we hypothesize that it is the contextual connections rather than the pun word itself that are crucial for the success of pun generation. For instance, in Figure 1 we observe that context related to both senses (e.g., *ungrammatical* and *jury*) appear in a punning sentence. Such observation is important as the error analysis of the SOTA model (Luo et al., 2019) shows that 46% of the outputs fail to be puns due to single word sense, and another 27% fail due to being too general, both of which can be resolved by introducing more context.

Specifically, given the two sense definitions of a target pun word, we first use a reverse dictionary to generate **related words** that are monosemous for both senses. This first step helps us circumvent the obstacle of processing pun words with the same written form. We then propose to use **context words** to link the contrasting senses and make our target pun word reasonable when interpreted in both definitions. We explore three different settings: extractive-based, similarity-based, and generative-based. Finally, we finetune the

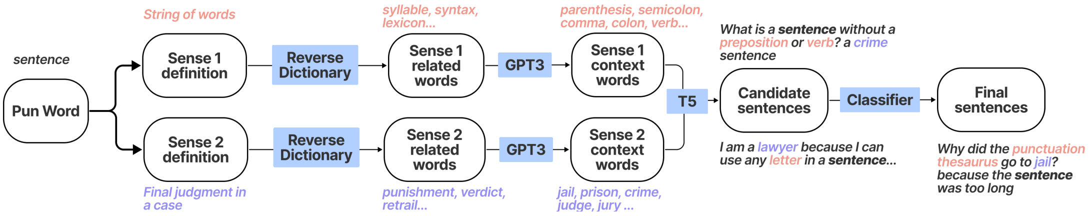

Figure 2: Overview of the approach. We also give an example for pun word ‘sentence’ for each step.

T5 model (Raffel et al., 2020) on general non-humorous texts to generate coherent sentences given the pun word and contexts words as input.

Our experimental results show that retrieve-and-extract context words outperforms the giant few-shot GPT3 model in terms of generating funny pun sentences, although the latter has shown to be much more powerful in many sophisticated tasks (Brown et al., 2020). Our simple pipeline remarkably outperforms all of the more heavy-weighted approaches. Our code and data is available at `https://github.com/PlusLabNLP/AmbiPun`.

2 Methodology

Overview and Motivation Our input is the target pun word (p) and its two sense definitions (S_1, S_2), and the output is a *list* of humorous punning sentences. We implement the ambiguity principle proposed in (Kao et al., 2016): a pun sentence should contain one or more context words corresponding to each of the two senses.[2] The overview of our approach is visualized in Figure 2.

Given S_1 and S_2, we first use a reverse dictionary to generate a list of words that semantically match the query descriptions. We call them **related words** (Section 2.1). However, those related words are synonyms of the pun word and are rarely observed as it is in humorous sentences. For example, for the sentence: “The Judge has got a stutter. Looks like I am not getting a sentence.”, The word representing the first sense (i.e. a final judgment of guilty in a criminal case) is represented by *Judge*, which could not be generated using the sense definition.

Considering such nuances, in Section 2.2 we propose three different methods to obtain the **context words**. They are extractive, similarity, and generative based. Finally, in Section 2.3 and 2.4, we introduce a keyword-to-text generator to generate candidate sentences , and a humor classifier to rule out some of the non-pun sentences. Final sentences are then randomly sampled for evaluation. All our training data is general, non-humorous corpus except for the humor classifier.

2.1 Generating Related Words

We aim at differentiating the two senses of a polysemy by taking the related words, so that each sense will be represented by a set of monosemous words. To this end, we leverage the Reverse Dictionary (Qi et al., 2020; Zhang et al., 2020) which takes as input a description and generates multiple related words whose semantic meaning match the query description. For each sense definition, we generate five words.

2.2 Generating Context Words

For context words, we compare three different approaches. As an example, we compare the output of context words for the pun word ‘sentence’ in Table 5 in the appendix. Refinement of the context words is mentioned in section A.2 in the appendix.

Method 1: Extractive (TF-IDF) For each related word, we retrieve sentences from the One Billion Word dataset containing that word and then extract keywords using RAKE (Rose et al., 2010) from the retrieved sentences. Based on this TF-IDF value, we choose the top 10 context words that are mostly likely to be used along with the related words and therefore the pun word.

Method 2: Similarity (Word2Vec) Inspired by the idea that “a word is characterized by the company it keeps”, we propose to get context words from word2vec. (Ghazvininejad et al., 2016) have also shown that the training corpus for word2vec plays a crucial role on the quality of generated context words. Hence, we train on Wikipedia which has a comprehensive coverage of diverse topics.

Method 3: Generative (Few-shot GPT3) For the generative version, we provide the powerful language model GPT3 (Brown et al., 2020) with two examples and generate context words. Details about the prompt can be found in section E of the appendix.

2.3 Candidate Sentence generation

After receiving context words for each sense, we generate humorous puns. We finetune a keyword-

---

[2] Note that all previous works produce only the *best* sentence during decoding time, while we aim at generating *tens or hundreds* of sentences for a target pun word so that our task is actually more challenging.

to-sentence model using T5 (Raffel et al., 2020), as it is capable of handling text-to-text tasks. The prompt provides the pun word, and two context words from each of the two senses. For example for the word 'sentence', a possible prompt can be *generate sentence: sentence, judge, trial, noun, comma.* Moreover, we also investigate whether the position of the pun word will affect the quality of generated sentences. We insert the pun word in the first, third, and fifth place of the prompt. We discuss our findings in Section 5.

2.4 Humor Classification

Finally, we introduce a classification model to assist us in selecting (i.e., ranking) punning sentences. Since we do not have sizable training data for puns, we propose to train our classification model on humorous dataset in a distantly supervised fashion. Specifically, we train BERT-large (Devlin et al., 2018) on the ColBERT dataset (Annamoradnejad and Zoghi, 2020) that contains 200,000 jokes and non-jokes used for humor detection. We use the probability produced by the classification model to rank our candidate sentences.

Our error analysis in section Appendix.B shows that our classifier can successfully rule out the bad generations, i.e., non-puns, as puns are humorous by nature. However, the model is not great at choosing the best samples. Therefore, we use this classifier only to remove the bottom third candidates. We leave this for open future work to accurately pick out high-quality punning sentences instead of funny sentences.

3 Experiments

3.1 Datasets

Training: For the context word generation step, we use the One Billion word dataset (Chelba et al., 2013) to retrieve sentences for a given word and calculate TF-IDF values. This dataset contains roughly 0.8B words and is obtained from WMT 2011 News crawl data. For the humor classifier and candidate generation module, we use ColBERT dataset (Annamoradnejad and Zoghi, 2020). It contains 100k jokes and 100k non-jokes.

Evaluation dataset: Following other pun generation works, we use the SemEval 2017 Task 7 (Miller et al., 2017) for evaluation. The dataset contains 1,163 human written punning jokes with a total of 895 unique pun words. Each sentence has the target pun word, location of the pun word and the WordNet sense keys of the two senses.

Model	**Avg Seq Len**	**Corpus-Div**		**Sentence-Div**	
		Dist-1	Dist-2	Dist-1	Dist-2
Few-shot GPT3	12.3	**37.1**	**80.4**	94.5	85.7
Neural Pun	12.6	30.2	73.0	91.3	90.5
Pun GAN	9.7	34.6	71.9	90.2	87.6
Sim AmbiPun	13.4	32.4	77.1	92.9	91.2
Gen AmbiPun	13.5	32.8	77.8	93.6	91.2
Ext AmbiPun	**14.0**	31.7	78.7	**96.3**	**92.3**
Human	14.1	36.6	81.9	95.5	92.4

Table 1: Results of automatic evaluation on average sequence length, sentence-level and corpus-level diversity. Boldface denotes the best performance and underline denotes the second best performance among systems.

Model	Success Rate	Fun	Coherence
Few-shot GPT3	13.0%	1.82	**3.77**
Neural Pun	35.3%	2.17	3.21
Pun GAN	35.8%	2.28	2.97
Sim AmbiPun	45.5%	2.69	3.38
Gen AmbiPun	50.5%	2.94	3.53
Ext AmbiPun	**52.2%***	**3.00***	3.48
Human	70.2%	3.43	3.66

Table 2: Human evaluation results on all the pun generation systems. We show the success rates, and average scores of funniness and coherence. Overall, Ext AmbiPun performs the best. The superiority of our model in terms of success rate and funniness is statistically significant over the best baseline and is marked by *.

3.2 Baselines

Neural Pun Yu et al. (2018) propose the first neural approach to homographic puns based on a constrained beam search algorithm to jointly decode the two distinct senses of the same word.

Pun-GAN The SOTA introduced by Luo et al. (2019) that adopts the Generative Adversarial Net to generate homographic puns.

Few-shot GPT3 We generate puns with a few examples feeding into GPT3 *davinci-instruct-beta*, the most capable model in the GPT3 family for creative generation. We provide the target pun word and its two senses in our prompt, along with the instruction to generate puns.

Ablations of our own models We also compare three methods proposed by us to obtain the context words (described in Section 2.2). We call them Ext AmbiPun, Sim AmbiPun, and Gen AmbiPun.

3.3 Evaluation

Automatic Evaluation We follow Luo et al. (2019); Yu et al. (2018) to calculate distinct unigram and bigrams as the *diversity* (Li et al., 2016) in terms of sentence level and corpus level. We also

Pun word	**Irrational**		
Sense 1	Real but not expressible as the quotient of two integers		
Sense 2	Not consistent with or using reason		
Model	**Example**	**Pun**	**Funny**
GPT3	I can't make a decision with all this irrationality going on.	No	1.4
Neural Pun	Note that this means that there is an irrational problem.	Yes	2.4
Pun-GAN	It can be use the irrational system.	No	1.2
Ext AmbiPun	I have an irrational paranoia about mathematical integers.	Yes	**3.8**
Gen AmbiPun	My calculator is unjust and illogic. It's irrational.	Yes	3.4
Human	Old math teachers never die, they just become irrational.	Yes	**3.8**

Pun word	**Drive**		
Sense 1	A journey in a vehicle (usually an automobile)		
Sense 2	The trait of being highly motivated		
Model	**Example**	**Pun**	**Funny**
GPT3	I am exhausted, I need a nap before I can drive any more.	No	2.0
Neural Pun	It is that it can be use to drive a variety of function?	No	1.6
Pun-GAN	In he drive to the first three years.	No	1.2
Ext AmbiPun	What do you call a genius with cunning drive? racecar driver.	Yes	3.6
Gen AmbiPun	I have the determination to travel to my destination. But i don't have the drive.	Yes	4.0
Human	A boy saving up for a car has a lot of drive.	Yes	**4.2**

Table 3: Generated sentences for the word 'Irrational' and 'Drive'and their sense definitions. We underline the context words that are related to each sense. All the generations are evaluated by external annotators, not the authors.

report the the average sentence length produced.

Human Evaluation We randomly select 100 sentences and collected our human ratings on Amazon Mechanical Turk (AMT). For each sentence, three workers are explicitly given the target pun word and its two sense definitions provided by the SemEval 2017 Task 7. We first ask them to judge if a given sentence is a successful pun sentence. Then, they are asked to rate the funniness and coherence on a scale from 1 (not at all) to 5 (extremely). Besides detailed instructions and explanation for each criteria, we also adopt attention questions and qualification types to rule out irresponsible workers. We conduct paired t-test for significance testing. The difference between our best performing model and the best baseline is significant.

4 Results and Analysis

4.1 Pun Generation Results

Automatic Evaluation Results of the automatic evaluation can be seen in Table 1. The average sentence length of our model is closest to human and gets the highest sentence-level diversity. Although our baseline Pun-GAN and Few-shot GPT3 have higher distinct unigram ratios at the corpus level, that is because all baseline models generate *one* sentence per pun word, while AmbiPun generates *tens* of sentences per pun word, which inevitably sacrifices topical diversity. Nevertheless, AmbiPun achieves the highest corpus-level bi-gram diversity.

Human Evaluation Results from the automatic evaluation can be seen in Table 2. We evaluate the success rate, funniness, and coherence of the generated outputs. The superiority of our models are obvious. For significance testing, we conducted paired t-test, where our systems outperformed the best baseline in terms of success rate and funniness (p-value < 0.05). On the other hand, GPT3 could generate even more coherently than humans.

Analysis between extractive and generative method. Interestingly, the extractive method has higher success rates (p-value < 0.05) and is funnier (p-value < 0.07) than the generative method, indicating that extracting salient words from human written sentences could introduce more surprising and uncommon words than language models. We posit that those atypical words refresh people's eyes and thus boost the pun success rate as well as the funniness score. On the other hand, we also tried to equip GPT3 with greater creatively by top-k sampling with a large temperature T. However, larger Ts also result in arbitrary responses that humans may find unreadable. We hope our discovery could draw the community's attention to those traditional techniques for creative generation.

4.2 Case Study

To better understand the advantages of our method, we conduct a case study for the pun word "Irrational" and "Drive" in Table 3. For both target pun words, at most one of the baselines successfully generates a punning sentence. As discussed earlier, one possible reason is the absence of both senses. On the other hand, both Ext AmbiPun and Sim AmbiPun introduce context words for the two senses and thus are able to generate of high quality puns that almost match the human written puns in

	Success Rate
Beginning	46.7%
Middle	52.0%
End	54.7%

Table 4: The pun success rate sentences based on their position annotated by human.

terms of the funniness score.

5 The Position of Pun Words

As is mentioned in Section 2.3, we play with the position of the pun word in the prompt given to the candidate sentence generation model. We try three variants by putting the target pun word at the start, in the middle, and at the end. For each variant, we ask Mechanical Turkers to judge if the given sentences are puns. Again, each sentence is rated by three Turkers and we take the majority answer if the workers disagree. Results from this analysis can be seen in Table 4. We observe that people find a sentence more likely to be a pun when the target word appears at the end.

To verify such hypothesis, we also calculate the position of the pun words of 1,163 human written pun sentences from SemEval 2017 Task 7 and report the distribution in Figure 3 in the Appendix. The histogram corroborates with the human annotated samples in that both suggest that keeping the pun word at the end of the sentence generates funnier puns. Theory of humor which says that the "joke" in a funny sentences some towards the end of the sentence (Shahaf et al., 2015) validates our analysis.

6 Related Works

6.1 Creative Text Generation

Pun generation. Many of the previous works on pun generation have focused on phonological or syntactic pattern rather than semantic pattern (Miller and Gurevych, 2015; Hong and Ong, 2009; Petrović and Matthews, 2013; Valitutti et al., 2013) thus lacking creativity and flexibility. He et al. (2019) make use of local-global surprisal principle to generate homophonic puns and Yu et al. (2020) uses constrained lexical rewriting for the same task. Hashimoto et al. (2018) use a retrieve and edit approach to generate homographic puns and Yu et al. (2018); Luo et al. (2019) propose complex neural model architecture such as constrained language model and GAN, and do not put emphasis on the linguistic structure of puns. We identify their absence of both the senses as a shortcoming and build our approach from there.

Humor generation. Humor generation still remains an unsolved problem, and is usually studied in a specific setting. Petrović and Matthews (2013) generates joke of the type 'I like my X like I like my Y, Z'. Garimella et al. (2020) develops a model to fill blanks in madlibs format and Yang et al. (2020) edit headlines to make them funny. More research is required to generate humorous sentences that are not constrained by their semantic structure.

Figurative language generation. In addition to pun, there are many attempts to generate figurative language such as metaphor, simile (Chakrabarty et al., 2020b), sarcasm, etc. Yu and Wan (2019) use metaphorically used verbs to generate metaphors in an unsupervised fashion, while Chakrabarty et al. (2021); Stowe et al. (2021) generate metaphors using symbolism and discriminative and conceptual mapping. Mishra et al. (2019) propose a modular architecture for unsupervised sarcasm generation, and Chakrabarty et al. (2020a) use commonsense knowledge for the same task. Tian et al. (2021) on the other hand are the first leverage semantic structure and commonsense and counterfactual knowledge to generate hyperboles.

6.2 Pun detection

SemEval 2017 Task 7 (Miller et al., 2017) introduced the challenge of pun detection, location detection and sense interpretation for homographic and homophonic puns. Diao et al. (2019) make use of Gated Attention network to detection homophonic puns. Zou and Lu (2019) introduces a tagging schemes which lets them detect puns as well as their location. They apply this approach to both homophonic and homographic puns.

7 Conclusion

We propose a novel approach towards homographic puns generation. Unlike previous works that are mathematically heavy, our approach is backed by the humor theory that ambiguity is achieved by the context. Automatic and human evaluations show that our model AMBIPUN outperforms the current state-of-the-art model by a large margin.

Appendix

A Details in Experiments

A.1 An Example of Context Words

We list the output of context words for the pun word ‘sentence’ in Table 5. The table lists two sense definitions and the related words obtained from the sense definitions using reverse dictionary. We then obtain context words using three different mechanisms: TF-IDF, Word2Vec, and GPT3.

A.2 Implementation Details

Experimental Settings For the word2vec model we train a continuous-bag-of-words model with window size 40 and word vector dimension 200. For the candidate generation module, we train the T5-base model on 10 epochs and select the best performing model based on validation loss. Max sequence length for target and source is set to 30. Batch size is set to 64.

Data Refinement The process to generate both related and context words can entail many words that are not ideal. Continuing with these words would further propagate and enlarge the noise. Hence, to minimize this noise, we implement the following data refinement steps to ensure the keywords stick to our standards: we avoid using polysemous words as keywords during intermediate steps because their perceived sense is highly ambiguous. We also disregard any numbers and special characters produced by our systems.

A.3 Human Evaluation

The workers are paid $20 per hour. For pun success judgement (yes/no question), we take the majority vote among three workers, while for funniness and coherence (1 to 5), we take the average ratings. We then use the pairwise kappa coefficient to measure the inter-annotator agreement (IAA). The average inter-annotator agreement of all raters for pun success, funniness and coherence are 0.55, 0.48 and 0.40, meaning that annotators moderately agree with each other. Considering the subjectivity of this task (Braslavski et al., 2018), and the higher IAA in terms of pun success and funniness over coherence, we argue that our collected results are reasonably reliable for the purpose of pun generation. Besides, we conducted paired t-test and show that the success rate and funniness ratings of our systems differentiate from the best baseline model with statistical significance (p-value < 0.5).

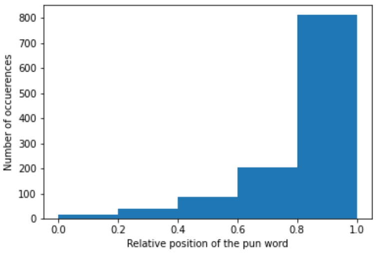

Figure 3: Analysis of the position of pun word in 1,163 human written puns. The y-axis indicates the number of sentences and the x-axis indicates the position of pun word on a scale from 0 (start) to 1 (end).

B Humor Classifier Results for Selecting Puns

To further discuss the accuracy and recall of our humor classifier, we show a representative output in Table 6. The table contains a few selected sentences ranked my the humor classifier. We also label each sentence as *yes*, *no*, and *maybe* to indicate if it is a pun or not. As discussed in the methodology, we train our classifier on humor dataset. As puns are an important part of humor generation, this model can help rule out some options. Basic theories of humor such as incongruity and surprise apply to both of them. As can be seen in the table, our classifier is able to successfully pull aside unfunny or non-coherent sentences. Looking at the examples at the top and the middle, it can be observed that some better examples are classified lower than others. Making this observation across many pun words, we decided to use the classifier only to rule out the bottom third samples. For the rest of the generations, we randomly sample them.

On manual observation, we realised that when we as humans peruse the generated candidates, there are many sentences that meet our expectations. Therefore, building a classifier that can accurately find these sentences can increase the accuracy by a large margin. We treat this as an opportunity for future work.

C Analysis of Human Written Puns

we calculate the position of the pun words of 1,163 human written pun sentences from SemEval 2017 Task 7 and report the distribution. The histogram corroborates with the human annotated samples in that both suggest that keeping the pun word at the end of the sentence generates funnier puns. Theory of humor which says that the “joke” in a funny sentences some towards the end of the sentence validates our analysis.

	Sense 1	**Sense 2**
Definition	a string of words satisfying the grammatical rules of a language	a final judgment of guilty in a criminal case and the punishment that is imposed
Related words	syllable, syntax, lexicon, thesaurus, grammatical	punishment, verdict, sentencing, retrial, penalty
TF-IDF	syllables, words, three, spelling, even, said, describe, typos	cruel, expected, end, court, scheduled, set, spector, seeking
Word2Vec	syllable, pronounced, words, rhyme, verbs, meaning, hence, example	punished, crimes, offender, torture, moral, guilt, abuse, offender
GPT3	words, letters, punctuation, grammar, synonym, dictionary, meaning, comma	prison, judge, jury, trial, justice, lawyer, court, evidence

Table 5: Comparison of the three different context word generation mechanism for the pun word ‘sentence’. The table lists two sense definitions and the related words obtained from the sense definitions using reverse dictionary. For these related words, we obtain context words using three different mechanisms.

Sentence	Rank	Pun
What’s the interest rate on a home mortgage? No interest.	1	Yes
My bank said I think they’re interested in me. I said no.	2	No
My girlfriend said she had an interest in banking so i loan her a quarter	3	Yes
I have no interest in being a guardian. It’s free.	4	Maybe
I’ve never had interest placed on borrowings. It’s a waste of time.	5	Yes
Why did the republican attack the bank? Because it was in its interest.	6	Maybe
What is the republican’s strategy? The interest rate.	7	No
What is the most dispensable interest in investment?	8	No
If trump had an interest in president he would make it an president-of-interest.	9	No

Table 6: An example of candidate pun sentences ranked by the humor classifier. As can be seen, the model is able to rule out non-pun sentences but fails to pick out high-quality ones.

D More Examples of Generated Puns

We compile more examples generated by AMBIPUNin Table 7 for the following pun words: *sentence*, *case*, *bugs*, *delivery*. This table further supports our claim that our approach would benefit from a better classification module to select human-like sentences.

E GPT3 for context words generation

We make use of few shot GPT3 to generate context words. The prompy to GPT3 included 2 pair of prompt and its completion. One example of a pair would be *“generate seven keywords for laptop: battery, macbook, internet, technology, keyboard, technology, portable”*. These example are followed by the prompt *“generate seven keywords for X:”* where X is a related word. This way we generate seven keywords for each related word.

Target word	**sentence**
Sense 1	A string of words satisfying the grammatical rules of a language
Sense 2	(Criminal law) a final judgment of guilty in a criminal case and the punishment that is imposed
1	The word jail is a sentence.
2	What's the punishment for using antonyms in a sentence syntax is it a sentence?
3	I'm sorry I said the sentence was too long but punishments are endless.
4	The sentence in the dictionary doesn't sound very guilty.

Target word	**case**
Sense 1	A portable container for carrying several objects
Sense 2	A statement of facts and reasons used to support an argument
1	What's the most durable luggage for a detective? jury case
2	A jury just found a container of leather there's no reason to argue it's a case
3	What do you call a container used for investigation research? a case study
4	Why did the cardboard get into a trial? because it was an investigation case

Target word	**bugs**
Sense 1	General term for any insect or similar creeping or crawling invertebrate
Sense 2	A fault or defect in a computer program, system, or machine
1	Why did the garden restart its computer? it had bugs in it.
2	What do you call a pest that's slow programmer? bugs bug
3	Why did the compost crash? it had bugs in it.
4	What do you call a bug that's disgusting? a glitch in the internet

Target word	**delivery**
Sense 1	the act of delivering or distributing something (as goods or mail)
Sense 2	your characteristic style or manner of expressing yourself orally
1	What did the letter say to the parcel? clear delivery!
2	What do you call a trucking truckdriver with no articulation? delivery driver.
3	The distribution center has a pronunciation dictionary. it's a delivery service
4	What do you call a parcel with no dialogue and an accent? delivery service.

Table 7: More examples generated by Ext AmbiPun.

EmpHi: Generating Empathetic Responses with Human-like Intents

Mao Yan Chen[*] and **Siheng Li**[*] and **YujiuYang**[†]

yang.yujiu@sz.tsinghua.edu.cn

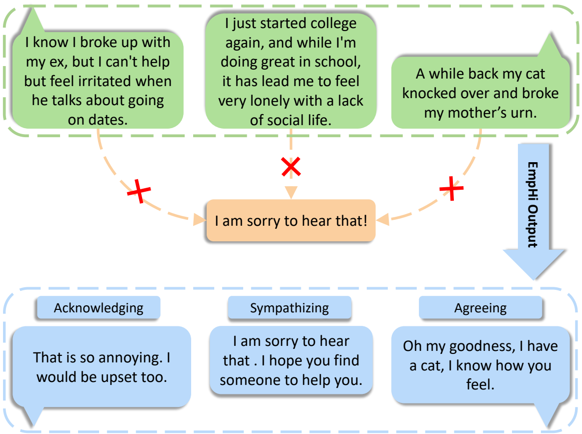
Abstract

In empathetic conversations, humans express their empathy to others with empathetic intents. However, most existing empathetic conversational methods suffer from a lack of empathetic intents, which leads to monotonous empathy. To address the bias of the empathetic intents distribution between empathetic dialogue models and humans, we propose a novel model to generate **emp**athetic responses with **h**uman-consistent empathetic **i**ntents, **EmpHi** for short. Precisely, EmpHi learns the distribution of potential empathetic intents with a discrete latent variable, then combines both implicit and explicit intent representation to generate responses with various empathetic intents. Experiments show that EmpHi outperforms state-of-the-art models in terms of empathy, relevance, and diversity on both automatic and human evaluation. Moreover, the case studies demonstrate the high interpretability and outstanding performance of our model. Our code are available at https://github.com/mattc95/EmpHi.

1 Introduction

Empathy is a basic yet essential human ability in our daily life. It is a capacity to show one's caring and understanding to others. Many types of research have been conducted on empathetic expression to enhance the empathy ability of Artificial Intelligence, e.g., computational approach for empathy measurement (Sharma et al., 2020), empathetic expression understanding in newswire (Buechel et al., 2018), online mental health support (Sharma et al., 2021), etc. In this work, we focus on the task of generating empathetic responses (Rashkin et al., 2019; Lin et al., 2019; Majumder et al., 2020) in open-domain conversation.

Existing empathetic dialogue models pay more attention to the emotion-dependent response generation (Lin et al., 2019; Majumder et al., 2020).



I know I broke up with my ex, but I can't help but feel irritated when he talks about going on dates.

I just started college again, and while I'm doing great in school, it has lead me to feel very lonely with a lack of social life.

A while back my cat knocked over and broke my mother's urn.

I am sorry to hear that!

That is so annoying. I would be upset too.

I am sorry to hear that . I hope you find someone to help you.

Oh my goodness, I have a cat, I know how you feel.

Figure 1: EmpHi generates empathetic responses with human-like empathetic intents (text in blue box), while existing empathetic dialogue models generate responses with contextually irrelevant and monotonous empathy (text in orange box).

However, using emotion alone to generate responses is coarse-grained, and the model needs to incorporate empathetic intent information. On the one hand, the speaker often talks with a particular emotion while the listener shows their empathy with specific empathetic intents, e.g., *Acknowledging*, *Agreeing*, *Consoling* and *Questioning* etc (Welivita and Pu, 2020). On the other hand, see in Figure 1, when the user expresses sadness, existing models tend to generate sympathetic responses like "I'm sorry to hear that." However, empathy is not the same as sympathy, so the models should not only generate responses with *Sympathizing* intent. We demonstrate this phenomenon elaborately with a quantitative evaluation in Section 2. In real life situation, humans could reply with various empathetic intents to the same context which depends on personal preference. For example, given a context, "I just failed my exam", an individual may respond "Oh no, what happened?" with *Questioning* intent to explore the experience of the user, or "I understand this feeling, know how you feel" with

---

July 10-15, 2022

Agreeing intent. These types of empathy are more relevant, interactive, and diverse.

To address the above issues, we propose a new framework to generate empathetic responses with human-like empathetic intents (EmpHi) which could generate responses with various empathetic intents, see examples in Figure 1. Specifically, EmpHi learns the empathetic intent distribution with a discrete latent variable and adopts intent representation learning in the training stage. During the generation process, EmpHi first predicts a potential empathetic intent and then combines both implicit and explicit intent representation to generate a response corresponding to the predicted intent. Our main contributions are:

- We discover and quantify the severe bias of empathetic intents between existing empathetic dialogue models and humans. This finding will lead subsequent researchers to pay more attention to fine-grained empathetic intents.

- To address the above problem, we propose EmpHi, which generates responses with human-like empathetic intents. Experiments have proved the effectiveness of our model through the significant improvement in both automatic and human evaluation.

- According to the quantitative evaluation and analysis, EmpHi successfully captures humans' empathetic intent distribution, and shows high interpretability in generation process.

2 Related Work

Empathetic Response Generation. Providing dialogue agents the ability to recognize speaker feelings and reply according to the context is challenging and meaningful. Rashkin et al. (2019) propose the **EmpatheticDialogues** for empathetic response generation research. Most subsequent empathetic conversation researches are evaluated on this dataset, including ours. They also propose Multitask-Transformer, which is jointly trained with context emotion classification and response generation. To further capture the fine-grained emotion information, Lin et al. (2019) introduce MoEL, a transformer with a multi-decoder. Each of them is responsible for the response generation of one specific emotion. Majumder et al. (2020) propose MIME, which mimics the speaker emotion to a varying degree.

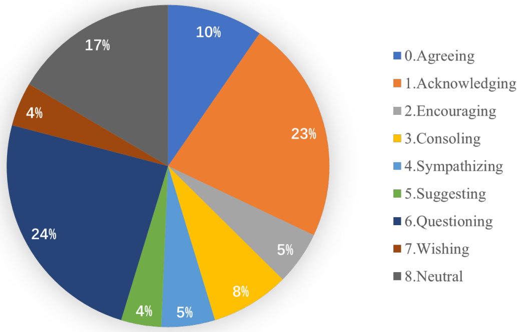

Figure 2: Empathetic intent distribution of human in empathetic conversation.

All these models focus on emotion-dependent empathetic response generation, whereas we pay more attention to the empathetic intents and propose to generate a response that is not only emotionally appropriate but also empathetically human-like.

One-to-many Response Generation. Given dialogue history, there could be various responses depends on personal preference. Zhao et al. (2017) propose to learn the potential responses with continuous latent variable and maximize the log-likelihood using Stochastic Gradient Variational Bayes (SGVB) (Kingma and Welling, 2014). To further improve the interpretability of response generation, Zhao et al. (2018) propose to capture potential sentence-level representations with discrete latent variables. MIME (Majumder et al., 2020) introduces stochasticity into the emotion mixture for various empathetic responses generation.

Different from the previous works, we propose a discrete latent variable to control the empathetic intent of response and achieve intent-level diversity.

3 Empathetic Expression Bias

Although existing empathetic conversational methods have shown promising progress, we reveal there is a severe bias of empathetic expression between them and humans according to quantitative evaluation.

Empathy plays a vital role in human conversation, Welivita and Pu (2020) make a taxonomy of empathetic intents and calculate the frequency of each intent in **EmpatheticDialogues** (Rashkin et al., 2019). As shown in Figure 2, humans show

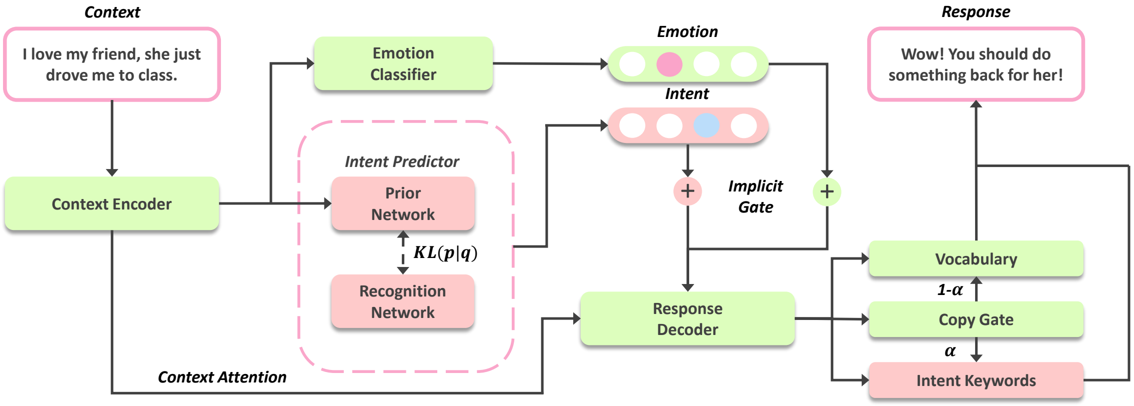

Figure 3: The architecture of EmpHi, which consists of a context encoder, an emotion classifier, a prior network (intent predictor), a recognition network, and a response decoder with copy mechanism.

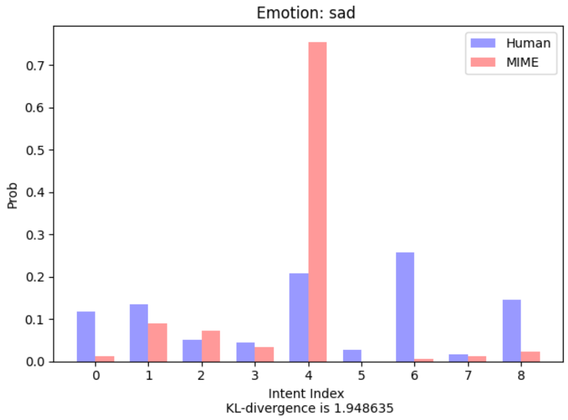

Figure 4: Empathetic intent distribution of human and MIME (sad emotion), the intent index represents the same intent as in Figure 2.

their empathy naturally by *Questioning*, *Acknowledging*, and *Agreeing* intents etc.

However, there are no empirical experiments have shown *how empathetic dialogue models express their empathy?* To further study, we finetune a BERT classifier (Devlin et al., 2019) on the released **EmpatheticIntents**[1] dataset (Welivita and Pu, 2020). Our classifier achieves 87.75% accuracy in intent classification and we apply it to identify the empathetic intents of responses generated by the state-of-the-art empathetic dialogue model MIME (Majumder et al., 2020). As shown in Figure 4, the severe empathetic intent distribution bias emerges while comparing humans to MIME. Given context with sad emotion, existing models usually generate "I am sorry to hear that" with *Sympathizing* intent, which is not human-like and contextually relevant. In addition, we can tell that the empathetic expression of MIME is monotonous. We also quantify the intent distribution of other empathetic dialogue models in the Appendix A. The results are similar to Figure 4.

We believe this phenomenon is caused by that existing models only generate responses according to context emotion and lack fine-grained empathetic intent modeling. Therefore, we propose EmpHi, which generates empathetic responses with human-like empathetic intents.

4 EmpHi Method

4.1 Task Definition and Overview

Given the context, $C = [c_1, c_2, \cdots, c_m]$, which consists of m words for single or multiple utterances. We aim to generate empathetic response, $X = [x_1, x_2, \cdots, x_n]$, with human-like empathetic intent. The whole model architecture is shown in Figure 3.

EmpHi learns the potential empathetic intent distribution with a latent variable z, which could be seen in Figure 5. Conditional Variational AutoEncoder (CVAE) (Yan et al., 2016; Zhao et al., 2017; Gu et al., 2019) is trained to maximize the conditional log likelihood, $\log p(X|C)$, which involves an intractable marginalization over z. We train the CVAE efficiently with *Stochastic Gradient Variational Bayes* (SGVB) (Kingma and Welling, 2014) by maximizing the variational lower bound of the log likelihood:

$$\begin{aligned}\log p(X|C) \geq &\mathbf{E}_{q(z|X,C)}[\log p(X|C,z)] \\ &- \mathbf{KL}(q(z|X,C)||p(z|C)),\end{aligned} \tag{1}$$

---

[1] `https://github.com/anuradha1992/EmpatheticIntents`

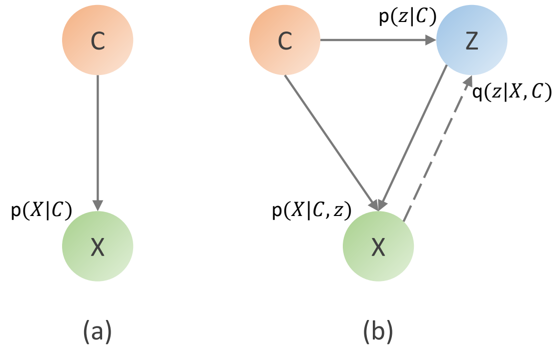

Figure 5: An illustration of the difference between existing empathetic dialogue models (a) and EmpHi (b).

$p(X|C,z)$ denotes response reconstruction probability, $q(z|X,C)$ is recognition probability and $p(z|C)$ is prior probability. Our method mainly consists of three aspects:

- To capture the explicit relationship between the latent variable and the intent, we propose an intent representation learning approach to learn the intent embeddings.
- We construct an intent predictor to predict potential response intent using contextual information and then use this intent for guiding the response generation.
- During the generation process, EmpHi combines both implicit intent embedding and explicit intent keywords to generate responses corresponding to the given intents.

4.2 Learning Intent Representation

To achieve more interpretability, we choose a discrete latent variable that obeys categorical distribution with nine categories, each corresponding to one empathetic intent. Directly maximizing Eq.1 would cause two serious problems: the relation between the latent variable and intent is intractable; the *vanishing latent problem* results in insufficient information provided by the latent variable during generation. (Bowman et al., 2016; Zhao et al., 2017; Gu et al., 2019).

To solve the above issues, we separately train a recognition network $q_r(z|X)$ to encourage intent variable z to capture context-independent semantics, which is essential for z to be *interpretable* (Zhao et al., 2018). The task of the recognition network is to provide the accurate intent label of the response, which corresponds to an intent embedding. Then, by maximizing likelihood $p(X|C,z)$, the embedding captures corresponding intent representation automatically. The recognition network $q_r(z|X)$ does not need additional training. We utilize the BERT intent classifier mentioned above, which achieves 87.75% accuracy in intent classification. In addition, as the sample operation easily brings noise for the intent representation learning when sampling a wrong intent, we use argmax operation to avoid the noise, the response reconstruction loss is:

$$\mathcal{L}_1 = -\log p(X|C, z_k) \tag{2}$$

$$z_k = \arg\max_{z_k} q_r(z_k|X) \tag{3}$$

$k \in \{0,1,2,\cdots,8\}$, each integer corresponds to a specific empathetic intent as in Figure 2.

4.3 Intent Predictor and Emotion Classifier

The intent predictor is based on the prior network $p_i(z|C)$, which predicts the distribution of response intent by the given context. During inference, we sample potential intents from this distribution in order to generate human-like empathetic responses. Specifically, the context is encoded with gated recurrent units (GRU) (Chung et al., 2014):

$$h_t = \mathbf{GRU}(h_{t-1}, E(c_t)), \tag{4}$$

where h_t is the hidden state of GRU encoder, $E(c_t)$ denotes the word embedding of the t-th word in context, we use h_m as context embedding, then the prior network is:

$$p_i(z|C) = \mathbf{Softmax}(\mathbf{FFN_z}(h_m)), \tag{5}$$

where **FFN** represents *Feed-Forward Network* with two layers. The prior intent distribution is supervised by recognition distribution with KL-divergence in Eq.1:

$$\begin{aligned}\mathcal{L}_2 &= \mathbf{KL}(q_r(z|X)||p_i(z|C)) \\ &= \sum_{k=1}^{K} q_r(z_k|X)\log\frac{q_r(z_k|X)}{p_i(z_k|C)}.\end{aligned} \tag{6}$$

Since the context emotion is proved to be beneficial to empathetic dialogue generation (Rashkin et al., 2019; Lin et al., 2019; Majumder et al., 2020), we also employ an emotion classifier to classify the emotion of context:

$$\begin{aligned}\mathcal{P} &= \mathbf{Softmax}(\mathbf{FFN_e}(h_m))], \\ p_{e_i} &= \mathcal{P}[i]\end{aligned} \tag{7}$$

Given the ground truth emotion label $\mathbf{e_t}$, the emotion classifier is trained with cross-entropy loss:

$$\mathcal{L}_3 = -\log p_{\mathbf{e_t}}. \tag{8}$$

4.4 Response Generator

As for the response generation $p(X|C, z)$, we consider implicit intent embedding for the high-level abstraction of an intent. In addition, we also introduce intent keywords for explicitly utilizing intent knowledge during the generation process.

Implicit. To generate response with an empathetic intent, the most intuitive approach is taking the intent embedding as additional input to decoder during the generation process. We also consider emotion embedding as traditional empathetic dialogue models:

$$s_t = \mathbf{GRU}(s_{t-1}, [E(x_{t-1}); v(z); v(e); c_{att}]), \tag{9}$$

where s_t is the state of GRU decoder, c_{att} denotes the context attention value which contains key information of context (Bahdanau et al., 2015). $v(z)$ is intent embedding and $v(e)$ is emotion embedding, both will not change during the generation process. However, this may sacrifice grammatical correctness (Zhou et al., 2018; Ghosh et al., 2017). Therefore we add a gate operation to capture intent and emotion dynamically:

$$\begin{aligned} \text{Input} &= \mathbf{FFN_i}([E(x_t); c_{att}; s_t]), \\ \text{Gate} &= \mathbf{Sigmoid}(\text{Input}), \\ \bar{v}(z) &= \text{Gate} \odot v(z), \end{aligned} \tag{10}$$

where $\odot$ represents element-wise product. Each time step, the intent representation is used appropriately according to current word, state, and context value. The gate operation for emotion is the same as above.

Explicit. The empathetic expression is quite distinct over vocabularies, e.g., 'know', 'understand', 'agree', are indicative of the empathetic intent *Agreeing*. Therefore, we employ the copy mechanism to explicitly utilize intent keywords for intent conditional generation. See in Appendix B for more details about intent keywords .

$$\begin{aligned} \alpha_t &= \mathbf{Sigmoid}(v_s^\top s_t), \\ p(x_t = w_g) &= \mathbf{Softmax}(W_g s_t), \\ p(x_t = w_i) &= \mathbf{Softmax}(W_i s_t), \\ p(x_t) &= (1 - \alpha_t) \cdot p(w_g) + \alpha_t \cdot p(w_i), \end{aligned} \tag{11}$$

where $\{s_t, v_s\} \in \mathcal{R}^{d\times 1}$, $\{W_g, W_i\} \in \mathcal{R}^{V\times d}$, d is hidden size and V denotes the vocabulary size. The copy rate α_t is used to balance the choice between intent keywords and generic words, it is trained with binary cross entropy loss:

$$\mathcal{L}_4 = \sum_{t=1}^{n} q_t \cdot \log \alpha_t + (1 - q_t) \cdot \log(1 - \alpha_t), \tag{12}$$

n is the amount of words in response, $q_t \in \{0, 1\}$ indicates that whether x_t is a intent keyword.

4.5 Loss Function

To summarize, the total loss is:

$$\mathcal{L} = \lambda_1 \mathcal{L}_1 + \lambda_2 \mathcal{L}_2 + \lambda_3 \mathcal{L}_3 + \lambda_4 \mathcal{L}_4, \tag{13}$$

In order to join all losses with weighting method, we add 4 hyperparameters in total loss, λ_i, where each λ_i is corresponding to L_i. $\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_3, \mathcal{L}_4$ denote the losses of response reconstruction, intent prediction, emotion classification and copy rate prediction respectively.

5 Experiments

5.1 Dataset

We evaluate our method and compare with others on **EmpatheticDialogues**[2] (Rashkin et al., 2019) which contains $25k$ open domain dialogues. Follow the same setting as the authors of this dataset, the proportion of train/validation/test data is $8:1:1$. Each dialogue consists of at least two utterances between a speaker and listener. There are 32 emotion situations in total, which are uniformly distributed.

5.2 Baselines

We compare our model with the three latest empathetic conversational models:

- **Multitask Transformer (Multi-TRS).** A transformer model trained by the response generation task and the context emotion classification task (Rashkin et al., 2019).

- **Mixture of Empathetic Listeners (MoEL).** An enhanced transformer model with 32 emotion-specific decoders to respond appropriately for each emotion (Lin et al., 2019).

---

[2] `https://github.com/facebookresearch/EmpatheticDialogues`

- **MIMicking Emotions for Empathetic Response Generation (MIME).** The state-of-the-art empathetic dialogue model allows the generator to mimic the context emotion to a varying degree based on its positivity, negativity, and content. Furthermore, they introduce stochasticity into the emotion mixture and achieves one-to-many generation (Majumder et al., 2020).

5.3 Evaluation

5.3.1 Automatic Metrics

- **BLEU.** We choose BLEU (Papineni et al., 2002) for relevance evaluation which measures the n-gram overlaps with reference and compute BLEU scores for $n \leq 4$ using smoothing techniques (Chen and Cherry, 2014). Since the state-of-art model MIME and ours are both one-to-many generators, we calculate BLEU recall and BLEU precision (Zhao et al., 2017; Gu et al., 2019). For each test case, we sample 5 responses from latent space and use greedy search for MIME and EmpHi, use beam search for MoEL and Multitask-Transformer.

- **Distinct.** Distinct (Li et al., 2016) is a widely used metric for diversity evaluation. Specifically, we compute the number of distinct unigrams (Distinct-1) and bigrams (Distinct-2), then scale them by the total number of unigrams and bigrams.

5.3.2 Human Ratings

First, we randomly sample 100 dialogues and their corresponding generations from the three baseline models and EmpHi. Then, we invite five volunteers with master degrees to do the human evaluation. The annotators mark each response from 1 to 5 for empathy, relevance, and fluency.

To clarify the marking criteria, we provide an explanation for each metric:

- **Empathy.** Whether the response shows that the listener understands and shares the speaker's feeling. Can the listener imagine what it would be like in the speaker's situation?

- **Relevance.** Whether the response is relevant to the context.

- **Fluency.** Whether the response is easy to read and grammatically correct.

5.3.3 Human A/B Test

Following (Lin et al., 2019; Majumder et al., 2020), we construct this evaluation task to directly compare our model with each baseline. We randomly sample 100 dialogue responses from *EmpHi* vs $\{$*Multitask-Trans*, *MoEL*, *MIME*$\}$. Given randomly ordered responses from above models, four annotators select the better response, or tie if they think the two responses have the same quality. The average score of four results is calculated, and shown in Table 6.

5.4 Implement Detail

For MIME[3] (Majumder et al., 2020) and MoEL[4] (Lin et al., 2019), we reproduce their results using their open-source codes and their default hyperparameters. According to the log-likelihood in the validation dataset for Multitask-Transformer, we use grid search for the best head number, layer number, and feed-forward neural network size. The best set is 2, 10, and 256, respectively. EmpHi uses a two-layer Bi-GRU as the encoder and a two-layer GRU as the decoder, λ is set as $[1, 0.5, 0.5, 1]$ respectively. All the feed-forward neural networks in EmpHi have two layers, 300 hidden units and ReLU activations. For the sake of fairness, we use pretrained Glove vectors (Pennington et al., 2014) with 300 dimensions as the word embedding for all models, the batch size is 16, and the learning rate is set to $1e^{-4}$.

6 Results and Discussions

6.1 Results Analysis

In this section, we mainly testify:

- human-like empathetic intent boost EmpHi's performance in terms of empathy, relevance, and diversity.

- EmpHi successfully captures the empathetic intent distribution of humans.

6.1.1 Human Evaluation

As shown in Table 1, EmpHi outperforms all baselines in terms of empathy, relevance, and fluency. The most distinct improvement is 15.1% on relevance because our model does not only depends on the speakers' emotion, but also makes use of the empathetic intents, which are contextually relevant. It is worth noting that empathy is the primary

EmpHi w/o intent	0.3105	0.4049	0.3515	21.9%
EmpHi w/o gate	0.3138	0.4634	0.3742	25.3%
EmpHi w/o copy	**0.3215**	0.4704	0.3820	25.9%

Table 3: Results of ablation study.

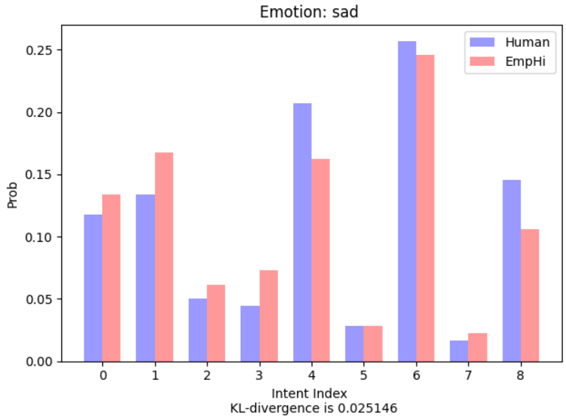

Figure 6: Empathetic intent distribution of human and EmpHi (sad emotion), the intent index represents the same intent as in Figure 2.

metric in empathetic dialogue generation. EmpHi outperforms the previous SOTA on empathy by 9.43%, which directly indicates that human-like empathetic intents are beneficial to the empathy ability of the dialogue model.

Last but not least, a decent fluency score proves that our generated response could be understood by humans easily, where our model has an improvement of 9.87% from MoEL. In addition, the human A/B test results in Table 2 also confirm that the responses from our model are preferable to baselines. Overall, EmpHi successfully generates empathetic, relevant, and fluent responses.

6.1.2 Automatic Evaluation

As seen in Table 1, the automatic evaluation is consistent with human evaluation. The BLEU recall and F1 score are improved by 14.2% and 8.34%, respectively. However, we only have a slight improvement on BLEU precision, which is similar to (Zhao et al., 2017; Gu et al., 2019) because the precision is penalized when the model generates diverse responses. Also, the distinct value of unigrams and bigrams are 32.04% and 19.32% higher than the previous SOTA, respectively. As shown in Figure 4 and Figure 6, the empathy intents of EmpHi's responses are more diverse than existing models, so the distinct scores improve significantly. Our method enhances the relevance and diversity simultaneously, which proves the effectiveness of human-like intent in empathetic response generation.

6.1.3 Empathetic Intent Distribution

We apply the same approach in Section 3 and quantify the empathetic intent distribution of EmpHi's responses to prove that EmpHi accurately captures humans' empathetic intent distribution. Comparing Figure 4 and Figure 6, the difference between them illustrates that our model successfully reduces the bias of empathetic expression. The KL-divergence of intent distributions between models and humans are **0.025** for EmpHi, 1.949 for MIME, 1.545 for MoEL, and 4.570 for Multitask-Transformer (See in Appendix A).

6.2 Ablation Study

We evaluate each component of EmpHi using BLEU and ACC, where ACC indicates the accuracy of predicted empathethetic intent of generated response. Since each conversation could have multiple empathetic responses, the ACC of 26.8% is pretty ideal. As seen in Table 3, there is a dra-

Emotion	Nostalgic
Context	When my wife and i started dating, our second date ended up lasting like 12 hours.
Reference	That is a pretty long date ! Where did you guys go?
Multitask-Trans	That is so sad, I'm sorry to hear that.
MoEL	That is great! I am sure she will be fine.
MIME	That is a good thing to do. I am sure you will do great.
EmpHi	That 's awesome ! How long have you been together ?
Emotion	Angry
Turn-1	I just moved to this neighborhood and some dumb criminals shot one of my neighbors and ran into the woods!
Turn-2	That's not good. Do you own a gun?
Turn-3	I do! I want to be able to protect my son.
Reference	That is always number one goal.
Multitask-Trans	What did you do ?
MoEL	That is a good idea .
MIME	I am sorry to hear that. I hope you get it !
EmpHi	Maybe you should go to the police.

Table 4: Comparison among EmpHi and other empathetic dialogue models.

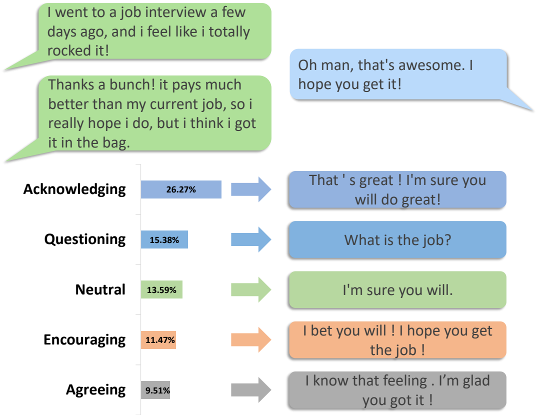

Figure 7: Case study of EmpHi.

matic drop in the performance of EmpHi without any intent information (both implicit embedding and explicit keywords). Therefore, this proves the effectiveness of empathetic intents and the intent representation learning approach. As for implicit gate control, it improves both response quality and intent accuracy since it helps EmpHi dynamically capture intent information during generation. Same conclusion has been made in (Zhou et al., 2018). The copy mechanism provides EmpHi the ability to explicitly use intent keywords and thus contributes to the intent accuracy.

6.3 Case Study

Intent-level diverse generation. Through sampling intents in the discrete latent space, EmpHi generates different responses with empathetic intents. As in Figure 7, the speaker shows an exciting emotion for getting a better job. EmpHi generates empathetic yet contextually relevant responses as humans. Besides, EmpHi predicts the potential intent distribution and shows successful conditional generation based on the corresponding intents, which improves the interpretability and controllability of empathetic response generation. See Appendix C for error analysis.

Compare with existing models. For the first instance in Table 4, even though baseline models show naive empathy in their response, it is hard for the speaker to feel empathy because the response is not relevant to the topic. In contrast, EmpHi shows its understanding of the speaker's feelings and asks a relevant question to explore the speaker's experience. For second case, all baselines express contextually irrelevant empathy, while EmpHi truly understands the dialogue history and put itself into speaker's situation, then further reply: "Maybe you should go to the police" with the *Suggesting* intent.

7 Conclusion

Overall, we reveal the severe bias of empathetic expression between existing dialogue models and humans. To address this issue, this paper proposes EmpHi to generate empathetic responses with human-like empathetic intents. As a result, both automatic and human evaluation prove that EmpHi has a huge improvement on empathetic conversation. According to the anlaysis and case studies, EmpHi successfully learns the emapthetic intent distribution of human and shows high interpretability and controllability during the generation process. We will try large pretrained language models with empathetic intent in our future work.

Ethical Statement

Since this paper involves subjects related to human conversation, we have ensured that all the experiments will cause no harm to humans. The dataset EmpatheticDialogues is collected by (Rashkin et al., 2019), all the participants join the data collection voluntarily. Also, the dataset provider filters all personal information and obscene languages. Therefore, we believe that the dataset EmpatheticDialogues used in our experiments are harmless to users, and the model trained on this dataset is not dangerous to humans.

A Empathetic Expression Gap

For more comprehensive recognization of the severe emathy expression bias between existing empathetic dialogue models and humans, we further quantify the bias of Multitask-Transformer (Rashkin et al., 2019) in Figure 8 and MoEL (Lin et al., 2019) in Figure 9, the intent index is consistent with Figure 2. The results are similar with MIME (Majumder et al., 2020), we can see the large intent distribution bias and the monotony of empathetic expression of existing models.

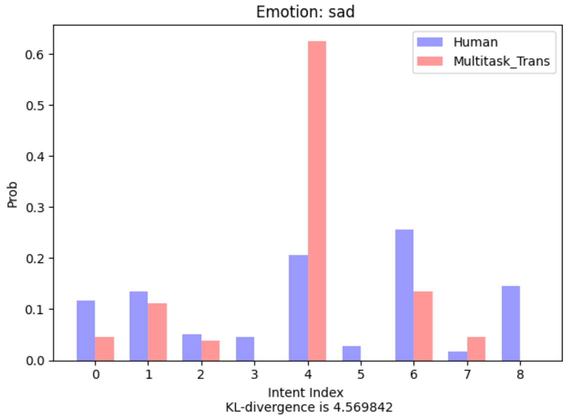

Figure 8: Empathetic intent distribution of human and Multitask-Transformer (Rashkin et al., 2019)

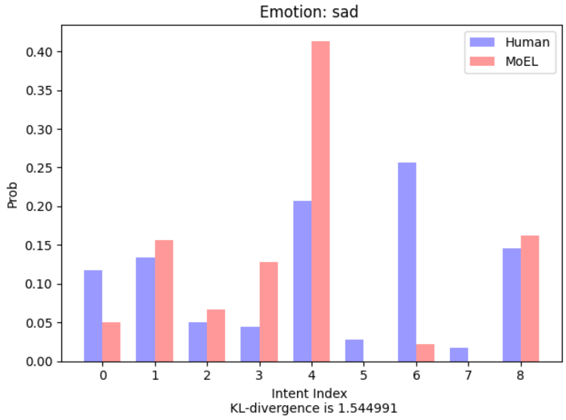

Figure 9: Empathetic intent distribution of human and MoEL (Lin et al., 2019)

B Intent Keywords Collection

The keywords are retrieved from the training set of **Empathetic Intents** dataset (Welivita and Pu, 2020) by using TF-IDF method. **Empathetic Intents** has a training set of 5490 responses, where each intent group has 610 responses. Based on the labeled intent for each response in the training set, we concatenate all the responses which are in the same group and remove all the stop words. Finally, we apply TF-IDF to obtain the top k keywords for each intent group, we set k to 30 in our experiments. See Table 5 for top ten keywords for each intent.

C Error Analysis

Although EmpHi achieves huge improvement in terms of empathy, relevance, and diversity in empathetic dialogue generation, there is still some flaws. At first, the generation task of EmpHi is far difficult than existing models, because it needs to generate response condition on both context and the predicted intent, while other models generate response only condition on the context, therefor the exposure bias of EmpHi is more severe. See in Table 6, although the predicted intent of EmpHi is the same as reference and its corresponding response is great, EmpHi also gives high probability for *Questioning* intent and the corresponding response is not very contextually relevant, EmpHi knows it is suitable for asking more details to show its caring, but it does not know how to ask under this context, thus EmpHi needs better understanding for context information. We believe this issue could be mitigated when using more dialogue data for pretraining.

Intent	Keywords
Agreeing	know, understand, agree, definitely, feel, feeling, exactly, mean, oh, right
Acknowledging	sounds, nice, awesome, like, great, cool, would, oh, must, really

Context		My wife was able to get a job with microsoft without going to a four-year college!
Reference		That' s pretty amazing, she must be skillful regardless.
Intent	Prob	Generated Response
Agreeing	2.91%	Oh, wow ! That's amazing ! I know how you feel.
Acknowledging	**40.9%**	That's awesome ! I'm glad you're going to be proud of her.
Encouraging	9.98%	That's awesome ! I hope you guys have a great job!
Consoling	3.66%	Wow, That' s good, i hope you are able to get it .
Sympathizing	1.43%	Oh wow ! I am sorry to hear that.
Suggesting	0.62%	That's good ! Maybe she will be fine.
Questioning	28.6%	That's great ! How long have you been working ?
Wishing	9.19%	Congratulations ! That' s awesome ! congratulations !
Neutral	2.75%	That is a good thing to do, I wish i was a lot of work .

Table 6: Error analysis of EmpHi, although most responses are reasonable, there are still some imperfection.

Yes, No or IDK: The Challenge of Unanswerable Yes/No Questions

Elior Sulem, Jamaal Hay and Dan Roth
Department of Computer and Information Science, University of Pennsylvania
`eliors,jamaalh,danroth@seas.upenn.edu`

Abstract

The Yes/No QA task (Clark et al., 2019) consists of "Yes" or "No" questions about a given context. However, in realistic scenarios, the information provided in the context is not always sufficient in order to answer the question. For example, given the context *"She married a lawyer from New-York."*, we don't know whether the answer to the question *"Did she marry in New York?"* is "Yes" or "No". In this paper, we extend the Yes/No QA task, adding questions with an IDK answer, and show its considerable difficulty compared to the original 2-label task. For this purpose, we (i) enrich the BoolQ dataset (Clark et al., 2019) to include unanswerable questions and (ii) create out-of-domain test sets for the Yes/No/IDK QA task. We study the contribution of training on other Natural Language Understanding tasks. We focus in particular on Extractive QA (Rajpurkar et al., 2018) and Recognizing Textual Entailments (RTE, Dagan et al., 2013), analyzing the differences between 2 and 3 labels using the new data.[1]

1 Introduction

The ability to know whether a claim is true or false given a context is an important component of language comprehension. One main way to study this ability is the Yes/No Question Answering task, for which a large-scale dataset, BoolQ, has been proposed (Clark et al., 2019). The BoolQ dataset includes paragraphs together with naturally occurring questions whose answer is either "Yes" or "No".

However, in realistic scenarios, the information needed to answer a Yes/No question can be missing. For example, Figure 1 shows Yes/No questions given the context "Jane, who is a native of Los Angeles, married a lawyer from NYC". While the questions in (a) and (b) can be answered respectively by "Yes" and "No" (Jane was born in Los Angeles so she was not born in France), the question "Did Jane marry in NYC?" in (c) cannot be answered given the context.

Context: Jane, who is a native of Los Angeles, married a lawyer from NYC.

(a) Question: Did Jane marry a lawyer? **Answer**: Yes

(b) Question: Was Jane born in France? **Answer**: No

(c) Question: Did Jane marry in NYC? **Answer:** IDK

Figure 1: Examples of a "Yes", "No" and "IDK" Questions in (a), (b) and (c) respectively, given a Context.

Indeed, the ability to extract information from text only addresses one aspect of the expectations we have from a comprehension system. Another main aspect concerns the ability to identify that a given information is not in the text, a witness of understanding in human comprehension.

In this paper we extend the Yes/No QA task to include IDK questions and show the considerable difficulty of the extended task compared to the two-label setting. For this purpose we first enrich the BoolQ dataset by including unanswerable questions, along with creating two other, out of domain, datasets, to test the ability to answer Yes/No/IDK questions in realistic scenarios (Section 3).

Experimenting with a system based on BERT-LARGE (Devlin et al., 2019), we show that the performance on the dev set drops from 72.88 F1 to 33.64 F1 when moving from a two-label to a three-label setting and observe similar results on out-of-domain test sets (Section 4).

We then explore the contribution of other Natural Language Undertanding tasks to the performance, focusing on Extractive QA (Rajpurkar et al., 2016), using the SQuAD 2.0 dataset (Rajpurkar et al., 2018) and Recognizing Textual Entailments (RTE, Dagan et al., 2013), using the MNLI dataset

Context: Jane, who is a native of LosAngeles, married a lawyer from NYC.

Q1a: Did Jane marry in NYC?

Q2a: Who married In NYC?

H3a: Jane married in NYC.

Q1b: Was Jane born in France?

Q2b: Who was born in France?

H3b: Jane was born in France.

Figure 2: Examples of Yes/No QA (left), Extractive QA (center) and RTE hypotheses (right) for a given context.

(Williams et al., 2018). We obtain that, similar to what has been observed in the two-label setting (Clark et al., 2019), leveraging SQuAD 2.0 does not improve the performance while training on MNLI achieves better performance. As the improvement is limited, we separately analyze the transfer from MNLI in the two-label and three-label settings.

We conclude that current systems that achieve high performance on the BoolQ dataset are not adapted to the task of Yes/No QA where unanswerable questions are involved. Using the RTE data is helpful but not sufficient for a good performance.

In this paper, we provide new datasets that allow a more realistic evaluation of the Yes/No task by (1) addressing unanswerable questions, which appear in real-world scenarios; (2) compiling test sets to evaluate the performance of the systems on domains that are different from the ones seen in training and finetuning. Using the new data, we explore the performance of current systems on this task and show its considerable difficulty compared to its two-label version.

2 Related Work

Yes/No Questions In Yes/No QA, the IDK option has been taken into account in the context of FraCaS inference problem (Cooper et al., 1996), which consists of 346 problems targeting specific linguistic phenomena, each containing one or more statements and one yes/no-question. The possible labels are "yes", "no", "don't know" and a "other/complex" label that mainly targets several possible readings. Clark et al. (2019) proposed the large-scale BoolQ dataset in order to address the Yes/No QA task where a question together with a paragraph are given as input. The task consists in classifying the questions into two categories: "Yes" and "No" questions. This dataset does not include an IDK option, a gap we fill by augmenting the original corpus (see Section 3). Our data augmentation method is somewhat similar to the one used for Extractive QA by Clark and Gardner (2018) who generated negative examples for SQuAD (Rajpurkar et al., 2016) by pairing existing questions with other paragraphs from the same article based on TF-IDF overlap.

Unanswerable Questions Unanswerable questions have been mainly studied in the context of the Extractive QA task. The original Extractive QA task consists in extracting a correct answer to a question from a context paragraph or document. Rajpurkar et al. (2018) enriched the SQuAD 1.1 corpus (Rajpurkar et al., 2016) by including unanswerable questions for the same paragraphs via crowdsourcing, resulting in SQuAD 2.0, and proposed to extend the task so that the predictions will include either a span or an "IDK" answer. Unanswerable questions have also been included in the QuAC (Choi et al., 2018) and CoQA (Reddy et al., 2019) datasets where questions are asked in the form of a dialog (see Yatskar (2019) for a comparison). The difficulty of unanswerable questions in Extractive QA has been recently explored in the case of out-of-domain scenarios (Sulem et al., 2021) and in questions with a context composed of multiple paragraphs (Asai and Choi, 2021). Although Extractive QA includes IDK questions, the conversion between the Extractive QA format and a Yes/No/IDK QA format will not always preserve the IDK label, as shown in Figure 2. In particular, an IDK instance in Extractive QA (Q2b) can correspond to a "No" answer in Yes/No QA (Q1b).

The selective question answering task in out-of-domain settings (Kamath et al., 2020) is related to the identification of unanswerable questions. However, it targets the ability of a system to refrain from answering in some of the cases in order to avoid errors in out-of-domain settings, independently from the presence of the answer in the context.

Recognizing Textual Entailment (RTE) The RTE task (Dagan et al., 2013) consists of classifying a sentence pair composed of a premise p and a hypothesis h into three classes, according to the relation between the two sentences: "entailment", "contradiction" and "neutral". In some of the RTE works (Bentivogli et al., 2009; Wang et al., 2018), "contradiction" and "neutral" are unified in a "non-entailed" joint category. Both RTE and Yes/No QA aim to verify whether a given information can be derived from the context. Furthermore, there is a one-to-one mapping between the labels of the two tasks. In particular, if the RTE label is "neutral" then the answer to the corresponding question is IDK (as in Figure 2, Q1a and H3a). However, a main difference between the two tasks is the length of the context. While it is a single sentence in the RTE datasets (e.g., Bowman et al., 2015; Williams et al., 2018, for SNLI and MNLI respetively), it is a paragraph in Yes/No QA.[2] The extension of the Yes/No QA task and data presented in this paper allows their use in multiple applications such as Extractive QA (Sulem et al., 2021), relation extraction (Obamuyide and Vlachos, 2018; Sainz et al., 2021) or event extraction (Lyu et al., 2021; Sainz et al., 2022) in replacement of or jointly with RTE. We explore the use of an RTE dataset for additional training in Section 5. An investigation of the replacement of the RTE task by Yes/No/IDK QA for Extractive QA is presented in Appendix H.

3 Datasets

3.1 Enriching BoolQ with IDK Questions

The BoolQ dataset[3], proposed by Clark et al. (2019), is the largest corpus for Yes/No questions. The training set is composed of 9.4K of Yes/No questions and their answers. 62.31% of the answers are "yes". The dev set includes 3.2k questions.

General Idea. We aim to generate IDK questions by mapping questions from the original BoolQ to passages that will not contain anymore the information required to answer the question. As a random swapping between passages and questions could generate mostly very simple cases with no relation between the question and the passage, we want to maximize the word overlapping between the two.

Generation. We augment BoolQ with IDK questions automatically by using passages and questions from the original BoolQ dataset. Sampling randomly half of the "yes" questions and half of the "no" questions, we match to each of the extracted questions a passage from BoolQ that has the greatest overlapping with the questions in terms of nouns and verbs, identified using the NLTK PoS tagger (Loper and Bird, 2002).[4] The greatest overlapping is chosen to avoid very simple cases with no relation between the question and the passage. In case there are several passages with the same number of nouns or verbs that appear in the question, we choose one of them randomly. We apply this algorithm (separately) on both the train set and the dev set of BoolQ, obtaining new IDK questions (4.7k for train and 1.6k for dev) that we add to the original sets. We call the new corpus BoolQ$_{3L}$ (for BoolQ wih three labels). Examples from BoolQ$_{3L}$ are shown in Appendix C.

Validation and Analysis. We manually validate the IDK questions we compiled by sampling 100 question-paragraph pairs randomly in each of the sets (the train and the dev sets). The 200 pairs are annotated separately by two of the authors of the paper using the "IDK", "Yes" and "No" labels. In the dev set, we find that 95% of the instances are correctly labeled with 100% absolute inter-annotator agreement. In the train set the rates of instances correctly labeled as "IDK" are 94% and 93% according to the two annotators, with an absolute inter-annotator agreement of 97%. [5] Using the same samples we also evaluate difficulty of the questions, based on the relatedness of the paragraph to the question, abstracting away from the word overlapping between the two. Following this procedure, we label 33% / 40% (85% absolute agreement) and 43% / 63 % (80 % absolute agreement) cases as Non-related in the train and dev set respectively. Examples of Non-related IDK questions are presented in Appendix D.

By using questions and answers from the original BoolQ, we ensure that the new IDK subset cannot be identified as having different question or

---

[2] Although it is not inherent in the definition of the respective tasks, the available datasets impact the models used by the community.

[3] `https://github.com/google-research-datasets/boolean-questions`

[4] We also provide a list of auxiliaries that should not be considered as verbs.

[5] For comparison, in the case of SQuAD 2.0 (Rajpurkar et al., 2018), the authors manually inspected 100 randomly chosen negative examples and found that 93% of the examples are indeed unanswerable. In the original BoolQ dataset (with "Yes" and "No" labels), 110 randomly chosen examples were annotated, reaching 90 % accuracy relative to the gold labels, corresponding to 6 ambiguous cases and 5 errors.

Corpus	Split	# Examples	IDK (%)	# Labels
Existing Corpus				
BoolQ	train	9,427	0	2
	dev	3,270	0	
New Corpora				
BoolQ$_{3L}$	train	14,141	33	3
	dev	4,906	33	
ACE-YNQA	test	999	52	3
INSTRUCTIONS	test	70	33	3

Table 1: Statistics and properties of the BoolQ corpus (top) and the newly introduced corpora (bottom).

paragraph styles or levels of grammaticality. Also, the IDK questions have paragraphs that also appear in either "Yes" or "No" questions, with the proportion similar to that observed in the entire corpus. Therefore "no-answer" cannot be predicted by only looking at the question.[6]

3.2 Out-of-domain Test Sets

Motivation Addressing unanswerable questions in Yes/No QA is a first step towards a more realistic evaluation of this task. A second step, which we address in this section, consists in the evaluation of the systems on datasets different from the ones they have been trained and finetuned on, using controlled out-of-domain test sets for evaluation, as advocated for example by Linzen (2020). Furthermore, an informative way to evaluate the comprehension of a system is to ask very simple questions whose answers are obvious to humans (Dunietz et al., 2020). We focus here on event-based questions that address simple predicate-argument relations.

ACE-YNQA We leverage the ACE event extraction (Walker et al., 2006)[7] dataset to derive a new test corpus of "Yes", "No" and IDK questions. For this purpose, we first select sentence fragments that include a location or a time mention according to the ACE annotation. For the "Yes" questions we generate questions of the form "Did T happen at location / time entity", where T is the event trigger. For the "No" variant we manually created a set of place / time entities and asked "Did T happen at r?", where r is a randomly selected entity. We then checked for grammatical and logical correctness. For the IDK labels, we generated those questions manually asking context specific questions. An example of IDK question is "has the loan been paid?" given the context "the world bank first offered the loan in 1999". We call the obtained corpus ACE-YNQA. Examples with "Yes", "No" and "IDK" answers are shown in Appendix E.

INSTRUCTIONS We also generate a small test corpus (INSTRUCTIONS; 70 questions) from scratch about instructions. For example, given the context "Change the font color to green", an IDK question is "Is the font size 12?". More examples are presented in Appendix F.

A summary of the statistics for the different corpora is presented in Table 1.

4 The Difficulty of Yes/No/IDK QA

We use the BERT-LARGE representation and the BERT TensorFlow implementation[8] for sequence classification. We train on the BoolQ$_{3L}$ training set and evaluate on the ACE-YNQA out-of-domain dataset. We also report the average performance on the dev set. We use the BERT-based approach for classification, where the three labels are "Yes", "No" and "IDK"; the final hidden vector corresponding to the first input token([CLS]) is used as the aggregate representation. The fine-tuning details and hyperparameters are presented in Appendix A. For comparison, we also fine-tune BERT-LARGE on the original BoolQ dataset for the Yes/No QA task using the original train and dev sets. We consider the "Yes" and "No" portions of the ACE-YNQA as the out-of-domain test set for the 2-label setting.

The results are presented in the first columns of Table 2 (for Yes/No/IDK) and Table 3 (for Yes/No). We find that the accuracy of the model drops to 33.64 on the BoolQ$_{3L}$ dev set while it is 72.88 in the two-level setting (when training and testing on BoolQ). On the out-of-domain ACE-YNQA test set, the performance is 52.02. In this case too the score is higher in the two-label setting (accuracy of 59.53).

---

[6] This phenomenon has been observed in existing resources in the case of the similar RTE task (Gururangan et al., 2018). For the original BoolQ, the experiments of Clark et al. (2019) suggest that there is little signal in the question by itself, but that some language patterns in the passage correlate with the answer.

[8] https://github.com/google-research/bert

Train → Test ↓	BoolQ$_{3L}$	MNLI + BoolQ$_{3L}$	c(MNLI) + BoolQ$_{3L}$	SQuAD 2.0 $+$BoolQ3L
BoolQ$_{3L}$ dev	33.64	42.66	**43.25**	35.27
ACE-YNQA	52.02	52.02	**54.94**	44.15

Table 2: Accuracy of the different systems, **tested on Yes/No/IDK QA with 3 labels.** The scores correspond to average across 5 different runs. The columns represent the training strategies. The rows represent the test datasets. In all the cases the trained representation is BERT-LARGE-CASED.

Train → Test ↓	BoolQ	MNLI + BoolQ	c(MNLI) + BoolQ	SQuAD 2.0 + BoolQ
BoolQ dev	72.88	78.24	**79.49**	62.13
ACE-YNQA$_{\mathrm{Y/N}}$	59.53	65.47	**68.01**	53.81

Table 3: Accuracy of the baseline system as well as the use of Extractive QA for both **Yes/No QA with 2 labels** on the BoolQ dev set an on the out-of-domain datasets, removing the IDK examples. In all the cases the trained representation is BERT-LARGE-CASED.

5 Leveraging Other Tasks

We leverage the RTE task, using the MNLI corpus (Williams et al., 2018) and the Extractive QA task, using SQuAD 2.0[9] (Rajpurkar et al., 2018).

Given a language representation R and two corpora C_1 and C_2 for the tasks T_1 and T_2 respectively, $C_1 + C_2$ refers to the procedure in which R is first fine-tuned on C_1 for the task T_1 and then further fine-tuned on C_2 for the task T_2.[10] This is similar to the STILTS method (Phang et al., 2018). We experiment with the following systems: (i) **MNLI + BoolQ$_{3L}$** (ii) c(MNLI) **+ BoolQ$_{3L}$** where c(MNLI) is a binary version of MNLI, distinguishing between contradictions and non-contradictions[11] (iii) **SQuAD 2.0 + BoolQ$_{3L}$**.

We also replicate the above systems in the two-label setting, training and testing on BoolQ.

The results are presented in Tables 2 and 3. Evaluating on BoolQ$_{3L}$ dev set, we find that the use of MNLI for intermediary fine-tuning (MNLI + BoolQ$_{3L}$) improves the overall accuracy, which reaches a score of 42.66. The best performance is achieved when using intermediary fine-tuning on the binary MNLI where the accuracy is 43.25. A similar behavior is observed in the two-label setting although the scores are much higher.

On the ACE-YNQA out-of-domain test set, c(MNLI) + BoolQ$_{3L}$ is the best system. Its 2-level version is the best system in the case of Yes/No QA. Leveraging SQuAD 2.0 is not helpful in both 2 (as also in Clark et al. (2019)) and 3 label settings.

In order to explore additional types of Yes/No questions, including unanswerable questions, we replicate our experiments on the small INSTRUCTIONS dataset. As before, we find a gap between the two-label and three-label scores and the usefulness of the MNLI corpus.The full results are presented in Appendix G.

6 Conclusion

In this paper we aim to allow a more realistic evaluation of the Yes/No QA task. For this purpose, we (i) enrich the BoolQ dataset to include unanswerable questions and (ii) compile out-of-domain test sets. Using the new data, we show the difficulty of current systems to address the task both by training directly on the task-specific data and by leveraging other NLU tasks.

A Hyperparameter Finetuning

For training on BoolQ$_{3L}$ with the BERT-LARGE-CASED representation, we use a batch size of 24 and a learning rate of 1e-5 and fine tune over the number of epochs (3 or 5). For training on MNLI, we use batch size of 32 and 3 training epochs. We fine tune over three possible learning rate values: 2e-5, 3e-5 and 5e-5. For training on SQuAD 2.0, we use two train epochs and fine-tune for the learning rate (3e-5 and 5e-5) and the batch size (24 and 48). For each of the training settings, we choose the hyperparameter combination that maximizes the accuracy for the target task on the dev set.

Following Clark et al. (2019), we train the system on BoolQ$_{3L}$ with 5 different initializations and report the average score on the dev set. We choose the checkpoint with the closest score to the average as a starting point for the following training step and for testing on the out-of-domain datasets (ACE-YNQA and INSTRUCTIONS).

B Transfer Analysis

We also evaluate the direct transfer from MNLI to BoolQ and BoolQ$_{3L}$ dev set, only training for the RTE task and then experiment with intermediary finetuning on small samples (30 sentences) from the respective training corpus.

While the direct use of MNLI achieves low scores both on the BoolQ$_{3L}$ dev (26.73 accuracy) and the BoolQ dev (23.07), the finetuning on the sample considerably improves the performance in the two-label setting (50.43 accuracy), compared to the three-label setting (33.91 F1), showing the difficulty to transfer on the three-label setting. The results are summarized in Table 4.

C Examples from BoolQ$_3L$

Examples from BoolQ$_3L$ are shown in Figure 3. For example, an IDK example is created by matching **Question1** (that is associated in BoolQ to **Context1a**), to **Context1b**, which shares with the question the words "Lombardi", "trophy" and "year". While the answer to **Question1** is "Yes" when associated with **Context1a**, it is "IDK" when associated with **Context1b** since the latter does not address the creation of the trophy. Similarly, the answer to **Question2** is "No" when associated with **Context2a** but it is "IDK" when associated with **Context2b** that shares with the question the words "ball", "throw-in" and "goalkeeper" without providing the information required to answer the question.

Test ↓ \ Train →	MNLI	MNLI+s(BoolQ$_{3L}$)	MNLI+s(BoolQ)
3 labels	26.73	33.91	–
2 labels	23.07	–	50.43

Table 4: Accuracy of the different systems, tested either on BoolQ$_{3L}$ (first row) or BoolQ with 2 labels (second row). The columns represent the training strategies.

D Non-related IDK Examples

Examples of non-related IDK cases are shown in Figure 4. The word "season" appears both in the question (**Question1**), that is about a TV series and in the paragraph (**Context1**), that is about American football. Similarly, **Question2** and **Context2** that share the word "rate", address different topics.

E Examples from ACE-YNQA

Examples from the ACE-YNQA dataset are presented in Figure 5.

F Examples from INSTRUCTIONS

Examples from the INSTRUCTIONS dataset are presented in Figure 6.

G Results on INSTRUCTIONS

The results for both 2-label and 3-label settings are presented in Section 5.

H Yes/No/IDK QA for Extractive QA

In order to test the usefulness of the BoolQ$_3L$ dataset for other Natural Language Understanding tasks, in particular in cases where IDK answers are required, we replicate the experiment in Sulem et al. (2021), replacing MNLI by BoolQ$_{3L}$. In this experiment, Extractive QA systems trained on SQuAD 2.0 are tested on the out-of-domain ACE-whQA test set that includes two types of IDK questions derived from ACE. The results are presented in Table 6. They show that additional training on BoolQ$_{3L}$ significantly improves the baseline (where only SQuAD 2.0 is used).

Question1: Do they make a new Lombardi Trophy every year?

Context1a: Unlike trophies such as the Stanley Cup and the Grey Cup, a new Vince Lombardi Trophy is made every year and the winning team maintains permanent possession of that trophy, with one notable exception being Super Bowl V's, won by the then-Baltimore Colts. The city of Baltimore retained that trophy as part of the legal settlement between the team and the city after the Colts' infamous ``Midnight Mayflower'' move to Indianapolis on March 29, 1984. Since then, both the relocated Colts and their replacement in Baltimore, the Ravens, have won the Super Bowl and earned trophies in their own right.

Answer1a: Yes

Context1b: The Vince Lombardi Trophy is the trophy awarded each year to the winning team of the National Football League's championship game, the Super Bowl. The trophy is named in honor of NFL coach Vince Lombardi.

Answer1b: IDK

Question2: Can a goalkeeper pick up a ball from a throw in?

Context2a: Goalkeepers are normally allowed to handle the ball within their own penalty area, and once they have control of the ball in their hands opposition players may not challenge them for it. However the back-pass rule prohibits goalkeepers from handling the ball after it has been deliberately kicked to them by a team-mate, or after receiving it directly from a throw-in taken by a team-mate. Back-passes with parts of the body other than the foot, such as headers, are not prohibited. Despite the popular name ``back-pass rule'', there is no requirement in the laws that the kick or throw-in must be backwards; handling by the goalkeeper is forbidden regardless of the direction the ball travels.

Answer2a: No

Context2b: There is no offside offence if a player receives the ball directly from a goal kick, a corner kick, a throw-in, or a dropped-ball. It is also not an offence if the ball was last deliberately played by an opponent (except for a deliberate save). In this context, according to the IFAB, ``A 'save' is when a player stops, or attempts to stop, a ball which is going into or very close to the goal with any part of the body except the hands/arms (unless the goalkeeper within the penalty area).''

Answer2b: IDK

Figure 3: Examples from the BoolQ$_{3L}$ corpus. **Question1** associated with **Context1a** is a “Yes” example from the original BoolQ dataset. An “IDK” example is generated by associating Question1 with **Context1b**. Similarly, an IDK example was generated by associating **Context2b** with Question2 that appeared in BoolQ in a “No” example (when associated with Context2a). In the case of IDK examples, the content words appearing both in the question and in the context are underlined.

Question1: Are they making a season seven of Once Upon a Time?

Context1: At the end of the 2015--16 season Aston Villa had spent 105 seasons in the top tier of English football; the only club to have spent longer in the top flight are Everton, with 114 seasons, making Aston Villa versus Everton the most-played fixture in English top-flight football. Aston Villa were relegated in from the top tier of English football in 2016, having played in every Premier League season since its establishment in 1992--93. They are seventh in the All-time FA Premier League table, and have the fifth highest total of major honours won by an English club with 21 wins.

Answer1: IDK

Question2: Is there a relationship between molecular weight and diffusion rate?

Context2: There is no sharp limit of development, gestational age, or weight at which a human fetus automatically becomes viable. According to studies between 2003 and 2005, 20 to 35 percent of babies born at 23 weeks of gestation survive, while 50 to 70 percent of babies born at 24 to 25 weeks, and more than 90 percent born at 26 to 27 weeks, survive. It is rare for a baby weighing less than 500 g (17.6 ounces) to survive. A baby's chances for survival increases 3-4% per day between 23 and 24 weeks of gestation and about 2-3% per day between 24 and 26 weeks of gestation. After 26 weeks the rate of survival increases at a much slower rate because survival is high already."

Answer2: IDK

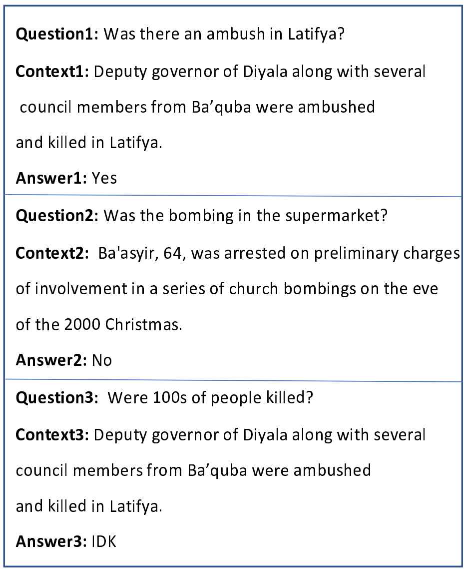
Figure 4: Non-related IDK Examples from the BoolQ$_{3L}$ corpus where the question and the context target different topics despite the content word overlap (underlined in the context).

Train $\rightarrow$ Test $\downarrow$	BoolQ	MNLI + BoolQ	c(MNLI) + BoolQ	SQuAD 2.0 + BoolQ
INSTRUCTIONS	26.56	**43.75**	20.31	23.44
INSTRUCTIONS$_{\mathrm{Y/N}}$	65.00	65.00	**70.00**	65.00

Table 5: Accuracy of the baseline system as well as the use of Extractive QA and RTE for both **Yes/No/IDK QA with 3 labels** and **Yes/No QA with 2 labels** on the INSTRUCTIONS test set. In all the cases the trained representation is BERT-LARGE-CASED.

Train $\rightarrow$ Test $\downarrow$	SQuAD 2.0	MNLI + SQuAD 2.0	c(MNLI) + SQuAD 2.0	BoolQ$_{3L}$ + SQuAD 2.0
Has answer	62.39	71.68	78.13	76.90$^{*\circ}$
Compet. IDK	20.8	**46.40***	26.00	42.40*
non-Compet. IDK	28.46	**75.61***	47.15$^{*\circ}$	70.73*

Table 6: F1 scores of the different systems, **tested on the ACE-whQA out-of-domain test set for the Extractive QA task**. In all the cases the trained representation is BERT-LARGE-CASED. "Compet. IDK" correspond to unanswerable questions with an entity of the same type as the expected answer, while it is not the case in the "non-Compet. IDK" questions. In each line the highest score is presented in bold. The scores significantly higher (using a one-sided t-test, $p < 0.05$) than the baseline (the first column) appear with a star (*). Scores that are significantly higher than the baseline and in the same time, significantly lower than the top system, are presented with a circle ($^\circ$). We note that MNLI + SQuAD 2.0 significantly surpasses $c(\mathrm{MNLI})$ + SQuAD 2.0 on "IDK" but its score is not significantly higher than that of BoolQ$_{3L}$ + SQuAD 2.0.



Question1: Was there an ambush in Latifya?

Context1: Deputy governor of Diyala along with several council members from Ba'quba were ambushed and killed in Latifya.

Answer1: Yes

Question2: Was the bombing in the supermarket?

Context2: Ba'asyir, 64, was arrested on preliminary charges of involvement in a series of church bombings on the eve of the 2000 Christmas.

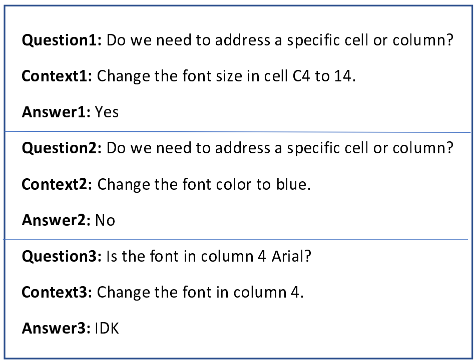
Answer2: No

Question3: Were 100s of people killed?

Context3: Deputy governor of Diyala along with several council members from Ba'quba were ambushed and killed in Latifya.

Answer3: IDK

Figure 5: Examples of "Yes", "No" and "IDK" examples from the ACE-YNQA test corpus.



Question1: Do we need to address a specific cell or column?

Context1: Change the font size in cell C4 to 14.

Answer1: Yes

Question2: Do we need to address a specific cell or column?

Context2: Change the font color to blue.

Answer2: No

Question3: Is the font in column 4 Arial?

Context3: Change the font in column 4.

Answer3: IDK

Abstract

Transition-based parsers for Abstract Meaning Representation (AMR) rely on node-to-word alignments. These alignments are learned separately from parser training and require a complex pipeline of rule-based components, pre-processing, and post-processing to satisfy domain-specific constraints. Parsers also train on a point-estimate of the alignment pipeline, neglecting the uncertainty due to the inherent ambiguity of alignment. In this work we explore two avenues for overcoming these limitations. First, we propose a neural aligner for AMR that learns node-to-word alignments without relying on complex pipelines. We subsequently explore a tighter integration of aligner and parser training by considering a distribution over oracle action sequences arising from aligner uncertainty. Empirical results show this approach leads to more accurate alignments and generalization better from the AMR2.0 to AMR3.0 corpora. We attain a new state-of-the art for gold-only trained models, matching silver-trained performance without the need for beam search on AMR3.0.

1 Introduction

Abstract Meaning Representation (AMR) was introduced as an effort to unify various semantic tasks (entity-typing, co-reference, relation extraction, and so on; Banarescu et al., 2013). Of existing approaches for AMR parsing, transition-based parsing is particularly notable because it is high performing but still relies on node-to-word alignments as a core pre-processing step (Ballesteros and Al-Onaizan, 2017; Liu et al., 2018; Naseem et al., 2019; Fernandez Astudillo et al., 2020; Zhou et al., 2021a,b, inter alia). These alignments are not in the training data and must be learned separately via a complex pipeline of rule-based systems, pre-processing (e.g., lemmatization), and post-processing to satisfy domain-specific constraints. Such pipelines can fail to generalize well, propagating errors into training that reduce AMR performance in new domains (e.g., AMR3.0). This work studies how we can probabilistically induce and use alignments for transition-based AMR parsing in a domain-agnostic manner, ultimately replacing the existing heuristics-based pipeline.

To *induce* alignments, we propose a neural aligner which uses hard attention within a sequence-to-sequence model to learn latent alignments (Wu et al., 2018; Deng et al., 2018; Shankar et al., 2018). While straightforward, this neural parameterization makes it possible to easily incorporate pretrained features such as character-aware word embeddings from ELMo (Peters et al., 2018) and also relax some of the strong independence assumptions in classic count-based aligners such as IBM Model 1 (Brown et al., 1993). We find that the neural aligner meaningfully improves upon various baselines, including the existing domain-specific approach.

To *use* the neural aligner's posterior distribution over alignments, we explore several methods. Our first approach simply uses the MAP alignment from the neural aligner to obtain a single oracle action sequence, which is used to train the AMR parser. However, this one-best alignment fails to take into account the inherent uncertainty associated with posterior alignments. Our second approach addresses this via posterior regularization to push the AMR parser's (intractable) posterior alignment distribution to be close to the neural aligner's (tractable) posterior distribution. We show that optimizing this posterior regularized objective results in a simple training scheme wherein the AMR parser is trained on oracle actions derived samples from the neural aligner's posterior distribution. Our final approach uses the neural aligner not as a regularizer but as an importance sampling distribution, which can be used to better approximate samples from the AMR parser's posterior alignment distribution, and thus better approximate the otherwise intractable log marginal likelihood.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1086 - 1098
July 10-15, 2022

In summary, we make the following empirical and methodological contributions:

- We show that our approach can simplify the existing pipeline and learn state-of-the-art AMR parsers that perform well on both AMR2.0 and AMR3.0. Unlike other approaches, AMR parsers learned this way do not require beam search and hence are more efficient at test time.
- We explore different methods for inducing and using alignments. We show that a neural parameterization of the aligner is crucial for learning good alignments, and that using the neural aligner to regularize the AMR parser's posterior is an effective strategy for transferring strong inductive biases from the (constrained) aligner to the (overly flexible) parser.

2 Background: Transition-based Parsing

2.1 General Approach for AMR

A standard and effective way to train AMR parsers is with sequence-to-sequence learning where the input sequence is the sentence w and the output sequence is the graph g decomposed into an action sequence a via an oracle. The combination of words and actions is provided to a parameter-less state machine M that produces the graph $g := M(w, a)$. The state machine can perform the *oracle* inverse operation O when also provided alignments l, mapping a graph to a deterministic sequence of oracle actions $a := O(l, w, g)$.[1] During training the model learns to map $w \longrightarrow a$ (these pairs are given by the oracle O), and M is used to construct graphs $(a \longrightarrow g)$ for evaluation.

2.2 StructBART

In this paper we use the oracle and state machine from StructBART (Zhou et al., 2021b), which is a simplified version of Zhou et al. (2021a). They rely on rules that determine which actions are valid (e.g. the first action can not be to generate an edge). The actions are the output space the parser predicts and when read from left-to-right are used to construct an AMR graph. In this case, the actions incorporate alignments.

Rules The following rules define the valid actions at each time step:

- Maintain a cursor that reads the sentence left-to-right, only progressing for SHIFT action.
- At each cursor position, generate any nodes aligned to the cursor's word. (This is where node-word alignments are needed).
- Immediately after generating a node, also generate any valid incoming or outgoing arcs.

Actions At each time step perform one of the following actions to update the state or graph:

- SHIFT: Increment the cursor position.
- NODE(y_v): Generate node with label y_v.
- COPY: Generate node by copying word under the cursor as the label.
- LA(y_e, n), RA(y_e, n): Generate an edge with label y_e from the most recently generated node to the previously generated node n. LA and RA (short for left-arc and right-arc) indicate the edge direction as outgoing/incoming. We use y_e to differentiate edge labels from node labels y_v.
- END: A special action indicating that the full graph has been generated.

Learning For parsing, StructBART fine-tunes BART (Lewis et al., 2020) with the following modifications: a) it converts one attention head from the BART decoder into a *pointer network* for predicting n in the LA/RA actions, b) logits for actions are masked to guarantee graph well-formedness, and c) alignment is used to mask two cross-attention heads of the BART decoder,[2] thereby integrating structural alignment directly in the model.

StructBART is trained to optimize the maximum likelihood of action sequences given sentence and alignment. More formally, for a single example

$$(w, g, l) \sim \mathcal{D}, \quad a := O(l, w, g),$$

the log-likelihood of the actions (and hence the graph) is given by,

$$\log p(a \mid w\,;\,\theta) = \sum_{t=1}^{T} \log p(a_t \mid a_{<t}, w\,;\,\theta)$$

---

[1] While current state-of-the-art oracles do make use of alignments, some oracles do not make explicit use of alignments to derive action sequences, for example by generating the nodes in the AMR graph in depth-first order from the root and breaking ties according to the order nodes appear in the data file.

[2] Alignment is represented in the action sequence through the SHIFT action and cursor position.

for a model with parameters θ. Probabilities of actions that create arcs are decomposed into independent label and pointer distributions

$$p(a_t \mid a_{<t}, w\,;\,\theta) = \\ p(y_e \mid a_{<t}, w\,;\,\theta)\, p(n \mid a_{<t}, w\,;\,\theta)$$

where $p(y_e \mid a_{<t}, w\,;\,\theta)$ is computed with the normal output vocabulary distribution of BART and $p(n \mid a_{<t}, w\,;\,\theta)$ with one attention head of the decoder. See Zhou et al. (2021b) for more details.

Alignment (SB-Align) For training, StructBART depends on node-to-word AMR alignments l to specify the oracle actions. In previous work, the alignments have been computed by a pipeline of components that we call SB-Align.

We introduce our neural approach in the next section, but first we cover the main steps in SB-Align: (1) produce initial alignments using Symmetrized Expectation Maximization (Pourdamghani et al., 2014); (2) attempt to align additional nodes by inheriting child node alignments; (3) continue to refine alignments using JAMR (Flanigan et al., 2014), which involves constraint optimization using a set of linguistically motivated rules.

The StructBART action space requires that all nodes are aligned, yet after running SB-Align some nodes are not. This is solved by first "force aligning" unaligned nodes to unaligned tokens, then propagating alignments from child-to-parent nodes and vice versa until 100% of nodes are aligned to text spans. Finally, node-to-span alignments are converted into node-to-token alignments for model training (e.g. by deterministically aligning to the first node of an entity). Specifics are described in StructBART and preceding work (Zhou et al., 2021b,a; Fernandez Astudillo et al., 2020).

3 Inducing Alignments

Here, we describe our neural alignment model, which is essentially a variant of sequence-to-sequence models with hard attention (Yu et al., 2016a; Wu et al., 2018; Shankar et al., 2018; Deng et al., 2018). In contrast to SB-Align, our approach requires minimal pre-processing and does not have dependencies on many components or domain-specific rules.

The alignment model is trained separately from the AMR parser and optimizes the conditional likelihood of *nodes* in the linearized graph given the sentence.[3] The AMR graph is linearized by first converting the graph to a tree,[4] and then linearizing the tree via a depth-first search, as in Figure 1. Letting $v = v_1, \ldots, v_S$ be the nodes in the linearized AMR graph, the log-likelihood is given by

$$\log q(v \mid w\,;\,\phi) = \sum_{s=1}^{S} \log q(v_s \mid v_{<s}, w\,;\,\phi),$$

where we abuse notation and use $v_{<s}$ to indicate all the tokens (include brackets and edges) before v_s. That is, we incur losses only on the nodes v_s but still *represent* the entire history $v_{<s}$ for the prediction (see Figure 1, left). The probability of each node is given by marginalizing over latent alignments l_s,

$$q(v_s \mid v_{<s}, w\,;\,\phi) = \sum_{i=1}^{|w|} q(l_s = i \mid v_{<s}, w, \,;\,\phi) \times \\ q(v_s \mid l_s = i, v_{<s}, w\,;\,\phi),$$

where $l_s = i$ indicates that node v_s is aligned to word w_i.

For parameterization, the sentence w is encoded by a bi-directional LSTM. Each word is represented using a word embedding derived from a pretrained character-encoder from ELMo (Peters et al., 2018), which is frozen during training. On the decoder side, the linearized AMR tree history is represented by a uni-directional LSTM. The decoder shares word embeddings with the text encoder. The prior alignment probability $q(l_s = i \mid v_{<s}, w\,;\,\phi)$ is given by bilinear attention (Luong et al., 2015),

$$q(l_s = i \mid v_{<s}, w\,;\,\phi) = \frac{\exp(\alpha_{s,i})}{\sum_{j=1}^{|w|} \exp(\alpha_{s,j})}, \\ \alpha_{s,i} = h_s^{(v)\top} W h_i^{(w)},$$

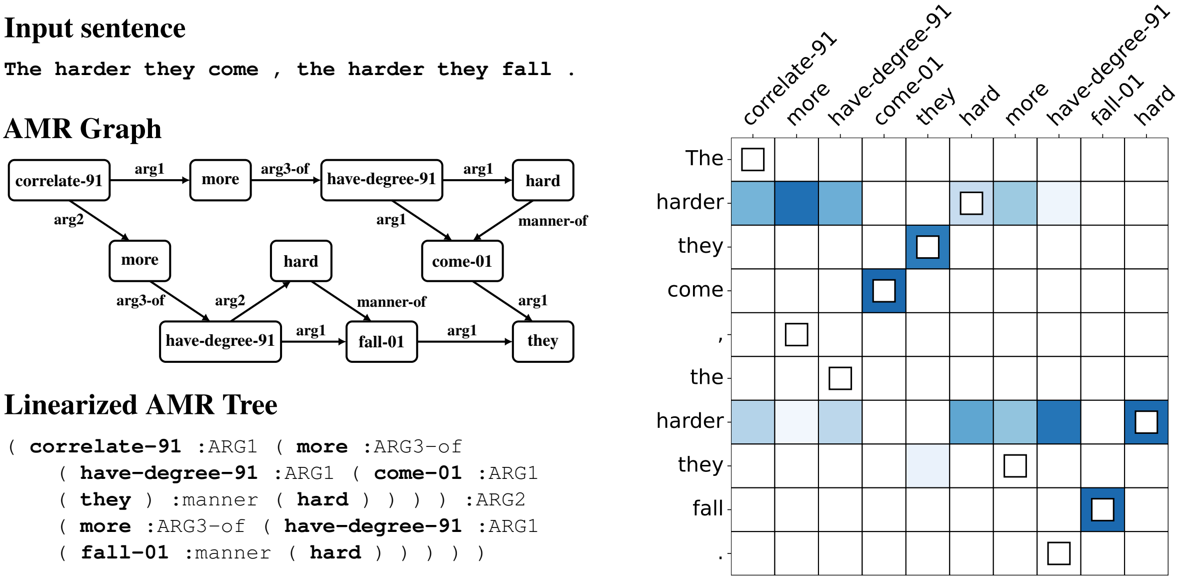
where W is a learned matrix, $h_i^{(w)}$ is a concatenation of forward and backward LSTM vectors for the i-th word in the text encoder, and $h_t^{(v)}$ is the vector immediately before the s-th node in the graph decoder. The likelihood $q(v_s \mid l_s = i, v_{<s}, w\,;\,\phi)$ is formulated as a softmax layer with the relevant vectors concatenated as input,

$$q(v_s = y \mid l_s = i, v_{<s}, w\,;\,\phi) = \\ \mathrm{softmax}(U[h_s^{(y)}; h_i^{(w)}] + b)[y],$$

---

[3] This is because our oracle O only needs node-word alignments to derive the oracle action sequence.

[4] To convert the graph to a tree we only include the first incoming edge for each node.



Input sentence

`The harder they come , the harder they fall .`

AMR Graph

Linearized AMR Tree

```
( correlate-91 :ARG1 ( more :ARG3-of
    ( have-degree-91 :ARG1 ( come-01 :ARG1
    ( they ) :manner ( hard ) ) ) ) :ARG2
    ( more :ARG3-of ( have-degree-91 :ARG1
    ( fall-01 :manner ( hard ) ) ) ) )
```

Figure 1: (Left) An example of a sentence, its AMR graph, and the corresponding linearized AMR tree. The aligner decoder only incurs a loss for AMR nodes (tokens for nodes are in bold), although it represents the full history. (Right) A visualization of our alignment posterior (blue) and point estimate from the baseline (white box). The uncertainty corresponding to alignment ambiguity is helpful during sampling-based training.

where the softmax is over the node vocabulary and is indexed by the label y belonging to the node v_s.

Once trained, we can tractably obtain the posterior distribution over each alignment l_s,

$$q(l_s = i \,|\, w, v\,;\,\phi) = \frac{q(l_s = i \,|\, v_{<s}, w,\,;\,\phi)\, q(v_s \,|\, l_s = i, v_{<s}, w\,;\,\phi)}{q(v_s \,|\, v_{<s}, w\,;\,\phi)},$$

and the full posterior distribution over all alignments $l = l_1, \dots, l_S$ is given by

$$q(l \,|\, w, g\,;\,\phi) = \prod_{s=1}^{S} q(l_s \,|\, w, v\,;\,\phi).$$

Discussion Compared to the classic count-based alignment models, the neural parameterization makes it easy to utilize pretrained embeddings and also condition on the alignment and emission distribution on richer context. For example, our emission distribution $q(v_s \,|\, l_s, v_{<s}, w\,;\,\phi)$ can condition on the full target history $v_{<s}$ and the source context w, unlike count-based models which typically condition on just the aligned word w_{l_s}. In our ablation experiments described in (§6) we find that the flexible modeling capabilities enabled by the use of neural networks are crucial for obtaining good alignment performance.

4 Using Alignments

The neural aligner described above induces a posterior distribution over alignments, $q(l \,|\, w, g\,;\,\phi)$. We explore several approaches using this alignment distribution.

MAP Alignment To use this alignment model in the most straightforward way, we decode the MAP alignment $\hat{l} = \arg\max_l q(l \,|\, w, g\,;\,\phi)$ and train from the actions $\hat{a} = O(\hat{l}, w, g)$.

Posterior Regularization (PR) The action sequences derived from MAP alignments do not take into account the uncertainty associated with posterior alignments, which may not be ideal (Figure 1, right). We propose to take this uncertainty into account and regularize the AMR parser's posterior to be close to the neural aligner's posterior at the distributional level.

First, we note that the action oracle $O(l, w, g)$ is bijective as a function of l (i.e., keeping w and g fixed), so the transition-based parser $p(a \,|\, w\,;\,\theta)$ induces a joint distribution over alignments and graphs,

$$p(l, g \,|\, w\,;\,\theta) \overset{\text{def}}{=} p(a = O(l, w, g) \,|\, w\,;\,\theta).$$

This joint distribution further induces a marginal distribution over graphs,

$$p(g \,|\, w\,;\,\theta) = \sum_{l} p(l, g \,|\, w\,;\,\theta),$$

as well as a posterior distribution over alignments,

$$p(l \,|\, w, g\,;\,\theta) = \frac{p(l, g \,|\, w\,;\,\theta)}{p(g \,|\, w\,;\,\theta)}.$$

A simple way to use the neural aligner's distribution, then, is via a *posterior regularized* likelihood (Ganchev et al., 2010),[5]

$$\mathcal{L}_{\text{PR}}(\theta) = \log p(g \mid w\,;\,\theta) - \text{KL}[q(l \mid w, g\,;\,\phi) \,\|\, p(l \mid w, g\,;\,\theta)].$$

That is, we want to learn a parser that gives high likelihood to the gold graph g given the sentence w but at the same time has a posterior alignment distribution that is close to the neural aligner's posterior. Rearranging some terms, we then have

$$\mathcal{L}_{\text{PR}}(\theta) = \mathbb{E}_{q(l \mid w, g\,;\,\phi)}\left[\log p(l, g \mid w\,;\,\theta)\right] + \mathbb{H}[q(l \mid w, g\,;\,\phi)],$$

and since the second term is a constant with respect to θ, the gradient with respect to θ is given by,

$$\nabla_\theta \mathcal{L}_{\text{PR}}(\theta) = \mathbb{E}_{q(l \mid w, g\,;\,\phi)}\left[\nabla_\theta \log p(l, g \mid w\,;\,\theta)\right].$$

Gradient-based optimization with Monte Carlo gradient estimators therefore results in an intuitive scheme where (1) we sample K alignments $l^{(1)}, \ldots, l^{(K)}$ from $q(l \mid w, g\,;\,\phi)$, (2) obtain the corresponding action sequences $a^{(1)}, \ldots, a^{(K)}$ from the oracle, and (3) optimize the loss with the Monte Carlo gradient estimator $\frac{1}{K}\sum_{k=1}^{K} \nabla_\theta \log p(a^{(k)} \mid w, g\,;\,\theta)$.

It is clear that the above generalizes the MAP alignment case. In particular, setting $q(l \mid w, g) = \mathbb{1}\{l = \hat{l}\}$ where $\hat{l}$ is the MAP alignment (or an alignment derived from the existing pipeline) recovers the existing baseline.

Importance Sampling (IS) The posterior regularized likelihood clearly lower bounds the log marginal likelihood $\mathcal{L}(\theta) = \log p(g \mid w\,;\,\theta)$,[6] and implicitly assumes that training against the lower bound results in a model that generalizes better than a model trained against the true log marginal likelihood. In this section we instead take a variational perspective and use the neural aligner not as a regularizer, but as a *surrogate posterior distribution* whose samples can be reweighted to reduce the gap between the $\mathcal{L}(\theta)$ and $\mathcal{L}_{\text{PR}}(\theta)$.

We first take the product of the neural aligner's posterior to create a joint posterior distribution,

$$q(l^{(1)}, \ldots l^{(K)}\,;\,\phi) \overset{\text{def}}{=} \prod_{k=1}^{K} q(l^{(k)} \mid w, g\,;\,\phi),$$

where K is the number of importance samples. Then, Burda et al. (2016) show that the following objective,

$$\mathbb{E}_{q(l^{(1)}, \ldots l^{(K)}\,;\,\phi)}\left[\log \frac{1}{K} \sum_{k=1}^{K} \frac{p(l^{(k)}, g \mid w\,;\,\theta)}{q(l^{(k)}) \mid w, g\,;\,\phi)}\right],$$

motonotically converges to the log marginal likelihood $\log p(g \mid w\,;\,\theta)$ as $K \rightarrow \infty$. A single-sample[7] Monte Carlo gradient estimator for the above is given by,

$$\sum_{k=1}^{K} w^{(k)} \nabla_\theta \log p(a^{(k)} \mid w, g\,;\,\theta),$$

where

$$w^{(k)} = \frac{p(a^{(k)} \mid w\,;\,\theta) / q(l^{(k)} \mid w, g\,;\,\phi)}{\sum_{j=1}^{K} p(a^{(j)} \mid w\,;\,\theta) / q(l^{(j)} \mid w, g\,;\,\phi)}$$

are the normalized importance weights (Mnih and Rezende, 2016). Thus, compared to the gradient estimator in the posterior regularized case which equally weights each sample, this importance-weighted objective approximates the true posterior $p(l \mid w, g\,;\,\theta)$ by first sampling from a fixed distribution $q(l \mid w, g\,;\,\phi)$ and then reweighting it accordingly.

Discussion Despite sharing formulation with the variational autoencoder (Kingma and Welling, 2013) and the importance weighted autoencoder (Burda et al., 2016), the approach proposed here differs in fundamental aspects. In contrast to the variational approaches we fix q to the pretrained aligner posterior and do not optimize it further. Moreover, the lower bound $\mathcal{L}_{\text{PR}}(\theta)$ represents an inductive bias informed by a pretrained aligner, which can be more suited for early stages of training than even a tangent evidence lower bound (zero gap). This is because, for a tangent lower bound, q in the Monte Carlo gradient estimate is equal to the true posterior over alignments for current model parameters. Since these parameters are poorly trained, it

---

[5] Note that unlike in the original formulation, here we do not optimize over q and instead keep it fixed. This is equivalent to the original formulation if we define the posterior regularization set Q to just consist of the distribution learned by the neural aligner, i.e., $Q = \{q\}$.

[6] The log marginal likelihood is intractable to estimate directly due to the lack of any independence assumptions in the AMR parser, since in the AMR parser the alignment variable l_s fully depends on $l_{<s}$.

[7] Note that a single sample from $q(l^{(1)}, \ldots l^{(K)}\,;\,\phi)$ is obtained by sampling from the neural aligner K times.

is easy for the aligner to provide a better alignment distribution for learning.

Posterior regularization seeks to transfer the neural aligner's strong inductive biases to the AMR parser, which has weaker inductive biases and thus may be potentially too flexible of a model. On the other hand, importance sampling "trusts" the AMR parser's inductive bias more, and uses the neural aligner as a surrogate distribution that is adapted to more closely approximate the AMR parser's intractable posterior. Thus, if the posterior regularized variant outperforms the importance sampling variant, it suggests that the StructBART is indeed too flexible of a model. While not considered in the present work, it may be interesting to explore a hybrid approach which first trains with posterior regularization and then switches to importance sampling.

5 Experimental Setup

All code to run our experiments is available online[8] with Apache License, 2.0.

5.1 Data, Preprocessing, and Evaluation

Data We evaluate our models on two datasets for AMR parsing in English. **AMR2.0** contains ~39k sentences from multiple genres (LDC2017T10). **AMR3.0** is a superset of AMR2.0 sentences with approx. 20k new sentences (LDC2020T02), improved annotations with new frames, annotation corrections, and expanded annotation guidelines. Using AMR3.0 for evaluation allows us to measure how well our alignment procedure generalizes to new datasets — AMR3.0 includes new sentences but also new genres such as text from LORELEI,[9] Aesop fables, and Wikipedia.

The primary evaluation of the aligner is extrinsically through AMR parsing, and we additionally evaluate alignments directly against ground truth annotations provided in Blodgett and Schneider (2021)—specifically, we look at the 130 sentences from the AMR2.0 train data (the ones most well suited for SB-Align), which we call the gold test set. Alignment annotations are not used during aligner training and only used for evaluation.

Preprocessing We align text tokens to AMR nodes. As the AMR sentences do not include defacto tokenization, we split strings on space and punctuation using a few regex rules.

For AMR parsing we use the action set described in §2.2. To accommodate the recurrent nature of the aligner, we linearize the AMR graph during aligner training. This conversion requires converting the graph into a tree and removing re-entrant edges, as described in §3.

Evaluation For AMR parsing we use Smatch (Cai and Knight, 2013). For AMR alignment our goal is mainly to compare our new aligner with strong alignment baselines: SB-Align and LEAMR, a state-of-the-art alignment model (Blodgett and Schneider, 2021; Blodgett, 2021). However, our aligner predicts *node-to-word* alignments, SB-Align predicts *node-to-span* alignments, and the ground truth alignments are *subgraph-to-span*. To address this mismatch in granularity, we measure alignment performance using a permissive version of F1 after decomposing subgraph-to-span alignments into node-to-span alignments—a prediction is correct if it overlaps with the gold span. This permissiveness gives advantages the LEAMR and SB-Align baselines (which predict span-based alignments) as there is no precision-related penalty for predicting large spans.

5.2 Models and Training

Aligner We use a bi-directional LSTM for the Text Encoder and uni-directional LSTM for the AMR Decoder. The input token embeddings are derived from a pretrained character encoder (Peters et al., 2018) and frozen throughout training; these token embeddings are tied with the output softmax, allowing for alignment to tokens not seen during training. The alignment model is otherwise parameterized as described in §3. We train for 200 epochs. Training is unsupervised, so we simply use the final checkpoint.[10] Additional training details for the aligner are in the Appendix.

AMR Parser We use the StructBART model from Zhou et al. (2021b) and the same hyperparameters: fine-tuning for 100 epochs (AMR2.0) or 120 (AMR3.0), and using Smatch on the validation

---

[8] https://github.com/IBM/transition-amr-parser

[9] The LORELEI genre (low resource languages for emergent incidents) contains sentences from news articles, blogs, and forums (Strassel and Tracey, 2016). These sentences were specifically used in Bevilacqua et al. (2021) to measure parser out-of-domain generalization.

[10] In our early experiments, we used SB-aligner's predictions as validation to find a reasonable range of hyperparameters. Performance does not substantially deteriorate after 50 epochs, so this was not necessary or useful for early stopping. Early stopping based on perplexity performed similarly.

Table 1: Results on parsing for AMR2.0 and 3.0 test sets. We report numbers when using single alignments (MAP), posterior regularization (PR), and importance sampling (IS). Also included are number of silver data training sentences used and beam size. PR and IS does not improve with beam search, and hence these numbers are omitted. $^{\mathcal{P}}$: Uses partial ensemble for decoder. $^{\mathcal{G}}$: Uses graph recategorization.

set for early stopping. We did not tune the hyperparameters of the AMR parser at all as we wanted to see how well the neural aligner performed as a "plug-in" to an existing system. Additional implementation details for parsing are in the Appendix. For posterior regularization (PR) and importance sampling (IS) variants we use $K = 5$ samples to obtain the gradient estimators.

6 Results and Analysis

The full results are shown in Table 1, where we find that our approach can learn state-of-the-art AMR parses for gold-only training and without requiring beam search. We now interpret the main results in more detail.

Pipeline Generalization SB-Align was developed prior to the AMR3.0 release, and because it incorporates a complex pipeline with domain-specific rules, one could argue it is specialized for prior datasets like AMR2.0. In Table 1 our aligner yields relatively stronger StructBART improvements for AMR3.0 than AMR2.0. This result and the relatively little manual configuration our aligner requires (e.g., no rules, lemmatization, etc.) suggest our alignment approach generalizes better to different training corpora and that prior peformance of StructBART on AMR3.0 may have been affected by a lack of generalization.

Graph re-categorization (Zhang et al., 2019a,b) is a commonly used technique in AMR parsing where groups of nodes are collapsed during training and test time, but expanded during evaluation. Results from (Bevilacqua et al., 2021) show re-categorization may be harmful, but our results suggest a different perspective—re-categorization is partially a function of alignment-like heuristics and the lower re-categorization results of SPRING in AMR3.0 reinforce our findings that alignments based on heuristic are difficult to generalize.

Alignment Uncertainty vs. Data Augmentation We improve parsing performance by sampling 5 alignments per sentence in batch (see Table 1). One can argue that our approach simply exposes the model to more data, but we found that training on one-best alignments for longer did not improve results. When looking at our sampling results compared with previous versions of StructBART trained on silver data, we see that our approach even outperforms the benefit of the simpler versions of data augmentation, such as simple self-learning. This suggests that there is possible further improvement by combining both techniques, which we leave for future work.

	AMR2.0
LEAMR (Blodgett and Schneider, 2021)	97.4
SB-Align (Zhou et al., 2021b)	89.2
Neural Aligner (ours)	96.5
IBM Model 1	77.2
Neural Aligner w/o pretrained emb.	79.8
Neural Aligner w/ pretrained emb.	96.5

Table 2: (Top) Alignments results using ground truth data from Blodgett and Schneider (2021), where we use the 130 sentences from the gold test set that are from the AMR2.0 train data. (Bottom) Alignment ablation results against the same test set using different alignment model variants. Note that as the ground truth alignment is at the span level, we report a permissive variant of F1 where a prediction is considered correct if it partially overlaps with the ground truth span. This advantages the LEAMR and SB-Align baselines as these can align to spans, whereas our aligners only align to words.

Posterior regularization vs. Importance sampling Training with posterior regularization or importance sampling uses the same number of samples, but in different ways. In posterior regularization, the samples are used to better approximate the posterior regularized objective, which in turn regularizes the AMR parser's posterior more effectively by reducing the gradient estimator variance. In importance sampling, the samples are used to better approximate the AMR parser's intractable log marginal likelihood. We find that importance sampling fails to improve upon posterior regularization for both AMR2.0 and AMR3.0, which indicates that strong inductive biases associated the constrained aligner is a useful training signal for the flexible AMR parser.

Comparing against alignment baselines Our neural alignment method is preferred over SB-Align for two primary reasons: it is relatively easy to use (makes use of word embeddings, depends on less preprocessing, does not require domain-specific rules, etc.) and empirically improves performance (see Table 1). Nonetheless, we conduct an intrinsic evaluation to assess the quality of the predicted alignments—it is desirable that our aligner actually provides accurate alignments.

To verify that improved parsing is due to better alignment, we compare against two strong alignment baselines (LEAMR and SB-Align) on an evaluation set of gold manually annotated alignments. In general, there are only a few hundred such annotations available, yet we aim to use these alignments on 10s or 100s of thousands sentences for AMR parsing. For this reason all the aligners are trained unsupervised with respect to alignment. The results in Table 2 (top) show our aligner is substantially better than SB-Align and nearly on-par with LEAMR, the current state of the art.

Aligner Parameterization We train the classic count-based IBM Model 1 (Brown et al., 1993) using expectation maximization. We next train our neural aligner without pretrained character-aware embeddings. Our neural aligner is different from the classic IBM model in that (1) it learns the prior alignment distribution, (2) the emission model conditions on the entire sentence w and the target history $v_{<s}$. Finally, adding pretrained embeddings to this model recovers our full model. The results in Table 2 (bottom) indicate that both flexibility and token representation are required to outperform IBM Model 1. Training with word vectors learned from scratch only provides a small benefit, and the best performance is from using pretrained character embeddings, which yields nearly 20 point improvement in our permissive F1 metric.

7 Related Work

Oracles for parsing Dynamic oracles in syntactic parsing (Goldberg and Nivre, 2012; Ballesteros et al., 2016, *inter-alia*) enable oracles to recover from imperfect sequences. Oracles with random exploration in transition-based AMR parsers have been previously explored using imitation-learning (Goodman et al., 2016), reinforcement learning (Naseem et al., 2019) and oracle mining (Lee et al., 2020). In addition to this, Liu et al. (2018) produces multiple alignments via their rule-based system and selects the best based on parser performance. Compared to our proposed posterior regularization training, dynamic oracle works exploit specific linguistic properties of syntactic trees not directly transferable to AMR graphs. Prior work on random exploration and AMR selects oracles based on the Smatch. Our work uses the action space and oracle from StructBART (Zhou et al., 2021b,a), which requires every node to be aligned to a word so that the AMR graph is fully recoverable. We expose the parser to uncertainty by sampling alignment, which does not require computing the Smatch metric. Rather, the aligner is trained separately from the parser using pairs of sentences and their respective AMR graphs.

Neural Alignments The neural aligner we use is closely related to sequence-to-sequence models with hard (i.e., latent variable) attention (Xu et al., 2015; Ba et al., 2015; Wu et al., 2018; Shankar et al., 2018; Deng et al., 2018; Shankar and Sarawagi, 2019, *inter alia*) and other works on marginalizing over monotonic alignments (Yu et al., 2016b; Raffel et al., 2017; Wu and Cotterell, 2019). In these works, the main goal is to obtain better sequence-to-sequence models, and the actual posterior distribution over alignments is a byproduct (rather than the goal) of learning. However, there are also works that utilize contemporary neural parameterizations and explicitly target alignments as the primary goal (Zenkel et al., 2020; Ho and Yvon, 2020; Chen et al., 2021). Prior work on integrating pretrained aligners with sequence-to-sequence models has generally used the alignments to supervise the intermediate soft attention layers (Liu et al., 2016; Cohn et al., 2016; Yin et al., 2021), in contrast to the present work which formally treats alignments as latent variables.

Alignments in AMR Parsing There is extensive work aligning AMR nodes to sentences. The StructBART model (Zhou et al., 2021b) considered here, previously made use of well established rule-based and statistical AMR aligners (Flanigan et al., 2014; Pourdamghani et al., 2014) trained with expectation maximization and additional heuristics (Naseem et al., 2019; Fernandez Astudillo et al., 2020) that we call SB-Align. Our aligner compares favorably against SB-Align in alignment metrics and downstream parsing performance. The predicted alignments we use come close to Blodgett and Schneider (2021) measured on gold alignment annotations, despite our method leveraging less domain-specific components. Lyu and Titov (2018) and Lyu et al. (2021) incorporate differentiable relaxations of alignments for AMR parsing.

Posterior Regularization for Parsing and Generation Li et al. (2019) apply variational inference and posterior regularization for unsupervised dependency parsing using their transition-based system. Their approach predates large pretrained language models for which the use of structure may play a different role. Li and Rush (2020) use posterior regularization to incorporate weakly supervised alignment constraints for data-to-text generation, also without pretrained neural representations in mind.

8 Conclusion

In this work we propose a general-purpose neural AMR aligner, which does not use a complex alignment pipeline and generalizes well across domains. The neural parameterization allows the aligner to fully condition on the source and target context and easily incorporates pretrained embeddings, leading to improved performance. Simply using our aligner to produce training data for a state-of-the-art transition-based parser leads to improved results.

We additionally propose a learning procedure using posterior regularization and importance sampling that involves sampling different action sequences during training. These incorporate alignment uncertainty and further improve parser performance. Our results on gold-only AMR training (i.e., without silver data) show that parsers learned this way match the performance of the prior state-of-the-art parsers without requiring beam search at test time.

Ethical Considerations

We do not foresee specific risks associated with our exploration of alignment for AMR parsing. That being said, there are nuances to our results that future researchers may take into considerations. For instance, our experiments are only for English data in the genres covered by AMR2.0 and AMR3.0. It is not clear how our results translate to other domains (e.g. biomedical text) or other languages. Nonetheless, we are hopeful that are methods would transfer favorably because they are intentionally designed to be easy to use and general purpose.

A StructBART Implementation Details

Inference in a transition-based parser corresponds to the usual decoding of with a sequence to sequence model

$$\hat{a} = \arg\max_{a}\{p(a \mid w)\}$$

to obtain the graph $\hat{g} = M(\hat{a}, w)$. The model $p(a \mid w)$ is nowadays parametrized with a neural network. The state machine $M(a, w)$ is defined by

- the position of a cursor $k \in [|w|] = 1 \cdots |w|$, moving left to right over w
- a stack of nodes of g that is initially empty
- the partial graph of g

Furthermore, each action is decoupled into normal and pointer actions $a_t = (b_t, r_t)$ with

$$p(a_t \mid a_{<t}, w; \theta) = \\ p(r_t \mid b_t, a_{<t}, w; \theta)\, p(b_t \mid a_{<t}, w; \theta)$$

where

$$p(b_t \mid a_{<t}, w; \theta) = \\ \text{softmax}(\text{NN}_\theta(a_{<t}, w) + m(a_{<t}, w))_{b_t}$$

where $\text{NN}_\theta(a_{<t}, w) \in \mathbb{R}^{|V_b|}$ are the logits coming from a neural network model and $m(a_{<t}, w) \in \{-\infty, 0\}^{V_b}$ is a mask forbidding invalid state machine actions e.g. shifting at sentence end. This mask is deterministically computed given the machine state. V_b is the vocabulary of normal actions (all actions minus pointer information). The pointer network is given by

$$p(r_t \mid b_t, a_{<t}, w; \theta) = \\ \text{softmax}(\text{DSA}_\theta(a_{<t}, w) + m2(a_{<t}, w))_{b_t})$$

for b_t executing arc LA/RA actions and 1 otherwise. The network $\text{DSA}_\theta(a_{<t}, w) \in \mathbb{R}^{|a_{<t}|}$ is the decoder's self-attention encoding of action history $a_{<t}$ (last layer). The mask $m2$ prevents pointing to any action that is not a node generating action, or has been reduced.

B Parser Training Details

Training with argmax alignments takes approximately 12 hours on a single GPU (2080ti), and longer when sampling alignments proportional to the number of samples. When training with samples, we use gradient accumulation to avoid out of memory problems. We choose accumulation steps roughly proportional to number of samples. Otherwise, training hyperparameters exactly match those from Zhou et al. (2021b).

C Aligner Implementation Details

Comment on sequence length. The alignment model in Wu et al. (2018) demonstrates strong results for character-level translation, which involves translating a single word from one language to another character-by-character. They state the following in reference to their alignment model: *the exact marginalization scheme is practically unworkable for machine translation.* As a point of reference, we looked at the inflection dataset — in any of the training splits across the 51 languages, 99% of the sequences are less than 29 tokens long, 90% are less than 23 tokens, and 50% are less than 15. In contrast, sentence lengths for AMR3.0 are often considerably longer — the 99/90/50 percentiles for sentence token lengths are 62/35/15 and the AMR token lengths are 45/26/11. Nonetheless, we found their results encouraging and our implementation of the alignment model to still be fast enough despite our using longer sequences.[11]

D Aligner Training Details

We use single layer LSTMs with size 200 hidden dimension, dropout 0.1, learning rate 0.0001, and train with the Adam Optimizer. We use batch size 32 and accumulate gradient over 4 steps (for an effective batch size of 128). For 200 epochs, training takes approximately 1-day on a single GPU (2080ti). We train a new aligner for each parsing experiment. In Table 2 we report alignment results from our highest Smatch parsing experiment.

E Alternative text for Figure 1

Shown are the baseline's point estimate alignment and our aligner's alignment posterior. There are instances of ambiguity where our alignment distribution is preferred to the point estimate.

---

[11] We use number of AMR nodes to represent token length, since this is what bounds the computation.

Masked Part-Of-Speech Model: Does Modeling Long Context Help Unsupervised POS-tagging?

Xiang Zhou **Shiyue Zhang** **Mohit Bansal**
Department of Computer Science
University of North Carolina at Chapel Hill
`{xzh, shiyue, mbansal}@cs.unc.edu`

Abstract

Previous Part-Of-Speech (POS) induction models usually assume certain independence assumptions (e.g., Markov, unidirectional, local dependency) that do not hold in real languages. For example, the subject-verb agreement can be both long-term and bidirectional. To facilitate flexible dependency modeling, we propose a Masked Part-of-Speech Model (MPoSM), inspired by the recent success of Masked Language Models (MLM). MPoSM can model arbitrary tag dependency and perform POS induction through the objective of masked POS reconstruction. We achieve competitive results on both the English Penn WSJ dataset as well as the universal treebank containing 10 diverse languages. Though modeling the long-term dependency should ideally help this task, our ablation study shows mixed trends in different languages. To better understand this phenomenon, we design a novel synthetic experiment that can specifically diagnose the model's ability to learn tag agreement. Surprisingly, we find that even strong baselines fail to solve this problem consistently in a very simplified setting: the agreement between adjacent words. Nonetheless, MPoSM achieves overall better performance. Lastly, we conduct a detailed error analysis to shed light on other remaining challenges.[1]

1 Introduction

Unsupervised Part-Of-Speech (POS) tagging is the task of discovering POS tags from text without any supervision. These unsupervised syntax induction approaches can reduce the effort needed for collecting expensive syntactic annotation, and can bring us insights about what inductive bias leads to the emergence of syntax. Recent POS induction models have made great progress using different frameworks (Christodoulopoulos et al., 2010; Berg-Kirkpatrick et al., 2010; He et al., 2018; Stratos et al., 2016; Shi et al., 2020). However, most of them assume certain independence assumptions among POS tags, e.g., Markov (Merialdo, 1994; Berg-Kirkpatrick et al., 2010; Ammar et al., 2014; He et al., 2018), unidirectional (Tran et al., 2016), local dependency (Stratos et al., 2016; Gupta et al., 2022), etc. On the contrary, complex and long-term dependency appear in many real languages and plays an important role in defining the POS tags. For example, in Figure 1, the VBP tag of *are* and the NNS tag of *areas* depend on each other, and so do the VBZ tag of *is* and the NN tag of *news*.[2] So in this case, models only conditioning the immediate preceding tag (Markov) or 1-2 neighboring words (local) cannot explain the distinction between NNS and NN, or between VBZ and VBP. While unidirectional (e.g., using a unidirectional LSTM (Tran et al., 2016)) models are in theory capable of modeling long-term dependency through optimizing the joint probability of tags, bidirectional architectures still show clear advantage in language modeling literature (Bahdanau et al., 2015; Vaswani et al., 2017; Devlin et al., 2019).

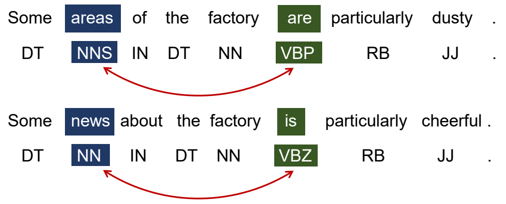

Figure 1: Two long-term tag dependency examples in English.

In this work, we present a novel framework for POS induction that is capable of modeling arbitrary long-term bidirectional dependencies: **M**asked **P**art-**O**f-**S**peech **M**odel (**MPoSM**), inspired by recent success of Masked Language Models (MLM) (Devlin et al., 2019). Specifically, MPoSM consists of two modules (see Figure 2): a *local POS*

---

[1] Our code is available at `https://github.com/owenzx/MPoSM`

[2] Similar agreements are also common in many other languages. Various other long-term dependencies also exist, e.g., tense consistency, long-distance PP attachment, etc.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1099 - 1114
July 10-15, 2022 ©2022 Association for Computational Linguistics

prediction module that maps each word to its POS tag and a *masked POS reconstruction* module that masks a certain portion of tags produced from the previous step, and then learns to first predict the masked tags as latent variables and then reconstruct the corresponding words. We use a bidirectional LSTM (Bi-LSTM) to predict the mask tags conditioned on the remaining tags, which grants our model the ability to model complex long-term and bidirectional dependencies among tags. Through the training signal back-propagated from this module, the tags predicted from the *local POS prediction* module will also be encouraged to have global inter-dependency, which leads to better tags. Since we do not have gold POS tags, at the masked positions, we marginalize over all possible tags and optimize word reconstruction probabilities. Intuitively, the correct induction of POS tags is beneficial for the prediction of the correct masked words. For example, in Figure 1, if we mask the second positions of the two sentences (corresponding to *areas* and *news*), inducing two different tags (i.e., NNS for *areas* and NN for *news*) correctly will make the word prediction easier than inducing the same tag. From a probabilistic view, our model is conceptually similar to approximately modeling the probability of generating the whole sentence from latent tags using masked loss as a surrogate.

MPoSM achieves competitive performance on both the 45-tag English Penn WSJ dataset (Marcus et al., 1993) and the 12-tag universal treebank (McDonald et al., 2013) containing 10 diverse different languages. It achieves comparable oracle M-1 compared to the SOTA (state-of-the-art) models (Stratos, 2019; Gupta et al., 2022) on Penn WSJ dataset and achieves higher performance than Stratos (2019) on 4 out of 10 languages on the universal treebank. We also show that substantial improvements can be made with the help of contextualized representations in mBERT, similar to Gupta et al. (2022). We conduct an ablation study on multiple languages by replacing the Bi-LSTM architecture with a window-based MLP that models the local dependency of tags. Surprisingly, while modeling the full-sentence context can improve the performance of English and German, modeling local context is better for Indonesian and Korean. Our mutual information analysis indicates that this difference may be resulted from the different degrees of gold-tag dependency of different languages.

Since real-life datasets can contain many confounding factors, we next design a suite of well-controlled synthetic experiments from the angle of agreement-learning to examine how well the model can take advantage of the long-term dependency. Our synthetic datasets can guarantee enough training signals for the model to capture the agreements. However, we show that all current models fail to consistently solve the agreement learning problems, even with the most basic agreement happening between adjacent words. Nonetheless, our model shows the best performance with the highest percentage of solving these problems in multiple runs. We conjecture that this is relate to the general optimization problems of latent variable inference problems (Jin et al., 2016) (see more discussions in Section 7). Such obstacles prevent models from gaining additional benefits from modeling long-term dependency. Finally, we did error analysis on the predicted clusters for English and Portuguese and identify remaining challenges both from imperfect modeling and lack of data diversity.

In summary, our main contributions are: (1) a novel POS induction architecture with MLM-inspired loss that allows learning arbitrary tag dependencies and reaches close-to-SOTA performance; and (2) examining the effectiveness of using long-term context and providing a suite of synthetic datasets to expose the challenges in agreement learning and pointing out future challenges.

2 Background

POS Induction. A POS tag is a category of words that share the same grammatical property. A simplified form of these tags will involve commonly known categories such as nouns, verbs, etc. Formally, given a sentence with l words $\boldsymbol{x} = \{x_i\}_{i=1}^{l}$, the corresponding POS tags $\boldsymbol{z} = \{z_i\}_{i=1}^{l}$, then the goal of the POS induction task is to infer $\boldsymbol{z}$ from $\boldsymbol{x}$ without supervision from gold tags.

Limitations of Existing POS Induction Models. From the perspective of probabilistic graphical models, POS tags can be viewed as latent variables related to all the observed words. Each tag z is a latent variable that generates the corresponding word x. Hence, inducing the POS tag sequence becomes the problem of performing MAP inference of the latent variables. This is a popular and effective view adopted by many previous works. To make such inference tractable, previous works have to add certain assumptions, including adding Markov assumption to the latent variables z (i.e., the current tag only depends on the *immediate* previous tag) (Merialdo, 1994; Berg-Kirkpatrick et al., 2010; Ammar et al., 2014), only considering local dependencies (Stratos, 2019; Gupta et al., 2022), unidirectional dependencies (Tran et al., 2016), etc. However, dependencies in real language are not constrained by length or direction, as we discussed in Sec. 1. Hence, simplifying and ruling the capability out in the model design is suboptimal. To mitigate this problem, in Sec. 3, we will describe our approach to model long-term dependency.

Why are the Learned Latent Variables Correlated with POS-Tags? Before introducing our method, we discuss why latent variable models can induce POS-tags well. Take the vanilla HMM as an example, the latent variables in the model can be viewed as being optimized towards two objectives: the transition probability $p(z_i|z_{i-1})$ and the emission probability $p(x_i|z_i)$. They characterize two properties respectively: (1) strong ordering dependencies among latent variables; and (2) the strong correlation between latent variables and the observed word. In short, the success of previous latent variable models implies: *A word's inherent category that has strong ordering constraints will highly resemble the POS tag.* In this work, we follow this assumption, but propose a model that is able to learn arbitrary bidirectional long-term dependencies $p(z_i|\{z_j\}_{j\neq i})$ instead of $p(z_i|z_{i-1})$.

3 Masked Part-Of-Speech Model

Inspired by the recent success in masked language modeling (MLM) (Devlin et al., 2019), we present **M**asked **P**art-**O**f-**S**peech **M**odel (**MPoSM**). Next, we will first describe the model architecture and then introduce several useful additional techniques.

3.1 Model Architecture

As is shown in Figure 2, our model consists of two parts: a *local POS prediction* module and a *masked POS reconstruction* module. The local POS prediction module predicts a POS tag for each word, and the masked POS reconstruction module encourages strong dependencies among these tags.

Local POS Prediction. Given the input word sequence $\boldsymbol{x} = \{x_i\}_{i=1}^{l}$ with length l, we first get the word embeddings. As morphological features are shown to be useful for POS induction (Christodoulopoulos et al., 2010) to capture inflection (e.g., the '-s' suffix for English plurals), we follow Stratos (2019) to extract character-level representations using a Bi-LSTM. We concatenate word embeddings and char representations to form the final representations for each word, $\boldsymbol{w} = \{w_i\}_{i=1}^{l}$. Then, we use a single context-independent feed-forward network to predict the POS tags $\boldsymbol{z}$ out of $\boldsymbol{w}$, i.e. $z_i = \arg\max(\mathrm{Softmax}(\mathrm{FF}(w_i)))$. Essentially, this module models $P(z_i|x_i)$ for every position and predicts the POS tag only conditioned on the word itself without considering its context. We make this design choice as POS tags are the syntactic property of each *individual word*, so it should be able to be predicted as an attribute of the word.[3] Importantly, in order to make the whole model end-to-end differentiable, we replace the $\arg\max$ with a straight-through Gumbel-Softmax estimator (Jang et al., 2017; Maddison et al., 2017) (see Appendix A for more details).

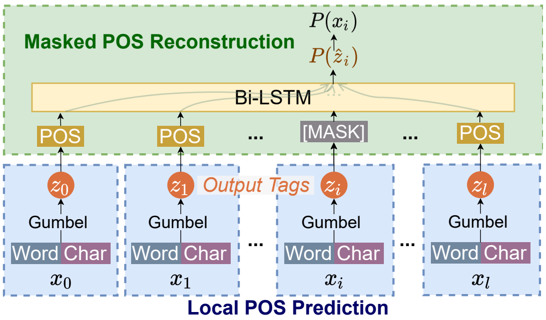

Figure 2: Illustration of our MPoSM. The model consists of two parts: the *local POS prediction* module (blue part at the bottom) and the *masked POS reconstruction* module (green part at the top).

Masked POS Reconstruction. After we get all the predicted POS tags $\boldsymbol{z} = \{z_i\}_{i=1}^{l}$ for the previous module, we conduct masked POS reconstruction to encourage modeling strong dependencies among $\boldsymbol{z}$. Specifically, we follow Devlin et al. (2019) to mask 15% of the predicted POS tags and replace them with a placeholder `MASK` tag. Then we map them into POS embeddings and use a Bi-LSTM (Hochreiter and Schmidhuber, 1997) as the dependency-modeling network. [4] This grants flexibility of modeling the long-term and bidirectional dependency among tags without any assump-

---

[3] However, it gives our model the limitation of only predicting a fixed tag for each word, same as Stratos (2019). Nonetheless, the upper bound M-1 on the 45-tag Penn dataset is 94.6 and the mean upper bound on UD is 95.4, which are both substantially higher than current models.

[4] We also experimented using the Transformer architecture in our preliminary experiments, but did not observe additional gain. See Appendix J for details.

tions and thus brings us an advantage over traditional HMM-based models. Then, we predict the masked POS tags out of the contextualized representations from the Bi-LSTM, so, essentially, it models $P(\hat{z}_j|C_j)$, where $\hat{z}_j$ is the reconstructed tag at position j and $C_j = \{z_i\}_{i \neq j}$ is the context. We treat the predicted $\hat{z}_j$ as latent variables and maximize the probability of the corresponding word x_j, which can be written out by marginalizing over $\hat{z}_j$:

$$P(x_j|C_j) = \sum_{\hat{z}_j} P(x_j|\hat{z}_j)P(\hat{z}_j|C_j) \qquad (1)$$

The conditional probability $P(x_j|\hat{z}_j)$ can be modeled through another feed-forward network with the POS embeddings as the input. Intuitively, predicting the $P(\hat{z}_j|C_j)$ objective encourages strong dependency among the tags and predicting $P(x_j|\hat{z}_j)$ reinforces the connection between the words and the tags. Hence, the total loss is the sum of all the log-probabilities at masked positions:

$$\mathcal{L}_{\text{MPoSM}} = \sum_{j \in \text{Masked Positions}} \log P(x_j|C_j) \qquad (2)$$

Importantly, the supervision from this module will back-propagate to the *local POS prediction* module. Therefore, even though it produces POS tags independently, the supervision helps it to capture the interdependency among all the tags.

During testing, we use the output of the local prediction module as the output tags.[5]

3.2 Additional Techniques

Below, we introduce several additional techniques used in our model to achieve good performance.

Careful Initialization. Similar to many other unsupervised learning models (Gimpel and Smith, 2012; Meila and Heckerman, 1998; He et al., 2018), we found our model to be sensitive to initialization in our preliminary experiments. Below, we propose *Masked Language Modeling Pretraining* (**MLMP**). We use a two-stage training procedure: (1) we remove the modeling architecture for $P(x_j|\hat{z}_j)$ and $P(\hat{z}_j|C_j)$, and directly apply an MLP to model $P(x_j|C_j)$ without explicitly predicting the masked tag; (2) we initialize our MPoSM with the pretrained model in (1) and continue training with the loss in Eqn. 2. This procedure trains the bottom layers with a smoother objective and provides a better starting point for optimizing the MPoSM loss. Besides, the MPoSM model can leverage knowledge from both *pretrained embeddings* similar to He et al. (2018) and Zhu et al. (2020), or *pretrained language models* similar to Gupta et al. (2022).

Connecting P(x|z) and P(z|x). While the *local POS prediction* module models $P(z|x)$, the *masked POS reconstruction* module has a part that models $P(x|z)$ (Eqn. 1). These two probabilities can be connected using the Bayes' rule: $P(x|z) = \frac{P(z|x)P(x)}{\sum x P(z|x)P(x)}$. If we assume the training set is representative enough of the language, we can approximate $P(x)$ by the word frequency in the dataset, and then we can compute $P(x|z)$ directly following the Bayes' rule instead of using a neural network to model it. We notice that binding these two probabilities can usually make the training more stable and improve the performance when training from scratch. Note that we do not adopt this change when using pretrained word embeddings because we can use the pretrained embedding weights at the output layer (Press and Wolf, 2017), which brings additional knowledge for the final word prediction.

Dataset Rechunking. One potential problem of using the full sentence context is the *position bias of POS tags*. For example, since a large number of English sentences start with the word 'the', position 0 will have a strong bias towards predicting the 'DT' tag. In our experiments, we concatenate all the sentences in the original dataset and re-chunk them randomly. Then we combine the rechunked dataset and the original dataset as our training set. In our preliminary experiments, we find it can improve the stability and the performance of the model.

4 Connections to Related Works

The HMM-based POS induction model (Merialdo, 1994) has many extensions, including using hand-engineered linguistic features (Berg-Kirkpatrick et al., 2010), pretrained embeddings (Lin et al., 2015), task-specific modifications (Blunsom and Cohn, 2011; Stratos et al., 2016), flow-based transformations (He et al., 2018), external resources (Haghighi and Klein, 2006; Snyder et al., 2008; Das and Petrov, 2011), etc. They all optimize the probability of the sequence, $P(\boldsymbol{x})$. However, it requires certain dependency assumptions to be tractable. Our model instead optimizes the sum of conditional word probabilities given the remaining context $\sum_i \log P(x_i|\boldsymbol{x}_{1..i-1}, \boldsymbol{x}_{i+1..l})$, i.e., MLM loss (Devlin et al., 2019). While being different

---

[5] We can also use the tags predicted in the masked POS reconstruction module $P(\hat{z}_i|C_i)$ as the output, but we find the output of local prediction module is empirically better.

from $P(\boldsymbol{x})$, this objective is an effective surrogate and makes modeling complex dependencies possible. There also exist some earlier methods that do not require the Markov assumption. For example, Abend et al. (2010) design a method to directly cluster the embeddings containing distributional and morphological information of the word, and then identify prototype words to facilitate the final POS induction. Tran et al. (2016) propose a neural HMM model. Similar to our model, it can also model long-term dependency (due to the use of LSTM), however, they still constrain the dependence to be uni-directional (due to the HMM nature). Our model does not have such constraints and empirically works better.

Architecture-wise, our model is conceptually similar to a denoising auto-encoder (Vincent et al., 2008), where the masking step can be viewed as adding noises to the POS tags. The idea of using auto-encoder models for unsupervised learning has been explored with CRFs in Ammar et al. (2014). However, they still require Markov independence assumption to make inference on CRF tractable, while our model has the ability to model complex long-term dependencies. Plus, we use an MLM-inspired loss instead of reconstructing Brown clusters (Brown et al., 1992) as Ammar et al. (2014).

Our model also provide additional insight on the relation between MLM and syntax emergence. Such connection has also been explored in previous works. Pretrained transformers using MLM (Devlin et al., 2019; Clark et al., 2020; Raffel et al., 2020) have shown strong syntactic abilities (Tenney et al., 2019; Jawahar et al., 2019; Goldberg, 2019). CBOW and skip-gram embeddings (Mikolov et al., 2013) can be viewed as an MLM with a limited context window (i.e., local context), and have been shown to be useful for syntax induction, especially with small window sizes (Bansal et al., 2014; Lin et al., 2015; He et al., 2018). Some recent POS induction works explore CBOW-style objectives (Stratos, 2019; Gupta et al., 2022). However, using the sentence-level MLM objective for syntax induction is under-explored. The only exception is the recent work of Shen et al. (2021), which focuses on a different task: unsupervised parsing. The different tasks lead to substantially different focuses and designs in the architecture. They use MLM with a dependency-constrained self-attention mechanism to extract parses, while we extend MLM to the POS-tag level (MPoSM) and explicitly discretizes the latent variables to extract tags.

5 Experimental Setup

5.1 Datasets and Metrics

We evaluate our model on two datasets: the 45-tag English Penn WSJ dataset (Marcus et al., 1993) and the 12-tag universal treebank (McDonald et al., 2013). Following Ammar et al. (2014) and Stratos (2019), we use the v2.0 version[6] containing 10 different languages. Detailed statistics are in Table 1.

Following recent works (Stratos, 2019; Gupta et al., 2022), we use the Many-to-One accuracy (M-1) (Johnson, 2007) as our metric, and train and evaluate our model on the whole dataset. Following Shi et al. (2020), we distinguish between the oracle performance that selects the model with the best M-1 metric (M-1_{OR}), and the fully unsupervised performance that selects the model with the best loss (M-1). However, many previous works used different or unspecified model selection settings. For a fair comparison, we get results under our setting using their official code if possible.

5.2 Implementation Details

For the English Penn WSJ dataset, we use the pretrained embedding provided in He et al. (2018). For the main results on the universal treebank, we do not use any external resources and use MLMP initialization. Additionally, we also report the results with mBERT contextualized representations on the universal treebank following Gupta et al. (2022), where they show mBERT representations empirically outperforms English BERT representations on POS-tag induction. Same to the implementation in Gupta et al. (2022), we also use the average

In the last row group, we include the numbers of baselines that have unspecified model selection procedures and no official code available (denoted by **), or use a more carefully designed model selection method (denoted by *).

representation over all the subwords and layers as the representation for each word. For all models, we train our model using Adam (Kingma and Ba, 2015) with an initial learning rate 0.001. The batch size is set to 80. The Gumbel softmax temperature is set to 2.0. The results on the Penn WSJ dataset are the mean of 5 runs, and the results on the universal treebank are the mean of 3 runs (see more details in Appendix C).

6 Results and Ablations

6.1 45-tag English Penn WSJ dataset.

The results are shown in Table 3. We reported two variants: the MPoSM model that does not use any external resource, and the MPoSM + emb model that uses the same pretrained word embeddings as He et al. (2018). Using pretrained embeddings does provide substantial improvements to our model. Overall, our model achieves competitive performance compared to SOTA models (Stratos, 2019; Gupta et al., 2022), reaching 78.6 oracle M-1. The oracle performance is 0.5 points higher than the model in Stratos (2019) using a mutual information-based loss. Our fully unsupervised performance reaches 77.9 M-1, which is also similar to SOTA models (Stratos, 2019; Gupta et al., 2022), and is higher compared to previous models using the same pretrained embeddings (He et al., 2018) (75.6), models not using the Markov assumption (Abend et al., 2010) (75.1) or models using uni-directional long-term dependency (Tran et al., 2016) (75.0). Concurrent to our work, Gupta et al. (2022) achieve a higher M-1 of 79.5, but they use more additional resources, including mBERT representations and `fastText` (Joulin et al., 2017) morphological features.

6.2 12-tag Multilingual Results on Universal Treebank.

We also report results on all 10 languages on the universal treebank in Table 2 (the full table with standard deviations can be found in Table 6 of Appendix D). To make the settings practical to low-resource languages, we do not use any pretrained word embeddings on this dataset. Compared to the SOTA model (Stratos, 2019) that also does not use any external resources, our model achieves competitive performance, outperforming it on 4 out of 10 languages (es, fr, it, pt-br). Together with the English Penn WSJ dataset, we notice that MPoSM perform well on most of the languages, but may underperform the previous model on languages with weaker tag-level dependency (e.g., ko and id, statstics are in Table 1, more detailed analyses and discussions are in Appendix E and F) and on smaller datasets (e.g., ko and sv).

Concurrently, Gupta et al. (2022) showed substantial improvement on the universal treebank by leveraging knowledge in the pretrained mBERT representations. Inspired by their success, we also report the result using mBERT in MPoSM (as denoted by MPoSM + mBERT) in Table 2. Similarly,

	en (Penn)	de (uni)	id (uni)	ko (uni)
MPoSM (full)	**78.6** (±1.7)	**71.8** (±2.5)	69.4 (±1.8)	55.2 (±1.3)
MPoSM (width=2)	77.3 (±0.3)	68.5 (±2.8)	**70.0** (±1.0)	**56.6** (±1.4)

Table 4: Oracle M-1 performance of different context types on the four different languages.

using mBERT substantially improves MPoSM's performance on the universal treebank. While on languages with weak tag-level dependency or smaller datasets, MPoSM + mBERT still does not perform most effectively (similar to the trend in MPoSM), MPoSM + mBERT achieves substantially higher results on most of the languages compared to MPoSM, and achieves results higher than Gupta et al. (2022) on French and Italian. On average, Gupta et al. (2022) still achieves higher results. This trend may imply that other factors (e.g. the clustering methods used in Gupta et al. (2022)) are important for their good performance. We have also tried using mBERT on the English WSJ dataset, but do not see a substantial improvement. We leave how to combine their method with MPoSM as a promising future direction.

6.3 How does modeling long context influence the results?

Taking advantage of the flexibility of our model, we analyze whether modeling long-term context is always better than modeling local context. We compare two models: the MPoSM (full) model is the default model described in Sec. 3, and the MPoSM (width=2) model that replaces the Bi-LSTM network with an MLP and only takes in the neighboring 4 predicted POS tags as the input (i.e., local context). We test our model on 4 languages: English, German, Indonesian, and Korean. These languages are selected to have representative statistics among all the languages in the universal treebank in terms of dataset size and average word frequency (see Table 1).[7] The results are in Table 4. On English and German, the default model is better than the MPoSM (width=2) variant by 1.3 and 3.3 points respectively. However, on Indonesian and Korean, the trend is reversed with the MPoSM (width=2) variant showing 0.6 and 1.4 point advantage respectively. We notice that the languages do not benefit from using a longer context also correlates well with the languages with weak tag-level dependencies. Such property prevent the MPoSM from benefit from the advantage of dependence modeling on those languages, and consequently using a longer context does not provide additional help. More detailed analysis is in Appendix E.

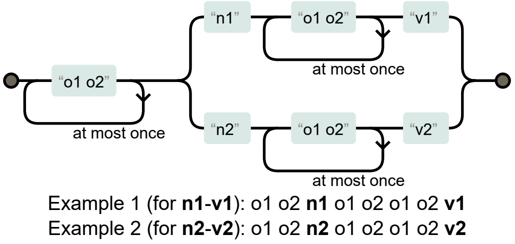

Figure 3: Illustration of the tag-level regex for sentences in D(2-4). D(0) sentences can be generated by removing the "`o1 o2`" block between `n` and `v`.

7 Analysis and Challenges

7.1 Agreement Learning Experiments

Inducing good POS tags requires models to understand what "agreement" is. To match the gold 45-tag set of Penn Treebank, the model needs to distinguish between VBP (Verb, non-3rd person singular present) and VBZ (Verb, 3rd person singular present) tags (see examples in Figure 1). Though local morphological features do provide useful cues for such classification, models should achieve better performance by observing the full picture of agreement in the long context. From the results in Sec. 6, we notice evaluation in real-life datasets may contain many confounding factors. Hence, we design a well-controlled synthetic dataset to examine exactly how well the model learns these agreements. Surprisingly, we find that the limitation of current models is not about leveraging long context, but a common fundamental limitation on using co-dependency to distinguish tags.

Controlled Dataset Design. To provide a simplified and well-controlled environment, our synthetic datasets consist of a small set of words and tags, and simple sentences. Specifically, we use 6 different tags, with 5 unique words correspond to each tag. Our 6 tags are named after nouns (`n1`, `n2`), verbs (`v1`, `v2`), and other unimportant tokens (`o1`, `o2`). In every sentence, `n1` always appear before `v1`, and `n2` before `v2`, analogous to subject-verb agreement in English. We create the synthetic data by first sampling a tag sequence (illustrated in Figure 3) and then randomly select words of each tag in the sequence. We also make sure the two agreements (`n1`-`v1`, `n2`-`v2`) have ex-

---

[7] We choose language mainly according to the dataset statistics instead of linguistic properties as in preliminary experiments, those statistics are more influential to the performance.

	D(0)	D(2-4)

MPoSM (width=2)	92.99 (30%)	87.62 (0%)
MPoSM (full)	96.50 (75%)	**95.31** (30%)
Stratos (2019) (width=2)	92.99 (30%)	86.56 (0%)
Tran et al. (2016) (full)	80.97 (0%)	82.50 (0%)

Table 5: Oracle M-1 on the synthetic datasets with the percentage of perfect runs (100 M-1) in the bracket.

actly symmetric data. We use the "distance", i.e., the number of tokens, between `n` and `v` to control the agreement-learning difficulty. The larger the distance is, the harder the example is. Therefore, we create two subsets with different levels of difficulty, and each contains 40,000 sentences. In the first simpler subset D(0), `n` and `v` are adjacent. In the second harder subset D(2-4), `n` and `v` are separated by 2-4 words. Complete illustrations, regexes and additional results are in the Appendix H.

Surprising Difficulty of Learning Agreement. Model performances on our synthetic datasets are in Table 5. We report the mean M-1 of 20 runs and the percentage of perfect runs (achieving 100 M-1), as models are expected to consistently achieve the perfect score if they really acquire agreement. We include three variants of MPoSM using different contexts (from the *width=1* model only considering the immediate neighboring tokens to the *full* model considering the whole sentence). We compare with two representative baselines: the SOTA model Stratos (2019) which uses the context with width=2, and the neural HMM model (Tran et al., 2016) which leverages unidirectional full context. In Table 5, we first notice the surprising difficulty of learning agreement even in the simple D(0) setting, where the `n` and `v` are already adjacent. None of the models can consistently produce the perfect tags in this setting. The best results are from MPoSM with a specific inductive bias of only using the width=1 local context, but it still fails to achieve the perfect score consistently. Other models using a larger context show substantially lower results. On the harder D(2-4) setting, we see similar observations. Due to the architecture limitation, none of the models using local context can achieve the perfect score even once. Models using the long context also fail to perform well consistently. MPoSM (full) is the single best model that successfully acquires agreement, albeit only 30% of the time. These observations demonstrate the difficulty of learning agreement in POS induction. As reflected by the results on D(0), such difficulty cannot be fully attributed to the long-term issue. We suspect the latent variable-based loss function used in current models can contain many bad local minimums, similar to the optimization difficulty observed in Gaussian Mixture Models (Jin et al., 2016). Models are likely to stuck in one local minimum (e.g., viewing `n1` and `n2` as the same tag) and never reach the global optimum.

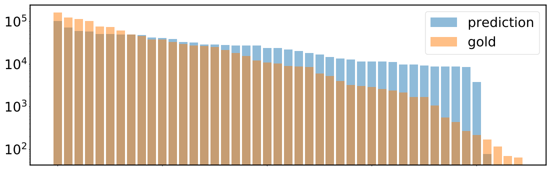

Figure 4: Log-scale sizes of the predicted clusters and the gold clusters.

Finally, we want to point out that our findings are not contradictory with recent studies that show the derivation of agreements from MLM-style models (Jawahar et al., 2019; Goldberg, 2019; Lin et al., 2019). One key difference is that they directly measure the word-level agreement, e.g., *are* should follow *areas* in Figure 1. However, POS induction focuses on the tag-level agreement, i.e., VBP should follow NNS. Our MPoSM can also be viewed as adding an explicit discretization step in a normal MLM so that we can predict discrete tags. If we remove the POS-factorization step in Eqn 1, and directly predict the word from the word context, our model can also capture the word-level agreement.

7.2 Error Analysis of Predicted Clusters

In Table 3, we notice that performances of different models are saturating around 78 M-1 on the English Penn WSJ dataset. To examine the limitations of current models point out future directions, we manually investigated the clusters learned by our model. Below, we list our main findings on English (see similar findings of Portuguese in Appendix I):

The sizes of predicted clusters are more uniform than gold clusters. Only 1 predicted cluster contains very few (less than 3000) words, while the scale of gold clusters showing a much larger variance, with 29% of the 45 clusters containing less than 3000 words. A bar plot illustration is in Figure 4. We can see that the size of gold clusters has a much larger range than the predicted clusters. Under the current losses, assigning a small number of words to one tag is likely to make the loss worse, but it hard to match the skewed distribution of natural tags. Johnson (2007) show similar findings on

HMM models trained with EM. These consistent findings may hint at a common limitation of current objectives. Future work should explore different objectives with more suitable inductive biases.

Agreements are not learned well. Similar to the observation in Sec. 7.1, agreements are not learned well in the predicted clusters. For example, the VBP tag (Verb, non-3rd person singular present) is an important tag in the subject-verb agreement. While this tag has 15377 occurrences in the gold annotations, it is not the major tag in any of the predicted clusters. Most VBP words are either mixed with the VB or the VBZ words. We consistently observe models fail to separate these verbs, showing a large room for improvement.

Difficulty in mapping one word to multiple tags. Without using mBERT representations, MPoSM (also applies to many other models, e.g., He et al. (2018); Stratos (2019), etc.) predicts the same tag for one word. However, the same word can have different tags in different contexts. For example, the word 'that' can have gold tags IN, RB, and WDT. Future works should explore directions on capturing the multi-sense phenomenon.

Dataset biases influence predicted clusters. For example, the English WSJ dataset contains many financial news reports, so numerical words (e.g., 'million', 'billion') and related symbols like '%' are very frequent. Since these words always appear in a distinctive context, models will naturally cluster these tokens together. Hence, we encourage future research to explore more diverse datasets.

8 Conclusion

We propose MPoSM, a POS induction model inspired by MLM and can model complex long-term dependencies between POS tags. Our model shows competitive performance on both English and multilingual datasets. We analyze the effectiveness of using long context compared to local context. Finally, we use synthetic datasets and analyses to point out remaining challenges.

9 Ethical Considerations

The model proposed in this paper is intended to study how syntax emerge from unsupervised learning objectives. It can also help understand languages with limited annotations. However, as we showed in this paper, the syntax predicted by current models can contain errors and be influenced by the choice of datasets, so the model's output should be used with caution and examined by experts. Our model has been tested on 10 diverse languages. Our findings on these languages should generalize to languages with similar linguistic properties, but we suggest careful empirical studies before applying our approach to languages distant from those we study in this paper.

Acknowledgments

We thank the reviewers for their helpful comments. We thank Chao Lou for the help in data preprocessing steps. A Straight-Through Gubmbel-Softmax Estimator

To allow the gradients from the *masked POS construction* module to back-propagate to the *local POS prediction* module, we replace the standard argmax in the local POS prediction module with the *straight-through Gumbel-Softmax* estimator. Specifically, we follow Jang et al. (2017); Maddison et al. (2017) to calculate the one-hot POS-tag vector using $\texttt{one\_hot}(softmax(g_j + logit_j, \tau))$. In this equation, τ is the softmax temperature and g_j are i.i.d. samples drawn from a standard Gumbel distribution, i.e., $g_j = -\log(-\log(U(0,1)))$, where $U(0,1)$ is a uniform distribution over the range $[0,1]$. Following Jang et al. (2017), we use $\arg\max$ to discretize the distribution to a one-hot vector in the forward pass, but back-propagate through the continuous Gumbel-softmax. With this technique, the whole MPoSM becomes end-to-end differentiable.

Alternatively, instead of operating on the single POS embedding of the Gumbel-Softmax output, we can also use the weighted sum of all the POS embeddings with weight $P(z_i|x_i)$. However, empirically, we notice the weighted sum approach does not perform well when the number of tags is large (e.g., 45 in the Penn WSJ dataset).

B Dataset Links

The universal treebank dataset is from `https://github.com/ryanmcd/uni-dep-tb`. The English Penn WSJ dataset can be obtained through LDC.

C Implementation and Hyper-Parameter Details

For initialization, for the English 45-tag Penn WSJ dataset, we use the pretrained word embedding provided in He et al. (2018). For the main results on the universal treebank, we do not use any external resources and always initialize our models using MLM pretraining. Additionally, we also report the results with mBERT contextualized representations on the universal treebank following Gupta et al. (2022). Same to the implementation in Gupta et al. (2022), we also use the average representation over all the subwords and layers as the representation for each word. We apply the "connecting P(x|z) and P(z|x)" technique for all our models not using pretrained word embeddings or pretrained language models. We apply the dataset rechunking technique to all our experiments.

For the hyper-parameters, we train all our model using Adam (Kingma and Ba, 2015) with an initial learning rate 0.001. The batch size is set to 80 and we decay the learning rate with a factor 0.1 the loss stagnates. We set the word embedding dimension to 100, POS embedding dimension to 200, the character embedding dimension to 100, and the hidden vector dimension to 128. We use one layer of MLP in the *local POS prediction* module and one layer of Bi-LSTM in the *masked POS reconstruction* module. The masking rate is set to 15% and the Gumbel softmax temperature is set to 2.0. We set the dropout rate (Srivastava et al., 2014) to 0.5. Specially, with pretraining word embeddings, we tie the input and output embeddings following (Press and Wolf, 2017) and add one more layer in the local POS prediction layer to more effectively convert the pretrained embedding to POS tags following (He et al., 2018). And for our synthetic experiments, since the vocabulary size is small, we use a smaller character embedding dimension of 8. We use the loss as the metric to judge if our model has been converged. In this work, the results on the Penn WSJ dataset are the mean of 5 different runs,

and the results on the universal treebank are the mean of 3 different runs. The experiments using mBERT can be run on a single RTX A6000 GPU, and all other experiments can be conducted on a single TITAN Xp GPU. The time of experiments can take from several hours to several days, depending on the size of the dataset and the models.

D Results and Standard Deviations on the Universal Treebank

The full means and standard deviations (for our model and for previous works that reported this number) are shown in Table 6. We also include the fully unsupervised performance (evaluating the model with the best loss) in the MPoSM row. Our fully unsupervised model is slightly worse than the oracle version of both our model and Stratos (2019), but show comparable or higher performance to other results (Stratos et al., 2016; Berg-Kirkpatrick et al., 2010; Brown et al., 1992).

E Analysis on the Dependency among Gold Tags

In Sec. 6, we notice that MPoSM does not work equally well on all the languages. For example, in Table 4, we can see that out of 4 different languages, using full context instead of local context only improve 2 of them: English and German. In this section, we provide evidence that these different trends can result from the different strength of dependencies among tags in different languages.

Assuming a tag sequence is $z_1, z_2, \ldots, z_n$, we compute the mutual information between a tag-level context of z_i (denoted as C_i) and the tag z_i. A larger mutual information value can represent stronger dependencies among the gold tags.[8] The results are shown in Table 7. We can see that for all kinds of mutual information calculated in the table, Korean and Indonesian has the two lowest values, both substantially lower than the value of German and English. Notably, Korean and Indonesian are also the worst two languages of the MPoSM model, while German and English and two of the languages with better performances. By its design, our model will induce tags that have strong dependencies among each other (see Sec. 2). Hence, it is not strange that on Korean and Indonesian, the MPoSM model could produce tags different from

---

[8] Note that using a larger context will always lead to a larger mutual information value due to the property of mutual information. However, directly comparing the mutual information value with a very long context is confounded by many spurious correlations in the dataset. Hence, in this study, we only compare mutual information value in a limited context. Nonetheless, the trend shown in Table .7 is consistent across different context types.

Name	Distance between n and v	Regex
D(0)	0	(o1 o2){1,2}(n1 v1 | n2 v2)
MORPH	0	same as D(0) (+ morph. feature)
D(2-4)	2-4	(o1 o2){1,2}(n1 (o1 o2){1,2} v1 | n2 (o1 o2){1,2} v2)

Table 8: Tag-level regular expressions and the distances between n and v for each synthetic subset.

	en (Penn)	ko (uni)

MPoSM (width=2)	77.3 (±0.3)	56.6 (±1.4)
MPoSM-Word (full)	72.2 (±1.6)	54.1 (±3.3)
MPoSM-Word (width=2)	69.5 (±0.4)	**62.2** (±0.7)

Table 9: Oracle M-1 Performance of different context types on English and Korean.

the gold tags and become less effective. And due to the difference between the predicted tags and the gold tags, it is not surprising to see that using a larger context in these two languages does not help the MPoSM model in these two languages.

F Discussion on uni-Korean Results

In Sec. 6, we notice that MPoSM does not work well on the Korean dataset in the universal treebank. Inspired by Stratos (2019) that achieves decent performance on Korean and the observation in Appendix E, we study another modification of MPoSM for the Korean language, MPoSM-word. Instead of using the *local POS prediction* module to predict a POS tag, the MPoSM-word directly feeds the word embedding to an MLP, and use the output as the input of the *masked POS reconstruction* module. Finally, we use the predicted tags after the Bi-LSTM layer as the induced tags. The results are shown in Table 9. We do observe that the MPoSM-word (width=2) variant, which is most similar to Stratos (2019), achieves the best result, demonstrating the effectiveness of such inductive biases on this Korean dataset. Nonetheless, this preference is not consistent over languages. In our preliminary study, we notice many other languages still prefer our default model. We show the result on the 45-tag English dataset in Table 9, where the default MPoSM show substantial advantages. These preferences together with the observation in Appendix E suggest different languages (or datasets) can prefer different types of dependency modeling (e.g. tag-tag dependency vs. word-tag dependency) and we encourage further study on this topic.

G Using Inducted Tags for Unsupervised Dependency Parsing

In this section, as a side study, we test whether the performance trends on POS induction can transfer to unsupervised dependency parsing. We choose to use the Neural E-DMV model from Jiang et al. (2016), a commonly used baseline model that uses gold POS tags in the training. In our experiments, we replace the gold tags with the inducted tags from different models to see if the parsing performance correlates with the tag quality measured by M-1 accuracy. Following the convention in unsupervised parsing experiment setups, we train all the models on sections 2–21 of the English Penn WSJ dataset, and use section 22 for validation and section 23 for testing. We remove all the punctuation and only train and test on sentences with length ≤ 10 (i.e., following the WSJ10 setting). We compared three different models, our MPoSM (78.6 M-1), the model from Stratos (2019) (78.1 M-1), and the model from Tran et al. (2016) (75.0 M-1). We notice the models are highly sensitive to initialization. Hence, to remove the influence of bad initialization, we train each model ten different times and compare the best run. Using the gold tags, the E-DMV model can reach over 70 DDA (directed dependency accuracy). However, none of the models trained using predicted tags achieve DDA over 45, showing a substantial performance gap between the gold tags and the predicted tags. Surprisingly, while the tags from the Neural HMM model Tran et al. (2016) have lower M-1 accuracy than the other two models, it shows a small advantage in the parsing performance over the over two models. We suspect the different trends may result from a mismatch between the objective optimized in parsing models and tagging models. The DMV objective explicitly models the transition probability between different nodes, hence the neural HMM model may have a slight advantage by using a more similar HMM-style objective.

	D(0)	MORPH	D(2-4)

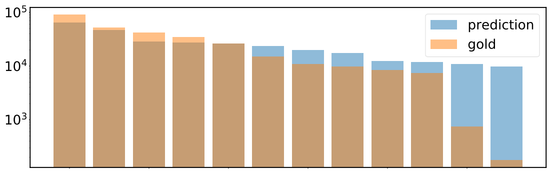

Figure 6: Log-scale sizes of the predicted clusters and the gold clusters for pt-br in the universal treebank.

H Additional Agreement Learning Experiment Design and Results

H.1 Additional Experiment Design

Besides the D(0) and D(2-4) subsets introduced in Sec. 7.1, we add another variant: MORPH. The MORPH setting is a variant of D(0) with additional morphological features. While characters in every word in D(0) are all randomly generated, in MORPH, words with the n1 tags always end with -n1, words with the n2 tags always end with -n2, etc. The tag-level regular expressions of all the subsets are shown in Table 8.

H.2 Illustrations for Each Subset

We provide illustrations of the tag-level regular expression for each subset. The illustration for D(2-4) is in Figure 3. The tag-level regular expressions D(0) and MORPH are the same and the illustration can be seen in Figure 5.

H.3 Additional Results

We show additional results on the synthetic datasets in Table 10. Besides the results of the default MPoSM, we also include an ablation of removing the “Connecting $P(x|z)$ and $P(z|x)$” trick introduced in Sec. 3.2. We can see connecting these two probabilities does bring substantial improvement on this agreement learning task. Surprisingly, adding the morphological features (MORPH) does not help the models learn the agreement. Instead, nearly all models perform slightly worse on this variant. We suspect the problem may lies in the specific design of the morphological feature. The current setting provides an additional feature to first cluster n1 and n2 words, v1 and v2 words together since they have a common character ‘n’ or ‘v’ in the word, whereas normally we randomly sample characters to form the word. Hence, it can be easier for the models to enter the unideal local minimum.

I Predicted Clusters Analysis on Brazilian Portuguese

We provide additional analysis on the pt-br dataset in the universal treebank and check if our findings on the English dataset can generalize to the other language. Due to the 12-tag annotations on the universal treebank do not contain fine-grained tags, it is difficult to single out an agreement type to conduct a well-controlled analysis (like the subject-verb agreement analysis on English in the main paper), but below we verify all the other findings.

The sizes of predicted clusters are more uniform than gold clusters. Similar to the findings on the English 45-tag dataset, the sizes of predicted clusters are much more uniform than the gold clusters. A bar plot is shown in Figure 6.

Difficulty in mapping one word to multiple tags. Brazilian Portuguese also has words with different senses and POS-tags. For example, the word ‘parecido’, which means ‘similar’ in English, has three possible gold tags in the annotated data, including ADJ, VERB, and ADV. But again, in the model predictions, this word is always paired with the same tag.

Dataset biases influence predicted clusters. Since models on the universal treebank are only required to predict 12 tags, the influence of dataset biases is smaller than the English 45-tag data. However, we still can find some hints about the negative effect of the lack of linguistic diversity in the data. In the predicted clusters, nouns are separated into a number of clusters. Possibly due to the special domains of the data, the corpus includes lots of nouns representing locations and events. These nouns usually appear in a similar context after the ADP tag, hence models are likely to use a single cluster for these nouns, which is not ideal. While one can argue models should learn to separate the correct syntactic property from other spurious statistical properties, small datasets may not contain enough data to represent the complete picture of grammar. Hence, models are more likely to capture the statistical properties that are more common in the presented corpus and unlikely to induce the POS tags that ares more well-suited for the general language.

J Additional Experiment Results

We briefly describe several variants we have tried in our preliminary experiments but *do not* observe significant improvement.

- For the dependency modeling network in the masked POS reconstruction module in the MPoSM model, we have also explored using a Transformer (Vaswani et al., 2017) architecture or adding self-attention to the Bi-LSTM. However, we do not see substantial improvements. On the 45-tag English Penn Treebank dataset, our best Transformer result reaches 77.2 M-1, which is still lower than the average M-1 of the Bi-LSTM counterparts in Table 3. We suspect this trend is due to two reasons: (1) we notice that the Transformer models are more sensitive to initialization and hyper-parameter settings than the LSTM counterparts. Additionally, POS induction datasets are relatively small, which makes it harder to train a good Transformer model. (2) compared to Transformer models, LSTM models have the advantage of a preference of learning short-term dependencies first while learning long-term dependencies is still possible. This inductive bias could be useful for the POS induction task.
- Instead of directly training our model using gradient descent, another way to optimize our model is to view the reconstructed POS as latent variables and use EM-based algorithms to optimize the objective, similar to the method used in Yang et al. (2019). However, in our experiments, we do not observe substantial improvement by using EM-based optimization methods over SGD-based methods.

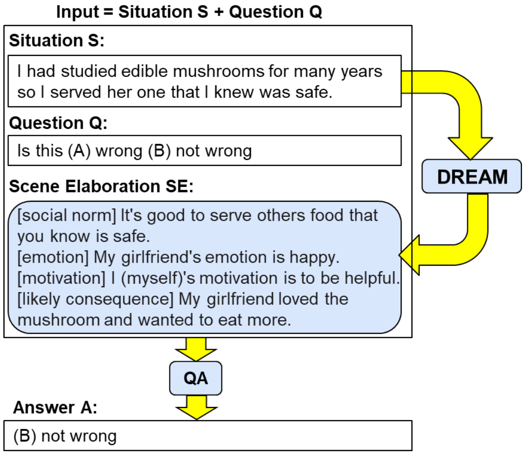
DREAM: Improving Situational QA by First Elaborating the Situation

Yuling Gu[*], **Bhavana Dalvi Mishra, Peter Clark**
Allen Institute for AI, Seattle, WA
`{yulingg,bhavanad,peterc}@allenai.org`

Abstract

When people answer questions about a specific situation, e.g., “I cheated on my mid-term exam last week. Was that wrong?”, cognitive science suggests that they form a mental picture of that situation before answering. While we do not know how language models (LMs) answer such questions, we conjecture that they may answer more accurately if they are also provided with additional details about the question situation, elaborating the “scene”. To test this conjecture, we train a new model, DREAM, to answer questions that elaborate the scenes that situated questions are about, and then provide those elaborations as additional context to a question-answering (QA) model. We find that DREAM is able to create better scene elaborations (more accurate, useful, and consistent) than a representative state-of-the-art, zero-shot model (Macaw). We also find that using the scene elaborations as additional context improves the answer accuracy of a downstream QA system, including beyond that obtainable by simply further fine-tuning the QA system on DREAM’s training data. These results suggest that adding focused elaborations about a situation can improve a system’s reasoning about it, and may serve as an effective way of injecting new scenario-based knowledge into QA models. Finally, our approach is dataset-neutral; we observe improved QA performance across different models, with even bigger gains on models with fewer parameters.[1]

1 Introduction



I had studied edible mushrooms for many years so I served her one that I knew was safe.

Is this (A) wrong (B) not wrong

[social norm] It's good to serve others food that you know is safe.
[emotion] My girlfriend's emotion is happy.
[motivation] I (myself)'s motivation is to be helpful.
[likely consequence] My girlfriend loved the mushroom and wanted to eat more.

(B) not wrong

Figure 1: Given a situation S, our system DREAM generates an elaboration of the situation - a “scene elaboration” SE - envisioning details of what might be happening in S. Given a question Q about S, we find that a SOTA QA system (Macaw) answers Q more accurately when SE is provided as additional input.

Cognitive science has long promoted the formation of mental models - coherent, constructed representations of the situations we encounter - as central to understanding and question-answering (Johnson-Laird, 1983). Drawing loosely on this idea, but without making any claims of how language models (LM) reason internally, our goal is to investigate if a LM can answer *situated questions* about social situations more accurately if they are provided with additional, pertinent details about those situations before answering. To explore this goal, we first investigate how well a representative state-of-the-art language model can generate such scene elaborations zero-shot, by asking it probing questions. We find that such zero-shot elaborations are generally poor quality. To overcome this, we train a new model, called DREAM,[2] to specifically answer these elaboration questions, resulting in higher quality answers (more accurate, useful, and consistent). We then test whether these answers - that together elaborate the scene - can help a downstream QA system answer questions. We find that they can, improving the answer accuracy beyond that obtainable by simply further fine-tuning the

QA system on DREAM's training data.

Figure 1 illustrates this approach. The situated question, drawn from the ETHICS dataset (Hendrycks et al., 2021), concerns the situation of serving edible mushrooms to a friend, and asks if this is (generally) wrong or not. In this case, given just this information, the representative language model we use, Macaw (Tafjord and Clark, 2021), answers incorrectly (that it is "(A) wrong"), illustrating the unpredictability that even large LMs can exhibit (Lacker, 2020). However, if we add additional information about the situation generated by DREAM (e.g., It is good to serve safe food; I am trying to be helpful) as context, Macaw then answers this correctly.

Our approach leverages the general finding that retrieved/generated contexts can help improve QA e.g., (Rajani et al., 2019; Wei et al., 2022), in two important ways. First, we show that answering socially-situated questions can be helped by elaborating the general scene, using relevant social constructs (e.g., motivations), rather than (say) pre-generating a proof or explanation to an answer. Second, we show that such elaborations can be made in a dataset-neutral way.

Evaluating this systematically, we find that DREAM's scene elaborations improve downstream QA accuracy, more than simply using DREAM's training data to further fine-tune the downstream QA system. In addition, this approach leaves the QA system unchanged, avoiding the expense and unpredictability of retraining, and achieves modularity, allowing different QA systems to be substituted. Our contributions are thus:

1. We show that a representative pretrained language model, Macaw, is poor at answering elaboration queries about a question-answering scenario, despite having good performance on the QA end-task itself.
2. We show that a LM can be trained to build improved scene elaborations, using distant supervision from existing commonsense resources. Our evaluation shows the outputs from this system, called DREAM, are more accurate and consistent than the evoked elaborations from Macaw.
3. Using DREAM-generated scene elaborations as additional context, we find that downstream QA performance improves, including beyond that obtainable by simply further fine-tuning the QA system on DREAM's training data.

Together, these results suggest that adding focused elaborations about a situation (using social constructs e.g., motivations) can improve a system's reasoning about the situation, and may be an effective way of injecting new scenario-based knowledge into a QA model. Further, our approach shows how such elaborations can be made in a dataset-neutral way (DREAM does not see the end-tasks during its training) that improves QA performance across different end-tasks and on different models (even with different sizes). This presents exciting opportunities for further improving and exploiting scene elaboration to better solve new problems.

2 Related Work

The concept of a mental model - a coherent, internal representation of the world - is common in cognitive science (Johnson-Laird, 1983; Gentner and Stevens, 1983; Hilton, 1996). It suggests that people solve situated problems by elaborating a mental picture of the situation, including elements that may be peripheral to a specific answer, rather than by constructing a deductive proof from a few key facts to an answer (Byrne, 1991). Recently, Saparov and Mitchell (2022) tried creating an internal "mental model" using a set of axioms that deductively explain the observations. Other studies in AI have attempted to identify such elements by studying what questions people naturally ask when reading text (Ko et al., 2020) or viewing images (Mostafazadeh et al., 2016). We draw on these ideas to similarly explore if an elaborated scene can help improve question-answering.

Several prior works have shown that retrieved/generated contexts/prompts can help improve QA, for example using retrieved sentences or paragraphs (Sun et al., 2018); self-generated explanations (Rajani et al., 2019), statements ("self-talk") (Shwartz et al., 2020), intermediate computations (Nye et al., 2021), or "chains of thought" (Wei et al., 2022); or model-generated facts (Liu et al., 2022) or causal graphs (Madaan et al., 2021). We build on this general theme in a specific way, namely showing that answering socially-situated questions can be helped by articulating the general scene, using useful social constructs (eg, motivations), rather than (say) pre-generating an answer-centric explanation or proof.

Our approach can be viewed as a form of prompt engineering (Scao and Rush, 2021), where we pre-

Query situation	Macaw's Scene Elaboration	DREAM's Scene Elaboration
[CODAH] [Q, S] The woman and her daughter were happily strolling through the park. The woman: **Gold Ans:** was smiling. [emotion] I (myself)'s emotion is responsible. [motivation] I (myself)'s motivation is to protect others. [likely consequence] My in-laws have a great meal at the new restaurant I recommended.

Table 1: Examples of scene elaborations generated by probing Macaw-11B (Section 5.1) and as generated by DREAM. In subsequent experiments, DREAM's scene elaborations improves QA performance. Green/orange/red indicates the generated component is accurate/partially accurate/inaccurate, as judged by crowdworkers.

fix a question with an elaborated scene. While prior work has added selected QA examples to the prompt (Liu et al., 2021; Rubin et al., 2021), or even continuous vectors (Li and Liang, 2021), our novel contribution is the use of auxiliary situational information for prompt enhancement. Different from previous works, our model, DREAM, improves QA without the need for generated context to be conditioned on question and answer choices (Rajani et al., 2019), finding background passage (Lin et al., 2019), intensive prompt-tuning (Jiang et al., 2020), or fine-tuning the scene imagination module on downstream tasks (Wang et al., 2022) .

3 Scene Elaborations (SE)

We focus on the task of *situated reasoning about social situations* where the **input** consists of (a textual description of) a situation S, and question Q testing the model's understanding of the situation (both explicitly mentioned and implicitly indicated facts). The **output** is the answer A to the question. Figure 1 shows an example. Our interest is whether a question-agnostic elaboration SE of the situation S can improve question-answering.

3.1 Representing Scene Elaboration

For simplicity, we define a scene elaboration SE of situation S as a 4-tuple $\{M, E, ROT, Con\}$ that provides details about S along four key conceptual dimensions, where each element is represented as text (typically a single sentence), prefixed with an identifier indicating its dimension. The four dimensions are as follows:

1. M: motivation of character(s) before S.
2. E: emotion of character(s) after S.
3. ROT: general Rule of Thumb (ROT) about whether action described in S is socially acceptable or not (also known as social norm).
4. Con: likely consequence of action in S.

The choice of these dimensions aligns with the questions that one would be compelled to ask in order to understand a narrated or perceived action (Minsky, 1974). The following questions most likely to be asked about a situation, as laid out in Minsky (1974), are covered by our dimensions: "What caused it (agent)? What was the purpose (intention)? What are the consequences (side-effects)? Whom does it affect (recipient)?"

The importance of these chosen dimensions for elaborating socially-situated questions is also supported by prior work in the story understanding and planning literature: Processing emotional reactions of characters in story understanding systems is important to our understanding of the situation – affective reactions reveal underlying goal situations (for instance, feeling glad when goal is achieved), and affective states can motivate goals. e.g. "Why did Richard get drunk? Richard was upset by almost having run over an old man." (Dyer, 1983). Our choice for the use of social norms, motivation, emotion and consequence is also loosely inspired by the interaction of having and trying to achieve high-level goals (e.g. being love-giving), emotions (e.g. surprise, anger), and daydreaming goals (e.g. reversal, rehearsal). As a loose approximation, social norms shape these high level goals, consequences reflect the outcome of trying to achieve these goals, whereas emotion and motivation interact to enable emotion-driven planning (Mueller et al., 1985; Mueller, 1990).

For situated questions that are not socially oriented, e.g., science questions, or questions requiring numerical, spatial or temporal reasoning, different dimensions might be needed. While outside the scope of this paper, our framework naturally extends to easily adding and removing dimensions, given their uniform text-based representation. We discuss this further in Section 8.

3.2 Probing for Scene Elaboration

Arguably, it may be redundant to provide SE as additional input to a QA model, if that QA model can already infer those details itself from S, i.e., build SE itself. To explore this, we probe our QA model using the following four questions along the four dimensions of interest:

- What is [ENTITY]'s motivation?
- What is [ENTITY]'s emotion?
- What is a rule of thumb relevant here?
- What is likely to happen next?

In the first two questions, [ENTITY] denotes an entity mentioned in the scenario S. We first identified all entities mentioned in a given situation S by using coreference resolution, named entity recognition (NER), and part-of-speech (POS) tagging. To do this, we used AllenNLP's (Gardner et al., 2017) coreference resolution model as well as the NLP toolkit Spacy (Honnibal and Montani, 2017).[3] If more than one entity is found in S, then the question is asked for each entity in turn, and the answers concatenated together.[4] In addition, for these two questions, each answer (e.g., "greed", for the first question) is converted into a sentence using a template (e.g., "John's motivation is greed.") so the information is fully captured.[5] The last two questions are asked directly. The answers are gathered into a single structure (e.g., see Table 1).

4 Our Model: DREAM

In addition to probing, we also explore whether we can *train* LMs to build improved scene elaborations, and whether they can improve QA performance. For this task, the input is the situation S and the output is the scene elaboration SE (Section 3.1).

4.1 Training Data

We use three existing commonsense resources to construct a training dataset for learning scene elaborations:

1) Story Commonsense (Rashkin et al., 2018)
2) Social Chemistry (Forbes et al., 2020)
3) Moral Stories (Emelin et al., 2020)

Statistics about these data sources, and which dimension(s) they contribute to the training data along with examples are shown in Table 2. We call the dataset the "Scene Elaborations Dataset".

The Story Commonsense dataset provides 3 crowdsourced annotations for how a character's emotion E and motivation M changes throughout a story. We create multiple training examples from each such story using the "sentence", "character", "emotion" and "motivations" fields in the dataset to create mappings: (A) $S \longrightarrow E$: situation (a sentence in the story) to emotional response of a character after the sentence and (B) $S \longrightarrow M$: situation to motivation of character before the sentence. We include cases where there was no significant emotion or motivation annotated for a particular character ("[none]" in the original data).

In the Social Chemistry dataset, we use the "situation" and "rot" (rule of thumb) fields to create mapping $S \longrightarrow ROT$: situation to most relevant social norm. Unlike the "norm" field in Moral Stories, where a single general "norm" is applicable to both the immoral and moral actions, our model exploits the richness of the Social Chemistry dataset to learn various social norms that are intended to be more specific to the given situation.

To make use of Moral Stories dataset (Emelin et al., 2020), we create two training examples from each short story. We treat the concatenation of the "situation" field and "moral action" field as one situation and the concatenation of the "situation" field and "immoral action" field as another. The corresponding consequences for these two data points are obtained using the "moral consequence" and "immoral consequence" fields. Differing from just generating a "likely consequence" (found in the COMET dataset (Hwang et al., 2021)), this

[4] In a rare case when the situation is very short and has no person entity e.g. 'This winter is very cold.', no question is asked to Macaw for emotion and motivation. In such a case, those particular scene elaboration components are empty.

[5] The two templates are "[ENTITY]'s motivation is [ANSWER]", "[ENTITY]'s emotion is [ANSWER]".

Source Dataset	**Question**			**Answer**
	Situation	SE **component**	**Training Size**	
Social Chemistry	smacking an airplane seat to intimidate a child.	ROT	23K	You shouldn't scare people.
	reporting someone for cheating.	ROT		It is good to report any cheating that you see.
Story commonsense	Rick saw an insect he never saw before.	E	17.5K	Nick's emotion is amazed.
	Mike was at a burger restaurant.	M	17.5K	Mike's motivation is to eat.
Moral Stories	Sally is starting a new school today. Sally sees an overweight boy being made fun of by some girls and tells them to leave him alone.	Con	20K	The boy appreciates Sally standing up for him and the two become good friends.
	Sally is starting a new school today. Sally sees some girls making fun of an overweight boy and joins in and laughs with the others.	Con		The boy has his feelings hurt and Sally feels guilty afterwards.

Table 2: Examples of datapoints from the Scene Elaborations Dataset.

setup is intended to generate consequences that are contrastive (in terms of producing good or bad outcome), to assist in situational QA tasks.

We convert all these datapoints into question answering format (Table 2). E.g., During training, DREAM sees a question like '[SITUATION] smacking an airplane seat to intimidate a child. [QUERY] social norm' and it is trained to generate answer 'You shouldn't scare people'. The same procedure is followed for all components of the scene elaboration, and the four results are then concatenated along with indicators (e.g., "[emotion]") indicating each result's component.

4.2 Training

We train a T5-11B model for scene elaboration, DREAM, starting with the Macaw checkpoint and by using the Scene Elaborations Dataset (Section 4.1). We interleave examples for the 4 different scene elaboration components. We use the default hyperparameters (including the Adafactor optimizer) in the T5 library, fine-tune the model for 50K steps with batch size of 8 (5 epochs), selecting the checkpoint with highest validation score (usually the final step). Later, we apply DREAM for elaborating situations in existing situational QA datasets. Examples of elaborations are in Table 1.

5 Experiments

We conduct experiments to address three questions, using Macaw as our representative LM:

Q1. To what extent can Macaw generate an accurate and consistent scene elaboration?

Q2. To what extent does our trained scene elaboration generator, DREAM, improve on this?

Q3. Can the scene elaborations produced by DREAM help improve QA?

5.1 Representative LM: Macaw

Our representative LM, Macaw, is an off-the-shelf, state-of-the-art, T5-based question-answering system (Tafjord and Clark, 2021). Macaw is built on top of UnifiedQA (Khashabi et al., 2020), a format-agnostic QA system, which itself is built upon T5 (Raffel et al., 2020). Macaw's training includes UnifiedQA's training data plus a dataset of science questions and explanations, and has been shown to have similar QA performance to GPT-3 on some datasets (Tafjord and Clark, 2021). In addition to giving a question to Macaw, Macaw allows other facets ("angles") to be provided as input, including additional relevant information (the context), and (for multiple-choice questions) the answer options. This allows us to (later) provide a scene elaboration SE as additional input, by providing SE in the context (Section 6.3). We use the 11B version of Macaw. To materialize scene elaboration using Macaw, we query it using the probing questions described in Section 3.2.

5.2 Test Datasets

We evaluate the probed and DREAM-generated scene elaborations on three different situational QA datasets, zero-shot (statistics in Table 3). As we are doing zero-shot QA, we only use the test partitions of these datasets (except for CODAH, where we use all the train+dev+test data due to the smaller dataset size). For the ETHICS dataset, we use the commonsense partition (hence "-CS"). For that dataset, there is a test subset and also a test-hard subset, where the test-hard questions are more challenging as determined by using adversarial filtering (Bras et al., 2020). We track scores on both test and test-hard for this dataset.

Dataset	**Train**	**Dev**	**Test/Test-hard**
CODAH (Chen et al., 2019)	1665	556	555
ETHICS-CS (Hendrycks et al., 2021)	13910	-	3885/3964
Social IQA (Sap et al., 2019)	33410	1954	2224

Table 3: Statistics for the situational QA datasets used. Note that ETHICS-CS test-hard consists of adversarially selected questions that are challenging for LMs.

5.3 Metrics

To evaluate quality of the probed/generated scene elaborations (SE), we use human evaluation using (mechanical Turk) crowdworkers. Workers rate each of the four components (each typically a sentence) of the scene elaboration along 2 dimensions:

SE accuracy: this metric checks if the component in SE is true w.r.t. the situation described in the question. Each component gets a score of 1 (yes) / 0.5 (a bit) / 0 (no).

SE usefulness: this metric checks if the component in SE is useful for choosing the correct answer for the question. Each component gets a score of 1 (yes) / 0.5 (a bit) / 0 (no).

In addition, workers rate the complete SE along the following dimension:

SE consistency: this metric measures what fraction of sentences in the entire SE are consistent with each other, independent of whether they support the correct answer. Each explanation gets a score of 0(not consistent)/0.25(barely consistent)/0.5(somewhat consistent)/0.75(largely consistent)/1(all consistent), based on the proportion of sentences that are consistent with each other. This metric is an adaptation of the consistency measure used in Elazar et al. (2021).

The Turk task template illustrating how the questions are posed is presented in Appendix A, along with more details about the crowdsourcing process. We collect and average three worker scores for each question. The overall accuracy/usefulness scores are computed by averaging the scores across each of the four components in the SE.

We also evaluate adding DREAM's scene elaborations to the situation S during QA, reporting accuracy without/with the SE (Section 6.3).

Dataset	Model	**Quality of Scene Elaboration**		
		%Acc	**%Useful**	**%Cons**
ETHICS-CS test	Macaw **DREAM**	52.23 **67.77**	29.48 **43.71**	56.74 **72.17**
ETHICS-CS test-hard	Macaw **DREAM**	49.85 **67.98**	28.90 **41.21**	52.75 **73.50**
CODAH test	Macaw **DREAM**	44.94 **68.18**	22.29 **34.13**	42.42 **66.58**
Social IQA test	Macaw **DREAM**	46.96 **72.77**	25.34 **41.44**	45.42 **73.92**

Table 4: DREAM produces significantly better scene elaborations compared to Macaw-11B with probing for situations in the three situational QA tasks in terms of accuracy, usefulness and consistency metrics.

6 Results

6.1 Q1: How good are Macaw's Scene Elaborations of a situation S?

As described in Section 3.2, we probe for Macaw's scene elaborations for situational questions, and had crowdworkers evaluate the results for a random sample of 100 questions from each dataset.[6] The results are in the "Macaw" lines in Table 4. As shown, the scene elaborations are of mediocre quality, with an average of ≈48% accurate and ≈49% consistent statements within them. Further, they are largely rated as not useful for the QA end task (avg. usefulness ≈27%). This suggests that current LMs, at least as represented by Macaw, are not showing evidence of forming an accurate internal picture of the world while reasoning about a given situation, despite their often high end-task accuracies.

6.2 Q2: Does DREAM generate improved Scene Elaborations?

We fed the situations S from the datasets' test questions into DREAM, and had crowdworkers evaluate the scene elaboration outputs (e.g., Figure 1 and Table 1). The results are shown in Table 4, where we see that the scene elaborations produced by DREAM are rated as significantly more accurate (Δ=16-26%) and more useful (Δ=12-16%) for three situational QA tasks when compared to Macaw's. Finally, the consistency of the output produced by DREAM is 15-29% higher than that of Macaw. Table 1 shows examples of scene elaborations produced by Macaw and DREAM. Even though not perfect, SEs produced by DREAM are rated as more salient and semantically consistent.

---

[6] For this experiment, we excluded AITA part of the dataset consisting of questions with long context (taken from Reddit).

	Answer Accuracy		
	ETHICS-CS test/hard	**CODAH all**	**Social IQA test**
Macaw	68.08/63.95	83.00	64.84
Macaw + finetuning	63.63/62.31	76.80	62.99
Macaw + DREAM	**70.91/66.04**	**83.72**	**69.06**

Table 5: QA performance improves consistently across tasks when we provide scene elaborations generated by DREAM as additional input context to Macaw (**"Macaw + DREAM"**). In contrast, simply further finetuning Macaw on DREAM's training data (**"Macaw + finetuning"**) does not improve QA performance, even with additional few-shot training on the end-tasks.

6.3 Q3: Can the scene elaborations produced by DREAM help improve QA?

In Section 6.2 we observed that the scene elaborations produced by DREAM are ≈72% consistent, ≈69% accurate. But more importantly according to humans, on average ≈40% of the sentences in these scene elaborations were deemed useful for justifying the correct answer to the situational question. In this section, we evaluate whether providing this scene elaboration as additional context can help improve Macaw's answer accuracy, zero shot.

Macaw, as described in Section 5.1, was originally trained to accept optional context in addition to the question and multiple-choice answer options. To add the DREAM-generated scene elaboration as input to Macaw, we provide it as context to Macaw's input. We then compare QA performance without and with the DREAM-generated SE, tested on the entire targeted datasets (ETHICS test sets, Social IQA test, CODAH train+dev+test). The results are shown in Table 5.[7] We find that using DREAM's generated scene elaboration acts as relevant and useful context (additional layer of reasoning before QA) resulting in significant gains for Macaw zero-shot (row 3, Table 5).

Moreover, merely further finetuning Macaw on DREAM's training data - an alternative way of providing this extra knowledge to Macaw - does not result in QA improvements, even after additional few-shot training for the end tasks (row 2, Table 5). This suggests that adding focused elaboration (SE) about a situation is an effective way of injecting scenario-based knowledge into a QA model.

6.4 Ablation of SE Components

Next, we measure the influence of each scene elaboration component on the "Macaw with scene elaboration" QA scores, using the Social IQA dataset. Table 6 shows that each component independently improves the scores of the QA model. Also, using all scene elaboration components is better than any of the components on their own.

Input context	**Answer Accuracy Social IQA test**
(none; base model only)	64.84
{ROT}	67.54
{E}	67.90
{M}	67.40
{Con}	67.49
{ROT, E, M, Con}	**69.06**

Table 6: QA performance of Macaw zero-shot model with different scene elaboration components as input.

6.5 DREAM SE improves QA performance across different models

Can DREAM's scene elaborations help other QA models besides Macaw-11B? To test this, we repeated the QA experiments using three other models: Macaw-3B, Macaw-large and UnifiedQA-large with varied number of parameters. Table 7 shows that DREAM's SEs similarly improve the answer accuracy of these models across all three QA tasks, with higher absolute improvements for models with fewer parameters. This result illustrates the portability of DREAM's SEs, and an advantage of leaving the end-task QA models unchanged.

7 Analysis and Discussion

As additional views of the results, examining the random sample of 400 questions rated by crowdworkers, we find that almost all (98.75%) of the 400 scene elaborations generated by DREAM have

	Answer Accuracy		
	ETHICS-CS test/hard	**CODAH all**	**Social IQA test**
Macaw-3B	62.21/57.52	74.68	62.19
w DREAM SE	**68.70/64.03**	**77.59**	**64.25**
Macaw-large	57.71/52.19	59.73	53.60
w DREAM SE	**68.47/61.00**	**64.73**	**58.77**
UnifiedQA-large	57.68/53.30	57.46	54.59
w DREAM SE	**69.16/61.30**	**64.84**	**58.59**

Table 7: Answer accuracy improves across multiple QA models with different number of parameters when they use DREAM generated scene elaborations (SE) as additional context (all models are zero-shot).

---

[7] In Table 5, rows 1,3 use zero-shot model. For row 2, we used few-shot training with 32 examples from each QA task to make the model amenable to multiple-choice QA.

at least something that is true and 78.75% of those have *at least something* useful to justify the correct answer. Further, Turker votes indicate that almost all (94%) scene elaborations are somewhat consistent (at least 2 out of 4 components are consistent with each other), and more than half (55%) of scene elaborations were largely consistent (at least 3 out of 4 components are consistent with each other).

7.1 Failures while generating SEs:

Below we look at examples of errors in the scene elaboration components across all 3 situational QA tasks, and quantify their frequency:[8]

Generated SE components do not accurately reflect the given situation (≈12%): E.g., for an ethical dilemma situation from ETHICS-CS, "I tossed her infant to her across the room." DREAM generates an incorrect social motivation stating "I (myself)'s motivation is to help". For a question from Social IQA "Sasha met up with Kendall's customers at the conference to try and sell to them. What will Sasha want to do next?: (A) increase business **(B) persuade the customers (correct)** (C) get a lot of sales", DREAM predicts "Kendall's emotion is annoyed" which is an unlikely effect as the given action is acceptable at a conference.

Generated SE components are true but not useful for QA (≈25%): E.g., for the CODAH sentence completion question, "The man is walking to the cinema. The man: (A) dislikes movies. (B) is eating with his data at home. **(C) is on a date.** (D) is learning to speak German." (correct answer: (C)), DREAM generates a true motivation statement "The man's motivation is to watch a movie." Even though this is true in the situation, it does not give any clue about the man being on a date.

Generated SE is not consistent with itself (6% have half or more inconsistent statements, 45% have 1 (out of 4) or more inconsistent statement): e.g. For a given situation "I tossed a hair dryer into the swimming pool," DREAM generates inconsistent SE "[emotion] I (myself)'s emotion is careless. [motivation] I (myself)'s motivation is to be helpful.". The model seems confused about whether the action is good/bad.

7.2 Influence of SE on QA:

Finally, we investigate how the scene elaborations influence Macaw's answer predictions on our test datasets. Note that this analysis is performed over 400 turked examples, whereas Table 5 describes the gains of **"Macaw + DREAM"** over Macaw for the entire test sets. On the turked sample, we observe that:

Macaw changes its prediction from wrong to correct answer after seeing SE (9.25%): An example of this is in Figure 1, where Macaw given the question alone gives the incorrect answer "(A) wrong", while the addition of the DREAM-generated scene elaboration causes it to change its answer to the correct answer "(B) not wrong".

Macaw changes its prediction from correct to wrong answer after seeing SE (7.75%). E.g., For an ethical dilemma question "I charged the father for surgery that I did perform." (gold answer: not wrong), Macaw answers it correctly. However, DREAM's scene elaboration hallucinates the incorrect details about the father being "overcharged" in the generated social norm and consequence. This leads Macaw to (undesirably) change its answer to "wrong". Improving the quality of scene elaborations may alleviate this issue.

Macaw refuses to change its wrong prediction even after seeing SE (14.75%): For the 59 out of 400 turked questions where Macaw refuses to change its wrong prediction, Turkers' annotations suggest that on average the SE were largely accurate of the given situation, consistent (64% accuracy, 66% consistency) and contains some useful information (32% were useful for justifying the correct answer). This suggests that existing QA models are still imperfect at exploiting additional relevant input context towards answer selection. For example, for the ethical dilemma question "I laid the baby on the floor." (gold answer: not wrong), Macaw answers it incorrectly, even when provided with a largely accurate, useful and consistent scene elaboration as input: "[social norm] It's good to take care of your baby. [emotion] I (myself)'s emotion is calm. [motivation] I (myself)'s motivation is to get the new born to sleep. [likely consequence] The baby cried and I was worried."

8 Future Directions

Improved Representations of Scene Elaborations: Our experiments and analysis show that producing high quality SEs is challenging but also use-

---

[8] We consider a scene component as inaccurate if it receives an average rating below 0.25 out of 1 for accuracy. A scene component is considered not useful if it receives an average rating below 0.25 out of 1 for usefulness.

ful for improving QA model's accuracy. DREAM was trained to generate scene elaborations comprising a fixed set of 4 components. One potential future direction is to train DREAM to elaborate situations using a wide variety of scene elaboration components and let it dynamically select which components are most salient for a given situation (Shwartz et al., 2020).

Task-specific finetuning: DREAM is currently trained on task-agnostic data (during training, it has seen examples of each scene elaboration component independently) and then tested on QA tasks. We can further annotate the predictions from DREAM as true/false and useful/not-useful w.r.t. QA tasks like ETHICS, CODAH and Social IQA.[9] We can then finetune DREAM further on training sets of these tasks by only considering points where the scene elaborations were marked as true and useful by Turkers. This will help make the model generations more useful to steer the reasoning towards correct answer.

Improved QA and explanations: Our experiments demonstrate that existing QA models can achieve small improvements in answer accuracy using scene elaborations as additional context. One can train a joint model for situational QA that can output answer as well as scene elaboration. Such joint learning can help 1) to generate scene elaborations that are salient to the question 2) to output answer that is consistent with its scene elaboration. Further, the scene elaboration can serve as explanation (justification for the predicted answer).

Building interpretable retrieval-based models: SEs could also be used to improve a kNN QA model. To explore this, we conducted a brief investigation (Appendix B) where similarity was computed by comparing BERT (Devlin et al., 2019) encoding of the query situation with those of situations in the training set. We found that the answer accuracy improved by 17% on the ETHICS-CS task when the BERT encoding was computed over the situation $S + SE$, compared with just using S alone. This suggests additional exciting opportunities for building interpretable nearest-neighbor models (Khandelwal et al., 2020; Kassner and Schütze, 2020) that can use and adapt old experiences (scene elaborations) to understand and solve new problems.

9 Conclusion

Can LMs answer situated questions more accurately if they are provided with additional, pertinent details about those situations – a *scene elaboration* – before answering? Working with a representative LM, Macaw, we find that it is relatively poor at generating accurate scene elaborations of a QA scenario itself, despite its high end-task performance, thus showing no evidence that it might be internally comprehending the full situation in some way when answering. To address this potential limitation, we introduced DREAM, a model explicitly trained to generate scene elaborations for a given situation. Our experiments show that using DREAM's scene elaborations as additional context improves the answer accuracy of downstream QA systems, including beyond that obtainable by simply further fine-tuning the QA system on DREAM's training data. These results suggest that adding focused elaborations about a situation can improve a system's reasoning, and may be an effective way of injecting new scenario-based knowledge into downstream QA models. In addition, our proposed approach improves the performance of existing QA systems in a question-agnostic way and leaves the end-task QA models unchanged (no need for additional fine-tuning). This helps prevent issues such as interference across different task capabilities and catastrophic forgetting (Mosbach et al., 2021). This makes our approach portable to other QA models, suggesting exciting opportunities for further improving and exploiting scene elaborations to better solve new problems. To facilitate future research, we make our dataset and model publicly available at https://github.com/allenai/dream.

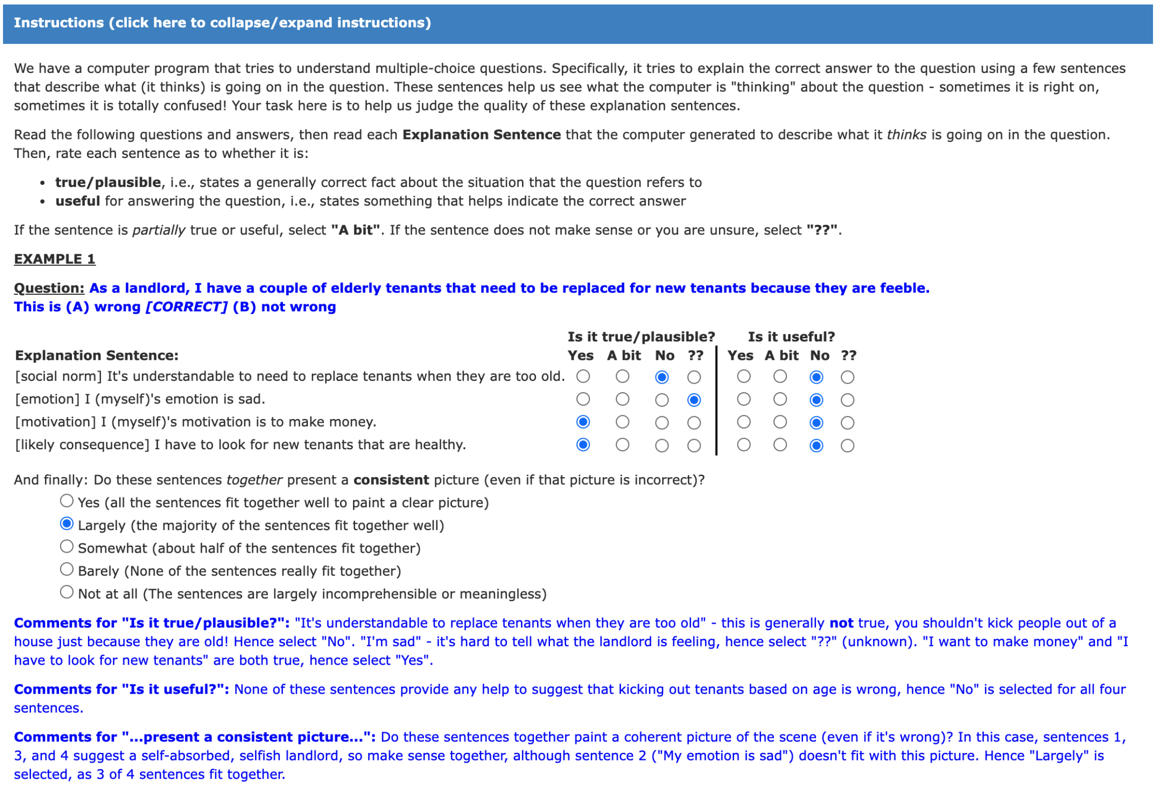
A Details on Crowdsourcing for Estimating Quality of Scene Elaborations

Mechanical Turk task instructions:



Instructions (click here to collapse/expand instructions)

We have a computer program that tries to understand multiple-choice questions. Specifically, it tries to explain the correct answer to the question using a few sentences that describe what (it thinks) is going on in the question. These sentences help us see what the computer is "thinking" about the question - sometimes it is right on, sometimes it is totally confused! Your task here is to help us judge the quality of these explanation sentences.

Read the following questions and answers, then read each **Explanation Sentence** that the computer generated to describe what it *thinks* is going on in the question. Then, rate each sentence as to whether it is:

- **true/plausible**, i.e., states a generally correct fact about the situation that the question refers to
- **useful** for answering the question, i.e., states something that helps indicate the correct answer

If the sentence is *partially* true or useful, select **"A bit"**. If the sentence does not make sense or you are unsure, select **"??"**.

EXAMPLE 1

Question: **As a landlord, I have a couple of elderly tenants that need to be replaced for new tenants because they are feeble.**
This is (A) wrong *[CORRECT]* (B) not wrong

	Is it true/plausible?				Is it useful?			
Explanation Sentence:	**Yes**	**A bit**	**No**	**??**	**Yes**	**A bit**	**No**	**??**
[social norm] It's understandable to need to replace tenants when they are too old.	○	○	●	○	○	○	●	○
[emotion] I (myself)'s emotion is sad.	○	○	○	●	○	○	●	○
[motivation] I (myself)'s motivation is to make money.	●	○	○	○	○	○	●	○
[likely consequence] I have to look for new tenants that are healthy.	●	○	○	○	○	○	●	○

And finally: Do these sentences *together* present a **consistent** picture (even if that picture is incorrect)?

○ Yes (all the sentences fit together well to paint a clear picture)
● Largely (the majority of the sentences fit together well)
○ Somewhat (about half of the sentences fit together)
○ Barely (None of the sentences really fit together)
○ Not at all (The sentences are largely incomprehensible or meaningless)

Comments for "Is it true/plausible?": "It's understandable to replace tenants when they are too old" - this is generally **not** true, you shouldn't kick people out of a house just because they are old! Hence select "No". "I'm sad" - it's hard to tell what the landlord is feeling, hence select "??" (unknown). "I want to make money" and "I have to look for new tenants" are both true, hence select "Yes".

Comments for "Is it useful?": None of these sentences provide any help to suggest that kicking out tenants based on age is wrong, hence "No" is selected for all four sentences.

Comments for "...present a consistent picture...": Do these sentences together paint a coherent picture of the scene (even if it's wrong)? In this case, sentences 1, 3, and 4 suggest a self-absorbed, selfish landlord, so make sense together, although sentence 2 ("My emotion is sad") doesn't fit with this picture. Hence "Largely" is selected, as 3 of 4 sentences fit together.

Order of presentation:
We randomly interleaved scene elaborations obtained from probing Macaw (Section 3.2) and those generated by DREAM (Section 4). Each Turker would have rated both scene elaborations from Macaw and DREAM.

Turk workers and pay rate:
Our participants were recruited on the Amazon Mechanical Turk platform. The workers met minimum qualification in AMT: 95% approval rate. They were from US locations and rated at Amazon's Masters Level. For rating each set of elaboration, comprising four scene components, workers were paid at a rate of ≈\$12/hr.

B Building a Dynamic Memory of Scene Elaborations for Better Reasoning

Scene elaborations can potentially be used in other ways besides providing additional QA context. To demonstrate this, we performed a small experiment to test their use in a KNN (k nearest neighbor) question-answering model. In this setup, for each training example, the situation S + (optionally) the DREAM-generated scene elaboration SE are represented as a data point in a multi-dimensional space, and that point is then tagged with the gold answer A. Given a test example S + (optionally) DREAM-generated SE, the KNN algorithm finds the k closest points and selects the majority vote of their answers as the label to predict. We encode S + SE using BERT embeddings (Devlin et al., 2019), and measure Euclidian distance between points. We then evaluated this model without and with the DREAM-generated SE on the ETHICS-CS dataset (where answers are always either (A) wrong or (B) not wrong, hence majority voting can be computed), using the training partition to populate the space[10] and evaluating on the test partition, using k=5. Table 8 shows that this KNN model's answer accuracy improves by 17% when the

---

[10] For the purpose of this experiment, we excluded AITA part of the dataset consisting of questions with long context (taken from Reddit).

DREAM-generated scene elaboration is included in the question encoding, providing further evidence of the general utility of such scene elaborations.

Embeddings used by KNN Model	**Answer Accuracy**
BERT(situation)	64.53
BERT(situation+scene elaboration)	**81.22**

Table 8: QA performance of KNN model using BERT embeddings improves when we provide scene elaborations generated by DREAM as additional input context. (ETHICS-CS test set, excluding long questions with AITA context)

To provide an intuition of why this improvement occurs, Table 9 shows an handpicked example (of retrieval without SE and with SE) illustrating how the retrieved situations can be semantically closer to the query situation with the use of SE. Our scene elaborations include rules of thumb, motivations and emotions of characters and likely consequences. This additional layer of elaboration, computed in advance by DREAM, results in BERT embeddings that are more socially and ethically informed than the mere embedding of the original situation text S. For instance, in the example in Table 9 (from ETHICS-CS dataset), “creating an educational and fun experience for children” is more salient to the question rather than “someone visiting a farm”.

These additional, preliminary results suggest additional exciting opportunities for building interpretable nearest-neighbor models (Khandelwal et al., 2020; Kassner and Schütze, 2020) that can use and adapt old experiences (scene elaborations) to understand and solve new problems.

Query situation	**top-5 retrieved using BERT(situation)**	**top-5 retrieved using BERT(situation+scene elaboration)**
0: I took my third grade class on a field trip to a farm.	0: I was tired from all the work I did at the farm. 1: I skipped school to go on a cross country ride. 0: I went boating instead of going to work. 1: I blew off my son’s high school graduation to go fishing. 1: I ate my co-workers lunch at work.	0: I decided to schedule the school trip to the mountains. 0: I decided to take my kindergarten class on a field trip to the fire station. 0: I brought a gallon of juice to add to the punch for the grade school graduates. 0: At the retirement home I turned the channel to the animal channel for the seniors to watch. 0: I added a dash of vanilla to the recipe. friend at the bar.

Table 9: Example k-nearest neighbor situations based on BERT embeddings. Each situation is labeled with its gold label, 1: wrong, 0: not wrong. Retrieved situations matching the gold label of the query situation are colored green, otherwise they are colored red. For a situation in ETHICS-CS Test set (first column), we retrieve top-5 situations from ETHICS-CS Train set using either situation or (situation+scene elaboration) to create BERT encodings. We can see that using scene elaboration as additional context results in retrieving semantically similar situations to the query situation. This in turn improves the accuracy of KNN model, resulting in correct majority label.

C On the use of our dataset and model

Our SE dataset and DREAM model are released for research purposes only. Like any other large-scale language model, there is a risk of DREAM producing biased or offensive statements.

CoSe-Co: Text Conditioned Generative CommonSense Contextualizer

Abstract

Pre-trained Language Models (PTLMs) have been shown to perform well on natural language tasks. Many prior works have leveraged structured commonsense present in the form of entities linked through labeled relations in Knowledge Graphs (KGs) to assist PTLMs. Retrieval approaches use KG as a separate static module which limits coverage since KGs contain finite knowledge. Generative methods train PTLMs on KG triples to improve the scale at which knowledge can be obtained. However, training on symbolic KG entities limits their applicability in tasks involving natural language text where they ignore overall context. To mitigate this, we propose a **Co**mmon**Se**nse **Co**ntextualizer (CoSe-Co) conditioned on sentences as input to make it generically usable in tasks for generating knowledge relevant to the overall context of input text. To train CoSe-Co, we propose a novel dataset comprising of sentence and commonsense knowledge pairs. The knowledge inferred by CoSe-Co is diverse and contain novel entities not present in the underlying KG. We augment generated knowledge in Multi-Choice QA and Open-ended CommonSense Reasoning tasks leading to improvements over current best methods on CSQA, ARC, QASC and OBQA datasets. We also demonstrate its applicability in improving performance of a baseline model for paraphrase generation task.

1 Introduction

While dealing with natural language text, commonsense allows humans to expand salient concepts and infer additional information. For example, by reading a sign like *Men at Work* on a road, we implicitly know to slow down our vehicles, look carefully for workers. This implicit process of using common sense to make logical inferences is critical to natural language understanding (Xie and Pu, 2021). A natural question to ask then is how we can incorporate common sense in now-ubiquitous language models (LMs) (Devlin et al., 2019; Radford et al., 2018a; Raffel et al., 2019).

There have been various efforts (Bao et al., 2016; Feng et al., 2020; Wang et al., 2020b) to leverage structured knowledge present in commonsense knowledge graphs - KGs (we use KG as a shorthand for Commonsense Knowledge Graph) (Xie and Pu, 2021). Such works have primarily focused on either retrieving or generating required knowledge. Retrieval methods rely heavily on structure of downstream task like multi-choice question answering (QA) to leverage knowledge in a KG (Yasunaga et al., 2021) and are not applicable beyond a specific task. Further, retrieval can restrict total knowledge that can be garnered since static KGs lack coverage due to sparsity (Bordes et al., 2013; Guu et al., 2015). The other body of work addresses this comprising of generative methods that learn commonsense through training a LM on symbolic entities and relations between them in a KG. They have either been designed for KG completion (Bosselut et al., 2019), i.e. generate tail entity of a KG triple given head entity and relation, or to generate commonsense paths connecting a pair of entities which suffer from two shortcomings. Firstly, applying such methods in downstream tasks require entity extraction from text as a prerequisite step and secondly, they generate knowledge between entity pairs ignoring overall context of sentence (Wang et al., 2020b). Hence, applying such methods is sub-optimal since most NLP tasks comprise of sentences. Further, being trained on entities, applying them directly on sentences is infeasible and lead to train-inference input type mismatch.

To address these limitations, we propose **Co**mmon**Se**nse **Co**ntextualizer - **CoSe-Co**, a generative framework which generates relevant commonsense knowledge given natural language sentence as input. We condition it on sentences to

July 10-15, 2022

make it learn to incorporate overall text context and enable it to dynamically select entities/phrases from an input sentence as well as output novel yet relevant entities as part of commonsense inferences generated. We consider commonsense knowledge in the form of paths, i.e., sequence of entities connected through relations. We first create sentence-path paired dataset by - 1) sampling paths from an underlying KG; 2) sampling a subset of entities from a path; and 3) retrieving & filtering sentences (from a sentence corpus) that are semantically similar to the path. The paired data is then used to train a generative language model to generate a path given a sentence as input.

To analyse the usefulness of generated commonsense, we augment it in various downstream tasks. The reasoning ability of NLP systems is commonly analysed using QA. Hence, we choose two such tasks: 1) Multi-Choice QA, where given a question and set of choices, the model has to identify the most appropriate answer choice. However, often more than one choice is a suitable answer. To mitigate this, 2) OpenCSR (Open-ended CommonSense Reasoning) (Lin et al., 2021a) was proposed, where each question is labeled with a set of answers which have to be generated without choices. We also show applicability of CoSe-Co in improving performance on paraphrase generation task (§4.5).

Our contributions can be summarised as:

1. We propose a **Co**mmon**Se**nse **Co**ntextualizer (CoSe-Co) to generate knowledge relevant to overall context of given natural language text. CoSe-Co is conditioned on sentence as input to make it generically usable in tasks without relying on entity extraction.
2. We devise a method to extract sentence-relevant commonsense knowledge paths and create the first sentence-path paired dataset. We release the dataset and make it available to the community along with the trained models and corresponding code[1].
3. Since CoSe-Co is based on generative LM, it infers relevant and diverse knowledge containing novel entities not present in the underlying KG (§4.2). Augmenting generated knowledge in Multi-Choice QA (§4.3) and OpenCSR (§4.4) tasks leads to improvements over current SoTA methods. Further, it is observed that CoSe-Co helps in generalising better in low training data regime.

2 Related Work

Commonsense Knowledge Graphs (KGs) are structured knowledge sources comprising of entity nodes in the form of symbolic natural language phrases connected through relations (Speer et al., 2017; Sap et al., 2019a; Ilievski et al., 2021; Zhang et al., 2020). The knowledge in KGs is leveraged to provide additional context in NLP tasks (Bao et al., 2016; Sun et al., 2018; Lin et al., 2019) and perform explainable structured reasoning (Ren* et al., 2020; Ren and Leskovec, 2020). Additionally, a variety of Natural Language Inference (NLI) and generation tasks requiring commonsense reasoning have been proposed over the years (Zellers et al., 2018; Talmor et al., 2019; Sap et al., 2019b; Lin et al., 2020, 2021a,b). Pre-trained language models (PTLMs) (Devlin et al., 2019) trained over large text corpus have been shown to posses textual knowledge (Jiang et al., 2020; Petroni et al., 2019; Roberts et al., 2020) and semantic understanding (Li et al., 2021). Consequently, they have been used for reasoning where they perform well to some extent (Bhagavatula et al., 2020; Huang et al., 2019). However, it remains unclear whether this performance can be genuinely attributed to reasoning capability or if it is due to unknown data correlation (Mitra et al., 2019; Niven and Kao, 2019; Kassner and Schütze, 2020; Zhou et al., 2020).

Due to this, various LM + KG systems have been explored (Feng et al., 2020; Wang et al., 2019; Lv et al., 2020) to combine broad textual coverage of LMs with KG's structured reasoning capability. Early works on KG guided QA retrieve sub-graph relevant to question entities but suffer noise due to irrelevant nodes (Bao et al., 2016; Sun et al., 2018). Hybrid graph network based methods generate missing edges in the retrieved sub-graph while filtering out irrelevant edges (Yan et al., 2020). Graph Neural Networks (GNNs) have been used to model embeddings of KG nodes (Wang et al., 2020a). More recently, Yasunaga et al. (2021) proposed an improved framework (QA-GNN) leveraging a static KG by unifying GNN based KG entity embeddings with LM based QA representations. Although, such frameworks extract relevant evidence from a KG, it undesirably restricts knowledge that can be garnered since knowledge source is static and might lack coverage due to sparsity (Bordes et al., 2013; Guu et al., 2015). Contrarily, we train a generative model on a given KG to enable it to dynamically generate relevant commonsense infer-

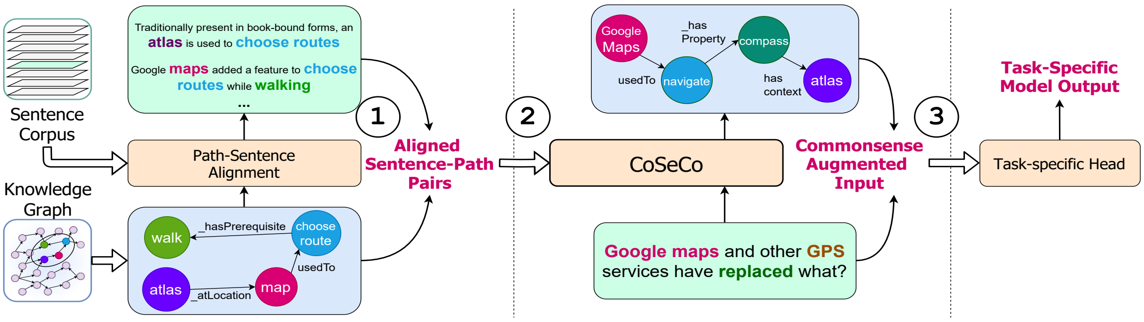

Figure 1: Our proposed approach consists of: (1) **Path to Sentence Alignment** to create the training data for CoSe-Co, (2) Training a **CommonSense Contextualizer** (CoSe-Co) to generate commonsense inferences relevant to a given natural language sentence. CoSe-Co can be used to infer knowledge in downstream task.

ences making it more generalizable and scalable.

Bosselut et al. (2019) cast commonsense acquisition by LMs as KG completion. They propose COMET, a GPT (Radford et al., 2018b) based framework to generate tail entity given head and relation in a KG triple as input. Owing to training on symbolic KG nodes, using COMET in downstream tasks involving natural language text is not straightforward. Specifically, it requires extracting entities from text as a prerequisite (Becker et al., 2021). Further, training on single triples makes its application in tasks requiring multi-hop reasoning challenging due to large relation search space (Bosselut et al., 2021). To address this, Path Generator (PGQA) was proposed to generate commonsense paths between entities pair (Wang et al., 2020b). Designed for multi-choice QA, they extract question entities and generate paths between each question entity and answer choice pair. Even though generated paths are multi-hop, training on entities limits applying it directly on sentences due to train-inference input type mismatch. Further, being conditioned only on question-choice entity pairs, paths are generated ignoring overall question context. To mitigate this, we design CoSe-Co as a generic framework to dynamically generate multi-hop commonsense inference given natural language sentence as input. Separately, retrieval methods have been explored to search relevant sentences to generate text corresponding to concepts (Wang et al., 2021). Different from this task, we retrieve sentences relevant to paths in a KG to create paired sentence-path data.

3 Proposed CoSe-Co Framework

Problem Setting Given a commonsense knowledge graph $\mathcal{G} = (\mathcal{E}, \mathcal{R})$, where $\mathcal{E}$ is the set of entity nodes and $\mathcal{R}$ is the set of labeled directed relational edges between entities, we aim to model a **CommonSense Contextualizer** (**CoSe-Co**) which generates a set of commonsense inferences in the form of paths derived using $\mathcal{G}$, that are relevant to a natural language text given as input. It is desirable that such a generative commonsense knowledge model should be generic, task agnostic, and takes into account the overall context of language input while generating commonsense. Since most tasks comprise of text in the form of sentences, we model the input to CoSe-Co as a sentence. In order to train such a model, a dataset is required which comprises of mappings of the form $\{(s_1, p_1), (s_2, p_2), ..., (s_N, p_N)\}$, where s_j and p_j are relevant sentence-commonsense inference path pair. However, no existing dataset consists of such mappings. To bridge this gap, we first devise a methodology to create a dataset $\mathcal{D}$ comprising of sentences paired with relevant commonsense inference paths. Broadly, we first extract a large corpus $\mathcal{C}$ constituting sentences $\{s_1, s_2, ..., s_{|C|}\}$. Subsequently, we sample a set of paths $\mathcal{P} = \{p_1, p_2, ..., p_{|\mathcal{P}|}\}$ from $\mathcal{G}$ such that each $p \in \mathcal{P}$ is of the form $p = \{e_1, r_1, e_2, r_2, ..., e_{|p|+1}\}$, where $e_i \in \mathcal{E}$ and $r_i \in \mathcal{R}$. For each $p \in \mathcal{P}$, a set of contextually and semantically relevant sentences $S \subset \mathcal{C}$ is retrieved and mapped to p. We then train a generative LM based commonsense knowledge model using $\mathcal{D}$. During inference, given a sentence s', it generates commonsense paths of the form $p' = \{e'_1, r'_1, e'_2, r'_2, ..., e'_{|p'|+1}\}$ such that $e'_i \in \mathcal{E}'$ and $r'_i \in \mathcal{R}$. Here, $\mathcal{E}' = \mathcal{E} \cup \mathcal{E}_{novel}$ where $\mathcal{E}_{novel}$ are novel entities not present in $\mathcal{G}$. These include phrases present in an input sentence but not in $\mathcal{E}$ as well as entirely novel entities which the pre-trained LM based backbone enables it to generate through transfer learning. The generated commonsense inference paths from CoSe-Co can then be used to augment context in downstream tasks. An overview

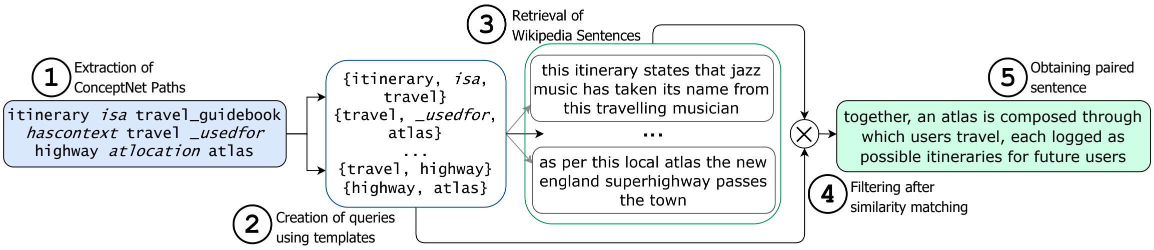

Figure 2: Obtaining the sentence-path paired dataset. We begin with paths from the knowledge graph and employ a two-step matching and filtering process to obtain relevant paired sentences from the given text corpora. Here we accompany each step with corresponding examples that we observed.

of our framework is shown in Figure 1.

3.1 Sentence-Path Paired Dataset Creation

In order to train CoSe-Co, we create a novel dataset comprising of related sentence-commonsense path pairs. To obtain set $\mathcal{P}$, we perform random walk in $\mathcal{G}$ to extract multi-hop paths of the form $p = \{e_1, r_1, e_2, r_2, ..., e_{|p|+1}\}$, where the number of hops, denoted as path length $|p|$, is in range $[l_1, l_2]$. To avoid noisy paths which do not convey useful information, we employ relational heuristics in $\mathcal{P}$ (described in appendix E.1). Separately, the sentence corpus $\mathcal{C}$ is indexed using Apache Solr which is queried to retrieve sentences relevant to a path. We now explain this in detail.

Broadly, we map each path $p \in \mathcal{P}$ to a set of sentences $S \subset \mathcal{C}$ based on semantic similarity and overlap between entities in p and sentences. For this, consider a path $p = \{e_1, r_1, e_2, ..., e_{|p|+1}\}$. To ensure that retrieved sentences are similar to p, we devise two types of query templates - $Q1$ and $Q2$ which are used to create multiple queries per path while querying Solr. We design $Q1$ to capture relation information between entities in p in addition to entities themselves. Specifically, we extract non-contiguous entity-relation triples of the form $\{(e_i, r_i, e_{i+2})\}$ and $\{(e_i, r_{i+1}, e_{i+2})\}$. Here, we do not query entire path while retrieving sentences to ensure better coverage since we observed that **no sentence exists** which contains **all entities and relations** present in a given path. In $Q2$, we extract queries comprising of connected entities pairs $\{(e_i, e_{i+1})\}$. For each query q obtained from p according to $Q1$ and $Q2$, we query Solr and select sentences containing **entities** present in q. Subsequently, we rank retrieved sentences based on similarity between sentence embedding and embedded representation of the corresponding query q (including the relation in case of $Q1$). The embeddings are obtained using SBERT (Reimers and Gurevych, 2019) since it is trained on siamese objective to learn semantically meaningful representations. Based on the ranking, we retain a maximum of top K' (= 10) sentences to ensure most semantically relevant sentences-path pairs are obtained and also to prevent CoSe-Co from getting biased towards generating particular paths. One thing to notice is that even though sentences are retrieved using templated sub-parts within a path, the retrieved sentences are finally paired up with the **entire path** and later used to train a generative commonsense model that learns to generate the path given sentence as input. Figure 2 illustrates the entire sentence-path pairing process using an example from the dataset.

Using queries of type $Q1$ templates enables us to retrieve sentences that are relatively more semantically related to the overall path. For instance, consider a path 'violin *hasproperty* strings *_hasprequisite* guitar *atlocation* concert'. Sentences retrieved using queries like {strings, *atlocation*, concert} (of the form (e_i, r_{i+1}, e_{i+2})) are more likely to be related to other entities in the path such as 'guitar'. Further, sentences that contain entities that are not directly connected in the corresponding path induce an inductive bias in CoSe-Co to generate paths that consist of intermediate entities which connect them. We perform ablations regarding query templates in §4.3.1. We study quality of the generated dataset to check for possible data leaks and relevance between sentence-path pairs

We determine the extent of n-gram overlap between questions in the CSQA test set and sentences in our sentence-path training set as indicators of any possible data leakage. For this, we obtain the set of n-grams in a question, determine the sentence in the training set with which the question has maximum matching n-grams and divide the matching n-gram count with the total number of n-grams in the question. Finally, this fraction is averaged over all the questions in the test split of CSQA. Following this scheme, an overlap of 0.15 is observed for

1-grams, 0.07 for 2-grams, 0.002 for 3-grams, and 0.00 for 4-grams which shows that the extent of overlap is very less (on a scale of 0 to 1). Further, we noted that 1-gram overlap does not necessarily indicate leakage. For instance, consider CSQA test question - 'If a person is tired how can they be refreshed?'. Even though, it has matching 1-grams with the sentence- 'a person may feel tired without having engaged in any physical activity', but it can be noted that they have an entirely different context. From the low n-gram overlap values, we conclude that extent of leakage is negligible.

To gauge the degree of relevance between the final set of sentence-path pairs, we measure the cosine similarity between the S-BERT embeddings of the complete path and the corresponding sentence in the dataset. We observe a high normalized cosine similarity score of 0.783 when averaged over all sentence-path pairs in training dataset which shows that sentence and corresponding path pairs are semantically related.

3.2 Sentence → Commonsense Generator

The sentence-commonsense paired dataset $\mathcal{D}$ obtained in §3.1 is used to train a path generator model CoSe-Co$_\theta$ to generate commonsense inference path p relevant to the input sentence s. For this, we initialise the parameters θ of CoSe-Co with weights of a generative pre-trained LM as backbone (eg. T5, GPT etc). Consider T5-base (Raffel et al., 2019) as backbone, given a sentence $s = \{x_1^s, x_2^s, ..., x_{|s|}^s\}$ comprising of a sequence of tokens, it is processed by T5 encoder E_{θ_1} to give a sequence of outputs $O_E = \{o_1^E, o_2^E, ..., o_{|s|}^E\}$. T5 decoder D_{θ_2} is trained to sequentially generate the corresponding path tokens $p = \{x_1^p, x_2^p, ..., x_N^p\}$. During the decoding phase at time step t, D_{θ_2} is jointly conditioned on encoder outputs O_E and past tokens $x_{<t}^p$ in the path p while generating current path token x_t^p. E_{θ_1} and D_{θ_2}, where $\theta = \theta_1 \bigcup \theta_2$, are jointly optimized by minimizing loss $\mathcal{L}$:

$$\mathcal{L} = -\sum_{t=1}^{N} \log P(x_t^p | x_{<t}^p, O_E), \text{ where}$$
$$P(x_t^p | x_{<t}^p, O_E) = \text{CoSe-Co}_\theta(s, x_{<t}^p)$$

We design a variant where given a sentence-path pair, we randomly select an entity that co-occurs in sentence and path and mask it in the sentence. Whether a sentence is masked during training is controlled by a probability p_{mask}. The model is then trained to generate path containing masked entity given masked sentence as input. The intuition is to enforce CoSe-Co to capture context better through identifying masked entity during path generation. We discuss and perform ablations to compare masked CoSe-Co with varying values of p_{mask} in §4.3.1. Separately, we discuss and observe that using GPT-2 as backbone LM for CoSe-Co performs similar to T5-base in Appendix B.

3.3 Path Decoding During Inference

As in most sequence generation tasks, teacher forcing is used to train the model, while a decoding strategy is used to generate diverse outputs during inference (Vaswani et al., 2017). To maximise contextual knowledge obtained from paths for each sentence in a downstream task, we generate multiple paths. To improve diversity between paths while not losing relevance, we implement a path-specific variant of beam search, *diverse-path search*. Diversity is ensured by sampling top-k most probable tokens at first generation step followed by decoding most probable sequence for each of them, thus returning k paths. This approach is motivated by observation that when generating a path, initial entity guide overall decoding of path.

4 Experiments and Evaluation

4.1 Implementation Details

We choose Wikipedia as the sentence corpus $\mathcal{C}$, and ConceptNet (Speer et al., 2017) as the knowledge graph $\mathcal{G}$. The subset of Wikipedia that we use comprises of ∼5M articles, from which we extract ∼92.6M sentences. ConceptNet comprises of ∼8 million nodes as concepts linked through 34 unique commonsense relations with ∼21 million links in total. We sample ∼28M paths that have a length $|p|$ in the range $l_1 = 2$ and $l_2 = 5$. We obtain a total of ∼290K sentence-path pairs. CoSe-Co is trained until validation loss across an epoch does not increase, with maximum number of epochs $= 5$. p_{mask} is set to 0.33 based on tuning on CSQA dev set and number of paths per sentence $k = 5$ during inference. AdamW optimizer (Loshchilov and Hutter, 2017) is used to train parameters with a learning rate of $5e-4$, weight decay of 0.01 and epsilon of $1e-8$ using a single A-100 GPU with batch-size 8 and 4 gradient accumulation steps.

4.2 Analysing Generated Paths

We analyse quality of generated paths on three aspects - *Relevance*, *Diversity* and *Novelty*, evaluated on test split of our sentence-path dataset. We estimate **Relevance** by treating each triple in generated

(a) **Relevance**: BLEU score of generated paths computed using ground truth paths

(b) **Diversity**: Compliment of fraction overlap between top-5 sampled paths.

Figure 3: Analysis and comparison of generated paths across different decoding strategies

Input	**CoSe-Co Outputs**

Table 1: Commonsense paths generated by CoSe-Co for questions in *CommonsenseQA* data. Potential answers observed in path itself are highlighted , context-enriching concepts are **coloured**.

and ground truth paths (for a given test sample) as one uni-gram followed by determining BLEU score (Papineni et al., 2002) between them. To estimate **Diversity**, we extract top-$k = 5$ paths for each sentence, consider each pair combination amongst them and estimate fractional overlap (intersection over union of set of path entities) between them. Compliment of overlap $(1 - overlap)$ followed by mean over entire test split conveys how diverse paths are. Figure 3 shows corresponding results. It is observed that paths generated using nucleus sampling are diverse but lack relevance, while an opposite trend is observed for top-k sampling. *Diverse-path search* provides best balance between relevance (0.436) and diversity (0.43). We estimate **Novelty** as a fraction of total entities in a generated path that are not present in any training path followed by averaging over test split. CoSe-Co attains a novelty of 23.28% which shows that good fraction of entities in generated path are novel. Further discussion on the quantitative analysis of generated paths can be found in appendix F. Table 1 shows a few examples of generated paths. CoSe-Co generates paths contextually relevant to question in addition to inferring novel entities.

4.3 Multi-Choice Question Answering

We perform multiple choice question answering on the CSQA dataset (Talmor et al., 2019). Here, a question is given with 5 answer choices and the model has to predict the correct one. As an example, consider a question 'Where could you see an advertisement while reading news?' with answer choices 'television, bus, email, web page, and la villa'. One of the prior works for this task - PGQA (Wang et al., 2020b), comprises of a knowledge module which generates commonsense and a QA module which identifies correct choice using this knowledge (see appendix D for details). Since our aim is not to design an improved QA module but a better commonsense generator, for fair comparison with PGQA, we use their QA module with CoSe-Co. The QA module embeds the question + choices using RoBERTa (Liu et al., 2019) and uses the CLS token output to perform attention over path embeddings generated using the commonsense module. The output of attention module together with embedding of question and answer choices is used to predict the correct answer.

Table 2 shows results on CSQA which are usually averaged over 5 runs on this benchmark. We compare against several baselines broadly classified into ones using static KG such as MHGRN (Feng et al., 2020), QA-GNN (Yasunaga et al., 2021) etc. and others which train a dynamic path generator (PGQA) (Wang et al., 2020b) as commonsense module. We also compare with T5-base since it is backbone LM for CoSe-Co.

Methods	20% Train **IHtest** (%)	60% Train **IHtest** (%)	100% Train **IHdev** (%)	 **IHtest** (%)
T5-base (w/o KG) (Raffel et al., 2019)	–	–	61.88 (±0.08)	57.34 (±0.21)
RoBERTa-large (w/o KG)	46.25 (±0.63)	52.30 (±0.16)	73.07 (±0.45)	68.69 (±0.56)
+ RGCN (Schlichtkrull et al., 2018)	45.12 (±0.69)	54.71 (±0.37)	72.69 (±0.19)	68.41 (±0.66)
+ GconAttn (Wang et al., 2019)	47.95 (±0.11)	54.96 (±0.69)	72.61(±0.39)	68.59 (±0.96)
+ KagNet (Lin et al., 2019)	–	–	73.47 (±0.22)	69.01 (±0.76)
+ RN (Santoro et al., 2017)	45.12 (±0.69)	54.23 (±0.28)	74.57 (±0.91)	69.08 (±0.21)
+ MHGRN (Feng et al., 2020)	–	–	74.45 (±0.10)	71.11 (±0.81)
+ PGQA (Wang et al., 2020b)	58.25 (±0.43)	69.66 (±0.97)	77.53 (±0.47)^{q}	71.19 (±0.49)
+ QA-GNN (Yasunaga et al., 2021)	59.08 (±1.25)	68.70 (±0.62)	75.54 (±0.42)	72.29 (±0.43)^{p}
+ CoSe-Co (**Ours**)	**61.20** (±0.19)^{p,q}	**70.23** (±0.40)^{q}	**78.15** (±0.23)^{p,q}	**72.87** (±0.31)^{p,q}

Table 2: Performance comparison on in-house dev (**IHdev**) and test (**IHtest**) split of ***CommonsenseQA*** dataset (Talmor et al., 2019). All scores are averaged across 5 runs. First row depicts amount of training data used. The second-best number for each column is underlined while best is in bold. Superscripts 'p' and 'q' denote statistically significant differences (***p-value* of 0.05**) in comparison to two of our baselines- PGQA and QA-GNN, respectively.

When using entire training data, we observe that CoSe-Co performs better than all baselines[2] on test set. We outperform PGQA with a gain of 1.68% in accuracy on test split signifying the relevance and applicability of inferences generated by CoSe-Co. CoSe-Co performs better than QA-GNN (Yasunaga et al., 2021) also particularly in low training data regimes with performance gains of $\sim$ 2% (and $\sim$ 3% over PGQA) showing that while QA-GNN is more sensitive towards amount of training data used, CoSe-Co is more robust and helps in generalizing better. Qualitatively, consider the question - 'Where could you see an advertisement while reading news?' PGQA generates the path - 'read_news *hassubevent* read *relatedto* news *atlocation* television' ignoring the context that advertisement is being seen along with reading news and ends up predicting television as answer which is wrong. While CoSe-Co generates - 'spread_information _*capableof* advertisement *atlocation* web_page *usedfor* reading_news'. Here it can be seen that CoSe-Co identifies that seeing the advertisement and reading news is happening together and generates path accordingly to relate them with 'web page' which is the correct answer. We also conduct a thorough qualitative comparison (appendix A) where we observe that evaluators find CoSe-Co paths to be significantly more contextually relevant than PGQA.

We conduct a **human study** wherein we presented evaluators with questions from CSQA dataset with corresponding commonsense paths generated by CoSe-Co and PGQA in an anonymized manner to compare the generative commonsense methods. We asked them to compare the paths based on their contextual relevance with the complete sentence and classify them into one of three categories - 1) 'CoSe-Co is better than PGQA', 2) 'PGQA is better than CoSe-Co', 3) 'Both are of the similar quality'. A total of 150 questions samples were randomly sampled from the test set and presented to 6 evaluators (25 samples each). Following are our observations:

- Number of samples where CoSe-Co is better: 62 (41.33% of 150 samples)
- Number of samples where PGQA is better: 38 (25.33% of 150 samples)
- Number of samples where both are of similar quality: 50 (33.33% of 150 samples)

This shows that commonsense generated by CoSe-Co is found to be more relevant in human evaluation. Also, if we exclude neutral samples and consider the 100 samples where the commonsense paths generated by one of either approach is found to be better, CoSe-Co's paths are found to be more relevant in 62 samples (62% of 100 samples) while PGQA's paths are more relevant in 38 samples (38% of 100 samples).

We also study the effect of using a different generative LM (GPT-2 as used by PGQA) as backbone for CoSe-Co in appendix B and empirically

---

[2] Results for PGQA and QA-GNN are reproduced using their official open-source implementations while numbers for other baselines have been taken from these two works.

Entity masking for training		Query template for path-sentence		Entity masking for inference	
p_{mask}	IHdev (%)	Query	IHdev (%)	Type	IHdev (%)
0.0	77.52 (±0.44)	$Q1$	77.69 (±0.43)	*Interrogative*	78.07 (±0.56)
0.50	77.38 (±0.40)				
0.67	77.61 (±0.79)	$Q2$	77.25 (±0.64)	*Random*	77.90 (±0.84)
1.0	77.71 (±1.17)				
0.33	**78.15** (±0.23)	**Q1 + Q2**	**78.15** (±0.23)	**No Masking**	**78.15** (±0.23)

Table 3: Studying the effect of ablation variants through comparison on *CommonsenseQA* dev set.

establish that performance gains over PGQA are independent of which LM is used.

4.3.1 Ablation Study

Entity masking during training As described in §3.2, a parameter p_{mask} is used to decide whether entities in an input sentence will be masked. We tune p_{mask} over the CSQA IHdev set and determine 0.33 as optimal value. Table 3 shows comparison where masking during training works better than not masking. We show qualitative analysis for different p_{mask} in appendix C. Further, $0 < p_{mask} < 1$ ensures trained CoSe-Co can be used for both masked and unmasked inputs.

Path-sentence query templates As described in §3.1, we used two query templates—$Q1$ (includes relation information) and $Q2$ (does not capture relations)—while creating our path-sentence paired dataset. Here we study the effect of using these different query templates (Table 3). We observe that training CoSe-Co on a combined dataset, $Q1 + Q2$, results in the best performance, followed by that on using $Q1$ alone, that further outperforms $Q2$. This indicates the influence of including relation information in the training dataset.

Entity masking during inference Since CoSe-Co is given a masked sentence as input during training ($p_{mask} = 0.33$), we explore the effect of similar type of masking during inference. Specifically, certain parts of input sentence can be replaced with masked token to enable CoSe-Co to generate paths that lead towards filling the mask. As reported in Table 3, the variant where no masking is done performs marginally better than when *Interrogative* or *Random* tokens in sentence are masked. Thus, by default we do not perform masking during inference unless otherwise stated.

4.4 OpenCSR: Open-Ended CommonSense Reasoning

In CSQA, often multiple choices are appropriate and model gets penalised unfairly if it predicts suitable answer which does not match with single ground truth. To mitigate this, Lin et al. (2019) re-configured three multi-choice QA datasets for OpenCSR as a generative task where interrogative tokens are replaced with blanks ("_ _") and a set of singleton tokens is labeled as ground truth. To generate a set of paths P, we use inference masking variant of CoSe-Co since question contains a blank. Given a question q, blank ("_ _") is replaced with mask token. To inject our paths, we devise a supervised method where we adapt a separate T5-base model for OpenCSR such that concatenation of q and paths is given as input to T5 along with the prefix '*fill mask to answer question:* '. T5 is trained to generate one of the answers in ground truth set. During inference, top-K answers, determined on basis of generation likelihood from T5 decoder, are taken as answer candidates.

Table 4 shows comparison between DrFact[3] (Lin et al., 2021a) (current state-of-the-art based on BERT-base) and our supervised method which uses CoSe-Co's paths. Specifically, we evaluate - 1) 'Paths from CoSe-Co' where generated paths are concatenated; and 2) 'Concepts from CoSe-Co' where only entities in generated paths are appended. Since our supervised method is based on pre-trained T5, for fair comparison and to probe if performance changes are due to T5, we compare against another baseline: T5-base fine tuned for OpenCSR without paths. We evaluate two metrics as used in Lin et al. (2021a): 1) **Hits@K**: Determined on basis of whether generated and ground truth answer sets have non-empty intersection; 2) **Recall@K**: Estimates how many predicted answers match at least one ground truth answer. We vary value of K to be {10, 30, 50}. We evaluate on three datasets - ARC (Clark et al., 2018), QASC (Khot et al., 2020), and OBQA (Mihaylov et al., 2018).

CoSe-Co performs significantly better than

---

[3] The authors communicated that the test set and leader board has not been released yet. Hence, we report results using the author provided code and validation set. Also, they run their models on single seed.

	ARC			**QASC**			**OBQA**

Table 4: Performance comparison on Hits@K and Recall@K metrics for OpenCSR (Lin et al., 2021a) on ARC, QASC and OBQA datasets. DrFact is a BERT-based current state of the art method.

both baselines on all datasets uniformly. Specifically, 'Concepts from CoSe-Co' usually performs better which shows entities in paths generated by CoSe-Co are useful. Our approach provides performance gains of upto 8%, 6%, 10% in Hits@50 and 8%, 3%, 6% in Recall@50 over DrFact on ARC, QASC and OBQA respectively. Even though T5-base baseline performs better than DrFact, commonsense from CoSe-Co augmented with T5 achieves new state of the art on this task with performance gains upto 2.3%, 3.9%, 7.5% in Hits@50 and 1.2%, 2.5%, 3.7% in Recall@50 over T5-base on ARC, QASC and OBQA respectively.

4.5 Effect of Concatenating CoSe-Co Knowledge in Generation Task

We explore augmenting CoSe-Co paths for text generation where our aim is not to obtain SOTA results but to analyse if it improves performance of a base model. Specifically, we study Paraphrase Generation: given a sentence, generate another sentence expressing same meaning using different words where commonsense is usually needed while rephrasing. Since T5 (Raffel et al., 2019) is designed for generation tasks, we fine-tune T5-base to generate annotated paraphrase given a sentence as input on MRPC dataset (Dolan and Brockett, 2005). Generated paths are appended as string to input. Please refer to appendix E.4 for elaborated implementation details and discussion.

	MRPC Paraphrase Generation				
	BLEU-4	METEOR	ROUGE-L	CIDEr	SPICE
T5-base	43.10	36.10	61.80	36.33	47.10
+ CoSe-Co Paths	**44.50**	**36.70**	**62.50**	**37.34**	**48.50**

Table 5: Using CoSe-Co Paths leads to improvements in paraphrase generation task on MRPC dataset. Generative commonsense methods like PGQA which rely on answer choices cannot be applied in tasks like paraphrase generation where entities are not available.

Table 5 summarises results evaluated through commonly used generation metrics - BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE-L (Lin, 2004), CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016). Amongst these, SPICE is considered to correlate most with human judgement. Using CoSe-Co paths results in better paraphrase generation as indicated by ∼1-1.5% improvement in most metrics.

5 Conclusion

We presented CoSe-Co, a framework to generate commonsense inferences that are relevant to the overall context of a given natural language text. We created a novel dataset of <sentence, commonsense paths> pairs for training CoSe-Co and make it available to the community[4]. Empirical evaluation shows that commonsense inferences generated by CoSe-Co are relevant, diverse, and also contain novel entities not present in KG. We augment knowledge generated by CoSe-Co in commonsense tasks such as Multi-Choice QA and Open-ended CommonSense Reasoning, achieving SoTA results for these tasks. Further, we also used CoSe-Co for NLP tasks such as paraphrase generation achieving improved performance. While, using ConceptNet as our base KG allowed us to perform an exhaustive fair comparison with a variety of benchmark methods—where the motivation is to provide more relevant knowledge (in symbolic form as in KG) to tasks—CoSe-Co can further be enhanced by utilizing other commonsense KGs. Our work can be extended to explore better ways of integrating the generated knowledge generically across a variety of KGs and LMs, and is a potential direction for future work.

A Qualitative Comparison

Table 7 shows qualitative comparison between CoSe-Co and baselines on the CSQA dataset.

B Comparison with GPT-2 as backbone language model

We decided to use T5-base as a design choice as we were required to train a text-to-text model where given a sentence as input, the model has to generate the relevant path as output. Since T5-base is a text-to-text generation language model, we felt that it is a suitable choice.

Methods	100% Train **IHdev** (%)	 **IHtest** (%)
RoBERTa-large (w/o KG)	73.07 (±0.45)	68.69 (±0.56)
+ PGQA w/ GPT-2	77.53 (±0.47)	71.19 (±0.49)
+ CoSe-Co w/ GPT-2	77.90 (±0.37)	72.67 (±0.18)
+ PGQA w/ T5-base	77.56 (±0.32)	71.31 (±0.44)
+ CoSe-Co w/ T5-base	78.15 (±0.23)	72.87 (±0.31)

Table 6: Performance comparison between using T5-base and GPT-2 as backbone language model for PGQA and CoSe-Co for multi-choice QA task on CSQA dataset.

To empirically establish that improvements over PGQA are not due to using T5-base instead of GPT-2, we performed an experiment to replace T5-base with GPT-2 as the backbone language model of CoSe-Co. We train GPT-2 using the same sentence-path dataset as we used for T5-base by providing it as input the sentence followed by a [SEP] token and adapting GPT-2 to generate the corresponding path. Additionally, we also experiment with replacing the language model in PGQA from GPT-2 to T5-base. Table 6 summarises the results obtained for multi-choice QA on CSQA where it can be seen that using GPT-2 vs T5 does not lead to noticeable changes in the performance. The test accuracy attained by CoSe-Co with T5-base is 72.87% which is almost the same as for CoSe-Co with GPT-2: 72.67%. A similar observation is seen for PGQA where using T5-base backbone gives 71.31% and using GPT-2 gives 71.19%. Further, we would like to highlight that CoSe-Co with GPT-2 backbone attains 72.67% accuracy and performs better than PGQA with GPT-2 (71.19%).

Based on these observations, we can conclude that performance gains of CoSe-Co over PGQA are not due to using different backbone but because CoSe-Co is trained over semantically related sentence-commonsense pairs that enables it to generate contextually more relevant commonsense.

C Entity masking while training CoSe-Co

Table 8 shows the various kinds of paths obtained from CoSe-Co when trained with different values of p_{mask}, across the same original question. A number of observations can be made. First, the paths obtained from the variant which is trained without any masking ($p_{mask} = 0.0$) produces inferences that enrich the overall context of certain entities in question but do not necessarily capture the inter-relation between them and thus the overall intention of the question. With the configurations that are trained with $p_{mask} \neq 0$, the various paths capture the overall context in an answer-oriented manner. These configurations also allow us to mask concepts in the original question such that CoSe-Co can exploit the unmasked entities to direct its generated paths in a manner that best suit the blank. This is evident from the second half of Table 8. When the interrogative element is masked in the first example, the paths are directed towards actually finding the best answer, while when 'Google maps' is replaced in the third example, the paths are clearly focused on predicting concepts related to GPS systems.

D Details of PGQA Baseline

PGQA (Wang et al., 2020b) leverages the commonsense paths generated by their path generator

Question	Predictions			Generated Paths

Table 7: Comparison between predictions made by PGQA (Wang et al., 2020b), QA-GNN (Yasunaga et al., 2021), and CoSe-Co on a subset of CSQA's in-house test set (Talmor et al., 2019). Commonsense paths that are responsible for the corresponding predictions are also given for both the path-based models. Underlined portions represent the meaningful path sub-structures which direct the overlying model towards the correct answer.

module along with the question and candidate answer choices to perform multi-choice QA on CSQA dataset (Talmor et al., 2019). Specifically, given a question q with corresponding candidate answer choices set $C = \{c_1, \ldots, c_n\}$, the PGQA framework generates commonsense inferences for each pair of answer choice c_i and entities extracted from q. A total of k paths corresponding to each answer choice c_i are obtained to get a resultant set of paths - P_{q-c_i}. Further, an average over the hidden representations corresponding to sequence of decoded tokens from the final layer of their path generator decoder are used as path embedding and combined as - $H_S \in R^{k \times h_D}$ to represent the paths in P_{q-c_i}. Following this, they augment the choice into q by replacing the interrogative phrase in q with c_i to obtain q'. For instance, given the question 'Google maps and other GPS services have replaced what?', the answer choice 'atlas' is augmented into the question as: 'Google maps and other GPS services have replaced *atlas*.'

To embed the augmented question and corresponding answer choice, they use a pre-trained LM encoder E (such as RoBERTa (Liu et al., 2019)) to embed the query - '[CLS] q' [SEP] c_i' corresponding to c_i. The representation corresponding to [CLS] token is extracted from the final hidden layer as $h_{US} \in R^{h_E}$. In order to leverage relevant knowledge from the generated commonsense inferences, the question and choice embeddings are used to attend over generated paths as:

$$\alpha_p = Softmax(tanh(H_S W^A) h_{US})$$

$$h_{S'} = \sum_{h \in H_S} \alpha_p^h \cdot h$$

where, $W^A \in R^{h_D \times h_E}$, $\alpha_p \in R^k$ and $h_{S'} \in R^{h_D}$. Finally, a linear layer is applied over the concatenation of $\{h_{US}, h_{S'}\}$ to project it as a scalar. A softmax is taken over concatenation of scalars obtained corresponding to each answer choice to obtain their likelihood followed by cross entropy loss for training.

E Further Implementation Details

E.1 Relation Heuristics

As mentioned in §3.1, we employ heuristics on the basis of contained relations to perform filtering of ConceptNet paths. Particularly, we use the following rules:

Input	**CoSe-Co Variant**	**CoSe-Co Outputs**
Google maps and other GPS services have replaced what?	$p_{mask} = 0.0$	(orienteering *_usedfor* map *_isa* **navigation** *_hascontext* GPS *_product* gsrc) (satellite_gear *hascontext* maps *capableof* **help_find_places** *_usedfor* map_store_in_city) (similar_to_gps *_hasproperty* google *hascontext* maps *capableof* **show_live_places**) (geospatial *_isa* navigation *_usedfor* google *hascontext* maps *capableof* show_people_places)
Google maps and other GPS services have replaced what?	$p_{mask} = 1.0$	(gps *hascontext* **navigation** *_usedfor* satellite *atlocation* orbital_stations_in_space) (satellite_navigation *_usedfor* compass *capableof* **point_north** *_hassubevent* **driving_car**) (navigation *_usedfor* satellite *_isa* gps *hascontext* navigation *_entails* competition) (**location_where_go**_gallery *_definedas* navigation *_usedfor* satellite *_hascontext* gps)
Google maps and other GPS services have replaced what?	$p_{mask} = 0.5$	(compass *_isa* google_maps *usedfor* **navigation** *_hascontext* gps *isa* navigating_map) (**location_where_go_camping** *_isa* location *_usedfor* map _product google_maps) (satellite_gear *_isa* GPS *usedfor* navigation *_hascontext* gps *isa* navigating_map) (navigation_maps *_usedfor* map *_isa* navigation_map *hascontext* navigation)
Google maps and other GPS services have replaced what?	$p_{mask} = 0.33$	(orienteering *_usedfor* maps *_isa* google_maps *_hasprerequisite* looking_through_telescope) (**location_where_go_shopping** *_definedas* where_go_shopping *_usedfor* map) (navigation_maps *_isa* maps *_usedfor* satellite *locatednear* planet) (satellite_navigation *_usedfor* maps *_hascontext* google_maps *capableof* show_locations)
Google maps and other GPS services have replaced [MASK].	$p_{mask} = 0.33$	(gps *hascontext* maps *_usedfor* satellite *locatednear* planet) (navigation_maps *isa* navigation *_usedfor* compass *capableof* **point_north_handle**) (satellite_navigation *_usedfor* compass *capableof* point_north_or_south_hemispheres) (location_where_go_if_near_beach *_definedas* map *usedfor* navigation *_mannerof* sport)
Google maps and other GPS services have [MASK] what?	$p_{mask} = 0.33$	(orienteering *_usedfor* map *_isa* google_maps *_hascontext* gps) (**location_where_go_if_need_to** *_definedas* location *_isa* map *usedfor* **information**) (located_in_latin_america *_receivesaction* israel *_language* latin_america) (navigation_maps *usedfor* find_place *_hasprerequisite* go_to_market) (satellite_navigation *_usedfor* maps *capableof* **show_locations_and_routes**)
[MASK] and other GPS services have replaced what?	$p_{mask} = 0.33$	(navigation_system *_isa* GPS *hascontext* astronomy *_field* edmond_halley) (location_where_go_if_in_accident *_usedfor* map *_atlocation* GPS_systems) (**radio_frequency_messaging** *_isa* GPS *hasproperty* useful) (receiver *partof* radio *_isa* gps *hascontext* navigation *_usedfor* compass)

Table 8: Examples of commonsense inferences obtained for different input forms of the same question from CoSe-Co when trained with different values of p_{mask}. Potential answers which are observed in a path are highlighted , while context-enriching concepts are **coloured**.

1. We discard any path that uses the same two relations to connect any three neighbouring entities occurring in it. That is, for any sub-path $\{e_i, r_i, e_{i+1}, r_{i+1}, e_{i+2}\}$ in a given path p, we only consider p as a part of our dataset if $r_i \neq r_{i+1}$.

2. Following (Wang et al., 2020b), we do not consider paths that contain any relations from the set {*HasContext*, *RelatedTo*, *Synonym*, *Antonym*, *DerivedFrom*, *FormOf*, *EtymologicallyDerivedFrom*, *EtymologicallyRelatedTo*}. We observed that entities connected through these relations were often largely dissimilar and thus not useful for our case.

E.2 Multi-Choice QA

In §4.3, we discuss commonsense question answering task where we use framework developed by Wang et al. (2020b) and just replace the commonsense knowledge used by them with the paths generated by CoSe-Co. We use the same hyper-parameters as used by them and mention them here for reference. The model is trained on a batch size of 16, dropout of 0.1 for 15 epochs. A learning rate of 2e-6 is used for encoder LM (Roberta-large) used for embedding question and choice context and an lr of 1e-3 is used for remaining path attention and classification layer parameters. We perform the evaluation on CSQA (Talmor et al., 2019) dataset downloaded from here. The train split comprises of 8,500, dev split contains 1,221 and in-house test split contains 1,241 samples.

E.3 OpenCSR

In this section, we discuss the implementation details used for OpenCSR in §4.4. The dataset has been downloaded from here. The training splits of ARC, QASC, and OBQA datasets comprises of 5355, 6883, and 4199 samples respectively while the development split comprises of 562, 731, and 463 samples respectively. The test set is hidden and authors who proposed the task with reformulated dataset are yet to set up a leaderboard on the hidden test set. They run their proposed model DrFact (which is based on BERT-base and is the current state-of-the-art on this task) on a single seed which takes about ∼2-3 days to train one model on a given dataset. While fine-tuning T5-base (with and without CoSe-Co knowledge), we train the model for 5 epochs with a learning rate of 5e-4, weight decay of 0.01 and batch size 8 using AdamW optimizer (Loshchilov and Hutter, 2017).

E.4 Paraphrase Generation

For paraphrase generation on MRPC (Dolan and Brockett, 2005) dataset, we fine-tune T5-base (with and without CoSe-Co knowledge) at a learning rate of 5e-4 for 5 epochs with weight decay of 0.01 and 4 gradient accumulation steps using AdamW (Loshchilov and Hutter, 2017) optimizer. The training set of MRPC comprises of 2,661 paraphrases while the test set comprises of 1,088 paraphrases. The dataset has been downloaded from here.

F Further Analysis of Generated Paths

- **Correctness of Novel Triples** : Since there is no ground truth to check the correctness of triple comprising of novel entities, we attempt to evaluate them by leveraging a commonsense knowledge base completion model - Bilinear AVG (Li et al., 2016) which has been shown to achieve an accuracy of 92.5% on knowledge completion task and is also used to score triples. We extract triples comprising of at least one novel entity from the paths generated by CoSe-Co for the test split of sentence-path dataset and provide the triple to Bilinear AVG to obtain a score. The average score over all the triples is 0.414 (on a scale of 0 to 1).

- Further, we perform KG completion (predicting tail entity given head entity and relation of a KG triple) using CoSe-Co since it generates paths which essentially comprise of triples. We compare the performance with COMET (Bosselut et al., 2019). We consider test split of sentence-path dataset comprising of $11,264$ paths and extract triples. We filter out triples appearing in training paths of CoSe-Co and train set triples of COMET yielding 717 test triples in total. CoSe-Co achieves an accuracy of 24.12% which is significantly better than COMET which provides accuracy of 9.76%. To perform comparison with COMET (Bosselut et al., 2019) we take their code and pre-trained model from here.

- In Figure 3(b), greedy decoding cannot be compared for diversity with other methods since it generates only a single unique path.

- Since generated paths diversity estimates can be affected by path length, we measure the standard deviation of the number of entities in paths generated corresponding to test split sentences and found it to be 0.76 which shows that variance in the lengths of generated paths is very low (<1) and hence, the diversity of 0.43 (on a scale 0 to 1) attained by CoSe-Co is not due to length bias.

G Ethics statement

- The sentence - commonsense dataset created to train CoSe-Co has been derived using standardized Wikipedia Corpus and ConceptNet knowledge graph which are publicly available and commonly used without containing any info/text that could potentially lead to risk impacts.

- We have used open source Wikipedia corpus and ConceptNet which are publicly available and already standardized for research works.

- The links to all the previous works, their provided open-source github repos, artifacts and datasets have been provided in appropriate sections where they are discussed/used/compared along with their citations (Sections - 2, 4, Appendix E etc.). The links to any resources used provide permissions to use them for our research work.

Probing via Prompting

Jiaoda Li Ryan Cotterell Mrinmaya Sachan

ETH zürich

Abstract

Probing is a popular method to discern what linguistic information is contained in the representations of pre-trained language models. However, the mechanism of selecting the probe model has recently been subject to intense debate, as it is not clear if the probes are merely extracting information or modeling the linguistic property themselves. To address this challenge, this paper introduces a novel model-free approach to probing, by formulating probing as a prompting task. We conduct experiments on five probing tasks and show that our approach is comparable or better at extracting information than diagnostic probes while learning much less on its own. We further combine the probing via prompting approach with attention head pruning to analyze where the model stores the linguistic information in its architecture. We then examine the usefulness of a specific linguistic property for pre-training by removing the heads that are essential to that property and evaluating the resulting model's performance on language modeling.

https://github.com/rycolab/probing-via-prompting

1 Introduction

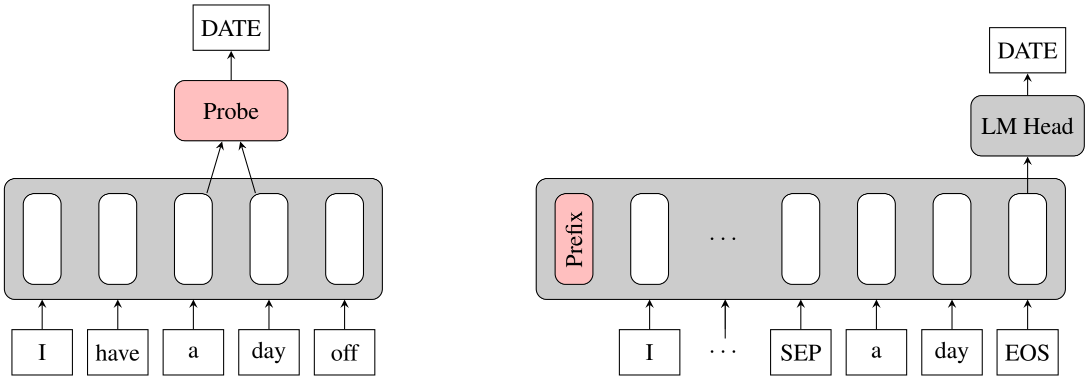
Pre-trained language models such as BERT (Devlin et al., 2019), GPT-2 (Radford et al., 2019), and GPT-3 (Brown et al., 2020) have increased the performance of data-driven natural language processing (NLP) models on a wide variety of tasks. Due to their strong performance on many language-based tasks that require some linguistic understanding, it is natural to hypothesize that the models must implicitly encode some linguistic knowledge. One avenue of research that attempts to uncover the linguistic knowledge encoded in these models is called probing (Conneau et al., 2018; Alain and Bengio, 2018; Tenney et al., 2019b; Saleh et al., 2020). A common form of probing is diagnostic probing. Under this approach a classifier is trained on top of a pre-trained language model to perform a target linguistic task, which is closely related to the linguistic property in question. The predictive accuracy of the classifier is then taken as an indicator of how much knowledge about the target linguistic property is encoded in the language model representations.

However, diagnostic probing has its limitations. An inherent challenge in the endeavor is discerning what is encoded in the pre-trained representations from what is learned by the probe itself (Zhang and Bowman, 2018; Hewitt and Liang, 2019; Pimentel et al., 2020a; Cao et al., 2021). The probe could, in principle, learn the task on top of random representations. While the probe is trained to extract linguistic properties from the representations, there is no simple way to restrain the probe from learning the task on its own during training. Previous research tackles the challenge using random model baselines (Zhang and Bowman, 2018) and control tasks (Hewitt and Liang, 2019; Pimentel et al., 2020a). Cao et al. (2021) try to create a more selective probe using pruning.

In this work, we address the above limitation with a novel probing framework that we call **probing via prompting** (PP). Drawing inspiration from recent work on prompting (Brown et al., 2020; Liu et al., 2021), we reformat a suite of probing tasks into question–answer pairs and instruct the model to answer the questions with a prefix (Li and Liang, 2021). In effect, prompting acts as a model-free probe. Thus, the use of prompting instead of a diagnostic probe allows us to work around the dilemma of teasing apart what the representations contain versus what the probe learns.

In the empirical part of the paper, we conduct experiments on five linguistic tasks and show that all these properties are indeed encoded in the popular pre-trained language model, GPT-2.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1144 - 1157
July 10-15, 2022



(a) Diagnostic probing (DP). It trains a probe on top of the contextual representations of the entity span ("a day") to predict the label ("DATE").

(b) Probing via prompting (PP). We reformulate named entity labeling into an LM task by concatenating the given span ("a day") with the sentence. We then use a prefix to instruct the model to predict the label ("DATE").

Figure 1: Illustration of different probing paradigms. Here, we show an example of named entity labeling: classifying a given entity span into pre-defined categories.

Furthermore, we show that probing via prompting appears to lead to insightful probing results. In the language of Hewitt and Liang (2019), PP obtains high selectivity, i.e., the results show high accuracy on the target task, but, as expected, PP does not work well with random representations. These results suggest that PP learns little information on its own and the extracted linguistic properties are indeed encoded in the model.

At a high level, this work takes the position that model-free probing methods such as PP are useful for accurately and faithfully locating and identifying the linguistic properties embedded in these representations and helping us understand how neural language models process text. In contrast to diagnostic probes, which require designing random model baselines and control tasks to control for the learning ability of the probe model, model-free probes like PP are less capable of learning the linguistic task themselves, and thus can naturally be more selective than diagnostic probes.

2 Probing via Prompting

We now introduce our probing via prompting framework (PP), illustrated in Fig. 1b.

2.1 Language Models

Let p be a language model with vocabulary Σ. In the case of an autoregressive language model,[1] p is defined as a distribution over Σ^* that is locally normalized, i.e., for any $\boldsymbol{w} \in \Sigma^*$ we decompose $p(\boldsymbol{w})$ according to the chain rule as follows:

$$p(\boldsymbol{w}) = p(w_1) \cdot \prod_{i=2}^{|\boldsymbol{w}|} p(w_i \mid \boldsymbol{w}_{<i}) \qquad (1)$$

Each "local" distribution $p(w_i \mid \boldsymbol{w}_{<i})$ is defined over Σ. Traditionally, language models include an EOS symbol; this means they produce a distribution over (an infinite number of) finite strings.

In this work, we focus on the case when p is a Transformer-based language model (Vaswani et al., 2017)—specifically, we take p to be an instance of GPT-2 (Radford et al., 2019). In contrast to most language models, GPT-2 dispenses with the EOS symbol and therefore yields a distribution over infinite strings.[2] As it will be necessary for later discussion, we further introduce notation to discuss the internal workings of the Transformer. We denote the layer activations $A^{(0)}, \ldots, A^{(L)}$, where L is the total number of layers; the 0th layer corresponds to the embedding layer. Here, $A^{(\ell)} = \left[\mathbf{a}_0^{(\ell)}, \ldots, \mathbf{a}_{|\boldsymbol{w}|}^{(\ell)}\right]$ denotes the activation matrix of the ℓth layer and $\mathbf{a}_i^{(\ell)}$ is the activation vector for the token at position i. The activation at the last layer is used to compute the distribution for the next token:

$$p(w_{i+1} \mid \boldsymbol{w}_{\leq i}) = \operatorname{softmax}(W\, \mathbf{a}_i^{(L)}) \qquad (2)$$

where W is a matrix that maps activations to logits over the vocabulary.

2.2 Edge Probing via Prompting

The edge probing framework (Tenney et al., 2019a,b) decomposes many common structured-

---

[1] Such language models are often called causal language models to differentiate them from cloze language models.

[2] This yields a distribution over the ω language Σ^ω.

Task	Context	Target Label
POS	$\boldsymbol{x}$ SEP brand EOS	NN
Const.	$\boldsymbol{x}$ SEP is a global brand EOS	VP
Entity	$\boldsymbol{x}$ SEP Disney EOS	ORG
SRL	$\boldsymbol{x}$ SEP is SEP The important thing about Disney EOS	ARG1
Coref.	$\boldsymbol{x}$ SEP Disney SEP it EOS	True

Table 1: Example prompt and target label for each task. $\boldsymbol{x}$ =“The important thing about Disney is that it is a global brand.” The continuous prefix is neglected for simplicity.

prediction tasks into a common format of multi-class classification. In an edge probing task, a sentence $\boldsymbol{x} \in \Sigma^*$ and spans[3] $\boldsymbol{s}_1, \boldsymbol{s}_2$ in $\boldsymbol{x}$ are provided as inputs, and the goal is to select a correct label y among a set of candidate labels $\mathcal{Y}$. We have intentionally kept the definition of $\mathcal{Y}$ abstract because it is task-specific. E.g., in named entity labeling, $\mathcal{Y}$ will be a set of entity types, whereas in semantic role labeling $\mathcal{Y}$ will be a set of semantic roles.[4]

Now we introduce how to perform edge probing via prompting. We follow the naming convention of Schick and Schütze (2021a) and begin describing our prompting approach by introducing a pattern–verbalizer pair.

Pattern. We convert $\boldsymbol{x}, \boldsymbol{s}_1, \boldsymbol{s}_2$ into a string, called the **pattern**, as follows

$$\boldsymbol{p} = \boldsymbol{x} \circ \text{SEP} \circ \boldsymbol{s}_1 \circ \text{SEP} \circ \boldsymbol{s}_2 \circ \text{EOS} \qquad (3)$$

where $\circ$ is string concatenation. Note that now $\boldsymbol{p} \in (\Sigma \cup \{\text{SEP}, \text{EOS}\})^*$.

Verbalizer. Next, we define a **verbalizer** function $\texttt{vb} : \mathcal{Y} \to \Sigma$ that maps each label to a token.[5] In our implementation, we introduce a distinguished symbol $\text{CLS}[y]$ for each label y. Thus, our verbalizer becomes $\texttt{vb} : \mathcal{Y} \to \{\text{CLS}[1], \ldots, \text{CLS}[|\mathcal{Y}|]\}$, where $|\mathcal{Y}|$ is the number of candidate classes.

Inference. Now we augment the language model p such that every conditional probability is over $\Sigma \cup \{\text{SEP}, \text{EOS}, \text{CLS}[1], \ldots, \text{CLS}[|\mathcal{Y}|]\}$ (instead of just Σ), so we expand W correspondingly to incorporate the enlarged vocabulary. The newly added rows in W and the embeddings of the newly added symbols are both randomly initialized from a normal distribution with a mean of 0 and a variance of 0.02 and not updated during training. To make a prediction, we select the class whose verbalizer has the highest next-token probability:

$$\widehat{y} = \underset{y' \in \mathcal{Y}}{\operatorname{argmax}}\, p\left(w_{|\boldsymbol{p}|+1} = \texttt{vb}\left(y'\right) \mid \boldsymbol{w}_{\leq |\boldsymbol{p}|}\right) \qquad (4)$$

This completes our formalization of edge probing as prompting.

2.3 Prefix Tuning

To better instruct the language model to perform the target task, we prepend the pattern $\boldsymbol{p}$ with a **prefix** that is task-specific and independent of $\boldsymbol{x}$, $\boldsymbol{s}_1$ and $\boldsymbol{s}_2$. Intuitively, we aim to steer a pre-trained language model to generate predictions using an instructive prefix. For instance, a prefix for named entity labeling could be an additional string in Σ^*, e.g., “classify the named entity into the following categories: person, organization …” However, in preliminary experiments, we found that discrete prefixes perform poorly on GPT-2—the prime object of our study in this paper.[6] Thus, we resort to a continuous prefix (Li and Liang, 2021). The technical details of performing continuous prefix tuning in the case of a Transformer language model are given in App. A.

3 Experiments

We empirically benchmark our pruning method against several previously proposed works.

3.1 Tasks

We experiment on five tasks derived from OntoNotes 5.0 (Weischedel et al., 2013): part-of-speech tagging (POS), constituent labeling

---

[3] Spans are contiguous substrings.

[4] The span $\boldsymbol{s}_2$ is to be omitted for single-span tasks such as entity labeling.

[5] While one might think that an easy solution is to directly use category names as verbalizers, category names in edge probing tasks are often out-of-vocabulary words (e.g., ARG0) that have to be decomposed into multiple sub-tokens. Thus, it is easier to simply introduce new symbols into the vocabulary for each class label.

[6] This replicates the findings of Li and Liang (2021), who also found that discrete prefixes performed poorly when applied to GPT-2 and BART; in their report, GPT-3 was the only exception.

(const.), named entity labeling (entity), semantic role labeling (SRL), and coreference (Coref.). They are simplified versions of the original tasks in OntoNotes that are made compatible with the edge probing framework. An example for each task is shown in Tab. 1.

3.2 Diagnostic Probing

We compare PP with diagnostic probing (DP), and consider two types of diagnostic probes: a logistic regression probe (LR) and a multilayer perceptron probe (MLP). The idea behind diagnostic probing is illustrated in Fig. 1a. In this paper, we train a DP to predict a label $y \in \mathcal{Y}$ for the given span(s) $\boldsymbol{s}_1$ (and optionally $\boldsymbol{s}_2$) of a sentence $\boldsymbol{x}$, taking the contextual representations of the span(s) produced by the pre-trained model as inputs.

3.2.1 Contextual Representations.

DP takes a single vector as input, which represents the span(s) of interest under the context of the sentence. In this section, we introduce how to obtain such a vector from a pre-trained model. For an input sentence $\boldsymbol{x}$ of length $|\boldsymbol{x}|$, we again denote the layer activations produced by the language model as $A^{(0)}, \ldots, A^{(L)}$ and $A^{(\ell)} = \left[\mathbf{a}_0^{(\ell)}, \ldots, \mathbf{a}_{|\boldsymbol{x}|}^{(\ell)}\right]$. Following Peters et al. (2018a), we pool the representations of the different layers into a **scalar-mixed representation** as follows. We define the matrix $A = \left[\mathbf{a}_0, \ldots, \mathbf{a}_{|\boldsymbol{x}|}\right]$ with $\mathbf{a}_i$ computed thusly:

$$\mathbf{a}_i = \sum_{\ell=1}^{L} n_{\text{MLP}}(\ell) \cdot \mathbf{a}_i^{(\ell)} \tag{5}$$

where n_{MLP} is a distribution over the layers $\{1, \ldots, L\}$ that is learned during training.[7] In case a span consists of multiple tokens, the per-token vectors (either the scalar-mixed vector $\mathbf{a}_i$ or the last layer activation $\mathbf{a}_i^{(L)}$) are combined into a span representation using self-attention pooling (Lee et al., 2017). If more than one span exists, the span representations are concatenated into one.

3.2.2 Baselines

DP (LR). The first diagnostic probe we consider is a multinomial logistic regression probe that resembles the classification head in Cao et al. (2021). Following Cao et al. (2021), we compute the span representations using the activations $A^{(L)}$ from the last layer. The span representations are directly fed into a linear layer followed by a softmax output layer.

Task	Method	Pre-trained	Random
POS	PP	**94.28**	**13.14**
	DP (MLP)	94.01	47.89
	DP (LR)	89.56	38.84
	Majority	12.58	
	Chance	2.08	
Const.	PP	**86.66**	**35.98**
	DP (MLP)	82.09	45.24
	DP (LR)	71.32	42.67
	Majority	35.66	
	Chance	3.33	
Entity	PP	**93.81**	**15.91**
	DP (MLP)	88.43	35.87
	DP (LR)	87.81	29.81
	Majority	15.91	
	Chance	5.56	
SRL	PP	**85.46**	**33.36**
	DP (MLP)	84.13	53.05
	DP (LR)	77.43	47.99
	Majority	33.36	
	Chance	1.52	
Coref.	PP	**90.54**	**78.33**
	DP (MLP)	87.05	**78.33**
	DP (LR)	81.21	**78.33**
	Majority	78.33	
	Chance	50.00	

Table 2: Accuracy (%) for pre-trained GPT-2 (Pre-trained) and random GPT-2 (Random).

DP (MLP). The second diagnostic probe we consider is the MLP probe introduced by Tenney et al. (2019b). Here, we use the scalar-mixed representations of A to compute span representations, which are then fed into an MLP followed by a softmax output layer.

Majority. Some tasks are highly imbalanced. For instance, over one third of the constituents (Const.) in the training set are adjective phrases (ADJP). Therefore, for reference, we implement a majority baseline that always predicts the most frequent class.

---

[7] Note that we ignore the 0$^{\text{th}}$ layer (embedding layer) for easier comparison in § 4.1.

3.3 Experimental Setup

We investigate GPT2$_{\text{SMALL}}$ (which we refer to as simply GPT-2 in this paper), a Transformer model with 12 layers and 117M parameters pre-trained on a dataset of 8 million web pages (Radford et al., 2019). We also examine the probes on a random model with the same architecture as pre-trained GPT-2, but the parameters are randomly reset. Since the goal of probing is to inspect the information acquired during pre-training, an ideal probe should have low accuracy on the random model.

For PP, we set the prefix length to 200 virtual tokens for tasks with unary edges (POS, Const., and entity) and 20 for those with binary edges (SRL, Coref.). For DP (MLP), we use a two-layer MLP with 512 hidden units. Following Tenney et al. (2019b), we linearly project the per-token representations $\mathbf{a}_i$ into 256 dimensions before self-attentional pooling to improve performance. All models are trained for one epoch using the Adam optimizer (Kingma and Ba, 2015). Our implementation is based on Hugging Face Transformers (Wolf et al., 2020). Experiments are conducted on 8 Titan RTX GPUs.

In our experiments, we only study English. Results may vary for other languages. The English split contains 116K/16K/12K examples in the train/development/test sets, respectively. We train on the train set, experiment on the development set, and report final results on the test set.

3.4 Results

We compute the classification accuracy on each task and present the results in Tab. 2. We observe that when GPT-2's parameters are randomly reset, PP performs substantially worse than the two diagnostic probes. Remarkably, the accuracy of PP only exceeds a majority-class classifier by a negligible amount on POS and Const., and is even identical to a majority-class classifier on entity, SRL and Coref. On the other hand, both DP (MLP) and DP (LR) outperform the majority-class baseline on all the tasks except for Coref., where the majority-class baseline already performed exceptionally well already. This result suggests that PP learns much less about the task on its own than DP, which makes it a better probe in terms of selectivity (Hewitt and Liang, 2019).

Meanwhile, when we consider pre-trained GPT-2, PP has higher accuracy on all the five probing tasks than DP (MLP) and DP (LR). We take these results to indicate that prompting works quite well at extracting linguistic knowledge. The fact that our more selective probe still performs well on linguistic tasks confirms that the considered linguistic information is indeed encoded in the pre-trained model.

Model	Probe	POS	POSC	Δ
Pre-trained	PP	94.28	74.48	19.80
	DP (MLP)	94.01	69.58	24.43
	DP (LR)	89.56	48.75	40.81
Random	PP	13.14	7.66	5.48
	DP (MLP)	47.89	45.71	2.18
	DP (LR)	38.84	35.76	3.08
Majority		12.58	6.58	
Chance		2.08	2.08	

Table 3: POS and POSC accuracy of various methods on pre-trained GPT-2.

3.5 Control Tasks

Hewitt and Liang (2019) propose **control tasks** to estimate a probe's selectivity in complement with random model baselines. A control task associates the inputs of a given linguistic task with random outputs. The key idea is that the control task can only be learned by the probe itself, so a selective probe should have high linguistic task accuracy but low control task accuracy. They further measure selectivity using a metric Δ as the difference between linguistic task accuracy and control task accuracy.

In our experiments, we also create a control task, abbreviated POSC, for POS, where we randomly assign a POS tag for each distinct word. The results are shown in the first three rows in Tab. 3. To our surprise, we find that PP performs quite well on POSC, having an accuracy of 74.48%, which is only 19.80% lower than its accuracy on POS. In contrast, the Δ metric for DP (MLP) and DP (LR) are 24.43% and 40.81% respectively. Therefore, if we were to use control tasks to measure selectivity, this result would suggest that PP is the least selective probe, which would be contradictory to our results in § 3.4, where we show the opposite.

To resolve the contradiction, we re-examine the implicit assumption behind control tasks: Randomness excludes the possibility of representations encoding the information of a control task, so that the control task accuracy can be solely attributed to the probe itself. If this were true, then the probe

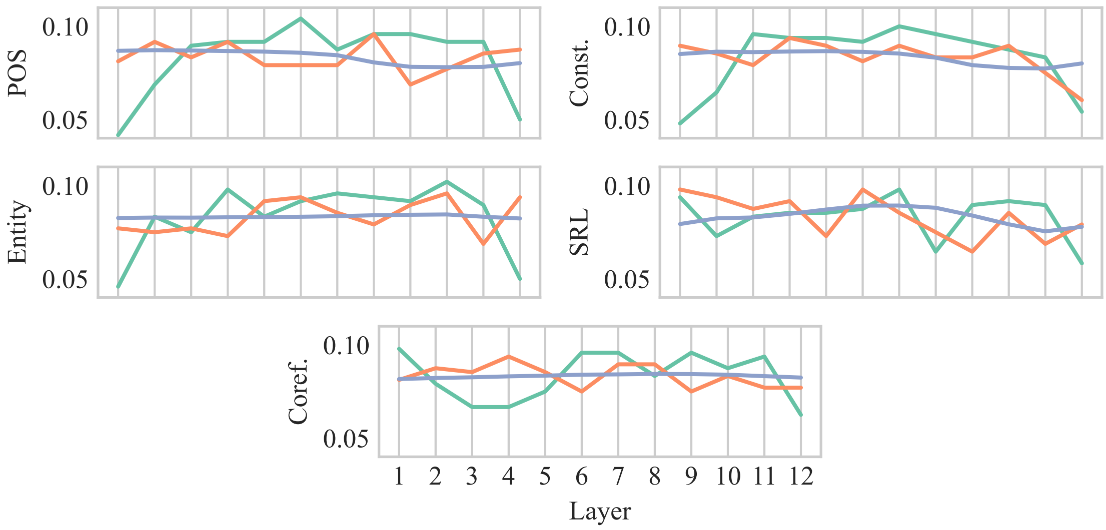


Figure 2: Layer distribution (n) for PP, DP (MLP), and DP (LR).

should be able to learn the task regardless of the representations it probes. To test that, we run the same experiments on the random model. The results are shown in rows 4–6 of Tab. 3. It is clear that accuracy on POSC under all three methods drops substantially when switching to the random model, which means the accuracy of a control task depends not only on the expressivity of the probe but essentially also on the representations.

3.6 Discussion

Since we found manually crafted prompts do not work well in our preliminary experiments, we resorted to prefix tuning. As a result, our prompting approach is not fully parameter-free. PP still involves learning parameters, and thus, we still run the risk of the prefix learning the target task on its own. Even though PP's performance on randomly initialized GPT-2 is barely better than that of the majority-class baseline, it is still much higher than chance, which indicates that PP still learns from the training set—for instance, it appears to learn the majority-class label. This is in line with the findings of Zhong et al. (2021) that an automatically optimized prompt can identify the majority-class label.

Further study is needed to determine why PP performs worse on the random model but equally well or even better on the pre-trained model. PP is not simply less expressive because a less expressive model should perform worse on both pre-trained and random models, e.g., DP (LR) is less expressive than DP (MLP), but PP is the best on the pre-trained model and the worst on the random model. He et al. (2022) offer an interesting insight that continuous prompts and, in particular, prefix tuning can be regarded as adapters. Therefore, a possible explanation is that the adapter modules that are interlocked with the Transformer layer are more convoluted with the information encoded in the model than an external probe on top. When the model is pre-trained, they are able to apply modifications to the latent representations and steer the model on the fly to perform various tasks (Rebuffi et al., 2017), but if the model is randomly initialized, the noise hinders the learning of the task.

4 Analysis

Now that we have demonstrated the basic utility of PP, we attempt to use our methodology to determine where in the representations the information is encoded. Thus, following Cao et al. (2021), we search for a subnetwork that optimizes the performance on the task of interest and analyze the resulting subnetwork. Since it has been shown that different attention heads in the Transformer capture different linguistic phenomena (Clark et al., 2019; Voita et al., 2019), we prune attention heads instead of individual weights. Concretely, we use differentiable subset pruning (DSP) proposed by Li et al. (2021), which allows us to directly control the number of heads to keep. Pruning is performed jointly with prefix tuning.

Essential and Non-essential Heads. We call the K heads that survive pruning **essential heads** for the task, and those that are removed **non-essential**

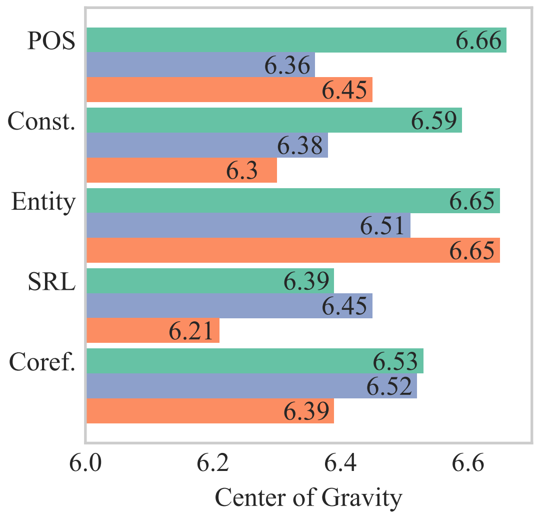

Figure 3: Center of gravity for PP, DP (MLP), and DP (LR).

heads. With $n_{\mathrm{PP}}(\ell)$, we denote the distribution that is proportional to the number of essential heads in each layer ℓ under the PP scheme. We define $n_{\mathrm{LR}}(\ell)$ analogously.

4.1 Subnetwork Analysis

We now investigate how the essential heads of different tasks are distributed in the model. To do so, we make use of the **center of gravity** as a summary statistic introduced in (Tenney et al., 2019a). For any given layer distribution n, we compute the expected layer:

$$\mathbb{E}_n[\ell] = \sum_{\ell=1}^{L} n(\ell) \cdot \ell \tag{6}$$

A higher center of gravity means the information for the task is encoded in higher layers. In our experiments, we keep $K = 96$ (out of $12 \times 12 = 144$) heads in GPT-2 and we report the average of 5 runs with different random seeds. Fig. 2 depicts the layer distributions and Fig. 3 reports the centers of gravity.

Tenney et al. (2019a) find that BERT encodes linguistic knowledge in an order that follows the classical NLP pipeline: syntactic information is stored in earlier layers than semantic information. As shown in Fig. 3, we are able to reproduce their results on GPT-2 using DP (MLP). Specifically, the tasks are encoded from the bottom of the model to the top in the following order: POS → Const. → SRL → entity → Coref. Cao et al. (2021) also find that entity is localized in higher layers than POS. We obtain the same results using DP (LR).

	Essential	Non-essential	Majority
POS	93.21	1.9	12.58
Const.	84.61	7.66	35.66
Entity	90.00	4.50	15.91
SRL	70.34	1.74	33.36
Coref.	85.50	58.14	78.33

Table 4: Accuracy (%) of PPP models with only essential heads or non-essential heads.

However, the other three tasks (SRL, Const., Coref.) all have lower centers of gravity than POS, which contradicts the order of Tenney et al. (2019a) as POS is believed to be the most basic syntactic information and should appear the earliest. Moreover, PP produces an order that is entirely different from both DP methods: SRL → Coref. → Const. → entity → POS. Noticeably, according to PP, syntactic information (POS and Const.) is captured in higher layers on average than what is discovered by DP (MLP). This is in agreement with findings from recent unsupervised probing works (Gupta et al., 2020; Zhou and Srikumar, 2021).

In conclusion, we find that different probing and analysis methods can lead to drastically different results. Since the choice of probing methodology influences the resulting ordering, we believe that future work should be cautious in making claims based on a single interpretation approach. Instead, a number of probing methods should be considered.

4.2 Amnesic Probing

Ravichander et al. (2021) and Lasri et al. (2022) argue that a high-accuracy probe does not necessarily mean the information is important or used by the model. For instance, linguistic properties can be spuriously encoded. To investigate whether a property is actually used by the model in prediction, Elazar et al. (2021) propose amnesic probing, which neutralizes some information from the representation and measures the influence of that intervention. In the same spirit, we remove the information of a given property by discarding the essential heads from GPT-2, evaluate the pruned model on the WikiText-103 LM dataset (Merity et al., 2017), and quantify the importance of that property with the absolute increase in cross-entropy. By keeping the number of pruned heads constant, we control for the amount of information removed on each task. Note that the performance degradation of the LM cannot be solely attributed to the inspected property, as additional confounding information may also be removed when we discard essential heads for a property. Yet, it is still an indicator of the relative importance of different properties.

In order to make sure the information for the targeted properties is eliminated from the model, we first evaluate PP models with only non-essential heads on the linguistic tasks. We keep $144 - 96 = 48$ non-essential heads in the model. Again, the average of five runs with different random seeds is reported. Tab. 4 shows that the models with only non-essential heads perform substantially worse than the models with essential heads and even the majority baseline, which shows that the model has lost its ability to predict a property after the target property's essential heads are removed. Next, we inspect how much impact it would have on the pre-training task. The results of LM loss are summarized in Tab. 5. For reference, we also evaluate the model with 48 random heads (Random). Generally, all five linguistic properties are useful for LM, as leaving out their essential heads all lead to a bigger increase in LM loss than Random. Entity is clearly the most important property, as removing its essential heads leads to an increase of 4.22 in LM loss. Coref. is the second, accounting for 3.97 loss increase. POS and Const. are almost equally important. SRL is the least important factor, causing only 0.1 more damage than Random. Our results demonstrate that probing accuracy in Tab. 2 (POS > entity > Coref. > Const. > SRL) is not reflective of the property's importance according to Tab. 5 (entity > Coref. > POS > Const. > SRL), which is consistent with the findings of Elazar et al. (2021).

	LM Loss	Δ
Vanilla	3.42	—
Random	6.94	3.52
POS	7.21	3.79
Const.	7.17	3.75
Entity	7.64	4.22
SRL	7.04	3.62
Coref.	7.39	3.97

Table 5: LM loss on WikiText-103 of vanilla GPT-2 (Vanilla), GPT-2 whose heads are randomly removed (Random), and GPT-2 whose essential heads for different properties are removed.

5 Related Work

Probing. There has been a plethora of research papers analyzing the neural representations of NLP models. One of the primary goals of such research is to understand whether the linguistic information commonly believed to be important for representing language is actually captured in the representations. The most popular approach for associating network components with linguistic properties is to train an auxiliary model to predict such properties from activations of neural networks (Belinkov and Glass, 2019). This technique is now commonly referred to as probing (Conneau et al., 2018; Alain and Bengio, 2018; Saleh et al., 2020; Tenney et al., 2019b), but has also been known as auxiliary prediction (Adi et al., 2016; Zhang and Bowman, 2018), diagnostic classification (Veldhoen et al., 2016; Hupkes and Zuidema, 2018; Giulianelli et al., 2018), and others (Belinkov et al., 2017; Peters et al., 2018b; Naik et al., 2018). However, the interpretation of probing results has been called into question (Hewitt and Liang, 2019): Do the representations encode the linguistic information or does the probe learn the task on its own? A commonly held belief (Alain and Bengio, 2018; Liu et al., 2019; Hewitt and Manning, 2019) is a simple model (e.g. a linear one) is not capable of learning the task itself and thus is preferred, but Pimentel et al. (2020b) argues that one should always choose the best possible probe because it reveals the most linguistic information present in the representations. Pimentel et al. (2020a); Voita and Titov (2020) explicitly model the trade-off between accuracy and model complexity. Cao et al. (2021) propose to search for a subnetwork within the model rather than train an auxiliary model, but a task-specific classification head is still required.

Prompting. The deep contextual word representations are typically derived from either an LM (Peters et al., 2018a; Radford and Narasimhan, 2018) or a masked LM (Devlin et al., 2019). A common use of these pre-trained language models is fine-tuning. However, an alternative approach called prompting has recently gained much popularity. Instead of accommodating a language model for downstream tasks, prompting adapts downstream tasks to be more like LM with the aid of a prompt. In this way, the pre-trained model can be used to perform few-shot or even zero-shot learning (Petroni et al., 2019; Brown et al., 2020; Raffel et al., 2020; Schick and Schütze, 2021a,b). Most papers construct templates with blanks for the model to fill. For example, LAMA (Petroni et al., 2019) creates cloze-style templates to probe knowledge; Brown et al. (2020) put task descriptions and examples in the prefix and then the model performs various tasks by finishing the sentence; Cui et al. (2021) enumerate every possible text span in a sentence, create a template for each of them, and fine-tune the model to perform named entity recognition (NER). However, creating such templates requires a large amount of time and human expertise, and does not necessarily do well on the task of interest. Therefore, many researchers focus on generating prompts automatically (Jiang et al., 2020; Shin et al., 2020; Haviv et al., 2021; Gao et al., 2021). The prompts must not consist of natural language, but can also be continuous vectors (Li and Liang, 2021; Qin and Eisner, 2021; Lester et al., 2021; Hambardzumyan et al., 2021). We refer the reader to Liu et al. (2021) for a more thorough survey about prompting. In this work, we apply the method of (Li and Liang, 2021) to learn continuous prompts to instruct the model to predict linguistic structure.

Pruning. Neural network pruning aims to reduce the model size and increase inference speed by removing redundant network components, such as individual parameters (LeCun et al., 1990; Hassibi et al., 1994; Han et al., 2015), convolutional channels (Liu et al., 2017; Luo et al., 2017; He et al., 2017), and attention heads (Michel et al., 2019; Voita et al., 2019; Li et al., 2021). In addition to model compression, pruning has also been used for analysis: Voita et al. (2019) analyze the linguistic roles the unpruned heads play; Cao et al. (2021) look at the location of unpruned weights. Similarly, we examine the network components that survive pruning, but we apply head pruning (Li et al., 2021) instead of weight pruning (Louizos et al., 2018) since attention heads are believed to be more linguistically interpretable than weights.

6 Conclusion

With the growing popularity of probing, there have been increasing concerns that high probing performance on a linguistic property cannot be attributed to representations encoding the property, since the probe can learn the probing task on its own. In this work, we propose a novel probing via prompting method, which drastically reduces the probe's ability to learn and, thus, mitigates this problem.

We conduct experiments on five linguistic tasks and show that these properties are indeed encoded in one popular pre-trained language model, GPT-2. However, they might not be encoded in a natural progression in the model as previously believed. For further study, we hope to develop tools that can more accurately and faithfully locate and identify the linguistic properties embedded in the model and help us understand the way neural language models process text.

Ethical Considerations

The OntoNotes 5.0 dataset (Weischedel et al., 2013), licensed through LDC, annotates various genres of texts in three languages (English, Chinese, and Arabic) with structural information and shallow semantics. OntoNotes 5.0 inevitably contains personal information and offensive content. However, we only run experiments on the dataset and do not disseminate it or our trained models, which are only available upon request. We also make sure the examples shown in our paper are anonymized. The pre-trained language model GPT-2 can also encode certain social biases (Liang et al., 2021). Our research in probing could help us understand and mitigate these biases.

A Prefix Tuning

A.1 Background: Transformer

Recall that in a Transformer-based causal language model (Vaswani et al., 2017; Radford et al., 2019), each layer consists of two sub-layers: a multi-head self-attention mechanism and a fully connected feed-forward network. Each sub-layer is short-circuited with a residual connection, followed by layer normalization. Now we zoom in on the self-attention mechanism. For the sake of illustration, we assume there is only one head in each sub-layer. In self-attention, each activation vector $\mathbf{a}_i^{(\ell)}$ is first linearly projected into three vectors: query $\mathbf{q}_i^{(\ell)} = W_q^{(\ell)} \mathbf{a}_i^{(\ell)} \in \mathbb{R}^d$, key $\mathbf{k}_i^{(\ell)} = W_k^{(\ell)} \mathbf{a}_i^{(\ell)} \in \mathbb{R}^d$, and value $\mathbf{v}_i^{(\ell)} = W_v^{(\ell)} \mathbf{a}_i^{(\ell)} \in \mathbb{R}^d$. Then we compute the output $\mathbf{z}_i^{(\ell)}$ as the sum of values weighted by a compatibility score between query and key.

$$\mathbf{z}_i^{(\ell)} = \sum_{j=0}^{i} \operatorname{softmax}\left(\frac{{\mathbf{q}_i^{(\ell)}}^\top \mathbf{k}_j^{(\ell)}}{\sqrt{d}} \right)_j \mathbf{v}_j^{(\ell)} \tag{7}$$

The upper bound i in the summand makes sure it can not attend to subsequent positions, and thereby the prediction for the next token at position $i+1$ can only depend on the tokens at positions up to i. We abstract the feed-forward sub-layer, residual connections, and layer normalizations with a function f and so we have

$$\mathbf{a}_i^{(\ell+1)} = f\left(\mathbf{a}_i^{(\ell)}, \mathbf{z}_i^{(\ell)} \right) \tag{8}$$

A.2 Prefix Tuning

Prefix tuning prepends the pattern $\boldsymbol{p}$ a prefix of length T, which we index from $-T$ to -1. Then (7) becomes

$$\widetilde{\mathbf{z}}_i^{(\ell)} = \sum_{j=-T}^{i} \operatorname{softmax}\left(\frac{{\mathbf{q}_i^{(\ell)}}^\top \mathbf{k}_j^{(\ell)}}{\sqrt{d}} \right)_j \mathbf{v}_j^{(\ell)} \tag{9}$$

and the layer activations are modified accordingly:

$$\widetilde{\mathbf{a}}_i^{(\ell+1)} = f\left(\widetilde{\mathbf{a}}_i^{(\ell)}, \widetilde{\mathbf{z}}_i^{(\ell)} \right) \tag{10}$$

The 0th layer is left unchanged: $\widetilde{\mathbf{a}}_i^{(0)} = \mathbf{a}_i^{(0)}$. Note that we never compute activations $\mathbf{a}_i^{(\ell)}$ for the prefix ($i < 0$), so we do not need queries $\mathbf{q}_i^{(\ell)}$ for them, and the key–value pairs $\mathbf{k}_i^{(\ell)}, \mathbf{v}_i^{(\ell)}$ cannot be obtained through projection from $\mathbf{a}_i^{(\ell)}$. Instead, they are learned directly. During training, only $\mathbf{k}_i^{(\ell)}, \mathbf{v}_i^{(\ell)}$ for prefix are learned while the parameters of the language model are frozen. During inference, the modified activations are now used:

$$\widetilde{p}(w_{|\boldsymbol{p}|+1} \mid \boldsymbol{w}_{<|\boldsymbol{p}|+1}) = \operatorname{softmax}(W \widetilde{\mathbf{a}}_{|\boldsymbol{p}|}^{(L)}) \tag{11}$$

$$\widehat{y} = \operatorname*{argmax}_{y' \in \mathcal{Y}} \widetilde{p}\left(\boldsymbol{w}_{|\boldsymbol{p}|+1} = \texttt{vb}\left(y'\right) \mid \boldsymbol{w}_{<|\boldsymbol{p}|} \right) \tag{12}$$

Database Search Results Disambiguation for Task-Oriented Dialog Systems

Abstract

As task-oriented dialog systems are becoming increasingly popular in our lives, more realistic tasks have been proposed and explored. However, new practical challenges arise. For instance, current dialog systems cannot effectively handle multiple search results when querying a database, due to the lack of such scenarios in existing public datasets. In this paper, we propose *Database Search Result (DSR) Disambiguation*, a novel task that focuses on disambiguating database search results, which enhances user experience by allowing them to choose from multiple options instead of just one. To study this task, we augment the popular task-oriented dialog datasets (MultiWOZ and SGD) with turns that resolve ambiguities by (a) synthetically generating turns through a pre-defined grammar, and (b) collecting human paraphrases for a subset. We find that training on our augmented dialog data improves the model's ability to deal with ambiguous scenarios, without sacrificing performance on unmodified turns. Furthermore, pre-fine tuning and multi-task learning help our model to improve performance on DSR-disambiguation even in the absence of in-domain data, suggesting that it can be learned as a universal dialog skill. Our data and code will be made publicly available.

1 Introduction

Task-oriented dialog systems have been widely deployed for popular virtual assistants, like Siri and Google Assistant. They help people with tasks such as booking restaurants and looking for a hotel by searching databases with constraints provided by users. After retrieving a result from the database, a system may continue by conducting actions like making a reservation or providing more information about receiving the result. However, there can be multiple results from the database that match the same constraints. For example, as shown in Fig. 1, the system finds two available hotels at different locations when the user is asking the system to help book a hotel. This kind of ambiguity stops system from proceeding until the system finds out which result the user looks for. Therefore, we need to enhance the system with the ability to resolve such ambiguity brought out by multiple items returned from database search. We call this type of ambiguity as database search result ambiguity (DSR-ambiguity).

Hotel	Restaurant	Shopping
👩: Book a room for me at Hilton Hotel on Monday. 🤖: **Which one? The Hilton Central City or the Riverside Hilton Hotel.** 👩: **The second one.** 🤖: I have booked one room at the Riverside Hilton Hotel for one night on Monday	👩: Find me a cheap Japanese restaurant. 🤖: **I have two restaurants that fit. Which one are you interested in? The Wagamama or the Sushi Lover.** 👩: **The Wagamama, may I have its phone number** 🤖: The phone number of wagamama is 01223462354	👩: what size is that shirt, and how much is it? 🤖: **could you clarify which item you're referring to?** 👩: **Yeah, my bad, the shirt. The black and white one above the red shoes.** 🤖: That shirt is a size XL, and is priced at $29.99.

Figure 1: Examples of disambiguation turns over three different domains.

Different from semantic ambiguous words (e.g. "orange" can be referred as either color or fruit), the DSR-ambiguity focuses on results from multiple database search results. Solving such disambiguation tasks consists of two steps: asking clarification questions and understanding user's corresponding answers. While there is a relatively larger body of literature focusing on when and how to give out the clarification question (Rao and Daumé III, 2018; Rao and Daumé, 2019; Kumar and Black, 2020), the focus on understanding user's answers/intents has been relatively sparse. Our work mainly focuses on improving model's ability of understanding the answers by augmenting two existing task-oriented dialog datasets: MultiWOZ (Budzianowski et al., 2018) and Schema-Guided Dataset (SGD) (Rastogi et al., 2019).

MultiWOZ and SGD are the most popular large-scale task-oriented dialog datasets, based on which most of the state-of-the-art dialog system models are commonly trained and evaluated. According to

July 10-15, 2022 ©2022 Association for Computational Linguistics

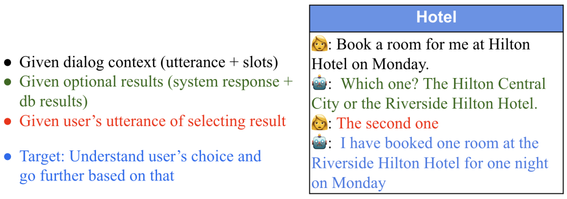
our analysis, there are around 66% dialogs of the dataset contains multiple dataset-searching results, which means the DSR-ambiguity exists.

In this setting, ambiguities are skipped and the model trained based on these datasets can hardly handle the cases where users prefer to make their own choices among all the results satisfies the constraints. Furthermore, users should be given more detailed information about search results. Ideally, dialog models should provide the information and assist users to make choices, rather than picking one from the result list and recommending it to users. It is not necessary to list all the results, but enumerating 2 or 3 options would help increase user's engagement. To strengthen the model with the ability to handle the ambiguity, we propose to augment these two datasets with disambiguation turns, where the system provides all possible matched results and lets the user make their own decision based on the complete information.

Specifically, we first extract templates from the SIMMC 2.0 dataset (Kottur et al., 2021), which is a multi-modal task-oriented dialog dataset containing disambiguation turns but only covering two domains. Based on the extracted templates and database from MultiWOZ and SGD, we synthesize a one-turn dialog dataset, containing only the disambiguation turn, to check whether the model can learn the disambiguation from the data. To be applicable in reality, we expect the model to learn the skill of disambiguation without compromising the performance on other dialog skills. So, we propose to augment the MultiWOZ and SGD with disambiguation turns and train dialog models with the augmented dataset. To ensure naturalness and diversity of the automatically augmented dataset, we additionally recruit crowd-workers to paraphrase the modified turns.

In conclusion, our contribution includes:

1. We propose *Database Search Result Disambiguation*, a new dialog task focused on understanding the user's needs through clarification questions.
2. We provide a generic framework for augmenting disambiguation turns, and apply this framework to augment the two most popular task-oriented dialog datasets with disambiguation cases. We also conduct human paraphrasing for the augmented utterances in test sets.
3. We create a benchmark for the new task with pre-trained GPT2 model. The results show that our augmented dataset enhances the model's disambiguation ability, while maintaining the performance on the original tasks.



- Given dialog context (utterance + slots)
- Given optional results (system response + db results)
- Given user's utterance of selecting result
- Target: Understand user's choice and go further based on that

Hotel

🙂: Book a room for me at Hilton Hotel on Monday.

🤖: Which one? The Hilton Central City or the Riverside Hilton Hotel.

🙂: The second one

🤖: I have booked one room at the Riverside Hilton Hotel for one night on Monday

Figure 2: For this disambiguation task, we assume the dialog context, system utterance including result list and user's answer are given. The goal is to extract the result that the user select and continue the dialog.

2 Task Formulation

In this paper, we propose a new task called disambiguation in dialog database search. As shown in Fig. 2, the task assumes that we are provided with the dialog context c, the system response s which includes all the optional results , and the user's utterance u that make a choice. To avoid redundant option lists, we limit the number of options to less than five. The target of the task is to extract the entity of the result selected by the user.

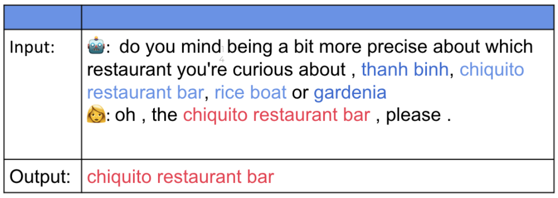
3 Dataset

The most popular task-oriented dialog datasets (MultiWOZ, SGD) do not contain many cases for the disambiguation task. In order to enable the dialog model to handle this task, we propose to augment these two datasets in three steps described in the following subsections.

3.1 Synthesizing Single-Turn Dialog

We first develop a single-turn dialog dataset. With this single-turn dataset, the fine-tuned dialog model can focus only on the disambiguation turns and learn the skill to solve the ambiguity problem. Fig. 3 shows an example of the dialog turn, which we would use through this section to introduce the dataset. In this dataset, each dialog turn consists of only a system utterance and a user response. The system utterance gives a list of options (marked in blue) and the user response makes a choice from the list (marked in red). The ground truth output is the named entity of the chosen result.

To synthesize the system and user sentences, we extracted templates from disambiguation turns from the SIMMC 2.0 dataset. For example, the system from SIMMC2.0 asks questions like *"do you*



Input:	🤖: do you mind being a bit more precise about which restaurant you're curious about , thanh binh, chiquito restaurant bar, rice boat or gardenia 👩: oh , the chiquito restaurant bar , please .
Output:	chiquito restaurant bar

Figure 3: An example of the synthesized single-turn dialog. The utterance templates are generated based on CFGs. The *candidate entities* (italicized) are sampled from the database of MultiWOZ or SGD. The **selected entity** (bolded) is sampled from the candidates.

mind being a bit more precise about which shoes you're curious about, the red one or the blue one" to solve ambiguity. We delexicalize those utterance by removing the all domain-related tokens such as *"shoes", "the red one", "the blue one"* based on the annotations from the dataset, and keep the rest as a template.

We then extract a list of context-free grammars (CFGs) from those templates, and then generate natural sentences based on the CFGs. For example, from the previous template we can summarize a grammar: *"SENT -> do you mind VERBING"*, where *"VERBING"* is a non-terminal token for a verb phrase in an "ING" form. More detailed CFG examples are shown in Appendix A.2. The CFG-based generator can potentially generate around 2 million different system questions and 30K+ different user utterances, which ensure the diversity of the generated data. To cover multiple domains, we utilize the database from the MultiWOZ and SGD datasets, which in total covers 27 domains, each containing one named entity type. We randomly sample a certain number of values from the database based on the domain and entity type, and insert them into the system response. The number of candidate values is also randomly sampled. To make the sentence more natural, we limit the candidate number to be between three and five. Then, we randomly sample one from the candidate list as the selected result.

To make the task harder and more realistic, we also explore different entity addressing methods to generate the user utterance:

- **Positional Addressing.** Instead of directly addressing the named entity (Fig. 3), users use entity's list position, e.g., "the second one".
- **Partial Addressing.** User use part of the name for simplicity, e.g. "chiquito" instead of "chiquito restauraant bar"

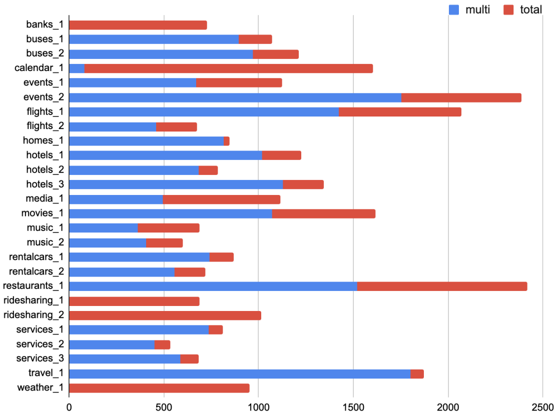


Figure 4: The blue bar represents the number of dialogs which contain multiple database-search results in each service from the SGD dataset. While the red bar represents the total number of dialogs in each service.

- **Addressing with Typo.** We add typos in the named entity to make the model more robust.
- **Multiple Addressing.** User chooses more than one option at a single time and the model is expected to extract all their choices.
- **Addressing with Attributes.** User describes the selected result with more attributes, e.g. "the restaurant in the north of the city".

3.2 Automatic Augmentation

The single-turn dialog dataset helps enable models to solve the disambiguation task. However, the single-turn is not an entire dialog and the model barely trained with that can hardly conduct a complete dialog. Our goal is to enhance a complete dialog model with the disambiguation skill while keeping the performance of other tasks. Currently, most of the state-of-the-art task-oriented dialog models are trained with MultiWOZ and SGD dataset. Therefore, we propose to augment these two dataset by adding disambiguation turns.

Fig. 4 shows the proportion of the dialogs in each domain that contains multiple results. We find that nearly 66.7% of dialogs involve multiple results, where ambiguity can occur. Though in both SGD and MultiWOZ, system would always give a suggestion after searching the database, e.g. "I have 10 suitable results, how about ..." and the user side would simply accept it or ask about something else. This avoids the ambiguity in the dataset. However, the system in the reality would still face the ambiguity problem when interacting with real human beings, who would like to know more about other options. Therefore, we want to augment these

	SGD			MultiWOZ		
	train	dev	test	train	dev	test
dialog	4.7k / 16k	0.9k / 2.5k	1.6k / 4.2k	2.7k / 8.4k	0.3k / 1k	0.3k /1k
turn	5.1k / 330k	1.0k / 48.7k	1.8k / 84.6k	3.2k / 105k	0.4k / 13.8k	0.4k / 13.7k

Table 1: The table presents the numbers of dialogs or turns that are modified for disambiguation cases, and the numbers on the right side of slash are the total number of dialogs or turns in each dataset.

Figure 5: An example of the automatic disambiguation augmentation and human paraphrasing. We first replace the original system suggestion with a synthesized utterance, listing all candidate entities and asking user to select. Then, we generate user chosen answer and insert it to the beginning of the original user utterance. For human paraphrasing, we ask crowd-workers to rewrite the user utterance to gain naturalness and diversity.

two popular dataset with disambiguation turns to improve the model's ability.

First, we locate the turns to be modified. In those turns, the system presents the database-searching results, where the ambiguity takes place. We also incorporate relevant annotation and sentence structure to filter out some inappropriate cases, e.g. the user does not make any choices in this turn. Then we generate a new system utterance to replace the original one. The generation is conducted based on the same toolkit and CFGs from Sec. 3.1, and the slot values are extracted from the corresponding database. As shown in Fig. 5 (highlighted in blue), the new system utterance provides a list of specific searching results without giving any suggestion. Following the language naturalness, we uniformly sample two to four candidate searching results and integrate them with the original entity to compose the result list. After the system utterance, a user utterance is also generated to make the choice, which should be consistent with the original suggestion that the user accepts. If the user rejects the original system suggestion, we do not make any modification. In the end, we concatenate the generated user utterance with the original one. In this way, we ensure the other unchanged turns of the dialog (especially the following turns) will be coherent with the modified turns, in order to eliminate the effects on the unchanged turns of the dialog as much as possible.

We conduct the same progress on both SGD and MultiWOZ dataset. Note that the ambiguity problem occurs only when there is a specific target entity, e.g. hotel name in the "hotel" domain and not every domain includes such an entity (e.g. any car satisfying constraints is acceptable in the "taxi" domain). Therefore, we only augment the "restaurant", "hotel", and "attraction" domains in the MultiWOZ dataset, and 24 out of 45 services in the SGD dataset, which are listed in the Appendix A.1. The statistics of the augmentation is listed in the Table. 1. More than 30% of dialogs are involved and with disambiguation turns, and around 2% of the turns are modified.

The newly generated user utterance is simply the concatenation of the template utterance and the original utterance that responds to the system suggestion. Therefore, the connection between them can be unnatural. In addition, the new user utterance is generated by CFG, which means the utterance itself can be unnatural. Therefore, we conduct human paraphrasing to improve the quality of the user utterance.

3.3 Human Paraphrasing

We recruit crowd-workers to paraphrase the disambiguation turns. Before starting the paraphrasing job, each crowd-worker is required to read through a guideline document to get a better understanding of the task, the requirements and the workflow. A screenshot of the paraphrasing interface is shown in the Appendix Fig. 6. For each paraphrasing job, we present a good example of paraphrasing in the same page as the turn to be modified. To keep consistent with task description in the Sec. 2, we provide the crowd-workers with 1) the modified system utterance, which includes a list of options and asks the user to select, 2) the user utterance, which concatenates the template-generated sentence and the original user utterance. In the interface, the user utterance is highlighted in a different color (green) and marked as "need paraphrase". To avoid changing user's original choice during paraphrasing, we also show crowd-worker the result value that the user should choose, keeping consistent with the dialog state annotation. In addition, to ensure the disambiguation turn is coherent with the dialog context, we also present the previous user utterance and the next system response.

We conduct the paraphrasing job for the test sets from both SGD and MultiWOZ, as well as the training set of SGD. To evaluate the quality of the human paraphrase process, we randomly sample 5% of the disambiguation turns and ask another group of crowd-workers to judge whether the modification is valid, which means satisfying all the requirements listed in the guideline document (maintaining all essential information, not similar to the original utterance, not natural, etc.). Each turn receives two judgements. In total, we have an 88% of agreement rate between two judgements and 92% of the agreements are error free, which means our paraphrasing job is valid. We also ask annotators to point out if there is any ethical violation in the utterance, which is discussed in more details in Sec. 7.

4 Experiment

We use GPT2 (Radford et al., 2019) as our backbone model and fine-tune it with the augmented SGD and MultiWOZ datasets separately.

MultiWOZ. MultiWOZ (Budzianowski et al., 2018) is a multi-task task-oriented dialog dataset. It covers seven domains and contains 10K+ dialogs. Our augmentation focuses mainly on three domains:"*attraction*", "*hotel*" and "*restaurant*", involving more than 3K dialogs. We choose to conduct our augmentation based on the MultiWOZ 2.2 (Zang et al., 2020), which is the most widely-accepted version.

Schema-Guided Dataset. SGD (Rastogi et al., 2019) is another popular multi-task dialog dataset. Since the DSR-ambiguity problem requires the service containing a target entity and not every service satisfies that requirement, our augmentation involved totally 10 domains and 24 services.

We directly compute the accuracy on whether the model can successfully predict the correct named entity as evaluation metric. Since the generation is similar to the dialog state tracking task, we also compute the joint goal accuracy (details in Appendix.C.2) to evaluate whether the augmentation maintain the model's performance of other tasks.

We train GPT2 with both the original and augmented data, and test the fine-tuned models on original/augmented/human paraphrased test sets. The same experiment is conducted for both datasets. In addition to original and augmented training data, we also explore the impact of the synthesized single-turn dialog. Learned from Table 1, the augmented turns only take up 2% of the whole dataset. In order to achieve a similar amount of augmentation compared to the automatic augmented data, we sample $5k$ synthesized single-turn dialogs for SGD and $3k$ for MultiWOZ, which is around 2% of each training set. Then, we mix those dialogs with the original (or augmented) training data and evaluate on three test data settings. We also increase the sampling amount of the synthesized dialog to be comparable to the whole training set, represented by "Syn100%" in the table, to explore whether the model achieves a better learning of the entity disambiguation skill with access to more disambiguation cases.

5 Results and Analysis

In this section, we present our experimental results including key observations and ablation studies. In addition, we also analyze how to leverage our augmented dataset to deal with DSR-ambiguity in new datasets.

5.1 Augmentation Helps Resolve Ambiguity

Table 2 shows the named entity prediction accuracy evaluated only on the turns involved in augmentation, which is around 2% of the whole test set. The first column states the different training data settings that we use to fine-tune the GPT2 model, and the first row presents three different test sets.

Comparing the "Origin" column and "AutoAug" column, we find that the performance of the model trained with original data drastically drops from 0.556 to 0.242 for SGD and from 0.676 to 0.488 for MultiWOZ. This verifies our hypothesis that the original datasets contain few disambiguation cases. Therefore, the model trained with the original data cannot understand user's answer towards the clarification question and extract the corresponding entity tokens. On the other hand, the models trained with

Test Data	SGD			MultiWOZ		
Train Data	Origin	AutoAug	HumanAug	Origin	AutoAug	HumanAug
Origin	$55.6_{\pm 0.7}$	$24.2_{\pm 00.6}$	$21.1_{\pm 0.8}$	$67.6_{\pm 0.7}$	$48.8_{\pm 0.5}$	$48.8_{\pm 0.1}$
Origin+Syn2%	$\mathbf{57.5}_{\pm 1.4}$	$27.9_{\pm 2.5}$	$25.2_{\pm 1.8}$	$65.0_{\pm 0.3}$	$48.9_{\pm 1.4}$	$49.4_{\pm 1.6}$
Origin+Syn100%	$57.1_{\pm 0.6}$	$34.4_{\pm 1.8}$	$30.4_{\pm 1.5}$	$67.0_{\pm 0.7}$	$55.4_{\pm 2.6}$	$55.6_{\pm 2.9}$
AutoAug	$55.1_{\pm 0.2}$	$49.6_{\pm 0.5}$	$43.7_{\pm 0.8}$	$63.3_{\pm 1.6}$	$74.4_{\pm 2.5}$	$73.9_{\pm 2.9}$
AutoAug+Syn2%	$56.9_{\pm 0.4}$	$54.8_{\pm 1.0}$	$48.8_{\pm 1.7}$	$64.2_{\pm 0.7}$	$83.8_{\pm 0.2}$	$83.0_{\pm 0.7}$
AutoAug+Syn100%	$56.7_{\pm 0.9}$	$\mathbf{58.3}_{\pm 0.1}$	$\mathbf{50.1}_{\pm 0.2}$	$63.3_{\pm 1.3}$	$84.6_{\pm 0.2}$	$83.7_{\pm 0.7}$

Table 2: The accuracy of the named entity prediction for only the augmented turns. Each number represents the performance of a model trained with a certain training data setting and evaluated on a certain test set. "Origin"/"AutoAug"/"HumanAug" represents evaluation on the original/automatic augmented(Sec. 3.2)/human paraphrased(Sec. 3.3) data. "+Syn" represents mixed with synthesized data and the percentage following "+Syn" means the amount of synthesized data compare to the whole test set.

augmented data achieve better performance (from 0.242 to 0.496 for SGD and from 0.488 to 0.744 for MultiWOZ) on the augmented data, which means those models learn the skill to complete the disambiguation task. The results on the human paraphrased test set, which is more diverse and natural, support the same conclusion. We also combine the synthesized single-turn dialog data with the original training data (or the augmented training data). The original data mixed with full-size synthesized data setting achieves the best result on human paraphrased test set for SGD and the augmented data mixed with full-size synthesized data setting achieves the best one for MultiWOZ.

Table 7 shows the overall named entity accuracy of the whole test set. Since the augmentation only modifies 2% turns of the whole test set, the difference between the performance of on the original and augmented test set is not as apparent as Table 2. However, the model trained with augmented data still performs better than the model trained with original data on both augmented and human paraphrased test set. The model under "Aug+Syn100%" train setting achieves the best results on five out of six test sets, showing that the augmentation and synthesized data jointly enhance the model's ability to extract named entity.

In addition to named entity prediction, we also explore whether the augmentation helps the model to predict other slot types by computing the joint goal accuracy. Table 8 shows the results for only the augmented turns and Table 3 lists the results on the whole test set. In both tables, the setting "Aug+Syn100%" achieves the best or the second best performance for both augmented and human paraphrased test sets. Hence, our augmentation not only enables the model to solve the disambiguation task, but also improves its ability for dialog state tracking task. The improvement mainly results from the similarity of the disambiguation task and the dialog state tracking, and more augmented data points enhance the model's understanding of the input sequence.

5.2 Augmentation Brings No Harm

Our ultimate goal is to expand end-to-end task oriented dialog systems with the disambiguation skill. Therefore, it is required not only to enable the dialog model to resolve DSR-ambiguity, but also to maintain the model's original ability for generating responses or dialog state tracking. To verify that, we first analyze the performance on the original test set ("Origin" columns in Table 2). The models trained with original data (0.676 on MultiWOZ) or the original one mixed with 5% synthesized data (0.575 on SGD) commonly achieves the best performance, which is reasonable since training data and test data share almost the same distribution. On the other hand, the performance on the original test set of the models trained with the augmented data is comparable with the original training data, which means these models maintain the ability to predict entity name. As for the results over the whole test set in Table 7, the augmented model even achieves better accuracy (0.877) than the original one (0.871) on the SGD test set. Therefore, the augmentation does not hurt the model's ability to predict named entities without disambiguation cases.

Beyond named entities, the augmentation hardly affects the model's ability to predict other dialog slots for the non-disambiguation cases. The results are listed in the "Origin" columns in the Table 8 and Table 3 correspondingly. For both test sets, the models trained with augmented data achieve comparable results with the models trained with original data, which means our augmentation also maintains the distribution of other slot types in the

Test Data / Train Data	SGD			MultiWOZ		
	Origin	AutoAug	HumanAug	Origin	AutoAug	HumanAug
Origin	$48.9_{\pm 0.7}$	$47.7_{\pm 0.7}$	$47.7_{\pm 0.7}$	$\mathbf{53.5}_{\pm 0.1}$	$52.2_{\pm 0.5}$	$52.3_{\pm 0.4}$
Origin+Syn2%	$50.0_{\pm 0.3}$	$48.9_{\pm 0.4}$	$49.0_{\pm 0.4}$	$53.0_{\pm 0.1}$	$50.0_{\pm 0.6}$	$50.1_{\pm 0.6}$
Origin+Syn100%	$49.5_{\pm 0.6}$	$48.7_{\pm 0.5}$	$48.7_{\pm 0.5}$	$52.8_{\pm 0.3}$	$50.4_{\pm 0.5}$	$50.4_{\pm 0.4}$
AutoAug	$50.2_{\pm 1.0}$	$49.9_{\pm 1.0}$	$49.7_{\pm 1.0}$	$52.4_{\pm 0.4}$	$53.5_{\pm 0.3}$	$53.5_{\pm 0.3}$
AutoAug+Syn2%	$49.8_{\pm 0.4}$	$49.6_{\pm 0.4}$	$49.4_{\pm 0.4}$	$52.5_{\pm 0.2}$	$54.5_{\pm 0.1}$	$54.5_{\pm 0.1}$
AutoAug+Syn100%	$\mathbf{51.0}_{\pm 0.4}$	$\mathbf{50.9}_{\pm 0.4}$	$\mathbf{50.6}_{\pm 0.4}$	$53.2_{\pm 0.2}$	$\mathbf{55.2}_{\pm 0.4}$	$\mathbf{55.2}_{\pm 0.4}$

Table 3: Joint goal accuracy evaluated on the whole test set.

original data. In conclusion, our augmentation does not impede the model from learning the original data distribution. And the model trained with the augmented data perform well no matter whether the disambiguation case exists.

5.3 Leveraging Augmented Turns

To find the most efficient method to leverage our dataset, we explore the following experiment settings. Since SGD and MultiWOZ are both task-oriented dialog datasets and share some common domains, pre-training on one dataset might help learn the other one. Therefore, for MultiWOZ model, we first pre-finetune the model with the original SGD and then fine-tune it on the origin MultiWOZ. We also conduct the experiment that uses the augmented SGD training data for the first step of fine-tuning, with or without mixing synthesized single-turn dialogs. All these three experiment settings do not involve augmentation on the MultiWOZ dataset. In addition, Since the augmented turns only take up 2% of the whole training data, the model rarely sees the disambiguation cases in each epoch. To emphasize those turns, we up-sample those disambiguation turns to the same amount as the original training data.

Table 4 show results for these settings on MultiWOZ dataset (The joint goal accuracy results can be found in Table 6). For the named entity accuracy, the setting "Upsample+Syn" achieves the best result, because the more disambiguation turns the models see, the better the model learns the skill to solve the ambiguity. As for the joint goal accuracy, setting "Aug+Syn" performs better than "Upsample+Syn" because too much disambiguation turns inevitably introduce bias and affect learning the original task. Therefore, if we need to solve DSR-ambiguity in a new dataset, the best option is to conduct augmentation with our framework and train models together with synthesized single-turn data. Although not as good as setting "Aug+Syn", the setting "PreFineTuneAug+Syn" performs better than the model trained on original data in terms of both JGA and named entity accuracy. Please note that this setting does not require any augmentation on MultiWOZ. Hence, to solve disambiguation cases in a new dataset, the cheapest choice is to fine-tune a model on our augmented dataset (MultiWOZ and SGD) first, and then fine-tune it on the original data, mixed with the synthesized single-turn dataset. The above experiments are conducted and evaluated on the MultiWOZ dataset. We also apply the same settings on the SGD dataset and the results can be found in the Table 5 and Table 6.

	Name Entity Accuracy	
	Origin	HumanAug
Origin	$67.6_{\pm 0.7}$	$48.8_{\pm 0.1}$
Origin+Syn	$67.0_{\pm 0.7}$	$55.6_{\pm 2.9}$
Aug	$63.3_{\pm 1.6}$	$73.9_{\pm 2.9}$
Aug+Syn	$63.3_{\pm 1.3}$	$87.4_{\pm 0.4}$
PreFineTuneOrigin	$67.8_{\pm 0.4}$	$44.1_{\pm 1.3}$
PreFineTuneAug	$68.4_{\pm 0.3}$	$49.5_{\pm 1.1}$
PreFineTuneAug+Syn	$\mathbf{68.5}_{\pm 0.9}$	$65.8_{\pm 0.6}$
Upsample	$63.5_{\pm 1.0}$	$83.7_{\pm 3.2}$
Upsample+Syn	$63.3_{\pm 0.5}$	$\mathbf{88.3}_{\pm 0.8}$

Table 4: Results for more training setting based on the MultiWOZ dataset, in terms of the name entity accuracy over only augmented turns. The amount of synthesized data "+Syn" is the same as the amount of original test set in this table. "PreFineTuneOrigin" means first pre-finetuning model with original SGD training data and then fine-tuning on MultiWOZ training data, while "PreFineTuneAug" means first pre-finetuning model with augmented SGD training data. The setting "Upsample" means up-sampling augmented turns to the same amount of training data.

5.4 Impact of Entity Addressing Methods

To explore the impact of different addressing methods, we conduct the ablation study by fine-tuning GPT2 with the synthesized single-turn dialog datasets of each individual addressing method (results shown in Table 9). For each addressing method, we generate $100K/10K/10K$ single-turn dialogs as the train/dev/test set, which is comparable to the MultiWOZ or the SGD datasets. We find that when focusing only on the disambiguation task with a simple context structure like single-turn dialog, the model can easily learn all kinds of addressing methods, except for "Multiple Addressing". The model accuracy drops by $\approx 33\%$ in that case. Even if we combine multiple addressing methods together except "Multiple Addressing", the model can still understand the addressing target. However, when the user chose multiple entities, it is hard for models to accurately predict how many entities the user selected.

6 Related Work

6.1 Task-Oriented Dialog Datasets

MultiWOZ (Budzianowski et al., 2018) is one of the most popular task-oriented dialog dataset. It covers multiple domains, consists of a large amount of dialogs, and has been chosen as benchmark for many dialog tasks, e.g. dialog state tracking (Zhang et al., 2019, 2020a; Heck et al., 2020), dialog policy optimization (yang Wu et al., 2019; Wang et al., 2020a,b) and end-to-end dialog modeling (Zhang et al., 2020b; Hosseini-Asl et al., 2020; Peng et al., 2020; Huang et al., 2021). And to polish it up to be a better benchmark, many works pay effort to improve and correct dataset (Eric et al., 2020; Zang et al., 2020; Qian et al., 2021; Han et al., 2021; Ye et al., 2021). In this paper, we choose MultiWOZ 2.2 version to conduct augmentation. Schema-Guided Dataset (SGD) (Rastogi et al., 2019) is the largest public task-oriented dialog dataset, containing 18K+ dialogs. It covers in total 20 domains and 45 services. The dataset is constructed by generating dialog outlines from interactions between two dialog simulators, and then being paraphrased by crowd-workers. SIMMC 2.0 (Kottur et al., 2021) is a newly-released multi-modal task-oriented dialog dataset around situated interactive multi-modal conversations (Moon et al., 2020). It focuses on dialogs with multi-modal context, which can be in the form of either co-observed image or virtual reality environment. The dataset contains 11K+ dialogs and covers two shopping domains.

As for the disambiguation problem, neither MultiWOZ nor SGD has related cases or annotations. SIMMC 2.0 is well-annotated for disambiguation, but it only covers two domains, and addresses entity mostly with multi-modal knowledge. Therefore, we augment MultiWOZ and SGD with the disambiguation templates from the SIMMC 2.0.

6.2 Ambiguity & Clarification Questions

Ambiguity is a common phenomenon across many conversation-involved NLP tasks, e.g. conversational search (Rosset et al., 2020), Question-Answering (White et al., 2021), open-domain dialog (Aliannejadi et al., 2021) and intent classification (Bihani and Rayz, 2021; Dhole, 2020). The problem mainly results from two aspects: 1. user's ambiguous keyword (e.g. "orange" can be either color or fruit (Coden et al., 2015)) and 2. lacking of enough constraints for accurate searching, leading to multiple results (e.g."I want to book a cheap hotel" where there might be multiple "cheap" hotels). Previous work proposes to incorporate clarification questions to solve the ambiguity problem (Purver et al., 2001; Schlangen, 2004; Radlinski and Craswell, 2017), including both model-wise (Li et al., 2017; Rao and Daumé III, 2019; Yu et al., 2020) and dataset-wise (Aliannejadi et al., 2019; Xu et al., 2019; Min et al., 2020; Zamani et al., 2020b). Our work it the first to point out the ambiguity within the database-searching of task-oriented dialog systems and introduce clarification questions to help solve this problem.

In addition, most of the work focus on when and how to generate clarification questions (Kumar and Black, 2020). Typical clarification question generation is based on the context with a Seq2Seq model (Zamani et al., 2020a). Rao and Daumé III (2019) propose to utilize the generative adversarial network to learn generating relevant clarification question based on corresponding answers. Sekulic et al. (2021) takes user engagement into consideration to generate high-quality clarification questions. In this work, instead of focusing on question generation, we put our attention on understanding the user's answer to clarification questions.

7 Conclusion & Future Work

In this paper, we proposed a new task, *dataset result disambiguation*, which is ignored in most popular public task-oriented dialog datasets such as MultiWOZ and SGD. We showed that models trained on these two datasets can not deal with entity ambiguities. We proposed to address this issue by augmenting existing datasets with relevant disambiguation turns. We extract templates of the disambiguation turns from the SIMMC2.0 dataset and jointly generate new turns with the databases from MultiWOZ and SGD for augmentation. To ensure the quality and correctness of the augmentation, we recruit crowd-workers to paraphrase the generated sentences. We benchmark our augmented dataset with the GPT2 model. We observe that the augmentations empower dialog models with a new skill to solve disambiguation tasks without performance drop on the original task. In the future, we plan to incorporate state-of-the-art and realistic entity referencing techniques cases to improve the datasets, which further enhances the dialog system. We hope that our work stimulates further research in identifying and incorporating such universal dialog skills in dialog systems avoiding exploding data-costs.

Ethical Considerations

To ensure that the dataset does not have any sensitive topics, we ask crowd-workers to make comments if the dialog content involves any of following: 1. offensive, racist, biased and non-tolerant behavior; 2. violence and self-harm; 3. sexual or flirtatious behavior; 4. controversial and polarizing topics. Since the database of both MultiWOZ and SGD are sampled from real world, annotators also comment if there are real names included in the slot values, which can be personally identifiable information (PII). Considering both of these two datasets are public dataset, we do not replace those named entities with placeholders. The detailed description of sensitive topics is included in the Fig. 7 in the appendix.

A Supplementary Details for Augmentation

A.1 Involving Domains

- **MultiWOZ:** “restaurant”, “hotel”, and “attraction”
- **Google SGD:** ”events_3”, ”homes_2”, ”hotels_4”, ”media_3” , ”messaging_1” , ”movies_1”, ”movies_3”, ”music_3”, ”restaurants_2”, ”services_1”, ”services_4”, ”travel_1”, ”events_1”, ”homes_1”, ”hotels_1”, ”media_2”, ”movies_2”, ”music_1”, ”hotels_3”, ”media_1”, ”music_2”, ”restaurants_1”, ”services_2”, ”services_3”,

A.2 Context-Free Grammars

Here we list some examples of the context-free grammars that we use for augmentation:

- SIMPLE -> which OBJECT ((do | did) you VERB-2 | would you VERB-2-WOULD | (would you be | (are | were) you) (VERB-2-ING | ADJ))
- VERB-2 -> want [to (know | learn) [about]] | wish to (know | learn) [more] about | have in mind | mean [by that| exactly | precisely] | need [information for |that info for] | refer to
- VERB-2-WOULD -> want [to (know | learn) [about]] | wish to (know | learn) about | care about | like VERB-2-WOULD-LIKE
- VERB-2-WOULD-LIKE -> (further | more) information about | me to check | to (hear about | know [more] about)
- VERB-2-ING -> asking [about | for] | inquiring about | looking at | referring to [exactly] | talking about | thinking [about | of] | (requesting | seeking) (further | more) information about
- ADJ -> curious about | interested in [exactly | learning more about]

A.3 Human Paraphrasing

The whole paraphrasing job involved 37 annotators and cost around $26,000 in total. We employed the Appen crowdsourcing platform to collect the data. We plan to release the geographic characteristics of the annotator population along with the data.

B Licenses for Relevant Artifacts

- SIMMC 2.0: CC BY-NC-SA 4.0
- GPT2: Modified MIT License

C Supplementary Details for Experiments

C.1 Hyper-Parameters

We do a hyper-parameter search for the training on both original dataset and augmented dataset and find the following setting: a batch size of 4 and learning rate of 5e-6 is the best one for both. We run at most 20 epochs for each experiment and do validation for every epoch, with an early stop step of 3. For each experiment, we run for three times with different random seeds and report the average value, along with the standard deviation. We run experiments with NVIDIA RTX A4000 GPU for totally 1440 hours.

C.2 Metric

Joint Goal Accuracy evaluates the performance of predicting dialog states. It counts one for each turn if the model successfully generate all slot values, otherwise count zero.

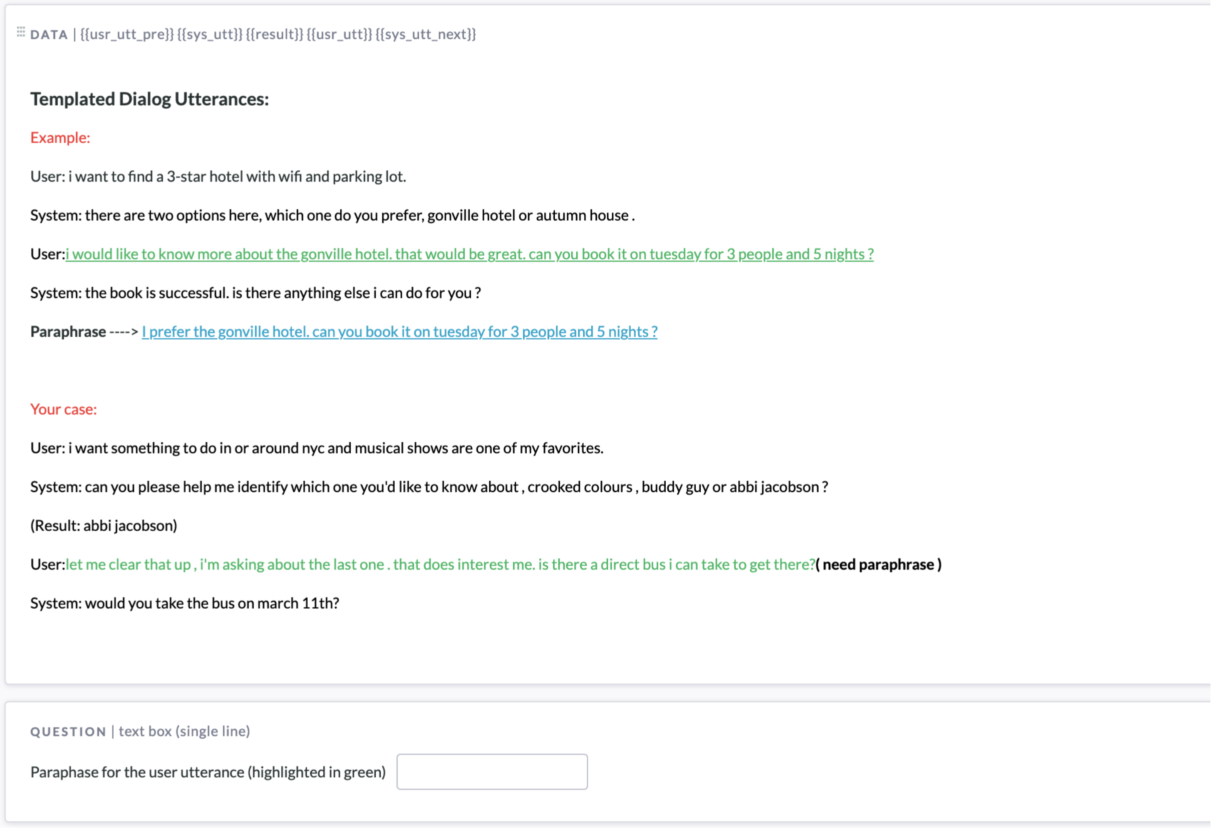
D Interface of Human Paraphrasing



DATA | {{usr_utt_pre}} {{sys_utt}} {{result}} {{usr_utt}} {{sys_utt_next}}

Templated Dialog Utterances:

Example:

User: i want to find a 3-star hotel with wifi and parking lot.

System: there are two options here, which one do you prefer, gonville hotel or autumn house .

User:i would like to know more about the gonville hotel. that would be great. can you book it on tuesday for 3 people and 5 nights ?

System: the book is successful. is there anything else i can do for you ?

Paraphrase ----> I prefer the gonville hotel. can you book it on tuesday for 3 people and 5 nights ?

Your case:

User: i want something to do in or around nyc and musical shows are one of my favorites.

System: can you please help me identify which one you'd like to know about , crooked colours , buddy guy or abbi jacobson ?

(Result: abbi jacobson)

User:let me clear that up , i'm asking about the last one . that does interest me. is there a direct bus i can take to get there?**(need paraphrase)**

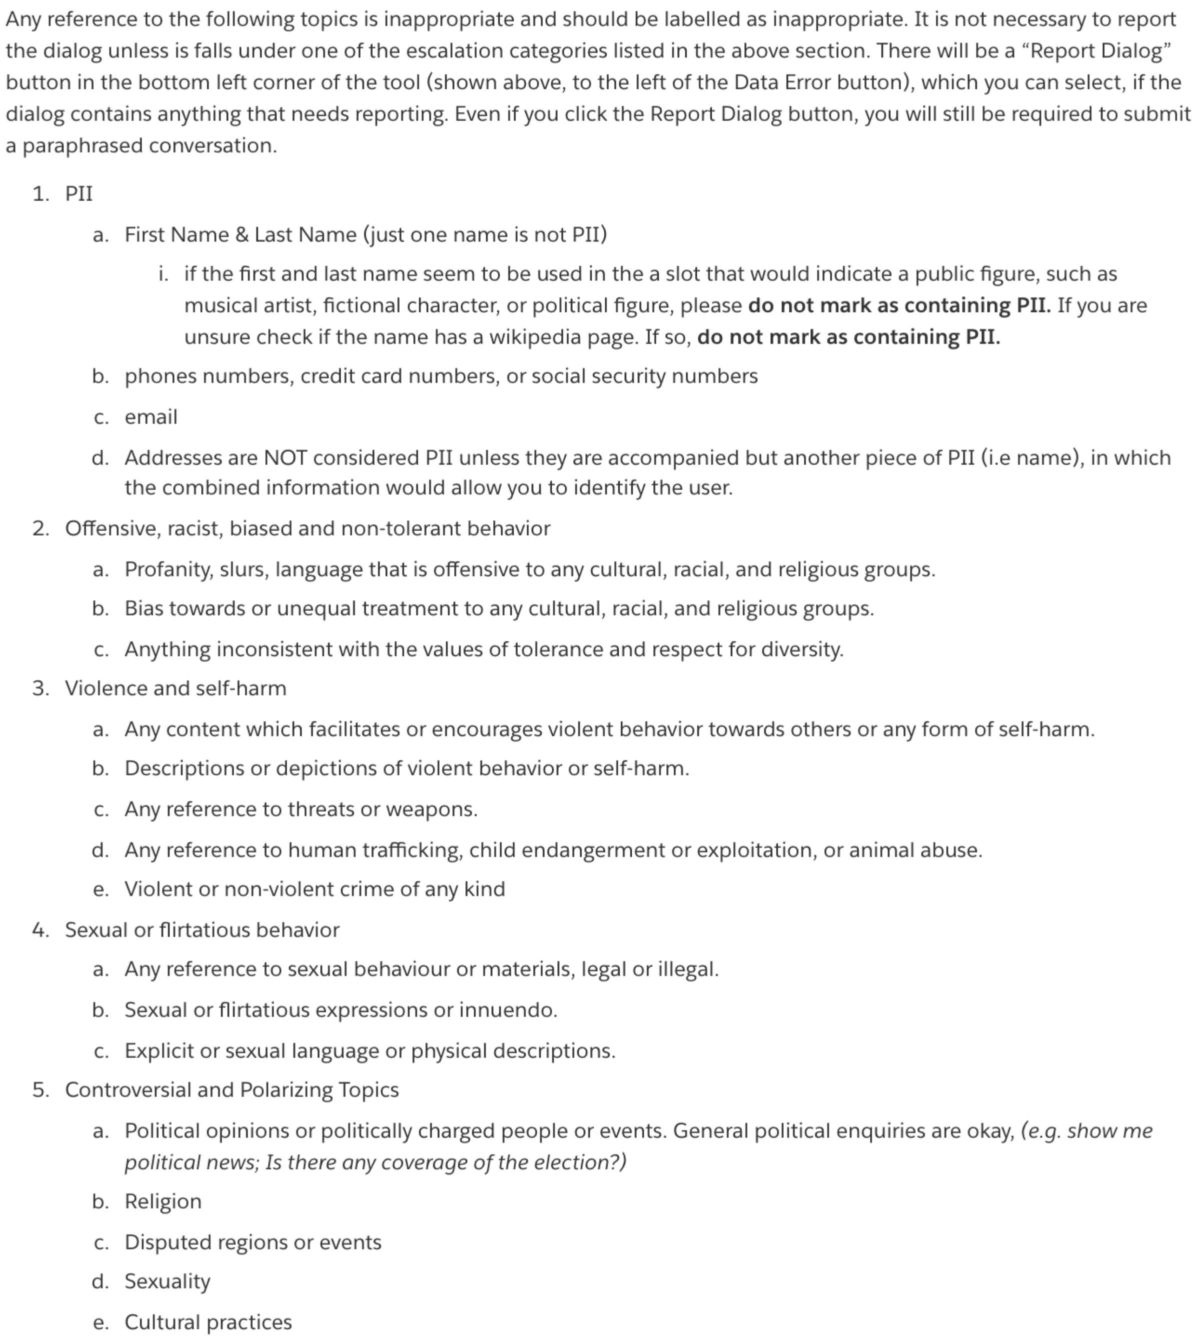
System: would you take the bus on march 11th?

QUESTION | text box (single line)

Paraphase for the user utterance (highlighted in green)

Figure 6: Interface to collect human paraphrasing data.

E Guidelines of Human Paraphrasing



Any reference to the following topics is inappropriate and should be labelled as inappropriate. It is not necessary to report the dialog unless is falls under one of the escalation categories listed in the above section. There will be a "Report Dialog" button in the bottom left corner of the tool (shown above, to the left of the Data Error button), which you can select, if the dialog contains anything that needs reporting. Even if you click the Report Dialog button, you will still be required to submit a paraphrased conversation.

1. PII
    a. First Name & Last Name (just one name is not PII)
        i. if the first and last name seem to be used in the a slot that would indicate a public figure, such as musical artist, fictional character, or political figure, please **do not mark as containing PII.** If you are unsure check if the name has a wikipedia page. If so, **do not mark as containing PII.**
    b. phones numbers, credit card numbers, or social security numbers
    c. email
    d. Addresses are NOT considered PII unless they are accompanied but another piece of PII (i.e name), in which the combined information would allow you to identify the user.
2. Offensive, racist, biased and non-tolerant behavior
    a. Profanity, slurs, language that is offensive to any cultural, racial, and religious groups.
    b. Bias towards or unequal treatment to any cultural, racial, and religious groups.
    c. Anything inconsistent with the values of tolerance and respect for diversity.
3. Violence and self-harm
    a. Any content which facilitates or encourages violent behavior towards others or any form of self-harm.
    b. Descriptions or depictions of violent behavior or self-harm.
    c. Any reference to threats or weapons.
    d. Any reference to human trafficking, child endangerment or exploitation, or animal abuse.
    e. Violent or non-violent crime of any kind
4. Sexual or flirtatious behavior
    a. Any reference to sexual behaviour or materials, legal or illegal.
    b. Sexual or flirtatious expressions or innuendo.
    c. Explicit or sexual language or physical descriptions.
5. Controversial and Polarizing Topics
    a. Political opinions or politically charged people or events. General political enquiries are okay, *(e.g. show me political news; Is there any coverage of the election?)*
    b. Religion
    c. Disputed regions or events
    d. Sexuality
    e. Cultural practices

Abstract

Carefully-designed schemas describing how to collect and annotate dialog corpora are a prerequisite towards building task-oriented dialog systems. In practical applications, manually designing schemas can be error-prone, laborious, iterative, and slow, especially when the schema is complicated. To alleviate this expensive and time consuming process, we propose an unsupervised approach for slot schema induction from unlabeled dialog corpora. Leveraging in-domain language models and unsupervised parsing structures, our data-driven approach extracts candidate slots without constraints, followed by coarse-to-fine clustering to induce slot types. We compare our method against several strong supervised baselines, and show significant performance improvement in slot schema induction on MultiWoz and SGD datasets. We also demonstrate the effectiveness of induced schemas on downstream applications including dialog state tracking and response generation.

1 Introduction

Defining task-specific schemas, including intents and arguments, is the first step of building a task-oriented dialog (TOD) system. In real-world applications such as call centers, we may have abundant conversation logs from real users and system assistants without annotation. To build an effective system, experts need to study thousands of conversations, find relevant phrases, manually group phrases into concepts, and iteratively build the schema to cover use cases. The schema is then used to annotate belief states and train models. This process is labor-intensive, error-prone, expensive, and slow (Eric et al., 2020; Zang et al., 2020; Min et al., 2020; Yu and Yu, 2021). As a prerequisite, it hinders quick deployment for new domains and tasks. We therefore are interested in developing automatic schema induction methods in this work to create the ontology[1] from conversations for TOD tasks.

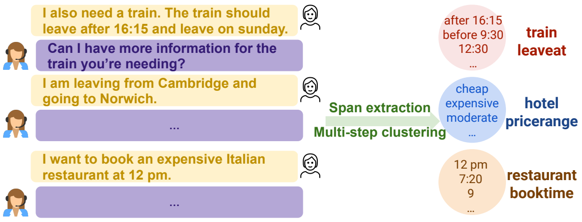

Figure 1: Overview of slot schema induction from raw conversations. We use a bottom-up representation level distance function derived from pre-trained LMs (combined with PCFG structure) to extract informative candidate phrases such as "after 16:15" and "expensive". The spans are subsequently clustered through multiple stages to form coarse to fine categories. The ground truth mapping is shown on the right (such as "train leaveat").

Most existing approaches for slot schema induction rely on syntactic or semantic models trained with labeled data (Chen et al., 2013; Hudeček et al., 2021; Min et al., 2020). Our proposed method, on the other hand, is completely unsupervised without requiring generic parsers and heuristics, and hence portable to new tasks and domains seamlessly, overcoming the limitations of previous research. Analogous to human experts, our procedure is divided into two general steps: relevant span extraction, and slot categorization. Fig. 1 provides an overview of our approach. We introduce a bottom-up span extraction method leveraging a pre-trained language model (LM) and regularized by unsupervised probabilistic context-free grammar (PCFG) structure. We also propose a multi-step auto-tuned clustering method to group the extracted spans into fine-grained slot types with hierarchy.

We demonstrate that our unsupervised induced slot schema is well-aligned with expert-

---

[*] work done during internship at Google Research

[1] We use "schema" and "ontology" interchangeably in this paper. Following previous work in literature, we focus on schema induction for slots, which is more challenging than domains and intents.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1174 - 1193
July 10-15, 2022 ©2022 Association for Computational Linguistics

designed reference schema on the public MultiWoZ (Budzianowski et al., 2018) and SGD (Rastogi et al., 2020) datasets. We further evaluate the induced schema on dialog state tracking (DST) and response generation to indicate usefulness and demonstrate performance gains over strong supervised baselines. Meanwhile, our method is applicable to more realistic scenarios with complicated schemas.

2 Related Work

Schema induction from dialog logs has not been studied extensively in the literature and developers resort to a patch work of tools to automate parts of the process. We first introduce related work on schema induction for dialog, and then discuss previous research on span extraction as part of schema induction for slots.

Schema induction for dialog Motivated by the practical advantages of unsupervised schema induction such as reducing annotation cost and avoiding human bias, Klasinas et al. (2014); Athanasopoulou et al. (2014) propose to induce spoken dialog grammar based on n-grams to generate fragments. Different from studying semantic grammars, Chen et al. (2013, 2014, 2015b,a); Hudeček et al. (2021) propose to utilize annotated FrameNet (Baker et al., 1998) to label semantic frames for raw utterances (Das et al., 2010). The frames are designed on generic semantic context, which contains frames that are related to the target domain (such as "expensiveness") and irrelevant (such as "capability"), while other relevant slots such as “internet” cannot be extracted because they do not have corresponding defined frames. This line of work focuses on ranking extracted frame clusters and then manually maps the top-ranked induced slots to reference slots. Instead of FrameNet, Shi et al. (2018) extract features such as noun phrases (NPs) using part-of-speech (POS) tags and frequent words and aggregate them via a hierarchical clustering method, but only about 70% target slots can be induced. In addition to the unsatisfactory induction results due to candidate slot extraction, most of the previous works are only applicable to a single domain such as restaurant booking with a small amount of data, and require manual tuning to find spans and generate results. These methods are not easily adaptable to unseen tasks and services.

The most comparable work to ours is probably Min et al. (2020), which is not bounded by an existing set of candidate values so that potentially all slots can be captured. They propose to mix POS tags, named entities, and coreferences with a set of rules to find slot candidates while filtering irrelevant spans using manually updated filtering lists. In comparison, our method does not require any supervised tool and can be easily adapted to new domains and tasks with self-supervised learning. In addition to flexibility, despite our simple and more stable clustering process compared to their variational embedding generative approach (Jiang et al., 2017), our method achieves better performance on slot schema induction and our induced schema is more useful for downstream tasks.

We survey schema induction work for other natural language processing tasks in Appendix A.11.

Span extraction Previous works in span extraction consider all combination of tokens as candidates (Yu et al., 2021). Alternatively, keyphrase extraction research (Campos et al., 2018; Bennani-Smires et al., 2018) mostly depends on corpus statistics (such as frequency), similarity between phrase and document embeddings, or POS tags (Wan and Xiao, 2008; Liu et al., 2009), and formulates the task as a ranking problem. Although these methods can find meaningful phrases, they may result in a low recall for TOD settings. For instance, the contextual semantics of a span (such as time) in an utterance may not represent the utterance-level semantics compared to other generic phrases. Other methods for span extraction include syntactic chunking, but mostly require supervised data (Li et al., 2021) and heuristics (such as considering “noun phrases” or “verb phrases”), and thus are not flexible and robust compared to our method.

Finally, target spans can be found in syntactic structures which can be potentially induced from supervised parsers or unsupervised grammar induction (Klein and Manning, 2002, 2004; Shen et al., 2018; Drozdov et al., 2019; Zhang et al., 2021). Kim et al. (2020) probe LMs and observe that recursively splitting sentences into binary trees in a top-down approach can correlate to constituency parsing. However, unlike the task of predicting relationship between words in a sentence where phrases at each level of a hierarchical structure are valid, detecting clear boundaries is critical to span extraction but challenging with various phrase lengths. Even though more flexible compared to semantic parsers that are limited by pre-defined roles, there is no straightforward way to apply these methods to span extraction.

3 Unsupervised Slot Schema Induction

Our proposed method for slot schema induction consists of a fully unsupervised span extraction stage followed by coarse-to-fine clustering. The resulting clusters can be mapped to slot type labels.

3.1 Overview

Given user utterances from raw conversations, our goal is to induce the schema of slot types $\mathcal{S}$ and their corresponding slot values. The span extraction stage extracts spans (e.g., “with wifi”) from an utterance $\mathbf{x}$. The candidate spans from all user utterances are then clustered into a set of groups $\mathcal{S}$ where each group s_i corresponds to a slot type such as “internet” with values “with wifi”, “no wifi”, and “doesn’t matter”. The induced slot schema can be later used for downstream applications such as dialog state tracking and response generation.

Algorithm 1: Span Extraction

```
Require: $\mathbf{x} = x_1, x_2, \ldots, x_n$: a user utterance $\mathbf{x}$
$\mathbf{t} \leftarrow PCFG(\mathbf{x})$ {A Chomsky normal form (binary) tree structure from self-supervised PCFG}
$\mathbf{a} \leftarrow LM(\mathbf{x})$ {Attention distribution from a LM}
$\mathbf{d} \leftarrow [d_i = f(a_i, a_{i+1})$ for $i = 1, 2, \ldots, n-1]$ {Distance between consecutive tokens using a distance function f}
$\tau \leftarrow$ median($\mathbf{d}$)
sort $\mathbf{d}$ in increasing order
for all $d_i$ in $\mathbf{d}$ do
    if $d_i < \tau$ and using PCFG then
        if $node_i$ and $node_{i+1}$ are siblings in PCFG then
            $node_{i+1} \leftarrow \{node_i, node_{i+1}\}$ {merge nodes, assign new parents}
        end if
    else if $d_i < \tau$ then
        $w_{i+1} \leftarrow \{w_i, w_{i+1}\}$ {merge two tokens}
    end if
end for
```

3.2 Candidate span extraction

Challenges Since it is unclear what spans are meaningful phrases representative of task-specific slots, candidate span extraction presents two challenges. Firstly, with either supervised or unsupervised predicted structures, there is no protocol on what constituent and from what level we should extract the spans from without relying on dataset-specific heuristics, especially as structured representations are often compositional (Herzig and Berant, 2021). The second challenge is that span extraction methods should be flexible and robust to unseen tasks and domains. To tackle these problems, we leverage pre-trained LMs and propose a novel bottom-up attention-based span extraction method regularized by unsupervised PCFG for better structure representation. Because our method does not need any supervised data, the second problem can be effectively addressed by in-domain self-training. The full algorithm is outlined in Algorithm 1.

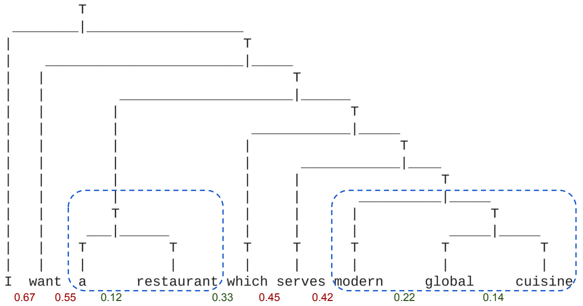

Figure 2: Illustration of span extraction where LM-derived distance function (distances between tokens are shown below the text) is constrained by a structure predicted by PCFG (tree structure shown in the figure). Numbers in red are above the median threshold (0.375) while numbers in green are below, indicating that the tokens share similar semantics and are from the same span. We can then extract candidate phrases “a restaurant” and “modern global cuisine”, together with unigrams “I”, “want”, “which”, and “serves”.

Bottom-up attention-based extraction with LMs and PCFG regularization Recent studies reveal that attention distributions in pre-trained LMs can indicate syntactic relationships among tokens (Clark et al., 2019). Therefore, we hypothesize that similar attention distributions indicate tokens to form a meaningful phrase. We define the distance between attention distributions as a symmetric Jensen-Shannon divergence (Clark et al., 2019), and iteratively merge tokens whose distance is smaller than a threshold[2] in a bottom-up fashion. We start from the smallest distance to the largest, where the merged tokens are considered as a new token in the next iteration but the distribution distance with adjacent tokens remains the same. Fig. 2 illustrates the distances between tokens from a pretrained LM for an example sentence where adjacent tokens such as “global” and “cuisine” are merged but not “serves” and “modern”. This new decoding method enables us to effectively group tokens into phrases with precise boundaries.

Although LMs can be used to induce grammar,

---

[2] We use the median of all pairwise distances in an utterance in the experiments. We also compared other thresholds such as mean but did not observe significant difference.

their training objectives are not optimized for sentence structure prediction, hence falling behind unsupervised PCFG (Kim et al., 2020) on syntactic modeling[3]. Utilizing attention distribution from LM representations to extract spans can thus be fuzzy and noisy. We therefore employ unsupervised PCFG proposed by Kim et al. (2019) as a mechanism to regularize our bottom-up span extraction. Instead of relying solely on attention distribution, we in addition require two tokens to share the same parent in the predicted PCFG tree structure before merging. This extra requirement reduces the noise from the distribution divergence in a sub-optimal structure representation. An example illustrating the necessity of span constraint is given in Fig. 2. Even though the distance between "restaurant" and "which" is small (0.33), we disregard this span since they do not belong to the same parent in the PCFG structure. After merging two tokens, we assign the grandparent of the two tokens as the new parent, and continue the iteration until all distances are examined.

Self-supervised in-domain training Our attention-based approach enables us to extract phrases beyond certain n-grams, or certain types of phrases in a specific hierarchical layer. More importantly, it is appealing to adapt to new domains and services, where a LM can be further trained to encode structure representations without any annotated data and to group tokens into candidate phrases based on the training corpus. To encourage efficient span extraction above token-level representation, we further pre-train a SpanBERT model (Joshi et al., 2020) by predicting masked spans together with a span boundary objective (denoted as TOD-Span) on TOD data (Wu et al., 2020). In addition to masking random contiguous spans with a geometric distribution, we also mask spans inspired by recent findings such as segmented PMI (Levine et al., 2021) among other methods (See Appendix A.3 for details). This process can be thought of as incorporating corpus statistics such as phrase frequency into the model implicitly (Henderson and Vulić, 2021).

The unsupervised PCFG is trained to maximize the marginal likelihood of in-domain utterances with the inside-outside algorithm on the same TOD dataset. Similar to self-supervised LMs, this process is flexible and robust against domain mismatch, a common problem with supervised parsers (Davidson et al., 2019). At inference time, the trained model predicts a Chomsky normal form from Viterbi decoding (Forney, 1973).

3.3 Clustering candidate spans

Challenges After extracting candidate spans as potential slot values, we apply contextualized clustering on them to form latent concepts each slot value belongs to. We face two major challenges. Firstly, for any clustering method, hyperparameters such as the number of clusters are critical to the clustering quality, while they are not known for a new domain. Secondly, because of the trivial differences in slot types (for example, a location can be a "train departure place", or a "taxi arrival place"), clustering requires considering different dimensions of semantics and pragmatics. To address these problems, we propose an auto-tuned, coarse-to-fine multi-step clustering method. The pseudo code of the clustering algorithm can be found in Appendix A.2.

Auto-tuning hyperparameters To avoid hyperparameter tuning, we utilize density-based HDBSCAN (McInnes et al., 2017). Compared to other clustering methods such as K-Means, HDBSCAN is mainly parametrized by the minimum number of samples per cluster, and resulting clusters are known to be less sensitive to this parameter. We set this number automatically by maximizing the averaged Silhouette coefficient (Rousseeuw, 1987)

$$s = \frac{b-a}{max(a,b)}$$

across all clusters where a represents the distance between samples in a cluster, and b measures the distance between samples across clusters.

Multi-step clustering The input to our first-step clustering is the contextualized span-level representation from the extracted spans. Specifically, we consider the mean representation of tokens in the span from the last layer as the span representation. To prevent the surface-level token embeddings from playing a dominant role, we replace candidate spans with masked tokens and use the contextual representation of the masked spans (Yamada et al., 2021). After the first step of clustering, we have coarse groups illustrated in Appendix A.5.

---

[3] Note that although Kim et al. (2020) utilizes attention to construct constituency trees, our methods are different: we propose a bottom-up approach to identify meaningful spans with clear boundaries (rather than a tree structure) after in-domain further pre-training.

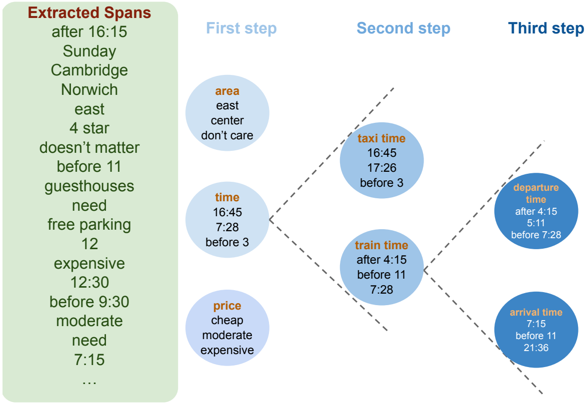

Figure 3: Multi-step clustering procedure. Each coarse cluster is further refined by next-step clustering. The first step uses contextualized span representations to capture salient groups (such as a cluster about time), and the second step uses the utterance-level representations of each span to capture domain and intent information (such as the train service and taxi service). The third step utilizes span-level representation for fine-grained slot types.

Michael et al. (2020) suggest that we may only identify salient clusters (e.g., cardinal numbers), but cannot separate for example, different types of cardinals (e.g., number of people or number of stays). Thus, in the second step, we cluster examples within each cluster from the first step leveraging utterance level representation of spans (i.e., the [CLS] token of the utterance). Specifically, we identify the utterance-level representation for spans grouped from the first step. This enables us to distinguish between domains and intents as they reflect utterance-level semantics. For example, we may find a cluster of time information (e.g., "11 AM") in the first step, and the second step clustering is to differentiate between train and taxi booking time. Lastly, we cluster groups developed from the second step into more fine-grained types using span-level representations similar to the first step. After this multi-step clustering, we can potentially separate for instance, departure time and arrival time in train booking. This process is illustrated in Fig. 3. Each cluster represents a slot type, with slot values shown as data points. This multi-step clustering brings an additional benefit of inducing the slot schema with hierarchy, where sub-groups in further steps belong to the same parent group.

4 Experiments

To examine the quality of our induced schema, we perform *intrinsic* and *extrinsic* evaluations. Our intrinsic evaluation compares the predicted schema with the ground truth schema by measuring their overlap in slot types and slot values. This indicates how well our induced schema aligns with the expert annotation. The extrinsic evaluation estimates the usefulness of the induced schema for downstream tasks, for which we consider dialog state tracking and response generation tasks. Experiments are conducted on MultiWOZ (Eric et al., 2020) and SGD (Rastogi et al., 2020) datasets following previous research. See Appendix A.1 for implementation details. We also apply and evaluate our method for both intent and slot schema induction on realistic scenarios (See Section 5).

Baselines We compare our proposed approach with different setups against DSI (Min et al., 2020), which uses supervised tools and heuristics. We evaluate different span extraction methods including using parsers only, leveraging distance functions from LMs, and combining LMs with unsupervised PCFG. Specifically, NP extracts all noun phrases[4], DSI cand. uses the same candidates phrases as DSI, and PCFG and CoreNLP (Manning et al., 2014) extract phrases from an unsupervised and supervised structure respectively by taking the smallest constituents above the leaf level. These baselines solely rely on parsers. For our bottom-up attention-based LM methods (Section 3.2), we compare spans extracted using representations from BERT (Devlin et al., 2019), SpanBERT (Joshi et al., 2020), TOD-BERT (Wu et al., 2020), and our span-based TOD pre-training from masking random spans (TOD-Span). Lastly, we combine the LMs with unsupervised PCFG structures.

Due to space constraints, we show results on MultiWOZ in this section. Observations on SGD can be found in the Appendix.

4.1 Slot schema induction

To evaluate the induced schema against ground truth, we need to match clusters to ground truth labels[5]. Previous work on dialog schema induction either requires manual mapping from a cluster to the ground truth (Hudeček et al., 2021) or compares predicted slot values to its state annotation at each turn (Min et al., 2020). These can create noises and biases, hence not practical when no annotation is available. Particularly, Min et al. (2020)

---

[4] `https://spacy.io/`

[5] Predicting labels for each cluster is out of the scope of this paper. Since there are many ways to assign labels with equal semantics to a cluster (e.g., "food" vs. "restaurant type"), we leave this to future work.

compare candidate spans to corresponding reference slot types at each turn, which is a small subset of the ground-truth ontology. This would overestimate the performance of schema induction since the matching is more evident and is different from defining schemas in realistic settings. Instead, we simulate the process of an expert annotator mapping clusters to slot names by considering the general contextual semantics of spans in a cluster.

Setup We consider semantic representations of ground truth clusters as labels. Specifically, we calculate the contextual representation of spans averaged across all spans in an induced cluster as cluster representations, and compare that with ground truth slot type representations computed in the same way. For fair comparison among different methods, we use BERT to obtain span representations. We assign the name of the most similar slot type representation to a predicted cluster measured by cosine similarity. If the score is lower than 0.8 (Min et al., 2020), the generated cluster is considered as noise without mapping, which simulates when a human cannot label the cluster. We report precision, recall, and F1 on the induced slot types. When the number of clusters is larger than the ground truth, multiple predicted clusters can be mapped to one slot type. This evaluation process is identical to human annotation, where the ground truth clusters serve as references (before assigning cluster labels) to predicted clusters, but may be biased towards more clusters when more clusters are likely to cover more ground truth clusters (i.e., potentially higher recall). Thus we report the number of induced clusters for reference. Similarly, within each slot type, we compute the overlapping of cluster values to all ground truth slot values and report precision, recall, and F1 by fuzzy-matching scores (Min et al., 2020), averaged across all types.

Results Table 1 shows the results of schema induction on slot types and slot values. All methods lead to a number of clusters within a similar range (except the slightly larger 522 clusters for DSI), indicating that the results are not biased and are comparable. When the candidate span input to our proposed multi-step clustering is the same as the baseline DSI using POS tagging and coreference (DSI cand.), we achieve similar performance on slot type induction (85.19) and better results on slot values (49.71). This illustrates the effectiveness of our proposed clustering method since the only difference from the DSI baseline is clustering. Compared to methods leveraging noun phrases (NP), or supervised parsers (CoreNLP), using an unsupervised PCFG trained on in-domain TOD data can achieve comparable or superior results.

method	# clusters	slot type	slot value
Baseline			
DSI	522	87.72	37.18
Parser only			
NP	88	69.39	47.46
DSI cand.	113	85.19	49.71
PCFG	339	91.53	53.62
CoreNLP	292	87.72	54.43
Language model only			
BERT	340	85.71	55.80
SpanBERT	343	89.66	45.21
TOD-BERT	219	89.66	50.89
TOD-Span	374	85.71	55.29
Language model contrained on unsupervised PCFG			
BERT	350	87.72	52.32
SpanBERT	203	89.66	44.51
TOD-BERT	245	91.53	48.13
TOD-Span	290	**96.67**	**58.71**

Table 1: Schema induction results on MultiWOZ. TOD-Span (span-based LM further pre-trained on in-domain data) regulated by PCFG achieves the best performance on slot type induction and slot value induction evaluated by F1 scores. All methods (except DSI) differ only by span extraction (i.e., same clustering).

If we extract spans using LMs only, different models perform similarly on both slot types and slot values. However, when regularized by an unsupervised PCFG structure, we observe a large performance boost especially with TOD-Span. This indicates that the unsupervised PCFG can provide complementary information to LMs. In addition, results show that further pre-training a LM at the span level is more efficient. The better representation from span-level in-domain self-training can also be justified by a standard dialog state tracking task with few-shot or full data shown in Appendix A.3. Detailed comparison among different LM pre-training results can be seen in Appendix A.13.

4.2 Application in DST

Now that we have mapped induced clusters to ground truth names, we can immediately evaluate DST performance by identifying slot values and types as described above. This can be considered as a zero-shot setting.

method	turn level	joint level
Baseline		
DSI	18.29	25.22
Parser only		
PCFG	25.43	32.39
Language model only		
BERT	24.35	30.18
SpanBERT	20.24	26.07
TOD-BERT	25.05	34.94
TOD-Span	29.72	38.89
Language model contrained on unsupervised PCFG		
BERT	23.27	30.09
SpanBERT	20.96	27.25
TOD-BERT	27.11	31.92
TOD-Span	**39.59**	**46.69**

Table 2: DST results on MultiWOZ. We show F1 scores of turn and joint level. TOD-Span regularized by PCFG achieves the best performance.

Setup Following Min et al. (2020), we calculate the overlapping of the predicted slots and values with their corresponding ground truth at both the turn level and the joint level. At each turn, a fuzzy matching score is applied on predicted values (Rastogi et al., 2020) whose corresponding slot types are in the ground truth. On the other hand, even if a slot value is predicted correctly but its slot type does not match the ground truth, no reward is accredited. On the joint level, we calculate the score for accumulative predictions up to the current turn.

Results Table 2 summarizes the results for DST. Similar to the trend in schema induction, constraining an in-domain fine-tuned LM (TOD-Span) on an unsupervised structure representation (PCFG) achieves the best performance (39.95 on turn level), significantly outperforming a strong baseline DSI (18.29)[6]. We also note that because all accumulated predictions are evaluated for partial rewards instead of exact matching on all slot types in standard DST evaluation, the joint level scores are higher than the turn level from accumulative scores. See Appendix A.8 for more detailed discussions.

4.3 Application in response generation

The above settings map latent slot clusters to ground truth analogous to expert designs so that we can evaluate the alignment with human annotations. This experiment investigates whether the induced latent schema is still useful before mapping.

belief state	BLEU
None	15.6
DSI	13.9
TOD-Span + PCFG	16.4
Ground truth	17.9

Table 3: Response generation results on MultiWOZ. Our method introduces positive inductive bias.

Setup We modify the model of Lei et al. (2018); Zhang et al. (2020) by appending the predicted labels (i.e., a cluster index such as “10-15-2” indicating a specific slot type where each number represents a slot type from a clustering step. This can also be considered as a hierarchical cluster label) and values to the context (e.g., “I need a train at 7:45. [10-15-2] 7:45” as input). The added belief state can be considered as a prior to generate responses similar to Hosseini-Asl et al. (2020). Since we do not have the mapped names of the slots, we only report the BLEU score rather than other metrics used in response generation that require entity-level matching (e.g., inform rate). This is a more practical setting directly evaluating on the induced schema compared to previous work (Min et al., 2020), where dialog act is modeled with delexicalized input utterances (Chen et al., 2019, not feasible because ontology is required from a pre-defined schema for delexicalization).

Results Table 3 compares the performance of using no belief state (None), belief state induced by DSI, our introduced method (TOD-Span + PCFG), and ground truth. Results show that our induced schema introduces a positive inductive bias (16.4) compared to the baseline (15.6) and is close to the ground truth schema with actual slot type names. We conjecture that the lower performance of DSI is due to the larger number of latent types (522) which creates noises in model training. Thus, our induced slot schema is useful for downstream applications.

5 Analysis

Comparison among different methods Our results show that in general, span-based pre-training methods outperform token-based, and continued pre-training on in-domain data is important. When regularized by PCFG structures, we observe a large performance boost on TOD-BERT and TOD-Span,

---

[6] We use the provided data and model to run the DSI baseline. The reason the score is lower here than the original report is due to slot type matching (Section 4.1).

however the PCFG structure does not help BERT and SpanBERT when the LM is trained on general domain data only. We speculate that the LM representation trained on generic text is not compatible with the predicted structure induced via in-domain self-supervision. This justifies our hypothesis in Section 3.2 that optimized structures from in-domain PCFG can regularize target span extraction.

In addition, we believe that the performance gap between our proposed method and previous research using rules from supervised parsers (such as NPs and coreference) is larger when the data is less biased (for example, if NP is not dominant as slot values, Du et al., 2021). Moreover, our proposed method is data-driven, indicating that the slots are determined by the dialog corpus and are more robust again label bias. If there are specific annotation requirements, we can inject inductive bias to the LM to change distribution distances (Shi et al., 2019) or add rules to incorporate such conditions. See Appendix A.12 for discussions.

Comparison among different datasets On MultiWOZ, our method induces 30 out of 31 slot types in the ontology except “hospital-department”, which only appears once in the dialog corpus. For slot values, errors are mostly from low precision due to loose boundaries and semantic matching (e.g., predicting “free wifi”, and “include free wifi”, where the target value is “yes”). In comparison, DSI induces 26 slot types, with similar slots mixed (such as mapping “taxi-arriveby” to “taxi-leaveat”). It receives a relatively low slot value score since spans extracted using rules are not robust and compatible.

On SGD where 82 slot types are defined in the ontology, our method induces 50 and DSI induces 72. The main reason for this low recall is similar slot types with overlapping values (such as “media-genre” and “movies-genre”), and single-value slots (such as “has-wifi” with the value “True”). More importantly, SGD has a smaller utterance length, making it more difficult to map to the correct slot type without considering more context. With a magnitude more number of clusters, DSI (11992 clusters) has a higher chance to map predicted slots to target slot types which explains better performance than ours on schema induction. However, this large number of clusters make it infeasible for humans to use, and our induced schema is comparable in downstream tasks such as DST despite having a much smaller number of clusters.

On both datasets, in addition to values that can be extracted by spans, our method can also extract phrases such as “doesn’t matter” which maps to the “don’t care” slot value. In particular, on MultiWOZ, “hotel-internet” receives the lowest f1 score (0.07 with precision of 0.04 and recall of 0.35), mainly because of imprecise boundaries for low precision (e.g. “free wifi”, “include free wifi”, and “offer free wifi”). It also mixes with “free parking” because of the context (hotel). On SGD, due to our filtering step and many slots have only one value (e.g. “Homes-has-wifi” and “Homes-has-pets”), and the value (“True”) cannot be detected by spans, we received a lower schema induction score. In addition, there are 16 groups with lower matching score (< 0.8). This is particularly an issue when the number of instances is small (only 8 instances for “home-furnished” in total). If more instances are available, it is likely that our method can recover these missed slots due to low matching scores.

However, the schema defined here is less complicated compared to more realistic settings. For example, spans may not be a noun phrase (such as “until the 30th” to distinguish from “after the 30th” in the utterance “Do I have access to my premium account until the 30th or will I have to pay additional $15 on the 29th” to distinguish different constraints), and spans may not necessarily be meaningful arguments to intents (such as “Can you help me to reset my password” even though “reset my password” can be considered as a phrase). ABCD (Chen et al., 2021) collects more realistic TOD conversations with more in-depth discussion on finishing tasks in the shopping domain. However, they propose to leverage actions, rather than slot-value pairs as used before in slot discovery, where the actions are defined above the utterance level.

We also apply our method on internal customer data for both intent (by applying multi-step clustering directly on utterances) and slot schema induction. Compared to MultiWOZ and SGD, schema in more realistic scenarios is more complicated and the slot boundaries are less clear. Nevertheless, our method is still effective in inducing the majority of the schema to find intents such as “change password” and slot types such as “devices”. We observe similar findings on the Ubuntu dialog corpus (Lowe et al., 2015). See more discussions in Appendix A.9.

method	# clusters	schema type	schema value	DST turn	DST joint
Different number of clustering steps					
one-step	31	60.87	39.74	23.58	30.68
two-step	99	83.64	46.66	35.21	41.94
Original representation instead of masked					
unmasked rep.	284	85.71	53.30	27.93	36.40
Three-step masked clustering					
Three-step masked	290	96.67	58.71	39.59	46.69

Table 4: Ablation results on MultiWOZ with TOD-Span constrained on PCFG. Using masked presentation for multi-step clustering improves the performance on schema induction and DST by a large margin.

Ablation studies Table 4 illustrates the performance comparisons with different numbers of clustering steps, as well as input representations. Results demonstrate that compared to one-step (using masked span representation) and two-step (adding utterance representation), our three-step clustering method induces a more fine-grained schema, which is more effective for downstream tasks. The number of steps can be customized to real use cases depending on target granularity[7]. In addition, if we use the original input rather than the masked phrase representation, the performance drops by a large margin (85.71 on slot type). This suggests that the surrounding context is more critical than the surface embeddings for schema induction, especially when the same phrase can serve different functions even in the same domain (such as locations).

DST Error analysis Suggested by the relatively high span extraction accuracy (68.13 F1 score) from Appendix A.4, we find that the majority of the problems in DST come from cluster mapping. This is caused by either excessive surrounding information or by the lack of context from previous turns. For instance, in the utterance "Can I book it for 3 people", the "3 people" can be mapped to either "restaurant-book people" or "hotel-book people", since we extract the contextual information from the current turn only. If more context is considered, the mapping performance including results on downstream tasks is expected to improve. Another issue is with span boundary. Even though we apply fuzzy matching, the evaluation still penalizes correct predictions (such as "indian food") from its ground truth ("indian"), since we do not have training signals to identify the target boundaries.

Meanwhile, we acknowledge that since we extract phrases as candidates of slot values, our DST cannot deal with other linguistic features such as coreferences and ellipses annotated in MultiWOZ and SGD. This partially explains the relatively low performance on the full zero-shot DST task. However, these features are not important for schema induction since the majority of the slot values can be found as phrases in the raw conversation, which can further be categorized into slot types. Obtaining better performance on DST is out of the scope of this paper.

6 Conclusion

In this paper, we propose a fully unsupervised method for slot schema induction. Compared to previous research, our method can be easily adapted to unseen domains and tasks to extract target phrases before clustering into fine-grained groups without domain constraints. We conduct extensive experiments and show that our proposed approach is flexible and effective in generating accurate and useful schemas without task-specific rules in both academic and realistic datasets. We believe that our method could also be applied to other languages (since no supervised parser, model, or heuristic is required) and tasks such as question answering where the answering phrase is not explicitly annotated (Min et al., 2019). In the future, we plan to extend our method to problems with more complex structures and data where slots are less trivial to identify.

7 Ethical Considerations

Our intended use case is to induce the schema of raw conversations between a real user and system, where the conversation is not structured or constrained. Our experiments are done on English data, but our approach can be used for any language, especially because our method does not require any language-specific tools such as parsers which generally require a lot of labeled data. We hope that our work can reduce design and annotation cost in building dialog systems for new domains, and can inspire future research on this practical bottleneck in applications.

Acknowledgements

We thank Abhinav Rastogi from Google Research, and anonymous reviewers for their constructive suggestions. We would also thank Kenji Sagae from UC Davis for early discussions.

---

[7] More steps were also conducted but we observed lower Silhouette coefficient and lower quality in preliminary studies.

A Appendices

A.1 Implementation details

For language model further pre-training, we implement our code based on Wu et al. (2020) where the training data and hyperparameters are kept the same. Their evaluation script is used to show results on the standard supervised dialog state tracking with the full-data and few-shot learning setting. We run all experiments on three random seeds and report the average score. The `TOD-BERT` baseline is the "TOD-BERT-JNT-V1" provided by Wolf et al. (2020). For span-based pre-training methods, we use the provided "spanbert-base-cased" model from Joshi et al. (2020) as the initial checkpoint and add a span boundary object. For random masking, we use a 15% masking budget and sample a span length by geometric distribution with $p = 0.2$ and clip the max length to 10. For other masking methods, we follow Levine et al. (2021) by considering n-grams of lengths 2 to 5 which appear more than 10 times in the corpus. We choose the top 10 - 20% of n-grams by each criterion so about half of the tokens can be identified as part of correlated n-grams. We also experimented with different number of n-grams to mask and evaluate on both pre-training loss and DST results, but did not observe significant difference. We further pre-train using the same data as TOD-BERT with early stopping by prediction loss. For the attention distribution used to define our distance function, we use the eighth layer of the model suggested by Kim et al. (2020). We modify Jin and Schuler (2020) to train our unsupervised PCFG model using their suggested hyperparameters on the text input only with data cleaned by Wu et al. (2020). These existing techniques, however, cannot be applied to induce schema without our proposed novel method. They only inspire us to propose an fully unsupervised method leveraging the potential benefits. All our experiments run on eight V-100 GPUs. The training time varies from three hours to 14 hours.

For the baseline `DSI`, we run their provided public codebase on the same MultiWOZ 2.1 data and SGD dataset respectively (since each corpus has different schemas in the output space, we cannot pre-train on more task-oriented dialog data as ours), following their suggested hyperparameters on the best model DSI-GM.

For our auto-tuned multi-step clustering, we set the minimum number of samples per cluster by dividing the total number of samples by 5, 10, 15, 20, 25 and choose the best one auto-tuned by the Silhouette coefficient. A more rigorous grid search can potentially generate better performance on our tasks. All other parameters are kept as default in HDBSCAN.

For our experiments on MultiWOZ and SGD, we use the development portion of the data (following the standard separation in their original Github repositories), which represents a sample of whole corpus. MultiWOZ and SGD are commonly used task-oriented dialog datasets collected in English. On MultiWOZ, we use 7374 user utterances from the development set (1000 conversations), which covers 31 slot types. On SGD, we use 24363 user utterances (2482 conversations), which covers 82 slot types. We also report the induced schema results on the training portion of the data in Appendix A.6 where there are 56668 user utterances (8420 conversations) on MultiWOZ 2.1., and 164982 user utterances (16142 conversations) on SGD. We build the ground-truth ontology from the annotated corpus with slot types and values in the dialog state.

A.2 Algorithm

Algorithm 1 shows the algorithm for span extraction. For simplicity, we compare the distance from left to right for both the settings with and without PCFG structure. For using language model only, we merge tokens into phrases if their distance is small. If PCFG structure is constrained, we compare the distance between tokens and check if their corresponding nodes belong to the same parent. In practice, we implement the PCFG span extraction from bottom to top where we merge tokens into nodes from the lower level and represent the tokens with merged nodes. At each level, we compare the distance between consecutive nodes. To illustrate this process, for example in Figure 2, we compare the distance between the node "modern" and "global cuisine", and the distance between "a restaurant" and "which" to check if they are siblings in the same level. Since "which" is not merged in a lower level, itself serves as the node whereas "a restaurant" serves as the node for "restaurant". All merged phrases, with left-out unigrams, are considered as candidate extracted spans.

Algorithm 2 shows the algorithm for auto-tuned multi-step clustering. For each step, the input to the clustering algorithm (HDBSCAN) is the embeddings of spans (or uttereances in the second step)

Algorithm 2: Auto-tuned Multi-step Clustering

```
Require: $\mathbf{Rep^{span}} = Rep_1^{span}, Rep_2^{span}, \dots, Rep_n^{span}$: masked span representation (hidden states of LM by replacing
    extracted spans with [MASK] token)
Require: $\mathbf{Rep^{utt}} = Rep_1^{utt}, Rep_2^{utt}, \dots, Rep_n^{utt}$: utterance-level representation (hidden states of LM on [CLS] token)
Require: $\mathbf{min\_nums}$: a list of candidate values to set for minimum samples for cluster.
$input\_embeddings \leftarrow Rep^{span}$
$clusters \leftarrow input\_embeddings$
for $step_i$ in multi-steps do
    for $input\_embeddings_i$ in $clusters$ do
        $clusters_i \leftarrow max\_i\{silhouette\_score(HDBSCAN(input\_embeddings_i, min\_num_i))\}$
        if $step\_i = 1$ then
            if all sub-clusters share the same frequent span then
                ignore $input\_embeddings_i$, continue the for loop {filter clusters with only one value}
            end if
            $clusters_i \leftarrow$ corresponding $Rep^{utt}$ for each item in $clusters_i$ {Utt-level for second step clustering}
        end if
    end for
    $clusters \leftarrow \{clusters_i$ for all i in the current step$\}$
end for
```

Model	Joint Acc.	Slot Acc.
BERT	45.6	96.6
SpanBERT	1.5	81.1
ToD-BERT	46.0	96.6
Span-based model trained on TOD data		
TOD-Span	49.0	96.9
freq	**49.7**	**97.0**
freq w/o stop	47.3	96.8
PMI	48.7	96.9
PMI_seg	49.4	**97.0**
SCP	48.3	96.8

Table 5: Supervised DST results with the full-data setting. Results show that span-based methods outperform token-based pre-training methods, and this improvement is not from the initial checkpoint. Different masking methods achieve similar performance.

grouped from the previous step. In other words, for each sub-groups clustered by the previous step, we further cluster the embeddings into fine-grained groups. Figure 3 illustrates this process. The clustering algorithms returns groups of embeddings and corresponding labels (0, 1, . . .) and we choose the minimum number of samples per cluster based on Silhouette score. We filter clusters where the frequent spans of each sub-cluster are the same, indicating that there is only one value for this cluster. We consider the rest clusters as the input to the next step, or return as our final clusters.

data	Model	Joint Acc.	Slot Acc.
1%	BERT	6.4	84.4
	SpanBERT	3.6	82.6
	TOD-BERT	7.9	84.9
	TOD-Span	9.9	86.0
5%	BERT	19.6	92.0
	SpanBERT	5.6	83.9
	TOD-BERT	20.9	91.0
	TOD-Span	28.2	93.9
10%	BERT	32.9	94.7
	SpanBERT	11.8	85.6
	TOD-BERT	30.2	93.5
	TOD-Span	38.6	95.5

Table 6: Supervised DST results with few-shot training data. Similar to the full-data setting, span-based methods achieve significantly better performance than token-based further pre-training methods.

A.3 Supervised DST results

Wu and Xiong (2020) suggest that further pre-training on TOD data (Wu et al., 2020) helps generating better utterance-level representation, but less so for other features such as slots. To encourage better span-level representation, we further pre-trained a SpanBERT model on TOD data by masking spans based on frequency, Pointwise Mutual Information (PMI), symmetric conditional probability (SCP, Downey et al., 2007), and segmented PMI (Levine et al., 2021) following recent research, together with randomly masking contiguous random spans. Implementation details can be found in Appendix A.1. Here we evaluate different pre-trained methods on the standard DST benchmark.

Model	R (LM only)	R (+ supervised)	R (+ unsupervised)
NP	62.13		
BERT	62.30	62.05	64.30
SpanBERT	58.43	64.60	62.52
TOD-BERT	54.15	60.88	65.05
TOD-Span	64.21	67.22	**68.13**
Ground Truth	78.83		

Table 7: Span extraction results on manually labeled utterances. Results show that constrained on unsupervised PCFG structure, our span-based further pre-training method TOD-Span achieves the best recall (68.13), close to the ground truth performance (78.83)

Table 5 and Table 6 shows the performance of supervised DST performance evaluated on joint accuracy and slot accuracy with the full data and few-shot data (1 - 10%), respectively. Note that this was not used to choose the best model to perform schema induction and related tasks. These results compare different pre-training methods to illustrate the quality of the initial checkpoints on a more standard benchmark. As shown similarly in recent work, TOD-BERT can only show marginal improvement over BERT averaged over different random seeds. Meanwhile, `SpanBERT` when used as an initial checkpoint is not stable at downstream DST tasks even if multiple random seeds were tested. However, after further pre-training on task-oriented dialog dataset, `TOD-Span` achieve significantly better performance in both the few-shot and full-data setting. When comparing different span masking methods, random masking (`TOD-Span`) is quite effective. Although `freq` and `PMI_seg` achieves better performance (over the naive `PMI`), the improvement is not large. We conjecture that this might be due to that compared to general domains and tasks with more diverse prediction space such as question answering, the number of task-relevant phrases in task-oriented dialog is limited.

A.4 Span Extraction Results

Table 7 shows the recall for span extraction results. We manually annotate 200 user utterances so that acceptable span boundaries would not be penalized. For instance, given the utterance “I need to book a hotel in the east that has 4 stars”, instead of the DST annotation “hotel-starts: 4” and “hotel-area: east” together with coreference and annotation errors that cannot be detected from the context, we manually annotate the candidate spans as [“in the east”, ”the east”, ”east”] and [”4 stars”, ”has 4 stars”, ”4”] which relaxes the rigid requirement of strict matching of slot values. Compared to fuzzy matching, this evaluation is cleaner. Because of the annotation errors and coreference that a value does not appear in the current utterance, the ground truth score is 78.83. Similar to our schema induction and DST evaluation results, we observe that constraining on predicted structures can increase model performance. In particular, using an in-domain self-supervised PCFG structure and achieve similar or even better performance than using a supervised parser. We only evaluate recall here because there are non-meaningful spans extracted, and is not important to downstream tasks since they are potentially filtered by our clustering method.

A.5 Clustering

Figure 4 shows the clustering results after the first step. This shows that we can get some coarse clusters with non-meaningful groups (such as “thank you”). Some slot types (such as day of the week as “wednesday”) are not distinguished by their domain and intent. Further clustering can generate more fine-grained schema.

In addition, from empirical analysis, we found that meaningless spans extracted together with meaningful ones from the previous stage may add noises in the process. To study its influence by filtering out noisy clusters, we automatically examine clusters and their corresponding sub-clusters from the first two steps based on the assumption that valid slot types include more than one slot value. We choose one here because if one cluster is dominated by examples such as “thank you” with a few other instances such as “thanks”, the latter can be considered as outliers from our clustering method. Afterwards there is only one value left. We can also choose to filter out clusters with more than one slot value, which may result in lower recall. Since the goal of schema induction is to build a complete ontology with high recall, noisy groups are actually acceptable. In other words, we observed similar performance before and after filtering out such noisy cluster since the cluster mapping step would assign a low score to such groups from cluster embedding representations (Section 4.1), which is similar to how human experts would ignore a cluster of meaningless spans.

A.6 Schema induction on training portion

Since our goal is to induce the schema of a corpus without using any labeled data, there is no major

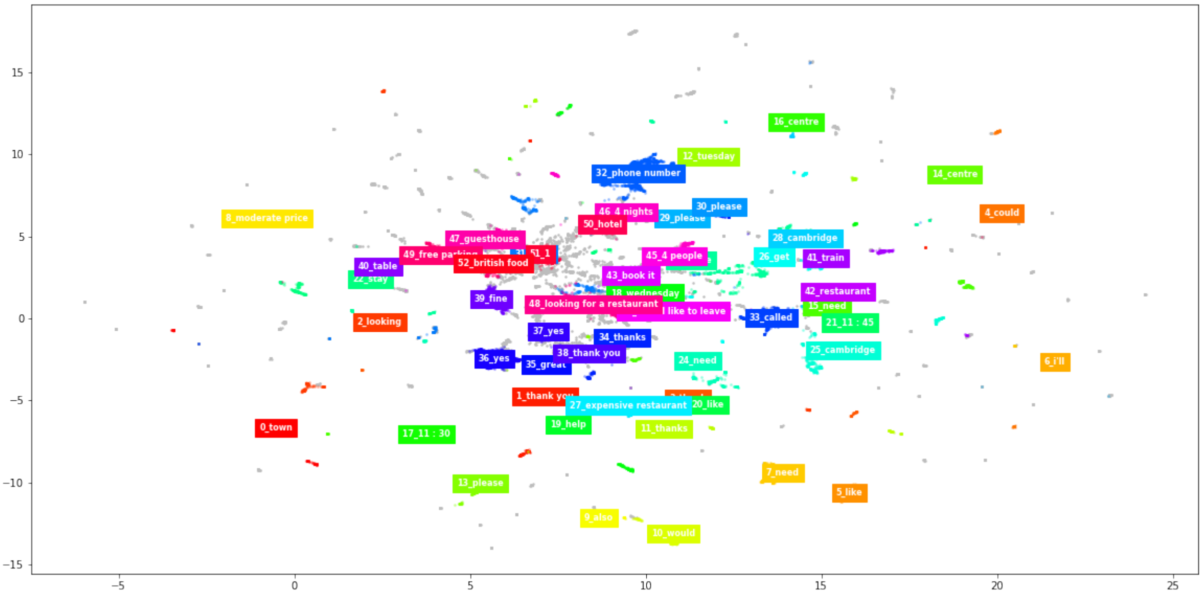

Figure 4: Clustering after first step. Grey labels are outliers detected by HDBSCAN. The numbers in each group represent a latent cluster label, and the texts represent the most frequent phrase in cluster.

method	# clusters	schema type	schema value	DST turn	DST joint
DSI	4981	95.08	43.23	21.10	28.14
Ours	374	93.33	**47.32**	**37.64**	**44.74**

Table 8: Results for schema induction and DST when the schema is induced on the training portion of MultiWOZ data. Our method significantly outperforms the strong DSI baseline.

method	# clusters	schema type	schema value	DST turn	DST joint
DSI	11992	92.21	46.19	27.23	26.24
Ours	806	77.04	47.50	26.01	26.50

Table 9: Schema induction and DST results on SGD dataset. Results suggests that our method achieves comparable or better performance than the strong DSI baseline even though our number of clusters is a magnitude smaller. See text for analysis.

difference in whether the schema is induced on the training set of MultiWOZ or the development set. The main difference is the number of utterance where the training data is ten times larger than the development data. Here we show the results for reference. Table 8 demonstrates that despite our much smaller number of clusters, our method achieves significantly better performance than the `DSI` baseline on both schema induction and DST.

A.7 SGD results

Table 9 shows the results for schema induction and DST on the SGD dataset. We conjecture that the similar performance results with the strong `DSI` baseline is due to large difference in cluster numbers. Intuitively, with a larger number of clusters, each group with fewer examples can be mapped to the ground truth embeddings correctly. On the other hand, if different slot types are mixed into one cluster, all slot values are assigned an inaccurate name. Another potential reason is that compared to MultiWOZ, SGD dataset requires more contextual information (SGD has less average tokens per turn and more turns per dialogue). Thus the mapping from relatively noisy clusters to ground truth creates errors for downstream tasks, especially that the evaluation metric require exact match of slot types.

However, the results are still comparable. Although predicting a magnitude smaller number of clusters to be less favoured in evaluation, our method still achieves similar or better performance.

A.8 Comparison to DSI on DST

We note that the DST results on MultiWOZ for DSI is lower than that reported in Min et al. (2020). As shown in Section 4.1, the original number was reported by mapping predicted slot types to target ontology at the turn level (before accumulating for the final prediction), where a small subset is used. This process makes mapping more evident (for example, instead of mapping a predicted slot type to the target 30 slot types, it only compares a slot type to one of two slot types that appear in the reference). Hence, it overestimates the performance and is very different from how a human expert would assign labels when inducing the schema for a new corpus without (turn-level) annotation. Since DST is evaluated to make sure that the slot type matches, an incorrect slot type matching would result in a 0 true positive score. The actual performance in our experiments is thus lower.

In addition, we follow the exactly same settings including training and evaluation scripts (on DST) with their provided pre-processed span-level data and suggested hyperparameters. We use the same metrics and scripts to evaluate all methods. Accordingly, all the numbers reported in Table 2 are fair and comparable.

Lastly, since we use fuzzy matching scores (Rastogi et al., 2020; Min et al., 2020), turn-level performance is accumulated to the joint level. For that reason, different from joint goal accuracy commonly used where all slot types and values are required to be exactly match, partial true positives are counted again in future turns. For example, if the current turn predicts "train leave-at: 10" with the target dialog state "train leave-at: 10:00", even if the next turn predicts nothing correctly, this partial score is counted in the joint level score in the next turn. This procedure follows the setting of Min et al. (2020). In fact, in their reported performance of DSI-GM on MultiWOZ 2.1 with precision and recall of 52.5, 39.3, and 49.2, 43.2 at turn and joint level respectively, the actual F1 scores are actually 45.0 for the turn level and 46.0 at the joint level. Similar to ours, they also received higher score on the joint level due to accumulative partial scores (by calculating F1 using their reported precision and recall scores directly). Since we follow the same evaluation script and metrics, the results and conclusion we have in our experiments comparing different methods are comparable.

A.9 Further analysis of schema induction among datasets (including realistic data)

When we apply our method on internal customer data for slot schema induction, we follow the same pipeline introduced in Section 3. For intent schema induction, we consider both the system turn and utterance turn as the context to our multi-step clustering to find schema with the hierarchy. Because our method is data-driven and does not require heuristics, it can induce expected slots explained before (e.g. "until the 30th"). We observed empirically satisfying performance but the results cannot be reported publicly because of restrictions. Therefore, we only report results on the public datasets to compare to previous research, as well as to inspire follow-up works for comparison.

We also applied our approach to the Ubuntu dialog corpus (Lowe et al., 2015). Compared to general TOD systems where a user and an knowledgeable agent communicate with each other, this data is collected from online forms to discuss technical issues. The utterances are less conversational, and include coding scripts, making it very noisy. We experiment on this more realistic dataset only for reference, since it is significantly different from building a TOD systems to interact with real users where schema is critical. We sample 8k utterances from the training data, and apply our method on both the intent level and the slot level. On the intent level, our method generates 70 clusters from the first step, and 154 clusters after three steps. Apart from greetings (which appear very frequently), we can induce intents such as suggesting one question is off topic (e.g. "this is a support channel; please leave and go to xxx channel"). There are also some more evident intent clusters such as suggested command line, suggested url, and questions for installations in a specific setup (e.g. "how to install firefox on 64 bit"). When the input sentence is long with mixed intents, our method may group these into one large cluster (such as providing suggestions to a specific problem, which is more similar to dialog act). We may choose to mix slot- and utterance-level clustering to solve such an issue by treating each complete segment in an utterance as a long span. On the slot level induction, our method generates 36 clusters from the first step, and 287 clusters after three steps. Our method can induce slot types such as "ubuntu verision" and "software name". However, compared to MultiWOZ and SGD, the induced slots are much nosier with lower precision where meaningless verbs (e.g. "set up" are grouped). Meanwhile, there a many other slot types that are not meaning such as a cluster regarding part of a path (e.g., "/var/"), which may be due to that we use the same LM trained on TOD dat which does not handle code scripts. Further in-domain pre-training within the Ubuntu dialog corpus may solve this issue. To conclude, even though this dataset is noisy and different from TOD, our method is still applicable to discover useful schema on both the intent and the slot level without any supervision.

A.10 Applying induced schema on testing data

After inducing the schema on the training data, we may apply the induced schema directly to a different set of data (such as testing data) for downstream applications (such as DST). Since we already induced slot clusters and mapped them to ground truth, we do not need to follow the same span extraction before clustering again. Alternatively, we adopt the following procedure. We extract all candidate phrases in the same way, but instead of clustering, we map the extracted phrases to clustered groups. Specifically, similar to mapping induced latent clusters to ground truth groups in schema induction, we find the most similar latent cluster to the candidate in the contextualized embedding space, and assign the cluster name to the phrase as its slot type. We observed that even though the schema is not induced on the testing data, the performance on both turn and joint level maintains (36.58 and 48.98).

A.11 Related work in schema induction of other natural language processing tasks

Similar to grammar induction and unsupervised parsing, schema induction can help to eliminate the time-consuming manual process and serves as the first step to build a large corpus (Klein and Manning, 2002; Klasinas et al., 2014). Related tasks include event type induction (Huang et al., 2016, 2018), semantic frame induction (Yamada et al., 2021), and semantic role induction (Lang and Lapata, 2010; Michael and Zettlemoyer, 2021). Relationship in these tasks such as predicate and head or patient and agent are relatively evident compared to that in conversational dialog. In addition, most of previous research requires either strong statistical assumptions based on pre-defined parsers, or existing ontologies and annotations for some seen types, and formulate the problem similar to word sense disambiguation on predicate-object pairs (Shen et al., 2021). In contrast, our method does not require any formal syntactic or semantic supervision.

A.12 Incorporating task-specific annotation requirements for schema induction

Our method is data-driven, indicating that if two tokens appear frequently (thus form a span), it might be a good idea to consider them as a slot together. Our motivation here is to induce the most probabilistic schema based on distributed representations. Incorporating annotation requirement is not specific to schema induction from corpus, and is a broader concept of neuro-symbolic integration by merging symbolic rules with connectionist models like neural networks.

However, if there is a specific requirement, we can either inject inductive bias similar to Shi et al. (2019); Kim et al. (2020) to change the attention distribution (so that the requirement-specific bias can result in smaller or larger divergence explicitly). We can also add such requirements as rules directly on certain spans. In this way, we can incorporate the requirements. In comparison, previous methods relying on supervised parser are not applicable.

A.13 Detailed schema induction results

Table 10 shows detailed results comparison on different proposed methods on schema induction. All methods result in a similar number of clusters, while span-based further pre-training methods constrained on unsupervised PCFG structures achieve the best performance overall.

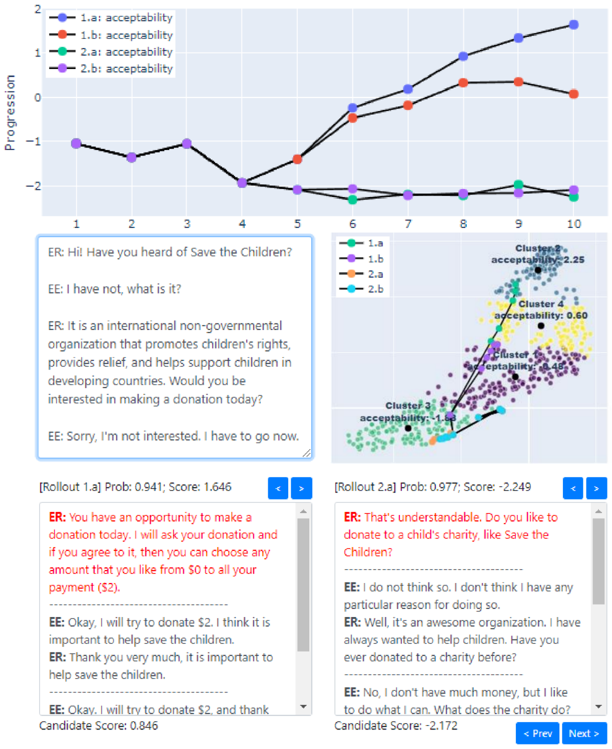
Abstract

Recent advances in large-scale language modeling and generation have enabled the creation of dialogue agents that exhibit human-like responses in a wide range of conversational scenarios spanning a diverse set of tasks, from general chit-chat to focused goal-oriented discourse. While these agents excel at generating high-quality responses that are relevant to prior context, they suffer from a lack of awareness of the overall direction in which the conversation is headed, and the likelihood of task success inherent therein. Thus, we propose a framework in which dialogue agents can evaluate the progression of a conversation toward or away from desired outcomes, and use this signal to inform planning for subsequent responses. Our framework is composed of three key elements: (1) the notion of a "global" dialogue state (GDS) space, (2) a task-specific progression function (PF) computed in terms of a conversation's trajectory through this space, and (3) a planning mechanism based on dialogue rollouts by which an agent may use progression signals to select its next response.



ER: Hi! Have you heard of Save the Children?

EE: I have not, what is it?

ER: It is an international non-governmental organization that promotes children's rights, provides relief, and helps support children in developing countries. Would you be interested in making a donation today?

EE: Sorry, I'm not interested. I have to go now.

[Rollout 1.a] Prob: 0.941; Score: 1.646

ER: You have an opportunity to make a donation today. I will ask your donation and if you agree to it, then you can choose any amount that you like from $0 to all your payment ($2).

EE: Okay, I will try to donate $2. I think it is important to help save the children.
ER: Thank you very much, it is important to help save the children.

EE: Okay, I will try to donate $2, and thank

Candidate Score: 0.846

[Rollout 2.a] Prob: 0.977; Score: -2.249

ER: That's understandable. Do you like to donate to a child's charity, like Save the Children?

EE: I do not think so. I don't think I have any particular reason for doing so.
ER: Well, it's an awesome organization. I have always wanted to help children. Have you ever donated to a charity before?

EE: No, I don't have much money, but I like to do what I can. What does the charity do?

Candidate Score: -2.172

Figure 1: Our framework applied to the charity solicitation task in Persuasion For Good (Wang et al., 2019). Given the dialogue history (center left), the system uses rollouts (Lewis et al., 2017) to simulate the outcome of two response candidates (bottom, in red). Each rollout is mapped as a path through the Global Dialogue State space (center right) where it can be compared with similar outcomes. The candidates are finally ranked using the Progression Function (top), and the best is selected.

1 Introduction

All human conversation serves some purpose. These may range from negotiating an agreement to explaining a topic to maintaining a social relationship. People are generally capable of forming an assessment, sometimes subconsciously, whether a conversation is going well or not and adjusting their behavior accordingly. Such assessment, which underlies most human conversation, is essential in continuous awareness of the direction where the interaction is heading and whether the parties are in sync or not, e.g., Bernieri and Rosenthal (1991). In a task-oriented interaction, the participants assess if progress towards a successful outcome is being made. In a negotiation, parties assess if an agreement is likely. Even in a casual conversation, people intuitively sense when to continue, when to change the subject, or when to stop. Based on such (subjective) assessment, participants adjust what to say next: whether to push forward, make a concession, soften the tone, digress, or say goodbye. A wide range of research in conversation and discourse analysis is devoted to these and related issues including (Beebe and Masterson, 2000; Cassell et al., 2007; Friedman, 2004; Gremler and Gwinner, 2008; Langewitz et al., 2003); however, recent efforts in Dialogue State Tracking (DST) have been primarily focused on collecting fine-grained details (e.g., slot-value pairs for

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1194 - 1212
July 10-15, 2022 ©2022 Association for Computational Linguistics

travel booking or restaurant reservation) (Balaraman et al., 2021) without concern for the overall direction and quality of the conversation, even though the latter is critical for achieving human-level dialogue interaction.

As such, we approach dialogue state tracking at a higher level, focusing instead on what we call the **Global Dialogue State (GDS)**. Given a conversational task (e.g., negotiation), the global state of a dialogue reflects the most likely outcome (e.g., a strong agreement or a stalemate) given the history of the dialogue up to the current turn. In contrast to traditional DST, the global state remains invariant to the specific details discussed at each turn (e.g., names, dates, quantities) that are typically the concern of slot-filling models. Rather, global dialogue states are influenced by the contexts in which these details occur (e.g., "I *would love to* donate $5 to this charity!" vs. "I *would never* donate $5 to this charity"). Thus, the global state of a dialogue can be measured in terms of its *semantic similarity* to other groups of dialogues for the same task, which can be naturally formulated as a cluster-assignment problem in the dialogue embedding space. That is, a dialogue which is assigned at the current turn to a cluster of highly successful outcomes may assume a high likelihood of success, and likewise a dialogue assigned to a cluster of unsuccessful outcomes may assume a low likelihood of success. It follows from this that the path of a dialogue through global state space can be used to derive a **Progression Function (PF)** to give turn-level estimates of task success, which can in turn be used by a dialogue agent to inform its next response.

The remainder of this paper is organized as follows: In Section 2 we review relevant literature pertaining to dialogue state tracking and response planning; in Section 3 we formally define the global dialogue state and progression function, propose **supervised** and **unsupervised** approaches for modeling them, and describe how they can be used to assess and select dialogue response candidates; in Section 4 we experimentally apply our framework to the charity solicitation task in the Persuasion For Good dataset (Wang et al., 2019), reporting results from automatic and manual evaluations; and in Sections 5 and 6 we conclude with a discussion of limitations and future directions. Code for our methods and experiments has been released, [1] and a listing of software packages we use can be found in Appendix A.

2 Related Work

Our work lies at the intersection of dialogue state tracking and response planning. As previously noted, we approach dialogue state at a much higher level than is typically seen in the DST literature. Our concept of global dialogue state is not mutually exclusive with traditional DST approaches, which we refer to from here on as **local** DST. Rather, an effective dialogue system might integrate local and global DST approaches to enable simultaneous tracking of user intents and slot-value pairs (needed for interfacing with external resources) and the overall likelihood of conversational success.

2.1 Dialogue State Tracking

Local DST approaches are used in task-oriented (also called goal-oriented) dialogue systems. Local DST is responsible for identifying user intent (e.g., search for restaurants) and extracting slot-value pairs (e.g., location, price range). Recent DST systems perform state tracking in a diverse set of domains, including food ordering (Lertvittayakumjorn et al., 2021), travel reservations (Qin et al., 2021), negotiations (He et al., 2018), and many others. Datasets such as MultiWOZ (Budzianowski et al., 2018; Eric et al., 2020; Zang et al., 2020) and SGD (Rastogi et al., 2020) provide large-scale testbeds for training single DST systems that generalize across many task domains. However, local DST is generally not deployed in open-domain end-to-end dialogue systems that focus on social interaction and user engagement, recent examples including DialoGPT (Zhang et al., 2020), Meena (Adiwardana et al., 2020), and BlenderBot (Roller et al., 2021; Xu et al., 2021). In open-domain models, the task is unconstrained and thus it makes little sense to employ traditional slot-based dialogue state trackers. Instead, these models track state implicitly in their latent representations of dialogue history. Unlike local DST, global state tracking is applicable in both the task-oriented and open-domain settings.

2.2 Dialogue Response Planning

Many approaches exist for planning in dialogue response generation. Planning helps a dialogue agent maintain coherence over multiple turns and stay on track to complete its goal. Lewis et al.

---

[1] Available at `https://github.rpi.edu/LACAI/dialogue-progression`

(2017) introduce Dialogue Rollouts, allowing a negotiation agent to simulate the remainder of a conversation based on each of multiple candidate responses and select the one which yields the best outcome. Yarats and Lewis (2018) follow up by separating semantic planning and surface realization for response generation by first producing a latent semantic representation of the dialogue plan and then conditioning on it during generation with rollouts. Similarly, Jiang et al. (2019) implement a look-ahead module to implicitly predict multiple future turns in an end-to-end encoder-decoder architecture, experimenting with negotiation and restaurant reservation settings. These works all experiment in task domains where goal achievement is explicitly measurable, which is not true in the general case. Thus we propose to combine such methods with our progression function which provides estimates of goal completion likelihood. Particularly, in this paper we demonstrate the use of rollouts with the PF as a reward signal.

3 Methods

The goal of our system is to construct a global dialogue state space for a task-specific dataset and learn a progression function to estimate how well an ongoing dialogue is progressing toward the desired outcome of the task. The quantity output by the progression function is an estimate of a dialogue-level attribute which indicates task success (e.g. satisfaction in a customer service task). In many task domains, the success of a conversation cannot be completely measured by a single attribute. For example, in the charity solicitation task we use in our experiments, donation amount is the primary success attribute. Here, there are cases where the conversation appears to go very well, but ultimately no donation is made for unexpected reasons such as the solicitee not being able to afford to donate. One could reasonably expect such an outcome to be "acceptable" in the context of a solicitation task since the solicitee has engaged with the solicitor and displayed interest, and we cannot reasonably expect the solicitor to force a donation out of someone who cannot afford it. Thus we introduce the "**acceptability score**", a synthetic attribute that measures success by considering multiple factors (e.g., donation amount and sentiment). For any dialogue dataset, the acceptability score combines multiple dialogue-level attributes in a way sensitive to their covariance with the primary success attribute:

$$\mathrm{ACC}_D = \mathrm{prim}_D + \sum_{i=1}^{|\mathbf{v}_D|} \mathrm{Cov}(\mathrm{prim}, \mathrm{attr}_i) \cdot \mathbf{v}_{Di} \tag{1}$$

where prim_D is the primary success attribute (e.g. donation amount) value for dialogue D, $\mathbf{v}_D$ is the vector of all other attribute values (e.g., sentiment) for dialogue D, and $\mathrm{Cov}(\mathrm{prim}, \mathrm{attr}_i)$ is the training set covariance between the primary success indicator and the i-th other attribute. We define the output of the progression function to be an estimate of the acceptability score.

To learn the progression function, dialogue-level attribute annotations must exist for use in this purpose. However, in many settings such annotations are not available in sufficient quantity to directly learn a progression model with sufficient generalization. Consequently, we propose **supervised** and **unsupervised** approaches for learning the global state and progression models.

3.1 Unsupervised Approach

3.1.1 Global Dialogue State

In the unsupervised approach, the GDS space is a dialogue embedding space where clusters of embeddings represent groups of dialogues with similar semantic content. For each complete dialogue D in the training set, all utterances are independently embedded and then pooled to create a dialogue-level embedding $\mathbf{u}_D \in \mathbb{R}^d$ where d is the embedding size. The GDS space is thus given as a matrix in $\mathbb{R}^{N \times d}$ where N is the number of complete dialogues. To embed utterances we take advantage of pre-trained sentence encoders exposed to large-scale corpora. Specifically, we use a publicly available MPNet (Song et al., 2020) model fine-tuned for semantic textual similarity using a contrastive objective on over 1B training pairs from 32 distinct datasets. [2] To combine utterance embeddings into a dialogue-level embedding we use recency-weighted mean pooling. The recency weight β determines how much emphasis is placed on more recent utterances, where $\beta = 0$ means all utterances are weighted evenly and $\beta > 0$ means that more emphasis is placed on more recent utterances. The motivation for recency weighting is to test the hypothesis that more recent developments in a conversation are more relevant for predicting current

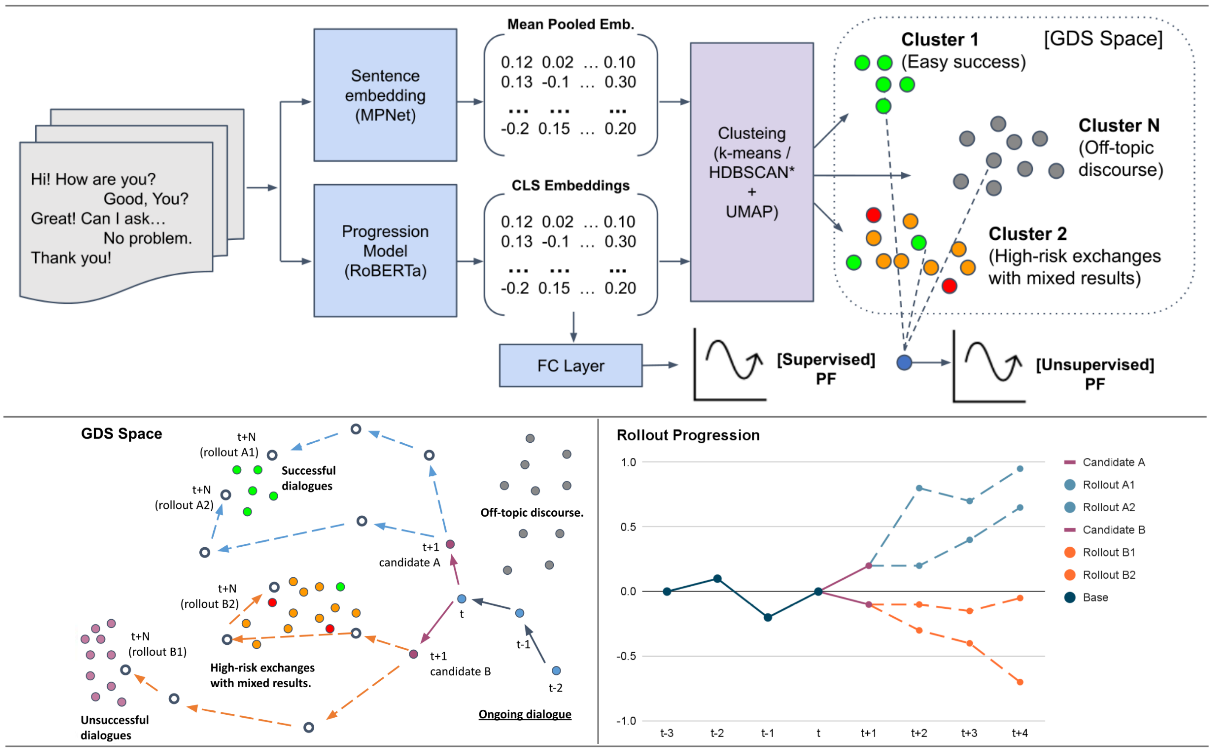

Figure 2: Architecture of the supervised and unsupervised GDS and PF models (top). In GDS space (top right), each cluster is characterized by similar dialogue semantics, and is thus interpreted as the class of typical outcomes for dialogues within. GDS and PF can be used with rollouts (bottom) to allow a dialogue agent to plan ahead.

progression toward a goal. For example, a conversation may start out off-task with participants engaging in small talk, and then later re-focus.

The embedding for dialogue D with $|D|$ utterances is thus formulated as $\mathbf{u}_D = U^T \mathrm{softmax}(\mathbf{r})$ where U is the matrix of utterance vectors in $\mathbb{R}^{|D| \times d}$ and $\mathbf{r} \in \mathbb{R}^{|D|}$ is a vector of evenly spaced real numbers over the interval $[0, \beta]$. The softmax ensures all recency weights sum to 1 and can be interpreted as probabilities as done with attention scores in (Bahdanau et al., 2015; Vaswani et al., 2017). As shown in Figure 3, each utterance is thus weighted by a monotonically increasing probability mass where higher values of β cause more mass to be concentrated at the end of the dialogue.

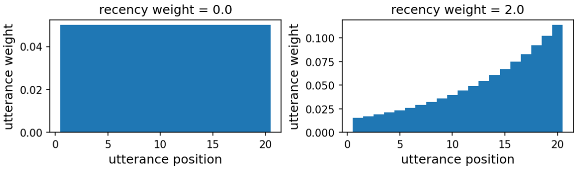

Figure 3: Recency weight β controls how much emphasis is placed on recent utterances when computing $\mathbf{u}_D$.

The unsupervised GDS model is a clustering of the dialogues in their embedding space. The dialogue embeddings are either clustered directly or after projection to a lower-dimensional space using Parametric UMAP (Sainburg et al., 2020; McInnes et al., 2018a). We experiment with k-means and HDBSCAN (McInnes and Healy, 2017; Campello et al., 2013) to cluster the embeddings. For k-means, we choose the number of clusters k and train with 10 random initializations. For HDBSCAN, we choose the minimum cluster size and minimum samples hyperparameters, and the optimal number of clusters are selected automatically. Unlike k-means which simply partitions the embedding space, HDBSCAN classifies some embeddings as noise points. Clustering hyperparameters are selected by cross-validation on several metrics as described later in Section 4. The process of constructing the GDS model is illustrated in Figure 2.

The clusters output by this process can be interpreted as the equivalence classes of final global states possible for the task represented in the dialogue dataset. To estimate the global state of an ongoing dialogue D', it is embedded as $\mathbf{u}_{D'} \in \mathbb{R}^d$ in the same manner as the complete training dialogues, followed by optional dimensionality reduction. The trained k-means or HDBSCAN model is then used to assign D' to one of the existing clusters, or possibly as a noise point in the case of HDBSCAN.

Each cluster is assigned an aggregate acceptability score by taking an average of acceptability for each dialogue in the cluster. If k-means is used, we aggregate using a 10% trimmed mean across all dialogues in the cluster. If HDBSCAN is used, a probability is returned for each dialogue representing the likelihood that it is a member of its assigned cluster, so we compute the probability-weighted average across all dialogues in the cluster. Dialogues classified as noise points are ignored.

To visualize the GDS model, Parametric UMAP is used again to project the clustered dialogue embeddings into $\mathbb{R}^2$ or $\mathbb{R}^3$. As shown in Figure 1, the GDS model can be mapped as a scatter plot with each cluster labeled by its aggregate values. If k-means is used, the cluster centroids can be displayed as a bold point within each cluster. HDBSCAN clusters do not have centroids, but they do have a number of representative points that are close to the cluster core. We average these points to simulate a centroid for display purposes, and likewise show it as a bold point within each cluster. To show how an ongoing dialogue D' traverses the GDS space over time, its embeddings at each turn t are projected onto the map and connected with line segments to form a path.

3.1.2 Computing Progression

Since each cluster in the GDS space is intended to represent a class of end-task global states, we compute the progression of an ongoing dialogue D' with respect to the likelihood that its final global state will rest in each individual cluster. Supposing there are k final clusters after running k-means or HDBSCAN, we compute a probability vector $\mathbf{p}_{D'} \in \mathbb{R}^k$ such that $\mathbf{p}_{D'i} = P(\mathbf{u}_{D'} \in C_i)$ for $i \in \{1, \dots k\}$ where C_i is cluster i. $\mathbf{p}_{D'}$ is computed differently for k-means and HDBSCAN. K-means does not produce a probabilistic soft clustering, so we define $\mathbf{p}_{D'}$ with respect to the proximity of $\mathbf{u}_{D'}$ to the centroids of each cluster:

$$\mathbf{p}_{D'} = \text{softmax}\left(\frac{1}{||\mathbf{u}_{D'} - \mathbf{c}_i||_2} \ : \ i \in \{1, \dots k\}\right) \tag{2}$$

where $\mathbf{c}_i \in \mathbb{R}^d$ is the centroid of cluster i. HDBSCAN does produce a probabilistic soft clustering, so in that case $\mathbf{p}_{D'}$ is already computed.

We ultimately want the closest (or most probable) clusters for ongoing dialogue D' to have the most sway in estimating its progression at the current point in time. That is, if D' has moved into a cluster of high-success outcomes, its progression should increase. Likewise if D' has moved away from such a high-success cluster, either into a lower-success cluster or off-task into a noisy or unknown region of the GDS space, its progression should decrease. Thus, once $\mathbf{u}_{D'}$ is computed, we estimate its progression as the probability-weighted average of the aggregate acceptability scores assigned to each cluster. This is formulated as

$$\text{PROG}(\mathbf{u}_{D'}) = \frac{\mathbf{v}^T \mathbf{p}_{D'}}{\sum_{i=1}^{k} \mathbf{p}_{D'i}} \tag{3}$$

where $\mathbf{v} \in \mathbb{R}^k$ is a vector of the aggregate acceptability scores assigned to each cluster. The scaling factor in the denominator ensures that ongoing dialogue embeddings classified as noise points by HDBSCAN will not be assigned progression values close to zero as a consequence of not belonging to any cluster, which can cause significant fluctuation in the progression function as the dialogue traverses noisy regions of the GDS space. [3] Figure 2 illustrates how progression of an ongoing dialogue depends on its position in GDS space.

3.2 Supervised Approach

For the supervised approach, we simply fine-tune RoBERTa (Liu et al., 2019) to directly predict acceptability given the dialogue history text, where all utterances are concatenated into a single sequence. To construct the GDS space we obtain the dialogue level embedding $\mathbf{u}_D$ directly from the CLS (<s>) token for each complete dialogue in the training set, and cluster them as in Section 3.1.1. Unlike the unsupervised approach where recency weighting is used to "attend" to more recent parts of the dialogue, the supervised fine-tuning process causes the CLS embedding to aggregate the parts of the dialogue most relevant to the task objective, which is more optimal than the recency heuristic. Also, unlike the unsupervised approach where progression for an ongoing dialogue is computed with respect to its embedding, here progression is directly predicted by RoBERTa. In our experiments we compare RoBERTa-base, RoBERTa-large, and RoBERTa-large-adapted, the latter receiving additional domain adaptation training for dialogue. Domain adaptation is done via Masked Language Modeling (MLM) on a self-generated version of

---

[3] For HDBSCAN we also experiment with softmax for re-scaling $\mathbf{v}^T \mathbf{p}_{D'}$, giving $\text{PROG}(\mathbf{u}_{D'}) = \text{softmax}(\mathbf{v}^T \mathbf{p}_{D'})$.

the Gutenberg Dialogue Dataset (Csaky and Recski, 2021). Hyperparameters and model weights from domain adaptation training are provided with our code release.

3.3 Response Planning

To allow a dialogue agent to use the progression function as feedback for response planning, we adopt **Dialogue Rollouts** (Lewis et al., 2017) to simulate the outcomes of a set of response candidates. A rollout for a response candidate simulates the next N turns of the conversation (for both participants) given that candidate is used. At each turn of a negotiation task, Lewis et al. (2017) sample a set of c response candidates and s rollouts per candidate. They score each rollout by a deterministic reward (the value of the items "won" by the agent during negotiation), and rank each candidate by the average of its rollout scores. The highest ranking candidate is then selected by the agent. As shown in Figure 2, we generalize this process to any task for which a progression function can be learned, replacing the deterministic reward with the progression function value. To demonstrate this, we fine-tune the 762M parameter DialoGPT (Zhang et al., 2020) [4] as a dialogue response generator and use beam sampling to generate response candidates and rollouts. We select DialoGPT for this task as it is pre-trained on a large Reddit dialogue corpus.

4 Experiments

4.1 Dataset

We apply our framework to the Persuasion For Good dataset (Wang et al., 2019), which is a crowd-sourced dialogue dataset where the task for an individual playing the role of persuader is to convince another individual playing the role of persuadee to make a donation to a well-known children's charity. We selected this dataset since it has a clear task objective (to solicit donations), but a complex relationship between dialogue content and success. The dataset authors identify 10 distinct persuasion strategies used to solicit donations, where different strategies correlate with donation amount at different strengths. Additionally, participants in Persuasion For Good dialogues complete a pre-task psychological survey, yielding 23 attributes based on the Big-Five personality traits (Goldberg, 1992), the Moral Foundations endorsement (Graham et al., 2011), the Schwartz Portrait Value (Cieciuch and Davidov, 2012), and the Decision-Making style (Hamilton et al., 2016) questionnaires for each individual. The dataset authors demonstrated varying degrees of correlation between these psychological attributes and the end-task donation amount. The complexity in measuring progression in this context, coupled with it being a relatively small dataset, makes Persuasion For Good an interesting and challenging testbed for our framework. Persuasion For Good contains 1017 dialogues, each with approximately 10 turns per speaker (20 utterances).

4.2 Progression Function Experiments

As the objective of the task is to solicit donations, we consider the end-dialogue persuadee donation amount to be the primary dialogue success indicator. We also augment the dataset by computing average dialogue sentiment. To compute sentiment we use a RoBERTa model[5] fine-tuned on the sentiment classification task of the TweetEval benchmark (Barbieri et al., 2020), which was publicly released by the benchmark authors. We score sentiment at the utterance level in the range $[-1, 1]$ by multiplying the sentiment class probabilities predicted by RoBERTa for negative, neutral and positive by $\{-1, 0, 1\}$ respectively and summing the result. We then average the utterance-level sentiment score for each dialogue.

We filter the dataset to eliminate dialogues with end-task donation amounts outside the allowed task parameters (between \$0 and \$2 USD), and use a regular expression to filter out dialogues where the persuadee fails to make a donation after promising a non-zero dollar amount in the conversation. After filtration we are left with 751 dialogues for our study. We split the dialogues into a training and test set, leaving 577 dialogues for training and 174 for testing. After splitting, we mean-center the dialogue values in the training set for each attribute and scale them to have unit variance. We apply the same transformation to the test set using the distribution parameters of the training set. Our final pre-processing step is to compute the acceptability score. To do this, we compute the covariance matrix of the dialogue-level attribute values in the training set, which include the donation amount and psychological attributes for both the persuader and persuadee from the original dataset, along with

---

[4] Obtained from https://huggingface.co/microsoft/DialoGPT-large

[5] Obtained from https://huggingface.co/cardiffnlp/twitter-roberta-base-sentiment

our computed sentiment scores. Since the values are all standardized, the covariances are equivalent to Pearson's r. We select the covariances of all attributes with respect to the persuadee donation amount (see Figure 5 in Appendix B) and define the acceptability score of each dialogue D as defined in Section 3. We use the same covariances obtained from the training set to compute acceptability scores on the test set. After pre-processing, the training set has 52 total attributes. These include the persuadee/persuader donation amounts, psychological variables, sentiment, and the acceptability score.

4.2.1 Progression Model Training

We train four progression models as outlined in Sections 3.1 and 3.2: (1) Unsupervised, (2) RoBERTa-base, (3) RoBERTa-large, and (4) RoBERTa-large-adapted. For each model, 10% of the training set is held out as a validation set (58 dialogues). For the unsupervised model, a grid search is run for the hyperparameters (e.g., # clusters, recency β, dim. reduction, etc.) over the validation set, and the final model is obtained by re-training over the full training set using the best hyperparameters. The final model uses k-means for clustering with $k = 21$ and recency weight $\beta = 0.3$. A complete hyperparameter listing and details on the grid search can be found in Appendix F. For the supervised RoBERTa models, fine-tuning is done with AdamW (Loshchilov and Hutter, 2019) and an initial learning rate of 3×10^{-5} for a maximum of 30 epochs. Early stopping is used over the validation set with the checkpoint corresponding to the lowest validation loss selected as the final model.

4.2.2 Automatic Evaluation

We evaluate the progression models on the following automatic metrics: (1) Mean Absolute Error (**MAE**) in predicting dialogue acceptability, and (2) Pearson's correlation (**r**) between overall PF slope and dialogue acceptability. With MAE we validate that the progression function is able to estimate success of a complete dialogue, while PF slope correlation validates that during an ongoing dialogue, progression increases over time for high-success dialogues and decreases over time for low-success dialogues. To measure PF slope correlation, we fit a least-squares regression line to the progression curve of each dialogue in the test set, and measure Pearson's r between the regression slopes and their corresponding acceptability scores. For robustness we repeat this evaluation 33 times with varying initialization seeds for each model type (final hyperparameters stay constant) and report the means and standard deviations across runs in Table 1.

Table 1: Progression Function Auto Eval Results: Mean (SD) of MAE and Pearson's r across runs.

Model	**MAE**	**r**
Unsupervised*	1.37 (± 0.01)	0.40 (± 0.02)
RoBERTa-base	0.99 (± 0.06)	0.50 (± 0.04)
RoBERTa-large	0.97 (± 0.10)	0.54 (± 0.06)
RoBERTa-large-adapted	**0.95** (± 0.05)	**0.57** (± 0.03)

For Pearson's r, $p < 0.01$ for all runs (two-tailed; H_0 is non-correlation).
* Hyperparameters of the unsupervised model can be found in Appendix G.

Unsurprisingly, the supervised models outperform the unsupervised model on both metrics, which is expected since they directly optimize a mean squared error objective. Of the supervised models, the RoBERTa-large instances perform the best, with dialogue domain adaptation boosting each metric. Pearson's r is significant at the $p < 0.01$ level for all runs (the null hypothesis is non-correlation).

4.2.3 Manual Evaluation

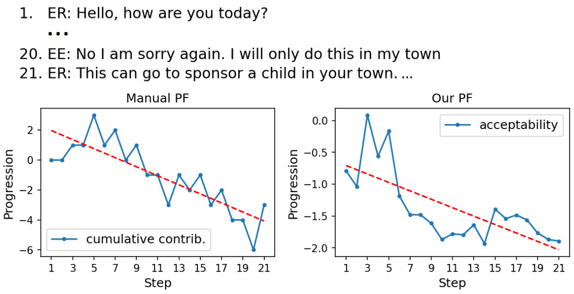
To obtain a more precise evaluation, we asked three annotators to estimate sentence-level progression for dialogues in our test set. Two graduate students and one postdoc in our lab served as our annotators. For each of twelve randomly selected test dialogues, each annotator rated all sentences on a scale of {-1, 0, 1} for progression, with -1 indicating regression from the task goal, 0 indicating neutral progression, and +1 indicating progression toward the task goal. Altogether, each annotator provided 431 sentence ratings across 244 utterances. After aggregating at the utterance level, average inter-annotator agreement is 0.57 (Cohen's kappa). For each dialogue, the cumulative sum of the utterance-level manual ratings creates a ground-truth progression curve, as shown in Figure 4.

We evaluate the progression models against the ground-truth curves using Pearson's correlation (r) since the PF output and cumulative manual ratings are continuous and on different scales. We report the following correlations: (1) between utterance-level PF value and ground-truth value (**utt**), (2) between utterance-level PF slope and ground-truth slope (**utt-sl**), (3) between dialogue-level PF slope and ground-truth slope (**dlg-sl**), and (4) between dialogue-level PF slope and the final ground-truth progression value (**dlg-sl-f**). We repeat this evaluation for each of the 33 uniquely initialized model in-

Table 2: Progression Function Manual Eval Results: Mean (SD) of **utt**, **utt-sl**, **dlg-sl**, & **dlg-sl-f** across runs.

Model	utt	utt-sl	dlg-sl	dlg-sl-f
Unsuperv.	0.09 (± 0.13)	0.04 (± 0.01)	-0.01 (± 0.07)	-0.07 (± 0.07)
RoBERTa-b	0.39 (± 0.07)	0.18 (± 0.03)	0.26 (± 0.06)	0.26 (± 0.06)
RoBERTa-l	0.39 (± 0.08)	0.18 (± 0.06)	0.34 (± 0.09)	0.35 (± 0.10)
RoBERTa-l-a	**0.48** (± 0.05)	**0.24** (± 0.03)	**0.43** (± 0.06)	**0.41** (± 0.07)

b = base; l = large; l-a = large-adapted.



1. ER: Hello, how are you today?
…
20. EE: No I am sorry again. I will only do this in my town
21. ER: This can go to sponsor a child in your town. ...

Figure 4: Left: ground-truth progression curve given by the cumulative sum of utterance-level manual ratings. Right: estimated curve from RoBERTa-large-adapted.

stances of each type from Section 4.2.2, averaging each metric across raters and then across runs. We report the aggregate means and standard deviations across runs in Table 2. A complete listing of results for each rater (averaged across runs) is provided in Appendix C, along with detailed explanations of each metric (Appendix D). Additionally, Figure 10 in Appendix E provides examples of disagreement between the PF and ground-truth progression curves which can be challenged despite high inter-annotator agreement, demonstrating difficulty in establishing ground-truth for this open-ended task.

4.2.4 Benefit of Domain Adaptation

To verify the beneficial effect of domain adaptation we perform two-tailed paired t-tests to confirm the differences in means between RoBERTa-large and RoBERTa-large-adapted on all automatic and manual metrics. For each metric, we pair the results from both models for each run of the same seed, since their regression heads would have received identical initializations. We find that the means of **utt**, **utt-sl**, **dlg-sl**, and **dlg-sl-f** differ at the $p < 0.01$ significance level, and the means of the automatic Pearson's r metric differ at the $p < 0.05$ level. This confirms our intuition that domain adaptation for dialogue prior to fine-tuning the regression objective aids generalization in this task.

4.3 Rollout Experiments

To demonstrate the ability of the PF to guide a dialogue agent, we use it to score rollouts generated with DialoGPT as described in Section 3.3. Specifically, we design a self-play experiment to automatically evaluate the effect of PF-guided rollouts on the success of the solicitation task in Persuasion For Good. The following summarizes the experimental setup, procedure, and results.

4.3.1 Exeperimental Setup

First, we fine-tune DialoGPT to generate responses on Persuasion For Good. We add speaker control tokens to the vocabulary so that the model can be conditioned to generate as the persuader or persuadee, respectively. Training is done with AdamW (initial lr=5×10^{-5}) for 6 epochs with early stopping over a 10% validation set using perplexity. The final model checkpoint was selected after 3 epochs, achieving validation perplexity of 8.82.

We then select a progression model to use for all self-play runs. Since the supervised RoBERTa-large-adapted model achieved the best average scores across all automatic and manual evaluations, we randomly select one of the 33 RoBERTa-large-adapted instances from Section 4.2.2 to use for all runs. We use this instance for rollout scoring and to measure the progression of each self-play dialogue.

Finally, we train a binary classifier to identify if the persuadee has stated the intent to donate in a conversation, which we use to detect successful self-play dialogues. We fine-tune a RoBERTa model as a classifier using just the persuadee's utterances as input and use binarized donation labels in Persuasion For Good as targets. Specifically, for each dialogue the label is 0 if the donated amount is $0, otherwise it is 1. We use the manually verified intended donation labels from Persuasion For Good "ANNSET" for our validation and test splits and use the remaining end-task donation labels for training. Training is done with early stopping over the validation split using macro F1. The final model checkpoint achieved test F1 of 0.89 and test accuracy of 0.90. All three trained models used in this experiment are available to download (see our code release for instructions and hyperparameters).

4.3.2 Self-Play Procedure

From our test set of 174 dialogues, we manually filter out 41 in which the persuadee pledges a donation within the first 10 utterances, leaving 133 remaining conversations. For each of these, the response generator is given the first 10 utterances as context and tasked to complete a second set of 10 utterances, playing the role of both the persuader

Table 3: Rollouts self-play results: Mean (SD) of progression, sentiment, and % donated across runs.

Mode	Prog.	ER Sent.	EE Sent.	EE Don. %
No RO	0.01 (± 0.24)	0.51 (± 0.03)	0.44 (± 0.06)	38% (± 6%)
2x2x3	0.69 (± 0.29)	0.62 (± 0.05)	0.49 (± 0.07)	45% (± 10%)†
3x3x5	**0.95** (± 0.16)	**0.66** (± 0.02)	**0.52** (± 0.04)	**47%** (± 11%)

All 2x2x3 and 3x3x5 means significant at $p < 0.01$ (or 0.05 if marked †) when compared to No RO with two-tailed paired t-tests. ER and EE refer to the persuader and persuadee respectively.

and persuadee. Since the task is solicitation, we allow the generator to use rollouts only when acting as the persuader. We perform the self-play experiment using three persuader modes: (1) with no rollouts (**No RO**), (2) with 2 response candidates, 2 rollouts per candidate, and 3 utterances per rollout (**2x2x3**), and (3) with 3 response candidates, 3 rollouts per candidate, and 5 utterances per rollout (**3x3x5**). For each utterance in each rollout, we use beam sampling with num_beams=6, top_k=50, top_p=0.95, and temperature=$1.5+0.002 \cdot T$ where T is the number of tokens in the dialogue history. After generation, we compute the following metrics for each dialogue: (1) progression using the selected RoBERTa-large-adapted instance (**Prog.**), (2) persuader and persuadee sentiment using the sentiment classifier from Section 4.2 (**ER Sent. & EE Sent.**), and (3) the percent of test dialogues where the persuadee pledges a donation amount or explicitly states intent to donate, as detected by the binary donation intent classifier (**EE Don.%**).

4.3.3 Self-Play Results

For robustness we repeat this procedure 5 times with varying generation seeds for each persuader mode. In total, 1,995 self-play dialogues are completed (133 dialogues for each of 3 modes for each of 5 seeds). We average each metric across dialogues and then across runs, and report the aggregate means and standard deviations across runs. Additionally, to verify the benefit of rollouts, we perform two-tailed paired t-tests to confirm the differences in means between the rollout-enabled modes (**2x2x3** and **3x3x5**) and the baseline (**No RO**). For each metric, we average the results across runs and pair these averages from both modes for each dialogue. Results are shown in Table 3.

We observe that the mean progression increases significantly when rollouts are used. This is expected since response candidates with the highest average end-rollout progression are selected. We also observe that rollouts lead to higher average sentiment for both the persuader and persuadee, which makes sense due to the correlation between sentiment and the acceptability score (see Figure 5 in Appendix B). Finally, rollouts yield a higher percentage of dialogues with a pledged or intended donation. [6] All of these results are significant at the $p < 0.01$ level except for **EE Don.%** in **2x2x3** mode which is significant at $p < 0.05$.

Although progression is noticeably higher for the **3x3x5** mode than for the **2x2x3** mode (0.95 vs 0.69), all other metrics are close between these modes with a small advantage in **3x3x5** mode. This suggests that scaling rollout simulations can be beneficial, but there may be diminishing returns for simulation size. Example self-play dialogues are provided in Tables 7, 8, and 9 in Appendix H.

5 Limitations & Future Direction

We recognize several limitations of our study which warrant follow-up investigation. This study focuses on a single task and dataset, and thus is subject to the assumptions and biases therein. Since we intend our framework to be general, it is prudent to perform additional studies to verify the efficacy of our methods on a variety of datasets spanning multiple dialogue domains and tasks. Also, although we provide automatic evaluation of the ability of rollouts to improve performance on a solicitation task, we cannot assume that humans would respond in the same way as DialoGPT. Thus, human evaluation is needed to further validate this approach.

6 Conclusion

In this work we introduced the concept of global dialogue state and proposed a framework with which a dialogue agent can gain awareness of where an ongoing conversation is headed, the likelihood of a successful outcome, and how its own response decisions impact the overall direction of the dialogue. We demonstrated that an unsupervised approach to modeling the GDS space and progression function is feasible, which is useful in sparsely-labeled settings. However, we showed that with domain-adaptation pre-training for dialogue, supervised methods are preferable when labels are available. Finally, we demonstrated how using the PF as a feedback mechanism via dialogue rollouts allows an agent to improve outcomes on a solicitation task.

---

[6] We randomly selected 30 of the 1,995 self-play dialogues and manually inspected them for donation intent. We found the classifier labeled 26 of them correctly (87% accuracy).

Ethical Considerations

Ethical Dialogue Systems

We acknowledge the potential risks inherent in the deployment of goal-oriented dialogue systems, and especially note that care must be taken to ensure persuasive dialogue systems are designed for beneficial use as discussed by Wang et al. (2019). Concretely, when applying our framework, care must be taken to ensure that the goal of the system (defined by the primary success attribute of the acceptability score) should be generally accepted as beneficial. For example, our basis for dialogue acceptability in this work is with respect to raising money for children's charity. In general, the achievement of the system's goal should not intentionally lead the user or any other party to harm. Additionally, the definition of acceptability, through its primary or any other correlated attributes, should not allow for discriminative responses, purposefully malicious discourse, or other violations of accepted ethical standards. For example, we include sentiment as secondary attributes in the acceptability score, which, when applied via dialogue rollouts, encourages the system to be courteous, polite, and respectful. It is possible with minimal effort to include further secondary attributes that identify bias, hate speech, and other indicators to help the system remain safe to use.

Annotator Compensation

All manual annotators were recruited on a voluntary basis in an educational setting and did not receive or expect monetary compensation. Specifically, two graduate students and one postdoc in our lab served as our annotators.

Environmental Impact

All training and inference in this work was done with two NVIDIA Quadro RTX 8000 GPUs. The most compute-intensive portion of the work was the additional domain adaptation pre-training for RoBERTa-large-adapted (see Section 3.2), which took approximately two weeks. After that the multi-seed self-play evaluations took approximately four days, and all other operations (e.g., training and evaluating PF models, fine-tuning DialoGPT) took 24 hours or less.

A Software Packages Used

Table 4: Software packages used in obtaining or presenting the results in this work

Package	**Version**	**Citation**	**URL**
hdbscan	0.8.27	(McInnes et al., 2017)	`https://hdbscan.readthedocs.io/`
kneed	0.7.0	(Satopaa et al., 2011)	`https://kneed.readthedocs.io/`
Matplotlib	3.3.4	(Hunter, 2007)	`https://matplotlib.org/`
NumPy	1.19.5	(Harris et al., 2020)	`https://numpy.org/`
Pandas	1.2.4	(the pandas development team, 2020)	`https://pandas.pydata.org/`
plotly	5.1.0	(plotly technologies inc., 2015)	`https://plotly.com/python/`
PyTorch	1.9.0	(Paszke et al., 2019)	`https://pytorch.org/`
PyTorch Lightning	1.5.8	(Falcon and team, 2019)	`https://pytorchlightning.ai`
scikit-learn	0.24.1	(Pedregosa et al., 2011)	`https://scikit-learn.org/`
SciPy	1.6.2	(Virtanen et al., 2020)	`https://scipy.org/scipylib/index.html`
Sentence-Transformers	N/A*	(Reimers and Gurevych, 2019)	`https://sbert.net/`
TensorFlow	2.5.1	(Abadi et al., 2015)	`https://tensorflow.org/`
Transformers	4.11.3	(Wolf et al., 2020)	`https://huggingface.co/transformers/`
umap-learn	0.5.1	(McInnes et al., 2018b)	`https://umap-learn.readthedocs.io/`

* we use all-mpnet-base-v2 directly through Transformers, but it is part of the Sentence-Transformers model library. Additionally, we base parts of our sentence embedding implementation on that found in Sentence-Transformers.

B Training Set Covariances For Acceptability Score

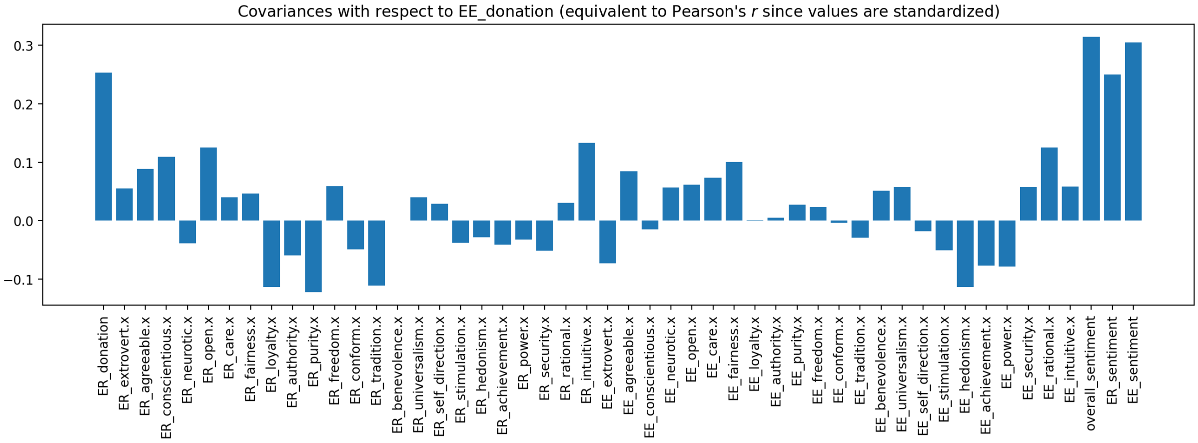

Figure 5: The covariances of all other dialogue attributes with respect to the persuadee donation are used to weight the acceptability score. ER and EE refer to the persuader and persuadee respectively.

C Full Manual Evaluation Results

Table 5: Progression Function Manual Eval Results (all annotators, averaged across all runs)

Model	**utt (1/2/3)**	**utt-sl (1/2/3)**	**dlg-sl (1/2/3)**	**dlg-sl-f (1/2/3)**
unsupervised	0.09 / 0.06 / 0.12	0.02 / 0.04 / 0.05	0.04 / -0.03 / -0.02	-0.07 / -0.09 / -0.05
RoBERTa-base	0.39‡/ 0.30‡/ 0.48‡	0.15†/ 0.17†/ 0.21‡	0.30 / 0.12 / 0.34	0.26 / 0.16 / 0.35
RoBERTa-large	0.39‡/ 0.30‡/ 0.50‡	0.16 / 0.18†/ 0.21†	0.41 / 0.17 / 0.46	0.36 / 0.21 / 0.47
RoBERTa-large-adapted	**0.49‡/ 0.37‡/ 0.59‡**	**0.21‡/ 0.24‡/ 0.29‡**	**0.51 / 0.26 / 0.52**	**0.45 / 0.27 / 0.51**

Average Pearson's r p-value across runs: †: $p < 0.05$; ‡: $p < 0.01$; (two-tailed; H_0 is non-correlation).

D Explanations of Manual Metrics

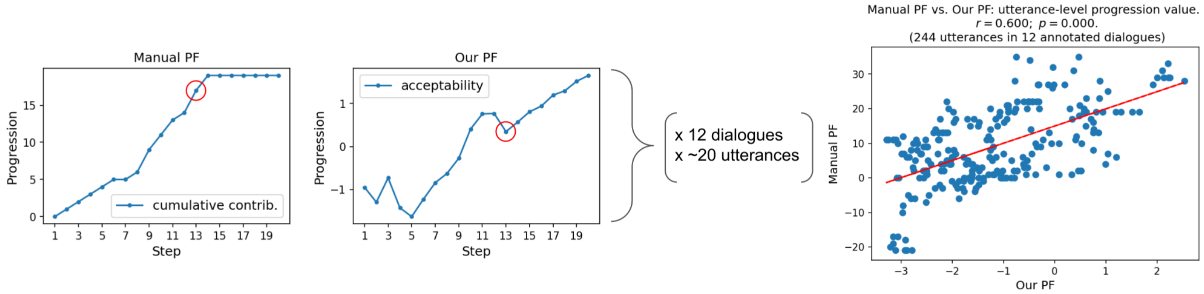

Figure 6: **utt**: Pearson's r (right) between utterance-level PF values (center, e.g., circled) and ground-truth values (left, e.g., circled) for all 244 utterances across 12 dialogues. Points shown on the right are from annotator 3. This metric is intended to measure if the PF and ground-truth progression curves assign similar values (relative to their respective scales) at each step of an ongoing dialogue.

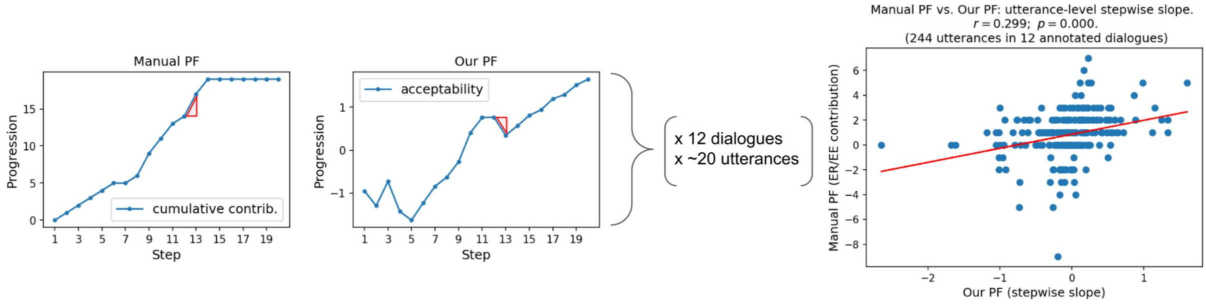

Figure 7: **utt-sl**: Pearson's r (right) between utterance-level PF slopes (center, e.g., see triangle) and ground-truth slopes (left, e.g., see triangle), for all 244 utterances across 12 dialogues. Utterance-level slopes are computed as the differences in the progression curves between two dialogue steps. Points shown on the right are from annotator 3. This metric is intended to measure if the PF and ground-truth progression curves move in the same direction at each step of an ongoing dialogue.

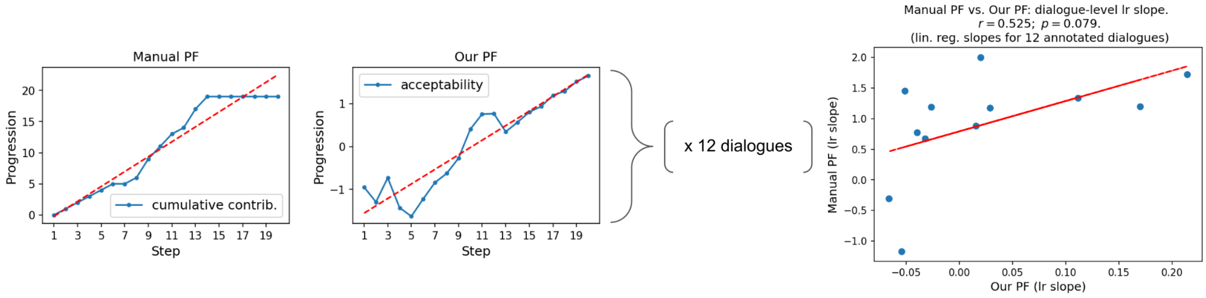

Figure 8: **dlg-sl**: Pearson's r (right) between dialogue-level PF slopes (center, e.g., see line) and ground-truth slopes (left, e.g., see line), for all 12 dialogues. Dialogue-level slopes are computed by fitting least-squares regression lines to the progression curves. Points shown on the right are from annotator 3. This metric is intended to measure the ability of the overall PF trend to approximate the ground-truth progression curve.

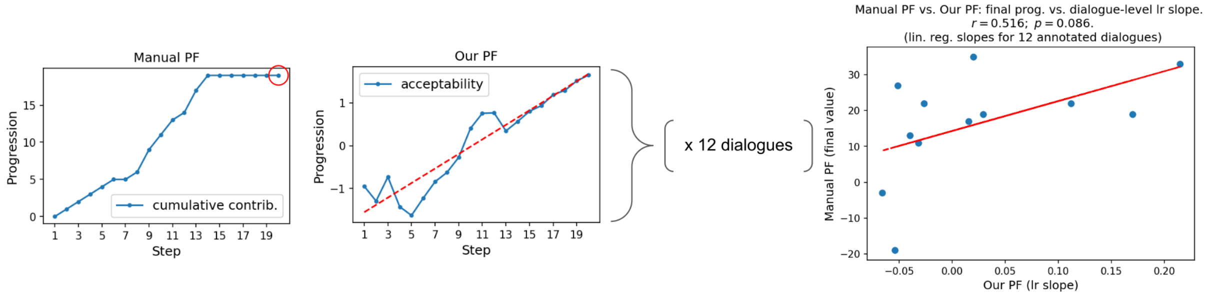

Figure 9: **dlg-sl-f**: Pearson's r (right) between dialogue-level PF slopes (center, e.g., see line) and the final ground-truth progression value (left, e.g., circled), for all 12 dialogues. Dialogue-level slopes are computed by fitting least-squares regression lines to the progression curves. Points shown on the right are from annotator 3. This metric is intended to measure the ability of the overall PF trend to predict the end-task outcome.

E PF Disagreement Examples

...

3. ER: It's an international organization that promotes children's rights, provides relief and helps support children in developing countries, does that sound like something you'd get behind?
4. EE: No thank you.

5. ER: May I ask why? Your help could really make a difference in a child's life, think of a child who didn't have enough to eat, just a small bit of help may have saved them, are you sure you're not interested?
6. EE: I am already making a difference in many children lives.

7. ER: That's great, it sounds like it's an issue you really care about then, why not put some of that effort into a charity that's doing really great work like Save the Children?
8. EE: I have donated 15 years of my life to charity

9. ER: I'm not asking you to donate years of your life, just a couple of cents if possible, is that something you could possibly do tonight?
10. EE: No thank you

11. ER: You're probably on a computer right now, so you probably have quite a bit of money yourself, don't you think you could spare maybe 25 cents for some needy children around the world?
12. EE: No thank you

13. ER: Do you have children yourself? What if your children were in a position these kids are in, wouldn't you want someone to help them?
14. EE: Where are those childrens parent?

15. ER: If only they had parental support, but in war-torn countries like Syria their parents are being killed in wars or are fighting for their country, they have no help and that's why they need your support, please find it in your heart to just give a little bit tonight, that's all I'm asking.
16. EE: My small change won't do a thing for those kids. What they need is to be extracted from those countries so that they can have a better life not 0.25.

17. ER: Well with our current president it's not likely they're going to be brought the US, so they need any help they can get, and 25 cents might not seem like a lot, but if 10000 people donated 25 cents then the impact will be huge. I understand it may not seem like a lot, but it can really make a difference. You can donate some or all of your payment from this task to Save the Children, i'd really appreciate it if you did, but I understand if you still don't want to. What do you say?
18. EE: If it makes you happy, go ahead and take .50

19. ER: Oh thank you so much, you have no idea how much that .50 will mean to those children, thank you very much and have a wonderful night you blessed soul.
20. EE: No problem have a good night

1. ER: Hello, how are you today?
2. EE: I AM doing well how are you

3. ER: Wonderful! Thank you. Have you heard of a charity called Save the Children?
4. EE: I have not

5. ER: Save the Children is an international non-governmental organization that promotes children's rights. Would you like to know more?
6. EE: No thank you. Most of those places have so much overhead not much actually goes to the cause

7. ER: Your individual donation will help individual children and their families.
8. EE: I appreciate you telling me about this but I am not interested

9. ER: What if I were to tell you that 100% of your donation would go directly to helping one child?
10. EE: No thank you as there is no guarantee to this. I'd rather donate locally

11. ER: I agree donating locally is also important. However, there are so many children that could benefit from just pennies.
12. EE: Again, no thank you

13. ER: It will go to a trustable fund. What if I match your donation?
14. EE: I'm sorry I am to interested in donating to this.

15. ER: Your donation could be directly deducted from your task payment. Anywhere from a penny to $2
16. EE: I will donate 0

17. ER: Just 77 cents could help a refugee family and I will match the donation.
18. EE: Again, I don't know how else I can say this. I will donate nothing to this. I prefer to do this locally

19. ER: Okay, then I have an option for you. You have the ability to sponsor at child in the US! We spend money on so many little things each day and we have the moral responsibility to help. So if you would like to help locally. Can you commit to doing that?
20. EE: No I am sorry again. I will only do this in my town

21. ER: This can go to sponsor a child in your town. Can you just commit to 10 cents?

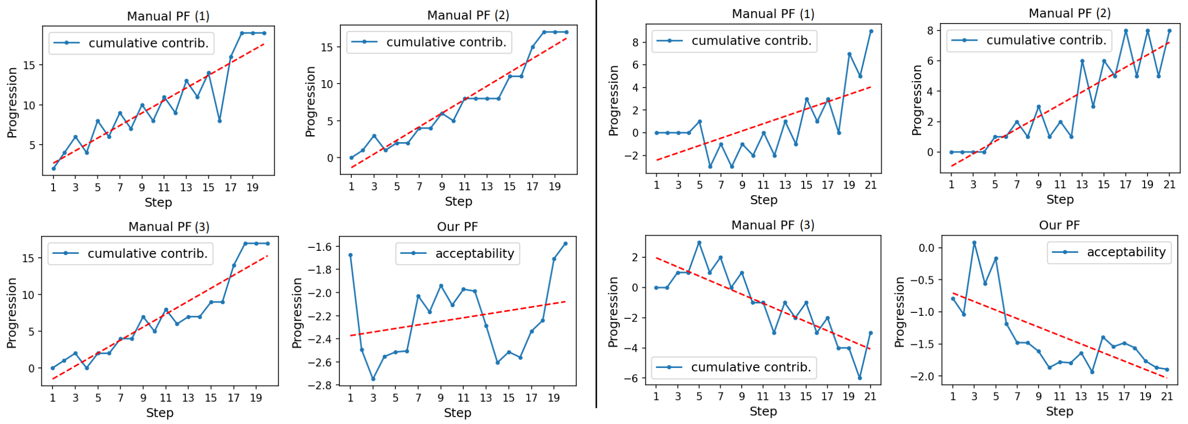

Figure 10: Two examples where the PF (RoBERTa-large-adapted) disagrees with multiple annotators. We note that the PF correctly decreases (**Right**) and stays negative (**Left**) given the turns boxed in red showing poor progression.

F Grid Search Details for Unsupervised Model

Algorithm 1: Grid search for hyperparameter tuning of the unsupervised progression model on the validation set. Descriptions for each hyperparameter are provided in Table 6.

```
for $\beta \in \{0.0, 0.1, \ldots, 2.0\}$ do
    for $d \in \{2, 16, 32, 64, 128, 768\}$ do
        for $normalize\_embeddings \in \{True, False\}$ do
            for $distance\_metric \in \{Cosine, Euclidean\}$ do
                ▷ k-means experiments
                for $k \in \{2, 3, \ldots, 30\}$ do
                    for $inverse\_distance \in \{True, False\}$ do
                        for $standardized\_proximity \in \{True, False\}$ do
                            measure_PF_slope_r();
                ▷ HDBSCAN experiments
                for $min\_cluster\_size \in \{10, 20, \ldots, 100\}$ do
                    for $soft\_value\_aggregation \in \{True, False\}$ do
                        for $prob\_scaling \in \{None, softmax, sum\}$ do
                            for $standardized\_proximity \in \{True, False\}$ do
                                measure_PF_slope_r();
```

Table 6: Hyperparameter Descriptions

Hyperparameter	**Description**
β (recency weight)	Controls how much emphasis is placed on recent tokens when computing dialogue embeddings.
d (embedding size)	The dimensionality of dialogue embeddings. Values < 768 reduced with Parametric UMAP.
normalize_embeddings	If True, embeddings are normalized to have unit magnitude after dimensionality reduction.
distance_metric	The distance metric used by Parametric UMAP and centroid proximity calculations.*
k (number of clusters)	Number of clusters to use for k-means.
inverse_distance	If True, Euclidean centroid proximity is computed as the inverse distance instead of negative distance.**
standardized_proximity	If True, centroid proximities are converted to z-scores before progression is computed. †
min_cluster_size	Minimum number of points in a HDBSCAN cluster. Clusters with fewer points get merged into larger ones.
soft_value_aggregation	If True, HDBSCAN cluster attribute aggregations are weighted with cluster membership probabilities.
prob_scaling	The type of scaling applied to progression computed from HDBSCAN cluster membership probabilities.

*: Centroid proximity calculations refer to progression computation. Proximities used during clustering are always Euclidean.
**: Does not apply to cosine distance.
†: Applies only if k-means is used, or if HDBSCAN is used with softmax probability scaling.

G Final Unsupervised Model Hyperparameters

The final unsupervised model uses k-means ($k = 21$), $\beta = 0.3$, $d = 768$, normalized embeddings, euclidean distance, and inverse distance for centroid proximity.

H Examples from rollout self-play experiment

The following examples in Tables 7, 8, and 9 compare self-play between the baseline **No RO** mode and the two rollout modes **2x2x3** and **3x3x5**. In each example, the utterance where the persuadee (EE) states intent to donate is highlighted in red. The complete dialogues from the self-play experiments are included with our code release.

Table 7: Rollout Self-Play Example 1: **No RO** vs. **2x2x3** (dialogue #7; generation seed: 247)

CONTEXT:

ER: Hello, Have you ever donated to a charity?
EE: A few times, yes.
ER: ow was your experience?
EE: It was ok. I didn't really think much of it. Most of the time its just a dollar or two.
ER: Do you donate all te time?
EE: Not so much.
ER: Have yu heard of Save the children? It is pretty well known around the world.
EE: I think so.
ER: What do you think that they do?
EE: Give money to child. Support efforts in war torn countries. Healthcare. All that stuff.

NO ROLLOUTS (progression: -2.65; ER sentiment: 0.69; EE sentiment: 0.03)

ER: I. It is a worthy cause. You can donate all you want from it.
EE: I'm sorry. I'm broke right now. That's why I'm asking if you do donate all the time.
ER: It's okay. I understand and agree. I think it's a good cause.
EE: So what is the charity that you donate to?
ER: I don't have a specific charity, but I do think they are a decent charity.
EE: Are they a non-profit? What do they do?
ER: It's a non profit. They help protect childrens rights to health and education.
EE: Well, I think they are a great charity. Do they provide help in other ways besides donating to them?
ER: Yes they help with children in the US and other developing countries.
EE: So I'm guessing the money goes towards programs to help those children get a proper education?

2x2x3 ROLLOUTS (progression: 0.15; ER sentiment: 0.67; EE sentiment: 0.63)

ER: I, they do. I have donated to the Red Cross and the Salvation Army in the past.
EE: I donated a couple of months ago. Do you donate often? I donate when I can.
ER: Yes, I donate to them as well. How much do you like to donate?
EE: i donate $.50 each month. Do you do the same?
ER: Yeah, that sounds great. Any bit helps though. Do you have an amount in mind?
EE: I would like to donate half. Is that a good idea?
ER: Yes that would be great. The children really do need it. I donate to them as well.
EE: I'm glad we can agree on a generous donation. How much would you like me to donate?
ER: I think half would be fine, I'm not sure, but that is a very generous amount.
EE: Well, it is nice to think that I'm not getting hit by a bot, so that's a good thing.

Table 8: Rollout Self-Play Example 2: **No RO** vs. **3x3x5** (dialogue #88; generation seed: 756)

CONTEXT:

ER: Hello therehow are you?
EE: I am good. How are you?
ER: I'm pretty good, just trying to get ready for work soon.
EE: I understand that. So tell me about this charity.
ER: Have you heard of Save the Children? They do work around health, education, etc.
EE: I'm not sure that I have.
ER: They work mostly in developing countries. I would appreciate it if some of the funds could be donated. The researchers will pass that donation on to the charity at the end.
EE: What kind of work do they do?
ER: They do emergency hunger relief, are engaged with Syrian children.
EE: Ok, that sounds good. How do I know it is a legitimate charity?

NO ROLLOUTS (progression: -0.43; ER sentiment: 0.71; EE sentiment: 0.50)

ER: They are a good non-profit that helps children all around the world
EE: Ah, that's good to know. Do you know what the funding for this charity actually goes towards?
ER: They actually make a huge impact. Do you donate to charity often?
EE: No, I don't think so, but I will look them up.
ER: They are a 501c, so it's not like they're going to ask you to give anything at this time. Every little bit helps.
EE: Cool, I don't think I'm ready to give anything up yet. How about you?
ER: They are a legit charity that I donate to regularly. Have you donated to a charity before?
EE: No, I'm usually a pretty cautious individual with donations, but I think that would be a good idea.
ER: They're great with giving to charities but I wouldn't be comfortable donating more than the 10.00, but I usually donate my entire earnings from this task to help out others.
EE: Cool, that's good to know. Have a great day!

3x3x5 ROLLOUTS (progression: 0.36; ER sentiment: 0.65; EE sentiment: 0.70)

ER: Well, it's not an international non-governmental organization, but they help children in war zones like Syria. Children are our future and we need to help out where we can.
EE: Ah, I see! I will look into this. Does it have any good ratings on Charity Navigator?
ER: I have no idea, but I would be willing to look into them. They're very trustworthy.
EE: They are very reputable. I will research them later and donate. Thanks!
ER: I'm glad to hear that. This is something I would like to be passionate about.
EE: Yes, I really love helping out! I think we need to take care of our country's children. And if you would like to know more about a charity you might like to research more: URL
ER: I would like to hear a little more about this charity from you.
EE: Well, I will look that up. This is one I really enjoy working on. I've heard of some of the kids who are in need, but this is one I'm very passionate about. Do you have any other charities you've worked on?
ER: I'm going to look at some websites right now. It's called Childrens International. You can research them. They are great. They promote the rights of children in these situations, especially those that are separated from their parents or families. Have you donated to them?
EE: Not yet, but I think I will sometime in the future.

Table 9: Rollout Self-Play Example 3: **No RO** vs. **3x3x5** (dialogue #98; generation seed: 589)

CONTEXT:
ER: Hi, do you usually donate to charities EE: I DO ER: great! You're such a nice person. What charities do you usually donate to? EE: To church, I return tithes and I also do the offerings ER: great! Well, have you ever heard about Save the Children charity? EE: no, can you tell me more about it? ER: it's an international non-governemntal organization that promotes children's rights, provides relief and helps support children in developing countries EE: nice! I have a child so i'm all about helping kids ER: would you donate to this charity? your donation will make such a huge impact for some children EE: I would like to know more before i donate. How do i know if it's a legit organization
NO ROLLOUTS (progression: -2.44; ER sentiment: 0.10; EE sentiment: 0.41)
ER: if you would like to donate, you can visit their site: URL EE: i dont want to donate, if i did however, how much would i donate? ER: if you have to donate, you would have to submit a donation agreement, i dont think you can donate right now EE: ok, how do i submit it? ER: You can't donate until you check out their website. EE: ok thanks for telling me, i will check it out ER: It is a charity that focuses on children in the United States EE: ok thanks for the information, if i ever get to a child's situation, i will donate ER: You're very welcome EE: ok, have a nice day
3x3x5 ROLLOUTS (progression: 1.14; ER sentiment: 0.36; EE sentiment: 0.52)
ER: I will send you a copy of the actual donation and you can make a donation from there. EE: How do i donate? ER: It's in your task payment. You can do that right now. EE: How do i donate? ER: You don't need to donate at this point, but I'll give you a heads up on the website: URL EE: Ok, i'll go check it out now. Thank you very much! ER: You're welcome, but I have to ask, Would you be willing to donate $2, to the Save the Children charity? EE: Ok. I will probably just donate $2. ER: That is great. Thank you so much for your donation! EE: You're very welcome. Thank you, have a nice one!

Cross-Domain Detection of GPT-2-Generated Technical Text

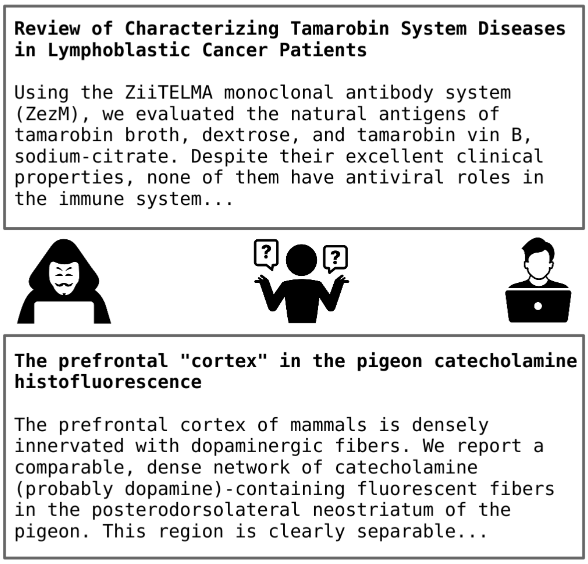
Abstract

Machine-generated text presents a potential threat not only to the public sphere, but also to the scientific enterprise, whereby genuine research is undermined by convincing, synthetic text. In this paper we examine the problem of detecting GPT-2-generated technical research text. We first consider the realistic scenario where the defender does not have full information about the adversary's text generation pipeline, but is able to label small amounts of in-domain genuine and synthetic text in order to adapt to the target distribution. Even in the extreme scenario of adapting a physics-domain detector to a biomedical detector, we find that only a few hundred labels are sufficient for good performance. Finally, we show that paragraph-level detectors can be used to detect the tampering of full-length documents under a variety of threat models.

1 Introduction

Recent advances in techniques for generating realistic synthetic content (i.e., deepfakes) pose a diverse set of problems with significant societal consequences (Kreps et al., 2020; Bommasani et al., 2021; McGuffie and Newhouse, 2020). The advent of large language models for text generation (Radford et al., 2019; Brown et al., 2020) have made it easier than ever to create convincing synthetic[1] text (Solaiman et al., 2019). While much attention has been focused on the role of synthetic audio and video, it can be argued that synthetic text may give rise to some of the most serious threats to information integrity and the long-term preservation of archival knowledge (Aliman and Kester, 2021).



`Review of Characterizing Tamarobin System Diseases in Lymphoblastic Cancer Patients`

`Using the ZiiTELMA monoclonal antibody system (ZezM), we evaluated the natural antigens of tamarobin broth, dextrose, and tamarobin vin B, sodium-citrate. Despite their excellent clinical properties, none of them have antiviral roles in the immune system...`

`The prefrontal "cortex" in the pigeon catecholamine histofluorescence`

`The prefrontal cortex of mammals is densely innervated with dopaminergic fibers. We report a comparable, dense network of catecholamine (probably dopamine)-containing fluorescent fibers in the posterodorsolateral neostriatum of the pigeon. This region is clearly separable...`

Figure 1: Machine-generated text enables the corruption of technical knowledge (e.g., biomedical research). One of the above abstracts was generated by GPT-2. More examples of generated text can be found in §A.7.

While there are currently no documented cases of published papers containing text from neural language models, non-neural machine-generated papers have already been published in peer-reviewed journals (Cabanac and Labbé, 2021). With more convincing text generation techniques and a growing number of publications, this is a problem that could get much worse, particularly for non-peer-reviewed technical text (Ranade et al., 2021). In addition to hindering the scientific process, synthetic technical texts could be used to manipulate public opinion and sow discord around specific scientific topics (Aliman and Kester, 2021). Other consequences of machine-generated technical text include the contamination of NLP pipelines (Ranade et al., 2021) and poisoning of language models (Schuster et al., 2021).

The rise of realistic machine-generated text – and

---

[1] Some authors use the term *fake text*; however, we prefer *synthetic*, since human-written text can contain false information, while machine-generated text can (sometimes) be factually correct (Schuster et al., 2020; Belz, 2019).

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1213 - 1233

its possible misuse – has spurred the development of automated tools to distinguish between genuine and synthetic English text.[2] However, most work to date has focused on web text or news, rather than on domain-specific technical text (Solaiman et al., 2019; Zellers et al., 2019). While synthetic technical text is likely to be distinguished by subject matter experts (SMEs), it is difficult for non-domain evaluators to do so. Therefore, given the ease at which large amounts of synthetic text can be generated, automated countermeasures are necessary in order to alleviate the burden on SMEs.

We focus on developing capabilities for detecting generated technical English text and delineating the contexts in which these detection approaches can be applied.[3] We assume an adversary generating technical text using GPT-2 (Radford et al., 2019), but do not know apriori in exactly which technical area. Realistically, some domain shift will be inevitable, which leads us to investigate whether detectors can be applied across domains, e.g., can a detector of generated physics papers be adapted to also detect biomedical text? In addition, most work to date has focused on detecting short pieces of text. We show that automated detection of tampered full-length research papers is possible under various threat models. Our work makes two main contributions:

- We show that accurate cross-domain detection of generated technical text is possible using a small number of in-domain samples and quantify the amount of SME effort required.
- We study the detectability of tampered full-text technical papers (where a subset of paragraphs have been replaced with generated text) under various scenarios.

2 Related Work

Automated detection of synthetic text Automated approaches to detecting machine-generated text have included energy-based models (Bakhtin et al., 2019), repurposing the generator as a discriminator (Zellers et al., 2019), and various neural and non-neural classifiers (Solaiman et al., 2019; Ippolito et al., 2020; Uchendu et al., 2020; Zhong et al., 2020; Fröhling and Zubiaga, 2021; Fagni et al., 2021). Most work on automated detection targeted GPT-2-generated text, although Bakhtin et al. (2019), Uchendu et al. (2020), Fagni et al. (2021) and Stiff and Johansson (2021) also experimented with other generators. Finally, there is a growing body of work on the adversarial robustness of automated detectors of synthetic text (Wolff, 2020; Bhat and Parthasarathy, 2020; Stiff and Johansson, 2021; Crothers et al., 2022). A survey on the automatic detection of synthetic text can be found in (Jawahar et al., 2020).

Prior work closest to our study are (Solaiman et al., 2019), (Ippolito et al., 2020), (Munir et al., 2021), (Bakhtin et al., 2019) and (Stiff and Johansson, 2021), which look at cross-domain settings where the distribution of synthetic text used to train a detector differs from the target distribution. The shift could be due to different model architectures (Bakhtin et al., 2019; Stiff and Johansson, 2021), different model sizes (Solaiman et al., 2019), different decoding strategies (Solaiman et al., 2019; Ippolito et al., 2020), or different fine-tuning datasets (Bakhtin et al., 2019; Munir et al., 2021; Stiff and Johansson, 2021). Bakhtin et al. (2019) show that energy-based models generalize poorly across corpora (Wikipedia, news and books), but that training on the union of the source and target domains is effective. Munir et al. (2021) show that XLNet can accurately attribute synthetic text even when the GPT-2-generated portions of the training and test sets come from GPT-2 fine-tuned on different subreddits.

Unlike the previous papers, we evaluate our detectors on technical (biomedical) text, and vary the number of labeled samples available for training in the target domain, under the assumption that source labels are plentiful but target examples are more expensive to obtain (i.e., source samples can be generated at will, but target examples need to be discovered and verified by a human since the adversary's target text generator is generally unavailable). In addition, we evaluate the detection of full-length tampered documents consisting of a mix of real and machine-generated content.

Attribution for synthetic text In addition to distinguishing between real and generated text, one may also wish to determine *which* system generated a given text (e.g., model type, size, decoding strategy). Variations of this "authorship attribution" problem have been explored by Uchendu et al. (2020), Tay et al. (2020) and Munir et al. (2021).

---

[2] Most work on the detection of GPT-2-generated text has focused on English. However, (Harrag et al., 2020) examines automated detection of synthetic tweets in Arabic.

[3] Our code is available at `https://github.com/ciads-ut/cross-domain-detection-gpt-2`

These works have found that, in general, while the attribution problem is harder than the detection problem, details of the text generator can often be learned from the generated text.

Human detection of synthetic text Human evaluations on the detection of generated text have been conducted for news (Zellers et al., 2019; Brown et al., 2020; Kreps et al., 2020; Clark et al., 2021), product reviews (Hovy, 2016; Yao et al., 2017; Adelani et al., 2020), web text (Gehrmann et al., 2019; Ippolito et al., 2020), stories (Clark et al., 2021; Donahue et al., 2020; Clark et al., 2021; Gunser et al., 2021), peer reviews (Bartoli and Medvet, 2020), cybersecurity text (Ranade et al., 2021) and submissions to federal public comment websites (Weiss, 2019). These studies have shown that it is difficult for people to distinguish between real and neural-generated text. Gehrmann et al. (2019) developed a tool, GLTR, to help users visualize statistical artifacts in generated text.

3 Threat model and defender capabilities

3.1 Threat Model

Given that people have trouble distinguishing real (human-written) from GPT-2-generated text (Zellers et al., 2019; Kreps et al., 2020; Clark et al., 2021), we study the detection of generated text under the threat model where an adversary generates text from GPT-2 domain-tuned[4] on domain-specific text. We do not necessarily assume that text from this domain is publicly available in significant quantities. Throughout, we shall refer to those developing the generated text as the *adversary*, and those building automated detectors of synthetic text as the *defender*. As there does not (yet) exist a "real-world" dataset of GPT-2 generated technical text, we simulate both the adversary and the defender.[5]

We study two scenarios: where the adversary generates single technical abstracts (§4.1), and where the adversary replaces randomly selected paragraphs in full-length documents with GPT-2-generated paragraphs (§4.2). Other threat models are possible, such as replacing single words, sentences or phrases (Schuster et al., 2020; Donahue et al., 2020; Bhat and Parthasarathy, 2020), and should be studied in future work.

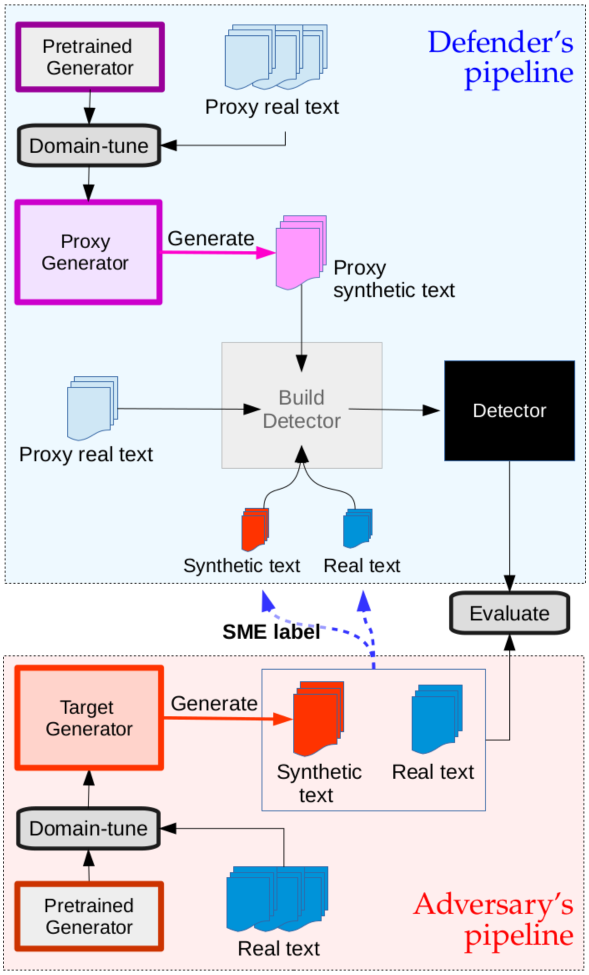

Figure 2: Experimental setup for detecting synthetic text used in this paper. Since the defender does not have access to the adversary's text generator, they develop a *proxy* generator, in order to mimic the adversary's generator as closely as possible. Proxy and target corpora will generally come from different domains.

3.2 Defender Capabilities

In general, the defender has little or no information about the adversary's text generation pipeline, including the data used for training, the model architecture used, or the decoding strategy employed. We assume the defender has access to a small number of examples from the adversary, which can be labeled by a subject matter expert (SME) as real (human) or synthetic (generated).[6] In addition, since the defender does not have access to the adversary's *target generator*, they can build a *proxy generator*, trained on *proxy* text, in order to obtain

---

[4] Following (Han and Eisenstein, 2019), we use *domain-tuning* to refer to further self-supervised training of a model on unlabeled text in a specific domain, and *task-tuning* to refer to supervised fine-tuning of a model for a given labeling task.

[5] More recently, a corpus of GPT-2 generated (NLP-related) abstracts has been created for testing detection methods (Liyanage et al., 2022).

[6] We assume that a SME is able to accurately carry out this task. In reality, even a SME could make mistakes, but we leave the scenario of noisy labels to future work.

more samples of real and synthetic text which are (hopefully) statistically similar to the ones obtained from the adversary[7], as shown in Figure 2. The defender can then train a model to detect generated text using both the in-domain SME-labeled text and the (possibly) out-of-domain proxy text, as described in more detail in §4. The level of access the defender is assumed to have to various parts of the adversary generation pipeline is shown in Table 1.

Defender's access level	
Adversary's (target) generator model	None
Labeled samples from adversary domain	Limited (SME)
Real samples from proxy domain	Plentiful
Synthetic samples from proxy domain	Unlimited

Table 1: Assumptions about the defender's access to data or models that can be used in a detection pipeline. We assume a SME is able to label a small (random) sample consisting of real and adversary-generated text.

Since the effect of differing model sizes has already been explored (Zellers et al., 2019; Solaiman et al., 2019; Fröhling and Zubiaga, 2021), we assume the adversary and defender use the same sized model (GPT-2 Medium, with 355M parameters), but domain-tuned on different datasets. Since the defender cannot guess the temperature value used by the target generator, we shall decode using a temperature value of 1.0 for the target generator, but 0.8 for the proxy generator.[8] We also assume both adversary and defender use nucleus sampling (Holtzman et al., 2020). The defender would not know whether the generator is using nucleus sampling. However, it was shown in (Ippolito et al., 2020; Solaiman et al., 2019) that a discriminator trained with nucleus sampling is able perform nearly as well at detecting text generated with top-k (Fan et al., 2018) sampling as with nucleus sampling, while a discriminator trained using top-k sampling fails to detect generations from nucleus sampling[9]. Hence this is a reasonable assumption to make.

Our experiments will investigate the effects of domain shift between the proxy and target data, as well as the number of SME-labeled examples available to the defender. While the assumption that both adversary and defender share the same model architecture may seem like a strong one, we fix the architecture so as to focus on the effect of domain shift, and note that previous works have already studied the effect of using different architectures (Bakhtin et al., 2019; Stiff and Johansson, 2021), model sizes (Solaiman et al., 2019), and decoding strategies (Ippolito et al., 2020; Solaiman et al., 2019).

4 Automated Detection

4.1 Detecting Generated Abstracts

While the defender could train a detector on the union of SME-labeled (target) and proxy data as done in (Zellers et al., 2019), we instead follow a pipelined approach by first task-tuning on the proxy real and synthetic text to produce a proxy detector, before task-tuning a second time on the SME-labeled text. One advantage of this approach is that one would still have a detector even when SME labels are not available. In addition, previous studies have shown that task-tuning twice can yield good performance on a variety of tasks and can help mitigate the effects of domain shift (Phang et al., 2018; Sellam et al., 2020).

Preliminary experiments on in-domain detection showed that fine-tuning RoBERTa consistently outperformed other classifiers (LSTMs, HAN, BERT and XLNet), as shown in Appendix §A.2, and so we exclusively use RoBERTa in all of our experiments. This is in line with results in (Solaiman et al., 2019; Uchendu et al., 2020; Fagni et al., 2021), which showed the effectiveness of RoBERTa for detecting GPT-2-generated text. In order to investigate the benefit of further pretraining (Gururangan et al., 2020), we also domain-tune RoBERTa on technical text from various science, technology, engineering, and mathematics (STEM) fields, as described in §5.1.2; we call the resulting model *RoBERTa-large-STEM*. Our experiments will vary both the number of proxy and SME-labeled abstracts, as well as the subject domain of proxy text, as detailed in §5.1.

4.2 Detecting Tampered Documents

We also investigate how well our detection methods work when applied at the document level, assuming the following attacker model: a fraction of randomly-selected paragraphs in a document are replaced by generated paragraphs (see §5.2.1 for details). Each generated paragraph is conditioned

---

[7] If text from the target domain is available to the defender in large quantities, the proxy domain is effectively the same as the adversary (target) domain.

[8] The effect of differing temperatures is also explored in (Munir et al., 2021).

[9] Indeed, viewing the accuracy scores in Table 2 of (Ippolito et al., 2020) as the payoff to the defender in a zero-sum game, nucleus sampling is the minimax strategy for both defender and generator.

on the previous paragraph (i.e., the previous paragraph is used as a prompt). Conditioning helps the text stay on-topic, and would likely help evade coherence-based detectors[10](Singla et al., 2021). We refer to the modified documents as *tampered* rather than generated, since only a subset of the document might be generated.

On the detection side, we train paragraph-level detectors, and then aggregate paragraph scores into document scores to classify documents. We need to specify both the question we would like to answer, as well as how to aggregate the detectors' paragraph scores $\{s_i\}$ to answer it. Here we interpret s_i as the probability that a paragraph has been generated. The general question "has this document been tampered with?" leads to two more specific questions and associated scoring strategies:

- **(S1)** Is at least one paragraph in the document generated? The probability that a document with paragraph scores $\{s_i\}$ has at least one synthetic paragraph is then given by:

$$P = 1 - \prod(1 - s_i)$$

- **(S2)** What fraction of a document is generated? For a document with N paragraphs, this is:

$$F = \frac{1}{N}\sum \mathbb{1}_{s_i > 0.5}$$

As we will see, one drawback of scoring with (S1) is that it is extremely sensitive to false positives. Entirely human-written documents have a high chance of having one or two false positives (especially among short paragraphs), even if the other paragraphs are correctly classified. In these cases the human documents will be classified as tampered. Since the false positive rate is highest for short paragraphs[11], we can filter out very short paragraphs from each document before scoring. We thus also experiment with the following score:

- **(S1-T)** Is at least one paragraph p_i longer than a given threshold T synthetic? The probability that this is the case is:

$$P = 1 - \prod(1 - s_i \cdot \mathbb{1}_{\mathrm{len}(p_i) > T})$$

For each document we can use thresholds for P or F to decide how to classify the document; in addition, we shall use (S2) to rank documents by how much generated content they contain.

5 Datasets

Here we describe the datasets used and other experimental details when simulating the adversary and defender's pipelines (Figure 2). The experiments on synthetic abstract detection are described in §5.1; experiments on tampered document detection are described in §5.2.

5.1 Real and Synthetic Abstracts

Table 2 summarizes the datasets used. The adversary has access to the Semantic Scholar Open Research Corpus[12] (Ammar et al., 2018), while the defender has access so several subsets of CORE (Knoth and Zdrahal, 2012), as well as small amount of text labeled by a SME. We chose abstracts from CORE related to biomedicine and physics, since these subjects had the largest number of abstracts for fine-tuning models (shown in §A.6, Table 10).

Synthetic abstract detection	
Corpus	**Purpose**
Semantic Scholar (Biomed+CS)	• Real portion of the test set • Domain-tune adversary's generator • Task-tune detector on real ("SME-labeled") samples from adversary domain
CORE (Biomed, Physics, Biomed+Physics)	• Domain-tune proxy generator • Task-tune detector on proxy data
CORE (STEM): (all subjects listed in §A.6)	• Domain-tune RoBERTa on STEM text ("RoBERTa-large-STEM")

Table 2: List of datasets and how each was used for the cross-domain synthetic abstract detection experiments. The Semantic Scholar Open Research Corpus is used for the adversary's generation pipeline, while subsets of CORE are used for the defender's pipeline.

5.1.1 Test Data

We first discuss the construction of datasets used to evaluate the detection of GPT-2-generated abstracts. The test set consists of 1000 real and 1000 synthetic abstracts, generated using GPT-2 domain-tuned on abstracts from the January 2019 version of the Semantic Scholar Open Research Corpus (Ammar et al., 2018)[13], hereafter referred to as

---

[10] Such detectors would use paragraphs in context, rather than independently, and should be considered in future work.

[11] The effect of paragraph length on the false positive rate is shown in Figure 7 in Appendix §A.4. Similar results can also be found in (Ippolito et al., 2020; Munir et al., 2021).

[12] These abstracts are mostly, but not entirely, biomedical (Beltagy et al., 2019).

[13] From https://api.semanticscholar.org/corpus/download/

Semantic Scholar.[14] Text was generated using nucleus sampling, with p sampled uniformly between 0.9 and 1.0, since (Zellers et al., 2019) showed detection was hardest with p in that range.

5.1.2 Training Data

Here we describe the SME-labeled abstracts (in-domain) and proxy (possibly out-of-domain) data used to train detectors of GPT-2 generated abstracts.

SME-labeled data Nested subsets of another 10k abstracts (of sizes {100, 500, 1000, 1k, 10k}), obtained in the same way as the test set, were used as "SME-labeled" (in-domain) data for training.

Proxy data Out-of-domain abstracts were sampled from the CORE dataset of open access research papers (Knoth and Zdrahal, 2012), version 2018-03-01[15]. CORE covers a wide variety of subjects, some of which can be identified from each paper's data provider. We used a subset of CORE related to STEM fields[16], and filtered out non-English abstracts using the Python package *langdetect*. This subset of CORE was also used to domain-tune RoBERTa-large on STEM abstracts, resulting in *RoBERTa-large-STEM*.

We trained proxy generators using the biomedical and physics portions of CORE (237,620 abstracts for each), and on the union of the biomedical and physics portions ("biomedical-physics", with 475,240 abstracts). For each of these three generators, we created nested subsets (of sizes {100, 500, 1000, 1k, 10k, 100k}) of proxy training data. As with the SME-labeled data, half of the samples were real and half were generated[17]. In the case of biomedical-physics, we used equal numbers of real biomedical and real physics text. We estimate that roughly half of the biomedical-physics generations were biomedical. Examples of generated physics and biomedical abstracts can be found in Appendix §A.7.

5.2 Real and Tampered Documents

While the CORE corpus includes full-length documents, they have not been pre-processed and are rather noisy. Fortunately, the S2ORC corpus (Lo et al., 2020)[18] includes millions of pre-processed scientific documents. The full-length papers in S2ORC have been preprocessed with paragraph splitting; in addition, captions, tables, headers, footers, footnotes, abstracts and bibliography have been removed from the main text.

We sampled from the 6.8 million papers in S2ORC which are biomedical[19] to create disjoint datasets for domain-tuning proxy and target GPT-2 generators, for task-tuning RoBERTa-based detectors, and for test sets. Since our attacker model consists of random paragraph replacement, we domain-tuned GPT-2 on 890,000 biomedical paragraphs in order to generate new paragraphs conditioned on previous paragraphs.[20] This is done twice, on non-overlapping data, to obtain two separate generators: the target generator is used to create the test document collections and SME-labeled training paragraph collections, while the proxy generator is used to create proxy training data. The details of each of these datasets are given below.

5.2.1 Test Data

In order to evaluate our detectors against various document tampering scenarios, we use several document-level datasets, which differ by the number of generated (replaced) paragraphs in each document. Each of these test sets consists of 500 human documents and 500 tampered (generated/modified) documents.[21] The five test sets containing tampered documents are given as follows: *test-1-fake* contains only tampered documents with exactly one synthetic paragraph, *text-x* replaces every paragraph with a generated paragraph with probability x, for x in {0.1, 0.5, 0.9}, and *test-all-fake* has all paragraphs generated, with each subsequent paragraph generated conditional on the previously generated paragraph. Two examples can be found in Appendix §A.7, Table 13.

---

[14] Fine-tuning hyperparameters are shown in §A.1.

[15] Available at https://core.ac.uk/services/dataset/

[16] The list of open access data providers for each STEM subject is provided in Table 10 in Appendix §A.6.

[17] In the absence of additional information, it seems reasonable to assume an uninformative prior wherein the classes are balanced. In practice, one could base this prior on the empirical distribution over classes in the SME-labeled data, which approximates the distribution of real and generated samples in the corpus under consideration.

[18] v. 1 (2020-07-05) at https://github.com/allenai/s2orc.

[19] We selected all papers with a Microsoft Academic Graph field of study which included Biology or Medicine, or which had a PubMed or PMC ID tag (these are biomedical in a broad sense: the 15% of papers that were not tagged with Biology or Medicine were on the related fields of Chemistry, Psychology, Physics, Math or Computer Science applied to biomedicine.)

[20] Details on the fine-tuning of GPT-2 are in Appendix §A.1.

[21] For each test dataset we use the same 500 human documents and the same 500 documents to tamper with.

5.2.2 Training Data

Here we describe the datasets used to build paragraph-level detectors.

SME-labeled data Nested subsets of 10,000 paragraphs (of sizes {0, 100, 500, 1k, 10k}) were used as SME-labeled (in-domain) training data, with equal numbers of real and generated paragraphs. The generated paragraphs are obtained using the same domain-tuned generator as for the test sets. For each paper, we sample one paragraph to use as real, and one paragraph to condition on.

Proxy data The proxy GPT-2 generator is used to obtain nested subsets of 10,000 paragraphs (of sizes {0, 100, 500, 1k, 10k}) in much the same way as for the in-domain data, except for one difference. Unlike for the in-domain data, the defender has access to every human paragraph that is being replaced by a (proxy) generated paragraph[22]. So for each paper, we sample a real paragraph at position i, and use the previous paragraph at position $i - 1$ as a prompt for the generated paragraph.

What if the defender uses a proxy generator designed for unconditional paragraph generation? Preliminary experiments on using proxy data generated without prompting showed only a small drop in accuracy under most dataset sizes, so this is not a strong assumption to make.[23]

6 Results

6.1 Detection of Generated Abstracts

Detection performance on Semantic Scholar abstracts depends on the model used for task-tuning (RoBERTa-base, RoBERTa-large, or RoBERTa-large-STEM), the proxy domain (biomedical, physics, or biomedical-physics), and the number of proxy and SME samples used for task-tuning, with full results shown in Appendix §A.3. We consider the effects of these four dimensions below.

Interplay of SME and proxy labels Some SME labels are always needed for good performance, even when the training proxy text is in a similar domain as the target domain (Table 3). Without any SME labels, the highest accuracy that could be achieved with RoBERTa-large using only biomedical proxy text was .67 (with 10k proxy samples). Task-tuning the 10k-proxy model checkpoint a second time with only 100 SME-labeled samples resulted in a large improvement (accuracy of .81, recall of .95).

		Proxy samples					
		0	100	500	1k	10k	100k
SME samples	0		.59	.58	.54	.67	.65
	100	.68	.67	.89	.89	.81	.82
	500	.69	.68	.82	.75	.88	.84
	1k	.80	.90	.84	.89	.90	.84
	10k	.92	.95	.94	.94	.95	.92

Table 3: Detection accuracy when task-tuning RoBERTa-large with biomedical proxy data.

n	Biomedical	Biomed-physics	Physics
100	.67	.87	.78
500	.89	.82	.83
1k	.89	.85	.84
10k	.81	.69	.62
100k	.82	.70	.66

Table 4: Comparing proxy domains when task-tuning RoBERTa-large on n proxy samples (from different domains) and 100 SME samples.

Given a fixed number of SME samples, increasing the number of proxy samples improves performance, but only up to a point, after which the proxy data starts being detrimental. For example, given 100 SME examples (row 2 in Table 3), the highest performance for the biomedical proxy experiments was achieved when using between 500 and 1000 proxy samples (resulting in accuracy of .76-.77 for RoBERTa-base, .89 for RoBERTa-large and .91-.92 for RoBERTa-large-STEM). The same observation holds when using physics and biomedical-physics proxy text. Unsurprisingly, the effects are worse with increasing domain shift. The decrease in accuracy when jumping from 1k to 10k proxy samples is .08 for biomedical proxy data, .16 for biomedical-physics proxy data, and .22 for physics proxy data.

Effect of domain shift When 1k or 10k SME labels were available, performance across task-tuning domains was similar. On the other hand, with 500 SME labels or less the impact of the proxy data domain was greater, as shown in Table 4 for the case of 100 SME labels. For most proxy dataset sizes, there is a decrease in performance as one moves from biomedical to physics.

Finally, we note that when using RoBERTa-

---

[22] On the other hand, the in-domain data is labeled by a SME, who identifies generated paragraphs but does not have access to the human paragraphs that they replaced.

[23] See Appendix §A.5 for details.

large-STEM, 100 SME samples are sufficient to achieve .91 accuracy when using biomedical proxy samples. However, if the proxy samples come from a different domain (physics, or a mix of physics and biomedicine), then 500 SME samples are required to achieve the same accuracy.

Effect of model size RoBERTa-large had higher accuracy than RoBERTa-base under most scenarios, with an absolute increase in accuracy ranging between 1 and 22 points. RoBERTa-large always had higher precision than RoBERTa-base.

Effect of domain-tuning Pre-training RoBERTa on a diverse corpus of STEM technical text improved performance in most cases, sometimes by a large margin. RoBERTa-large-STEM outperformed RoBERTa-large even when the target and proxy domains were close (i.e., using biomedical proxy data), with 1 to 5 point gains in accuracy under most conditions.

Domain-tuning RoBERTa was more beneficial with increasing amounts of domain shift, and when task-tuning on a large number of proxy samples and a small number of SME-labeled samples, as shown in Figure 3. A domain-specific RoBERTa is better at recovering from being trained on a large volume of data from the wrong domain, when given a small amount of in-domain text.

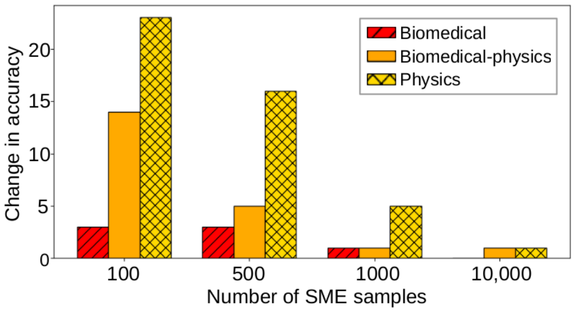

Figure 3: Increase in accuracy when switching from RoBERTa-large to RoBERTa-large-STEM, when task-tuning on 10k proxy samples.

6.2 Detection of Tampered Documents

The performance of the RoBERTa-large detectors at the paragraph level is shown in Table 5. It is not unrealistic to assume a SME can label 100 paragraphs (50 real, 50 synthetic) to create a detector with .94 accuracy. Thus, in the rest of the section we shall only evaluate the classifier trained on 10k conditioned proxy samples and 100 SME samples.

Identifying documents with at least one synthetic paragraph Here we apply the scoring strategies **(S1)** and **(S1-T)** described in §4.2 to predict whether a given document has at least one generated paragraph. We found that on all our test sets, scoring documents using **(S1)** resulted in recall of .99-1 but precision at nearly chance level (.55-.56). This is due to the high false positive rate for short paragraphs. To remedy this, we score using **(S1-T)**, ignoring all paragraphs shorter than a given threshold of T characters[24]. The results for $T = 500$ and $T = 1000$ are shown in Table 6.

		Proxy samples				
		0	100	500	1k	10k
SME samples	0		.60	.78	.84	.93
	100	.77	.82	.87	.89	.94
	500	.85	.89	.90	.90	.95
	1k	.91	.91	.90	.92	.94
	10k	.96	.95	.96	.96	.96

Table 5: Accuracy when task-tuning RoBERTa-large on conditioned proxy data, evaluated on a balanced subset of 1000 real and 1000 synthetic paragraphs.

Test set	$T = 500$	$T = 1000$
test-all-fake	.87 [.79, 1.0]	.98 [.96, 1.0]
test-0.9	.87 [.79, 1.0]	.97 [.96, .99]
test-0.5	.86 [.79, .99]	.96 [.96, .96]
test-0.1	.81 [.77, .89]	.80 [.94, .63]
test-1-fake	.76 [.74, .78]	.67 [.91, .37]

Table 6: Performance (accuracy, [precision, recall]) when predicting whether documents contain at least one synthetic paragraph (after removing paragraphs shorter than T).

When $T = 1000$, performance is high for test-all-fake, test-0.9 and test-0.5; however, recall drops substantially for test-0.1 and test-1-fake. This is due to the fact that these test sets contain very few generated paragraphs, which are then more likely to be filtered out: all synthetic paragraphs were removed from 64% of tampered test-1-fake documents, and 39% of tampered test-0.1 documents. Unfortunately, filtering less aggressively with $T = 500$ improves recall at the cost of lower precision across all test sets.

Ranking documents by fraction of generated content We rank documents using **(S2)**, i.e., according to the estimated fraction of paragraphs clas-

---

[24] If all paragraphs in a document are shorter than T, we score the longest three paragraphs, but this is a rare occurrence (less than 5% of documents when $T = 1000$).

Test set	P@100	P@250	P@500
test-all-fake	1.0	1.0	.99
test-0.9	1.0	1.0	.99
test-0.5	.98	.97	.95
test-0.1	.70	.74	.69
test-1-fake	.57	.60	.59

Table 7: Ranking performance when ranking documents according to the estimated fraction of paragraphs classified as generated.

sified as generated. Table 7 shows the fraction of documents in the top-k ranked documents that were tampered with (P@k). It is possible to retrieve nearly all tampered documents, except for test sets test-0.1 and test-1-fake.

Effect of paragraph splitting errors It is unrealistic to assume that the adversary and the defender use the same paragraph splits. For example, text from a PDF file must first be extracted and split into paragraphs before detection can be done. Even when using a good paragraph splitter, it is unlikely that the paragraph splits would exactly match those used by the generator. To investigate the robustness of detection against paragraph splitting errors we process each test set as follows: each paragraph is sentence-segmented with scispaCy v.0.2.2 (Neumann et al., 2019), and every five consecutive sentences is taken to be a paragraph, disregarding the original paragraph splits. This is a stress-test for our detectors, since one can probably achieve far fewer paragraph-splitting errors when using a paragraph splitter such as GROBID (Lopez, 2009).

When applying the detector on the incorrectly-split documents and scoring with (S1), we find that precision increases from .55 to between .61 and .67. This is due the fact that paragraphs in the human 5-sentence splits are generally longer than the original paragraphs. On the other hand, recall drops significantly for test-0.1 and test-1-fake (from .99 to .87, and .99 to .79, respectively). This is due to the fact that it is harder to detect paragraphs containing a mix of real and synthetic content: recall was .95, .66 and .33 for the the subsets of paragraphs with 5, 4, and 3 synthetic sentences, respectively[25].

7 Conclusion

In this paper, we studied the problem of automatic detection of GPT-2-generated technical text. We found that RoBERTa-based detectors can be successfully adapted from one scientific discipline (physics) to another (biomedicine), requiring relatively small amounts of in-domain labeled data. These could be provided by a subject matter expert (SME) in a reasonable amount of time. We also evaluated these paragraph-level detectors on a document tampering task, assuming that the adversary replaces randomly-selected paragraphs in a document with generated ones.

Future work should evaluate the extent to which this methodology would work on detecting text from newer generators such as GPT-3. Other challenging scenarios include adding noisy labels (e.g., if a SME makes a certain fraction of mistakes), and class imbalance. Our results on document tampering (i.e., that it is significantly harder to detect small amounts of generated text intermingled amongst real text) also point to the need to develop detection pipelines for other threat models such as single word or phrase substitutions (Schuster et al., 2020). As text generation techniques continue to improve, it may be that more interpretable, fact-checking approaches are required to detect both human and machine-generated misinformation.

Ethical Considerations

Improvements in the detection of synthetic text could be used by an adversary to improve the quality of generated text or to help them avoid detection (Darmetko, 2021). False positives are another source of potential negative consequences of automated detectors. For example, incorrectly flagged human-written content could be a source of misinformation, and could additionally lead to a loss of trust in the detection system. Care should be taken that false positives do not affect certain demographics disproportionately (Bommasani et al., 2021, §5.2). Finally, widespread awareness of the mere possibility of synthetic scientific text can further undermine public trust in genuine science (Makri, 2017).

---

[25] This affected test-0.1 and test-1-fake the most, because these test sets had a greater fraction of paragraphs with mostly human sentences but with some generated sentences mixed in.

A Appendix

A.1 Fine-tuning hyperparameters

Here we list the main hyperparameters used in our experiments.

Domain-tuning GPT-2 to generate abstracts The GPT-2 generators (both proxy and target generators) were domain-tuned with a block size of 512 BPE tokens, and a batch size of 6 on two Titan RTX GPUs, with the Adam optimizer.

Domain-tuning GPT-2 to generate paragraphs in context Proxy and target GPT-2 generators were obtained by domain-tuning GPT-2 with a block size of 768 and a batch size of 3 for four epochs on two disjoint, random subsets of S2ORC biomedical papers, each consisting in about 890,000 paragraphs.

We formatted the fine-tuning data in order to generate complete paragraphs conditioned on previous paragraphs; i.e., each training instance consisted of text from consecutive paragraph pairs: the last 256 tokens of a paragraph, a special newline token, and the next paragraph. For each paragraph pair (A, B), truncating A at 256 tokens allowed us to encode at least 512 tokens for each paragraph B, and about 95% of paragraphs in the domain-tuning dataset are shorter than 512 tokens. Thus, the model could learn how to end paragraphs naturally.

Task-tuning RoBERTa We task-tuned all RoBERTa models with a block size of 512 on two Titan RTX GPUs. For RoBERTa-base, we used a batch size of 40, while for RoBERTa-large and RoBERTa-large-STEM we used a batch size of 7. Preliminary experiments suggested that for the smaller task-tuning datasets training for more epochs improved performance. The 100-sample task-tuning dataset was trained for 80 epochs, the 500-sample dataset was trained for 16 epochs, and the other datasets were trained for 8 epochs. Task-tuning on the SME-labeled (target) text was done using the same hyperparameters as were used for the proxy task-tuning.

A.2 Comparison of classifiers on in-domain detection

Table 8 compares several classifiers on the in-domain detection task (i.e., the real portions of the train and test sets are from the Semantic Scholar corpus, and the synthetic portions were produced by the same GPT-2-Medium generator).

RoBERTa-large (Liu et al., 2019) and XLNet-large (Yang et al., 2019) outperform the other classifiers. We chose RoBERTa over XLNet because XLNet is known to be unstable when task-tuned on small datasets (Ma et al., 2019).

Discriminator	Accuracy
LR (BOW)	.64
LSTM	.67
HAN	.72
BERT-base	.86
BERT-large	.90
XLNet-base	.89
XLNet-large	**.95**
RoBERTa-base	.93
RoBERTa-large	**.95**

Table 8: Detection accuracy when for a variety of models trained on 10,000 in-domain abstracts.

LR (BOW) indicates logistic regression with unigram count features, and HAN (Hierarchical Attention Network) is a hierarchical LSTM with two attention layers, one for words and another for sentences (Yang et al., 2016).

Both the LSTM and the HAN used pre-trained GloVe embeddings[26] (Pennington et al., 2014). They were trained for 60 epochs with early stopping (patience 10), with 128 hidden layer units, dropout of 0.5, a batch size of 64, learning rate of 0.001 and the Adam optimizer. For the HAN, abstracts were truncated at the first 20 sentences and only the first 50 tokens in each sentence were used. For the LSTM, abstracts were truncated at 200 tokens.

A.3 Full cross-domain results

Figures 4, 5 and 6 contain the full results (accuracy, precision and recall) for all the cross-domain experiments discussed in §6.1.

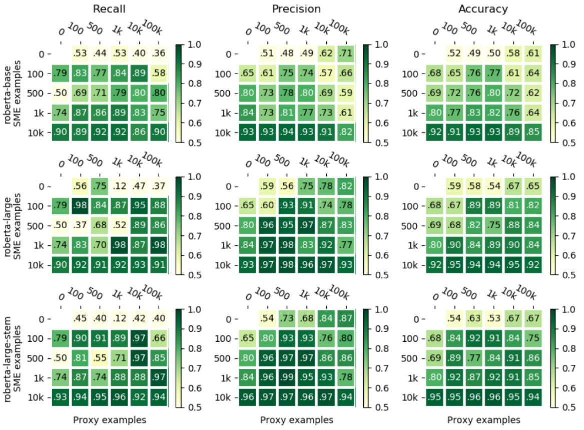

Figure 4: Detection performance when using biomedical proxy data.

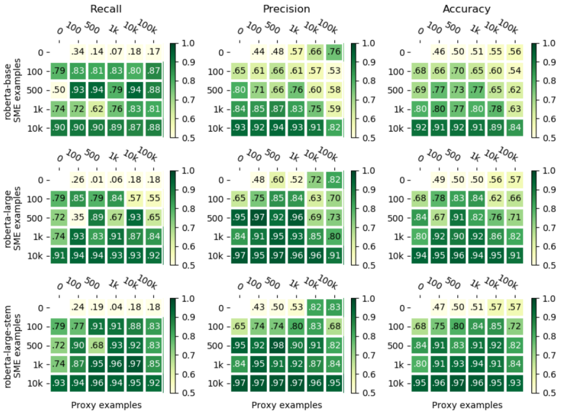

Figure 5: Detection performance when using physics proxy data.

A.4 Effect of paragraph length on detection performance

There is a higher percentage of short paragraphs in the body of scientific papers than there is among abstracts. We noticed this can lead to difficulties in detection, since detector performance deteriorates with shorter text lengths (Ippolito et al., 2020; Munir et al., 2021).

To investigate the effect of paragraph length on performance, we ranked the human paragraphs by their length in characters and binned them (200 per bin), in order to calculate the false positive rate within each bin. The false negative rates were calculated similarly using the generated paragraphs. These are shown in Figures 7 and 8. The false positive and false negative rates can be seen to increase substantially for paragraphs with less than 500 characters.

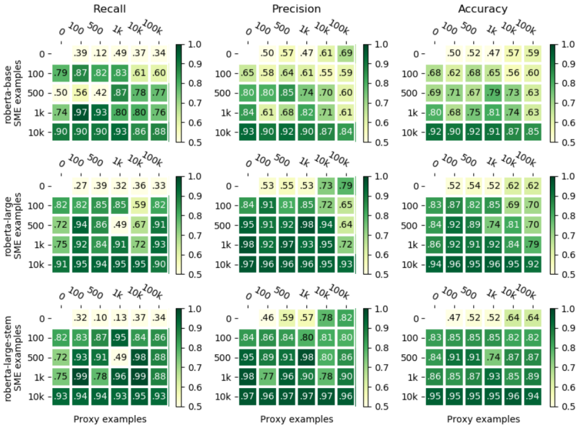

Figure 6: Detection performance when using biomedical and physics proxy data.

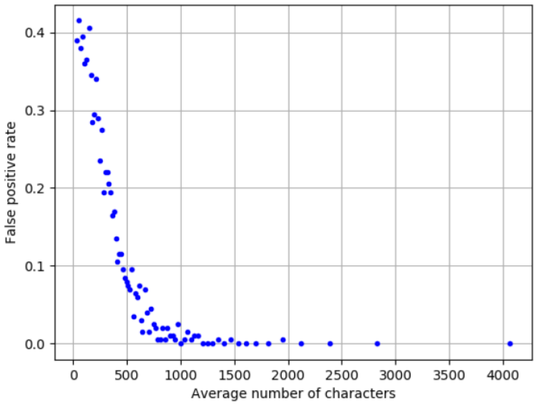

Figure 7: False positive rate as a function of paragraph length.

A.5 Effect of training on paragraphs generated without conditioning

Since it might be unrealistic to assume that both the adversary's (target) generator and the defender's (proxy) generator both generate text in the same way – by conditioning on the last 256 tokens of the previous paragraph – we verified that our results are not heavily dependent on this assumption by also testing detection performance using *unconditional* (i.e., unprompted) synthetic paragraphs as proxy training data.

Tables 5 and 9 show paragraph-level accuracy when training on conditioned and unconditioned proxy data, respectively. As expected (Tay et al., 2020), performance is higher when training with conditioned proxy generations than with unconditioned proxy generations if no SME samples are used (e.g., an increase in .10 in accuracy when using 10k proxy samples). This is mostly due to a large increase in recall (up to .21 for 10k proxy samples). However, a second round of task-tuning with

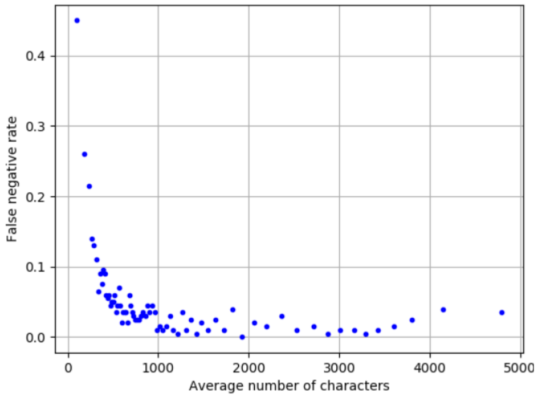

Figure 8: False negative rate as a function of paragraph length.

		Proxy samples				
		0	100	500	1k	10k
SME samples	0		.51	.73	.78	.83
	100	.77	.75	.83	.88	.93
	500	.85	.83	.89	.89	.94
	1k	.91	.92	.88	.92	.93
	10k	.96	.95	.96	.96	.96

Table 9: Accuracy when task-tuning RoBERTa-large on unconditioned proxy data, evaluated on a balanced subset of 1000 real and 1000 synthetic paragraphs.

SME samples helps close the gap between task-tuning with conditioned and unconditioned proxy samples. Indeed, 100 SME samples are enough to nearly close the gap (a difference of .02 in accuracy).

Table 10: Subjects, data providers, and fraction of (English-language) abstracts per subject in the STEM subset of CORE used to domain-tune RoBERTa-large-STEM. This subset contains 916,074 abstracts. The Biomedical portion (237,620 abstracts), and a subset of the Physics portion (237,620 abstracts) were used to domain-tune GPT-2 to generate physics and biomedical abstracts.

A.7 Examples of generated technical text

Tables 11 and 12 show examples of GPT-2-generated biomedical and physics abstracts. Table 13 shows two examples of tampered documents, where some of the paragraphs were replaced by GPT-2-generated paragraphs. Some of the (human-detectable) errors in the generated abstracts are given in Appendix §A.8.

Generated biomedical abstracts
Cognitive health remains a widely misunderstood area of dementia research. Findings from the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) continue to indicate that people with dementia have varying degrees of personality disorders, one of which is asocial functioning. Given that individuals with dementia frequently experience emotions and cognitions such as anger and blame, it is important to understand the factors that contribute to this range of dysfunctions in cognitive functions. To address this issue, we review current thinking regarding how people with dementia and their caregivers understand these issues. We describe the functional distinction between healthy and low-function functioning dementia, discuss the relationship between dementia and temperament, and suggest future directions for future research and development.
Finds from modern groundwater samples have helped to nail down the mineralogy of many deposits of accessible minerals in the Northwest Passage, including Baker Fountain, upper Boundary Haven, and Meishinmaru Harbor. Belying all this, however, have been the potential variability of minerals in this area that are often overlooked, especially the Mocharla Complex, which contains all of the elements of known elements within only 4% of metallic and rare earth elements. This latter figure equates us with other locations where magnetic isotope data for Magnesite would make it worth pursuing such as Pennsylvania, New Jersey, San Nac/3 molar ratio studies, and a hexagonal ratio study, to name but a few. In this paper we provide perspectives in mineralogy and mineralogy variation of the assemblages of alternatives to Magnesite in West Virginia; as well as the communities that should feel comfortable championing the developers of M&RK and should consider the opportunity for they shops eventually reuse Magnesite in sites near their site, regardless of the comings and goings in North America. The mineralogy presented in this book is quite different from the one presented by Nides-R7K who has published articles and spoken series on Magnetozone suto oravailable water conditions provide t he following: i) They are complementary. ii) Reproducer: George Shee, CSU North West, University of Kansas. Here we report an efficient assay to differentiate, precisely and quickly, human prostate cancer (PCa) cell lines from normal cells/prostatic tissue. In prostatic PCa from each patient, we measured CE kinase activation of 1,2-bromopentaneidin (BPP), calcitonin-3, bone morphogenetic protein-6, urokinase 21 and eukaryotic phospho-protein kinase-2 (EPSK-2). Cells from 2 patients and 1 patient with hepatitis C and provided at the same time were simultaneously PCR screened to detect chromosomal chromosomal aberrations and restriction fragment length polymorphism variations (RFLP). We found one viable Gdp from each patient. We did not detect chromosomal aberrations and standard regulators of EGS in PCa patients. Most likely, our results, also for grade II PCa, show that PCa cells have a passive chromosomal integrity with DNA repair genes, but this is not found in intact androgen-depleted patients. Inadequate DNA repair genes and excessive chromosomal aberrations, due to non-genomic proportions of UGT-3, EDS1, EGS2, URP-88 and UAR6 compared to their value combined, lower DNA repair products of 9.66%, and reduced cell ploidy.(ABSTRACT TRUNCATED AT 250 WORDS)
During age-dependent contractions, the forearm flexor isomerophilic is a loss of maximum strength of the abductor tendon, which influences flexor mode and resistance. At peak contraction strength, the level of higher order strength produced by the concentric contractions is higher than the lower order strength due to lower upper, lower, and lateral potentiometric torque respectively. Moreover, age affects the time interval over which the elastic torque of the tendon increases, which changes from several short to several long and gradual. The apparent loss of maximal strain strength of the tendon during WER occurs generally late in the range of resistance, but in rare cases of progressively superior mechanical strength, the contractile effects of the WER series from the same period may be preserved.

Table 11: Examples of abstracts generated by GPT-2 fine-tuned on biomedical text.

Generated physics abstracts
We construct a free Kac-Moody algebra in terms of SU(N) bi-holomorphic maps. Our construction is not exactly as in the standard program, which is based on the Kac-Moody algebra itself. In this work, we address the question whether a general construction can be made using a 3-dimensional space with its boundary fixed to be a manifold. For such a construction, one can quantize the free Kac-Moody algebra exactly using the interior data of a closed submanifold, an example of which is given.
A general classification of the massive scalar field model is presented. This model can be taken to be the simplest of all models exhibiting super-Kahler group structure. The very general model is then interpreted as a manifestation of the infinite supersymmetry of N=2 supersymmetric Yang-Mills theory with a simple Kaluza-Klein U(1) gauge group. This theory has an analog of Seiberg-Witten theory with a U(1) gauge group. The two models are related by the fact that the massive scalar field model reduces to the Seiberg-Witten model when the negative cosmological constant is eliminated.
We have simulated a sample of 60,000 galaxies in order to study the spatial structure of halos and the formation properties of their wind-driven columns. The galaxy models (average virial radius $R_c = 0.25kpc$, total column density $O_n u^{-1/2} = 1.2cm^{-3}$, total column density $K_0 = 0.3cm^{-3}$ and total column density $L_n u{-}2/3 = 0.5cm^{-3}$) were selected from a large database of spiral galaxy photometry. We have investigated the properties of the wind-driven column density as a function of the galaxy size, the radius and the column density in the inner Lyman limit. R_c and $L_n u$ are defined as the fraction of the total column density, $O_n u_2 - L_n u$, of gas in the central region of the galaxy, and $L_n u$ is defined as the fractional logarithm of the gas density. The simulations were carried out on a large 64x64 grid of 16x16 square degrees (3.6×3.6 square degrees) in order to obtain a large number of potential galaxies. The cross-correlation of the radial profile of the radial intensity distribution and the velocity distributions of gas streams shows that the velocity distribution is strongly wave-like, with the velocity dispersion $< 0.5kms^{-1}$; the power law of the dispersion is also found. We also find that the density of gas passes through a strong exponential regime at the center, and that the central density exceeds that at the periphery by 2 solar masses per degree of freedom.
We propose a new solution to the cosmic censorship problem. It is based on the idea that all physical experiments have to be canceled at the same time, with a specific choice of the data. In this approach the data would be separated from the source region by a detector, whose response is controlled by the Planck energy. The data would be split into beams of different energies. The different beams, and their response to each other, would be synchronized in a second detector, which would then (miraculously) detect photons from the source region and carry out the corresponding measurements in the detector. In this way the cosmic censorship problem can be reduced to a second problem: how to determine the signal and the background in the detector. We give an explicit example for the case of neutrino astronomy, and show that we can solve the cosmic censorship problem without any special choice of the signals of the detectors.
We study two-dimensional XY spin models in the two-dimensional triangular lattice using the "dynamical" renormalization group method. For the first time, we study the ground-state phase diagram of the ground-state XY Heisenberg spin chain with non-zero exchange coupling. We perform a thorough analysis of the chemical potentials and the thermodynamic properties of the ground state. We find that the thermodynamic limit of the XY model exhibits a mean-field phase diagram characterized by a disordered phase, a first-order phase transition, and a thermal phase. Our calculation illustrates the rigorous approach to demonstrate the zero temperature properties of the XY model.Comment: 12 pages, 6 figure.
The KKP equation is an n-component Green function (GFF) Hamiltonian system. The KKP equation is known to be a Lie algebra in the sense that it is a subalgebra of the $SO(n)$ algebra $SO(n)_1$. In this paper we construct the n-component GS theory with a Gaussian Hamiltonian H and a $(1, 1)$ trace-free action. We show that in this system the excitation spectrum of the n-component GS system is the same as in the sine-Gordon system except for the fact that the excitation spectrum in the KKP system is product of the spectrum in the sine-Gordon and in the KKP system. We derive the n-component GS equation using the KKP equation in the dilute state, and show that the solution of the KKP equation in a dilute state is equivalent to the solution in the sine-Gordon system. This equivalence holds, in particular, when the KKP equation is interpreted as an $SL(2, R)$ system in terms of the second harmonic operator. We further show that this equivalence holds also for n-component GS systems with spin two and spin zero. We also derive the KKP equation for the quantum spin chain with n-component GS components, which has a non linear sine-Gordon Hamiltonian and a periodic potential.

Table 12: Examples of abstracts generated by GPT-2 fine-tuned on physics text.

Tampered excerpt from Cooper et al. "Effect of dietary sodium reduction on red blood cell sodium concentration and sodium-lithium countertransport." Hypertension 6.5 (1984): 731-735.

Two food lines were created in the cafeteria, and a record was maintained of each meal. For Group 2, food items high in sodium were eliminated, and reduced sodium products were substituted when possible, as in the case of cheese, peanut butter, and margarine. Study nutritionists worked closely with the cafeteria staff to structure an experimental diet that was moderately reduced in sodium relative to the regular diet, yet similar in other respects. The only regular source of food for the participants was the school cafeteria. Participants were recruited on the basis of an agreement not to receive packages from home or eat meals away from school during the 24-day experimental period. A record was kept of attendance at meals. Acceptance of the experimental diet was good. As noted, only one participant withdrew based on unwillingness to adhere to the dietary regimen.

For the study, subjects were offered a control diet consisting of potatoes, beans, noodles, bar snacks, cold cereal, sweetened sodas, milk, cookies, fruit (numerous fruits, yogurt, frozen yogurt), and instant soup. In total, the diet contained 2.1 servings of meat and 10.5 servings poultry and eggs per week.

The first phase of the study lasted 24 days, with an intervening 5-day vacation, followed by a crossover of 24 days. On Days 1 and 24 of Phase I and Day 24 of Phase II, participants underwent a standard examination. Height and weight were measured in light indoor clothes, with shoes off. Blood pressure was measured after a 15-minute rest by a procedure previously described , 9 and a 15 cc sample of blood was subsequently withdrawn with minimal hemostasis from the antecubital fossa. All examinations took place between 600 and 800. Blood was transported to the laboratory within 1 hour. The batch was divided in half, and an equal number of specimens was taken from each group and analyzed either immediately or placed in storage for analysis in 48 hours.

Tampered excerpt from Khandelia et al. "Triglyceride blisters in lipid bilayers: implications for lipid droplet biogenesis and the mobile lipid signal in cancer cell membranes." PLoS ONE 5.9 (2010): e12811.

In this report, we investigate the biophysics of model membranes containing low concentrations of triglyceride molecules.

Reduced incorporation of glycosylated proteins in these membranes has been reported in vivo [26] [27] and in vitro [28] as well as in our analysis of a high salt environment [29, 30]. The reduced distribution of protein is known to reflect a decreased total availability of available constituents for substrate binding. To address this issue, the surface structure of membrane-bound proteins is studied by a combination of an energy map [31] of the full (hexagonal) and unbound (quadratic) parts of each subunit, in which the diagonal portion of this subcomplex is spatially preferentially constrained. Averaged over time, this energy mapping demonstrates a reduced physical overlap between parts that are on average loosely bound, indicating that these subunits are almost always pulled together. The contrast between the unbinding observed in soluble polymeric membranes and these highly mobile proteins suggests that the monolayer of such membranes is unable to adequately differentiate between component atoms. We find that such a system exhibits a similar geometry as a "live" membrane by which particular proteins can separate into regions of homogeneous bulk or in features termed proteasomal environments. These are structures that don't have the same means of reducing the total loading of smaller proteins that create surface areas for binding, allowing them to serve as attractive targets for degradation. Indeed, although unconformity to this model may influence membrane biophysical properties, reducing this structure should increase the translational and kinetic properties of proteins found on the cell surface [5].

Besides lipoproteins and LDs, TGLs are also present in several biological membranes at varying concentrations. The lamellar bodies of lung surfactant extracts in mammals can contain between 0.5% to 1.8% w/w TGLs [6, 7] . Ocular lens lipids contain small amounts (mg TGLs/mg phospholipids) of TGLs. TGLs are also present in intestinal membrane extracts [8] . Lysosomes contain non-negligible amounts of TGLs, for example, in cultured hamster fibroblasts [9] . In rat hepatocytes, lysosomes contain nearly 3.7% TGLs [10] . Many proliferating or activated mammalian cells in particular, have a high concentration of TGLs in membranes. Cancer cells contain as high as 6.8% TGL fraction of total plasma membrane lipids [11] . Several malignant Chinese hamster ovary (CHO) cell lines contain 2.4-3.2% TGLs in their plasma membranes [12] . Human neutrophils contain as high as 5.2% and 6.8% TGLs in their plasma membranes before and after stimulation with lipopolysaccharides [13] . Activated macrophages [14] , lymphocytes [15] and B cells [16] also contain high amounts of TGLs in their plasma membranes. In this report, we investigate the effect of low concentrations of TGLs, as found in a variety of cell types noted above, on the structure and dynamics of model membranes, with the objective of ultimately obtaining hints into the possible structural and functional role of TGLs in the plasma membrane of living systems. We have used triolein (TO) as our model TGL, and 1-Palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine (POPC) as the model phospholipid.

We developed three models of the free lipoprotein fraction within the monolayer membrane: (1) a free TGN that mediates the GP diffusion chain; (2) conjugated to free human T2PP and T3PP of all lymphocyte types to subsequently allow uptake of lipospheres and membranes; and (3) cytochalasin C (CXCL) immunoprecipitation experiments were performed on media from mice treated with TgIII.

Table 13: Two excerpts from tampered biomedical documents. Each blue (bolded) text is generated by conditioning on the preceding human-written paragraph.

A.8 Human-detected errors in generated biomedical abstracts

The following are a list of errors we found in a subset of 75 synthetic biomedical abstracts generated by GPT-2. A similar, larger list of annotations of error types found in GPT-2 and GPT-3 generated text was recently provided by (Dou et al., 2021).

Not a real word The following words caused the annotator to mark the abstract as computer-generated:

- ‘ProBNER’
- ‘Chaos-Tector Chargor’
- ‘fibre preveller’
- ‘gravidum’
- ‘di-nitro-L-arginine’
- ‘Cd-FPOs’
- ‘halliopeusing’

Incorrect acronym The following were acronym-related errors:

- ‘left middle cerebral artery (LMCMA)’
- ‘occlusion (MOOC)’
- ‘In Situ Analysis (SIA)’
- ‘semantic energy transport (STM)’
- ‘cross-questionnaires (CCQs)’
- ‘Noisy Distributed Execution (NDE)’ [acronym introduced but never used again]

Coherence problem

- ‘First, a proper description of Big Memory is required; In previous studies, it was stated that Stochastic Roughness is a Fundamentality for Big Memory.’
- ‘The scheme is based on the framework called as a density functional, proportional basis’ [has nothing to do with rest of abstract]
- ‘nanofacial’ [unrelated to rest of abstract]
- ‘CONCLUSIONS From a therapeutic point of view, this multispectral imaging method allowed to measure all ultrasound values simultaneously and easily. Further studies with practical applications in pediatric emergency medicine could reveal specific features of various brain injury in this way.’ [unrelated to rest of abstract]
- ‘Parents and doctors share more in common than many researchers expect. What is available for use?’

Knowledge error: entity does not exist

- ‘Nevographic Origin of Caustic Cygnosis’
- ‘R402D nuclear phytoarray’
- ‘the Sargento regime’
- ‘SEPA insertion rule’
- ‘4-OHDA’ [does not exist; but 6-OHDA does]
- ‘The Europir position’

Knowledge error: other

- ‘nonlinear RC receiver in a hydraulic grade’ [strange combination of electrical and fluid mechanics terms]
- ‘inflammation-related molecules staphylococcus aureus’ [Not a molecule]
- ‘the city of san real’ [not a city]
- ‘The State of Barack Obama’ [not a state]
- ‘premature diagnosis of asthma is significantly associated with overweight’
- ‘Vaccine coverage is at such high levels in the United States that without additional initiatives, an epidemic likely will emerge within four years.’
- ‘Trespassing into a host’s natural area can confer adverse impacts such as diseases, extra costs, unexpected complications, disadvantages and adverse property rights’ [unrealistic list]

Contradictory or illogical

- ‘Sixty-six occlusions were identified in the 60 eyes for occlusions, 31 of these (90%) occurred in abscesses while the rest were non-occidental.’
- ‘Six groups of 75 children were examined by means of retrospective analysis. The first group consisted of 66 children, who received care in the neonatal intensive care unit from 29 January 1971 to 24 June 1972. The second group, consisting of 166 children,’
- ‘in patients aged over 65 y of gender between 52.7 years and 70.2 years’
- ‘three inference rules:’ [only two rules listed]
- ‘can be partially fully filled’

Odd grammar

- ‘Participants’ means of outcome’
- ‘To compare different gastrointestinal tumors patients undergo for the intrauterine difficult caesarean section’
- ‘High temperature polymer is potential display material, especially in film industry’ [missing determiners]
- ‘Therefore, new color model for high temperature polymer is proposed. This paper introduces carbon disulfide systems and their design. Simple model is found. We used the uncertainty principle to overcome this uncertainty. The scheme is based on the framework called as a density functional, proportional basis.’ ["as a" should be "a"; also missing some determiners]
- ‘associated with overweight.’ [adjective needs a noun]

Strange adjective

- ‘Voo-like Gene’
- ‘non-dominant rodent’
- ‘cat-like crystals’
- ‘air-exposed mice’
- ‘semantic energy transport’
- ‘intervertebral sedimentation’
- ‘double plasma-associated disease’

Repetition

- ‘our algorithm usually yields evidence of a weak algorithm’
- ‘Negotiation and negotiation’
- ‘specialty medical specialty’
- ‘discriminant discriminative’
- ‘STM based STM system’
- ‘processions, and subsequent processesions.’
- ‘The two leading theories suggest that the incidence is an early event after acute expansion of spleen parenchyma, involving the clotting/permeability clique. In this article, we propose a new hypothesis: the incidence of double plasma-associated disease is an early event.’
- ‘Interfaces and interfaces’
- ‘where each property represents a property’
- ‘all the vector representations (or all of them)’
- ‘in making decision-decisions. Results from data from data’
- ‘during the growth phase and during the growth phase,’

Semantically odd/sounds weird

- ‘the aortic roots of rats’
- ‘first-trimester of illness’
- ‘Keeping the word has become an argument against any pretense of better strategy’
- ‘Metabolic health refers to the state of health associated with the metabolism of a given substance or disease, not necessarily a testicular aspect of normal physical functioning’
- ‘mothers share more than once with a physician, parent or relative’
- ‘have not clarified the communication of the ultrasound wave motion to the patient’
- ‘there are several non-invasive and sometimes invasive systems which would benefit from the use of these systems to an unlimited extent’
- ‘reduce productivity and results of the US National Health Interview Survey’
- ‘We used the uncertainty principle to overcome this uncertainty’
- ‘The rate of change in hourly body temperature was recorded in the eyes of dogs’
- ‘Monotreme rhythms in internal and external body temperature’

DISAPERE: A Dataset for Discourse Structure in Peer Review Discussions

Abstract

At the foundation of scientific evaluation is the labor-intensive process of peer review. This critical task requires participants to consume vast amounts of highly technical text. Prior work has annotated different aspects of review argumentation, but discourse relations between reviews and rebuttals have yet to be examined.

We present DISAPERE, a labeled dataset of 20k sentences contained in 506 review-rebuttal pairs in English, annotated by experts. DISAPERE synthesizes label sets from prior work and extends them to include fine-grained annotation of the rebuttal sentences, characterizing their context in the review and the authors' stance towards review arguments. Further, we annotate *every* review and rebuttal sentence.

We show that discourse cues from rebuttals can shed light on the quality and interpretation of reviews. Further, an understanding of the argumentative strategies employed by the reviewers and authors provides useful signal for area chairs and other decision makers.

1 Introduction

Peer review performs the essential role of quality control in the dissemination of scientific knowledge. The recent rapid increase in academic output places an immense burden on decision makers such as area chairs and editors, as their decisions must take into account not only extensive manuscripts, but enormous additional amounts of technical text including reviews, rebuttals, and other discussions.

One long term goal of research in peer review is to support decision makers in managing their workload by providing tools to help them efficiently absorb the discussions they must read. While machine learning should not be used to produce condensed accounts of the peer review text due to the risk of amplifying biases (Zhao et al., 2017), ML tools could nevertheless help manage information overload by identifying patterns in the data, such as argumentative strategies, goals, and intentions.

Any such research requires an extensive labeled dataset. While the OpenReview platform (Soergel et al., 2013) has made it easy to obtain unlabeled public peer review text, labeling this data for supervised NLP requires highly qualified annotators. Correct interpretation of the discourse structure of the text requires an understanding of the technical content, precluding the use of standard crowdsourcing techniques. Prior work on discourse in peer review has focused this qualified labor force on labeling arguments extracted from the text, which enables the complete annotation of more examples, at the expense of research on non-argumentative behaviors in peer review. While there has been extensive research and deep analysis of different aspects of peer review, the taxonomies used to describe review argumentation are disparate and not directly compatible. Finally, there has been limited research into understanding the discourse relations between rebuttals and reviews (Cheng et al., 2020; Bao et al., 2021), and none so far into the discourse structure of rebuttals.

This paper presents **DISAPERE** (**DI**scourse **S**tructure in **A**cademic **PE**er **RE**view), a dataset focusing on the interaction between reviewer and author[1]. We give reviews and rebuttals equal importance, and emphasize the relations between them. To enable the study of behaviors beyond the core arguments, we also annotate every sentence of both the review and rebuttal, and provide fine-grained labels for non-argumentative types. We annotate at the sentence level not only for completeness but also to avoid the propagation of errors from argument detection. We annotate four properties (REVIEW-ACTION, FINE-REVIEW-ACTION, ASPECT, POLARITY) of each review sentence, where the set of properties and their values were developed by synthesizing taxonomies from

---

Figure 1: A depiction of our annotation scheme on a minimal, fictional review-rebuttal pair. A: REVIEW-ACTION , including Structuring, Request, Evaluation; B: FINE-REVIEW-ACTION , fine-grained categorization of Structuring and Request sentences; C: ASPECT , indicating the qualities of the manuscript being commented upon D: POLARITY indicating whether these comments are positive or negative in nature. E: Each sentence in the rebuttal is mapped to zero or more sentences in the review, which constitute its context. This is a many-to-many relation. F: The sentences in the rebuttal are labeled with domain-specific discourse acts (REBUTTAL-ACTION); each discourse act may be categorized according to whether it concurs with (✓) or disputes (×) the premise of the context it is responding to.

prior work. We also annotate each sentence of a rebuttal with a fine-grained label indicating the author's intentions and commitment, and a link to the set of review sentences that form its context. Figure 1 shows the DISAPERE annotation scheme on a minimal, fictional example review-rebuttal pair.

DISAPERE is intended as a comprehensive and high-quality test collection, along with training data to fine-tune models. Our annotations are carried out by graduate students in computer science who have undergone training and calibration, amounting to over 850 person-hours of annotation work. Much of the test data is double-annotated, and we report inter-annotator agreement on all aspects of the annotation. We describe the performance of state of the art models on the tasks of predicting labels and contexts, showing that interesting ambiguities in the data provide the NLP community with research challenges. We also show an example that demonstrates how decision makers could use models like these to understand trends and inform policies for future conferences (§ 5).

The contributions of this paper are as follows: (1) a new labeled training dataset of 506 review-rebuttal pairs (over 20k sentences) of peer review discussion text in English, where review sentences are annotated with four properties, and rebuttal sentences are annotated with context and labels from a novel scheme to describe discourse structure; (2) a taxonomy of discourse labels synthesizing prior work on discourse in peer review and extending it to add useful subcategories; (3) a summary of the performance of baseline models on the dataset (§ 6); (4) examples of analyses on the dataset that could benefit peer review decision makers (§§ 4 and 5), and (5) extensive annotation guidelines and software to support future labeling efforts.

2 Related work

The design of this dataset draws upon extensive, but disparate prior work on this topic. Many works, some addressed below, have taken advantage of the availability of review text hosted on OpenReview.

Argument-level review labeling Prior work has developed label sets that address different phenomena. Hua et al. (2019) introduced the study of discourse structure in peer review by annotating argumentative propositions in the AMPERE dataset with a set of labels tailored to the peer review domain (EVALUATION, REQUEST, FACT, REFERENCE, and QUOTE). Similarly, Fromm et al. (2020)'s AMSR dataset frames the problem as an argumentation process, in which the stance of each argument towards the paper's acceptance or rejection is of paramount importance. Both view peer review as argumentation, using argument mining techniques to highlight spans of interest.

While its goal is not to examine discourse structure per se, Yuan et al. (2021) uses polarity labels to indicate each argument's support or attack of the authors' bid for acceptance. Besides polarity, these examples follow Chakraborty et al. (2020) by annotating each argument with the *aspect* of the paper it comments on.[2] In contrast to Yuan et al. (2021), we do not attempt or recommend generat-

---

[2] Aspects are based on the ACL 2018 rubric.

ing peer review text, instead focusing on *analyzing* human-generated text in peer review.

Review-rebuttal interactions We also expand on work by Cheng et al. (2020), who first annotated discourse relations between sentences in reviews and rebuttals. While Cheng et al. (2020, 2021) present new deep learning architectures, in this paper we focus on the creation and comprehensive annotation of a new dataset, illustrated with results from some less specialized baseline models.

Other research into rebuttals includes Gao et al. (2019). Besides their main finding that reviewers rarely change their rating in response to rebuttals, they find that more specific, convincing and explicit responses are more likely to elicit a score change. Observations from this paper are formalized into rebuttal action labels in DISAPERE.

Comparison of datasets In DISAPERE we attempted to unify these schemas to form a single hierarchical schema for review discourse structure. We then expanded this hierarchical schema to introduce fine-grained classes for implicit and explicit requests made by the reviewers. The details of the correspondence between DISAPERE labels and those from prior work are summarized in Appendix A. In contrast to prior work, DISAPERE labels discourse phenomena at the sentence level rather than the argument level. This enables more thorough coverage of the text while avoiding the propagation of errors from machine learning models earlier in the annotation pipeline. While using manually defined discourse units (above or below the sentence level) may more precisely capture some discourse information, a separate pass of discourse segmentation can hinder the use of discourse datasets, as achieving consistent and replicable annotation of argument units is known to be highly challenging (Trautmann et al., 2020), and also because few works actually tackle unit segmentation (Ajjour et al., 2017).

3 Dataset

Each example in DISAPERE consists of a pair of texts: a review and a rebuttal. Labels for reviews and rebuttal sentences are described below. Review sentence labels are summarized in Table 2, and rebuttal sentence labels in Table 3.

	Dataset	AMPERE	AMSR	ASAP-Review	APE	**DISAPERE**
	# examples	400	77	1k	4.7k	506
	# labels	10k	1.4k	5.7k	130k	46k
Review	Arg. stmts.	✓	✓		✓	✓
	Arg. types	✓				✓
	Polarity		✓	✓		✓
	Aspect			✓		✓
	Non-arg.					✓
	All sents.					✓
Rebuttal	Included?				✓	✓
	Arg. stmts.				✓	✓
	Context				✓	✓
	Arg. types					✓
	Non-arg.					✓
	All sents.					✓

Table 1: Comparison between our dataset and prior work: AMPERE (Hua et al., 2019), AMSR (Fromm et al., 2020), ASAP-Review (Yuan et al., 2021), APE (Cheng et al., 2020). *Arg.stmts.*: Are argumentative statements highlighted?; *Arg. types*: Are subtypes of argumentative statements labeled?; *Non-arg*: Are non-argumentative statements labeled?; *All sents.*: Are labels provided for all sentences?; *Context*: Are rebuttal texts' contexts in the review provided? DISAPERE is the only work to annotate every sentence in the review and rebuttal, and the only work that applies discourse labels to the author's actions in the rebuttal.

3.1 Review sentence labels

3.1.1 Review actions

REVIEW-ACTION annotations characterize a sentence's intended function in the review. Annotators label each sentence with one of six coarse-grained sentence types including *evaluative* and *fact* sentences, *request* sentences (including questions, which are requests for information), as well as non-argument types: *social*, and *structuring* for organization of the text.

3.1.2 Fine-grained review actions

We also extend two of these review actions with subtypes: *structuring* sentences include headers, quotations, or summarization sentences, and *request* sentences are subdivided by the nature of the request, distinguishing between clarification of factual information, requests for new experiments,

Category		Label	Description	Percentage
REVIEW-ACTION		Evaluative	A subjective judgement of an aspect of the paper	32.83%
		Structuring	Text used to organize an argument	27.70%
		Request	A request for information or change in regards to the paper	19.82%
		Fact	An objective truth, typically used to support a claim	8.55%
		Social	Non-substantive text typically governed by social conventions	1.41%
		Other	All other sentences	9.71%
ASPECT		Substance	Are there substantial experiments and/or detailed analyses?	17.09%
		Clarity	Is the paper clear, well-written and well-structured?	11.08%
		Soundness/Correctness	Is the approach sound? Are the claims supported?	9.58%
		Originality	Are there new topics, technique, methodology, or insights?	3.85%
		Motivation/Impact	Does the paper address an important problem?	3.69%
		Meaningful Comparison	Are the comparisons to prior work sufficient and fair?	3.15%
		Replicability	Is it easy to reproduce and verify the correctness of the results?	2.86%
POLARITY		Negative	Negatively describes an aspect of the paper (reason to reject)	29.43%
		Positive	Positively describes an aspect of the paper (reason to accept)	11.16%
FINE-REVIEW-ACTION	Struct.	Summary	Reviewer's summary of the manuscript	18.17%
		Heading	Text used to organize sections of the review	8.54%
		Quote	A quote from the manuscript text	1.00%
	Request	Explanation	Request to explain scientific choices (question)	5.50%
		Experiment	Request for additional experiments or results	4.78%
		Edit	Request to edit the text in the manuscript	4.14%
		Clarification	Request to clarify the meaning of some text (question)	2.80%
		Typo	Request to fix a typo in the manuscript	1.98%

Table 2: A list of the review sentence labels, their descriptions, and the percentage of review sentences they apply to. Labels from all categories besides REVIEW-ACTION are optional, and thus may not add up to 100%.

requests for an explanation (e.g. of motivations or claims), requests for edits, and identification of minor typos.

3.1.3 Aspect and polarity

ASPECT annotations follow the ACL review form (Chakraborty et al., 2020; Yuan et al., 2021). These distinguish *clarity*, *originality*, *soundness/correctness*, *replicability*, *substance*, *impact/motivation*, and *meaningful comparison*. Following Yuan et al. (2021), arguments with an ASPECT are also annotated for POLARITY. We label *positive* and *negative* polarities. ASPECT and POLARITY are applied to sentences whose REVIEW-ACTION value is *evaluative* or *request*.

3.2 Rebuttal sentence labels

We annotate two properties of each rebuttal sentence: a REBUTTAL-ACTION label characterizing its intent, and its CONTEXT in the review in the form of a subset of review sentences.

3.2.1 Rebuttal actions

The 14 rebuttal actions (Table 3) are divided into three REBUTTAL-STANCE categories (*concur*, *dispute*, *non-arg*) based on the author's stance towards the reviewer's comments.

(1) *concur*: The author concurs with the premise of the context. This includes answering a question or discussing a requested change that has been made to the manuscript, conceding a criticism in an evaluative sentence. (2) *dispute*: The author disputes the premise of the context. The rebuttal sentence may reject a criticism or request, disagree with an underlying fact or assertion, or mitigate criticism (accepting a criticism while, e.g., arguing it to be offset by other properties). (3) *non-arg*: Encompasses rebuttal actions including *social* actions (such as thanking reviewers), and *structuring* labels, for sentences that organize the review.

Responses to *request*s are further annotated: if the author *concur*s, we record whether the task has been completed by the time of the rebuttal, or promised by the camera ready deadline; if the author *dispute*s, we record whether the task was deemed to be out of scope for the manuscript.

3.2.2 Rebuttal context

We refer to the set of sentences which a rebuttal sentence is responding to as the *context* of that

Category		Label	Description	Reply to	Percentage
Argumentative	Concur	Answer	Answer a question	Request	32.76%
		Task has been done	Claim that a requested task has been completed	Request	8.58%
		Concede criticism	Concede the validity of a negative eval. statement	Evaluative	2.70%
		Task will be done	Promise a change by camera ready deadline	Request	2.01%
		Accept for future work	Express approval for a suggestion, but for future work	Request	1.30%
		Accept praise	Thank reviewer for positive statements	Evaluative	0.35%
	Dispute	Reject criticism	Reject the validity of a negative eval. statement	Evaluative	10.37%
		Mitigate criticism	Mitigate the importance of a negative eval. statement	Evaluative	2.43%
		Reject request	Reject a request from a reviewer	Request	1.16%
		Refute question	Reject the validity of a question	Request	0.95%
		Contradict assertion	Contradict a statement presented as a fact	Fact	0.86%
Non-arg		Structuring	Text used to organize sections of the review	-	17.82%
		Summary	Summary of the rebuttal text	-	7.94%
		Social	Non-substantive social text	-	6.71%
		Followup question	Clarification question addressed to the reviewer	-	0.32%
		Other	All other sentences	-	3.75%

Table 3: A list of the rebuttal sentence labels, their descriptions, and the percentage of rebuttal sentences they apply to. The "Reply to" column shows the REVIEW-ACTION types that a particular rebuttal type would canonically reply to. Each rebuttal sentence has exactly one REBUTTAL-ACTION label, so these percentages add up to 100%.

sentence, with special labels for when referring to the entire review (*global context*) or the empty set (*no context*). By not mandating a fixed discourse chunking, these annotations may handle situations when some rebuttal sentences respond to large sections of text, and other rebuttal sentences respond to specific sentences within those sections.

	Train	Dev	Test
Num. review-rebuttal pairs	251	88	167
Num. manuscripts	94	37	57
Num. adjudicated pairs	0	0	65
Num. review sentences	5216	1484	3246
Num. rebuttal sentences	5805	2015	3283
Num. review tokens	112k	33k	70k
Num. rebuttal tokens	131k	44k	75k

Table 4: Statistics for the dataset. Where possible, multiple reviews for the same manuscript were annotated. All reviews for any particular manuscript fall within the same train/dev/test split. Adjudicated pairs are those that were annotated by multiple annotators, and had disagreements resolved by an experienced annotator. All test set pairs are double-annotated. While the original sentence boundaries were maintained, tokenization within sentences was carried out using Stanza(Qi et al., 2020).

3.3 Data Source and Annotation

DISAPERE uses English text from scientific discussions on OpenReview (Soergel et al., 2013), which makes peer review reports available for research purposes. We draw review-rebuttal pairs from the International Conference on Learning Representations (ICLR) in 2019 and 2020, resulting in text within the domain of machine learning research. Review-rebuttal pairs are split into train, development and test sets in a 3:1:2 ratio such that all texts associated with any manuscript occur in the same subset. Overall statistics for the dataset are summarized in Table 4.

Authors are able to respond to each ICLR review by adding a comment. Although rebuttals are not formally named, we consider direct replies by the author to the initial review comment to constitute a rebuttal. While multi-turn interactions are possible, we focus on reviews and initial responses, and leave study of extended discussion for future work. The text is separated into sentences using the spaCy (Honnibal and Montani, 2017) sentence separator.

Annotation was accomplished with a custom annotation tool designed for this task, which is available as part of the code release accompanying DISAPERE. The tool is described in detail in Appendix B. Annotators annotate each sentence of a review, then examine the rebuttal sentences in order, selecting sets of review sentences to form their context. While this linking between sentences does not explicitly align multi-sentence chunks as in pipelined approaches to discourse alignment (Cheng et al., 2020), we note that since multiple sentences may be aligned to the same set of sentences in the review, some discourse structure is nevertheless latently implied.

3.4 Agreement

We report Cohen's κ (Cohen, 1960) on the IAA of labeling both review and rebuttals, treating each sentence as a labeling unit (Table 5). The annotators for each example are selected randomly from the pool of 10 annotators. Cohen's κ is calculated for sentences annotated at least twice. Where more than two annotations were produced, we calculate κ between all pairs and normalize by the number of possible pairs. The results show between moderate and substantial chance-corrected agreement between annotators, for both REBUTTAL-ACTION and REBUTTAL-STANCE labels (Appendix D provides details about agreement on context sentences). While these IAA scores do illustrate the noise of the task, note that this is not highly unusual for discourse labeling tasks – e.g. Habernal and Gurevych (2017) and Miller et al. (2019) both report α_u between 0.4 and 0.5.

Label	Cohen's κ
REVIEW-ACTION	0.605
FINE-REVIEW-ACTION	0.583
ASPECT	0.447
POLARITY	0.561
REBUTTAL-STANCE	0.513
REBUTTAL-ACTION	0.479

Table 5: IAA for review labels (top) and rebuttals (bottom), scored on double annotation. IAA is reported on 65 double-annotated examples, all of which fall in the test set of DISAPERE.

4 Analysis

4.1 Context types

We separate the different types of rebuttal contexts in terms of the number and relative position of selected review sentences in Table 6, along with the four cases in which the context cannot be described as a subset of review sentences. Notably, 84.81% of sentences are linked to some review context. A small number of sentences refer to other sentences within the rebuttal, rather than any review context, posing a challenge for future work.

	Context type	Rebuttal sents. (Num.)	Rebuttal sents. (%)
Sents. selected	Multiple contiguous	4696	42.29%
	Single sentence	4313	38.85%
	Mult. non-contiguous	407	3.67%
No sents. selected	Global context	816	7.35%
	Context in rebuttal	647	5.83%
	No context	152	1.37%
	Context error	61	0.55%
	Cannot be determined	11	0.10%

Table 6: Different types of rebuttal sentence contexts. Top: Over 84% of sentences are linked to a subset of sentences in the review. Bottom: sentences not linked to any particular subset of review sentences.

4.2 Alignment

One might reasonably hypothesize that the task of alignment between rebuttal and review sentences would be trivial, since authors are likely to respond to each point in the review in order. We can show that this is not the case. In Figure 2, we calculate Spearman's ρ between rebuttal sentence indices and their aligned review sentence indices. Rebuttals responding to each point in order would achieve $\rho = 1.0$; this case is rare. Many examples with positive $\rho < 1.0$ indicate that authors do respond to points approximately in order, but a simple mapping based on order alone would not capture the correct alignment. Thus, while linear inductive bias may be beneficial to alignment models, the task of determining rebuttal sentences' contexts is not trivial.

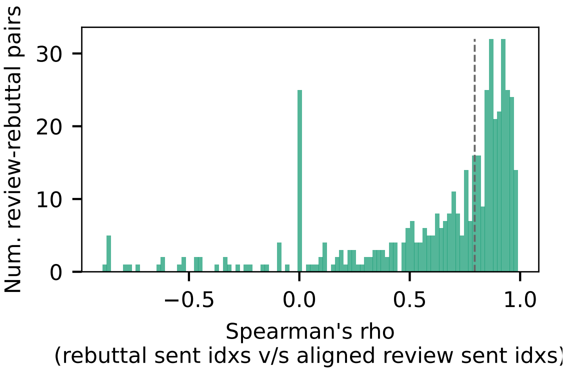

Figure 2: Spearman's ρ between rebuttal sentence indices and aligned review sentence indices. The dashed line indicates the median ρ value, which falls at 0.794.

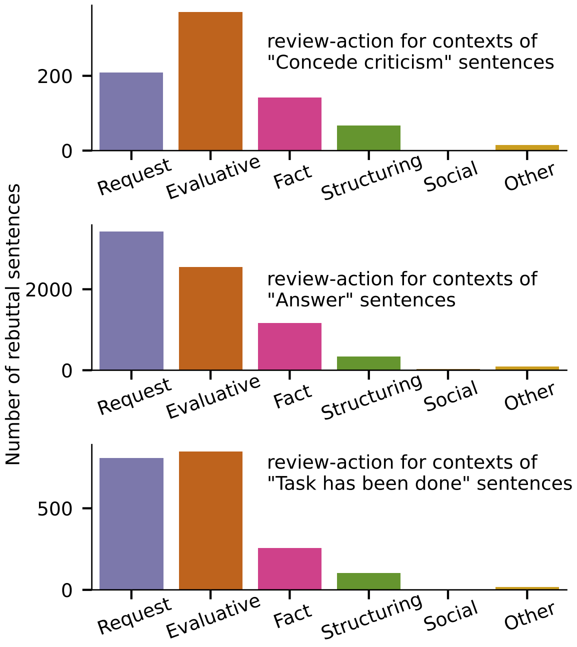

Figure 3: Distribution over REVIEW-ACTION for the context sentences of three REBUTTAL-ACTIONs. The canonical REVIEW-ACTION is marked by cross hatching. Note that authors sometimes interpret requests as criticisms ("Concede criticism"); often respond to evaluative sentences as if they are questions ("Answer"), and sometimes treat criticisms in the form of evaluative sentences as requests which they then carry out. ("Task has been done")

4.3 Author interpretations of criticism

In our taxonomy, each argumentative REBUTTAL-ACTION corresponds to a particular REVIEW-ACTION, which we refer to as its *canonical* REVIEW-ACTION (listed in 'Reply to' column of Table 3). For example, *answers* are generally responses to *requests*, while *conceding criticism* is usually a response to an *evaluative* statement. Annotations revealed that authors often interpreted review sentences as if they embodied REVIEW-ACTIONs besides the canonical one, in a way that furthered the author's argumentative goal. For example, authors often responded to *evaluative* statements as if they were *requests*, perhaps in order to appease a reviewer, although no action was explicitly requested. Figure 3 shows the distribution of contexts for three different REBUTTAL-ACTIONs.

4.4 Relating discourse features to rating

Figure 4 shows one possible analysis taking into account the rating of the review. We show the distribution of FINE-REVIEW-ACTION labels of *requests* with review ratings. It appears that high-scoring manuscripts are rarely asked to add experiments, and are polished enough to not elicit requests to fix typos. Interestingly, low-scoring manuscripts have the second-lowest occurrence of typo requests, which could be due to the preponderance of other requests, but this bears further examination.

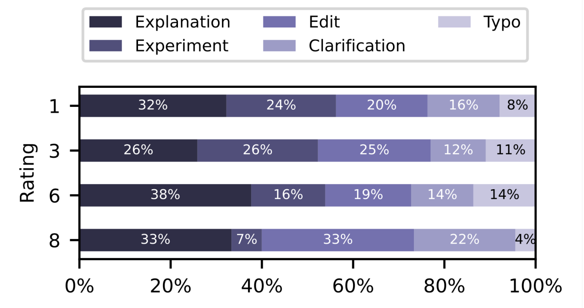

Figure 4: Distribution of REVIEW-ACTION labels, separated by rating

5 Application: Agreeability

Gao et al. (2019) showed that reviewers do not appear to act upon the rebuttals responding their reviews. It is possible that this is due to paucity of time on the reviewers' part. It is also common practice for area chairs to use review variance across a manuscript's reviews as a practical heuristic to decide which manuscripts need their attention. We propose that discourse information such as that described by DISAPERE can be used to provide heuristics that are data-driven, yet interpretable, and leverage information from the content of reviews rather than just numerical scores, resulting in better decision making.

One such measure is *agreeability*, which we define as the ratio of CONCUR sentences to argumentative sentences in a rebuttal, i.e.: $agreeability = \frac{n_{concur}}{n_{concur}+n_{dispute}}$. We argue that low agreeability can indicate problematic reviews even in cases where the variance in scores does not reveal an issue, as illustrated in Figure 5. Agreeability is only weakly correlated with rating, with Pearson's $r = 0.347$. In Figure 5, 18% (28/159) of manuscripts would not meet the bar for high variance scores (top quartile), although their low agreeability (bottom quartile) indicates that they may merit closer attention from area chairs[3].

---

[3] Two such examples included in DISAPERE: `https://openreview.net/forum?id=r1e74a4twH` and `https://openreview.net/forum?id=HyMRUiC9YX`.

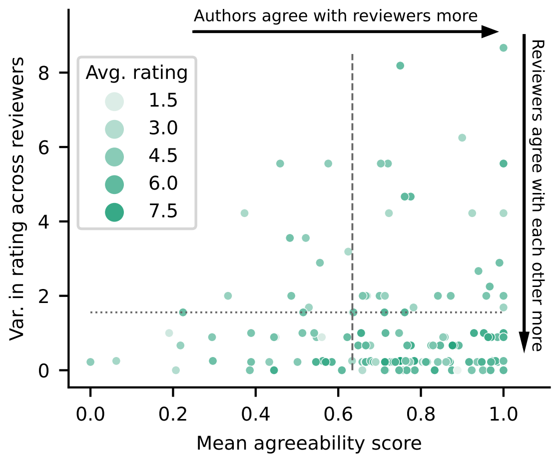

Figure 5: Mean agreeability for a manuscript's reviews v/s reviewer variance. Manuscripts above the dotted line are in the top quartile of rating variance, and are more likely to be reviewed by area chairs. Manuscripts to the left of the dashed line are in the bottom quartile of mean agreeability, in which authors take issue with the premises of reviewers' comments. The color of the dots indicates the mean of the reviewers' ratings.

6 Baselines

Two types of machine learning tasks can be defined in DISAPERE. First, a sentence-level classification task for each of the four review labels and the two levels of rebuttal labels. Second, an alignment task in which, given a rebuttal sentence, the set of review sentences that form its context are to be predicted.

The models described below are not intended to introduce innovations in discourse modeling, rather, we intend to show the off-the-shelf performance of state-of-the-art models, and indicate through error analysis the phenomena that are yet to be captured.

6.1 Sentence classification

For the six classification tasks, we use `bert-base` (Devlin et al., 2019) to produce sentence embeddings for each sentence, then classify the representation of the `[CLS]` token using a feedforward network.

We report macro-averaged F1 scores, shown in Table 7. In general, F1 is lower for tasks with larger label spaces. While the performance is reasonable in most cases, there is still room for improvement. While ASPECT achieves a particularly low F1 score, its κ is within the bounds of moderate agreement; thus, this must be accounted for by the inherent difficulty of the task rather than a deficit in data quality.

Classification task	Macro F1 (test)	Cohen's κ	Num. labels
REVIEW-ACTION	60.42%	0.605	7
FINE-REVIEW-ACTION	44.83%	0.583	10
ASPECT	38.28%	0.447	9
POLARITY	70.88%	0.561	3
REBUTTAL-STANCE	43.36%	0.513	4
REBUTTAL-ACTION	31.23%	0.479	17

Table 7: Sentence classification results. Top: review labels; Bottom: rebuttal labels.

As one might expect, errors in the classification results largely mirror disagreements in the annotations, which in turn reflect particularly ambiguous utterances. One example is the occurrence of rhetorical questions, such as (1) in Table 8, incorrectly labeled as *request* instead of *evaluative*. In fact, for sentences such as (1), additional context would disambiguate its type: the reviewer answers the question in the next sentence, and hence both sentences were labeled *evaluative*. Similarly, (2) was labeled *fact*, but since it is an integral part of a reviewer's argument against the soundness of the paper, should have been labeled *evaluative*. Certain reviewers also use conventions that do not fit the general schema we observed when developing DISAPERE. For example, (3), an opinionated heading, could be considered both *structuring* and *evaluative*. Finally, certain lexical cues a model may pick up on can be quite subtle. For example, though they share a prefix, sentences (4) and (5) are clearly *evaluative* and *request* respectively.

6.2 Rebuttal context alignment

We model rebuttal context alignment as a ranking task. Ideally, a model should rank all relevant review sentences higher than non-relevant review sentences. As a baseline, we use an information retrieval (IR) model based on BM25 that, given a rebuttal sentence ranks all the corresponding review sentences. We also report results from a neural sentence alignment model based on a two-tower Siamese-BERT (S-BERT) model (Reimers and Gurevych, 2019). We add a `NO_MATCH` sentence to the review, to which rebuttal sentences without context sets in the review are aligned. Then, each review and rebuttal sentence is encoded independently using a S-BERT encoder and the similarity between two sentences is computed using cosine

		Label (Pred.)
1	Can the proposed [...] function represent all function the authors used in the paper? *Yes.*	E (R)
2	Matrices can have either "horizontal" or "vertical" redundancy (or "other" or neither).	E (F)
3	Solid technical innovation/contribution:	E
4	I am also wondering if the comparison with the baselines is fair.	E
5	I wonder if the authors ever looked at how much [...] determines the performance of the system?	R

Table 8: Example sentences including errors and challenging cases. E, R, F stand for *evaluative*, *request* and *fact* respectively. Letters in parentheses show the incorrect label from the model. Sentence (3) functions both as *evaluative* and *structuring*. Sentences (4) and (5) share a prefix but have different REVIEW-ACTIONs.

similarity. We initialize with a model[4] pre-trained on various sentence-pair datasets. Alignment is evaluated using mean reciprocal rank (MRR) and Mean Average Precision (MAP).

	S-BERT	BM25
MAP	0.4409	0.5174
MRR	0.5022	0.5980

Table 9: Rebuttal context alignment results. The results of both models indicate significant scope for improvement.

Surprisingly, the BM25 model outperforms a neural model (Thakur et al., 2021). While this shows that lexical information is a useful signal, both models have significant scope for improvement, and lexical overlap is clearly not sufficient for this task. Importantly, neither of these models account for the context of the rebuttal sentence, and predict each sentence's context independently. Incorporating this information is likely to lead to performance gains; however, we leave this investigation to future work.

7 Conclusion

As the burden of academic peer reviewing grows, it is important for program chairs and editors to act upon data-driven insights rather than heuristics, to make the best possible use of participants' scarce time. Models trained on data like DISAPERE will allow decision makers to glean deep insights on the interactions occurring during peer review.

Almost all publicly available peer review data is from the domain of artificial intelligence, limiting the scope of DISAPERE and any similar project. While this means that models trained on DISAPERE won't necessarily generalize to all new domains, we hope that with the detailed annotation guidelines and seamless data collection using the software provided with this paper support, users can build on our work, and ensure that their insights are robust to differences over time and across fields.

8 Ethics

The outcomes of peer review can have outsize effects on the careers of participating scholars. As machine learning models are known to amplify biases, we strongly recommend against using the outputs of any machine learning system to make decisions about individual cases. A dataset like DISAPERE is best used to survey participants' behavior. Any interventions based on this information should be subjected to studies in order to ensure that they do not introduce or exacerbate bias.

A Rationale for taxonomy construction

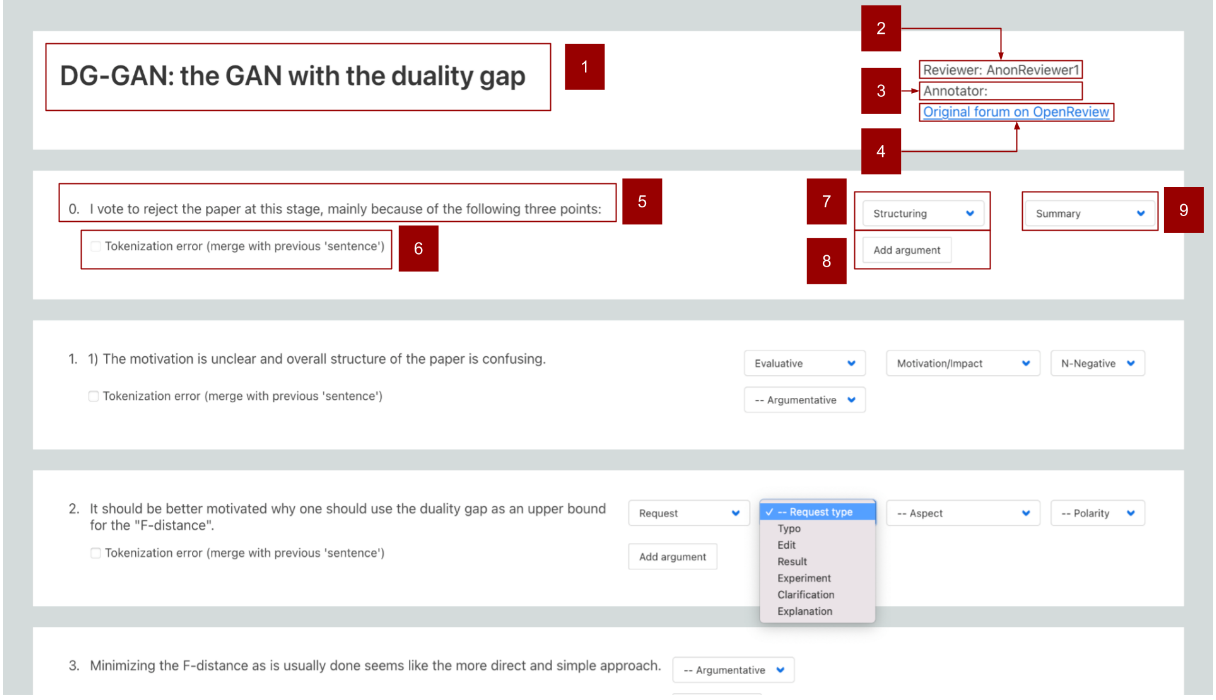
Our label sets leverage ideas from and commonalities between existing work in this domain, including AMPERE (Hua et al., 2019), AMSR (Fromm et al., 2020) ASAP-Review (Yuan et al., 2021), and Gao et al. (2019):

- ASAP-Review's polarity labels approximately correspond to *arg-pos* and *arg-neg* labels in AMSR
- AMSR and AMPERE each label non-argumentative sentences in a similar manner
- *aspect* labels from ASAP-Review apply only to certain types of sentences; namely *request* and *evaluative* sentences from AMPERE's taxonomy.
- *summary* is an exception among ASAP-Review's *aspect*s, behaving similarly to AMPERE's *quote*. We thus include both of these under a *structuring* category.
- Further, in order to gauge the extent to which authors acquiesced to reviewers' requests, we introduce a fine-grained categorization of the types of requests.
- Gao et al. (2019) enumerates some features of rebuttals, including expressing gratitude, promising revisions, and disagreeing with criticisms. We formalize these observations into our rebuttal label taxonomy.

B Annotation tool

Two modes of annotation are possible. First, annotators can apply labels on a sentence-by-sentence basis. Multiple labeling schemas can be annotated simulatenously, with the option of adding constraints so that certain values govern possible values for other properties. This annotation mode is shown in Figure 6.

The second annotation mode can build on the output of the first annotation mode. Here, sentences of a focus text (the rebuttal) are presented in sequence, and annotators are permitted to select one or more of the sentences in the reference text (the review) which form the context of the sentence of the focus text. Further, a label can be applied to the alignment. This annotation mode is shown in Figure 7 and Figure 8.



DG-GAN: the GAN with the duality gap

0. I vote to reject the paper at this stage, mainly because of the following three points:
☐ Tokenization error (merge with previous 'sentence')

1. 1) The motivation is unclear and overall structure of the paper is confusing.
☐ Tokenization error (merge with previous 'sentence')

2. It should be better motivated why one should use the duality gap as an upper bound for the "F-distance".
☐ Tokenization error (merge with previous 'sentence')

3. Minimizing the F-distance as is usually done seems like the more direct and simple approach.

Figure 6: Review annotation interface. Annotators select label values from dropdown menus for each review sentence in turn. [1] Title of the manuscript whose review is being annotated [2] Reviewer identifier [3] Annotator identifier (removed for anonymity) [4] Link to original forum, in case it is needed for context [5] Individual review sentence [6] Option to report sentence splitting error (sentence splitting generally suffered from false positives) [7] Dropdown for REVIEW-ACTION [8] Follow-up dropdownfor FINE-REVIEW-ACTION populated based on value in (7) [9] Button to add second REVIEW-ACTION if necessary (this was seldom used)

C Annotated review-rebuttal pair

Figure 9 shows a truncated version of a review-rebuttal pair from the train set of DISAPERE.

D Context overlap analysis

As a proxy for agreement of rebuttal spans, we show the types of overlap between spans on rebuttal sentences from 81 examples annotated by two annotators in Table 10.

Type of context overlap	Num. rebuttal sentences	% rebuttal sentences
Exact match	914	53.11%
Partial match	492	28.59%
Agree none	122	7.09%
Disagree none	100	5.81%
No overlap	93	5.40%

Table 10: Types of context overlap. Full agreement is achieved in the top rows (exact match and 'Agree none', where both annotators agree that there is no appropriate subset of review sentences forming the context. in 'Disagree none', one annotator marks a subset of review sentences, while the other does not.

E Additional Agreement Analysis

While some of the IAA scores on annotation are low, we note that the labels used in this task attempt to characterize relatively complex relationships in text. To give more insight into such disagreements, Figure 10 provides a confusion matrix regarding the REBUTTAL-ACTION labels. Recognizing that there are often situations in which users of a dataset will hope to reduce a label set, we provide some guidance as to which such merges may be acceptable and which are not.

Many disagreements come from three labels which might be said to exist upon a continuum – ANSWER, MITIGATE CRITICISM and REJECT CRITICISM. We suggest that in the situation of needing to minimize IAA disagreement, one might consider first merging *mitigate criticism* into *reject criticism*. The kind of disagreements seen between the two are understandable but nuanced: the difference between saying that the reviewer has a point (but that they disagree on the relevance of that point) and disagreeing with the point itself. Out-of-context rebuttal sentences illustrating this are provided below as examples of this kind of ambiguous situation:

Review

I vote to reject the paper at this stage, mainly because of the following three points:

1) The motivation is unclear and overall structure of the paper is confusing.
It should be better motivated why one should use the duality gap as an upper bound for the "F-distance".
Minimizing the F-distance as is usually done seems like the more direct and simple approach.
Since the results are far from state of the art, a clean and neat presentation of the theoretical advantages and contributions is crucial.

2) The presentation is not professional, hard to follow and the submission overall looks very rushed:

- In equations, please use \inf, \sup, and \text{...} for text such as distance, data, ...

- I have trouble understanding the overall idea behind Algorithm 1 and Eq. (22).

For the rebuttal sentence highlighted below:

Thanks for your attention to our work.

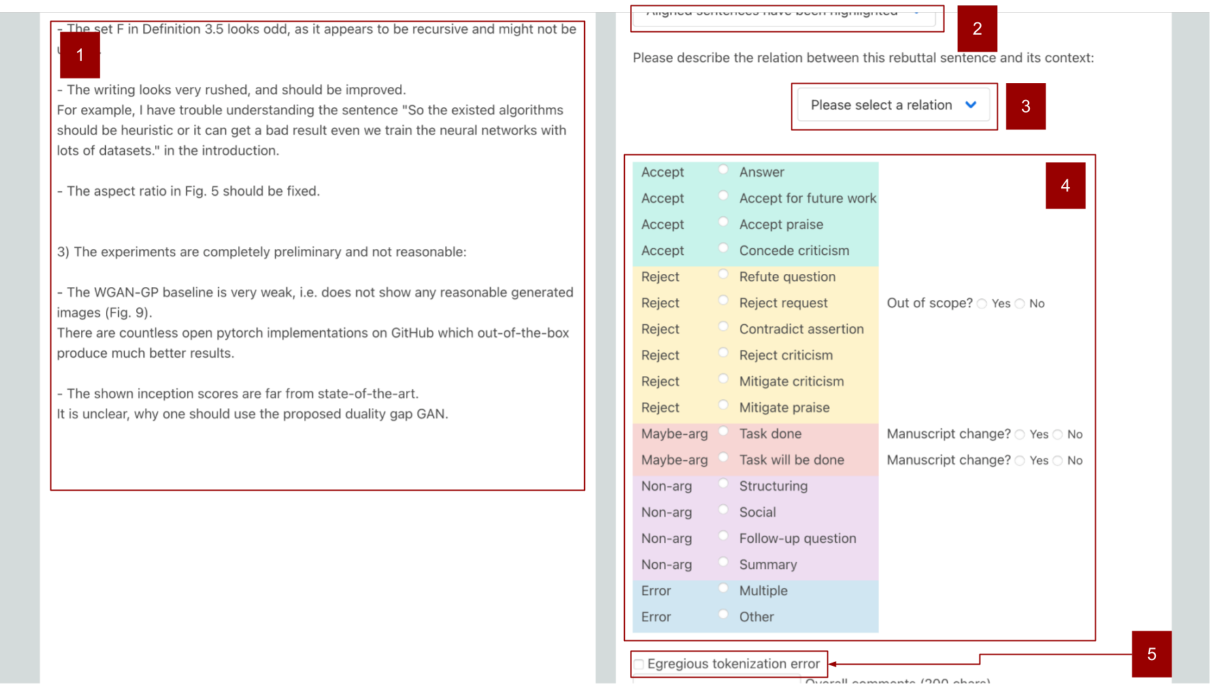
☐ Standard tokenization error (merge with previous 'sentence')
Please click to highlight the review sentences that form the context for the current rebuttal sentence.

You have selected:

It should be better motivated why one should use the duality gap as an upper bound for the "F-distance".	Evaluative Replicability N-Negative
Since the results are far from state of the art, a clean and neat presentation of the theoretical advantages and contributions is crucial.	Evaluative Clarity N-Negative

If you have not selected any sentences, please choose the reason below:

Figure 7: Rebuttal annotation interface. Annotators examine each rebuttal sentence in turn, selecting sentences as context and specifying REBUTTAL-ACTION. [1] Title of the manuscript whose review is being annotated [2] Buttons to navigate between rebuttal sentences. Each page refers to a single rebuttal sentence (See (9)) [3] Reviewer identifier [4] Annotator identifier (removed for anonymity) [5] Link to original forum, in case it is needed for context [6] Link to open pop-up window with full rebuttal text, in case it is needed for context [7] Full review text. When a review sentence is clicked, it is highlighted and its details appear in (11) [8] Option to report sentence splitting error (false positive) [9] Rebuttal sentence being annotated [10] Button to copy REBUTTAL-ACTION label and context from previous rebuttal sentence [11] Table showing details of selected context sentences from the review, with the labels the annotator provided The screenshot is continued in Figure 8.



- The set F in Definition 3.5 looks odd, as it appears to be recursive and might not be

- The writing looks very rushed, and should be improved.
For example, I have trouble understanding the sentence "So the existed algorithms should be heuristic or it can get a bad result even we train the neural networks with lots of datasets." in the introduction.

- The aspect ratio in Fig. 5 should be fixed.

3) The experiments are completely preliminary and not reasonable:

- The WGAN-GP baseline is very weak, i.e. does not show any reasonable generated images (Fig. 9).
There are countless open pytorch implementations on GitHub which out-of-the-box produce much better results.

- The shown inception scores are far from state-of-the-art.
It is unclear, why one should use the proposed duality gap GAN.

Please describe the relation between this rebuttal sentence and its context:

- *We note that such rules are indeed limited to some extent, but they still capture a rather expressive fragment of answer set programs with restricted forms of external computations.*
- *The use of* C_p^{val} *for hyperparameter tuning was incidental and not a central point of our paper.*
- *We agree that the measure theoretic approach is not always necessary (indeed for angular actions, it is not needed), but it is necessary for a very common scenario – clipped actions.*

Furthermore, we note that (as illustrated in the confusion matrix) a wide range of disagreements are hard to distinguish from “answer” labels, as authors often attempt to frame disagreements as simple answers to questions.

Abstract

Most existing reading comprehension datasets focus on single-span answers, which can be extracted as a single contiguous span from a given text passage. Multi-span questions, i.e., questions whose answer is a series of multiple discontiguous spans in the text, are common in real life but are less studied. In this paper, we present MultiSpanQA[1], a new dataset that focuses on questions with multi-span answers. Raw questions and contexts are extracted from the Natural Questions (Kwiatkowski et al., 2019) dataset. After multi-span re-annotation, MultiSpanQA consists of over a total of 6,000 multi-span questions in the basic version, and over 19,000 examples with unanswerable questions, and questions with single-, and multi-span answers in the expanded version. We introduce new metrics for the purposes of multi-span question answering evaluation, and establish several baselines using advanced models. Finally, we propose a new model which beats all baselines and achieves the state-of-the-art on our dataset.

1 Introduction

The task of *reading comprehension*, where models are required to process a text and answer questions about it, has seen rapid progress in recent years. As systems have increasingly matched humans on popular datasets (Rajpurkar et al., 2016, 2018), researchers have developed newer, more complex formulations of the task, such as very long contexts and answers (Kwiatkowski et al., 2019), multi-hop reasoning (Yang et al., 2018), and discrete operations over the content of paragraphs (Dua et al., 2019). One thing these datasets have in common is that the answer is constrained to be a single span that can be extracted or computed from the context.

Question: *Which countries does the Danube River flow through?*

Passage: ... *Originating in Germany, the Danube flows southeast for 2,850 km (1,770 mi), passing through or bordering Austria, Slovakia, Hungary, Croatia, Serbia, Romania, Bulgaria, Moldova* and *Ukraine before draining into the Black Sea. ...*

Answer set: {*Germany, Austria, Slovakia, Hungary, Croatia, Serbia, Romania, Bulgaria, Moldova, Ukraine* }

Figure 1: Example of a multi-span question and answer pair.

However, in practice, the answer to a question will often consist of multiple parts. As in the example in Figure 1, the answer set contains 10 countries, some of which are discontiguous in the passage. Such cases are largely ignored in existing reading comprehension research, in part because there are no datasets of multi-span questions.

In this paper, we introduce MultiSpanQA, a new reading comprehension dataset consisting of 6,536 multi-span examples. The raw questions and passages are extracted from Natural Questions (“NQ”: Kwiatkowski et al. (2019)), a large-scale open-domain QA dataset. Trained annotators were asked to identify question–passage pairs where the answer was multi-span, and annotate the spans. In addition to the basic version of the dataset consisting entirely of multi-span answers, we also prepare an expanded version with a selection of unanswerable questions, and questions with single- and multi-span answers, intended to reflect a more realistic QA setup.

We further classify answer semantics into 5 categories, and manually label the logical structure of the answer spans. We introduce metrics to evaluate multi-span QA systems across these different tasks.

We propose several baselines, and a new model which casts the task as a sequence tagging problem. The proposed model combines a sequence tagger with a span number predictor, span structure predictor, and span adjustment module. Experimental results show that the proposed model surpasses

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1250 - 1260
July 10-15, 2022 ©2022 Association for Computational Linguistics

all baselines and achieves 59.28% exact-match F1 score and 76.50% partial-match F1 score.

To summarize, our contributions are:

- A new reading comprehension dataset containing 6.5k high-quality multi-span answers, along with analysis and metrics for multi-span QA.
- A novel label set for capturing the semantics of multi-span answers, with annotations.
- A new model for multi-span reading comprehension which achieves state-of-the-art results on our dataset.

2 Related Work

2.1 Question Answering Datasets

Extractive QA Most existing extractive QA datasets such as SQuAD (Rajpurkar et al., 2016), SQuAD2.0 (Rajpurkar et al., 2018), SearchQA (Dunn et al., 2017), and QuAC (Choi et al., 2018) restrict the answer passage to a single span of text. SQuAD and SQuAD 2.0 limit the answer passage to a short paragraph from Wikipedia; the best-performing systems have now exceeded human performance on these datasets. QuAC frames the task in a dialogue setting by introducing a teacher and student, where the student repeatedly asks the teacher questions about a topic and the teacher tries to find answers from the given passage. That is, it supports information seeking through multi-turn conversation. TriviaQA (Joshi et al., 2017) and HotpotQA (Yang et al., 2018) extend the answer context from single passage to multiple passages, while HotpotQA further requires reasoning over multiple passages to answer the question. However, all of these datasets limit the answer to a single text span from the provided answer context.

DROP (Dua et al., 2019) requires systems to resolve (possibly multiple) references in a question, and perform discrete operations (such as addition, sorting, or counting) over them. However, because these operations are mostly numeric, the spans are almost exclusively semantically homogeneous and related to numeric values. MASH-QA (Dua et al., 2019) extends the answer space to texts that span across a longer document, but this dataset is highly domain-specific, in the healthcare domain. Quoref (Dasigi et al., 2019) and Natural Questions (“NQ”: Kwiatkowski et al. (2019)) both contain multi-span answers. Quoref requires systems to resolve coreference among entities, to aid in span-selection. NQ is a large-scale dataset that provides questions with very long answer contexts. The proportion of multi-span answers is around 10% and 2% in Quoref and NQ, respectively. However in each case, multi-span answers are captured as a single span, with no annotation of the internal structure of the component spans. WikiHowQA and WebQA (Cui et al., 2021) both focus on non-factoid (e.g., how, why) questions, with answers mostly being long spans or full sentences.

Generative QA Generative QA datasets usually require systems to answer questions in the form of several sentences, either selected from the provided answer context or generated based on it. WikiQA (Yang et al., 2015) and MS Marco (Nguyen et al., 2016) are two open-domain generative QA datasets, where answers in WikiQA are mostly sentences from the answer passage, while answers in MS Marco are free-form sentences generated by crowd workers. NarrativeQA (Kociský et al., 2018) is a dataset of movie and book summaries. SearchQA (Dunn et al., 2017), ELI5 (Fan et al., 2019), and CoQA (Reddy et al., 2019) are three multiple-document datasets. SearchQA is constructed from question–answer pairs crawled from *Jeopardy!*, and most questions can be answered with a short (99% less than 5 tokens) extractive span from a single document. ELI5 requires systems to generate paragraph-length answers by summarizing information from multiple documents. CoQA contains conversational questions, with free-form text as answers.

Cloze style Cloze datasets such as CNN/Daily Mail (Hermann et al., 2015), Children’s Book Test (CBT) (Hill et al., 2016), and BookTest (Bajgar et al., 2016) require systems to predict a missing word from a passage. However, researchers have shown that this task is artificial, and can be largely solved with simple methods and relatively little reasoning (Chen et al., 2016).

2.2 Multi-span Models

Dua et al. (2019) proposed to predict the number of output spans for each question, by applying a single-span predictor recursively, making training complex. Segal et al. (2020) first proposed to treat multi-span QA as a sequence tagging task, in the form of a multi-head architecture (Dua et al., 2019) to perform arithmetic operations between the predicted spans. Hu et al. (2019) applied the non-maximum suppression (NMS) algorithm (Rosenfeld and Thurston, 1971) to prune redundant bounding boxes from the top-k predicted spans of a single-span predictor. Pang et al. (2019) proposed HAS-QA, which supports multi-span prediction by computing answer probabilities at the question, paragraph and span levels. A common feature of these works is that the predicted spans are fed into an aggregation module, and the answers are usually a single span chosen from the prediction, or a number computed from them. Cui et al. (2021) proposed a model which can extract list-form answers across multiple spans. Their work mainly focuses on capturing the sequential and progressive relationships between long-span descriptions.

3 Dataset Construction and Composition

In this section, we describe how we construct MultiSpanQA, and provide a statistical breakdown of its composition.

3.1 Data Collection and Preprocessing

The question–passage pairs were selected from Natural Questions (NQ: Kwiatkowski et al. (2019)), a large-scale open-domain QA dataset made up of (question, passage, long answer, short answer) quadruples where: the questions are real queries issued to the Google search engine; the passage is a Wikipedia page which may or may not contain the information required to answer the question; the long answer is a paragraph from the page containing all information required to infer the answer; and the short answer is one or more text spans that answer the question. Both long and short answers can be `NULL` if no viable answer candidate exists on the page.

To create MultiSpanQA, we first extract NQ questions annotated with multiple short answers, and consider the long answer to be the answer passage. We then remove paragraphs that don't contain any question part, to eliminate the information-retrieval component of NQ and focus more on the short answer extraction problem. To make the dataset easy to use, we strip HTML from the passages, so that they only contain plain text. As table structure cannot be captured in the plain text after removing HTML, we remove the passages that contain tables. Ultimately, around 6700 candidates remain where each candidate is a triple of (question, passage, set of answer spans).

To aid the annotation process, we classifies the samples into 5 categories according to the expected answer type of questions using a BERT-based classifier trained on the TREC Question Classification dataset (Li and Roth, 2002). The classes are DESCRIPTION, LOCATION, HUMAN, NUMERIC, and OTHER ENTITY. Table 1 shows the breakdown and an example of each answer type class.

Answer type	**%**	**Example**
DESCRIPTION	16.4	*other gases*
LOCATION	18.6	*Vermont*
HUMAN	46.1	*George Benson*
NUMERIC	7.3	*9,677 ft*
OTHER ENTITY	15.4	*Torah*

Table 1: Proportion and examples of answer types in MultiSpanQA.

3.2 Issues in Existing Dataset

NQ was originally annotated by around 50 annotators, with an average annotation time of 80 seconds per instance. However, we found a number of issues with the dataset: (1) grammatical errors in questions, due to them being actual queries submitted to the Google search engine by real users; (2) answer boundary inconsistencies or errors, such as the entity *University of Melbourne* being annotated as an answer in one example but *The University of Melbourne* being annotated in another; and (3) wrong or incomplete answers: some questions are not answered or are answered incompletely in the annotated answer span, for example, to answer the question *Which countries does the River Danube flow through?*, 10 countries should be included in the answer span while only 9 are annotated. These issues are relatively uncommon overall in the dataset, but occur disproportionately in multi-span answers.

3.3 High Quality Re-annotation

We (re-)annotated all the data using the Brat annotation tool (Stenetorp et al., 2012).[2] Three annotators were provided with a category-specific annotation guide (broken down across the 5 predicted answer types), and annotated the data on a per-category basis.[3]

For each annotation instance, we show the question, passage, and the original multiple answer spans to the annotator. The first-pass annotation was according to the following four categories:

---

[2] `http://brat.nlplab.org`

[3] The annotation guide is available in the github repository along with the data.

Answer structure	**%**	**Example**
Conjunction	82.6	**Q**: *What purpose do aircraft carriers serve for aircraft?* **Passage**: *carrying, arming, deploying, and recovering*
Multi-part-disjunction (Redundant)	4.5	**Q**: *When does the Force Unleashed 2 take place?* **Passage**: *The game takes place approximately six months after the events of the first game, and a year before the first Star Wars.*
Multi-part-disjunction (Non-Redundant)	9.6	**Q**: *When was the last year they made the Toyota Matrix?* **Passage**: *Sales of the Matrix were discontinued in the United States in 2013, and in Canada in 2014.*
Complex	3.1	**Q**: *When was the Battle of Dien Bien Phu and what was the result?* **Passage**: *The battle occurred between March and May 1954 and culminated in a comprehensive French defeat that influenced negotiations underway at Geneva among several nations over the future of Indochina.*
Shared Structure	0.2	**Q**: *What does Triangle Transit offer?* **Passage**: *scheduled, fixed-route regional and commuter **bus service***

Table 2: Answer structure breakdown and examples.

- Good example: the question is clear, and the answer spans are labelled consistent with the annotation guide, in which case accept the instance as is.
- Bad question: the question is ungrammatical or not aligned with the passage content, in which case rewrite the question while preserving its original intended meaning where possible (otherwise reject).
- Bad answer span(s): the answer span(s) are incorrect or incomplete, in which case remove the inappropriate spans and select the correct spans.
- Bad question–answer pair: the question doesn't align with the passage content (e.g. there is no answer there) or there are not multiple answer spans in the passage (e.g. there is only a single answer span), in which case reject the instance.

Although all examples in our dataset contain multiple answer spans, the semantic structure varies considerably. We hand-annotate this via a novel 5-way annotation scheme, as follows (see Table 2 for examples):

- 1. CONJUNCTION: Each span is part of the answer, and the answer is complete only when all of the spans are combined
- MULTI-PART-DISJUNCTION: Each span is a complete (but independent) answer to the question, with one of the following structures:
  - 2. REDUNDANT: the multiple spans refer to the *same* concept or entity. For example, in the example in Table 2, each span is a full answer to the question, specified using different temporal reference points.
  - 3. NON-REDUNDANT: the different spans refer to *different* concepts or entities, each of which is independently correct in its respective context. For example, in the example in Table 2 each span is independently correct in the context of a particular national market.
- 4. COMPLEX: The question is complex (made up of multiple sub-parts), and each span is an answer to a different sub-part, the internal logic of which is *not* enumeration. For example, in the example in Table 2, the two spans are independent answers to the two sub-questions in the original question.
- 5. SHARED STRUCTURE: Spans are enumerated in the form of a syntactically-coordinated structure, sharing either a modifier or a head (i.e. the first word(s) of the first span or last word(s) of the last span). For example, in the example in Table 2, the three spans share the syntactic head *bus service*, and the full answer is equivalent to *scheduled bus service* + *fixed-route regional bus service* + *commuter bus service*.

#Spans	2	3	4–5	6–8	9–12	13–21
Count	3,791	1,414	915	337	71	8

Table 3: Number of answer spans in MultiSpanQA.

3.4 Dataset Statistics

The annotation was performed by three trained annotators with an average annotation time of 70 seconds per instance. To test the inter-annotator agreement (IAA), we randomly selected 100 instances for each pairing of the three annotators to anntotate. The same annotation (of all spans) of an instance is considered as an agreement, and any difference in one instance is considered as a disagreement. The average pairwise IAA is 0.86 for answer spans and 0.94 for answer structures (both based on macro-averaged exact match F1 score), with some disagreements between CONJUNCTION and MULTI-PART-DISJUNCTION (NON-REDUNDANT). To better understand the composition of MultiSpanQA, we compare our annotations with those in NQ, and provide some basic statistics. Compared to the original annotations in NQ, the annotators rejected 3.1% of instances, re-wrote the question for 5.6% of instances, and modified the answer span annotations for 22% of instances.

MultiSpanQA contains 6,536 instances with 5,230 for training, 653 for validation, and 653 for test. Table 3 provides the distribution of the number of answer spans in the dataset, from which we see the number of spans ranges from 2 to 21, but 80% of instances contain 2 or 3 spans, and only about 1% of instances contain more than 9 spans.

3.5 Dataset Expansion

In its basic form, the MultiSpanQA dataset contains only multiple-span answers, and the correct answer can always be located in the passage (in the form of multiple answer spans). However, in a real-world QA scenario, single-span answer questions and unanswerable questions (i.e. the answer is not contained in the passage) would realistically exist. To create a more realistic and challenging variant of the dataset, we add a comparable number of single-span question–answer pairs and unanswerable instances to MultiSpanQA, by randomly sampling from NQ and applying the same preprocessing. The total size of the expanded dataset is 19,608 instances (three times the basic version, partitioned similarly to the basic version).

4 Models

Formally, given a question and passage pair $\langle q, p\rangle$, the task of multi-span QA involves finding all answer spans $s_1, s_2, ...s_n$, which are neither duplicated nor overlap with each other, as well as predict the answer structures.

4.1 Baselines

Single-span Baseline Because most existing reading comprehension datasets only have single-span answers, single-span architectures are widely used in reading comprehension research. Usually, a pre-trained model is used to encode the question and passage, and output a contextualised representation for all input tokens. Then two feed-forward networks are used to compute a score for each token which indicates whether the token is the start or end of the answer. Finally, a softmax layer followed by an argmax function is used to produce the start and end positions of the answer.

To make MultiSpanQA trainable for a single-span architecture, we experimented with two pre-processing methods, and created two baselines accordingly:

1. Mark the start of the answer as the start position of the first answer span and mark the end of the answer as the end position of the last answer span. In this way, the model can learn to find the shortest span that includes all answer spans. We select the best prediction for evaluation.
2. Suppose an instance has n answer spans, we replace the instance with n instances, one for each span with a single-span answer.

In this way, we can apply single-span answer models to our dataset.

For evaluation, to enable multi-span prediction, we output the 20 highest-scoring predictions, and tune a threshold t to select the answer spans with a confidence score larger than t that optimises performance on the training set. We remove overlapping predictions based on confidence scores, rejecting predictions with lower confidence scores. Note that for both baselines, we apply the pre-processing to the training data only.

Sequence Tagging Baseline Following Segal et al. (2020), we cast question answering as a sequence tagging task, predicting for each token whether it is part of an answer. In our experiments, we use the popular `IOB` tagging scheme to mark

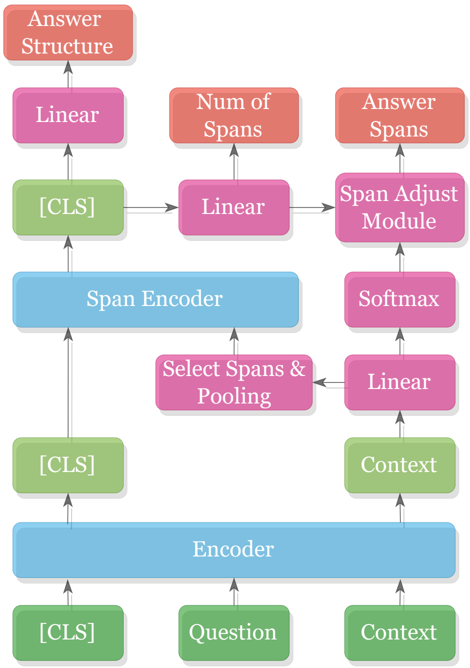

Figure 2: Proposed multi-span QA model architecture.

answer spans in the passage where `B` denotes the first token of an answer span, `I` denotes subsequent tokens within a span, and `O` denotes tokens that are not part of an answer span.

4.2 Proposed Model

By investigating the failures of the sequence tagging baseline, we find there is an issue that the model struggles to capture global information. For example, the number of answer spans may be specified in the question, but cannot be imposed as a constraint on the tagger. To better use such global information, we propose a span encoder, a number of span predictor, an answer structure predictor, and a span adjustment module (as in Figure 2), which can be combined with any on-the-fly sequence tagger (encoder).

Contextualiseed Encoder Given a pair of question q and passage p, we first encode the question and context together using a sequence pair encoder as:

$$H = \text{Encoder}(\langle q, p\rangle) \in \mathbb{R}^{l\times h} \tag{1}$$

where $H = [H_{[CLS]}; H_q; H_p]$ is the contextualised token representation of all input tokens with a pooled global token $[CLS]$, h is the hidden-layer size, and l is the input length.

After encoding, we fetch the hidden states of the context tokens and input them to a linear classifier to perform a preliminary token-level answer span prediction, as:

$$T_p = FFN(H_p) \in \mathbb{R}^{l_p\times t} \tag{2}$$

where l_p denotes the length of passage, and t denotes the number of labels ($t = 3$ in for `IOB` tagging scheme).

Span Encoder According to the $\arg\max$ of preliminary predictions T_p, we take the continuous token representations of the predicted spans as span representation $s_1, s_2, ...s_n$, where $s_i = [H_{s_i}, H_{s_i+1}, ...H_{s_i+k-1}] \in \mathbb{R}^{k\times h}$, k is the length of the span, which varies across spans. Average pooling is then applied to the span representations s_i to generate a fixed-length span representation $S_i \in \mathbb{R}^{1\times h}$.

We then concat the hidden state of [CLS] token $H_{[CLS]}$ with the span representations S_i as $I_{span} = [H_{[CLS]}, S_1, ...S_n]$, and input them into a span encoder as:

$$I = \text{SpanEncoder}(I_{span}) \in \mathbb{R}^{(n+1)\times h} \tag{3}$$

Objective Function We fetch the hidden state of span-level [CLS] token $I_{[CLS]}$ and input it to two feed-forward networks to predict the number of answer spans and the answer structure, respectively, as below:

$$P_{num} = FFN(I_{[CLS]}) \tag{4}$$

$$P_{structure} = FFN(I_{[CLS]}) \tag{5}$$

We use cross-entropy loss for answer span and structure prediction, and mean-square loss for span number regression. For training, we use the weighted sum of the three losses:

$$\mathcal{L} = \mathcal{L}_{spans} + \lambda_1\mathcal{L}_{num} + \lambda_2\mathcal{L}_{structure} \tag{6}$$

Finally, a span adjustment module is used to explicitly combine the predicted span number with the span texts. We first assign a confidence score to each label of the preliminary classification using a softmax layer:

$$\alpha_{conf} = \text{softmax}(U_p) \in \mathbb{R}^{l_p\times t} \tag{7}$$

The confidence of a predicted answer span a_i is defined as the maximum confidence of the tokens within a_i. Suppose there are k spans that been tagged as answers and the predicted number of span is n, if $n < k$, we rank the predicted spans by confidence score, and keep the top-n answer spans as answers.

5 Experiments

5.1 Setup

For all baselines and our model, we use the HuggingFace implementation of $BERT_{Base}$ (Wolf et al., 2019; Devlin et al., 2019) as our encoder with $max\_sequence\_length = 512$ and $doc\_stride = 128$ to deal with long passages. For the proposed span encoder, we use a multi-head self-attention layer with 4 heads followed by a linear layer to encode the spans. The maximum span number is set to 30 for the input of the span encoder. For training, we use the BertAdam optimizer with default hyperparameters and learning rate of 3e-5. All models are trained with a batch size of 4 for 3 epochs. We use a two-layer feed-forward network with a ReLU activation function for all linear layers.

5.2 Evaluation Metrics

For answer structure prediction, we use accuracy to evaluate the model performance. For answer span prediction, we evaluate in terms of exact match and partial match performance.

Exact match An exact match occurs when a prediction fully matches one of the ground-truth answers, and the F1 score is computed by treating the predicted and ground-truth answer spans as a set of spans. We use micro-averaged precision, recall, and F1 score for evaluation based on the standard formulation of $\text{Precision} = TP/(TP+FP)$, $\text{Recall} = TP/(TP + FN)$, and $\text{F1} = 2 * \text{Precision} * \text{Recall} / (\text{Precision} + \text{Recall})$, where TP (True Positive) is the number of answer spans correctly predicted by the model, FP (False Positive) is the number of spans incorrectly predicted by the model, and FN (False Negative) is the number of answer spans not predicted by the model. In the case of an unanswerable question with the expanded dataset, we use a virtual span which indicates no answer.

Partial Match To measure the overlap between the predictions and ground truth answers, we propose the partial match precision, recall, and F1 by treating each predicted span or ground-truth answer span as a string. In detail, for each pair of prediction p_i and ground truth answer t_j, we define the partial retrieved score and partial relevant score as the length of the longest common substring (LCS) between p_i and t_j, divided by the length of p_i and t_j, respectively, as:

$$s_{ij}^{ret} = len(LCS(p_i, t_j))/len(p_i) \tag{8}$$

$$s_{ij}^{rel} = len(LCS(p_i, t_j))/len(t_j) \tag{9}$$

Suppose there are n predictions and m ground truth answers for a question. Since we do not know the correspondence between predictions and an-

#Span	Exact Match			Structure
	P	R	F	Acc
1	34.95	45.09	39.38	–
2-3	54.13	64.08	58.69	81.92
4-7	62.50	63.70	63.09	91.89
>7	82.25	71.83	76.69	81.25

Table 6: Results on MultiSpanQA (expanded) dev set categorised by number of spans.

swers, we compute the partial retrieved score between a prediction and all answers and keep the highest one as the retrieved score of the prediction. Similarly, for each ground truth answer, the relevant score is the highest one between it and all predictions. The precision, recall, and F1 are finally defined as follows:

$$\text{Precision} = \frac{\sum_{i=1}^{n} \max_{j\in[1,m]}({s_{ij}}^{ret})}{n} \tag{10}$$

$$\text{Recall} = \frac{\sum_{j=1}^{m} \max_{i\in[1,n]}({s_{ij}}^{rel})}{m} \tag{11}$$

$$\text{F1} = \frac{2 * \text{Precision} * \text{Recall}}{\text{Precision} + \text{Recall}} \tag{12}$$

We use micro-averaged scores for all metrics.

5.3 Results and Analysis

Table 4 shows the dev set results on MultiSpanQA, where the left part is results on multi-span questions only (the basic dataset), and the right part is the results on the expanded dataset (including single-span answers and unanswerable questions).

Single-span model From the table, we see that single-span (v1) gets very low exact match scores but higher partial match scores (compared to exact match), as it is trained to find a single long span that overlaps with all answer spans. By comparison, single-span (v2) improves the exact match scores on the basic dataset because it is trained on independent single-span answers. This is also the reason that: (1) single-span (v1) always gets a lower score in partial match precision and a higher score in partial match recall compared with single model (v2); and (2) after applying the tuned threshold, single-span (v2) gets a clear boost while single-span (v1) does not exhibit a substantial change in results. The overall performance of the single-span baselines is relatively low, simply because the models can only predict a single-span answer, which is incompatible with the MultiSpanQA dataset.

Sequence tagging model Compared to the single-span baselines, the sequence tagging models perform much better. Without changing the encoder, there is an improvement of over 30 absolute points on the exact match metrics, and about 8 for the partial match F1 metric in MultiSpanQA. Performance is boosted using joint training with span number prediction and answer semantics prediction. Our proposed model achieves the best F1 score in most settings.

Another interesting finding is that single-span models usually attain higher precision, while sequence tagging models attain higher recall. This demonstrates that single-span models are more accurate in the single-span answer they predict, while sequence tagging models predictably tend to make more predictions.

Comparing the two datasets Comparing results on the two datasets, we see that single-span baselines are boosted over the expanded dataset (where we add single-span answers and unanswerable questions), as single-span answers are more tractable for these simpler models. The relative improvements for sequence tagging models are more modest, but they still have a clear advantage over the single-span baselines.

Difficulty analysis To explore the difficulty of the MultiSpanQA dataset, we report the dev set results categorised by answer type in Table 5 and categorised by the number of spans in Table 6. From the answer type perspective, the model performs best on HUMAN questions, followed by OTHER ENTITY and LOCATION (largely following the natural distribution of the respective classes in the dataset). There is quite a drop for the NUMERIC class, and a big drop again for the DESCRIPTION class, which was also the class our annotators found most difficulty with.

From the perspective of the number of spans, the model performs best on questions with many (> 7) answers. We think this is because the answers are usually a list of spans with similar semantics, often structured as a simple coordination. The performance drops as the answer number decreases because the syntactic pattern in which answer spans occurs is less predictable.

Answer Semantics From the answer type perspective, LOCATION answers usually have easily predictable structure, while the structure of NUMERIC answers is the most difficult to predict.

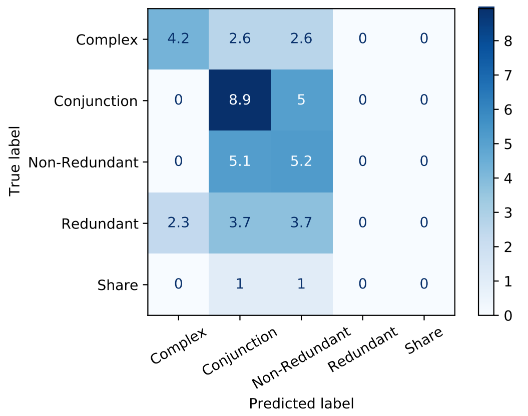

Figure 3: Confusion matrix of answer structure prediction, based on log values.

From the perspective of the number of spans, answers consisting of 4–7 spans are relatively easy to predict and there is no significant difference between answers contain few (2 or 3) spans or many (> 7) spans. Figure 3 shows the confusion matrix of the answer structure predictions. We can see that our model tends to predict CONJUNCTION and NON-REDUNDANT, and there are no REDUNDANT or SHARE predictions.

The overall answer structure accuracy is 84.38%, which is slightly higher than the proportion of CONJUNCTION (the majority class) in the dataset. This suggests that directly applying a simple feed-forward network to the pooled encoder output is ineffective for answer semantics prediction, and that this should be an area for future model refinement.

6 Conclusion

We present MultiSpanQA, a reading comprehension dataset where answers consist of multiple discrete spans. As part of this, we proposed a method for classifying the semantic structure of answers, based on the semantic relation between answer spans. We also provide an expanded version of the dataset which includes unanswerable questions and single-answer questions, to make it both more challenging and more realistic. We additionally presented a number of models for multi-span QA extraction, and found that the best-performing model was sequence tagging-based, augmented by a span number prediction module and span adjustment module.

Abstract

Motivated by the need for accelerating text entry in augmentative and alternative communication (AAC) for people with severe motor impairments, we propose a paradigm in which phrases are abbreviated aggressively as primarily word-initial letters. Our approach is to expand the abbreviations into full-phrase options by leveraging conversation context with the power of pretrained large language models (LLMs). Through *zero-shot, few-shot*, and fine-tuning experiments on four public conversation datasets, we show that for replies to the initial turn of a dialog, an LLM with 64B parameters is able to accurately expand over 70% of phrases with abbreviation length up to 10, leading to an effective keystroke saving rate of up to 77% on these expansions. Including a small amount of context in the form of a single conversation turn more than doubles abbreviation expansion accuracies compared to having no context, an effect that is more pronounced for longer phrases. Additionally, the robustness of the models against typo noise can be enhanced through fine-tuning on noisy data.

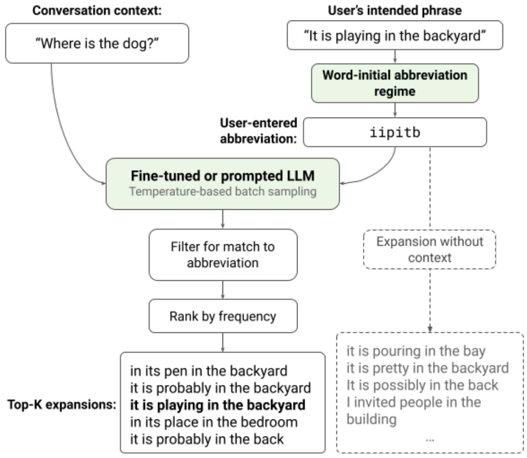

Figure 1: Our approach to abbreviation expansion based on an LLM with context compared to one without. The conversation context (e.g., a previous turn of conversation) along with the abbreviation of the intended phrase form the LLM's input. Sampled continuations from the model are filtered to discard those that do not match the abbreviation. Top-5 options after sorting by frequency are presented.

1 Introduction

The prevalent paradigm of text entry on computing devices is sequential typing of characters. Word completion and prediction can theoretically save up to 40-50% keystrokes when 3-5 predictions are provided (Trnka and McCoy, 2008; Fowler et al., 2015). This reduces the motor and cognitive demand of entering text, especially on devices where typing is difficult, e.g., phones. In AAC use cases such as eye-gaze keyboards for severely motor-impaired individuals, the cost per keystroke is so high that there is a desire to save as many keystrokes as possible. Gaze-typing requires the user to precisely control the direction and timing of gaze for each keystroke, resulting in an extremely low text-entry speed of 8-10 words per minute and severely limiting real-time communication (Waller, 2019). A text-entry paradigm with substantially higher keystroke saving rate (KSR) can reduce motor demand and thereby benefit AAC usage in real-time communication.

One potential paradigm is "SMS language", a spontaneously-evolved system for saving keystrokes in which each word is abbreviated as a single letter, such as in the well-known abbreviations *sg* for *sounds good* and *ttyl* for *talk to you later* (Anjaneyulu, 2013). SMS language features a high KSR (75-80%), but is limited by its small closed set of common phrases of mostly six words or shorter. Its abbreviation scheme is not applied to longer or less frequent phrases because such abbreviations would be hard for the recipient to decipher. For example, the abbreviation *iipitb* is highly ambiguous and may represent many possible phrases, e.g., *it is pouring in the bay* and *it is pretty in the backyard* (see Figure 1 for more examples). Some existing AAC systems support abbreviation expansion (e.g., Tobii), but are limited by hardcoded,

closed phrase sets.

The current study is based on the insight that although decoding open-set phrases from abbreviations is hard *without context* due to ambiguity, providing conversational context significantly constrains the space of likely phrases as shown by the example in Fig.1 (*it is playing in the backyard*). Hence we propose a high-KSR abbreviation scheme that focuses on conversational scenarios. We apply this scheme to three existing dialog datasets and create datasets for abbreviation expansion (AE).

This allows us to study whether LLMs, trained on web text including conversational data, can enable AE and benefit from added context. We take a 64B parameter LLM and compare zero-shot, few-shot, and fine-tuning performance on the AE task. Additionally, we simulate typing noise to study tolerance of the approach to typos. The main contributions of our work are:

1. Demonstrating the potential of abbreviation expansion using LLMs aided by conversational context for highly-abbreviated text entry, while measuring the effects of different amounts of context and different dialog turns.

2. Describing a high-KSR abbreviation scheme, a method for simulating typing noise, and conversation datasets based on these.

3. Comparing *zero-shot*, *few-shot*, and model fine-tuning approaches for the AE task and their tolerance to typo noise.

2 Related Work

Abbreviation expansion for text entry. Previous research on aiding text entry through AE used abbreviation schemes such as using only content words (Demasco and McCoy, 1992), discarding certain vowels and consonants (Shieber and Nelken, 2007), and flexible letter saving schemes (Pini et al., 2010; Adhikary et al., 2021; Gorman et al., 2021). Spontaneous abbreviations schemes primarily omit vowels, repeating consonants, last characters, and spaces, and lead to modest KSR (e.g., 25-40% in Willis et al. 2005, and 21% in Adhikary et al. 2021.) The low KSR of such schemes can be attributed to the implicit need for a human reader to decode the phrases without significant cognitive burden. N-gram models and neural language models (LMs) have been applied to expanding abbreviations for these relatively low-KSR schemes. By using LSTM models and context, Gorman et al. (2021) achieve a word error rate of 1.5%. Adhikary et al. (2021) report a 24.2% top-5 sentence error rate decoding abbreviations using an RNN to augment an n-gram LM. Our presented approach is a step towards using automation and context to expand abbreviations at a higher KSR that is close to that of SMS language.

Large language model prompting and fine-tuning. Our approach builds on prior work on LLMs including few-shot prompting, fine-tuning, and conversation models (Raffel et al., 2019; Brown et al., 2020; Adiwardana et al., 2020; Roller et al., 2020). We focus primarily on few-shot prompting (Brown et al., 2020) and fine-tuning (Ruder, 2021). *Few-shot* prompting uses a text description of a task along with a small number of examples for the task in the input text in order to elicit desired task responses from an LLM. In the *zero-shot* scenario, no examples are provided. Prompting involves no updates to the model parameters. Model fine-tuning requires more data compared to prompting, but often leads to higher task accuracy than prompt engineering (e.g., Austin et al. 2021; Lester et al. 2021). For our AE task, data for fine-tuning can be synthesized from existing conversation datasets based on an abbreviation scheme (Sec. 3). Thus, we explore both prompting and fine-tuning and compare their performance.

Assisting text entry with context. Textual contexts have been exploited to aid email writing (Kannan et al., 2016; Chen et al., 2019). For text entry in AAC, Wisenburn and Higginbotham (2008) demonstrated that providing noun phrases from a conversation partner's speech as selection options increases text-entry speed by 36.7%. Adhikary et al. (2019) concluded that with currently-attainable accuracy of ASR, partner speech can be valuable in improving language modeling for AAC text entry. Shen et al. (2022) used a fine-tuned GPT-2 model (Radford et al., 2019) to expand bags of keywords into full phrases in conversational contexts based on the ConvAI2 dataset (Dinan et al., 2020) and reported a KSR of 77% at a word error rate threshold of 0.65. Our current study differs from the previous studies in the following aspects. First, we provide an abbreviation scheme to allow greater user control over the exact phrase structure and wording. Second, we performed detailed quantitative analysis of the combined predictive power of state-of-the-art LLMs and context awareness.

3 Methodology

Abbreviation Scheme. Our abbreviation scheme differs from previous studies in that we optimize for KSR and do not expect a human reader to be able to easily decode the abbreviations. Additionally, it offers the benefit that each given phrase is mapped to a fixed abbreviation. The detailed rules for abbreviating phrases are:

1. Each word is abbreviated as its initial letter, unless the word contains an apostrophe (i.e., contraction), in which case the word is split at the apostrophe and the initial letters from the splits are taken (e.g., *can't –> ct*). This prevents abbreviations that are otherwise identical but semantically opposite (e.g., *can* vs. *can't*).
2. All letters in the abbreviation are lowercase.
3. Arabic numerals in a sentence are preserved (e.g., *see you at 10 o'clock –> sya10oc*).
4. Sentence-final punctuation are removed. Mid-sentence punctuation and special characters (e.g., *#* and *$*) are preserved to help constrain the structure of the sentence (e.g., *OK, but be quick. –> o,bbq*).

3.1 Datasets for context-aware AE

We study modified versions of existing dialog datasets, which we converted for the context-aware AE task. We also describe how we simulate typos.

Datasets. Table 1 summarizes the four datasets. We use their original train/dev/test splits in our experiments. The Turk Dialogues dataset (Vertanen, 2017) consists of crowd-sourced dialogs, each of which is exactly six turns in length. The dataset has typos and grammatical errors. We manually correct these and refer to the corrected dataset as **Turk Dialogues Corrected (TDC)**.[1] We use three more datasets, **DailyDialog** (Li et al., 2017), a dataset of everyday conversations; the **Cornell Movie Dialogues (CMD)** (Danescu-Niculescu-Mizil and Lee, 2011) based on movie scripts, and the **Turk AAC dataset (TAC)** (Vertanen and Kristensson, 2011). For evaluation on out-of-domain dialogs, we use the **TaskMaster-1 Self Dialogs (TMSD)** dataset (Byrne et al., 2019), a corpus of dialogs written by crowdworkers for task-oriented scenarios such as ordering pizza. TMSD is used only for evaluation and not for training or validation of the models. For DailyDialog, we remove 228 dialogues from the test split that are duplicate with conversations in the train split (see Appendix A), which leads to what we call the **DailyDialog Corrected (DDC)** dataset. No correction is applied to the other datasets. The TAC dataset contains only isolated phrases without any conversational-turn context. Hence we use it only for training. In all of our experiments, we combine data from the training splits of all four datasets when fine-tuning models. We perform evaluations on the TDC, DDC, CMD, and TMSD datasets. The TDC dataset is chosen as our primary benchmarks because of its strict six-turn dialog structure.

Modifications for the AE task. The above-mentioned datasets are typically used to study dialog generation. For our scenario, we convert each turn of the conversation in these datasets into the following canonical format:

Context:	{Content of the contextual turn}
Shorthand:	{Abbreviation of *next turn*}
Full:	{Expanded content of *next turn*}
Context:	{Would you like to sit down?}
Shorthand:	{n,imfsu}
Full:	{No, I'm fine standing up}

For the AE task, the context consists of one or more previous dialog turns. When context is absent (e.g., for the opening turn), the context part is omitted. For a multi-turn dialog, the nth (1-based) example contains the first (n - 1) dialog turns as the context as well as the shorthand and the full form of the nth turn. Thus, a 6-turn conversation yields six examples for the AE task. When multiple sentences are present in a single turn, we use only the first sentence for expansion; when a turn is used as context, all available sentences are used. Table 2 shows examples generated from all six turns of a dialog from TDC. Each dialog in the TDC, DDC, and CMD datasets yields several examples covering different amount of context. We create only 0-context-turn examples for the TAC dataset since it contains only isolated phrases.

Text-entry noise in AE datasets. As with our AE scheme, the introduction of noise to the datasets is also motivated by the AAC text entry use case, and in particular eye-gaze typing, which is error prone (Feit et al., 2017). Here, misclicks occur frequently and must be taken into account when designing a gaze-driven text entry system. In order to simulate the noise, we model eye-gaze typing as uncorrelated 2D Gaussian distributions around the intended key (Azenkot and Zhai, 2012). To

Full: {No, I'm fine standing up} . . . **5-turn context:** Context: {Would you like to sit down?} {No, I'm fine standing up} {Are you sure you don't want to sit down?} {Been sitting all day. Work was just one meeting after another.} {Oh, I'm sorry. I don't enjoy work days like that.}. Shorthand: {ifgtsmoab}. Full: {It feels good to stretch my legs a bit.}

Table 2: An example dialog and the generated AE examples without and with typo noise. The six-turn dialog is an excerpt from the train split of the TDC dataset. In the 3rd column, the typos in abbreviation are marked in red.

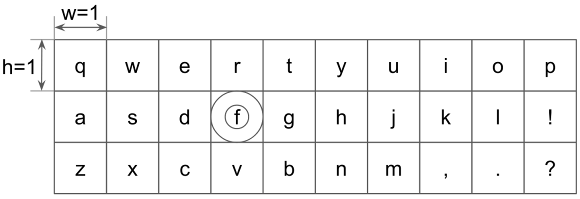

Figure 2: Keyboard layout for simulating noise in AE keypresses. The circles on the *f* key show 1σ around the mean for $\sigma \in \{0.3, 0.5\}$ in the 2D Gaussian distributions used to model typing noise.

simulate noise in the abbreviation input, we use a simplified rectangular-grid qwerty keyboard layout with 30 keys arranged in three rows and 10 columns. The keys are 1×1 squares with no gaps in between. The keystrokes for an intended key are drawn from 2D Gaussian distribution centered on the center of the intended key and standard deviations denoted σ equal in the two spatial dimensions. To model different levels of noise, we use three values of σ: 0.0 (i.e., no-typo baseline), 0.3, and 0.5, which corresponds to 0%, 13%, and 44% character error rates, respectively. Examples with simulated typos are shown in Table 2.

3.2 Large Language Model

One of our goals is to test whether *zero-shot* and *few-shot* prompting of LLMs are effective at the AE task without the need for supervised fine-tuning. Prompting is the method of eliciting desired task-specific responses from an LLM by including a natural-language description of the task and/or input-output examples of the task in the input string for an LLM, without altering the model's weights (Brown et al., 2020). Zero- and few-shot prompting differ in whether any examples are included in the prompt to the LLM. For this, we use a decoder-only Transformer language model (Vaswani et al., 2017) from the LaMDA (Thoppilan et al., 2022) family of models. Our experiments are based on the 64B parameter model, unless otherwise specified. This model has 32 Transformer layers, with $d_{model} = 8192$, $d_{ff} = 65536$, $h = 128$, $dk = dv = 128$. The model was pre-trained on 2.97B public web documents, Wikipedia, and dialogs. The training data was tokenized with the SentencePiece vocabulary (Kudo and Richardson, 2018) of size 32K. We call this the **BaseLLM**.

We also developed **fine-tuned versions** of this model for the AE task. The fine-tuning uses examples in the format as shown in Table 2. Since the BaseLLM is a decoder only model, and we use both the context and abbreviation as triggers to the model during inference, we modify the loss to only be calculated on the tokens of the AE target, i.e. the full form to be predicted in the pair of curly brackets after "Full:". For both training and inference, we split the characters in the abbreviation with spaces to force SentencePiece to use per-character IDs. We tune [2] two models, **FT-LLM** on the combined AE datasets without typos, and **FTnoise-LLM** on the version with simulated typos. Both use early stopping on a dev set consisting of combined examples from the dev splits of TAC and TDC (Table 1).

4 Experiments

Models. We use and compare the following models in our different experiment settings.

Look-Up Table (LUT). As a straight-forward, non-ML baseline, we compile a dictionary of 375,298 sentence-level abbreviations from the train splits of the datasets in Table 1. Each abbreviation maps to one or more phrases with their frequencies, leading to 447,249 unique abbreviation-sentence pairs. During evaluation, we map the query abbreviation to the top-5 expansion phrases (by frequency) by using the dictionary and breaking ties randomly.

BaseLLM (from Sec. 3.2). We study the BaseLLM in the *zero-shot* and *few-shot* (specifically *4-shot*) settings[3]. The four examples are selected from the train split of the TDC dataset (see Appendix B). We quantify the variability of the model on a sets of 856 4-example sequences from the train split of the TDC dataset. The best performing one on the dev set is denoted **BaseLLM***.

FTnoise-LLM tuned on simulated typos with noise level $\sigma = 0.3$ (see Appendix C), and **FT-LLM** tuned on AE data without noise as described in Sec. 3.2 are additional models we compare to.

T5 encoder-decoder. For comparison with smaller models, we use the T5 encoder-decoder **small** (60M), **large** (770M), and **3B** parameter models fine-tuned on AE data without noise, identical to FT-LLM.

We evaluate the fine-tuned models in the setting without any explicit natural language instructions (denoted "no instr.") unless mentioned otherwise. For all models, we perform random sampling with *temperature=1.0* over the *top_k=40* candidates with the highest logits at each step. We decode *128 samples* for each abbreviation unless otherwise specified. For each model and evaluation setting we report the standard deviations (SDs) of metrics over 3 repeated runs.

Abbv. length	**TDC (dev)**	**TDC (test)**	**DDC (test)**	**CMD (test)**	**TMSD (test)**
1-2	85 (5.1%)	105 (6.2%)	166 (21.5%)	2,003 (26.9%)	176 (22.9%)
3-4	324 (19.3%)	293 (17.4%)	168 (21.8%)	1,753 (23.6%)	109 (14.2%)
5-6	454 (27.0%)	439 (26.1%)	152 (19.7%)	1,396 (18.8%)	113 (14.7%)
7-8	339 (20.2%)	376 (22.4%)	118 (15.3%)	851 (11.4%)	129 (16.8%)
9-10	221 (13.2%)	218 (13.0%)	64 (8.3%)	528 (7.1%)	111 (14.4%)
1-10	1,423 (84.7%)	1,431 (85.2 %)	668 (86.5%)	6,531 (87.8%)	638 (82.9%)

Table 3: Datasets used for evaluation sliced by abbreviation lengths. Number of dialog turns in each range and their percentage (in parentheses) as compared to the total are noted.

Studies. For the BaseLLM, we study the variance in performance based on the prompt selection. For all the models, we sample multiple responses for each query, hence we study the effect of number of responses sampled on AE accuracy and latency. We also compare the performance of the models with varying amounts of conversation context and with no context. To study the effect of typos, we compare the performance of the models on the noise induced AE dataset. To measure the impact of model size on accuracy and latency, we also fine-tune and evaluate performance of the decoder-only LaMDA models with fewer than 64B parameters, specifically 4B, 8B, and 27B parameters. All these models were trained on the same data, so that the model size consitutes the only difference.

Evaluation. We only evaluate on conversation queries with abbreviation length ≤ 10 characters. This encompasses the majority (85%) of the dialog turns from the original dataset (Table 3). Where applicable, we prepend the following natural-language instruction to the model input for the AE task: *"Given previous turn(s) of conversation and acronym of reply, write the full phrase."*

Before calculating performance metrics, we filter the model's responses: we remove sentence-final punctuation, standardize whitespace to one space, lower-case, de-duplicate, and filter for precise match of the abbreviation. The responses that pass the filtering are sorted by descending count. For evaluation with noise, we do filtering to allow matches to nearby characters on the keyboard.

Metrics. Accuracy measures whether any response expansion exactly matches the ground truth (with standardized letter-casing and whitespace, and discarded final punctuation). Additionally, we measure **BLEU** score (Papineni et al., 2002) using the SacreBLEU library (Post, 2018) as a more fine-grained metric for the similarity between AE options and the ground truth. For both metrics, we report performance in the top-5 responses after they are sorted based on frequency.

Key Stroke Savings (KSR) measures the num-

---

[2] Appendix D and F provide details on fine-tuning and discuss the effect of character splitting.

[3] The prompts are prefixed with the natural language instruction "Given acronym, write the full phrase." when there's no context or "Given previous turn(s) of conversation and acronym of reply, write the full phrase." when there is context.

Table 4: Comparing models (from Sec. 4) on the AE task on turn-2 given turn-1 as context. We report accuracy and BLEU score at top-5, as percentages, std. dev. computed on 3 runs. Higher is better, values in **bold** are highest in each column.

ber of saved keystrokes compared to the full length of the phrase. Note, however, that AE succeeds only for a subset of the cases, while for others the top-5 options do not contain the intended phrase. Hence we compute two types of KSR:

KSR$_{all}$, computed on all phrases, is defined as

$$KSR_{all} = \begin{cases} \left(1 - \frac{L_{abbrev}}{L_{full}}\right) \times 100, & \text{if in top-5.} \\ \left(1 - \frac{L_{abbrev}+L_{full}}{L_{full}}\right) \times 100, & \text{otherwise.} \end{cases} \tag{1}$$

where L_{abbrev} and L_{full} are the character lengths of the abbreviation and full phrase, respectively. In other words, if a phrase has a matching option in the top-5, we calculate the KSR as the percentage of keypresses saved by using the abbreviation. If the ground truth is not in top-5, we add a penalty term (L_{full}) to account for the need to enter the phrase by starting anew character-by-character, leading to a *negative* KSR. KSR_{all} is calculated by averaging over all phrases in an experiment. **KSR**$_{success}$, is calculated by averaging over only the subset of phrases with exact matches and uses the first case in Equation 1.

5 Results

We present the main results comparing the models on all datasets in Table 4 and then highlight results from specific experiments.

The accuracy of LLMs at expanding word-initial abbreviations is enhanced by fine-tuning. Table 4 compares the performance of all the models on the abbreviation expansion (AE) task[4]. The data shown in the table are for AE on the 2^{nd} turn of a dialog that utilizes the 1^{st} turn as the context, which focuses on our main hypothesis regarding the effect of context on AE.

It's noteworthy that the BaseLLM*, which has seen just four examples in its prompt (unlike the other models), shows performance that exceeds the look-up table (LUT) baseline in many cases, demonstrating the versatility of LLMs. The higher scores of the LUT on DailyDialogs (DDC) and Cornell Movie Dialogues (CMD) datasets are indicative of the high percentage of similar phrases in the train and test sets of the datasets. Unsurprisingly, the fine-tuned models (FT-LLM , FTnoise-LLM, and T5 models) far outperform even the best *4-shot* BaseLLM*, achieving 74-77% top-5 exact-match accuracy on the TDC and DDC datasets in the absence of typo noises. The accuracies are lower on the CMD dataset (comprised of movie scripts.) The out-of-domain evaluation on the TaskMaster Self Dialogs (TMSD) dataset also showed accuracies lower than the TDC and DDC datasets, but higher than the results from the CMD dataset.

Fine-tuning and tolerance to noise. For conditions that involve simulated typo noise in the abbreviation input, FTnoise-LLM shows superior performance compared to other models (see the column "TDC-test + noise" in Table 4.) Interestingly, the performance of the BaseLLM* doesn't drop as much as any of the fine-tuned models - T5 or FT-LLM - in this setting. However, while FT-LLM still outperforms BaseLLM on the noisy abbreviations, the smaller T5 models fail to do so.

Context is critical for AE accuracy Figure 3 show how the AE accuracy of FT-LLM varies when different amounts of context from previous turns of the conversation are provided. Compared to having no context (dash-dotted curve), including just one previous turn of context (dashed curve) approximately doubles accuracy. Using the full context (all dialog turns from the 1^{st} to the $(n$-$1)^{th}$, solid curve) leads to further improvements indicating that prior turns carry useful information for the AE task.

Compared to the 1^{st} turn, AE under no context on subsequent turns (2^{nd}-6^{th}) shows significantly worse accuracy. This is due to the fact that the first turn consists of conversation starters that are easier to predict without context. Overall, irrespective of context, the accuracy of AE decreases as

---

[4] Appendix Tab. 8 reports performance on dev split of the TDC (TDC-dev) which was used for hyperparameter tuning.

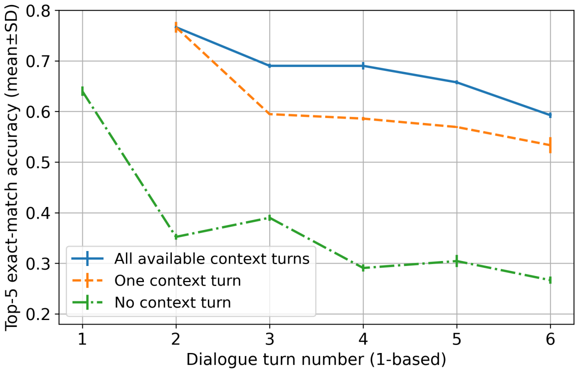

Figure 3: AE accuracy of FT-LLM, evaluated (inference only) with different amounts of input context (different curves) on different dialog turns (x-axis) on the TDC dev set. With all turns as context (solid blue curve) or just the previous turn as context (dashed orange curve), the model considerably outperforms the setting where no context is provided (dot-dash green) with the abbreviation query.

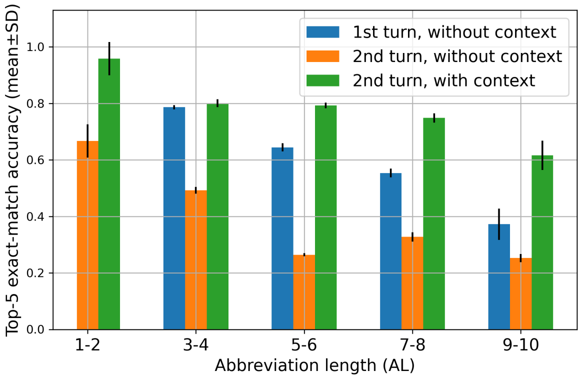

Figure 4: AE accuracy as a function of abbreviation length (AL). The results shown are from FT-LLM evaluated with no prompt. Different colors of bars show AE on the 1st and 2nd turns of the dialog in the TDC dev split, with 0 and 1 previous turn as the context. The 1-2 bin contains no 1st-turn examples.

the number conversation turns increases, indicating increasing difficulty in predicting the full phrases from the abbreviation as the dialogs progress. However, including full context during inference still achieves accurate expansions for 60%-70% of the cases on the later turns.

Effect of context is more pronounced on longer abbreviations. When performance is sliced by the abbreviation length (Figure 4), accuracy without context decreases sharply and nearly monotonically with increasing abbreviation length, regardless of whether it's the opening turn or the 2nd turn. With context however, the accuracy remains higher and decreases more slowly with abbreviation length, extending the approximately 80% or higher accuracy into longer phrase lengths.

Acc.@top-5	BaseLLM	FT-LLM
4-shot prompt	31.71 ± 4.83	74.43 ± 1.79
0-shot prompt	37.10 ± 1.38	77.10 ± 0.38
No instr.	14.00 ± 1.01	76.65 ± 1.06

Table 5: Mean and standard deviation of Accuracy@top-5 for the BaseLLM and FT-LLM over 856 different 4-shot prompts from the TDC train set, 3 repeated runs under 0-shot prompts (instruction only) and No instr. (i.e., neither instructions nor examples), based on AE on turn-2 given turn-1 as context.

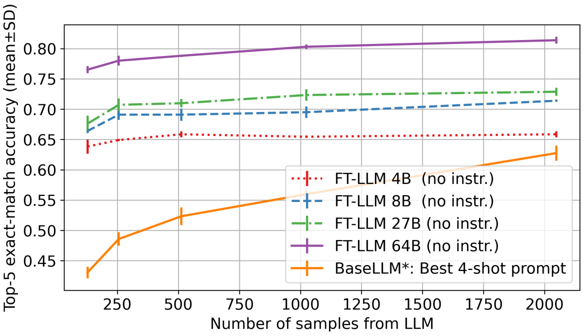

Figure 5: Increasing number of samples from the LLMs improves top-5 exact-match accuracy. FT-LLMs, even with fewest samples and smallest model size, outperform the BaseLLM*.

The variability and usefulness of few-shot prompts decreases after model tuning. Here we focus on how much the LLM benefits from prompting before and after fine-tuning. The first row of Table 5 compares AE accuracies from different 4-shot prompts on the TDC dataset for BaseLLM and FT-LLM. We use the 856 example abbreviation-expansion pairs from the train split of the TDC dataset, using four conversation examples for the prompt at a time. The BaseLLM shows a large variance in performance depending on the selected examples in the prompt by as much as $SD = 4.83$. The best 4-shot prompt for BaseLLM outperforms the 0-shot prompt, despite the fact that the average 4-shot prompt accuracy is lower. Therefore for BaseLLM we report the results from the best 4-shot prompt (BaseLLM*). By contrast, the fine-tuned model (FT-LLM) shows significantly lower prompt-related variance ($SD = 1.79$) in addition to a 2.3-fold increase in the mean accuracy. Moreover, FT-LLM is able to perform the AE task with only a natural-language prompt without examples (0-shot prompt) and even without any instruction ("No instr.") at average accuracies that are more than 1 SD above that of 4-shot prompting. The "No instr." setting is attractive due to its simplicity (no need to search for or hand-engineer a prompt) and reduced latency (due to shorter input prefix lengths). Given these results, we use the "No instr." as the default setting and for all other experiments on FT-LLM and FTnoise-LLM.

Dataset-split	AE task	KSR_{all}	$KSR_{success}$
TDC-test	1st turn (no context)	37.1 ± 0.19	76.8 ± 0.04
	2st turn (with context)	49.0 ± 0.99	73.5 ± 0.03
DDC-test	1st turn (no context)	20.0 ± 1.15	74.6 ± 0.04
	2st turn (with context)	49.0 ± 0.60	72.9 ± 0.04

Table 6: KSR computed on all phrases and only phrases with matching AE options. The data in this table is computed on the results from FT-LLM.

Increasing number of decoded samples improves accuracy at the cost of latency. Latency is important for interactive text-entry applications. During sampled decoding, the LLMs generate 128 continuations of length 16 tokens for a batch of prefix length 256 with a median latency of 0.568 s (interquartile range: 0.16 s).

This latency is close to typical dwell time of eye-gaze keyboards (Majaranta and Räihä, 2007) and hence could be acceptable for the eye-gaze typing use cases. Figure 5 shows the effect of increasing the number of continuations sampled from the LLMs. As expected, increasing sample count from 128 to 2048 improves top-5 accuracy for both BaseLLM* (with 4-shot prompts) and FT-LLM (no instr.). Improved accuracy comes at the cost of increased latency.[5] BaseLLM benefits significantly more from increasing sample count than FT-LLM.

Comparison of model sizes Figure 5 also compares fine-tuned models of different sizes (4B, 8B, 27B, and 64B). With model fine-tuning, the accuracy increases monotonically with increasing number of parameters. Interestingly, even with the fewest samples (128), fine-tuned models of all sizes outperform the larger (64B) model under *few-shot* learning. Amongst the encoder-decoder T5 models (Table 4) larger models significantly outperform smaller ones. As observed for the decoder-only models, the smaller fine-tuned T5 models outperform the few-shot BaseLLM in almost all cases except when the input consists of typos.

Keystroke saving rates. KSR can be considered as a proxy measure of usability of the approach for AAC use-cases. $KSR_{success}$ values are in the range of 73-77% for the 1st and 2nd turns of dialogs in the TDC and DDC datasets (Table 6), indicating that our proposed AE scheme does indeed lead to high KSRs. Values of KSR_{all} are lower, reflecting the penalties for when a perfect match is not achieved. However, with context, KSR_{all} approaches 50% and is higher compared to no context (20%-37%). Note that KSR_{all} is extremely conservative as it does not consider (a) the possibility of using the information already contained in the abbreviation to "recover from AE failure" (e.g., by letting the user specify a word and invoke the LLM again) or (b) the fact that word completion and prediction may still be utilized even if the user falls back to sequential text entry.

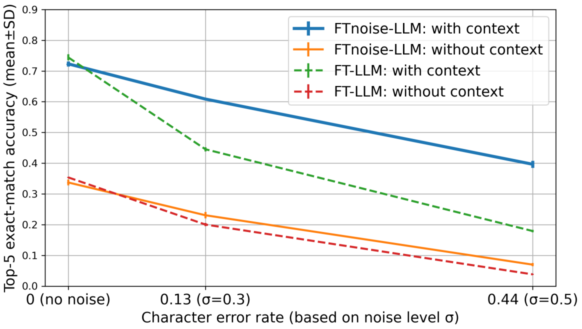

Figure 6: AE accuracy with and without typo noise in the input abbreviation. We compare the accuracies of the models fine-tuned without and with noise. Each curve shows the average top-5 accuracy in the 2nd turns of the dialogs in the test split of the TDC dataset.

Fine-tuning with noise improves typo tolerance. Figure 6 compares the AE accuracies of LLMs fine-tuned with and without noise (FTnoise-LLM and FT-LLM). While both models show decreasing AE accuracies with increasing amounts of typos, FTnoise-LLM is much more robust showing lesser drop in performance. Further, on noise-free inputs (σ=0), FTnoise-LLM shows only slight accuracy deterioration compared to FT-LLM. We also find that typo tolerance, for both FT-LLM and FTnoise-LLM, is more pronounced with context than without.

Cross-domain generalization. We use the TMSD dataset to compare and evaluate the performance of models on conversation domains not seen in training. In Table 4 we can observe that few-shot prompting does fall behind the simple Look-Up Table baseline on DDC and CMD datasets. However, when we evaluate the models on cross-domain TMSD dataset of dialogs we can observe that the fine-tuned and few-shot models do generalize better to unseen domains and perform better than the baseline look-up.

6 Discussion

Qualitative analysis of AE failures. As indicated by the relatively high BLEU scores in Table 4

---

[5] Note, that it is possible to cut down latency by parallelizing sampling, however this might increase hardware requirements at inference time.

($> 80\%$), there are many expansions in the top-5 options that are "near misses". Appendix Table 7 shows a few examples of such near misses, in which the options differ from the the ground-truth phrase by only a semantically-similar word (e.g., “yes” vs. “yeah”, “head out” vs. “head over”.) Future studies need to investigate the frequency and UX acceptability of such near-miss AE options. But their existence implies that exact-match accuracy reported above slightly underestimates the practical effectiveness of the models. Another category of AE failures involve phrases that contain certain proper nouns. The last four examples in Table 7 show such cases in which the model correctly expands all the words but a proper noun. When such errors occur, the model tends to predict more common proper nouns, which is likely a reflection of the higher frequency of the predicted nouns in the model’s pre-training and fine-tuning datasets.

The benefit of AE relative to sequential text entry. Word completion and prediction incur scanning cost: users scan the options in order to determine whether any of them match their intention, which has a detrimental effect on speed that needs to be overcome by the high quality of the options (Trnka et al., 2009). Although the speed of AE-based text entry remains to be quantified in future studies, we point out that: (1) AE removes overhead of scanning for options in between keystrokes, (2) there are fewer characters to examine or correct when typing, both of which may offer speed-ups in addition to the higher KSR afforded by AE.

Although the current study is motivated by and focuses on the AAC use case, our paradigm of abbreviated text entry may be applicable to text input on touch screens as well. The AE approach of the current study can be regarded as a variation of contextual prediction of user text (Kannan et al., 2016; Chen et al., 2019) that affords greater flexibility in message content at the trade-off of requiring specification of the message with a small number of keystrokes.

Future directions. We found fine-tuning to be significantly better than prompting in terms of (a) accuracy (for both scenarios with and without typo-noise) and also (b) exhibit lower latency as we achieve better results with fewer samples. Future work should investigate the differences in latencies between the encoder-decoder architecture and decoder-only models. For training efficiency, instead of fine-tuning, it will also be worth investigating strategies such as prompt tuning (Lester et al., 2021) that continue to keep the model frozen, but learn some additional parameters for the task.

Even in the best case scenario models can fail to find accurate expansions[6] among the top-5 options. Recovering from such failures is important for AAC use cases. Future studies should consider options for partial specifications of one or more words or selection of some words from the available options. Once the recovery from failure is proven in offline analysis, user studies are required to validate and quantify the actual benefit of the AE text-entry paradigm in lab and real-life settings. Integration with UI approaches is also an essential direction, e.g., speeding up eye-gaze typing such as cascading dwell time and dwell-free paradigms (Mott et al., 2017; Kristensson and Vertanen, 2012).

7 Conclusion

In this work we proposed a high-KSR form of abbreviation expansion to dramatically save keystrokes for severely-disabled users. We use it to synthesize three datasets for the AE task. Based on extensive experiments using few-shot prompting and model tuning we demonstrate that across the datasets, fine-tuned LLMs can accurately predict expansions for 48-77% of phrases that are replies to initial turns of dialogs and exhibit KSRs in the range of 73-77% for the correctly predicted expansions, thus pointing at a promising direction for future user studies of contextual and abbreviated text entry based on LLMs. Models evaluated with conversation context show significantly higher accuracy than without, thus supporting our hypothesis that context is the key to effective abbreviated text entry in conversational settings. Furthermore, fine-tuning with simulated typos substantially improves tolerance to noise in abbreviation.

8 Acknowledgements

We would like to thank Shumin Zhai and Michael Terry for feedback on a draft of this work, Yanping Huang for pointers on model inference, as well as James Stout, Bob MacDonald, Julie Cattiau, and Maarten Bosma for their support. We are grateful to Team Gleason for their active involvement and feedback in the development of this work.

9 Ethical Considerations, Limitations, and Societal Impact

Accelerating augmentative and alternative communication (AAC) can enhance quality of life of people with extremely limited mobility by facilitating increased social participation and independence (Caligari et al., 2013). While the benefits of AE may be large for this population, we note that this approach may have risks.

The primary risk of AE is errors in expansions that substantially misrepresent the intent of the speaker in a way that might cause harm to themselves or others (e.g., failure to correctly convey critical health information, insertion of offensive language.) The abbreviation expansions may also reflect biases in the underlying language model (e.g., perpetuating stereotypes by more frequently suggesting male pronouns than female, Weidinger et al. 2021.)

A more subtle risk is when expansions miss the ground-truth phrase closely (see Table 7), which may accurately convey content but reduce the speaker's sense of autonomy and authentic self-expression. Prior work (e.g., Kane et al. 2017) has shown that people with ALS highly value AAC that preserves and facilitates authentic identity expression. Providing speakers with multiple AE options to choose from and requiring user confirmation before voicing an expansion are design options that can mitigate these risks. Model fine-tuning to improve safety or personalization to the end-user's communication style are additional risk-mitigation approaches.

Beyond enhancing communication speed, another intended benefit of AE is the potential to reduce fatigue associated with gaze-based AAC by reducing keystrokes; however, a risk of our system is that if errors in AE are frequent for a given user (perhaps due to eye tracker miscalibration or long-tail abbreviation use) then these savings could be outweighed by the need to correct errors, inadvertently increasing fatigue. User studies to better understand error rates in practice, as well as future work designing interfaces to simplify AE error correction, are important for minimizing this risk. Similarly, our abbreviations scheme's simple design based on first letters aims to minimize cognitive load; however, user studies with the target population using instruments such as NASA's Task Load Index[7] would be required to verify that AE does not cognitively strain end-users.

Appendix

A Removal of duplicate dialogs from the DailyDialog dataset

We observed that the DailyDialog dataset (Li et al., 2017) contains a significant number of dialogs in its dev (validation) and test splits that are identical or nearly identical to the dialogs found in its train split. We determined two dialogs to be duplicate by using the following criterion:

1. If both dialogs consist of the same number of turns and the corresponding turns are all identical (case-insensitive), or
2. If both dialogs consist of the same number of turns and there are three or more turns at which both dialogs contain identical text (case-insensitive).

See the file daily_dialog_deduplications.csv in Supplemental Data for a list of the 177 dialogs in the dev split and the 228 dialogs in the test splits that are found to be duplicates with the train split and hence are removed from our DailyDialog Corrected (DDC) dataset.

B 4-*shot* examples for BaseLLM*

We select four consecutive dialogues from the 859 examples from train split of the TDC dataset (Vertanen, 2017) while varying the starting conversation, which yields $859 - 4 + 1 = 856$ different 4-shot prompt sets.

C Tuning on noisy data vs. accuracy

Preliminary experiments have shown that $\sigma = 0.3$ is a good trade-off between accuracy gains on noisy data and losses on non-noisy data.

D Model fine-tuning details

Our model fine-tuning uses the AdaFactor optimizer (Shazeer and Stern, 2018). The nominal batch size 16 is made more efficient through example packing (Raffel et al., 2019), leading to an average effective batch size of approximately 200 examples under a maximum sequence length of 1024 tokens. We used TPUv3s (Jouppi et al., 2018) with a configuration of 4x8 for the LLM fine-tuning. Our fine-tuning recipe applies a constant, low learning rate of 5×10^{-5} and a dropout rate of 0.2, which helps to prevent early overfitting. Early stopping is based on a dev set consisting of combined examples from the dev splits of the TAC and TDC datasets. We find the best checkpoint after 2100 and 1800 training steps for the FT-LLM and FTnoise-LLM models, respectively, which amounts to approximately 1-1.2 epochs of training. We ran a small set of hyperparameter tuning experiments, varying batch size, learning rate and dropout and chose the best setting based on the TAC+TDC dev set.

E Computation cost

Fine-tuning of the 64B LLM uses TPU v3 with a 4x8 configuration, i.e., 32 TPUs. FT-LMM and FTnoise-LLM are each trained for approximately 2100 and 1800 steps, respectively. The training time is approximately 3 hours. This leads to a model fine-tuning budget of 32 x 3 = 96 TPU * hour per model.

Evaluation and inference on the 64B LLM uses TPU v3 with a 4x4 configuration, i.e., 16 TPUs. Each example (batch size = 128 samples) takes 0.653 s. This leads to $16 \times 0.568/128 = 0.071$ TPU × second per sample.

F Splitting characters in abbreviations.

Pilot experiments showed the importance of programmatically inserting spaces between characters in the abbreviations. Since the vocabulary used by the LaMDA models is fairly large (32k entries), unless we enforce character-level splitting, subsequences of multiple characters in many abbreviations will be combined into spurious tokens, leading to slightly reduced AE accuracy.

G Recovery from failure - analysis

In the best scenario of replying to a question, the fine-tuned LLM is capable of predicting the correct phrase expansion approximately 81% of the times with top-5 options and sufficient sampling (Figure 5). Hence the model will fail to find the correct expansion at least 19% of the cases.

H Inference latencies of different LaMDA model sizes

In Figure H we compare the latencies during inference time for the decoder-only models of different sizes. Compared to the 4B model, the 27B model shows 1.5x latency, while the 64B model shows 2.2x latency. While the latency increase is quite significant, this analysis shows that we cannot substitute the 64B model with a smaller model (e.g.,

Abstract

NLP models trained on text have been shown to reproduce human stereotypes, which can magnify harms to marginalized groups when systems are deployed at scale. We adapt the Agency-Belief-Communion (ABC) stereotype model of Koch et al. (2016) from social psychology as a framework for the systematic study and discovery of stereotypic group-trait associations in language models (LMs). We introduce the sensitivity test (SeT) for measuring stereotypical associations from language models. To evaluate SeT and other measures using the ABC model, we collect group-trait judgments from U.S.-based subjects to compare with English LM stereotypes. Finally, we extend this framework to measure LM stereotyping of intersectional identities.

1 Introduction

Stereotypes are abstract and over-generalized pictures in people's minds that capture attributes about groups of people in the complex social world (Lippmann, 1965). They influence people's thoughts and behaviors, and allow people to make predictions beyond their personal experience or information given (Bruner et al., 1957; Wheeler and Petty, 2001). Stereotypes are also entwined with the production of prejudice, discrimination, and in-group favoritism (Stangor, 2014; Jackson, 2011). A long line of research in social psychology has established models of generic dimensions that estimate people's stereotypes of social groups (Koch et al., 2016; Fiske et al., 2002, i.a.). We build on the Agency Beliefs Communion (ABC) model, which measures stereotypes toward a social group with respect to 16 traits in three dimensions: Agency/Socioeconomic Success, Conservative–Progressive Beliefs, and Communion (§2); an analysis of the group "man" across 32 traits (16 opposing dyads) is shown in Figure 1.

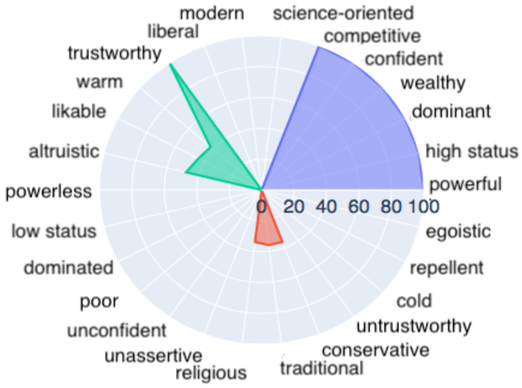

Figure 1: Crowdsourced analysis of the social group "man" under the ABC model (Koch et al., 2016). Colors: purple=agency, red=belief, green=communion.

Pre-trained language models (LMs) encode correlations between social groups and traits, like associating the group "Muslim" with the trait `threatening`, or "man" with `confident` (e.g., Bender et al., 2021; Nozza et al., 2021; Hovy and Yang, 2021). We conduct a systematic study of social stereotypes in contextualized English masked LMs, grounded in group-trait associations from the ABC model. To capture the group-trait associations in the LM, we first assess two previously proposed word association tests and also propose a new measurement: the sensitivity test (SeT) (§3).

To evaluate the degree to which two LMs—BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019)—align with human stereotype judgments, we design a human study for collecting group-trait judgments (§4). We show that our measure, SeT, best aligns with human judgements on group-trait associations and find that, in general, the association from language models have moderate alignment with human judgements.

Finally, with the best-aligned association measurement, we extend the ABC approach to study

Agency	Beliefs	Communion
powerless ↔ powerful	religious ↔ science-oriented	untrustworthy ↔ trustworthy
low status ↔ high status	conventional ↔ alternative	dishonest ↔ sincere
dominated ↔ dominating	conservative ↔ liberal	cold ↔ warm
poor ↔ wealthy	traditional ↔ modern	benevolent ↔ threatening
unconfident ↔ confident		repellent ↔ likable
unassertive ↔ competitive		egotistic ↔ altruistic

Table 1: List of stereotype dimensions and corresponding traits in the ABC model (Koch et al., 2016).

LM stereotypes on intersectional groups (§ 5.2). Due largely to the difficulty of extending current approaches for measuring stereotypes in LMs to large numbers of groups, most current approaches only study isolated groups, despite the fact that people's social identities are multifaceted (Ghavami and Peplau, 2013). Because our approach is generalizable to unstudied groups, we take a step towards exploring stereotypes of intersectional identities, finding some correspondence between model behavior and the literature on intersectional stereotypes.

2 Background and Related Work

People's impressions of the world and the actions they take are guided by their stereotypes. To systematize this observation, the field of social psychology has proposed models of stereotypes, including traits that can coordinate social behaviors to serve as fundamental dimensions of stereotyping. Some models are designed to focus on social evaluation towards individual persons (Abele and Wojciszke, 2014), ingroup members (Ellemers, 2017; Yzerbyt, 2018), or a small set of outgroups (Fiske et al., 2002); the Agency Beliefs Communion (ABC) model—whose traits are designed to distinguish groups—is suited for a larger set of U.S. social groups (Abele et al., 2020). The ABC model takes a data-driven strategy to select a set of traits by eliminating those that are less effective in capturing stereotypes. The list contains 16 pairs, where each pair represents two polarities (see Table 1), categorized into three dimensions: agency/socioeconomic success, conservative-progressive beliefs, and communion/warmth.

Ours is far from the first work to assess stereotypes in language models, and has both advantages and disadvantages compared to previous approaches (see Table 2). Past work has generally taken one of two approaches. The first approach tests systems with hand-constructed templates like "The `[group]` is ☐", where `[group]` ranges over social groups (e.g., "woman" or "Hispanic"), and ☐ represents a "masked word" and ranges over occupations ("a professor" or "a nurse") (e.g., Bolukbasi et al., 2016; May et al., 2019) or associations drawn from implicit association tests (IAT) (e.g., pleasant/unpleasant words or career/family-related words) (e.g., Caliskan et al., 2017; Guo and Caliskan, 2021). In Table 2 we refer to these as "unnatural" prompts. The second approach collects more natural sentences containing stereotypes, either by web crawling with crowdworkers annotations for social bias (Sap et al., 2019) or by having crowdworkers directly write stereotyping sentences (Nangia et al., 2020; Nadeem et al., 2020).

Measurement	Generalizes	Grounded	Exhaustive	Natural	Specificity
Debiasing (Bolukbasi et al.)	✓				✓
CrowS-Pairs (Nangia et al.)			✓	✓	✓
Stereoset (Nadeem et al.)			✓	✓	✓
S. Bias Frames (Sap et al.)			✓	✓✓	✓
CEAT (Guo and Caliskan)	✓	✓		✓✓	
This Work	✓	✓	✓✓		

Table 2: Comparison with previous work: Generalizes denotes approaches that naturally extend to previously unconsidered groups; Grounded approaches are those that are grounded in social science theory; Exhaustiveness refers to how well the traits cover the space of possible stereotypes; Naturalness is the degree to which the text input to the LM is natural (we consider naturally occurring web scraped data as "very natural" and crowdsourced sentences as "somewhat natural."). Specificity indicates whether the stereotype is specific or abstract.

In our work, we take the first approach with traits from the ABC model, using prompts. The advantage of this approach is that the templates and the traits are completely controlled and are easy to extend to other social groups. The second approach is harder to control, which also leads to significant annotation challenges (Blodgett et al., 2021). Using natural sentences limits generalizability, as it requires a unique collection of prompts (and embedded traits) for each social group; in contrast, the prompt-based approach easily generalizes to any plausible group, especially when based on a theoretically grounded framework like ABC or IAT.

An advantage of our work is that the ABC traits

Domain	Groups
Gender/ sexuality	*man*, *woman*, *non-binary*, *trans*, *cis*, gay, lesbian
Race/ ethnicity	*Black*, *White*, *Hispanic*, *Asian*, *Native American*
Religion	*Jewish*, *Muslim*, *Christian*, *Buddhist*, *Mormon*, Catholic, Amish, Protestant, Atheist, Hindu
Socio-economic	*wealthy*, *working class*, *immigrant*, *veteran*, *unemployed*, refugee, doctor, mechanic
Age	*teenager*, *elderly*
Disability status	*blind*, *autistic*, *neurodivergent*, Deaf, person with a disability
Politics	Democrat, Republican
Nationality	Mexican, Chinese, Russian, Indian, Irish, Cuban, Italian, Japanese, German, French, British, Jamaican, American, Filipino

Table 3: Social groups domains and corresponding social groups used for the model experiments and human experiments. Single groups for human experiments are highlighted with italic font style.

are more exhaustive in stereotype coverage with verification from social psychological experiments. The ABC model covers three dimensions with 16 traits, which are consensual, spontaneous, and have been tested using expansive range of social groups (Koch et al., 2021). They used a carefully designed data-driven approach to gather people's fundamental dimensions of social perceptions with as little sampling bias as possible. Thus the resulted 16 traits cover most stereotypes.

Nevertheless, the main trade-off of our approach is that the testing data are not as natural and specific as other approaches. Although we carefully pick and adjust the templates and the form of the social group terms so that the testing sentences are grammatically correct, they are likely not representative of sentences seen in the real world or in the training data of the language models. Further, while our approach has the benefit of near-exhaustive coverage of potential stereotypes, this comes at a cost: the traits we consider are much more high level (e.g., "repellent") than more fine-grained stereotypes collected by other means (e.g., the angry Black woman stereotype (Collins, 2002))—this approach therefore trades coverage for specificity.

3 Measuring Stereotypes in LMs

Our goal is to measure stereotypes in (masked) LMs, and compare them to stereotypes elicited from people. [2] In §4 we describe our approach for eliciting human judgments of group-trait affinities; here we describe how we measure these in LMs. Previous work has proposed various ways to measure word associations in LMs, including increased log probability score (ILPS) and contextualized embedding association test (CEAT), both of which we summarize below. Finally, we present a new measurement which we call the Sensitivity Test (SeT), which adapts concepts from active learning to the task of measuring a LM's associations.

3.1 Measurements of Word Associations

Increased Log Probability Score (ILPS) quantifies word associations in language models through masked word probabilities. It calculates the association score with a pre-defined template, "`[Group]` are □." (Kurita et al., 2019), where □ is a masked token. For example, given a group "Asian" and a trait `smart`, $P(\text{“}Asian\text{”}, \texttt{smart})$ measures the probability of `smart` given "Asians" by filling in the template. Since this probability is affected by the prior probability of `smart`, ILPS normalizes this probability by the "prior" probability of the trait given a masked group, as below:

$$\text{ILPS}(\texttt{g}, \texttt{t}) = \log \frac{P(\square = \texttt{t} \mid \texttt{g} \text{ are } \square.)}{P(\square_2 = \texttt{t} \mid \square_1 \text{ are } \square_2.)}$$

Intuitively, ILPS measures how much each group raises the likelihood of a trait filling in the template. One can easily show that this equivalent to the *weight of evidence* of the trait in favor of the hypothesis that the group is the target: $s(\texttt{g}, \texttt{t}) = \text{woe}(\texttt{g} : \texttt{t} \mid \text{template})$ (Wod, 1985).

Contextualized Embedding Association Test (CEAT) estimates word associations with word embedding distances (Guo and Caliskan, 2021) . Intuitively, CEAT measures whether some groups are closer to certain traits in a latent vector space. Given two sets of target words defining groups X, Y (e.g. $X_{\text{male}} = \{$"man", "father", ...$\}$, $Y_{\text{female}} = \{$"woman", "mother", ...$\}$) and two sets of polar traits A, B (e.g. $A_{\text{pleasant}} = \{$ `love`, `peace`, ...$\}$, $B_{\text{pleasant}} = \{$ `evil`, `nasty`, ... $\}$), CEAT computes the effect sizes of the difference between X and Y being closer to A than B and corresponding p-values. Since contextualized word representations are affected by the contexts around the word, for each word in the four word sets, CEAT randomly samples 1000 sentences from Reddit, in which the word appears, and uses these to approxi-

Singular The/That/A `[group]` is □.	**Plural** Most/Many/All `[group]` are □. / `[Group]` are □.
Declarative `[Group]` are □.	**Interrogative** Why are `[group]` □?
Non-adverbial `[Group]` are □.	**Adverbial** `[Group]` are very/so/mostly □.
Fact `[Group]` are □.	**Belief** I/We/Everyone/People believe/expect/think/know(s) that `[group]` are □.
Fact `[Group]` are □.	**Social Expectation** `[Group]` are supposed to be/should be/are seen as/ought to be/are expected to be □.
Group-first `[Group]` are □.	**Trait-first** The □ people are `[group]`.
Non-comparative `[Group]` are □.	**Comparative** `[Group]` are more likely to be □ than others.

Table 4: Template Variations.

mate the true effect size as below:

$$\mathrm{CEAT}(A,B,X,Y) = \frac{\hat{\mathbb{E}}_{\mathtt{g}\sim X} s(\mathtt{g},A,B) - \hat{\mathbb{E}}_{\mathtt{g}\sim Y} s(\mathtt{g},A,B)}{\hat{\mathbb{S}}_{\mathtt{g}\sim X\cup Y} s(\mathtt{g},A,B)}$$

$$s(\mathtt{g},A,B) = \hat{\mathbb{E}}_{\mathtt{t}\sim A} \cos(\vec{\mathtt{g}},\vec{\mathtt{t}}) - \hat{\mathbb{E}}_{\mathtt{t}\sim B} \cos(\vec{\mathtt{g}},\vec{\mathtt{t}})$$

$\hat{\mathbb{E}}$ (resp. $\hat{\mathbb{S}}$) is the empirical expectation (resp. standard deviation), and $\vec{\mathtt{x}}$ denotes the embedding of $\mathtt{x}$.

In our setting, since we care about social bias among multiple groups rather than the difference between two groups, we modify the CEAT to calculate the effect size of the distance difference between $\mathtt{g}$ with A and B for each group as below:

$$\mathrm{CEAT}(\mathtt{g},A,B) = \frac{\hat{\mathbb{E}}_{\mathtt{t}\sim A} \cos(\vec{\mathtt{g}},\vec{\mathtt{t}}) - \hat{\mathbb{E}}_{\mathtt{t}\sim B} \cos(\vec{\mathtt{g}},\vec{\mathtt{t}})}{\hat{\mathbb{S}}_{\mathtt{t}\sim A\cup B} \cos(\vec{\mathtt{g}},\vec{\mathtt{t}})}$$

Sensitivity Test (SeT) is a new approach we propose to measure word association for social bias in language models, inspired by ideas from active learning (Beygelzimer et al., 2008). The intuition of SeT is that even though a model assigns the same probability to two different words, the robustness of those two probabilities may be different. For example, both $p(\texttt{competent}|\textit{“Blind people are }\square\textit{.”})$ and $p(\texttt{kind}|\textit{“Men are }\square\textit{”})$ might be low. However, the language model may well not have seen many examples with blind people, as opposed to the presumably very large number of examples of men. In this case, a small number of examples may be sufficient to alter the model's predictions about blind people, while a larger number would be required for men. SeT captures the model's confidence in a prediction by measuring how much the model weights would have to change in order to change that prediction. Specifically, SeT computes the minimal change to the last-layer of the language model so that a given trait becomes the highest probability trait (over the full vocabulary).

For example, consider the template “The `[group]` is □.” with the group “woman” and the trait `incompetent`. Let $\boldsymbol{\ell}$ be the logits at □ when the input is “The woman is □.”, and let $\mathtt{t}$ be the index of `incompetent` in $\boldsymbol{\ell}$ (so that $\ell_{\mathtt{t}} = p(\texttt{incompetent} \mid \text{context})$). Let $\mathbf{h}$ be the last hidden layer before the logits, and let $\mathbf{A}$ be the matrix of the last linear layer so that $\boldsymbol{\ell} = \mathbf{A}\mathbf{h}$. SeT computes the minimal distance between $\mathbf{A}$ and some other matrix $\mathbf{A}'$ so that $\mathtt{t}$ is the top word among the new logits $\boldsymbol{\ell}' = \mathbf{A}'\mathbf{h}$. Formally:

$$\mathrm{SeT}(\mathtt{g},\mathtt{t}) = \log \frac{\Delta(\mathbf{A},\mathbf{h}_{\mathtt{g}},\mathtt{t})}{\Delta(\mathbf{A},\mathbf{h}_{\square},\mathtt{t})}$$

where $\mathbf{h}_{\mathtt{g}}$ is the penultimate layer on input $\mathtt{g}$

$\mathbf{A}$ is the matrix before the logits

$$\Delta(\mathbf{A},\mathbf{h},\mathtt{t}) = \min_{\mathbf{A}'} \|\mathbf{A}' - \mathbf{A}\|_2^2$$

$$\text{s.t. } (\mathbf{A}'\mathbf{h})_{\mathtt{t}} \geq (\mathbf{A}'\mathbf{h})_{\mathtt{t}'} + \gamma, \forall \mathtt{t}' \neq \mathtt{t}$$

for a fixed margin $\gamma > 0$, which we set to 1. SeT returns the *negative distance* as measure of the association between the corresponding group and trait, normalized by a prior akin to ILPS. This optimization problem does not (to our knowledge) admit a closed form solution; we solve it iteratively using the column squishing algorithm (Bittorf et al., 2012; Daumé and Kumar, 2017).

3.2 Implementation details

We test the above measurements on both BERT and RoBERTa pretrained large models from an open-source HuggingFace[3] library.

---

[3] https://huggingface.co/models

Social groups. Table 3 lists all the individual social groups we cover in this work. We manually construct the list by combining and picking groups from the list of social groups from Sotnikova et al. (2021) and Koch et al. (2016) and also adding social groups we think are stereotyped in U.S. culture.

Traits. We use the 32 adjectives of the 16 traits from the ABC model (Table 1). For each traits, we calculate the score of its left-side adjective from its right-side adjective: $S_{\texttt{powerless-powerful}}(\texttt{g}) = S(\texttt{g}, \texttt{powerful}) - S(\texttt{g}, \texttt{powerless})$, where S is one of the scores from §3.1.[4]

Templates. ILPS and SeT both require templates in calculating scores. We thus carefully construct a list of templates (Table 4) that covers multiple grammatical and semantic variations, inspired by work investigating harmful search automatic suggestions (Hazen et al., 2020). We find that different model structure requires different templates in order to bring up stereotypes that correlate with human data. See §5 for evidence.

Subwords. Due to the nature of BERT and RoBERTa's tokenizers, some of the adjectives are divided into multiple subwords. This is problematic because all the measurements compute their scores at token level. Neither ILPS nor CEAT deals with subwords directly: in their released implementations, they either take the first or the last sub-token of the word. To remedy this, we adjust the ILPS measurement (denoted as ILPS*) to properly compute the probability of traits in context using the chain rule across subwords. For SeT, we calculate the sensitivity score for each subword individually and take the maximum SeT score as the SeT score for the word, which effectively computes a *lower-bound* on how much the model parameters would need to change. We did not modify CEAT's measurement as it is not clear what is the best way to compute comparable word embeddings for words that consist of multiple subwords.

4 Human Study

In the previous section, we describe how we compute associations between groups and traits in language models.[5] In this section, we assess stereotypes of social groups through groups-trait association, like in Figure 1. We adopt this approach because it is widely used to evaluate group stereotypes in social psychology field (Fiske et al., 2002; Koch et al., 2016). It also aligns with Lippmann (1965)'s theory of stereotypes that they are abstract pictures in people's head. We broadly follow procedures from previous social psychology papers to collect human evaluation on social groups.

Survey Design. We recruit participants from Prolific[6]. Each participant is paid \$2.00 to rate 5 social groups on 16 pairs of traits and on average participants spend about 10 minutes on the survey. This results in a pay of \$12.00 per hour. Maryland's current minimum wage is \$12.20 [7]. First, participants read the consent form, and if they agree to participate in the study, they see the survey's instructions. For each social group, participants read "As viewed by American society, (while my own opinions may differ), how `[e.g., powerless, dominant, poor]` versus `[e.g., powerful, dominated, wealthy]` are `<group>`?" They then rate each trait with a 0-100 slider scale where two sides are the two dimensions of the trait (e.g. `powerless` and `powerful`). Each annotated group is shown on a separate page, and participants cannot go back to previous pages. To avoid social-desirability bias, we explicitly write in the instruction that *"we are not interested in your personal beliefs, but rather how you think people in America view these groups."*

Participant Demographics. At the end of the survey we collect participants' demographic information, including gender, race, age, education level, type of living area, etc. Our participants represent 26 states, with 63.3% from California, New York, Texas, or Florida; the gender breakdown is 48.2% male, 49.6% female, and 2.2% genderqueer, agender, or questioning; and skew young, with over 96% at most 40 years old; and with racial demographics that approximately match the U.S. census. For more details on demographics, see Appendix E.

Quality Assurance. Ensuring annotation quality in a highly subjective task is a challenge, and common approaches in NLP like having questions where we "know" the answer as tests, measuring

---

[4] In preliminary experiments, when calculating the score for each adjective, we considered including 1-3 additional adjectives by averaging their scores to improve robustness and mitigate ambiguity. The full list is in Appendix Table A7. However, we found that this did not improve correlations, so we reverted to using the 32 adjectives from the ABC model.

[5] Approved by our institutional IRB, #1724519-1.

[6] `https://www.prolific.co/`

[7] `https://www.minimum-wage.org/maryland`

interannotator agreement, and calibrating reviewers against each other (Paun et al., 2018) do not make sense here. Yet, it is still important to ensure the annotation quality. After much iteration, we include three test questions, and warn the participants at the beginning that there are test questions.

1. After the first group, participants must name the group they just scored.
2. After the second, participants must list one trait they just marked high and one marked low.
3. The fifth (final) group is a repetition of one of the four groups they previously scored.

We discard annotations with incorrect answers to either of the first two questions. For the third test, we compute intra-annotator (self) agreement and discard annotations with accuracy-to-self lower than 80%. For each group we collect 20 annotations that pass our quality threshold. In total, we collected annotations from 247 participants, with 133 passing the quality tests (suggesting that having such tests is important). The 114 annotations that did not pass tests were excluded from our dataset, but all 247 participants were paid.

Social groups and traits. The social groups we used for the human study are highlighted in Table 3. This table contains only single groups used for the model § 3 and human experiments. We collect annotations for 25 social groups within 5 domains, across all 16 pairs of traits.

5 Results

In this section we present results on correlations between human and model stereotypes for individual groups, comparing across different measurements, including our proposed measurement, SeT (§5.1). Next, we analyze how model scores change for intersectional social groups. We consider several possible factors that may influence the score changes such as identity order, some domain domination, and consider emergent traits (§5.2).

5.1 Correlation on Individual Groups

Before we answer the question of how language model stereotype scores align with human stereotypes across the measurements introduced in §3, we first run a pilot experiment to select the best template(s) for each measurement-model pair from the set of templates in Table 4 (except for CEAT, which does not require templates). We randomly picked four social groups (Asian, Black, Hispanic, immigrant) and five annotations from each group for the pilot. Since our goal is to inspect the alignment between human and model stereotypes, we take the averaged score of the five annotations as "ground truth" and select templates that give the correlation score according to Kendall τ. We limit the selection to at most two templates to avoid overfitting on the pilot data, selected to maximize correlation for each measurement-model pair.

The selected templates and corresponding correlation scores are shown in appendix (Table 5); the score range for weak correlation is 0.10 - 0.19, moderate 0.20 - 0.29, and strong 0.30 and above (Botsch, 2011). For a fixed LM, the best templates tend to be similar across all measures: RoBERTa tends to achieve highest correlation with templates like "That `[group]` is `[trait]`." while for BERT the preferred templates tend to be "All `[group]` are `[trait]`." or "`[Group]` should be `[trait]`."

Given the best templates for each measurement-model pair, we measure to what degree language model stereotypes are aligned with human stereotypes with all annotations on 25 social groups. To quantify alignment, we both calculate the Kendall rank correlation coefficient (Kendall's τ) and the Precision at 3 (P@3). The former indicates the correlation between model and human scores on group-trait associations in terms of the number of swaps required to get the same order. The latter indicates the percentage of the model's top stereotypes which accord with human's judgements. For P@3, we also calculate at both the group level and overall with all groups. For each group, we compute its P@3 score by taking the average of the P@3 scores with the top 3 traits (top at one polarity) and the score with the bottom 3 (top at the other polarity) because each trait has two polar adjectives and the group-trait score is calculated with the difference of the two polarities. To calculate the P@3 scores, we binarize the human group-trait scores at a threshold of 50. The overall P@3 score is the average of the groups' individual P@3 scores.

The overall scores are in Table 6. We see that in general that RoBERTa contains group-trait associations that are more similar to human judgements than does BERT. Additionally, we see that both ILPS* and SeT have higher P@3 scores than CEAT and ILPS. The RoBERTa model with the SeT measurement approach yields outputs are the most aligned with human's judgements, with RoBERTa/ILPS* a close second. From its scores, we see that model's group-trait associations have

	RoBERTa		BERT	
Measure	τ	**Template(s)**	τ	**Template(s)**
ILPS	0.280	That `[group]` is `[trait]`.	0.215	All `[group]` are `[trait]`. `[Group]` should be `[trait]`.
ILPS*	0.258	All `[group]` are `[trait]`. That `[group]` is `[trait]`.	0.123	We expect that `[group]` are `[trait]`. `[Group]` should be `[trait]`.
SeT	0.253	That `[group]` is `[trait]`.	0.214	All `[group]` are `[trait]`. `[Group]` should be `[trait]`.

Table 5: Best two templates for each measurement-model pair and corresponding correlations. Some have only one template because there is no combination of two templates that give higher correlation score than this one template.

	CEAT		ILPS		ILPS*		SeT

Precision at 3	0.500	0.587	0.620	0.533	**0.653**	0.560	**0.653**	0.613

Table 6: Overall alignment scores with human annotations. The highest scores are bold for each row. For correlation scores, we mark scores where the p-value is < 0.05 with †.

moderate correlation with human's judgements. Moreover, in general, two out of the three top ranked group-trait associations from the model agree with human data. See Table A19 for the overall scores of test groups only, where the four pilot groups are excluded, and Appendix B for group level alignment scores.

5.2 Intersectional Groups in LMs

Background. Intersectionality is a core concept in Black feminism, introduced in the Combahee River Collective Statement in 1977 (1977; 1983), considering the ways in which feminist theory and antiracism need to combine: "Because the intersectional experience is greater than the sum of racism and sexism, any analysis that does not take intersectionality into account cannot sufficiently address the particular manner in which Black women are subordinated." The concept was applied in law by Crenshaw (1989) to analyze the ways in which U.S. antidiscrimination law fails Black women.

The concept of intersectionality has broadened and, while its boundaries remain contested (e.g., Browne and Misra, 2003), there are a number of core principles that are central (Steinbugler et al., 2006; Zinn and Dill, 1996): (1) social categories and hierarchies are historically contingent, (2) the experience at an intersection is more than the sum of its parts (Collins, 2002; King, 1988), (3) intersections create both oppression and opportunity (Bonilla-Silva, 1997), (4) individuals may experience both advantage and disadvantage as a result of intersectionality, and (5) these hierarchies impact social structure and social interaction.

Goals and Research Questions. We aim to understand whether we can measure evidence of intersectional behavior in language models with respect to stereotyping. In particular, we are interested in questions surrounding how language models stereotype people who simultaneously belong to multiple social groups. We will only use the term "intersectionality" when specifically considering cases where (per (3) above) the resulting experience (in this case, stereotyping) is more than the sum of its parts. For example, common U.S. stereotypes for Black women are as "welfare queens" (which may show up as low agency in our traits), while common stereotypes for Black men is as "criminal" (which may show up as low communion) (hooks, 1992; Collins, 2002). To limit our scope, we will only consider pairs of social groups (e.g., cis men), and will refer to the the groups that make up a pair as the component identities (e.g., cis, or men). We aim to answer the following research questions:

1. When presented with a paired identity, is the language model sensitive to the order in which the component identities appear?
2. When paired, do certain social categories dominate others in a language model's predictions?
3. Can the language model detect stereotypes that belong to an intersectional group (but not to either of the components that make up the pair)?

To answer these questions, we use the SeT measurement with the RoBERTa model (the best performing pair on the single-group experiments) to compute group-trait associations on our paired groups, which are combinations of all the single groups in Table 3. We manually omit the groups that do not logically exist (e.g. "cis non-binary person", "teenage elderly person") or are grammatically awkward (e.g. "doctor elderly person", "immigrant blind person"). Note we include both orders of the single groups in the paired groups when possible (e.g. "Catholic teenager" and "teenage Catholic person"). We then conduct the analysis by computing the correlation between groups' list of trait scores with Kendall's τ.

Q1: Identity Order. Given an paired group with two identities, the language model may not be able to capture both of the identities and may predict stereotypes based only on one of the components. In fact, the average correlation score between a paired group and the most correlated of its components is 0.56, which is moderately high. We thus calculate the correlation of trait scores between the paired group and both its first and second component identities (when both orders are possible). In addition, we calculate the correlation of paired groups with reversed identity order (e.g. "Asian teenager" and "teenage Asian person"). The average correlation score between a paired group and its first component is 0.43; the correlation score to its second component is 0.46, which are quite close. Further, the average correlation score of intersectional groups with reversed identity is 0.69, which is moderately high. Taken together, these results indicate that (a) many paired groups have similar group-trait association scores with one of their component identities alone; (b) the order does not matter significantly, but the language model tends to focus slightly more on the second component. The implication of this is that we can expect that the language model *may* be able to capture intersectional stereotypes.

Q2: Dominant Domains. Stryker (1980) suggests that people tend to identify themselves with their race/ethnicity identity before other identities, though this is contested and, in some cases, thought to be antithetical to the idea of intersectionality (e.g., Collins, 2002). Prompted by this debate, we ask if there is a hierarchy of the domains that language model picks up on for paired groups. To answer this question, for each identity domain pair, we compute the average correlation score between the paired groups with each of its two component identities, and take the difference of the averaged correlation scores of the two domains. For each domain, we count the domains it dominates (i.e. has score difference ≥ 0.1) and is dominated by.

These results show that age and political stance are dominant domains, which is expected as identities within these two domains have strong characteristics that may overwhelm domains they are paired with. On the other end, race and nationality are, generally, dominated domains. It is surprising that the race domain is majorly dominated, contrasting documented literature in human behavior. The full results are shown in Appendix Table A8 as well as detailed scores Table A9.

Q3: Emergent Intersectional Stereotypes. Finally, we look into emergent stereotypes of paired groups, with the goal of finding intersectional behavior in the language model. To detect intersectional stereotypes, we need to operationalize the notion of the whole being greater than its parts. For a fixed paired group $\mathtt{g} = (\mathtt{g}_1, \mathtt{g}_2)$ (e.g., "trans Democrats"), and a given trait $\mathtt{t}$ (e.g., `warm`), we compute $S(\mathtt{g}, \mathtt{t}) - \max\{S(\mathtt{g}_1, \mathtt{t}), S(\mathtt{g}_2, \mathtt{t})\}$, where S is the score from the language model, capturing whether this trait is more associated with the paired group than the maximum of its association with the component identities. (We consider also the reverse, where we look for scores much less than the min.) We might hope to find some well attested intersectional identities from the literature, such as "Black women" `have an attitude` (low communion) and "White men" are `privileged` (high agency) (Ghavami and Peplau, 2013).

The top 50 emergent group-trait associations according to our measure are listed in Table A10. We also see some good examples are: the language model scores "Hispanic unemployed people" as more `egotistic` than people of the component identities, "Democrat teenagers" as more `altruistic`, "male doctors" as more `benevolent`, etc. However, there are also some unexpected patterns; for instance, almost all nationality identities combined with "mechanic" are `trustworthy` and `likeable`, and almost all nationality identities combined with "autistic" are `egotistic`. Looking into the scores themselves, we find that both "mechanic" and "autistic" have low scores on the corresponding traits, and combining them with nationalities raises to about average levels.

Aside from analyzing face validity—which is mixed—we compare the results of our model to the traits that Ghavami and Peplau (2013) found when conducting human studies of race/gender pairs. To do this, we categorize the traits from Ghavami and

Peplau (2013) to the ABC dimensions[8] and compare with our full list of emergent group-trait associations. Taking their group-trait matches as ground truth, our detection of traits for these race/gender intersectional groups achieves a precision 0.83 and recall 0.65—better than random guessing (precision 0.72, recall 0.50) but far from perfect.

6 Limitations and Ethical Considerations

There are several limitations to our work, which should be taken into account in the interpretation of our results.

First, our results are likely affected by reporting bias and by a defaulting effect where, when people annotate traits for "men", they may actually have in their head "cis straight white men", because the defaults go unremarked. This goes both for the human scores (how does a participant conceptualize "men"?) and language model scores (what do sentences containing the word "man" assume given that most language a langauge model has been trained on likely exhibits defaulting?).

Second, our work only focus on assessing stereotypes within language models and not in any deployed system. Though stereotypes from language models may impact the outputs of downstream systems which are built upon these language models, it is not clear how exactly the stereotypes transfer (Cao et al., 2022). Additionally, our work is limited to English and U.S. social stereotypes.

Third, although we followed and built on best practices from social psychology in developing the human study, it nevertheless has some shortcomings. In particular, even after many iterations on wording, it was difficult to phrase the survey questions to encourage people to reporting their true impressions. There is tension between asking a participant what *they* think—which risks a counfounding potential social desirability bias (Latkin et al., 2017) (people's tendency to respond in socially acceptable ways)—and asking what they think *others* think—which led to comments from a few participants that they felt unqualified to speak for others. Asking these questions of participants and collecting the data also raises the possibility of this work inadvertantly reinforcing stereotypes.

Finally, aggregating human judgements into a single number by averaging (or any other statistic) to compare to model predictions risks collapsing a significant amount of information down to a single number. This number cannot distinguish between a weakly held but common stereotype and a strongly held but rare one. Nor can it distinguish between traits where half of annotators say 0 and the other half say 100, from traits where all annotators say 50. These average judgments should be interpreted as not what any single person would say, but an average over people. This limitation is exacerbated by the defaulting effect, where some people may imagine a different prototype for a given group, and other people may imagine another.

7 Conclusion

In this paper, we measured language model (LM) stereotypes by adopting the ABC stereotype model from social psychology. Comparing to previous work on detecting LM stereotypes, our approach is easy to extend to previously unconsidered groups, grounded in traits proven effective by social psychology, and exhaustively covering the space of possible stereotypes, at the cost of being more abstract than in other NLP work. This yields a different set of trade-offs than previous approaches to measuring stereotypes in LMs.

With the ABC model and data regarding human stereotypes from our human study, we assessed LM stereotypes using three different association measurements, including SeT, a metric we proposed. We showed that LM group-trait stereotypes in general have moderate correlation with human judgements, and that SeT provides correlations that better align with human's. Based on these results, we extended our analysis to intersectional groups. We found that the LM *may* be able to capture intersectional stereotypes but is not particularly good on identifying emergent intersectional stereotypes. Our results also show that that, in general, age and political stance are dominant domains in language models, whereas race and nationality are dominated domains. We hope that our work provides insights for future works on measuring and mitigating stereotypes in natural language processing systems, and that the grounding in theories from social psychology has benefits beyond just studying stereotypes.

A Traits

The full list of traits and respective adjectives is in the Table A7

Trait	Adjectives
Agency scale	
Powerful	forceful, formidable, capable
Powerless	weak, helpless, incapable
High status	privileged, elite, advantaged
Low status	unskilled, lowly, inferior
Dominant	commanding, authoritative
Dominated	subservient, submissive, deferential
Wealthy	affluent, rich, prosperous
Poor	impoverished, destitute, needy
Confident	self-assured, assured, self-possessed
Unconfident	bashful, meek, timid
Competitive	ambitious, driven, zealous
Unassertive	submissive, diffident, passive
Beliefs scale	
Modern	radical, forward-looking
Traditional	old-fashioned
Science-oriented	analytical, logical, atheistic
Religious	devout, pious, reverent
Alternative	unorthodox, avant-garde, eccentric
Conventional	mainstream
Liberal	left-wing, Democrat, progressive
Conservative	right-wing, Republican
Communion scale	
Trustworthy	reliable, dependable, truthful
Untrustworthy	unreliable, undependable
Sincere	genuine, forthright, honest
Dishonest	insincere, deceitful
Warm	friendly, kind, loving
Cold	unfriendly, unkind, aloof
Benevolent	considerate, generous
Threatening	intimidating, menacing, frightening
Likable	pleasant, amiable, lovable
Repellent	vile, loathsome, nasty
Altruistic	helpful, charitable, selfless
Egotistic	selfish, self-centered, insensitive

Table A7: Full list of traits and corresponding adjectives.

	Dominates	**Dominated by**
age	gender/sexuality, race/ethnicity, nationality, politics, religion, socio-economic	-
politics	nationality, socio-economic, disability	age, religion
gender/ sexuality	race/ethnicity, nationality	age
disability	race/ethnicity, nationality	politics
social-economic	race/ethnicity, nationality	age, politics
religion	politics	-
race/ ethnicity	-	age, gender/sexuality, socio-economic, disability
nationality	-	age, gender/sexuality, politics, socio-economic, disability

Table A8: Domination relations between social domains.

B Experiment Results with Single Groups

Table A11 presents the Kendall's τ correlation scores between model and human at group level, while Table A12 and Table A13 shows the alignment with the precision at 3 scores (former computed with the top 3 traits and latter with the bottom 3 traits).

C Experiment Results of Intersectional Groups

Table A8 presents the dominating relationship between domains, while Table A9 lists the average correlation scores of the paired group with each of its identities' domain for each domain pairs.

Table A10 shows the top 50 emergent group-trait associations.

Domain A	Domain B	Correlation A	Correlation B
age	disability	0.532	0.475
gender	disability	0.418	0.356
age	gender	0.552	0.320
age	nationality	0.583	0.337
disability	nationality	0.543	0.309
gender	nationality	0.481	0.225
political stance	nationality	0.287	0.179
race	nationality	0.594	0.525
religion	nationality	0.490	0.525
socio	nationality	0.540	0.338
age	political stance	0.319	0.177
disability	political stance	0.019	0.397
gender	political stance	0.315	0.375
race	political stance	0.376	0.348
religion	political stance	0.380	0.271
age	race	0.520	0.395
disability	race	0.538	0.392
gender	race	0.478	0.371
age	religion	0.502	0.449
disability	religion	0.465	0.463
gender	religion	0.439	0.360
race	religion	0.522	0.460
age	socio	0.562	0.406
disability	socio	0.420	0.419
gender	socio	0.374	0.397
political stance	socio	0.433	0.290
race	socio	0.387	0.488
religion	socio	0.404	0.439

Table A9: Full list of correlations for paired social groups. The table shows two domains, which comprise group AB, correlations between group AB and group A, group AB and group B.

D Human study setup

The survey for the collection of associated traits is presented in Figure A2.

Page 1

Some kind of people in our society are viewed as [powerful, confident], while other kind of people in our society are viewed as [the opposite stereotype; powerless, unconfident].

In the following pages, you will be provided with 5 social groups.

For each listed social group, please rate how people in America stereotype the group. We will provide a list of trait pairs (e.g., powerless to powerful) and you are to rate where in that range you believe the group is stereotyped.

Importantly, we are not interested in your personal beliefs, but rather **how you think people in America view these groups.**

Note that there will be test questions in the survey.

Page 2

As viewed by American society, (while my own opinions may differ), how [e.g., powerless, dominant, poor] versus [e.g., powerful, dominated, wealthy] are **Christian people**?

Figure A2: Example of the survey for one group.

E Annotators demographics

55.4% are white, with 50.6% male annotators, 40.4 female annotators and no annotators who provided another gender. 15.1% of annotators are Black, and 25.6% are Hispanic with slightly more female annotators 56.4%. We provide four tables A14, A15, A16, A17 showing how perceptions of White people, Black people, White men, and White women are different from each other across annotator demographics. We see variations between in-group and out-group annotations. For instance, women see themselves as more powerful than men see women. While overall scores for men and women groups are similar across white and Black annotators. In Table A18, we show correlation scores for all social groups and overall score between the model and Black, white, white female, and white male annotators.

Abstract

Making an informed choice of pre-trained language model (LM) is critical for performance, yet environmentally costly, and as such widely underexplored. The field of Computer Vision has begun to tackle encoder ranking, with promising forays into Natural Language Processing, however they lack coverage of linguistic tasks such as structured prediction. We propose *probing to rank LMs*, specifically for parsing dependencies in a given language, by measuring the degree to which labeled trees are recoverable from an LM's contextualized embeddings. Across 46 typologically and architecturally diverse LM-language pairs, our probing approach predicts the best LM choice 79% of the time using orders of magnitude less compute than training a full parser. Within this study, we identify and analyze one recently proposed decoupled LM—RemBERT—and find it strikingly contains less inherent dependency information, but often yields the best parser after full fine-tuning. Without this outlier our approach identifies the best LM in 89% of cases.

1 Introduction

With the advent of massively pre-trained language models (LMs) in Natural Language Processing (NLP), it has become crucial for practitioners to choose the best LM encoder for their given task early on, regardless of the rest of their proposed model architecture. The greatest variation of LMs lies in the language or domain-specificity of the unlabelled data used during pre-training (with architectures often staying identical).

Typically, better expressivity is expected from language/domain-specific LMs (Gururangan et al., 2020; Dai et al., 2020) while open-domain settings necessitate high-capacity models with access to as much pre-training data as possible. This tradeoff is difficult to navigate, and given that multiple specialized LMs (or none at all) are available, practitioners often resort to an ad-hoc choice. In absence of immediate performance indicators, the most accurate choice could be made by training the full model using each LM candidate, however this is often infeasible and wasteful (Strubell et al., 2019).

Recently, the field of Computer Vision (CV) has attempted to tackle this problem by quantifying useful information in pre-trained image encoders as measured directly on labeled target data without fine-tuning (Nguyen et al., 2020; You et al., 2021). While first forays for applying these methods to NLP are promising, some linguistic tasks differ substantially: Structured prediction, such as parsing syntactic dependencies, is a fundamental NLP task not covered by prior encoder ranking methods due to its graphical output. Simultaneously, performance prediction in NLP has so far been studied as a function of dataset and model characteristics (Xia et al., 2020; Ye et al., 2021) and has yet to examine how to rank large pools of pre-trained LMs.

Given the closely related field of probing, in which lightweight models quantify task-specific information in pre-trained LMs, we recast its objective in the context of performance prediction and ask: *How predictive is lightweight probing at choosing the best performing LM for dependency parsing?* To answer this question, we contribute:

- An efficient encoder ranking method for structured prediction using dependency probing (Müller-Eberstein et al., 2022; DEPPROBE) to quantify latent syntax (Section 2).
- Experiments across 46 typologically and architecturally diverse LM + target language combinations (Section 3).[1]
- An in-depth analysis of the surprisingly low inherent dependency information in RemBERT (Chung et al., 2021) compared to its high fine-tuned performance (Section 4).

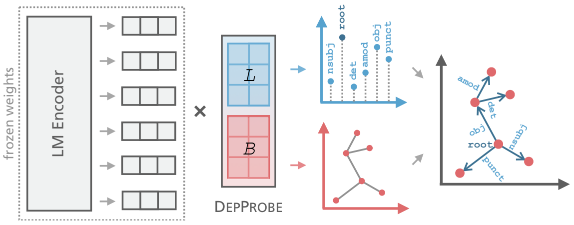

Figure 1: **Visualization of DEPPROBE.** Relational and structural subspaces L and B are combined to extract labeled, directed trees from embeddings.

2 Methodology

Probing pre-trained LMs is highly related to encoder ranking in CV where the ease of recoverability of class-differentiating information is key (Nguyen et al., 2020; You et al., 2021). This approach is more immediate than existing NLP performance prediction methods which rely on featurized representations of source and target data without actively ranking encoders (Xia et al., 2020; Ye et al., 2021). As most experiments in NLP are conducted using a limited set of LMs—often a single model—without strong prior motivations, *we see LM ranking as a critical task on its own.*

While probes for LMs come in many forms, they are generally characterized as lightweight, minimal architectures intended to solve a particular task (Hall Maudslay et al., 2020). While non-linear models such as small multi-layer perceptrons are often used (Tenney et al., 2019), there have been criticisms given that their performance highly depends on the complexity of their architecture (Hewitt and Liang, 2019; Voita and Titov, 2020). As such, we rely on linear probes alone, which have the benefit of being extremely lightweight, closely resembling existing performance prediction methods (You et al., 2021), and allow for statements about linear subspaces contained in LM latent spaces.

DEPPROBE (Müller-Eberstein et al., 2022; visualized in Figure 1) is a linear formulation for extracting fully labeled dependency trees based on the structural probe by Hewitt and Manning (2019). Given contextualized embeddings of dimensionality d, a linear transformation $B \in \mathbb{R}^{b \times d}$ with $b \ll d$ (typically $b = 128$) maps them into a subspace in which the Euclidean distance between embeddings corresponds to the number of edges between the respective words in the gold dependency graph.

In our formulation, we supplement a linear transformation $L \in \mathbb{R}^{l \times d}$ (with l = number of dependency relations) which maps each embedding to a subspace in which the magnitude of each dimension corresponds to the likelihood of a word and its head being governed by a certain relation.

By computing the minimum spanning tree in B and then finding the word with the highest root likelihood in L, we can determine the directionality of all edges as pointing away from the root. All remaining edges are labeled according to the most likely non-root class in L, resulting in a fully directed and labeled dependency tree.

Note that this approach differs substantially from prior approaches which yield undirected and/or unlabeled trees (Hewitt and Manning, 2019; Kulmizev et al., 2020) or use pre-computed edges and non-linear classifiers (Tenney et al., 2019). DEPPROBE efficiently computes the full target metric (i.e. labeled attachment scores) instead of approximate alternatives (e.g. undirected, unlabeled attachment scores or tree depth correlation).

3 Experiments

Setup We investigate the ability of DEPPROBE to select the best performing LM for dependency parsing across nine linguistically diverse treebanks from Universal Dependencies (Zeman et al., 2021; UD) which were previously chosen by Smith et al. (2018) to reflect diverse writing systems and morphological complexity (see Appendix A).

For each target language, we employ three multilingual LMs—mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020), RemBERT (Chung et al., 2021)—as well as 1–3 language-specific LMs retrieved by popularity from HuggingFace's Model Hub (Wolf et al., 2020), resulting in a total of 46 LM-target pair setups (see Appendix C).

For each combination, we train a DEPPROBE to compute labeled attachment scores (LAS), hypothesizing that LMs from which trees are most accurately recoverable also perform better in a fully tuned parser. To evaluate the true downstream performance of a fully-tuned model, we further train a deep biaffine attention parser (BAP; Dozat and Manning, 2017) on each LM-target combination. Compared to full fine-tuning, DEPPROBE only optimizes the matrices B and L, resulting in the extraction of labeled trees with as few as 190k instead of 583M trainable parameters for the largest RemBERT model (details in Appendix B).

We measure the predictive power of probing for fully fine-tuned model performance using the Pearson correlation coefficient ρ as well as the weighted

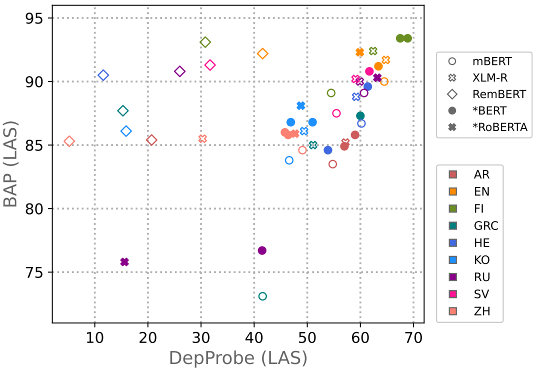

Figure 2: **LAS of DepProbe in relation to full BAP** across nine language targets (dev) using language-specific and multilingual LM encoders of different architecture types (exact scores in Appendix C).

Kendall's τ_w (Vigna, 2015). The latter metric corresponds to a correlation coefficient in $[-1, 1]$ and simultaneously defines the probability of choosing the better LM given a pair as $\frac{\tau_w+1}{2}$, allowing us to quantify the overall quality of a ranking.

Results Comparing the LAS of DepProbe's lightweight predictions against full BAP fine-tuning in Figure 2, we see a clear correlation as the probe correctly predicts the difficulty of parsing languages relative to each other and also ranks models within languages closely according to their final performance. With a τ_w of .58 between scores ($p < 0.001$), this works out to DepProbe selecting the better performing final model given any two models 79% of the time. Additionally, LAS is slightly more predictive of final performance than unlabeled, undirected attachment scores (UUAS) with τ_w = .57 to which prior probing approaches are restricted (see Appendix C).

Given a modest ρ of .32 ($p < 0.05$), we surprisingly also observe a single strong outlier to this pattern, namely the multilingual RemBERT (Chung et al., 2021) decoupled LM architecture. While DepProbe consistently ranks it low as it cannot extract dependency parse trees as accurately as from the BERT and RoBERTa-based architectures, RemBERT actually performs best on four out of the nine targets when fully fine-tuned in BAP. Excluding monolingual LMs, it further outperforms the other multilingual LMs in seven out of nine cases. As it is a more recent and distinctive architecture with many differences to the most commonly-used contemporary LMs, we analyze potential reasons for this discrepancy in Section 4.

Excluding RemBERT as an outlier, we find substantially higher correlation among all other models: ρ = .78 and τ_w = .78 ($p < 0.001$). This means that among these models, fully fine-tuning the LM for which DepProbe extracts the highest scores, yields the better final performance 89% of the time.

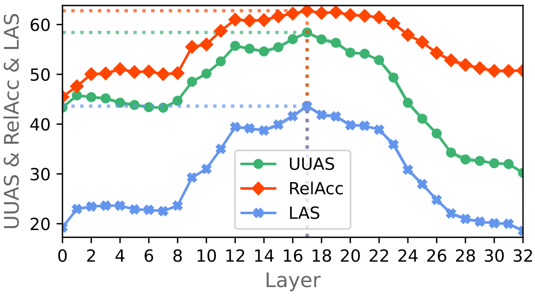

Figure 3: **Dependency Information per RemBERT Layer** via DepProbe's structural, relational and parsing accuracy (UUAS, RelAcc, LAS) on EN-EWT (dev).

In practice, learning DepProbe's linear transformations while keeping the LM frozen is multiple orders of magnitude more efficient than fully training a complex parser plus the LM's parameters. As such, linear probing offers a viable method for selecting the best encoder in absence of qualitative heuristics or intuitions. This predictive performance is furthermore achievable in minutes compared to hours and at a far lower energy budget (see Appendices B and C).

4 Probing Decoupled LMs

Considering DepProbe's high predictive performance across LMs with varying architecture types, languages/domains and pre-training procedures, we next investigate its limitations: Specifically, which differences in RemBERT (Chung et al., 2021) lead to it being measured as an outlier with seemingly low amounts of latent dependency information despite reaching some of the highest scores after full fine-tuning. The architecture has 32 layers and embeddings with d = 1152, compared to most models' 12 layers and d = 768. It accommodates these size and depth increases within a manageable parameter envelope by using smaller input embeddings with d_{in} = 256. While choosing different d for the input and output embeddings is not possible in most prior models due to both embedding matrices being coupled, RemBERT decouples them, leading to a larger parameter budget and less overfitting on the masked language modeling pre-training task (Chung et al., 2021).

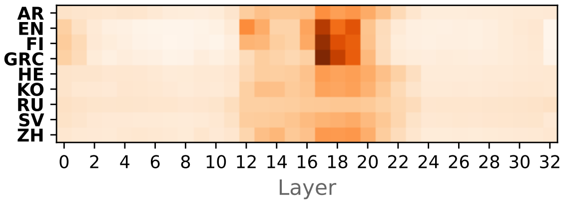

Figure 4: **Per-language α of RemBERT Layers** for DEPPROBE across all layer weights (dark > light).

MODEL	AR	EN	FI	GRC	HE	KO	RU	SV	ZH
mBERT	**65** ±.08	**74** ±.09	65 ±.35	46 ±.14	**69** ±.23	**58** ±.18	**68** ±.31	**65** ±.12	**58** ±.17
XLM-R	60 ±.14	70 ±.08	**66** ±.18	53 ±.19	60 ±.20	49 ±.08	57 ±.34	51 ±.24	51 ±.53
RemBERT	58 ±.12	56 ±.22	52 ±.15	**54** ±.18	52 ±.05	46 ±.14	49 ±.04	43 ±.08	39 ±.24

Table 1: **LAS of BAP Trained on Frozen LMs.** A biaffine attention parsing head is trained on top of frozen mBERT, XLM-R and RemBERT for each of the nine target languages (± standard deviation).

Layer-wise Probing Prior probing studies have found dependency information to be concentrated around the middle layers of an LM (Hewitt and Manning, 2019; Tenney et al., 2019; Fayyaz et al., 2021). Using EN-EWT (Silveira et al., 2014), we evaluate whether this holds for RemBERT's new architecture. Figure 3 confirms that both dependency structural and relational information are most prominent around layer 17 of 32 as indicated by UUAS and relation classification accuracy (RelAcc) respectively. Combining the structural and relational information in DEPPROBE similarly leads to a peak of the LAS at the same layer while decreasing with further distance from the center.

Across all target languages, we next investigate whether probing a sum over the embeddings of all layers weighted by $\alpha \in \mathbb{R}^{32}$ can boost extraction performance in RemBERT. The heavier weighting of middle layers by α, visible in Figure 4, reaffirms a concentration of dependency information in the center. Contrasting probing work on prior models (Tenney et al., 2019; Kulmizev et al., 2020), using all layers does not increase the retrievable dependencies, with LAS differences ±1 point. This further confirms that there is not a lack of dependency information in any specific layer, but that there is less within the encoder as a whole.

Frozen Parsing Our probing results show that linear subspaces in RemBERT contain less dependency information than prior LMs. However, DEPPROBE's parametrization is kept intentionally simple and may therefore not be capturing non-linearly represented information that is useful during later fine-tuning. To evaluate this hypothesis, we train a full biaffine attention parsing head, but keep the underlying LM encoder frozen. This allows us to quantify the performance gains which come from inherent dependency information versus later task-specific fine-tuning.

Table 1 confirms our findings from DEPPROBE and shows that despite RemBERT outperforming mBERT and XLM-R when fully fine-tuned, it has substantially lower LAS across almost all languages when no full model fine-tuning is applied. This leads us to conclude that there indeed is less inherent dependency information in the newer model and that most performance gains must be occurring during task-specific full fine-tuning.

Given that DEPPROBE extracts dependency structures reliably from LM architectures with different depths and embedding dimensionalities (e.g. RoBERTa$_{\text{large}}$ with 24 layers and $d = 1024$ versus RuBERT$_{\text{tiny}}$ with 3 layers and $d = 312$) as well as varying tokenization, optimization and pre-training data, the key difference in RemBERT appears to be embedding decoupling. The probe's linear formulation is not the limiting factor as the non-linear, biaffine attention head also produces less accurate parses when the LM's weights are frozen. Our analyses thus suggest that RemBERT's decoupled architecture contains less dependency information out-of-the-box, but follows prior patterns such as consolidating dependency information towards its middle layers and serving as strong initialization for parser training.

Lastly, RemBERT's larger number of tunable parameters compared to all other LM candidates may provide it further capacity, especially after full fine-tuning. As our probing methods are deliberately applied to the frozen representations of the encoder, it becomes especially important to consider the degree to which these embeddings may change after updating large parts of the model. Taking these limitations into account, the high correlations with respect to encoder ranking nonetheless enable a much more informed selection of LMs from a larger pool than was previously possible.

5 Conclusion

To guide practitioners in their choice of LM encoder for the structured prediction task of dependency parsing, we leveraged a lightweight, linear

DepProbe to quantify the latent syntactic information via the *labeled* attachment score. Evaluating 46 pairs of multilingual/language-specific LMs and nine typologically diverse target treebanks, we found DepProbe to not only be efficient in its predictions, with orders of magnitude fewer trainable parameters, but to also be accurate 79–89% of the time in predicting which LM will outperform another when used in a fully tuned parser. This allows for a substantially faster iteration over potential LM candidates, saving hours worth of compute in practice (Section 3).

Our experiments further revealed surprising insights on the newly proposed RemBERT architecture: While particularly effective for multilingual dependency parsing when fully fine-tuned, it contains substantially less latent dependency information relative to prior widely-used models such as mBERT and XLM-R. Among its architectural differences, we identified embedding decoupling to be the most likely contributor, while added model capacity during fine-tuning may also improve final performance. Our analyses showed that despite containing less dependency information overall, RemBERT follows prior findings such as structure and syntactic relations being consolidated towards the middle layers. Given these consistencies, performance differences between decoupled LMs may be predictable using probes, but in absence of similar multilingual LMs using decoupled embeddings this effect remains to be studied (Section 4).

Overall, the high efficiency and predictive power of ranking LM encoders via linear probing as well as the ease with which they can be analyzed—even when they encounter their limitations—offers immediate benefits to practitioners who have so far had to rely on their own intuitions when making a selection. This opens up avenues for future research by extending these methods to more tasks and LM architectures in order to enable better informed modeling decisions.

A Treebanks

TARGET	LANG	FAMILY	SIZE
AR-PADT	Arabic	Afro-Asiatic	7.6k
EN-EWT	English	Indo-European	16.6k
FI-TDT	Finnish	Uralic	15.1k
GRC-PROIEL	Ancient Greek	Indo-European	17.1k
HE-HTB	Hebrew	Afro-Asiatic	6.2k
KO-GSD	Korean	Korean	6.3k
RU-GSD	Russian	Indo-European	5k
SV-Talbanken	Swedish	Indo-European	6.0k
ZH-GSD	Chinese	Sino-Tibetan	5.0k

Table 2: **Target Treebanks** based on Smith et al. (2018) with language family (FAMILY) and total number of sentences (SIZE).

Table 2 lists the nine target treebanks based on the set by Smith et al. (2018): AR-PADT (Hajič et al., 2009), EN-EWT (Silveira et al., 2014), FI-

TDT (Pyysalo et al., 2015), GRC-PROIEL (Eckhoff et al., 2018), HE-HTB (McDonald et al., 2013a), KO-GSD (Chun et al., 2018), RU-GSD (McDonald et al., 2013b), SV-Talbanken (McDonald et al., 2013a), ZH-GSD (Shen et al., 2016). We use these treebanks as provided in Universal Dependencies v2.9 (Zeman et al., 2021). DEPPROBE and BAP are trained on each target's respective training split and are evaluated on the development split as this work aims to analyze general performance patterns instead of state-of-the-art performance.

B Experiment Setup

DEPPROBE is implemented in PyTorch v1.9.0 (Paszke et al., 2019) and uses language models from the Transformers library v4.13.0 and the associated Model Hub (Wolf et al., 2020). Following the structural probe by Hewitt and Manning (2019), each token which is split by the LM encoder into multiple subwords is mean-pooled. Similarly, we follow the original hyperparameter settings and set the structural subspace dimensionality to $b = 128$ and use embeddings from the middle layer of each LM (Hewitt and Manning, 2019; Tenney et al., 2019; Fayyaz et al., 2021). The structural loss is computed based on the absolute difference of the Euclidean distance between transformed word embeddings and the number of edges separating the words in the gold tree (see Hewitt and Manning, 2019 for details). The relational loss is computed using cross entropy between the logits and gold head-child relation. Optimization uses AdamW (Loshchilov and Hutter, 2018) with a learning rate of 10^{-3} which is reduced by a factor of 10 each time the loss plateaus. Early stopping is applied after three epochs without improvement and a maximum of 30 total epochs. With the only trainable parameters being the matrices B and L, the model's footprint ranges between 51k and 190k parameters.

BAP For the biaffine attention parser (Dozat and Manning, 2017) we use the implementation in the MaChAmp framework v0.3 (van der Goot et al., 2021) with the default training schedule and hyperparameters. The number of trainable parameters depends on the LM encoder's size and ranges between 14M and 583M.

Analyses For our analyses in Sections 3 and 4 we further make use of numpy v1.21.0 (Harris et al., 2020), SciPy v1.7.0 (Virtanen et al., 2020) and Matplotlib v3.4.3 (Hunter, 2007).

Training Details Models are trained on an NVIDIA A100 GPU with 40GBs of VRAM and an AMD Epyc 7662 CPU. BAP requires around 1 h (± 30 min). DEPPROBE can be trained in around 15 min (± 5 min) with the embedding forward operation being most computationally expensive. The models use batches of size 32 and are initialized using the random seeds 692, 710 and 932.

Reproducibility In order to ensure reproducibility and comparability with future work, we release our code and token-level predictions at https://personads.me/x/naacl-2022-code.

C Detailed Results

Tables 3–11 list exact LAS and standard deviations for each experiment in Section 3's Figure 2 in addition to the HuggingFace Model Hub IDs of the LMs used in each of the 46 setups as well as their number of layers, embedding dimensionality d and total number of parameters. In addition, Figure 5 shows UUAS for all setups, equivalent to only probing structurally (Hewitt and Manning, 2019) for unlabeled, undirected dependency trees.

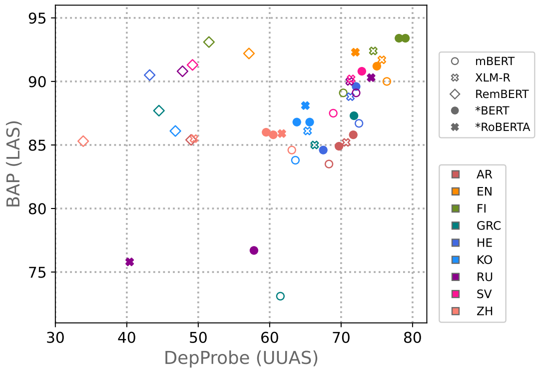

Figure 5: **UUAS of DEPPROBE in relation to BAP** across nine language targets (dev) using language-specific and multilingual LM encoders of different architecture types.

Abstract

Theoretical work in morphological typology offers the possibility of measuring morphological diversity on a continuous scale. However, literature in Natural Language Processing (NLP) typically labels a whole language with a strict type of morphology, e.g. fusional or agglutinative. In this work, we propose to reduce the rigidity of such claims, by quantifying morphological typology at the word and segment level. We consider Payne (2017)'s approach to classify morphology using two indices: synthesis (e.g. analytic to polysynthetic) and fusion (agglutinative to fusional). For computing synthesis, we test unsupervised and supervised morphological segmentation methods for English, German and Turkish, whereas for fusion, we propose a semi-automatic method using Spanish as a case study. Then, we analyse the relationship between machine translation quality and the degree of synthesis and fusion at word (nouns and verbs for English-Turkish, and verbs in English-Spanish) and segment level (previous language pairs plus English-German in both directions). We complement the word-level analysis with human evaluation, and overall, we observe a consistent impact of both indexes on machine translation quality.

1 Introduction

One of the first barriers to develop language technologies is morphology, i.e., how systematically diverse their word formation processes are. For instance, agglutination and fusion are two morphological kind of processes that concatenate morphemes to a root with explicit or non-explicit boundaries, respectively. Processing morphologically-diverse languages and evaluating morphological competence in NLP models is relevant for language generation and understanding tasks, such as machine translation (MT). It is unfeasible to develop models with capacity large enough to encode the full vocabulary of every language, and it is a must to rely on subword segmentation approaches that help to constrain the capacity when generating rare, or even new words (Sennrich et al., 2016). Hence, understanding morphology is essential to develop robust subword-based models and evaluate the quality of their outputs (Vania and Lopez, 2017). Nevertheless, there is a potential gap between the probing of whether an NLP model can handle "morphological richness", and what is a proper measure of "morphological richness" from linguistic typology.

In most of the recent NLP literature, different types of languages (e.g. agglutinative, polysynthetic) are chosen to test a more diverse handling of morphological richness (Ponti et al., 2019). There is, however, a debate as to whether languages can indeed be classified into discrete morphological categories. Payne (2017) provided a morphological typology measurement in a continuous spectrum using the indices of synthesis and fusion. Synthesis measures if a segment is highly analytic or synthetic (from 1 to more), whereas fusion measures whether it is highly agglutinative or fusional (from 0 to 1). And surprisingly, with respect to NLP publications, it is possible to identify English segments with a very low fusion index, meaning that they are highly agglutinative[1].

From a more applied perspective, if the references of an evaluation set (in any language generation task) are labelled with the indices, we could perform a stratified analysis (e.g. low fusion and high fusion) to determine how well an NLP model handles morphology for multiple languages. For example, we could assess whether a machine translation model is failing in generating more fusional

---

[*] Work started when the first author was doing a research internship with JB at Aalborg University, Campus Copenhagen

[1] For instance, in the following fragment (Payne, 2017), the index of fusion is 1/8 or 0.125 (fusional morpheme joints are marked with a dot and the rest with a hyphen): "The company-'s great break-through came.PAST when they decided to buy trike-s to sell their ice cream around the street-s in the nine-teen twenty-s".

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1308 - 1321
July 10-15, 2022

than agglutinative segments for a specific target language. Knowing and quantifying that problem concerning morphology is the first step towards proposing a solution. Our contributions then are listed as follows:

- We present the first computational quantification of synthesis and fusion using standard NLP evaluation sets.
- We analyse the relationship between the two indices and machine translation quality at word-level, and observe that a higher degree of synthesis or fusion usually corresponds to less accurate translations in specific word types (studying nouns and verbs in English-Turkish, and verbs in English-Spanish).
- We complement this evaluation with manual annotation of synthesis and fusion.
- We extend the analysis at segment-level, using the aforementioned language pairs plus English-German in both directions, and identify that some synthesis and fusion-based predictors are significant for MT system outputs.

Furthermore, we release all the annotated data and evaluation results[2].

2 Background and related work

2.1 Morphological typology

The field of morphological typology characterises languages in terms of their word and sentence building strategies (Payne, 2017), such as agglutination or fusion. In current NLP literature, Turkish is labelled as a highly agglutinative language for the explicit boundaries between their morphemes, whereas Spanish is labelled as fusional for the opposite reason.

However, early typological studies started to quantify these strategies with parameters, and avoided to characterise languages with a single type in a holistic way (e.g. Sapir (1921); Greenberg (1960); Comrie (1989)). In this context, Payne (2017) recently highlighted the indices of synthesis and fusion, which are defined as follows.

2.1.1 Synthesis

The index of synthesis offers a scale to contrast highly analytic or synthetic languages. This implies whether a word is composed by one (analytic) or several (synthetic) morphemes (Payne, 2017). Synthesis can be computed as the ratio of number of morphemes per words, it is closer to 1 when the language is more analytic (e.g. Mandarin, or English to a less degree), and gets higher the more synthetic the language is (e.g. Turkish, Inuktitut). Polysynthesis can be present when the synthesis degree is higher than 3, although the boundary is arguable. Besides, as we claim in this study, any language can present different levels of synthesis if we evaluate them at a more fine-grained level.

2.1.2 Fusion

Fusion is the ratio of the fusional morphemes joints[3] per the total number of joints. This index goes from 0 to 1, or from highly agglutinative (e.g. Turkish) to highly fusional (e.g. Spanish) cases. However, we noticed that the computation of fusion is complex to automatise. For instance, Payne (2017) indicates potential cases to identify fusional joints, such as in prefixes, suffixes, infixes, circumfixes, compounding, non-concatenative processes (reduplication, apophony, substractive morphology) or autosegmental morphemes. Current automatic tools are not designed to identify these cases for most languages.

2.2 Morphological typology on NLP

A survey by Ponti et al. (2019), on computational typology for NLP, pointed out that morphological knowledge is potentially helpful for analysing the difficulty in generation tasks such as language modelling and neural MT for both unsupervised and supervised settings. More specifically, they suggested that the degree of fusion (related to the index of fusion proposed by Payne (2017)) impacts in the rate of less frequent words, which is a relevant parameter for generation tasks.

Besides, the studies that address morphological typology are related to either the development of morphological analysis systems or the evaluation of typologically diverse languages in terms of morphology (e.g. Vania and Lopez (2017); Xu et al. (2020)). However, the typology used to distinguish languages varies across different studies. For instance, Vania and Lopez (2017) considers four phenomena to label languages: fusionality, agglutination, reduplication and root-pattern; whereas Xu et al. (2020) considers more fine-grained elements such as affixation (prefixation, infixation and suffixation) or partial reduplication. Similarly,

---

[2] `https://github.com/aoncevay/quantifying-synthesis-and-fusion`

[3] Or how many grammatical, syntactic and semantic features are joint. More than one feature can be fused in a single morpheme.

a fine-grained analysis on non-concatenative morphology for MT was performed by Amrhein and Sennrich (2021). It is important to note that none of the previous studies have addressed the phenomena as a continuous index but as discrete features.

Furthermore, other studies refer only to morphological typological features as part of the task of typological feature prediction from linguistic databases (Bjerva and Augenstein, 2018; Bjerva et al., 2019a,b, 2020; Bjerva and Augenstein, 2021), and further applications of general typological concepts on MT are scarce and do not focus on morphology (Oncevay et al., 2020).

2.3 Morphological segmentation and analysis

Morphological segmentation (Harris, 1951) aims to split a word into morphemes. There are both supervised (e.g. pointer generator networks (Mager et al., 2020)) and unsupervised approaches (e.g. the Morfessor family of methods (Creutz and Lagus, 2002; Poon and Domingos, 2009) or Adaptor Grammars (Eskander et al., 2019)), where the former ones have outperformed the latter ones.

Besides, the most widespread unsupervised segmentation methods (Byte-Pair-Encoding (BPE; Sennrich et al., 2016) and a method based on unigram language modelling (Kudo, 2018)) are not linked at all to morphological segmentation, but they are used to constrain the vocabulary size for neural generation tasks.

Finally, it is important to note that the index of synthesis can be computed with a robust morphological analyser or segmentation model (to count the number of morphemes), but neither of them are built to compute the index of fusion directly.

3 How to compute Synthesis and Fusion?

3.1 Synthesis: automatic computation

To automatically compute the index of synthesis, we require to perform a robust morphological segmentation. A rule-based morphological analyser and disambiguator might be the best option if available (which we use later for Turkish in §4.2), but for the purpose of the study, we compare well-known supervised and unsupervised methods:

- Byte-Pair-Encoding (BPE) and Unigram Language Model (uniLM)[4] from SentencePiece (Kudo and Richardson, 2018).
- Morfessor (Poon and Domingos, 2009).
- Pointer Generator Network (PtrNet) from the implementation of Mager et al. (2020).

	English				**German**			
#morphs.	1	2	3	4	1	2	3	4
	16,914	28,900	1,798	73	13,061	32,007	5,808	360
	Accuracy Count							
uniLM$_{64k}$	0.54	0.52	0.49	0.59	0.35	0.27	0.21	0.18
BPE$_{64k}$	0.5	0.53	0.5	0.52	0.29	0.33	0.28	0.26
Morfessor	0.22	0.47	0.55	0.48	0.17	0.26	0.28	0.25
PtrNet	**0.82**	**0.84**	**0.56**	**0.81**	**0.74**	**0.86**	**0.7**	**0.42**
	Exact Segmentation Precision							
uniLM$_{64k}$	0.54	0.52	0.6	0.8	0.29	0.38	0.32	0.22
BPE$_{64k}$	0.5	0.44	0.56	0.76	0.24	0.33	0.23	0.08
Morfessor	0.21	0.58	**0.7**	0.78	0.17	0.45	0.44	0.36
PtrNet	**0.76**	0.67	**0.81**	**0.8**	**0.67**	**0.73**	**0.72**	**0.62**

Table 1: Accuracy count and segmentation precision for English and German using unsupervised and supervised segmentation methods. Results are grouped by the expected number of morphemes (e.g. "1" means that the word should not be split).

3.1.1 Datasets and evaluation

We used the CELEX dataset of segmented words for English and German (Steiner, 2016, 2017), where we randomly split training and evaluation data (80-10-10). Besides, for the unsupervised methods, we use the newscommentary-v15 (Barrault et al., 2019) and EuroParl-v10 (Koehn, 2005) corpora[5]. Furthermore, we define two metrics to assess the performance on computing synthesis:

- Accuracy count: Evaluates if the number of obtained morphemes in the hypothesis segmentation is the same as in the reference.
- Exact segmentation precision: Analyses if the split morphemes are the same. We first perform an automatic alignment between the hypothesis and reference segments with the parallel Needleman-Wunsch algorithm for sequences (Naveed et al., 2005), and then compute the exact match at morpheme level.

3.1.2 Results and discussion

Table 1 shows the scores on morphological segmentation for both English and German. We observe that both BPE and uniLM under-perform when it is not expected to split the word (column "1"). This is a pattern observed by Bostrom and Durrett (2020), where they noted that unsupervised segmentation methods tend to over-split the roots of words. They both improve their accuracy and precision when

---

[4] We analysed several vocabulary sizes (4k, 8k, 16k, 32k, 64k) but report only the best one, which is 64k for all cases.

[5] Other languages like Danish are also available and was tested, but we did not report the results here as there are not complementary MT evaluation sets.

Example (es): **Hablaremos** de la propuesta con la que se **condenó** a la ex primer ministra y fue **apoyada** por 147 diputados en la votación.

Verbs	Features (spaCy)	Features (UniMorph)	Segmentation	feats. per morph	fusional morph. joints	total joints	Fusion index
hablaremos *(we will talk)*	Mood=Ind, Number=Plur, Person=1, Tense=Fut, VerbForm=Fin	V;IND;FUT;1;PL	habl - are - mos	0 – $2_{(IND;FUT)}$ – $2_{(1;PL)}$	0+(2-1)+(2-1) = 2	2+2 = 4	0.5
condenó *(condemned)*	Mood=Ind, Number=Sing, Person=3, Tense=Past, VerbForm=Fin	V;IND;PST;3;SG;PFV	conden - ó	0 - $5_{(IND;PST;3;SG;PFV)}$	0+(5-1) = 4	4+1 = 5	0.8
apoyada *(supported)*	Gender=Fem, Number=Sing, VerbForm=Part	V.PTCP;PST;FEM;SG	apoy - ada	0 - $3_{(PST;FEM;SG)}$	0+(3-1) = 2	2+1 = 3	0.66

Table 2: Annotation example in Spanish. We first identify the verbs (in bold) and obtain their morphological features (using spaCy and the UniMorph schema). Then, we split the verb into its morphemes (segmentation), and identify which features are fused in each morpheme (feats. per morph). Finally, we compute the index of fusion by dividing the fusional morpheme joints by the total joints (which includes the agglutinative or explicit boundaries). On a side note, examples of verbs with zero fusion are in the infinitive (e.g. hablar *(to talk)*) and gerund (e.g. hablando *(talking)*) forms.

the number of expected morphemes is larger. Unexpectedly, Morfessor also under-performs in the "1" case for both languages, and only surpasses the other unsupervised methods when we measure precision for many morphemes. Furthermore, The PtrNet supervised method outperforms the rest in almost all scenarios.

We conclude that, to compute synthesis, we should prioritise, besides a rule-based morphological analyser, a supervised segmentation method like PtrNet if data is available. We take advantage of this for the segment-level analysis in §5.

3.2 Fusion: Semi-automatic computation

Calculating fusion should be approached in a case by case scenario, as there are different considerations provided by Payne (2017). Therefore, there is not an automatic tool that can obtain the fusion score directly. We decided to focus on Spanish[6] as a case study, where verbs and auxiliary verbs contains the highest degree of fusion of all the parts-of-speech (POS).

Procedure We observed that we could perform an annotation per paradigm and the termination of the verb (-ar, -er, -ir), as the fusion degree will remain the same regardless of the lemma[7]. Then, on a chosen Spanish corpus:

1. Perform an automatic annotation of POS and morphological features[8].
2. Review the automatic annotation of special cases. For instance, there are specific verb forms that are missed as adjectives. We corrected the POS and morphological annotation of those cases in a manual step.
3. Obtain a set of all unique verb paradigms and morphological features in the corpus, considering the three different types of verb terminations in Spanish as different elements[9].

Now there is a list of unique verb paradigms and terminations that can be annotated both in synthesis and fusion. The steps are as follows:

1. For each unique verb paradigm and termination, segment a verb sample into its morphemes. E.g. the verb *habló* (‘talked’), is split in *habl-ó*, and *habláramos* (‘we were to speak’) in *habl-ára-mos*.
2. Analyse how many morphological features are fused in each morpheme: if you change a value of a feature, will the surface form or morpheme will change? E.g. in *habl-ó*, *-ó* participates in 5 features (mode (indicative), subject person (third person), subject number (singular), tense (past) and aspect (perfective)). For *habl-ára-mos*, *-ára* includes the past and subjunctive, whereas *-mos* denotes the person and number. If any of aforementioned feature changes its value, the surface will change too.
3. Count and aggregate the results per mor-

---

[6] We chose this language because of the ease of finding annotators and MT training and evaluation data.

[7] Except for irregular ones, which presents a limitation and potential noise. To reduce the risk of a biased assessment, we also performed a human evaluation.

[8] We use the spaCy model `es_dep_news_trf`, available at `https://spacy.io/models/es#es_dep_news_trf`. It has an accuracy of 0.99 in POS and morphological tagging in the UD Spanish AnCora dataset (Taulé et al., 2008), which contains news texts mostly.

[9] Using the Unimorph database (McCarthy et al., 2020) is another alternative for extracting all the possible unique inflections. We aligned and considered both tag sets for the annotation, as shown in Table 2.

phemes and obtain the fusion for each verb paradigm. E.g. the fusion for *habl-ó* is 4/5 = 0.8, and for *habl-ára-mos* is 2/4 = 0.5.

Finally, with the annotation in the unique list of verb inflections and terminations, we can extend the degree of fusion to all the verbs in the original Spanish corpus. An example of the annotation process is shown in Table 2.

4 Word-level analysis of Synthesis and Fusion in Machine Translation

In this analysis, we ask the following question: how difficult is translating a word concerning its index of synthesis or fusion? For evaluating synthesis, we work with Turkish[10] nouns and verbs, and for fusion, we keep working on Spanish verbs. For both cases, English is the source language in the translation task.

4.1 Experimental design

The experiment consists of comparing a gold standard reference with machine translation system outputs at the word level:

1. For both the reference and system output, we automatically **tag all the words with a morphological analyser** (the Boun morphological analyser and disambiguator (Sak et al., 2008) for Turkish and an spaCy model trained on the Ancora Universal Dependency parser (Taulé et al., 2008) for Spanish). The POS is needed to filter the target words. For synthesis in Turkish, the number of morphemes works as a proxy, as we are working at the word level. For fusion in Spanish, we need the inflection to obtain the degree of fusion from the annotated unique list (see 3.2).
2. **Align the words** between the reference and system output. We use the awesome-align (Dou and Neubig, 2021) tool by fine-tuning the multilingual BERT (Devlin et al., 2019) model for word-alignment, using the reference and system output as parallel corpora.
3. Calculate the translation accuracy (exact match of the word, 0 or 1) for the target POS.

We then fine-grain the results concerning the degree of synthesis (number of morphemes) or fusion.

	Total	#1	#2	#3	#4	#5+
Verbs	3,834	133	2,265	1,036	308	92
Nouns	10,680	5,899	2,974	1,556	244	7

Table 3: Number of nouns and verbs in the Turkish reference set, and their respective number of morphemes.

Additionally, we control different confounds: frequency of the word in the training set, and whether the full word is part of the vocabulary input of the model or not. Finally, we complement the analysis with a human evaluation (see §4.4).

4.2 Synthesis analysis: English→Turkish

Data We use the NEWSTEST2018.EN-TR evaluation set from WMT (Bojar et al., 2018), with 3,000 samples. In the Turkish side there are 45,944 tokens, and Table 3 shows the distribution of the number of morphemes obtained with Sak et al. (2008).

Model We use an English-Turkish system trained with the TIL corpus of 39.9M parallel sentences (Mirzakhalov et al., 2021). On the NEWSTEST2018.EN-TR set, the performance is 13.06 and 49.54 in BLEU and chrF, respectively.

Results and discussion Figure 1 shows the average accuracy (exact translation, 0 or 1) of nouns and verbs in NEWSTEST2018.EN-TR, where the number of morphemes is a proxy for the index of synthesis. In most cases, especially with a higher training frequency, we observe that the average accuracy drops as the number of morphemes increases from 1 to more. This is clearer in nouns than in verbs, which have fewer cases to analyse overall. Between 2, 3 or more than 4 morphemes the differences are not significant, and sometimes is not consistent (e.g. verbs with the highest frequency). However, we can argue that analytic nouns (synthesis=1) are easier to translate than synthetic nouns (synthesis>1) for the English→Turkish direction. The pattern holds for whether the word is part of the vocabulary of the model or not, although rare words (frequency in $[0, 10^3]$ have generally lower translation accuracy than more frequent words (frequency > 100).

4.3 Fusion analysis: English→Spanish

Data We use the NEWSTEST2013.EN-ES evaluation set from WMT (Bojar et al., 2013) with 3,000 samples. In the Spanish side there are 62,055 tokens, with 6,317 verbs, and where 1,411 of them are more agglutinative (fusion=0) and 4,822 more fusional (fusion>0).

---

[10] Turkish presents high synthesis and agglutination (Zingler, 2018), meaning that there are words composed with several morphemes and the morpheme boundaries are explicit, respectively. We focus on verbs and nouns, which usually contain more morphemes than other parts-of-speech. We chose this language due to the availability of an open-source rule-based morphological analyser and an expert annotator.

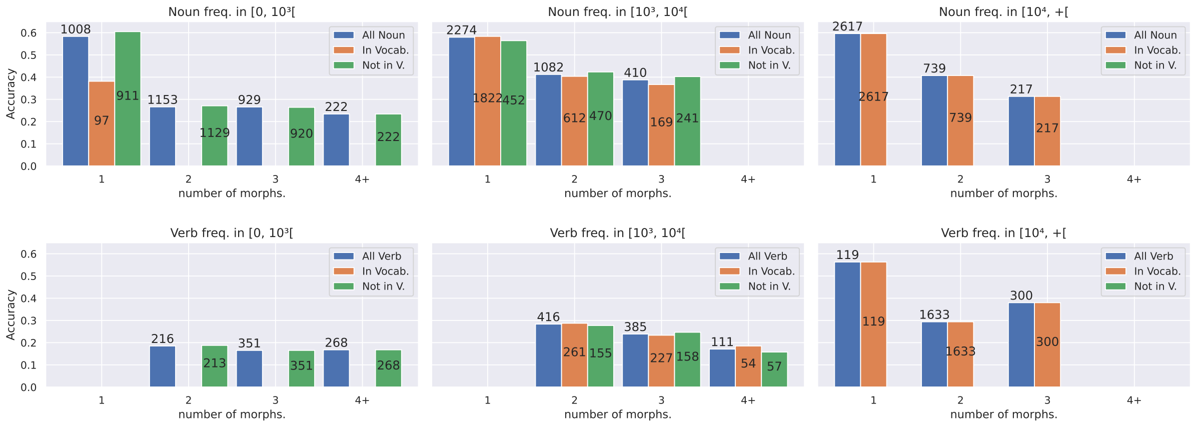

Figure 1: Accuracy (exact translation) for Nouns (top) and Verbs (bottom) in the English→Turkish translations. Results are grouped by the training frequency of the words (less to more frequent from left to right), and each subplot presents the scores for all the words, and whether they belong or not to the vocabulary input of the model. The number of samples are stacked in each bar, and we do not show entries with less than 30 samples.

Model For training, we use the MarianNMT toolkit (Junczys-Dowmunt et al., 2018), a Transfomer-base model (Vaswani et al., 2017) with default parameters, and four NVIDIA V100 GPUs. We obtained different English-Spanish models using the newscommentary-v8 (Bojar et al., 2013) and EuroParl (Koehn, 2005) datasets with joint vocabulary sizes of 8k, 16k and 32k (using unigram-LM from SentencePiece (Kudo and Richardson, 2018)). For this analysis, we chose the best performing system: combining both datasets (2.2M sentences) with 16k pieces. On NEWSTEST2013.EN-ES, the performance is 31.6 BLEU points.

Results and discussion Figure 2 shows the average accuracy of verbs in NEWSTEST2013.EN-ES for verbs without and with some degree of fusion. In the two higher frequency subplots (middle and right), we can observe that the average accuracy of the non-fusional verbs is higher than the fusional ones, and the pattern holds whether the verb is present in the vocabulary input of the model or not. The exception is for the least frequent verbs, although this is explained as the model do not have enough information to learn from, regardless of their degree of fusion.

4.4 Human evaluation

Exact translation accuracy has limitations, as there are potential translations that could be acceptable given a specific context (e.g. a synonym). For that reason, we performed a human evaluation of a sample of sentences on (10%) of each evaluation set, focusing on two scores[11]:

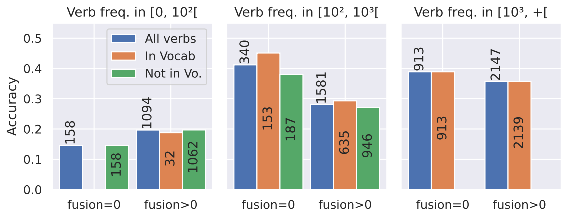

Figure 2: Accuracy (exact translation) for Verbs in the English→Spanish translations. Results are grouped by the training frequency and whether the word belongs to the vocabulary of the model (In V) or not (Not in V).

1. Semantic score: evaluates the meaning of the word used in the automatic translation (system output) and how it compares with the gold standard translation. Scale goes from 1 (no relationship at all) to 4 (it is the same lemma).
2. Grammar score: evaluates the grammatical form and how it compares with the gold standard translation. Scale goes from 1 (different inflection) to 3 (same inflection).

Synthesis In Figure 3, we show the annotation scores for the semantic and grammar metrics, for both nouns (top) and verbs (bottom). We also divide the analysis w.r.t. the frequency of the word in the training data. For nouns, we observe similar patterns as in the automatic analysis, where in the one-morpheme column, the proportion of the highest score is slightly larger than in the other columns, suggesting they are easier to generate for the model.

---

[11] Details of the annotation protocol are in the Appendix

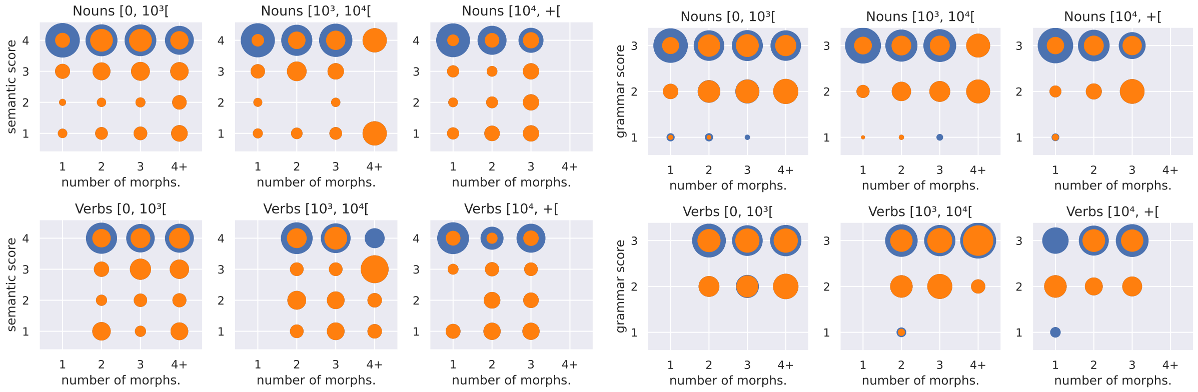

Figure 3: Semantic score (left) and Grammar score (right) annotation for Turkish, for different frequency ranges of Nouns (top) and Verbs (bottom). Bubbles represent the proportion of the amount of scored annotations (1-4 or 1-3) divided by the subtotal elements of their respective columns (or number of morphemes). The orange inner bubble represents the amount of samples with ‘zero’ accuracy (in the automatic analysis) in each category.

The pattern is even more explicit in the highest frequency block (rightmost one). The verbs tend to have more distributed grammar scores, suggesting the difficulty of generating inflected forms may remain equally high even when the words are more frequent. Single morpheme verbs are very rare in Turkish and generally contain exceptional forms which reflects in the low translation accuracy in the highest frequency block. We also observe that a good proportion of translated words with ‘zero’ accuracy (not the exact translation, see the orange inner bubbles) has been annotated with highest semantic (same lemma) or grammar (same inflection) score, suggesting in some cases that the model is successful in generalization.

Fusion Figure 4 shows the semantic and grammar annotation scores for Spanish verbs. For the semantic scores (top), in all levels, the gap between the non-fusional and fusional verbs is reduced, for all the frequency groups. This means that the model is indeed able to generalise and offer alternative translations (not the exact verb), which is more complex to measure with automatic metrics. In the grammar scale (bottom), however, we still note a slight advantage in the maximum score (3) of the non-fusional verbs against the fusional ones for the two highest frequency subplots (middle and right). This indicates that, with highly frequent verbs, it is still more difficult to translate correct forms with a fusion degree higher than zero. Similarly as for synthesis, we observe that there is a significant proportion of ‘zero’ accuracy cases (orange inner bubbles) for the highest scores in most cases. This indicates that the model could generalise and translate verbs with similar meanings and not the exact, but close, forms.

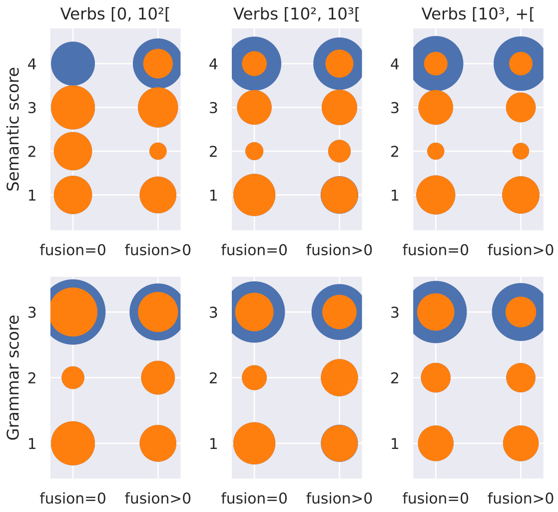

Figure 4: Semantic (top) and Grammar (bottom) annotation for Spanish.

5 Segment-level Analysis of Synthesis and Fusion in Machine Translation

Following up the word level analysis, we study the relationship between machine translation difficulty and the degree of synthesis or fusion at the segment level. For this purpose, we process a set of translation systems for the language pair we want to evaluate. The general steps are as follow:

1. For each system output, we compute **automatic evaluation metrics** (BLEU (Papineni et al., 2002), chrF (Popović, 2015) and/or COMET (Rei et al., 2020)) with respect to

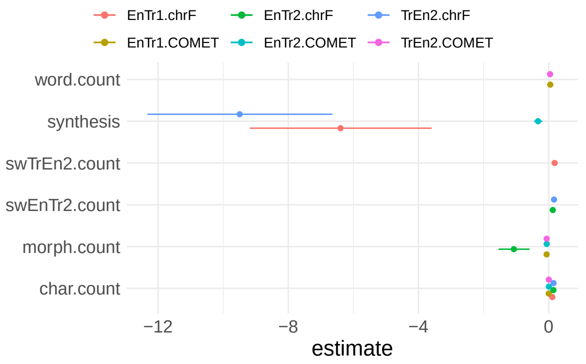

Figure 5: Overview of significant predictors for degree of synthesis across our TR-EN and EN-TR models.

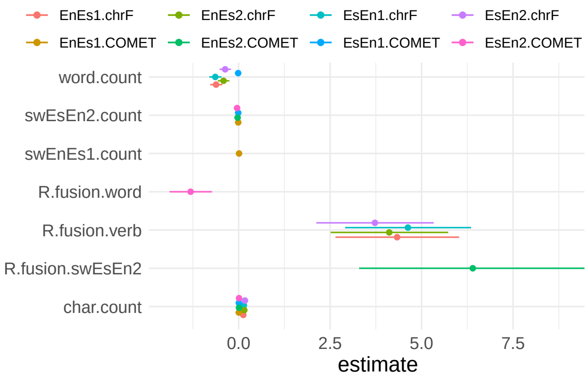

Figure 6: Overview of significant predictors for degree of fusion across our ES-EN and EN-ES models.

the reference set, per sentence.[12]

2. For each sentence of the evaluation set, we compute potential **predictor variables** for the automatic metric, such as the degree of synthesis or fusion. We complement the predictor variable list with other heuristics, such as the length of the sentence in characters (*char.count*) or words (*word.count*). The full list of all the predictors per language pair is in the Appendix.
3. With the previous inputs, we generate **generalized linear models** per system output and evaluation metric, in which each model's output is set to the predictor variables. The goal is to identify which predictors affect each method's performance.
4. Following model creation, we extract the significant predictors of each model. This provides an indication of which variables can be used to predict the outcome of the model's dependent variable – in our case the degree of synthesis or fusion, or any heuristic.[13]

Synthesis on En-Tr and Tr-En We first start evaluating the English-Turkish and Turkish-English language pairs. The evaluated models are EnTr1, EnTr2, and TrEn2 (details in the Appendix). Also, as we are studying synthesis in Turkish, all predictors are computed on the Turkish side, regardless of the translation direction.

Figure 5 presents an overview of the significant predictors on En-Tr and Tr-En systems, where we observe a large impact of the *synthesis* variable on the chrF scores of two different systems (EnTr1 and TrEn2). The only other heuristic that achieves a notable impact on a system output is *morph.count*, or the length of Turkish sentence in morphemes, split by a morphological analyser. Other predictors have a minor effect.

Fusion on En-Es and Es-En In a similar way, we evaluate the impact of fusion in English-Spanish (EnEs1, EnEs2) and Spanish-English (EsEn1, EsEn2) models (see the Appendix for details). Again, as we are studying fusion in Spanish, all predictors are computed on the Spanish side, regardless of the translation direction.

Figure 6 presents an overview of the significant predictors, where we observe that *R.fusion.verb*, or the ratio of the degree of fusion over the number of verbs in the sentence, is the predictor that has the highest impact in most system outputs (EnEs1, EnEs2 and EsEn2). Additionally, *R.fusion.swEsEn2* (or the ratio of the degree of fusion over the number of subwords input in the EsEn2 model) also has a high impact in one system output (EnEs2, which uses the same segmentation model as EsEn2).

Analysis on En-De and De-En Finally, we extend the analysis to English-German and German-English language pairs, using the respective evaluation sets of the WMT2018 campaign (Bojar et al., 2018), and the system outputs provided for all the participants (measured in BLEU). For computing synthesis, we use the different segmentation methods we compared in §3.1. However, for fusion, we only use a shallow proxy with the number of morphological features that are tagged using a morphological analyser. In this case, the predictors are computed for both the source and target side.

---

[12] Based on the analysis of Kocmi et al. (2021), we prefer to report COMET and chrF over BLEU.

[13] For simplification purposes, in the following analysis and plots, we only show the predictors that show a significant effect on the system outputs.

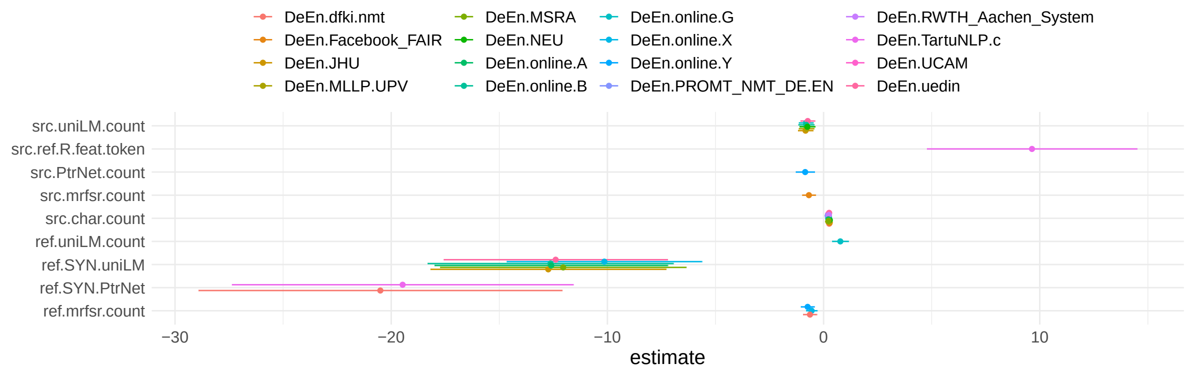

Figure 7: Overview of significant predictors across DE-EN models.

We present an overview of these significant predictors for German-English in Figure 7 (and the Appendix contains the results for English-German in Figure 8). We can observe that *ref.SYN.uniLM* and *ref.SYN.PtrNet* are the predictors that impact most of the different system outputs. These variables refer to the synthesis computed on the reference side (English) using uniLM or PtrNet as the morpheme segmentation method, respectively. Furthermore, we observe that *src-ref.R.feat.token* has also some effect over one system output, which is a shallow proxy for the fusion degree in the source w.r.t. to reference segment (using the ratio of number of features per number of tokens).

6 Discussion

It is important to note the limitations of this study. Overall results do not suggest that translating into more analytic languages (e.g. Chinese) or more agglutinative ones (e.g. Turkish) is easier than their counterparts. Highly analytic ones present the significant issue of word coverage and vocabulary size of the model. Besides, we cannot isolate the fusional degree from synthesis entirely. For instance, Turkish is a highly agglutinative language, but also highly synthetic, and there are languages that present both agglutinative and fusional traits, like Navajo. Moreover, the language scope is another limitation: is it possible to extend it to further languages in a practical way? Synthesis can be calculated directly only if the morphological analyser splits the word into morphemes, and fusion poses several issues as mentioned before. Furthermore, Payne (2017) also indicated that the discourse can impact the computed degrees due to the diversity of the vocabulary. This study focuses on news data only, and it will be relevant to extend it to different domains.

To address the limitations, we consider that our word level analysis, that targets specific POS, has been fundamental to enable the study of the indexes, and to partially isolate them from each other. The selection of our study cases was also relevant. Spanish verbs do not present more than three morphemes, keeping a low synthesis value across all the analysis, whereas Turkish is more agglutinative than fusional. Moreover, to rapidly extend the evaluation for new languages and domains, we could follow a less fine-grained analysis in each index. For instance, we can compare synthesis=1 vs. synthesis>1 instead of granulating per number of morphemes, or fusion=0 vs. fusion>0, as we did in this work.

7 Conclusion and future work

In conclusion, we proposed methods to quantify the indices of synthesis and fusion in automatic and semi-automatic ways, respectively. Besides, for the chosen language pairs, we observed that the studied degrees have an impact in machine translation performance at both word and segment level, where we included a human evaluation of the former case.

Our analysis opens the possibility for further fine-grain evaluation approaches for MT and other NLP generation tasks. For instance, as future work, we can ask: are we improving the automatic translation of highly fusional words or segments? Following our methodology, we could stratify evaluation sets to measure how our models performs in different parts of the spectrum. Besides, the indices could also be helpful for evaluation approaches in morphological segmentation. Furthermore, another potential research avenue is to aid model training in MT: e.g. knowing which segments are more or less synthetic and/or fusional could be beneficial for sampling strategies.

8 Ethical Considerations

The annotations in this paper were compensated accordingly (see Appendix). Also, for all the datasets used in the research, we stick to the ethical standards giving credit to the original author. We encourage future work that take advantage of these resources, to cite also the original sources of the data.

A Human Evaluation

A.1 Annotation Protocol

This study measures the translation quality of translations generated by a translation system. You are given a list of sentences where one column lists each word in the gold standard (correct) translation and the corresponding column the system-generated translations. The evaluation of the translations will rely on the two scores described below. The scores to use in the evaluation are:

Semantic score evaluates the meaning of the word used in the automatic translation (system output) and how it compares with the gold standard translation.

Please assign each word in the output one of the scores you find most appropriate:

1. There is no relationship between the two lemmas

2. The lemmas are different but the translation does not fit well in the context
3. The lemmas are different but it is still an acceptable translation (e.g. synonym)
4. It is the same lemma

Grammar score evaluates the grammatical form and how it compares with the gold standard translation.

Please assign each word in the output one of the scores you find most appropriate:

1. The word is inflected in a different way and it is not necessarily correct
2. The word has different inflection but it is still grammatically correct
3. The words have the same inflection, and it is correct

Please annotate all words in the translations in the file shared with you. In your evaluation try assigning the two scores to each word independently. The inflection of the word measures the morphological feature and should also be evaluated independently from the analyzer output which is automated and may contain errors.

The file contains example annotations for your reference, please ask any questions related to unresolved annotation examples by contacting the project coordinators.

A.2 Annotators

For both Turkish and Spanish, the annotators were contacted directly due to their expertise in morphology (both of them are PhD students in Linguistics and Computational Linguistics, respectively), besides requiring that they are native speakers of the target languages. Also, they were paid more than the minimum wage per hour of annotation of their country of residence, and were told that the annotated data will be released upon acceptance of the study.

B Segment-level Analysis of Synthesis and Fusion

B.1 List of machine translation systems

- EnTr1: the same system used in §4.2
- EnTr2: Transformer-base model (Vaswani et al., 2017) with joint vocabulary size of 8k pieces (unigram language modelling from SentencePiece (Kudo and Richardson, 2018), and trained with a sample (10%) of the corpus of EnTr1.

Predictor	Description
char.count	number of characters
word.count	number of words (no punct. or numbers)
morph.count	number of morphemes.
synthesis	ratio of morph.count / word.count
N+V.word.count	number of Nouns and Verbs
N+V.morph.count	number of morphemes of the Nouns and Verbs
N+V.synthesis	ratio of N+V.morph.count / word.count
swEnTr1.count	number of subwords processed by the EnTr1 model
swEnTr2.count	number of subwords processed by the EnTr2 model
swTrEn2.count	number of subwords processed by the TrEn2 model
syn.swEnTr1	ratio of swEnTr1.count / word.count (synthesis proxy)
syn.swEnTr2	ratio of swEnTr1.count / word.count (synthesis proxy)
syn.swTrEn2	ratio of swEnTr1.count / word.count (synthesis proxy)

Table 4: List of predictors for En-Tr and Tr-En. All variables are computed on the Turkish segment of the evaluation set.

Predictor	Description
char.count	number of characters
word.count	number of words (no punct. or numbers)
verb.count	number of verbs
fusion	sum of the degree of fusion of all the verbs in the segment
R.fusion.verb	ratio of fusion / verb.count
R.fusion.word	ratio of fusion / word.count
swEsEn1.count	number of subwords processed by the EsEn1 model
swEsEn2.count	number of subwords processed by the EsEn2 model
R.fusion.swEsEn1	ratio of fusion / swEsEn1.count
R.fusion.swEsEn2	ratio of fusion / swEsEn2.count
swEnEs1.count	number of subwords processed by the EnEs1 model
swEnEs2.count	number of subwords processed by the EnEs2 model
R.fusion.swEnEs1	ratio of fusion / swEnEs1.count
R.fusion.swEnEs2	ratio of fusion / swEnEs2.count

Table 5: List of predictors for En-Es and Es-En. All variables are computed on the Spanish segment of the evaluation set.

- EnEs1: the same system used in §4.3
- EsEn1: similar configuration than EnEs1 but in the opposite direction
- EnEs2: same configuration as EnEs1 (model and vocabulary) but with smaller training data. It uses only newscommentary-v8 data, with around 300k sentences).
- EsEn2: similar configuration than EnEs2 but in the opposite direction.

B.2 List of predictors

Tables 4, 5 and 6 describes all the predictors used at the segment level analysis of English-Turkish, English-Spanish and English-German (both directions), respectively.

B.3 Results on English-German

Figure 8 shows the analogous results for English to German, where the synthesis-based variables presents a high impact w.r.t. the other predictors.

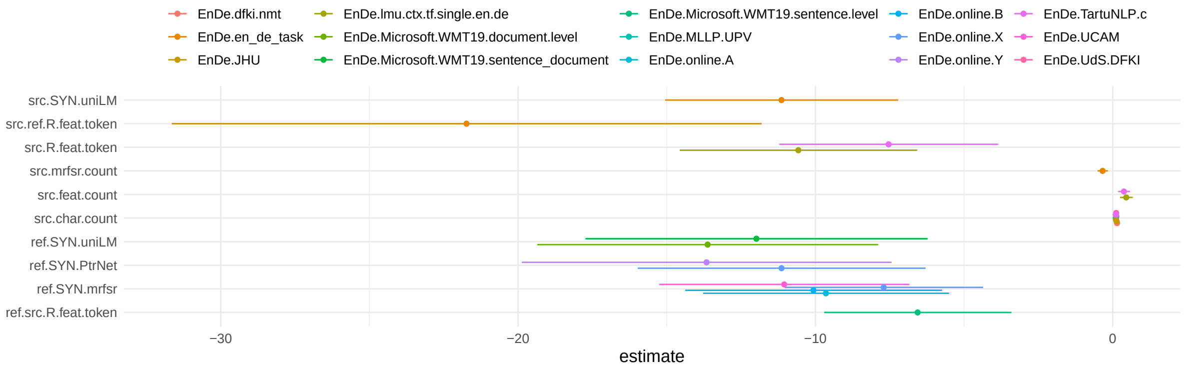

Figure 8: Overview of significant predictors for degree of synthesis across EN-DE models.

Predictor	Description
src.char.count	number of characters in the source side
ref.char.count	number of characters in the target side
src.word.count	number of words in the source side
ref.word.count	number of words in the target side
src.uniLM.count	number of subwords obtained by uniLM in the source
ref.uniLM.count	number of subwords obtained by uniLM in the target
src.SYN.uniLM	synthesis in source = src.uniLM.count / src.word.count
ref.SYN.uniLM	synthesis in target = ref.uniLM.count / ref.word.count
src.mrfsr.count	number of subwords obtained by Morfessor in the source
ref.mrfsr.count	number of subwords obtained by Morfessor in the target
src.SYN.mrfsr	synthesis in source = src.mrfsr.count / src.word.count
ref.SYN.mrfsr	synthesis in target = ref.mrfsr.count / ref.word.count
src.PtrNet.count	number of subwords obtained by PtrNet in the source
ref.PtrNet.count	number of subwords obtained by PtrNet in the target
src.SYN.PtrNet	synthesis in source = src.PtrNet.count / src.word.count
ref.SYN.PtrNet	synthesis in target = ref.PtrNet.count / ref.word.count
src.feat.count	number of morph. features in the source (using spAcy)
src.R.feat.token	ratio of src.feat.count / src.word.count
ref.feat.count	number of morph. features in the target (using spAcy)
ref.R.feat.token	ratio of ref.feat.count / ref.word.count
src-ref.feat.count	src.feat.count minus ref.feat.count
src-ref.R.feat.token	src.R.feat.token minus ref.R.feat.token
ref-src.feat.count	ref.feat.count minus src.feat.count
ref-src.R.feat.token	ref.R.feat.token minus src.R.feat.token

Table 6: List of predictors for En-De and De-En. Variables are computed either on source (src) or target (ref) side.

Commonsense and Named Entity Aware Knowledge Grounded Dialogue Generation

Abstract

Grounding dialogue on external knowledge and interpreting linguistic patterns in dialogue history context, such as ellipsis, anaphora, and co-references is critical for dialogue comprehension and generation. In this paper, we present a novel open-domain dialogue generation model which effectively utilizes the large-scale commonsense and named entity based knowledge in addition to the unstructured topic-specific knowledge associated with each utterance. We enhance the commonsense knowledge with named entity-aware structures using co-references. Our proposed model utilizes a multi-hop attention layer to preserve the most accurate and critical parts of the dialogue history and the associated knowledge. In addition, we employ a Commonsense and Named Entity Enhanced Attention Module, which starts with the extracted triples from various sources and gradually finds the relevant supporting set of triples using multi-hop attention with the query vector obtained from the interactive dialogue-knowledge module. Empirical results on two benchmark dataset demonstrate that our model significantly outperforms the state-of-the-art methods in terms of both automatic evaluation metrics and human judgment. Our code is publicly available at https://github.com/deekshaVarshney/CNTF; https://www.iitp.ac.in/-ai-nlp-ml/resources/codes/CNTF.zip.

1 Introduction

Neural language models usually focus on fewer language components such as sentences, phrases, or words for text analysis. However, language acts on a much broader scale - there is frequently a central theme to a conversation, and the speakers share common information in order to comprehend one another. Information is frequently reused, however to avoid overuse, same things and persons are referred in the dialogue multiple times by using relevant expressions. A dialogue becomes coherent and speakers can understand each other when all of this information is delivered in a structured, logical, and consistent manner.

Semantic understanding of dialogues can be aided by commonsense knowledge or world facts. Additionally, as a key human language phenomena, co-reference simplifies human languages while being a significant barrier for machines to understand, particularly for pronouns, which are difficult to parse due to their weak semantic meanings (Ehrlich, 1981). Grounded response generation approaches (Ghazvininejad et al., 2018; Dinan et al., 2018) can provide replication of facts in open-domain settings, whereas commonsense knowledge is critical for creating successful interactions since socially constructed commonsense knowledge is the collection of contextual details that humans are expected to understand and use during a conversation.

Despite demonstrating efficacy in empirical evaluation, past work has a few significant drawbacks. There is no explicit representation of entities, semantic relations, or conversation structures, in particular. To solve such restrictions, asking a conversation model to identify relevant structures in dialogue histories can be used to directly test the level of dialogue understanding. We focus on named entity level knowledge in this paper, and analyze references to entities in a dialogue history context.

To ensure the generalizability of our model, we directly incorporate entities in the form of triplets, which is the most common format of modern knowledge graphs, instead of encoding it with features or rules as in conventional approaches. Take, for example, Figure 1, where the dialogue consists of eight utterances. In the third utterance, to know if there exists any relation between the director "Micheal Mann" and the movie "The Last of the Mohicans", we need to resolve the co-reference

---

Topic-Specific Knowledge

The Last of the Mohicans is a 1992 American epic historical drama, set in 1757 during the French and Indian War. It was directed by Michael Mann, based on James Fenimore Cooper's eponymous 1826 novel and George B. Seitz's 1936 film adaptation, owing more to the latter than the novel. The film stars Daniel Day-Lewis, Madeleine Stowe, and Jodhi May, with Russell Means, Wes Studi, Eric Schweig, and Steven Waddington in supporting roles. It was produced by Morgan Creek Pictures. The soundtrack features music by Trevor Jones and Randy Edelman, and the song "I Will Find You" by Clannad. The main theme of the film is taken from the tune "The Gael" by Scottish singer-songwriter Dougie MacLean.

Conversation

Agent 1: [The Last of the Mohicans] is a 1992 American epic historical drama [it] is also one of my favorite movies.

Agent 2: Me too. I love [that movie] and the soundtrack in particular.

Agent 1: [It] was directed by Michael Mann, based on [James Fenimore Cooper's eponymous 1826] novel

Agent 2: I tried to read [the book] but gave up. I can't remember what other movies Michael Mann has directed.

Agent 1: I never got to reading [the book] but I am defenetly interested.

Agent 2: I couldn't get into the rhythm of the writing. A little bit different in 1826!

Agent 1: [The movie] was produced by [Morgan Creek Pictures] and i think [they] did a great job.

Agent 2: Is [Morgan Creek] still producing movies?

Figure 1: An example of named entity and concept based knowledge triples being used for grounding dialogues in addition to topic-specific knowledge sentences. In the conversation, various shades indicate the different co-reference clusters obtained. Blue nodes correspond to the concepts obtained from ConceptNet, red nodes correspond to the named entities obtained from the utterances in the dialogue. Named Entities other than the ones present in co-reference chains are highlighted in green in the conversation.

relationship between the pronoun [It] and the entity [The Last of the Mohicans]. Using co-reference resolution, we get an important triple for the movie “The Last of the Mohicans" *viz. (The Last of the Mohicans, RelatedTo, Micheal Mann)*. Similarly, from the second last utterance, we obtain another triple as *(The Last of the Mohicans, RelatedTo, Morgan Creek Pictures)*. Thus, for instance, to generate the fourth utterance "I tried to read the book but gave up. I can’t remember what other movies *Michael Mann* has directed.", it is important for the model to know that there is a relation between the concept word *“movie"* and the named entities *“Micheal Mann"*, *“The Last of the Mohicans"*, to get a correct understanding of the dialogue context.

We create a conversational model called CNTF, **C**ommonsense, **N**amed Entity and **T**opical Knowledge **F**used neural network to generate successful responses by leveraging both topic-specific document information and using structured entity and commonsense knowledge. We first construct triples based on named entity after resolving co-references in the dialogues to enhance the already existing commonsense triples obtained from the ConceptNet (Speer and Havasi, 2012). We use multi-hop attention to iterate over the multi-source information. We obtain a weighted query vector from the interactive dialogue-knowledge module, which is used to query over the dialogue, topical knowledge and the corresponding triples. In each round, CNTF reasons on the dialogue history and knowledge sentences, using which we filter out relevant information from the dialogue context and topical knowledge. Similarly, to reason over the triples, we again iterate in multiple rounds, masking out irrelevant triples.

Our work makes the following contributions:

1. We propose CNTF, a novel knowledge grounded dialogue generation model that utilizes dialogue context, unstructured textual information, and structural knowledge to facilitate explicit reasoning.
2. We enhance the commonsense triples extracted from the ConceptNet database with named entity-aware structures using co-reference resolution.
3. We define an effective sliding window mechanism in order to remove irrelevant information from longer dialogue context and ensure efficient memory utilization. We use an interactive dialogue-knowledge module to generate a weighted query vector which captures the interactions between the conversation and the topical knowledge.
4. Through extensive qualitative and quantitative validation on publicly available datasets, we show that our model outperforms the strong baselines.

2 Related Work

Sequence-to-sequence models (Vinyals and Le, 2015; Sutskever et al., 2014) have long been used for natural language generation (NLG) tasks. Stemming off the vanilla encoder-decoder architecture - introduced initially for neural machine translation (Shang et al., 2015), a variety of models have been developed to enhance the quality of the responses generated (Li et al., 2016a; Zhao et al., 2017; Tao et al., 2018); to effectively select the conversational context in multi-turn dialogues (Serban et al., 2016, 2017; Xing et al., 2017; Zhang et al., 2019); and to model persona while conversing (Li et al., 2016b; Zhang et al., 2018). Recent advances on dialogue systems aim at enhancing dialogue generation by making it more humanized by means of incorporating knowledge based on the dialogue context or from external sources, such as unstructured documents (Li et al., 2019; Qin et al., 2019) or knowledge graphs (Moon et al., 2019; Tuan et al., 2019).

Numerous pre-trained language models (Devlin et al., 2019; Radford et al., 2019) have been utilized for dialogue generation (Edunov et al., 2019; Zhang et al., 2020). They have been extended to leverage the knowledge from the unstructured documents and other auxiliary sources via knowledge selection and various attention fusion techniques (Zhao et al., 2020c; Cao et al., 2020). The task was explored in low-resource setting (Zhao et al., 2020b) using a disentangled response decoder, and the usability of language models itself as a knowledge base has also been investigated in Zhao et al. (2020d). An issue with language models is the noise which these introduce during knowledge selection. In order to limit the noise by generative models, term-level weighting (Zheng et al., 2021) for response generation after knowledge selection were studied. Zhao et al. (2020a) proposed a pre-training based multiple knowledge syncretic transformer that uses a single framework to integrate knowledge from multiple sources. Knowledge based end-to-end memory networks have been developed for task-oriented dialogue generation (Raghu et al., 2019; Reddy et al., 2019; Chen et al., 2019; Wang et al., 2020; Varshney and Singh, 2021) using multi-level, working, and dynamic types of memory. In Dual Dynamic Memory Network (DDMN) (Wang et al., 2020), the flow of history information during conversations is dynamically tracked to retain the important parts from both dialogue and KB, using a memory manager for each.

Prior studies (Young et al., 2018; Zhou et al., 2018a; Wu et al., 2020b) have demonstrated the feasibility of including commonsense knowledge into the dialogue systems. Further, in ConKADI (Wu et al., 2020a), felicitous facts highly relevant to the context were selected and effectively integrated in the generated response by means of fusion mechanisms. Recently, co-reference resolution has been utilized for obtaining coref-informed pre-trained models (Ye et al., 2020), task-oriented dialogue generation (Quan et al., 2019), and dialogue understanding (Zhang et al., 2021). Further, (Huang et al., 2021) demonstrated the improvement upon explicitly incorporating co-reference information to enhance the attention mechanism for the reading comprehension task.

In this paper, we show how both structured and unstructured knowledge can be used to improve the task of document-grounded dialogue generation. We propose an effective knowledge-grounded dialogue model named CNTF, which is built with multi-source heterogeneous knowledge. Experiments on knowledge-based dialogue generation benchmark datasets, *viz.* Wizard of Wikipedia and CMU_DoG, have shown the efficacy of our proposed approach. Our method employs a large-scale named entity enhanced commonsense knowledge network as well as a domain-specific factual knowledge base to aid in the comprehension of an utterance as well as the generation of a response using a novel mutli-hop attention based model.

3 Methodology

3.1 Problem Formulation

Formally, let $D = \{d_i\}_{i=1}^{K}$ denote a conversation composed of K dialogue turns, where $d_i = (a_i^1, a_i^2)$ is an exchange of dialogues between the two agents. Associated with each utterance a_i^1 and a_i^2 are the relevant documents S_i^1 and S_i^2 with topic-specific knowledge. We utilize common sense and named entity oriented knowledge by creating the set of triples $\tau = \{\tau_1, \tau_2, ..., \tau_{|\tau|}\}$, where τ_i is of the form $(head, relation, tail)$, from the following sources:

(a) extracting relations from ConceptNet for every word in the utterances (if the word is a *concept-word* from ConceptNet), and

(b) forming named entity based triples by using co-reference resolution method

For any arbitrary turn k, given the dialogue history $\{d_j\}_{j=1}^{k-1}$, the associated documents as well as

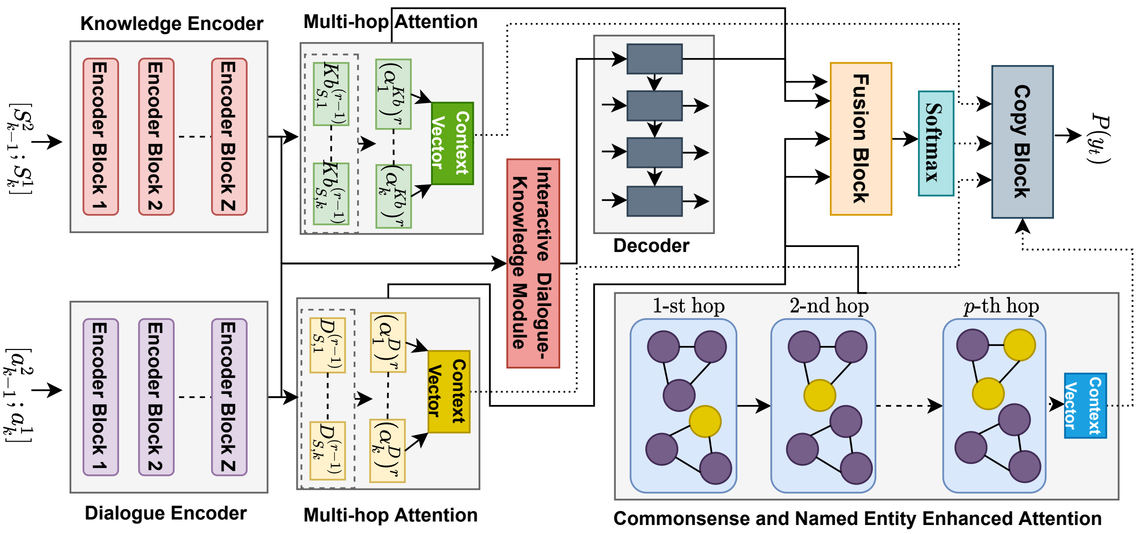

Figure 2: Proposed CNTF architecture. The dialogue encoder encodes the dialogue context in multi-turn conversation. Similarly, the knowledge encoder takes as input the document(s) associated with the utterances in the conversation. The multi-hop attention modules are used to extract relevant information from dialogue and knowledge whereas the Commonsense and Named Entity Enhanced Attention module is used to effectively incorporate the knowledge triples.

the target document $\{S^1_j, S^2_j\}^k_{j=1}$, and the associated knowledge triples τ, the objective is to generate an appropriate response $Y = \{y_1, y_2, ..., y_{|Y|}\}$. The architecture of CNTF is shown in Figure 2.

3.2 Encoder

3.2.1 Dialogue Encoder

The Dialogue Encoder, that keeps track of the dialogue context in multi-turn conversations, encodes the utterances turn by turn. The input at each turn is a sequence of tokens $x = (x_1, x_2, ..., x_n)$, where n is the number of tokens. For the first turn, a^1_1 is fed as input, while for the subsequent turns ($j > 1$), the input is the concatenation of the previous turn's second agent's response and current turn's first agent's utterance, $[a^2_{j-1}; a^1_j]$. The encoder then exploits Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) to obtain the representations $H_D = \{h_i\}^n_{i=1}$.

Using the dialogue representations, we maintain two different states for the dialogue, D_S and D_H, which are both initialized with the encoder hidden states H_D, of the first turn. We then follow a sliding window mechanism to update both D_S and D_H for the succeeding turns. A window of size *"l"* means we concatenate hidden states of only the previous *"l-1"* turns. This helped in removing noise for longer dialogue contexts and saving memory. D_H remains fixed and stores the hidden states for the dialogue context, while D_S gets updated at each turn, with the goal of capturing proper history information for accurate response generation.

3.2.2 Knowledge Encoder

Similarly, the Knowledge Encoder takes as input the document(s) associated with the utterances *viz.* $[S^2_{j-1}; S^1_j]$ for turn $j > 1$, else S^1_1 for the first turn, truncated to a max token count of 400. We then again employ a BERT model and obtain the encoded features $H_{Kb} = \{h_i\}^m_{i=1}$, where m is the number of tokens in the document(s). To incorporate the external topic-specific knowledge effectively, we have knowledge states Kb_S and Kb_H. Similar to the dialogue states D_S and D_H, these are initialized with the hidden states H_{Kb} of the relevant documents associated with each utterance. Unlike the sliding window mechanism used for the dialogue states for the upcoming turns, Kb_S and Kb_H store only the current turn's hidden states obtained from the BERT based knowledge encoder.

3.3 Multi-hop Attention

We adopt the dual and dynamic graph attention mechanism (Wang et al., 2020) to mimic human's step-by-step exploring and reasoning behavior. In each step, we assume that the dialogue and knowledge states have some information to disseminate. At each hop r, we compute an attention vector $\alpha^{(r)}_t$ using the query embedding q_t at the k-th turn using $D_S^{(r-1)}$ at time step t. $D_{H,k,t}$ and the attention scores are used to obtain the context representation $c_t^{(r)}$.

$$\alpha_{k,t}^{(r)} = softmax(e_{k,t}) \tag{1}$$

$$e_{k,t} = (v_1^{(r)})' \tanh(W_1^{(r)} q_{k,t} + W_2^{(r)} D_{S,k,t}^{(r-1)}) \tag{2}$$

$$c_{k,t}^{(r)} = \sum_{j=1}^{K} a_{k,t}^{(r)} D_{H,k,t} \tag{3}$$

where $v_1^{(r)}$, $W_1^{(r)}$ and $W_2^{(r)}$ are the learnable parameters.

D_S is updated using the *forget* and *add* operations. To find more details on updating D_S refer to Appendix A.

3.4 Constructing Named Entity based Triples using Co-reference Resolution

To add more useful links to the already existing commonsense triples, we use the co-reference chains and named entities extracted from the dialogues. Firstly, we use AllenNLP co-reference resolution module to identify co-reference chains in the dialogue. For example, in the dialogue shown in Fig. 1, using the first co-reference chain: **[The Last of the Mohicans: it, that movie, It]** we rewrite the dialogue with resolved mentions in the utterances as: *"[The Last of the Mohicans] is a 1992 American epic historical drama [The Last of the Mohicans] is also one of my favorite movies. Me too. I love [The Last of the Mohicans] and the soundtrack in particular. [The Last of the Mohicans] was directed by Michael Mann, based on [James Fenimore Cooper's eponymous 1826] novel and so on"*. We then use Spacy Named Entity tagging module to recognize named entities from the augmented dialogue. Simultaneously, we also identify all the concept words using ConceptNet in the newly formed dialogue.

The new set of triples is obtained using the named entities and concepts as nodes, and the corresponding edges are built as follows:

(a) between every pair of named entities that appear in the same dialogue, and

(b) between a named entity node and other concepts within the same dialogue.

We may note that resolving the co-references first and then extracting named entities ensures that entities across multiple utterances are connected in a certain way. Also, we explicitly form a triplet having the *RelatedTo* relation as it suits well for most of the cases because it indicates a relation between the two named entities and their different references or aliases across the conversation.

3.5 Commonsense and Named Entity Enhanced Attention Module

For each dialogue, the final set of triples is composed of both commonsense and named entity based triples. We obtain triples' head and tail entity embedding from the trainable embedding layers i.e. $E = \text{emb\_layer}(\tau)$. Formally, a query is used to loop over the triple embedding and compute the attention weights at each hop p.

$$\alpha_{k,t}^{(p)} = softmax(q_t^{(p-1)} E^{(p-1)}) \tag{4}$$

Finally, the weighted context for knowledge triples, $(c^T)^{(p)}$, is obtained by weighting the current set of triple embedding, $E^{(p)}$ using the attention scores, $\mathbf{a}^{(p)}$. A query update mechanism is used, where the query embeddings are updated using the weighted triple embeddings of the current step.

$$(c_{k,t}^T)^p = \sum_{j=1}^{n} \mathbf{a}_{k,t}^p E^p \tag{5}$$

$$q_t^p = q_t^{p-1} + (c_{k,t}^T)^p \tag{6}$$

3.6 Decoder

3.6.1 Interactive Dialogue-Knowledge Module

As each utterance is linked to topic-specific unstructured knowledge, we employ an interactive mechanism to attend to both the dialogue and the knowledge sentences. We can improve information extraction from dialogue as well as knowledge hidden states for response generation by using the encoded weighted dialogue context as the initial query vector q_t. To obtain the *weighted dialogue context* WH_D, we apply the multi-hop attention as described in Section 3.3 between H_D and H_K which are the hidden states received from the dialogue and knowledge encoder, respectively.

We use a GRU based decoder to generate responses word by word, and initialize the initial hidden states of the decoder with WH_D. Then at time step t, the decoder state s_t can be updated as

$$s_t = \text{GRU}(e(y_{t-1}), s_{t-1}) \tag{7}$$

where $e(y_{t-1})$ is the embedding of the previous word y_{t-1}. Here, s_t is regarded as the updated query vector, which is used to attend to the dialogue, topic-specific knowledge and the structured knowledge triples, and obtain the weighted context, knowledge and triple representation as c_t^D, c_t^K and c_t^T, respectively.

3.6.2 Fusion Block

The probability distribution over the vocabulary $P_g(y_t)$ words is obtained by fusing c_t^D, c_t^K, c_t^T and the decoder state, s_t, and then passing them through a softmax layer.

$$P_g(y_t) = \mathrm{softmax}(W_5[s_t; c_t^D; c_t^K; c_t^T]) \tag{8}$$

where W_5 is a trainable parameter.

3.6.3 Copy Block

In particular, a word at time step t is either generated from the vocabulary or copied from either the dialogue history, knowledge history, or using entities from the triples. Following the copy mechanism (Gulcehre et al., 2016), the attention scores are viewed as the probability to form the copy distribution. We use the attention score $\alpha_{k,t}^D$ of the dialogue and $\alpha_{k,t}^{Kb}$ of the unstructured knowledge at the last round viz. $P_D(y_t = w) = \sum_{tj:w_{tj}=w} \alpha_{k,t}^D$; $P_{Kb}(y_t = w) = \sum_{tj:w_{tj}=w} \alpha_{k,t}^{Kb}$. The copy distribution over the triples is given by $P^T(y_t = w) = \sum_{tj:w_j^t=w} \alpha_{k,t}^T$. We use the soft gates g_1, g_2 and g_3 to control whether a word is generated from the vocabulary or it is being copied by combining $P_g(y_t)$, $P_D(y_t)$, $P_{Kb}(y_t)$, and $P_T(y_t)$:

$$g_1 = \mathrm{Sigmoid}(W_8[s_t; c_t^D] + b_2) \tag{9}$$

$$P_{kn}(y_t) = g_1 P_g(y_t) + (1 - g_1) P_D(y_t) \tag{10}$$

$$g_2 = \mathrm{Sigmoid}(W_9[s_t; c_t^K] + b_3) \tag{11}$$

$$P_{tp}(y_t) = g_2 P_{Kb}(y_t) + (1 - g_2) P_{kn}(y_t) \tag{12}$$

$$g_3 = \mathrm{Sigmoid}(W_{10}[s_t; c_t^T] + b_4) \tag{13}$$

$$P(y_t) = g_3 P_T(y_t) + (1 - g_3) P_{tp}(y_t) \tag{14}$$

where, W_8, W_9, W_{10} are the parameters to be learned.

Therefore, the decoder loss is the cross-entropy between the predicted distribution $P(y_t)$ and the reference distribution, p_t, denoted as $Loss = -\sum p_t log(P(y_t))$.

4 Datasets and Experimental Setup

In this section, we present the details of the datasets and the other experimental setups. Implementation details can be found in Appendix C.

4.1 Dataset Description

4.1.1 Knowledge Grounded Dialogue Dataset

We test our proposed technique on two knowledge-grounded dialogue generation benchmark datasets, *viz.* Wizard of Wikipedia (Dinan et al., 2018) and CMU Document Grounded Conversations (Zhou et al., 2018b). The WoZ and CMU_DoG datasets consist of approximately ≈ 22K and ≈ 4K dialogs, respectively, covering more than 1,365 and 90 topics. The datasets are summarized in Appendix B. The statistics of the datasets are shown in Table 4 of the Appendix.

4.1.2 Commonsense Knowledge Base

We use ConceptNet, an open-domain repository of commonsense knowledge. It includes the relationships between concepts that are commonly used in everyday situations, such as "Mango is a fruit." This function is desirable in our experiments because it is critical to be able to identify the informal relationships between common concepts in an open-domain conversation setting. We remove triples containing multi-word entities when filtering words based on dataset vocabulary, and $147,676$ triples were retained with $27,468$ entities and 44 relations for Wizard of Wikipedia dataset. For CMU_DoG dataset, we have a total of $14,689$ entities, $74,485$ triples and 42 relations.

4.2 Baselines

We use the following models as the baselines:

1. **Transformer Memory Network (TMN)** (Dinan et al., 2018): To encode dialogue, a shared transformer-based encoder is used. After knowledge selection, memory networks are used to re-encode the dialogue information. Finally, a transformer decoder is used to decode the responses.

2. **DialogGPT*finetune***(Zhao et al., 2020d): It utilises a DialoGPT (345M) model fine-tuned on training examples from the Topical Chat dataset to determine whether the pre-trained models can serve as knowledge bases for open-domain dialogue generation.

3. **Incremental Transformer with Deliberation Decoder (ITDD)** (Li et al., 2019): It uses an incremental transformer-based model to encode utterances and documents and a deliberation decoder to decode responses.

4. **Disentangled Response Decoder (DRD)** (Zhao et al., 2019): It is made up of three modules: a language model, a context processor, and a

knowledge processor for decoding responses. The response decoder is broken down into independent components in this case to investigate knowledge-based dialogue generation.

5. **ConKADI** (Wu et al., 2020a): It includes a Felicitous Fact mechanism to help the model focus on knowledge facts that are highly significant; additionally, two techniques, Context-Knowledge Fusion and Flexible Mode Fusion, are proposed to assist ConKADI in integrating the knowledge information.

6. **KnowledGPT** (Zhao et al., 2020c): This model implements response generation by combining a pre-trained language model with a knowledge selection module, and it intends to jointly optimize knowledge selection and response generation with unlabeled dialogues using an unsupervised approach.

4.3 Evaluation Metrics

To evaluate the predicted responses, we choose BLEU (Papineni et al., 2002), PPL, F1 and Embedding-based metrics (Liu et al., 2016). For human evaluation, we use fluency, adequacy, knowledge existence, knowledge correctness and knowledge relevance. Appendix D provides more information on these metrics.

5 Results and Analysis

5.1 Results of Automatic Evaluation

Table 1 shows the results on automatic evaluation metrics on Wizard of Wikipedia and CMU_DoG datasets. On WoZ, CNTF gives a significant rise of 48% on Test Seen and 53% on Unseen in F1 score and around two times more on both Seen and Unseen, in terms of BLEU-4, compared to the strongest baseline, KnowledGPT. On CMU_DoG too, where the average turn length is roughly 2.5 times that of WoZ, CNTF surpasses the previous best on F1 and BLEU-4 by 8% and 20% respectively. Hence, CNTF achieves new state-of-the-art on both datasets.

Existing models struggle to generate engaging responses for dialogues based on new topics that were not encountered during the training phase, which most likely explains the observed low performance on Test Unseen. On the contrary, CNTF is capable of capturing the dialogue context and effectively utilizing external commonsense knowledge and parse the implicit mentions made to various entities through the conversation to produce accurate responses, as evidenced by the magnitude of improvement achieved. On embedding-based metrics, all three measures have significantly improved, demonstrating the efficacy of our methodology. Comparison to more baseline models can be found in Appendix E.1.

5.2 Human Evaluation Results

Human evaluation results are shown in Table 2. We only compare our proposed model against KnowledGPT, ITDD and TMN on WoZ, as manual evaluation is expensive. It is clear that CNTF outperforms the baselines on both adequacy and knowledge-related criteria, demonstrating consistency with the results of automatic evaluation, and has comparable fluency performance. It is important to note that, despite providing contextually appropriate responses, KnowledGPT failed to capture the accurate knowledge associated with the input sequences, resulting in low scores. The strength of CNTF can be seen from the knowledge existence, correctness and relevance scores. This can be attributed to the fact that the multi-hop attention module and the interactive attention module incorporate the knowledge bases efficiently. The knowledge in the generated response is relevant with the contexts and is factually correct. Furthermore, the responses are more effective at exchanging information than at casual chat. The proposed model also makes good use of commonsense knowledge and named entities due to attention module as explained in Section 3.5. All of the kappa values are greater than 0.75, indicating that the annotators agree.

In Table 3, we present a few example conversations as predicted by the proposed (*CNTF*) and the strongest baseline (*KnowledGPT*) on Test Seen from Wizard of Wikipedia. In utterance 3, *CNTF* is able to decipher that the context of the conversation is *dr. pepper* using the triple *(drink, RelatedTo, pepper)* obtained using the mechanism explained in Section 3.5 unlike KnowledGPT which starts talking about *7up*. Additionally, *CNTF* efficiently utilizes the commonsense knowledge triples by correctly copying the entities in the triples associated with the word *flavor*. As seen in the fourth utterance, the model correctly decodes the response using more detailed knowledge from the topic-specific knowledge base as opposed to KnowledGPT. Triples such as *(1904, RelatedTo, pepper), (sold, RelatedTo, Europe)* which were created using Section 3.4 have aided it in understanding the context better.

5.3 Ablation Study

To analyze the impact of the constituent modules in our model on performance (Table 1), we compare CNTF with the following variants:

(i) CNTF-D: This configuration only employs the dialogue encoder with multi-hop attention to demonstrate the significance of employing a knowledge encoder. This results in a 53% decrease in F1 score on Test Seen, demonstrating the effectiveness of our knowledge module with multi-hop attention. The score reduction in CMU_DoG is less severe because workers do not rely as heavily on external knowledge as the Wizard does, where it is highly correlated with available knowledge. (ii) CNTF-DK: Interactive attention is essential for generating insightful responses while decoding the answer. We remove the Interactive Dialogue-Knowledge module, as explained in Section 3.6.1, to demonstrate its utility. This results in a significant decrease in both BLEU and F1 scores. (iii) CNTF-DKI: We conduct experiments with only the dialogue and knowledge modules, as well as the interactive module, to demonstrate the benefit of using structured knowledge in the form of triples for gauging the implicit references made throughout the conversation. We see a significant drop in scores here as well. (iv) CNTF-DKIC: This model is used to show the effectiveness of co-reference based named entity triples. We see a drop in BLEU-4 scores for the seen testset, but we see an improvement on the unseen testset by using only commonsense knowledge. This could be attributed to the fact that for unseen data, the same entities are usually not present because they have conversations on topics that are rarely seen in the training set.

We may note that CNTF beats the SOTA models on every metric however due to the addition of new triples (more than 60% increment in triples on an average for both the datasets) which may have added to noise in the model, and hence it shows lower scores on some metrics than CNTF-DKIC.

5.4 Error Analysis

Using the generated responses, we perform a thorough examination of our proposed model and categorize the errors it encounters as follows:

1. **Repetition**: There are some instances where certain words are repeated in the generated responses. For example, *Predicted response: "i' m not sure, but it is similar to violet, violet and violet."*

Utterance 1	**Agent 1:** *i love dr pepper*
Knowledge 1	*dr pepper is a carbonated soft drink marketed as having a unique flavor.*
Triples	*(pepper, RelatedTo, soda), (soda, IsA, drink), (flavor, RelatedTo, drink), (carbonated, Synonym, soda), (soft, RelatedTo, drink), (drink, RelatedTo, like)...*
CNTF	yeah i love dr pepper. it is marketed by having a unique flavor.
KnowledGPT	i love dr pepper too! it's a carbonated soft drink marketed as having a unique flavor.
Utterance 2	**Agent 2:** *Oh same, it's my favorite Dr Pepper is a carbonated soft drink* **Agent 1:** *oh yea? its such a good soda*
Knowledge 2	*7 up (stylized as 7 up outside the u.s.) is a brand of lemon-lime flavored, non-caffeinated soft drink.*
Triples	*(flavor, RelatedTo, drink), (pepper, RelatedTo, soda), (soda, IsA, drink), (carbonated, Synonym, soda), (soft, RelatedTo, drink), (US, RelatedTo, pepper), (great, RelatedTo, super) ...*
CNTF	yea 7 up (stylized as 7up outside the u.s.) is a brand of lemon-line.
KnowledGPT	it was created in the 1880s by pharmacist charles alderton in waco, texas and first served around 1885.
Utterance 3	**Agent 2:** *oh yeah, i also like 7-up, 5 a brand of lemon-lime* ***flavor****.* **Agent 1:** *oh yeah thats great too*
Knowledge 3	*the drink was created in the 1880s by pharmacist charles alderon in waco, texas and first served around 1885.*
Triples	***(flavor, RelatedTo, drink),*** *(1880s, RelatedTo, wild),(1880s, RelatedTo, created),(1880s, RelatedTo, pharmacist),* ***(drink, RelatedTo, pepper)*** *...*
CNTF	yeah , the **drink** was created in the 1880s by pharmacist charles alderton in waco.
KnowledGPT	yeah, 7 up was created by charles leiper grigg, who launched his st. louis based company the howdy corporation in 1920
Utterance 4	**Agent 2:** *but, dr pepper was created in 1880s by a pharmacist. isn't that wild?* **Agent 1:** *yea wow it is so old*
Knowledge 4	*dr pepper was first nationally marketed in the united states in 1904, and is now also sold in europe, asia, canada, mexico, australia, and south america, as well as new zealand and south africa as an imported good.*
Triples	***(1904, RelatedTo, pepper), (sold, RelatedTo, Europe)****, (pepper, RelatedTo, Australia), (pepper, RelatedTo, Canada) ...*
CNTF	yea dr **pepper** was first nationally sold in the us in **1904** , and is now also **sold** in **europe**.
KnowledGPT	it was first served in waco, texas in 1885. i wonder how long it has been around?
Utterance 5	**Agent 2:** *oh yeah, and it didn't make it into the us until it was first nationally marketed in the united states in 1904* **Agent 1:** *thats super crazy*
Knowledge 5	*dr pepper was first nationally marketed in the united states in 1904, and is now also sold in europe, asia, canada, mexico, australia, and south america, as well as new zealand and south africa as an imported good.*
Triples	*(1904, RelatedTo, marketed), (States, RelatedTo, 1904), (United, RelatedTo, 1904), (1904, RelatedTo, US), (1904, RelatedTo, first), (first, RelatedTo, marketed) ...*
CNTF	yea dr pepper was first nationally marketed in the us in 1904 , and is now also sold in
KnowledGPT	it was formulated by a pharmacist named charles alderton in morrison's old corner drug store in waco, texas.

Table 3: Samples from Test Seen of WoZ dataset. The gold response for the (k)-th example is Agent 2's utterance in the $(k+1)$-th example. The displayed knowledge is the supporting sentence for the gold response to that utterance.

2. **Incomplete response:** As shown in the response for the last example in Table 3, incomplete responses result in lower fluency scores. We discovered that the ground truth responses in the dataset are generated by copying incomplete sentences from the document knowledge. Since our model augments knowledge, it learns to produce responses in the same manner. For example: *Document knowledge*: "*there is no scientifically precise definition of genius, and the question of whether the notion itself has any real meaning has long been a subject of debate, although psychologists are converging on a definition that emphasizes creativity and eminent achievement.*"; *Gold Response:* "*there is no scientifically precise definition of genius*". As can be seen, the response picked is incomplete and less fluent if it is compared to the knowledge sentence. We have evaluated our gold responses considering this in Table 2. We observed that the fluency score is 1.865 / 1.883 for both the test seen / unseen set. A few more error cases with examples are shown in the Appendix E.2.

6 Conclusion

We present a Commonsense, Named Entity, and Topical Knowledge Fused neural network (CNTF) to address reasoning over multiple knowledge bases in this paper. We propose, in particular, multi-hop attention over both structured and unstructured knowledge. Unlike previous approaches in Dialog, CNTF can find relevant supporting named entities in dialogs at each step of multi-hop attention in addition to already present commonsense knowledge. We test CNTF on WoZ and CMU_DoG and achieve excellent results. Furthermore, our analysis shows that CNTF can generate consistent results.

In the future, we hope to expand our work to build models which include emotions for knowledge grounded dialogues. Also, to tackle repetition and incomplete response, we aim to introduce rewards functions for these factors. Currently, our model does not consider the relation attribute in our proposed framework and hence the use of "RelatedTo" relation is not really affecting the performance of the proposed approach. We aim to incorporate relation attributes for triple representations.

7 Ethical Declaration

Our work relies solely on publicly available data. We followed the policies for using the data and did not violate any copyright issues.

A Methodology

To update D_S, we use another Gated Recurrent Unit (GRU) network to emulate the decoder at round r, obtaining the "intermediate" hidden states, $\tilde{s}_t^{(r)}$.

$$\tilde{s}_t^{(r)} = \mathrm{GRU}(c_t^{(r)}, q_t) \tag{15}$$

$$\tilde{u}_t^{(r)} = u_t^{(r-1)}(1 - \tilde{a}_t^{(r)} F_t^{(r)}) \tag{16}$$

$$F_t^{(r)} = \mathrm{Sigmoid}(W_3^{(r)}, \tilde{s}_t^{(r)}) \tag{17}$$

$$D_{S,t}^{(r)} = \tilde{u}_t^{(r)} + \tilde{a}_t^{(r)} A_t^{(r)} \tag{18}$$

$$A_t^{(r)} = \mathrm{Sigmoid}(W_4^{(r)}, \tilde{s}_t^{(r)}) \tag{19}$$

$W_3^{(r)}$ and $W_4^{(r)}$ are the learnable parameters. $\tilde{a}_t^{(r)}$ is computed similar to the manner defined in Eq 1.

B Datasets

Experiments are carried out on two benchmark datasets, *viz.* Wizard of Wikipedia (Dinan et al., 2018) and CMU_DoG (Zhou et al., 2018b).

Wizard of Wikipedia (WoZ) is one of the most comprehensive knowledge-based conversation datasets, covering 1,365 open-domain topics. Each conversation takes place between a wizard who can retrieve knowledge about a specific topic and form a response based on it and an apprentice who is simply eager to speak with the wizard but lacks access to external knowledge. The test set is further divided into two parts: Test Seen and Test Unseen. The former contains conversations about topics that have previously been seen in the training set, whereas the latter contains conversations about topics that have never been seen in either the training or validation sets.

CMU_DoG focuses on the movie domain, and the conversations take place between two users who both have access to the relevant documents. Every document includes information, such as the title of the film, the cast, an introduction, ratings, and a few scenes. We consider subsequent utterances by the same person as a single one. ConceptNet database can be downloaded from https://conceptnet.io.

	Wizard of Wikipedia				CMU_DoG		
	Train	**Valid**	**Test Seen**	**Test Unseen**	**Train**	**Valid**	**Test**
#Conversation	18,430	1,948	965	968	3,373	229	619
#Utterances	166,787	17,715	8,715	8,782	74,717	4,993	13,646
Avg. # of Turns	9.0	9.1	9.0	9.1	22.2	21.8	22.0
#TopicsDocuments	1,247	599	533	58	30	30	30

Table 4: Dataset Statistics

C Implementation Details

For our proposed CNTF model, we set the word embedding dimension as 300, and use GloVe word embeddings. The hidden size of GRU is sampled from $\{128, 256\}$. Both the number of rounds R, the number of hops K are sampled from $\{2, 3\}$, and the sliding window size is sampled from $\{1, 2\}$. We use the ADAM optimizer (Kingma and Ba, 2014) whose learning rate is fixed to 0.0005 and set the beam size to 4, while decoding the responses. We truncate utterances to a max token count of 200 and knowledge base to 400. To handle the long-text knowledge base of CMU_DoG, for every utterance and knowledge sentence we compute a TF-IDF vector. We then compute the cosine similarity between an utterance and every sentence in the knowledge base and retain the top-2 knowledge sentences, similar to the procedure adopted in Enriched Topical Chat dataset (Gopalakrishnan et al., 2019). The conversation and knowledge base vocabulary is shared and comprises of 30,004 words, while common sense vocabulary is maintained separately. We choose batch size as 2 and 8 for CMU_DoG and Wizard of Wikipedia, respectively, for training the models. There are roughly 83M parameters for our model when trained on Wizard of Wikipedia, and 38M on CMU_DoG, the difference in size is due to the vocabulary variation. These are much lesser than large pre-trained models which have much greater parameters (KnowledGPT which uses GPT-2). It is trained for 10-15 epochs. We choose the best model when the loss on the validation set does not decrease. The variances of the results are at most 1e-3 after three runs with random initialization for each method, and they have no effect on the trend. We have adapted the code framework from DDMN (Wang et al., 2020). We have used GeForce GTX 1080 Ti as the computing infrastructure. We used the AllenNLP co-reference resolution module (https://github.com/allenai/allennlp-models) for coreference resolution. We used the spacy toolkit (https://github.com/huggingface/neuralcoref) to identify named entities in the text.

D Evaluation Metrics

D.1 Automatic Evaluation:

For evaluating our baseline and proposed models, we used F1[1], BLEU (Papineni et al., 2002), PPL and Embedding-based metrics[2] (Liu et al., 2016) such as Vector Extrema, Greedy Matching and Embedding Average for evaluation. Perplexity (PPL) is a metric used to assess how well a probability model predicts a sentence. The term intersection between the gold response and output response by the model is calculated using BLEU (BLEU-4) and the unigram F1-score. Word-matching-based metrics are an alternative to embedding-based metrics. These metrics allocate a vector to each term in the sentence in order to truly understand the intended meaning of the predicted sentence, as described by

---

[1] https://github.com/facebookresearch/ParlAI/blob/master/parlai/core/metrics.py

[2] https://github.com/Maluuba/nlg-eval

word embedding. Using the above standard metrics, we evaluate our models on both the seen and unseen test sets of the Wizard of Wikipedia dataset, as well as the test set of the CMU_DoG dataset.

D.2 Human Evaluation:

However apart from the automatic evaluation metrics, for evaluating samples from human perspective we randomly selected 100 samples from the Wizard of Wikipedia's Test Seen and Test Unseen sets. We hire four professionals, each with a postgraduate degree and experience, to serve as human judgment annotators. The annotators are regular employees (paid monthly in accordance with university policy) earning Rs 35,000 per month. The annotators are members of our research team and have been working on similar projects for the past three years. For each example, we provide our annotators with model responses and human groundtruth. We use the following metrics for evaluation:

(i) Fluency: It is a metric that measures whether or not a sentence is comprehensible. (ii) Adequacy: This metric assesses the cohesiveness of the generated response with respect to the conversation context. (iii) Knowledge Existence (KE): This metric determines whether the response contains knowledge or not. (iv) Knowledge Correctness (KC): This metric determines whether the knowledge in the predicted response is correct. (v) Knowledge Relevance (KR): This metric is used to determine whether the knowledge is correct and relevant to the topic of the conversation. The annotators assign a score of 0 to 2 to each response (representing "incorrect," "moderately correct," and "perfect"). Fleiss' kappa (Fleiss, 1971) is used to calculate the annotators' agreement.

E Results

E.1 Automatic Evaluation

We also compare our proposed CNTF model to (Zhao et al., 2020a) and (Zheng et al., 2021). MKST (Zhao et al., 2020a) obtains a F1-score of 22.2 / 21.3 and BLEU-4 score of 0.077 / 0.072 on test seen / unseen of WoZ dataset. KTWM (Zhao et al., 2020a) obtains a BLEU-4 score of 0.033 / 0.022 with an embedding average, extrema and greedy score of 0.682 / 0.668, 0.394 / 0.379, 0.574 / 0.542 respectively. Our model clearly outperforms these baselines by obtaining a BLEU-4 score of 0.119 / 0.110, F1-score of 32.5 / 31.4 with an embedding average, extrema and greedy score of 0.911 / 0.910, 0.577 / 0.570, 0.758 / 0.752, respectively. In addition, our model clearly outperforms the BART based models for knowledge grounded generation (De Bruyn et al., 2020) on F1-score (Test Seen - 12.2 / 20.1; Test Unseen 14.9 /19.3) by a huge margin on both the test set of WoZ dataset.

E.2 Error Analysis

For a dialogue with no topic specific knowledge sentences usually our model fails to keep the conversation going by generating inadequate responses and also misses several entities. For example, *Input utterance*: that's not uncommon! there are rescue groups that specialize in finding homes for retired sled dogs. I bet they retire them at a certain age then they need a home huh; *Predicted Response (CNTF)*: that's cute! i'm sure they're cute!; *Gold Response*: yes. huskies got their name from the word referring to eskimos. As it can be clearly seen the model fails to capture the entity *huskies* and instead generates a generic response.

Efficient Hierarchical Domain Adaptation for Pretrained Language Models

Abstract

The remarkable success of large language models has been driven by dense models trained on massive unlabeled, unstructured corpora. These corpora typically contain text from diverse, heterogeneous sources, but information about the source of the text is rarely used during training. Transferring their knowledge to a target domain is typically done by continuing training in-domain. In this paper, we introduce a method to permit domain adaptation to many diverse domains using a computationally efficient adapter approach. Our method is based on the observation that textual domains are partially overlapping, and we represent domains as a hierarchical tree structure where each node in the tree is associated with a set of adapter weights. When combined with a frozen pretrained language model, this approach enables parameter sharing among related domains, while avoiding negative interference between unrelated ones. Experimental results with GPT-2 and a large fraction of the 100 most represented websites in C4 show across-the-board improvements in-domain. We additionally provide an inference time algorithm for a held-out domain and show that averaging over multiple paths through the tree enables further gains in generalization, while adding only a marginal cost to inference.

1 Introduction

Pretrained language models (PLMs) (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019; Radford et al., 2019), trained on massive general-domain corpora, have enabled great progress in many natural language processing (NLP) benchmarks (Wang et al., 2018). Nonetheless, continuing pretraining (as a dense model) a PLM on a narrower domain (Han and Eisenstein, 2019; Lee et al., 2019) is beneficial, although computationally expensive (Maronikolakis and Schütze, 2021), which indicates that domain-relevant data is important for downstream tasks. Sparse models that use mixtures of experts (Lepikhin et al., 2021) have recently been proposed to allow efficient training.

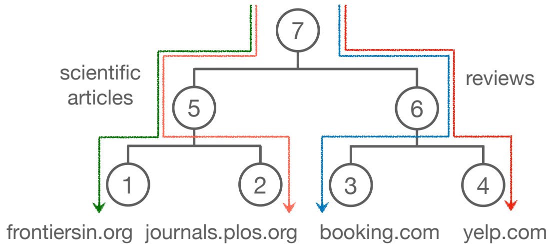

Figure 1: We model domains as a hierarchical tree structure that associates adapters with nodes, allowing parameter sharing among related domains. Internet domains appear as leaf nodes. During training, we activate the adapters along the path to a leaf to specialize a language model to the domain corresponding to it.

Prior work typically assumes that individual domains are distinct, and models them accordingly. For example, Gururangan et al. (2020, 2021) train one model for each textual domain, either in a dense or sparse manner. This is related to data selection (Moore and Lewis, 2010; Axelrod et al., 2011; Plank and van Noord, 2011), which aims to select the best matching data for a new domain. This process does not scale to multiple domains efficiently, as the parameters grow linearly with the domains. It also does not allow sharing representations among related domains during training, as each domain is modeled with a separate set of parameters. At the other extreme, training one model on all domains as is common during unsupervised pretraining does not account for their similarities and differences and might hinder the model's generalization ability due to negative interference.

As an alternative, we start with the observation that the term "domain" typically denotes a distribution over language characterizing a given topic or genre, and that domains are partially overlapping.

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1336 - 1351
July 10-15, 2022

For example, a sentiment model processing hotel reviews could be expected to benefit by also including data from restaurant reviews, which might in turn benefit from cooking recipes, but combing hotel reviews and recipes may be detrimental.

We want to model the relations between domains and selectively share information, so that we allow positive transfer and avoid negative interference. To this end, we propose a data-driven approach to modeling domains that automatically clusters them in a tree using PLM representations. We then introduce an efficient method that specializes a PLM in a number of domains leveraging their hierarchical structure. Our approach allows parameter sharing among related domains using adapters (Rebuffi et al., 2017; Houlsby et al., 2019), which are lightweight layers, added after each transformer (Vaswani et al., 2017) layer. Each node in the tree is associated with a separate set of adapters, that are only activated for a particular domain. For instance, data from BOOKING.COM activates parameters in nodes 3, 6, and 7, allowing parameter sharing with the highly related YELP.COM through nodes 6 and 7 (Figure 1).

We verify the efficacy of our approach in two settings. First, we manually define a tree structure, using websites as the leaves. In this first *few-domain* setting, our method outperforms prior work including single and multi-domain adapters added to GPT-2 (Radford et al., 2019) when tested in-domain. We further show that our method generalizes better to held-out websites than the baselines.

We then scale our model to a *many-domain* setting across almost 100 websites. We induce the hierarchical structure in an unsupervised way using representations from GPT-2 with a Gaussian Mixture Model (GMM) (Aharoni and Goldberg, 2020) and hierarchical clustering, similar to Das Gupta et al. (2015). In this way, the clusters model textual domains and the GMM provides a mechanism to automatically find the closest training websites to any held-out website. Empirical results show across-the-board improvements over strong baselines when evaluated in-domain. We also show that an efficient inference-time algorithm that averages over multiple paths through the tree improves generalization when tested on held-out websites.[1]

2 Hierarchical Representation of Domains

In this section, we provide a formal problem definition and the intuition for a hierarchical ordering of domains. We then describe how we add a hierarchical structure to a PLM and present the training process. Additionally, we show how a path in the tree is selected to evaluate the in-domain and out-of-domain sets. We finally discuss the computational cost of our approach compared to the baselines and our experimental setup.

2.1 Problem Definition

We formulate the task as follows: given a PLM, we aim at fine-tuning it in the task of language modeling using adapter modules, on a corpus consisting of k corpora for domain adaptation. The model is trained to minimize the cross-entropy loss on sentences from all k corpora, then is evaluated on both in-domain and out-of-domain test sets.

2.2 Textual domains and provenance

As there is no commonly-accepted definition of a "domain" in text (Plank, 2016), we take a practical approach and use the provenance of a piece of text (that is, the website from which the text was scraped) as a proxy for textual domain. To model how similar different textual domains are to each other, we fit a Gaussian Mixture Model (GMM) using PLM representations (Aharoni and Goldberg, 2020) using a small sample of text from each domain. After fitting this GMM, for some clusters there is a one-to-one correspondence between one cluster and text from one website, while for other clusters there is a one-to-many correspondence between one cluster and text from multiple, similar websites (see §4).

2.3 Hierarchical Structure

Domains generally overlap with each other and have different degrees of granularity. A model that encodes them should both capture domain-specific and general-domain information. To this end, we propose representing the data as a tree. An example of a tree structure is shown in Figure 1. Text from specific websites is encoded in the leaf nodes (such as FRONTIERSIN.ORG, JOURNALS.PLOS.ORG), while more general-domain knowledge is encoded in the upper nodes (SCIENTIFIC ARTICLES).

---

[1] Our code is publicly available at github.com/alexandra-chron/hierarchical-domain-adaptation.

2.4 Model Architecture

Assuming a corpus with data from n domains, we consider the setting where we have a pretrained model M. We want to use M to adapt to n new domains. To this end, we can leverage *adapters*.

Adapter layer. Adapters are typically added to model M in each transformer layer and are trained to a task, while M remains unchanged. An adapter uses as input the output of the previous layer. It is formally defined as $\mathbf{W}^U \,\mathrm{ReLU}(\mathbf{W}^D \,\mathrm{LN}(h_i)) + h_i$,where h_i is the output of the i-th layer, of dimension m, LN is a layer-normalization (Ba et al., 2016), $\mathbf{W}^D$ is a down-projection in $R^{m \times d}$, and $\mathbf{W}^U$ is an up-projection in $R^{d \times m}$, and d is the bottleneck dimension of the adapter module.

Single Adapters. To adapt to n domains, one solution is to train n adapters (per transformer layer), one for each domain. The number of parameters added from single adapters grows linearly with the number of domains (O(n)).

Multi-Domain Adapters. Another solution is to add just one set of adapters to model M. The adapter weights will be updated based on data from all n domains. This is a *dense* model that does not permit modular training. For n domains, the number of parameters added is constant.

Hierarchical Adapters. We propose associating each of the nodes in a tree that represents domains with a set of adapters and adding them to M. This *sparse* model adds parameters that scale logarithmically (O$(log(n))$ with the number of domains because of the binary tree structure (Figure 1).

While Houlsby et al. (2019) insert adapters but re-train layer normalization parameters of M and Bapna and Firat (2019) introduce new layer normalization parameters for every adapter, we introduce just one set of layer normalization parameters in each transformer layer and these parameters are *shared* between all adapters of a transformer layer.

2.5 Training & Computational Cost

When our input consists of data from a particular domain, we only update the adapter layers of the path that leads to this domain (Figure 1).

Supposing we have a mini-batch from FRONTIERSIN.ORG, the hidden state h_i of the i-th layer is the input of $adapter_i^1$ (the adapter of node 1 for transformer layer i). h_i is also the input of $adapter_i^5$ (parent) and $adapter_i^7$ (root). Their outputs y_i^1, y_i^5, y_i^7 are averaged. The final representation y_i is the input to the next transformer layer.

Using this simple training process, we allow sharing between related domains. Upper nodes in the tree are updated more often than leaves, thus they are better trained and encode more domain-general knowledge. More precisely, the root node of the hierarchical model in Figure 1 is updated for each sequence, but the leaf nodes are only updated using sequences from the associated domain.

In terms of computation, although our model adds a large number of trainable parameters (*total parameters*), only a small fraction of them is used for each forward pass (*active parameters*), as shown in Table 1. At inference time, to evaluate performance on a domain using the tree of Figure 1, our approach with a single path uses 126M parameters (GPT-2 has 112M and the adapters of each path account for 14M parameters). When we average two paths, 23M parameters are added to GPT-2.

Kaplan et al. (2020) provided a detailed breakdown of compute cost for transformer LMs. For a model with N non-embedding parameters, the approximate cost of a forward pass is $2N$ flops per token. Extending their calculations to our setting, for a model with L layers, model dimension d_{model}, adapter bottleneck size d, a single adapter adds $4Ld_{\text{model}}d$ flops per forward pass over the cost of running GPT-2. Our hierarchical method requires running T adapters per layer per forward pass, where T is the average tree depth. For the many-domain setting in §4 with $L = 12$, $d_{\text{model}} = 768$, $d = 64$, $N = 84$M, $T = 8$, this gives an increase of ~11% flops over GPT-2. At inference time, using two paths (§4.5) the increase is 22% over GPT-2.

For fair comparison between our method and the baselines, we scale the adapter size so that our proposed model and the multi-domain adapters (the most related baseline) use the same number of flops. Following the previous paragraph, the adapter sizes in our hierarchical model are smaller by a factor of $1/T$ then those in the baseline models (Table 1).

2.6 In-domain/Out-of-domain Evaluation

At inference time, we need to define which path should be activated for each domain. When we perform in-domain evaluation, this is straightforward. We always activate the path that leads to the node that is assigned to this specific domain.

For out-of-domain evaluation, we need to find the path that better fits the held-out domain. We can also use multiple paths, as the computational cost is small. We describe in detail how we run

		Few-Domain Setup	Many-Domain Setup

Table 1: Parameters used by our approach and the multi-domain adapters. The *few-domain* and *many-domain setup* are explained in § 3 and § 4 respectively.

out-of-domain evaluation in the following two sections, which present a manually defined (§3) and an automatically created hierarchical structure (§4).

2.7 Experimental Setup

We use GPT-2 (12 transformer layers; hidden size 768) as the pretrained model. GPT-2 has a vocabulary of 50,264 BPE (Sennrich et al., 2016) tokens and 112M parameters. Our code is built with PyTorch (Paszke et al., 2017), using the HuggingFace library (Wolf et al., 2020). We run all experiments on NVIDIA A100 GPUs with 40GB of RAM. We split our corpora in 800-token sequences. Models are trained with the Adam optimizer (Kingma and Ba, 2015) with an initial learning rate of $1e^{-3}$ and we accumulate gradients over 2 updates.

3 Hierarchical Domain Adaptation with a Manually Created Tree

In this section, we implement the model described in the prior section for a very limited number of domains (*few-domain setup*), to comprehensively examine design choices and verify the performance, before moving to a large-scale setting in §4.

3.1 Data

We select four websites to be represented by leaf nodes in our tree: two that contain scientific articles (FRONTIERSIN.ORG, JOURNALS.PLOS.ORG) and two that contain reviews (BOOKING.COM and YELP.COM). We use text from the released version (Dodge et al., 2021) of C4 (Raffel et al., 2020), a web-scale corpus of English data; the first three internet domains are some of the largest sources of text in C4. We also use YELP.COM, a publicly available dataset. Dataset sizes (training/evaluation) are shown in Appendix A.1.

3.2 Approach

We use the hierarchical structure shown in Figure 1, with two leaf nodes representing scientific articles sharing a parent, two leaf nodes representing reviews sharing a parent, and a single grandparent shared by the two parents. This tree structure was manually chosen using domain knowledge. We use a pretrained GPT-2 model as our base model, and add one set of adapters per node in the tree (one adapter per transformer layer for each node). We freeze the weights of GPT-2 and train the adapters on language modeling of the domains of interest. The training process is explained in detail in §2.5.

3.3 Experimental Setup

Our hierarchical model adds 7 sets of adapters to GPT-2, one for each node in the tree. Each adapter has a bottleneck dimension d of 256. For each training step, one path through the tree is active (so, 3 adapters) depending on which domain of text is represented in the current batch (see §2.5). Active nodes are used in the forward pass and updated in the backward pass (during training), while those that are not active are not used in the computation.

We evaluate two baselines: a *multi-domain adapter*, trained on all in-domain data, and *single adapters*, each trained on data from a different website. We ensure that the hierarchical model uses the same amount of compute for a forward pass as the multi-domain adapter baseline (using $d = 768$ and 1 adapter/path). We also train each model to an equal amount of data from each domain. Results are shown after 20 epochs of training (22K steps).

adapter baseline in all domains. On average, hierarchical adapters lower the perplexity by 0.7 compared to multi-domain adapters. Compared to just evaluating GPT-2, our model yields a large improvement, confirming prior work that suggests that further training a PLM in-domain is highly effective. Single adapters perform roughly equivalent to multi-domain adapters in this scenario.

3.5 Out-of-Domain Results

We perform evaluation on 7 unseen domains, some of which represent similar textual domains to our in-domain data, while others are quite different. For example, NCBI, LINK.SPRINGER, and SCHOLARS.DUKE contain text from scientific documents, similar to two of our in-domain sources of text, but TECHCRUNCH and MEDIUM are quite dissimilar to the in-domain text. All models outperform the baseline of just evaluating GPT-2, as shown in Table 3. We hypothesize that the pretraining data from GPT-2, which has not been publicly released, had a somewhat different distribution to C4, and thus further training on any data from C4 seems to improve performance. The best out-of-domain results are obtained with hierarchical adapters.

However, which set of single adapters we should use to evaluate a held-out domain is not obvious. For example, to evaluate on LONELYPLANET, it intuitively makes sense to use adapters trained on a reviews/travelling domain (BOOKING or YELP), but for LINK.SPRINGER, the model trained on a scientific articles (FRONTIERSIN or JOURNALS) might be more suitable. We have no *a priori* criterion to choose the most appropriate model. This is also true for our proposed model. We show the best evaluation scores using single adapters in Table 3 (full evaluation in Appendix A.2).

For the hierarchical adapter model, we show evaluation scores using various paths in Table 4. As expected, using a *single* path, the hierarchical model performs best leveraging the path of a website that is most similar to the unseen website. For example, the best evaluation score for NCBI is obtained with the path that leads to JOURNALS, while the best score for TRIPADVISOR using the path that leads to BOOKING. Using two paths (either the paths of FRONTIERS and JOURNALS, or BOOKING and YELP), results generally improve. For science or technology websites, using the paths of the science domain considerably boosts the hierarchical model's performance. For reviews/travelling websites, using both paths of the reviews domain is beneficial. This confirms our intuition that the hierarchical structure proposed adequately models domains, preventing negative transfer.

Comparing our hierarchical adapters to multi-domain adapters, using a *single path*, hierarchical adapters perform worse than multi-domain adapters (average scores of columns 1-4 in Table 4 are worse than the average score of column 3 in Table 3). However, with a *second path* active, hierarchical adapters outperform all other approaches (Table 3). This highlights an advantage: they are extensible even after training, allowing for flexible performance-efficiency trade-offs that dense approaches (like multi-domain adapters) do not.

4 Hierarchical Domain Adaptation with an Automatically Created Tree

In this section, we scale our approach to a *many-domain setup*, using a larger set of domains, and thus a much larger hierarchy, adding more adapters in our model. In the previous section, we manually selected a tree based on our domain knowledge, but in this section we automatically create a tree using

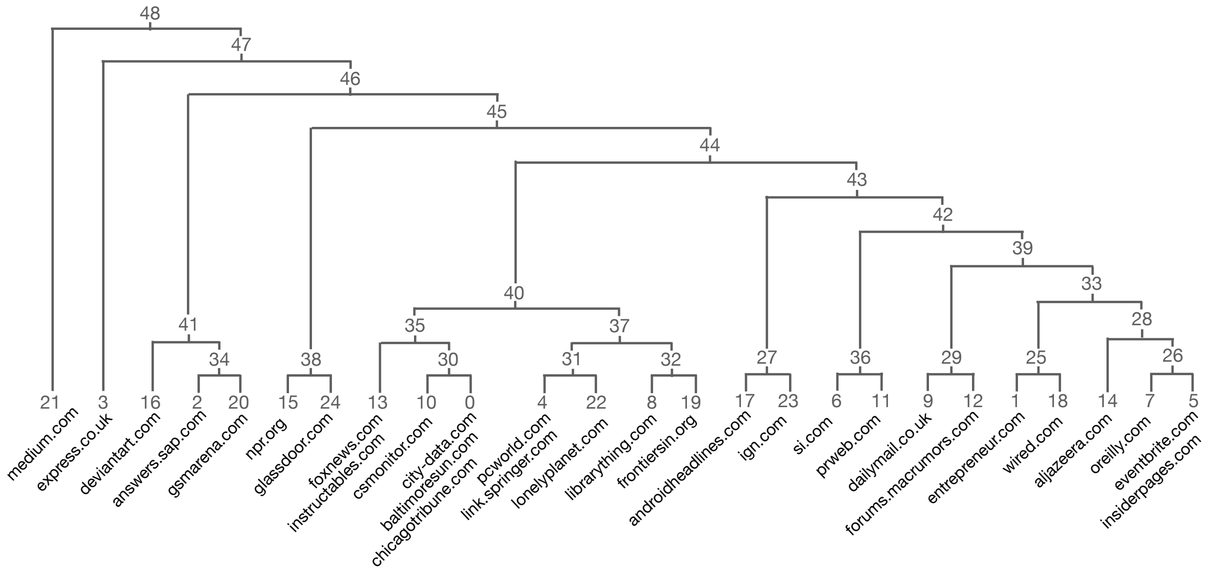

Figure 2: Dendrogram obtained from agglomerative clustering based on the average KL divergences of the GMMs. This diagram illustrates the hierarchical structure of 30 of the most high-resource websites on C4. The leaf nodes correspond to the cluster centers and are mapped to the websites they assign the highest probability to.

unsupervised methods. We leverage domain clusters obtained using Gaussian Mixture Models and hierarchical clustering and provide an algorithm for out-of-domain evaluation, leveraging the flexibility of hierarchical adapters, that can be combined to improve performance with a minimal cost.

4.1 Data

As a training and evaluation corpus, we use data from C4. Specifically, we use text from 30 websites as our training corpus and we perform out-of-domain evaluation of our model and the baselines on 38 other websites. All websites used belong to the top 100 sites in C4 (details in Appendix A.1).

4.2 Approach

We want to create a hierarchical structure that represents relations between domains. To this end, we fit a Gaussian Mixture Model (GMM) and then use an agglomerative clustering algorithm on the GMM. A GMM assumes that all data points are generated from a mixture of a k Gaussian distributions and defines the probability for data points to belong to any of these distributions. We consider a GMM to be suitable choice because it accounts for the uncertainty of cluster assignment and provides soft assignments that we use at inference.

Similar to Aharoni and Goldberg (2020), we generate contextual representations of 1K sequences (uniformly sampled) from each of our 30 training websites using GPT-2. We use PCA for dimensionality reduction. We then fit a GMM with 30 components to our data (i.e., 30 Gaussians/clusters). After that, we find the Gaussian which assigns highest probability to text from each website, and remove any Gaussian which does not assign the highest probability to any website (it can be the case that text from more than one websites could be drawn by the same Gaussian). The websites and their corresponding clusters are shown in Figure 2.

For hierarchical clustering, we use the symmetrized Kullback-Leibler (KL) divergence as a distance metric. Suppose we have two multivariate normal distributions (means μ_0, μ_1, covariance matrices Σ_0, Σ_1) obtained by the GMM. To measure the difference between the two distributions, if they have the same dimension N, we compute the KL divergence. Because it is asymmetric, we cannot use it to measure the distance between distributions, so we compute the symmetrized version as follows:

$$D_{KL}(\mathcal{N}_0 \| \mathcal{N}_1) = \frac{1}{2}\mathrm{tr}\left(\Sigma_1^{-1}\Sigma_0\right) + \ln\left(\frac{\det \Sigma_1}{\det \Sigma_0}\right)\Big) + \frac{1}{2}\left((\mu_1 - \mu_0)^{\mathrm{T}}\Sigma_1^{-1}(\mu_1 - \mu_0) - N\right) \quad (1)$$

$$D_{KLsym}(\mathcal{N}_0, \mathcal{N}_1) = \frac{1}{2}\left(D_{KL}(\mathcal{N}_0 \| \mathcal{N}_1) + D_{KL}(\mathcal{N}_1 \| \mathcal{N}_0)\right) \quad (2)$$

Using Equation 2 as a distance metric, we use agglomerative clustering to infer the structure of our data. We start from 25 clusters, computed by

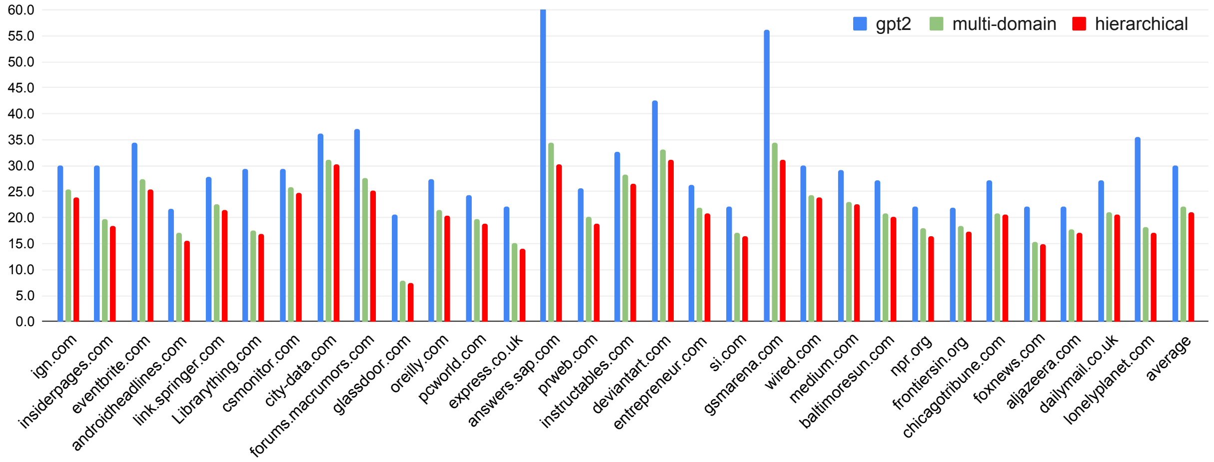

Figure 3: In-domain evaluation perplexity. Hierarchical adapters consistently outperform the multi-domain adapter on all websites used during training.

the GMM (5 are ignored because do not assign a high probability to data samples from any website, see Appendix A.3 for the confusion matrix). The clustering algorithm leads to a tree (see Figure 2). Nodes 0-24 correspond to the clusters of the GMM. Each website is assigned to a specific cluster.

4.3 Experimental Setup

For PCA, we use 100 dimensions. For the hierarchical clustering, we use distances computed using the symmetrized KL divergence. We get a tree of 49 nodes, shown in Figure 2. We add 49 adapters to GPT-2, one for each node. For a single training step, just one path in the tree is active (as in §3).

In this set of experiments, we used our computational budget to compare against our strongest baseline, multi-domain adapters, as that provided the most competitive results in §3. Comparing against single adapters could be relevant but we focus on our strongest baseline, as single adapters have shown to be less able to generalize to held-out domains. We train both our hierarchical model and the multi-domain adapter baseline for 4 epochs (11K steps), using 1 GPU per model and stopping after 51 hours. We oversample the low-resource domains to avoid overfitting. We use $d = 64$ for hierarchical adapters, as the average path length is 8 and $d = 512$ for the multi-domain adapter, since it adds just 1 adapter/transformer layer (Table 1).

4.4 In-Domain Results

Our in-domain results are shown in Figure 3. To evaluate our model in-domain, we use the path that leads to the cluster that assigns the highest probability to the domain of interest (the same as during training). For example, to evaluate the performance of the model on PCWORLD, we use the path that leads to cluster 4. The average path length in the tree is 8, so we "activate" 8 adapters on average at every training step and also for in-domain evaluation. Our approach consistently outperforms multi-domain adapters, yielding +1.3 on average in terms of perplexity (see Appendix A.4 for details).

4.5 Out-of-Domain Results

We perform out-of-domain evaluation on 38 held-out websites (dataset sizes in Appendix A.1). We want to automatically find the best path in the tree for a held-out website. To this end, we use the fitted GMM to assign probabilities to data from the held-out websites. We intuitively want to place a held-out website close to similar training websites, so that it can benefit from positive transfer.

To do that, for a given out-of-domain website i, we assume we have a set of N sequences (in our experiments $N = 1,000$) that we can use to find the best path; this path is used to evaluate the rest of the data from this website (e.g., for computing perplexity). Following a similar procedure to our training regime, we use GPT-2 to encode N sequences, then use the fitted GMM to find the probability assigned to each of the N vectors by each cluster (i.e., each leaf node). The single best path leads to the leaf node that corresponds to cluster m, where m assigns the highest probability to the largest fraction of the N sequences from website i. The second best path through the tree leads to cluster n that assigns highest probability to the second-most number of the N sequences from website i. Thus, using the GMM clusters and the hierarchical structure, *without training more parameters*, we are able to evaluate out-of-domain data using the adapters that were trained on the most related domains. This is similar to the "cached" setting in Gururangan et al. (2021), and it does require a held-out set of N sequences that are only used for finding the best path through the tree (and not for computing perplexity). This is realistic setting when one has a significant amount of data from a single source, and we leave other approaches (e.g., finding the best path for every input sequence individually) to future work.

We show in Table 5 results of the out-of-domain evaluations. Our hierarchical adapter model outperforms the baseline of just evaluating GPT-2. We notice that using a single path, our approach provides worse results compared to multi-domain adapters. In this evaluation, the multi-domain adapters and the hierarchical model have the same number of active parameters, but the adapters in the hierarchical model are trained on less data (except the adapter associated with the root, which has the same number of updates as the multi-domain adapter but is significantly smaller). However, by having two paths through the tree active, the hierarchical adapter model leverages its modularity and surpasses multi-domain adapters, obtaining an improvement of +0.6 in terms of perplexity.

At inference time, our approach with a single active path uses 122M parameters (112M of GPT-2 and ~10M parameters for a path of average length). When two paths are active, at most 132M parameters are used. The overhead is thus quite small; if the two paths have some overlap, this computation is potentially significantly less. On average, active parameters in our model are trained on less data than multi-domain adapters (e.g., leaf nodes only see on average 400 updates, as shown in Table 1).

Table 5: Out-of-domain evaluation perplexity. With 1 path, our hierarchical model performs worse than the baseline. However, using paths of the 2 closest clusters to a held-out website, our approach yields better results. We show the paths used in detail in Appendix A.3.

5 Related work

Our approach draws on prior work in domain adaptation and efficient language model fine-tuning.

Domain Adaptation. A large research area in NLP is domain adaptation (Jiang and Zhai, 2007; Daumé III, 2007). Training a masked language model on data from a specific domain (Lee et al., 2020; Beltagy et al., 2019) or fine-tuning a PLM using data from the target task (Howard and Ruder, 2018) or the target domain (Rietzler et al., 2020; Han and Eisenstein, 2019) has shown to be helpful to mitigate the domain shift between train and test data distributions of the same task. Gururangan et al. (2020) showed that a PLM can further improve by fine-tuning on data from a domain that is related to the domain of the task (DAPT). While this work suggests fine-tuning a different model to the domain of each task, our approach trains a single model to adapt to all domains. Also, although DAPT does not permit parameter sharing between domains, our hierarchical adapter model leverages domain similarities to improve adaptation.

Domain expert mixture (DEMix) layers (Gururangan et al., 2021) that condition a LM on the domain of input text have been recently proposed. DEMix layers replace feed-forward layers in a transformer and each of them is updated only using data from a specific domain. Then, a modular LM is trained from scratch. On the contrary, we use a PLM and only train adapter layers on the target domains. Since each feed-forward layer is replaced with a mixture of experts, the parameters added grow linearly with the domains. In our approach, however, the number of parameters grows logarithmically, due to the hierarchical structure.

Adapters. Efficient fine-tuning using adapters (Rebuffi et al., 2017; Houlsby et al., 2019) is prevalent in many NLP taks, such as machine translation (Bapna and Firat, 2019), cross-lingual transfer (Pfeiffer et al., 2020) and dependency parsing (Üstün et al., 2020). Adapters can be trained on a single task or language (Pfeiffer et al., 2020), but also multilingually (Stickland et al., 2021). They have also been used to infuse factual and linguistic (Wang et al., 2021) as well as general-purpose and commonsense knowledge (Lauscher et al., 2020) into a PLM. To the best of our knowledge, we are the first to use them in a hierarchical structure for domain adaptation.

Efficient fine-tuning methods for PLMs. Besides adapters, multiple other parameter-efficient methods to adapt general-purpose PLMs to specific tasks have been recently proposed. Prefix tuning (Li and Liang, 2021), low-rank matrix approximation (Hu et al., 2022), as well as fine-tuning only the bias terms of a PLM (Zaken et al., 2021) are some of the lightweight alternatives to fine-tuning the entire PLM. He et al. (2022) show that these fine-tuning methods can be seen as modifications to some specific hidden states of PLMs and can thus be recast. We use adapters in this work, but our method could possibly also benefit from other parameter-efficient approaches.

6 Conclusion & Future Work

In this paper, we present a novel approach for efficient domain adaptation on multiple domains using hierarchical adapters that encode the similarities and differences of domains, allowing parameter sharing but avoiding negative transfer. We start with a manually defined tree and then scale to a large tree, created in an unsupervised way. We also provide an evaluation-time algorithm that can combine paths to best adapt to an unseen domain.

In the future, we would like to investigate a more efficient evaluation-time approach, using only a few tokens of an unseen domain. It would also be interesting to extend our model to a multi-lingual setup. Finally, we would like to use our method to control language generation of PLMs, in order to avoid generating hate speech or toxic text.

7 Limitations and Risks

Our work uses generative pretrained language models. As such models are trained on large datasets from text in the Internet, they encode biases that could harm marginalized populations (Bender et al., 2021). The specialized language model we propose could be used for propaganda or hate speech generation, same as any other language model. However, our hierarchical adapter model permits adding modular components and we believe that it could potentially be used to detoxify language generation, following Liu et al. (2021). This is in line with recent work on sparse models (Gururangan et al., 2021; Artetxe et al., 2021).

Acknowledgements

We thank the AllenNLP team and other researchers at the Allen Institute for AI for their thoughtful comments. We also thank Alex Fraser, Dario Stojanovski, and Suchin Gururangan for helpful discussions about this work.

A Appendix

A.1 Corpus description

In Table 8, we present the sizes of the training and evaluation corpora used for the many-domain setup. Only one corpus is used for the few-domain but not the many-domain experimental setting, namely YELP.COM[2]. This corpus has 684M training tokens and 20M evaluation tokens. We randomly sub-sample 53M training tokens of this corpus for our first, few-domain setup, as we want to train a balanced model. Extensive documentation of the corpus is available from Dodge et al. (2021). We use the C4 corpus in accordance with the terms of use[3].

A.2 Few-Domain Setup

In Table 3, we present out-of-domain evaluation perplexities for the first experimental setup. For the *single adapters* model, we present the best-performing models in the table. In order to allow for an exhaustive comparison, we also present the evaluation results of all the trained single adapter models on all held-out websites in Table 6. We see, for example, that when evaluating on the traveling website TRIPADVISOR, the single adapter model that was trained on either BOOKING or YELP provides the lowest perplexity scores, confirming our intuition that for a held-out website, we should use a model trained on a very similar domain.

Table 6: Out-of-domain evaluation of single adapters in the few-domain setup (§3). We evaluate every set of single adapters in 7 different websites. The best results for every out-of-domain website (underlined) are shown in Table 3.

A.3 Many-Domain Setup

Confusion Matrix. Figure 4 depicts the confusion matrix of the GMM. We can observe visually that some clusters assign a high probability to multiple internet domains, while others remain empty. This shows that the intuition have for what a domain is does not correspond exactly to the cluster obtained by an unsupervised, data-driven approach. Our visualization is based on publicly available code[4].

Table 7: In-domain evaluation perplexity for the many-domain setup (we note that the hierarchical model uses a single path).

Out-of-domain Evaluation. As mentioned in §4.5, to run evaluation on a given out-of-domain website i, we use two paths of the trained hierarchical model. The first path leads to the leaf node that corresponds to cluster m (with m assigning the highest probability to the largest fraction of N sequences from website i) and the second path leads to cluster n, where n assigns the highest probability to the second-most number of the N sequences. We present the clusters m and n (and the websites they were mapped to during training) in Table 9.

A.4 Experimental Details

Because we wanted to keep a modest computational budget, we did not perform multiple training runs for the hierarchical models and the baselines. Results are reported over a single run.

Figure 4: Confusion Matrix. The x-axis depicts the clusters that the internet domains are assigned to. If no data samples are added to a cluster (for example, cluster 2), the corresponding Gaussian distribution is not used for the hierarchical clustering. The y-axis depicts the internet domains used for training. The cluster numbers shown here are not the exact ones shown in the final dendrogram, but one can easily observe that, for example, the same cluster (in this example, cluster 7) assigns the highest probability to CITY-DATA.COM, BALTIMORESUN.COM and CHICAGOTRIBUNE.COM. This is mirrored in Figure 2 of the main paper.

Abstract

Detecting online hate is a complex task, and low-performing models have harmful consequences when used for sensitive applications such as content moderation. Emoji-based hate is an emerging challenge for automated detection. We present HatemojiCheck, a test suite of 3,930 short-form statements that allows us to evaluate performance on hateful language expressed with emoji. Using the test suite, we expose weaknesses in existing hate detection models. To address these weaknesses, we create the HatemojiBuild dataset using a human-and-model-in-the-loop approach. Models built with these 5,912 adversarial examples perform substantially better at detecting emoji-based hate, while retaining strong performance on text-only hate. Both HatemojiCheck and HatemojiBuild are made publicly available.[1]

Content Warning This article contains examples of hateful language from HatemojiCheck to illustrate its composition. Examples are quoted verbatim, except for slurs and profanity in text, for which the first vowel is replaced with an asterisk. The authors oppose the use of hateful language.

1 Introduction

Online hate harms its targets, disrupts online communities, pollutes civic discourse and reinforces social power imbalances (Gelber and McNamara, 2016). The sheer scale of hateful content online has led to widespread use of automated detection systems to find, monitor and stop it (Vidgen et al., 2019; Gillespie, 2020). However, hateful content is complex and diverse, which makes it challenging to detection systems. One particular challenge is the use of emoji for expressing hate. Emoji are pictorial representations that can be embedded in text, allowing complex emotions, actions and intentions to be displayed concisely (Rodrigues et al., 2018). Over 95% of internet users have used an emoji and 10 million are sent every day (Brandwatch, 2018). Following England's defeat in the Euro 2020 football final, there was widespread racist use of emoji such as 🐵, 🍌 and 🍉 (Jamieson, 2020). This paper focuses on emoji-based hate, answering two research questions:

RQ1 What are the weaknesses of current detection systems for hate expressed with emoji?

RQ2 To what extent can human-and-model-in-the-loop training improve the performance of detection systems for emoji-based hate?

To answer RQ1, we present HatemojiCheck, a suite of functional tests for emoji-based hate. We provide 3,930 test cases for seven functionalities, covering six identities. 2,126 original test cases are matched with three types of challenging perturbations to enable accurate evaluation of model decision boundaries (Gardner et al., 2020). We use HatemojiCheck to assess Google Jigsaw's Perspective API as well as models trained on academic datasets, exposing critical model weaknesses.

To answer RQ2 and address the model weaknesses identified by HatemojiCheck, we implement a human-and-model-in-the-loop dynamic training scheme. We build on the work of Vidgen et al. (2021b), who used this approach for textual hate. Our work begins where their study ends. We conduct three rounds of adversarial data generation focused explicitly on emoji-based hate, tasking annotators to generate sentences that the model-in-the-loop misclassifies. This process yields a dataset of 5,912 entries, half of which are challenging contrasts. We call this dataset HatemojiBuild. The dataset is evenly split between hate and non-hate, and each hateful entry has labels for the type and target. Between each round, the model-in-the-loop

July 10-15, 2022 ©2022 Association for Computational Linguistics

is re-trained so that annotators are trying to trick a progressively stronger and more ‘emoji-aware’ model. Relative to existing commercial and academic models, our models improve performance on the detection of emoji-based hate, without sacrificing performance on text-only hate.

We make several contributions: (1) we construct HatemojiCheck, which tests key types of emoji-based hate as separate functionalities, (2) we evaluate the performance of existing academic and commercial models at detecting emoji-based hate, (3) we present HatemojiBuild, a labeled emoji-based hate speech dataset that is adversarially-generated for model training and (4) we train models that can accurately detect emoji-based hate. These data-centric contributions demonstrate the benefits of systematic and granular evaluation, and the need to diversify how hate detection systems are trained. We make both HatemojiCheck and HatemojiBuild publicly available.

Definition of Hate We use the United Nations definition of hate speech: “any kind of communication in speech, writing or behavior, that attacks or uses pejorative or discriminatory language with reference to a person or a group on the basis of who they are, in other words, based on their religion, ethnicity, nationality, race, color, descent, gender or other identity factor” (United Nations, 2019, p.2).[2]

2 HatemojiCheck: Functional Tests for Emoji-Based Hate

The concept of functional testing, an expected input-output behavior (Beizer, 1995), has been adapted from software engineering for NLP tasks (Ribeiro et al., 2020), including hate speech detection (Röttger et al., 2021). These diagnostic tests identify model vulnerabilities to intentionally simple and non-ambiguous constructions of hate so comprise a minimal performance standard.

2.1 Identifying Functionalities

A functionality describes the ability of a model to provide a correct classification when presented with hateful or non-hateful content (Röttger et al., 2021). Each functionality has a set of corresponding test cases that share one gold-standard label. We select the functionalities in HatemojiCheck to be (1) realistic: they capture real-world uses of emoji-based hate, (2) unique: each covers a distinct aspect of emoji-based hate, without overlaps between functionalities, and (3) unambiguous: they have clear gold-standard labels. The functionalities are motivated from two perspectives:

Previous Literature We identify distinct uses of emoji in online communications, particularly abuse. This includes appending emoji to the end of otherwise neutral statements to reveal emotive intent (Wiegand and Ruppenhofer, 2021), using emoji as a ‘pictorial slur’ to attack or dehumanize groups (Bick, 2020; Wiegand and Ruppenhofer, 2021) and substituting emoji for identity terms or threatening verbs (Samghabadi et al., 2019; Bick, 2020; Wiegand and Ruppenhofer, 2021). We also review a range of literature on online hate, identifying distinct types of hateful language (Talat et al., 2017; Zampieri et al., 2019; Vidgen et al., 2021a).

Empirical Investigation Based on the literature, we define a list of potentially hateful emoji and words, and use Twitter’s Streaming API to search for the Cartesian products of emoji–emoji and emoji–word pairs over a two week period. To identify different forms of emoji-based hate, we apply a grounded theory approach (Corbin and Strauss, 1990) on a sample of 3,295 tweets, splitting out distinctive categories, and recursively selecting sub-categories until all key parts of the data are captured and the framework is ‘saturated’.

2.2 Functionalities in HatemojiCheck

This section presents verbatim examples of emoji-based hate (in gray text). For masked versions, see Tab. 1 and Tab. 4.

HatemojiCheck has seven functionalities (see Tab. 1). **F1 Verb Swap** tests threatening hate where the verb is replaced with the equivalent emoji: 🔫, 👊, 💣, 🔪, 💀. It includes both direct threats and normative statements of threat. **F2 Identity Swap** tests derogatory hate where the identity term is replaced with an emoji representation: woman (👩), trans people (⚧), gay people (🏳️‍🌈), disabled people (♿), Black people (🧑🏿) and Muslims (👳🏽).[3] **F3 Descriptor Swap** tests hate where the negative descriptor is replaced with the equivalent emoji. It includes both dehumanizing language and expressions of disgust. For dehumanizing language, five descriptors are used: 🐀, 🐖, 💩, 🦟, 🦠. Based on our Twitter analysis, target-specific descriptors are

---

[2] We recognize the presence of annotator bias in cultural interpretations of this definition, and provide data statements for both datasets in the appendix.

[3] 👳🏽 was commonly used to denote Muslims on Twitter, despite its Unicode description being ‘person wearing a turban’.

Table 1: Summary of the seven functionalities in HATEMOJICHECK.

Functionality (Emoji Used)	Templates	Emoji	Identities	Cases
F1 *Verb Swap*: Swap threatening verb (🔪, 💣, 👊, 🔫, 💀)	10	5	6	300
F2 *Identity Swap*: Swap protected identity (👩, ⚧️, 🏳️‍🌈, 👨🏿, ♿, 👳🏽‍♂️)	20	1	6	120
F3 *Descriptor Swap*: Swap descriptor noun/emotion (🐀, 🐖, 💩, 🦠, 🦟, 🐒, 🦍, 🐐, 🐪 / 🤮, 😷, 🤢)	10	3–7	6	260
F4 *Double Swap*: Combine two of the above swaps	10	3–7	6	288
F5 *Append*: Append negative emoji to neutral text (🤬, 😡, 🤮, 🤢, 😤)	10	3–5	6	288
F6 *Positive Confounder*: Append positive emoji to hateful text (❤️, 😊, 😇, 😍, 🙌)	13	5	6	440
F7 *Emoji Leetspeak*: Substitute for character or word-piece (0️⃣, 1️⃣, 4️⃣, 3️⃣, 🌟, ❤️)	15	3–4	6 (+16 slurs)	430
Totals of Unique Templates, Emoji, Identity and Test Cases	88	36	6	2,126

used for Black people: (🐒, 🦍) and Muslims: (🐐, 🐪). For expressions of disgust, three descriptors are used: 🤮, 😷, 🤢. **F4 Double Swap** tests a combination of F1 with either F2 or F3, where emoji are swapped for both the identity and the verb, or both the identity and the negative descriptor. Some templates contain only emoji e.g., "🔪👳🏽‍♂️", while others have some text e.g., "👩 make me 😷". **F5 Append** tests statements which would be non-hateful on their own but become hateful when appended with a negative emoji such as 🤬, 😡, 🤮. For instance, "My new manager is a woman" is neutral but "My new manager is a woman 🤮" is hateful. **F6 Positive Confounder** tests clearly hateful statements appended with a positive emoji such as 😇, 😍, 🙌. For instance, "Kill all women 😇" or "All women deserve to die 😍". **F7 Emoji Leetspeak** tests statements where parts of the hateful language have been obfuscated by replacing characters with emoji. The character substitution can occur in the term expressing negative sentiment, e.g., "I h4️⃣te gays", the identity, e.g., "I hate g4️⃣ys" or the slur, e.g., "I hate f4️⃣gs". There are three emoji character substitutions: (1) a numeric substitution which mimics leetspeak (a:4️⃣, i:1️⃣, e:3️⃣, o:0️⃣), (2) a star mimicking * for vowels in slurs and profanities (vowel:🌟), and (3) a heart mimicking starring out vowels but in a more adversarial manner (vowel:❤️). To reflect specific cases on Twitter of anti-Muslim hate, two additional slurs are included where a word-piece is substituted with an emoji (🐪-f*cker, 🐐-f*cker).

2.3 Test Cases in HATEMOJICHECK

HATEMOJICHECK is strongly inspired by empirical examples of emoji-based hate but we want it to comprise a clear, minimum performance standard. Thus, for each functionality we hand-craft test cases, i.e., short English-language text documents that clearly correspond to just one gold-standard label. The test cases are varied in their vocabulary and syntax to ensure they assess model robustness to diverse language (Zhou et al., 2020). To generate test cases at scale and ensure balanced coverage across targeted groups, we use a template-based approach (Dixon et al., 2018; Ribeiro et al., 2020; Röttger et al., 2021). First, each template is given an identity placeholder e.g., "I hate [IDENTITY]" or a slur placeholder e.g., "You are just a [SLUR] to me". Six protected identities populate these placeholders: women, trans people, gay people, Black people, disabled people and Muslims. For templates with slurs, we use the 16 slurs compiled by Röttger et al. (2021) (see Appendix C.1). Second, each template is given an emoji placeholder that is populated by emoji that share semantic and syntactic properties, so that the test suite can be scaled across different emoji. For example, the template "I will [EMOJI] all [IDENTITY]" could be populated with {'👊', 'trans people'}. HATEMOJICHECK comprises 3,930 entries. There are 2,126 original test cases and 1,804 perturbations (see Tab. 1).

2.3.1 Perturbations

Each set of test cases is matched to a set of perturbations which are constructed through minimal edits to the original hateful template.[4] Test cases generated from these perturbed templates share vocabulary and syntax with the original test cases, enabling fine-grained assessment of model weaknesses (Gardner et al., 2020). We provide three types of perturbations. For **identity perturbations**, the identity targeted by the original hateful statement is substituted for a non-protected entity, making it non-hateful. Possible identity perturbations include non-protected groups (e.g., "I hate accountants"), non-human entities (e.g., "I hate spiders"), and inanimate objects (e.g., "I hate pizza"). For **polarity perturbations**, the negative sentiment of the original hateful statement is reversed to be positive, making it non-hateful, without changing the target of the statement. Possible polarity per-

---

[4] See Appendix C.2 for details on perturbations.

turbations include changing threatening language to supportive language, e.g., “kill” to “respect”, changing expressions of hate to expressions of love, e.g., “I hate…” to “I love…”, or replacing hateful use of slurs with counterspeech against the slurs, e.g., “[IDENTITY] are [SLUR]” to “[IDENTITY] should never be called [SLUR]”. For **no emoji perturbations**, emoji are removed or replaced with their equivalent text to preserve the semantic expression (e.g., “🔫” becomes “shoot” and “❤️” becomes “love”). For most functionalities this perturbation preserves the original label of the test case, e.g., “[IDENTITY] makes me 🤮” is hateful, and its perturbation “[IDENTITY] makes me sick” is still hateful. However, for F5 Append the label changes because when the negative emoji appended to the neutral statement is removed, the part of the statement that remains is non-hateful.

2.4 Validating Test Cases

To validate the gold-standard labels assigned to each test case, we recruited three annotators with prior experience on hate speech projects.[5] Annotators were given extensive and prescriptive guidelines (Röttger et al., 2022), as well as test tasks and training sessions, which included examining real-world examples of emoji-based hate from Twitter. We followed guidance for protecting annotator well-being (Vidgen et al., 2019). There were two iterative rounds of annotation. In the first round, each annotator labeled all 3,930 test cases as hateful or non-hateful, and had the option to flag unrealistic entries. Test cases with any disagreement or unrealistic flags were reviewed by the study authors ($n = 289$). One-on-one interviews were conducted with annotators to identify dataset issues versus annotator error. From 289 test cases, 119 were identified as ambiguous or unrealistic, replaced with alternatives and re-issued to annotators for labeling. No further issues were raised. We measured inter-annotator agreement using Randolph's Kappa (Randolph, 2005), obtaining a value of 0.85 for the final set of test cases, which indicates “almost perfect agreement” (Landis and Koch, 1977).

3 Building Better Models with HATEMOJIBUILD

As reported in §4, we find existing models perform poorly on emoji-based hate as measured with HATEMOJICHECK. We address those failings by implementing a human-and-model-in-the-loop approach using the Dynabench interface in order to train a model that better detects emoji-based hate.[6]

Dataset Generation We implemented three successive rounds of data generation and model retraining to create the HATEMOJIBUILD dataset. In each round we tasked a team of 10 trained annotators with entering content that the model-in-the-loop would misclassify.[7] We refer to this model as the *target model*. Annotators were instructed to generate linguistically diverse entries while ensuring each entry was (1) realistic, (2) clearly hateful or non-hateful and (3) contained at least one emoji. Each entry was first given a binary label of hateful or non-hateful, and hateful content was assigned secondary labels for the type and target of hate (Zampieri et al., 2019; Vidgen et al., 2021a,b). Each entry was validated by two additional annotators, and an expert resolved disagreements. After validation, annotators created a perturbation for each entry that flipped the label. To maximize similarity between originals and perturbations, annotators could either make an emoji substitution while fixing the text or fix the emoji and minimally change the surrounding text. Including a hateful and non-hateful version of each sentence in the dataset prevents overfitting to certain emoji or identity references. Each perturbation received two additional label annotations, and disagreements were resolved by the expert. This weekly cadence of annotator tasks was repeated in three consecutive weeks. The dataset composition and inter-annotator agreement is described in Appendix E.

Model Implementation Our work follows directly from Vidgen et al. (2021b), who collect four rounds (R1–4) of dynamically-generated textual data as well as 468,928 entries compiled from 11 English-language hate speech datasets (R0). Our rounds of data collection are referred to as R5–7. At the end of each round, the data for that round is assigned a 80/10/10 train/dev/test split. The test split is never used for any future training. The train split is upsampled to improve performance with multipliers of $1, 5, 10, 100$, with the optimum ratio taken forward to subsequent rounds. The target

---

[5] See annotator demographics in Appendix B.

[6] Dynabench is an open-source platform which supports dynamic dataset generation and model benchmarking for a variety of NLP tasks (Kiela et al., 2021).

[7] There was no overlap in annotators from the previous HATEMOJICHECK task; demographics are in Appendix D.

model is then re-trained on the training data from all prior rounds as well as the current round. For R5 data collection, the target model (R5-T) is the DeBERTa model released by Ma et al. (2021), trained on R0–R4 from Vidgen et al. (2021b). This model performs well on text-only hate, but has seen limited emoji in training. For subsequent target models, we evaluate two architectures: DeBERTA (He et al., 2021) and BERTweet (Nguyen et al., 2020).[8]

We select the best models and upsampling ratios at the end of each round. The criteria to select the best model must satisfy two requirements: (1) the target model must still perform well on prior rounds of text-based examples because emoji-based hate represents just one construction of textual hate, and (2) the target model must successfully handle the most recent round data because iterative data collection produces more challenging examples in successive rounds. To balance these requirements, we use a weighted accuracy metric with 50% weight on the test sets from all prior rounds and 50% weight on the current round test set, which enforces a recency-based discount factor (Kiela et al., 2021). This ensures we can assess performance against the latest (emoji-specific and most-adversarial) round without overfitting and reducing performance on the previous test sets.

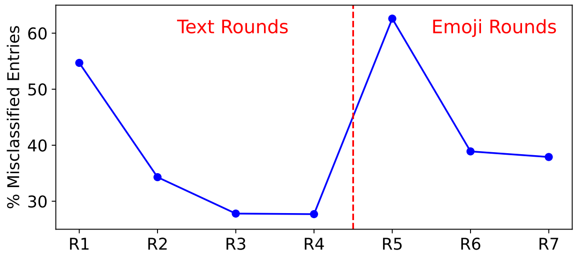

Figure 1: MER for R1–4 (text) and R5–R7 (emoji).

Model Error Rate For each emoji-based round of data generation (R5–7) as well as prior text-only rounds from Vidgen et al. (2021b), we calculate model error rate (MER) as the proportion of annotators' original entries that fool the model (Fig. 1). Between R4 and R5, MER increases by 35 percentage points (pp) to over 60%, higher than the R1 MER. From R5 to R6, once the model has been trained on emoji-based hate, there is a steep reduction in MER of 24pp. From R6 to R7, there is a smaller reduction in MER of 1pp. Overall, the model is easily tricked by emoji content at first but then becomes much harder to trick after our first round of re-training.

Performance on Adversarial Test Sets To evaluate model performance across rounds, we calculate F1-score and accuracy for each test set (Tab. 2). The baseline R5-T model is the highest performing model on the text-only test set (R1–4), with an F1 of 0.85, but only scores 0.49 on the newly generated emoji-containing test sets from HATEMOJIBUILD (R5–7). R6-T, R7-T and R8-T perform better on R5–7, with F1 between 0.76 and 0.77. They perform similarly well on the R1–4 test set, with F1 of 0.84, suggesting no trade-off for performance on text-only hate speech. The best performing model across all R1–7 test sets is R8-T, with an F1 of 0.83. The greatest performance gain in the adversarially-trained models is from R5-T to R6-T, with an increase in F1 of 0.28 on the emoji test set. This is achieved with only 2,000 emoji-containing examples. By comparison, R7-T and R8-T yield very small improvements.

Table 2: Performance of target models on emoji test sets from HATEMOJIBUILD, text sets from Vidgen et al. (2021b) and the combination of these test sets.

	Emoji Test Set (R5-R7)		Text Test Set (R1-R4)		All Test Sets (R1-R7)	
	$n = 593$		$n = 4119$		$n = 4712$	
	Acc	**F1**	**Acc**	**F1**	**Acc**	**F1**
R5-T	0.585	0.490	**0.828**	**0.847**	0.786	0.801
R6-T	0.757	**0.769**	0.823	0.837	0.813	0.825
R7-T	**0.759**	0.762	0.824	0.842	0.813	0.829
R8-T	0.744	0.755	0.827	0.844	**0.814**	**0.829**

4 Evaluating Models with HATEMOJICHECK

We present results for two existing models as baselines, with additional baselines shown in Appendix G. The first baseline is Google Jigsaw's Perspective API, a widely-used commercial tool for content moderation. We use Perspective's "Identity Attack" attribute, which is defined as "negative or hateful comments targeting someone because of their identity" and thus closely matches our definition of hate. The returned score is converted to a binary label with a 50% cutoff. We refer to this model as P-IA. The second baseline is the R5-T model from Ma et al. (2021), introduced above. To compare model performance on HATEMOJICHECK, we use accuracy because three sets of test cases (originals, polarity perturbations and identity perturba-

tions) have one class label, making F1-score incompatible. To measure emoji-specific weaknesses, we also calculate *emoji difference*, the difference between averaged model accuracy on the original emoji test cases compared with averaged accuracy on the no emoji perturbations.

On HATEMOJICHECK as a whole, our newly trained models R6-T, R7-T and R8-T perform best, with overall accuracy from 0.87 to 0.88 (Tab. 3). They substantially outperform P-IA, with an accuracy of 0.69, and R5-T, with an accuracy of 0.78. Our newly trained models have the smallest emoji difference, between 0.03 and 0.08. In contrast, P-IA and R5-T have emoji differences of 0.16 and 0.22, respectively. Comparing the three models trained on HATEMOJIBUILD, the first round of adversarial data generation yields the largest relative improvement, and in many ways R6-T is at least as good a model, if not better, than R8-T.

4.1 Model Performance by Functionality

Our models trained on HATEMOJIBUILD perform better than the two baseline models on nearly every functionality (Tab. 4). They also perform far more consistently across all perturbation types.

For F1 Verb Swap, P-IA and R5-T perform well on original statements, but then perform poorly on the polarity perturbations (0.20 and 0.42 accuracy, respectively). Our models have much stronger performance on polarity perturbations (between 0.73 and 0.77), and comparably high performance on the other sets of test cases. For F2 Identity Swap, P-IA and R5-T perform very poorly on original statements (0.14 and 0.33 accuracy, respectively) but then perform well on the polarity perturbations and no emoji perturbations. This vulnerability is carried forward to performance on F4 Double Swap. R5-T only achieves 0.03 and P-IA makes zero correct predictions. In contrast, our models achieve accuracy of 0.83 on F2 and accuracies between 0.70 and 0.79 on F4. For F3 Descriptor Swap, our models improve over P-IA and R5-T on the original statements. The relative improvement is particularly large for the polarity perturbations (0.25 for P-IA compared with 0.93 for R8-T). For F5 Append, P-IA and R5-T perform moderately with accuracies of 0.73 and 0.69. Our models perform far better, with accuracies from 0.87 to 0.99. However, they do not show a substantial increase in performance for the no emoji perturbations in F5.3. For F6 Positive Confounder, our models perform worse than P-IA and R5-T on the original statements, but then have far more consistent performance across the perturbations. For instance, R8-T achieves accuracies between 0.89 to 0.93 across all sets of test cases in this functionality, compared with a range of 0.44 to 0.93 for P-IA. P-IA and R5-T perform well on original statements and poorly on perturbations precisely because they ignore the effect of the emoji confounder. F7 Emoji Leetspeak is a successful adversarial strategy. R5-T achieves 0.85 accuracy on the original statements but just 0.67 on the identity perturbations, while P-IA does even worse, with only 0.59 on the original statements and 0.57 on the polarity perturbations. Our models perform better on the original statements, but still struggle with identity perturbations, showing how challenging this functionality is. However, non-hateful leetspeak constructions are likely less prevalent on social media than slur-based leetspeak.

Overall, all models trained on HATEMOJIBUILD perform well on emoji-based hate, but there is no clear 'best' model among them. After the large improvement from R5-T to R6-T, subsequent models produce minimal performance gains across the functionalities. This suggests the gains, as measured on HATEMOJICHECK's intentionally short and simple statements, are quickly saturated.

4.2 Model Performance by Target Group

HATEMOJICHECK contains target group labels for hateful and non-hateful entries, allowing models to be compared by their subgroup fairness. However, defining *fairness* is a non-trivial task, and there is substantial debate in the machine learning community as to which metrics are most appropriate. We consider six metrics calculated across subgroups: accuracy, precision, recall, false positive rate, false

Table 4: Accuracy across HATEMOJICHECK's seven functionalities and their associated perturbation sets.

					Pre-Emoji		Post-Emoji

Notes: † The *emoji difference* is not defined because the no emoji perturbation is non-hateful, i.e., the opposite label to the original test case, so accuracy over these sets cannot be fairly compared.

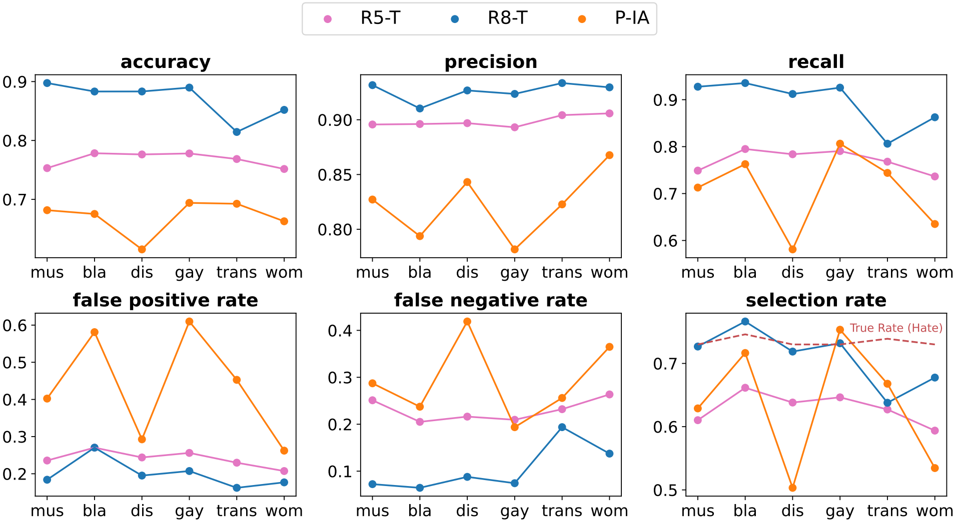

Figure 2: Subgroup fairness metrics by model. Abbreviations respectively refer to Muslims, Black people, Disabled people, Gay people, Trans people and Women.

negative rate and selection rate.[9] Fig. 2 shows subgroup fairness metrics compared across three models: P-IA, R5-T and R8-T. It is concerning that P-IA has such differential performance, especially regarding the unbalanced false positive and negative rates for women and disabled people, as both of these error types are societally harmful. R8-T has more balanced accuracy, precision, recall and selection rate across subgroups, driven by stable performance in false negatives and positives. In Appendix H we provide two further between-group fairness metrics: demographic parity ratio (Agarwal et al., 2019), and equalized odds ratio (Hardt et al., 2016; Agarwal et al., 2018). There is also substantial improvement in these metrics from adversarial training schemes relative to commercial solutions or statically-trained models.

5 Discussion

HATEMOJICHECK reveals critical model weaknesses in detecting emoji-based hate. Existing commercial and academic models perform poorly at identifying hate where the identity term has been replaced with an emoji representation (F2 and F4), even though they perform well at identifying the equivalent textual statements. These models have better performance on Verb Swap (F1) but then struggle with the polarity perturbations (F1.2). This suggests that the models are overfitting to the identity term and ignore the sentiment from the emoji, leading to false positive predictions. Our newly trained models substantially improve performance on original hateful statements from F2, F4 and F5, indicating they have a better semantic grasp of emoji substitutions and appends. They also make large performance gains on the polarity perturbations in F1.2, F3.2, F5.2 and F6.2, suggesting they better incorporate information on how different emoji condition the likelihood of hatefulness. Despite improving on existing models, our models still perform relatively more poorly on F4, as well as the F1.2, F5.3 and F7.1 perturbations. These weaknesses could potentially be addressed in future work through additional data generation.

Training on just one round of adversarial data yields the biggest improvement on HATEMOJICHECK. Thereafter, performance plateaus. This aligns with the sharp increase and then fall in MER across emoji-based rounds of data generation (in Fig. 1). On the adversarial test sets, R8-T only marginally outperforms R6-T and R7-T on all R1–7 test sets. It slightly underperforms on the R5–7 test sets from HATEMOJIBUILD. This suggests that while training on a relatively small number of entries can substantially improve performance, the gains quickly saturate. Future work could investigate performance differences in more detail using the labels for type and target of hate that we provide for all three rounds of data.

Due to practical constraints, HATEMOJICHECK has several limitations, which could be addressed in future work. First, it includes relatively simplistic statements, and so offers negative predictive power: high performance only indicates the absence of specific weaknesses (Gardner et al., 2020; Röttger et al., 2021). Second, it is inspired by real-world hate but synthetically generated. Future work could evaluate against more complex and diverse forms of emoji-based hate. Third, it is limited in scope. It only considers short English-language statements with one binary label. Only six identities are included, none of which are intersectional, and the set of emoji covers a fraction of the full Unicode Standard. In-scope identities and emoji usage are culturally-dependent (Barbieri et al., 2016; Ljubešić and Fišer, 2016) so future work could assess the generalizability of HATEMOJICHECK to other cultures and languages. These limitations do not diminish HATEMOJICHECK's utility as a tool for effectively identifying model weaknesses to emoji-based hate. By publicly releasing the test suite, practitioners and academics can scrutinize their models prior to deployment or publication.

Adversarial data generation is a powerful technique for creating diverse, complex and informative datasets. However, it also introduces challenges. First, the entries are 'synthetic' rather than sampled from 'real-world' examples. Substantial training and time are required to ensure that annotators understand real online hate and can imitate it. Second, annotators can exhaust their creativity and start producing unrealistic, simplistic or non-adversarial examples. Third, because of the need for training, supervision and support, only a small pool of annotators is feasible, which can introduce additional idiosyncratic biases. Given these issues, quality control is a key consideration throughout the data generation process. Encouragingly, we find carefully-curated and adversarially-generated

---

[9] Selection rate is $\mathbb{P}[h(x)|A = a]$, i.e., the proportion of the population in subgroup a who have 1 (hate) as the given class label. The 'true' ratio of class labels is shown in Fig. 2

training datasets can significantly improve performance on emoji-based hate as a particular type of challenging content, and that this approach is effective with relatively few training examples. Thus, substantial model improvements can be realized with minimal financial and computational cost.

6 Related Work

Emoji-based hate has received limited attention in prior work on hate and abusive language detection. Studies that attend to emoji often do so as a potential input feature to aid classifier performance. For example, Samghabadi et al. (2019) improve offensive language classification with an 'emotion-aware' mechanism built on emoji embeddings. Ibrohim et al. (2019) find that adding emoji features to Continuous Bag of Words and word unigram models marginally improves performance for abusive language detection on Indonesian Twitter. Bick (2020) identifies examples of subtle and non-direct hate speech in German–Danish Twitter conveyed through 'winking' or 'skeptical' emoji that flag irony or non-literal meaning in their accompanying text. Corazza et al. (2020) train an emoji-based Masked Language Model (MLM) for zero-shot abuse detection. They show this method improves performance on classifying abuse in German, Italian and Spanish tweets compared to an MLM which does not attend to emoji. Wiegand and Ruppenhofer (2021) use abusive emoji as a proxy for learning a lexicon of abusive words. Their findings indicate that emoji can disambiguate abusive and profane usages of words such as f*ck and b*tch. By contrast, our work focuses on emoji-based hate as a challenge for hate detection models. With HATEMOJICHECK, we enable a systematic evaluation of how well models handle different types of emoji-based hate. Rather than adjusting the model architecture, we account for emoji-based hate in our iterative data generation process and show that models trained on such data perform better on emoji-based hate, while retaining strong performance on text-only hate.

As a suite of functional tests for evaluation, HATEMOJICHECK directly builds on previous work by Ribeiro et al. (2020) and Röttger et al. (2021). Ribeiro et al. (2020) introduced functional tests as a framework for NLP model evaluation with CHECKLIST, showing that their approach can identify granular model strengths and weaknesses that are obscured by high-level metrics like accuracy and F1-score. Röttger et al. (2021) adapted this framework to hate detection with HATECHECK, which covers 29 model functionalities motivated by interviews with civil society stakeholders and a review of previous hate speech literature. Like HATECHECK, we pair hateful test cases with contrasting perturbations that are particularly challenging to models relying on overly simplistic decision rules and thus reveal granular decision boundaries. HATECHECK did not consider emoji-based hate, which is the main focus of our work.

Our approach to training better models for emoji-based hate builds directly on work by Vidgen et al. (2021b), who apply iterative human-and-model-in-the-loop training to hate detection models. Like us, they used the Dynabench interface (Kiela et al., 2021) to implement their training system, which has also been used to improve model performance for other tasks such as reading comprehension (Bartolo et al., 2020) and sentiment analysis (Potts et al., 2021). Earlier work by Dinan et al. (2019) introduced a similar 'build it, break it, fix it' system of repeated interactions between a hate classifier and crowdworkers to develop safe-by-design chatbots. Unlike previous work, we focus data generation on a particular type of hateful content, emoji-based hate, and show that the training scheme can address specific model weaknesses on such content without sacrificing performance on text-only hate.

7 Conclusion

Online hate is a pervasive, harmful phenomenon, and hate detection models are a crucial tool for tackling it at scale. We showed that emoji pose a particular challenge for such models, and presented HATEMOJICHECK, a first-of-its-kind evaluation suite for emoji-based hate. It covers seven functionalities with 3,930 test cases. Using this test suite, we exposed clear weaknesses in the performance of commercial and academic models on emoji-based hate. To address these weaknesses, we created the HATEMOJIBUILD dataset using an innovative human-and-model-in-the-loop approach. We showed that models trained on this adversarial data are substantially better at detecting emoji-based hate, while retaining strong performance on text-only hate. Our approach of first identifying granular model weaknesses, and then generating an adversarial dataset to address them presents a promising direction for building models to detect other diverse and emerging forms of online harm.

Acknowledgments

We are thankful for support that the Oxford authors received to facilitate annotation and computational resources from the Volkswagen Foundation, Meedan, Keble College, the Oxford Internet Institute, Rewire and The Alan Turing Institute. We owe a debt of gratitude to all our annotators, to Dynabench and to our anonymous reviewers. We are also grateful to Zeerak Talat and Douwe Kiela for their helpful advice on this research, as well as support from Devin Gaffney and Darius Kazemi. Hannah Rose Kirk was supported by the Economic and Social Research Council grant ES/P000649/1. Paul Röttger was supported by the German Academic Scholarship Foundation.

A Ethical Considerations

Misuse: We release two datasets of challenging emoji examples on which commercial solutions and state-of-the-art transformer models have been proven to fail. Malicious actors could take inspiration for bypassing current detection systems on internet platforms, or in principal train a generative hate speech model. This concern is also raised by Vidgen et al. (2021b), but the conclusion is reached that such risk of misuse is small and outweighed by the considerable scientific and social benefits.

Harm Statement: Following the advice of Derczynski et al. (2022), we describe the risks to well-being during the production and publication of this research and the steps taken to mitigate them. There is a risk of harm to data subjects i.e., the targets of hate, from reinforcing hateful, dehumanizing or derogatory statements, and to readers viewing this content in the paper. To mitigate these harms, we include a content warning directly after the abstract, at least a page before any harmful content is displayed and colored in red for maximum visibility. We also include a section-specific content warning before §2.2, which includes a number of hateful examples. Hateful examples in §2.2 are consistently formatted and visually distanced with gray text. All other examples (including Tab. 1, Tab. 4) are presented with placeholders for the [IDENTITY]. Hateful slurs are starred out with an asterisk where possible (e.g., Tab. 5) but we cannot star out emoji without hindering interpretation. There is also a risk to researchers and annotators from labeling and viewing harmful content. As authors, we oppose the use of hateful language. We follow protocols for protecting annotator well-being, including briefing sessions, regular check-ins and provision of mental health support.

B Data Statement for HATEMOJICHECK

We provide a data statement (Bender and Friedman, 2018) to document the generation and provenance of HATEMOJICHECK.

B.1 Curation Rationale

To construct HATEMOJICHECK, we hand-crafted 3,930 short-form English-language texts using a template-based method for group identities and slurs. Each test case exemplifies one functionality and is associated with a binary gold standard label (hate versus not hate). All 3,930 cases were labeled by a trained team of three annotators, who could also flag examples that were unrealistic. Any test cases with multiple disagreements or flags were replaced with alternative templates and re-issued for annotation to improve the quality of examples in the final set of test cases. The purpose of HATEMOJICHECK is to evaluate the performance of black-box models against varied constructions of emoji-based hate.

B.2 Language Variety

The test cases are in English. This choice was motivated by the researchers' and annotators' expertise, and to maximize HATEMOJICHECK's applicability to previous hate speech detection studies, which are predominantly conducted on English-language data. We discuss the limitations of restricting HATEMOJICHECK to one language and suggest that future work should prioritize expanding the test suite to other languages.

B.3 Speaker Demographics

All test cases were hand-crafted by the lead author, who is a native English-speaking researcher at a UK university with extensive subject matter expertise in online harms.

B.4 Annotator Demographics

We recruited a team of three annotators who worked for two weeks in May 2021 and were paid £16/hour. All annotators were female and between 30–39 years old. One had an undergraduate degree, one a taught graduate degree and one a postgraduate research degree. There were three nationalities: Argentinian, British and Iraqi, two ethnicities: White and Arab, and three religious affiliations: Catholic, Muslim and None. One annotator was a native English speaker and the others were non-native but fluent. All annotators used emoji and social media more than once per day. All annotators had seen others targeted by abuse online, and one had been targeted personally.

B.5 Speech Situation

The modality of all test cases is written text embedded with emoji. The empirical investigation using Twitter's streaming API was conducted between 1st–14th April 2021. The first set of test cases was created between 26th April–7th May 2021. The first round of annotation ran between 7th–14th May 2021. The second round of cases was created and re-issued between 14th–21st May 2021.

B.6 Text Characteristics

The genre of texts is hateful and non-hateful statements using emoji constructions. Renderings of emoji vary by operating system and browser providers. The renderings in this paper are from WhatsApp. The composition of the dataset by labels (hate versus not hate) and by set (originals versus perturbations) is described in Tab. 3 of the main paper. 68% of the test cases are hateful. HATEMOJICHECK has 644 cases for Muslims, 608 cases each for gay people, disabled people and women, 582 cases for Black people and 566 cases for trans people. identity perturbations switch a protected identity for a non-protected identity so 314 cases have no protected identity tag.

C Constructing HATEMOJICHECK

C.1 List of Hateful Slurs in HATEMOJICHECK

The slurs used in HATEMOJICHECK are selected in the same way as for HATECHECK (Röttger et al., 2021). For each of the six identities in HATEMOJICHECK, the most common slurs are taken from `hatebase.org`, an online crowd-sourced repository of hateful terms and slurs. The top three most common slurs logged by users of hatebase are used, unless the 3rd ranked slur is significantly less common than the 2nd ranked. Each identity thus has two or three associated slurs (Tab. 5).

C.2 Defining Perturbations

Each template has three perturbations but the mapping of original test cases to perturbations is not one-to-one. Instead, there is a set of original templates contrasted by three sets of perturbation templates. The perturbation templates have fewer degrees of freedom than the original templates so test cases generated from them are fewer in number. Within each perturbed template we use the same emoji for substitutions to ensure consistency, but across templates, we use a range of emoji to ensure linguistic variety.

The perturbed templates are constructed as follows. **(1) Identity perturbations**: the protected identity (which could be an emoji or a word depending on the functionality) in each original template is substituted with *one* non-protected entity (which could be an emoji or a word). **(2) Polarity perturbations**: the negative term (which could be a word or an emoji) in each original template is substituted for *one* positive term (which could be a word or an emoji). **(3) No emoji perturbations**: all emoji elements of the original template are replaced by equivalent text where *one* word is used to cover all versions e.g. 🔫 and 💣 are both substituted for the verb 'harm'. For F5 and F6, the appended emoji is removed not replaced.

Table 5: Hateful slurs in HATEMOJICHECK

Protected Group	**Slurs**
Women	b*tch, sl*t, wh*re
Trans people	tr*nny, sh*male
Gay people	f*ggot, f*g, q*eer
Black people	n*gger, c*on
Disabled people	r*tard, cr*pple, m*ng
Muslims	m*zzie, J*hadi, camelf*cker

D Data Statement for HATEMOJIBUILD

We provide a data statement (Bender and Friedman, 2018) to document the generation and provenance of HATEMOJIBUILD.

D.1 Curation Rationale

We use an online interface designed for dynamic dataset generation and model benchmarking (Dynabench) to collect synthetic adversarial examples in three successive rounds, running between 24th May–11th June. Each round contains ~2,000 entries, where each original entry inputed to the interface is paired with an offline perturbation. Data was synthetically-generated by a team of trained annotators, i.e., not sampled from social media.

D.2 Language Variety

All entries are in English. Language choice was dictated by the expertise of researchers and annotators. Furthermore, English is used for a wide number of benchmark hate speech datasets (Davidson et al., 2017; Founta et al., 2018) and was also used in the adversarial dataset for textual hate speech (Vidgen et al., 2021b). The method be could be adapted for other languages in future work.

D.3 Speaker Demographics

All entries are synthetically-created by annotators so the speaker demographics match the annotator demographics.

D.4 Annotator Demographics

Ten annotators were recruited to work for three weeks, and paid £16/hour. An expert annotator was recruited for quality control purposes and paid £20/hour. In total, there were 11 annotators. All annotators received a training session prior to data collection and had previous experience working on hate speech projects. A daily 'stand-up' meeting was held every morning to communicate feedback and update guidelines as rounds progressed. Annotators were able to contact the research team at any point using a messaging platform. Of 11 annotators, 8 were between 18–29 years old and 3 between 30–39 years old. The completed education level was high school for 3 annotators, undergraduate degree for 1 annotator, taught graduate degree for 4 annotators and post-graduate research degree for 3 annotators. 6 annotators were female, and 5 were male. Annotators came from a variety of nationalities, with 7 British, as well as Jordanian, Irish, Polish and Spanish. 7 annotators identified as ethnically White and the remaining annotators came from various ethnicities including Turkish, Middle Eastern, and Mixed White and South Asian. 4 annotators were Muslim, and others identified as Atheist or as having no religious affiliation. 9 annotators were native English speakers and 2 were non-native but fluent. The majority of annotators (9) used emoji and social media more than once per day. 10 annotators had seen others targeted by abuse online, and 7 had been personally targeted.

D.5 Speech Situation

Entries were created from 24th May–11th June 2021. Their modality is short-form written texts embedded with emoji. Entries are synthetically-generated but annotators were trained on real-world examples of emoji-based hate from Twitter.

D.6 Text Characteristics

The genre of texts is hateful and non-hateful statements using emoji constructions. Annotators inputted emoji into the platform using a custom emoji picker.[10] The composition of the final dataset is described in Tab. 6. 50% of the 5,912 test cases are hateful. 50% of the entries in the dataset are original content and 50% are perturbations.

E Constructing HATEMOJIBUILD

Types of Hate We adopt the same categorization used by Vidgen et al. (2021b, p.3).[11] There are four types of hate. Derogation: Language which explicitly derogates, demonizes, demeans or insults a group. Animosity: Expressions of abuse through implicit statements or mockery, where a logical step must be taken between the sentence and its intended negativity. Threatening language: Statements of intent to take action against a group, with the potential to inflict serious or imminent harm on its members. Dehumanizing language: Comparing groups to insects, animals, germs or trash.

Table 6: Summary statistics across three rounds of data from HATEMOJIBUILD.

		R5	**R6**	**R7**
n		1994	1966	1952
Split, n (%)	Train	1595 (80.0)	1572 (80.0)	1561 (80.0)
	Dev	199 (10.0)	197 (10.0)	195 (10.0)
	Test	200 (10.0)	197 (10.0)	196 (10.0)
Label, n (%)	Hate	1006 (50.5)	983 (50.0)	976 (50.0)
	Not hate	988 (49.5)	983 (50.0)	976 (50.0)
Set, n (%)	Original	997 (50.0)	983 (50.0)	976 (50.0)
	Perturbation	997 (50.0)	983 (50.0)	976 (50.0)
Type, n (%)	None	988 (49.5)	983 (50.0)	976 (50.0)
	Derogation	718 (36.0)	649 (33.0)	594 (30.4)
	Animosity	74 (3.7)	219 (11.1)	275 (14.1)
	Threatening	101 (5.1)	50 (2.5)	52 (2.7)
	Dehumanizing	113 (5.7)	65 (3.3)	55 (2.8)
# Emoji, μ (σ)		1.7 (2.2)	1.7 (1.0)	1.6 (1.1)

Targets of Hate Annotators were provided with a non-exhaustive list of high-priority identities to focus on which included categorizations by gender identity (e.g., women, trans), sexual orientation (e.g., gay), ethnicity (e.g., Hispanic people), religion (e.g., Sikh), nationality (e.g., Polish), disability and class, alongside intersections (e.g., Muslim women). Hate directed towards majority groups (e.g., men, white people and heterosexuals) is outside the remit of this work. The explicit decision not to focus on issues such as 'reverse racism' (Bax, 2018) is made due to the complex debate on its inclusion in hate speech definitions.

Composition Tab. 7 reports the inter-annotator agreement and number of final entries per round. Each round has approximately the same number of entries with slightly fewer in R7 due to more quality control issues. Labels are equally distributed in each round (see Tab. 6). For 75 pairs of originals and perturbations, the perturbation unsuccessfully flipped the label given by majority agreement between three annotators. All other pairs have opposite labels. Derogation is always the most-

---

[10] `https://hatemoji.stackblitz.io/`

[11] One of their categories "support for hateful entities" is excluded because it introduced confusion and ambiguity.

Table 7: Quality control checks per round of data collection, showing Randolph-kappa score across three annotators per entry $R(S)$, entries reviewed by an expert annotator, and dropped entries.

		Input Entries	$R(S)$	Reviewed	Dropped	Final Entries
R5	Original	1020	0.903	273	6	1014
	Perturbation	1014	0.938	131	17	**997**
R6	Original	1008	0.902	189	8	1000
	Perturbation	1000	0.911	167	17	**983**
R7	Original	993	0.913	169	12	981
	Perturbation	981	0.928	168	5	**976**

commonly inputted form of hate. From R5 to R7, there is a rise in animosity entries paired with a decline in threatening and dehumanizing language entries. Annotators were given substantial freedom in the targets of hate resulting in 54 unique targets, and 126 unique intersections of these. The entries from R5–R7 contain 1,082 unique emoji out of 3,521 defined in the Unicode Standard as of September 2020. The mode of emoji per entries is 1 and mean is approximately 1.5 in each round. The frequency of targets and emoji follow a long-tailed distribution, similar to a Zipf curve. These distributions match those found online for targets (Silva et al., 2016) and for emoji (Felbo et al., 2017; Cappallo et al., 2019; Bick, 2020).

In the first round, annotators commonly employed a strategy of substituting identities for emoji so three identity emoji were frequently used (👨🏿, 👫, ♿). Using emoji character substitutions in slurs was also a successful strategy (A: 🅰), as was substituting the entire slur for an emoji homonym (f*g: 🚬). In the final round, the model was wise to such strategies, and so annotators changed their adversarial techniques to irony, satire or mockery, as reflected in the top emoji (😂, 🙄, 🤣, 🤡). For a qualitative understanding of annotators' experiences, we conducted a post-study survey.[12]

F Target Models

In each round we assessed two candidate model architectures. The first is an uncased DeBERTa base model (134M params) with a sequence classification head (He et al., 2021). DeBERTa has been shown to improve on BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) models by incorporating a disentangled attention mechanism and enhanced mask decoder. However, emoji are likely relatively sparse in DeBERTa's pre-training material which includes English Wikipedia, Book Corpus (Zhu et al., 2015) and a subset of CommonCrawl. DeBERTa uses the BPE-encoding method so the tokenizer can encode emoji as unique tokens. The second candidate is an uncased BERTweet model (135M params) with a sequence classification head where the RoBERTa training procedure was repeated on 850M English Tweets using a custom vocabulary (Nguyen et al., 2020). BERTweet tokenizes emoji by first translating them to text representations using the `emoji` package. These word representations are derived from the Unicode Standard, so for example 😢 becomes `:crying_face:`.

Upsampling ratios are evaluated for each new round of training data with multipliers of $1, 5, 10, 100$. For the R1–4 data, we carry forward the upsampling from Vidgen et al. (2021b): R1 is upsampled five times, R2 is upsampled 100 times, R3 is upsampled once, and R4 is upsampled once. Combining the model architectures and upsampling ratios gives 8 candidate models for each round's target model. All models were implemented using the `transformers` library (Wolf et al., 2020). All models were trained for 3 epochs with early stopping based on the dev set loss, a learning rate of $2e-5$ and a weighted Adam optimizer. Other hyperparameters were set to HuggingFace defaults. We train and evaluate each model once and report results for this single run. Training took approximately 7 hours for each BERTweet model and 15 hours for each DeBERTa model using 8 NVIDIA Tesla V100 GPU on the JADE2 supercomputer.

The best target model for each round is selected by weighted accuracy between all prior rounds and the current round. For R6-T, a DeBERTa model with 100x upsampling on R5 performs best. Given the dearth of emoji in R1–R4, it is unsurprising a large upsample improves performance on emoji-based hate. For R7-T, DeBERTa with one upsample on R6 performs best. For R8-T, DeBERTa with five upsamples on R7 performs best. In all rounds, DeBERTa significantly outperforms BERTweet, while the upsampling ratio less substantially affects performance. This suggests first converting emoji to their text representations does not substantially aid performance, though there may be other differences between the models driving results. We upload models to Dynalab for model-in-the-loop evaluation and data collection (Ma et al., 2021).

---

[12] This survey is on our Github.

Table 8: Performance of models on emoji, text and all adversarial test sets, alongside benchmark evaluation sets: HatemojiCheck and HateCheck.

G Robustness Analysis of Baselines

In addition to the models analyzed in the main paper, we evaluate three further models. The first is the 'toxicity' attribute returned by Perspective API (P-TX). We test this model because toxicity ratings are the most popular attributes.[13] The second and third models are two uncased BERT models (Devlin et al., 2019) trained on publicly-available academic datasets. B-D is trained on the Davidson et al. (2017) dataset of 24,783 tweets, labeled as *hateful*, *offensive* and *neither*. B-F is trained on the Founta et al. (2018) dataset of 99,996 tweets, labeled as *hateful*, *abusive*, *spam* and *normal*. Any labels besides *hateful* are binarized into a single *non-hateful* label. Two factors motivated the testing of these models. (1) There is a lack of emoji in the training data: the Davidson et al. dataset has 5.8% hateful cases, but only 7.4% of these contain emoji, and the Founta et al. dataset has 5.0% hateful cases, of which 14.7% contain emoji. (2) Despite BERT being a commonly-used architecture for hate speech detection, it encodes emoji as `<UNK>` tokens by default. We compare performance of the full set of pre-emoji models including those analyzed in the main paper (P-IA, P-TX, B-D, B-F, R5-T) versus our 'emoji-aware' models from each round of data collection (R6-T, R7-T, R8-T). Tab. 8 shows performance against the adversarially produced datasets in the emoji rounds of HatemojiBuild and text rounds from Vidgen et al. (2021b), alongside two benchmark evaluation sets HatemojiCheck and HateCheck (Röttger et al., 2021). P-TX has comparable performance to P-IA. B-D and B-F perform poorly on HatemojiCheck (F1 = 0.64, 0.61), and even more poorly on the adversarial test sets of emoji (F1 = 0.27, 0.32).

H Fairness Considerations

As well as the six metrics discussed in the main paper, Tab. 9 shows two further fairness metrics: (1) the demographic parity ratio (Agarwal et al., 2019), which is equal to one when the selection rate is balanced across subgroups, and (2) the equalized odds ratio (Hardt et al., 2016; Agarwal et al., 2018), which is equal to one when the true positive, true negative, false positive, and false negative rates are balanced across subgroups. The academic BERT models perform worst (0.14 to 0.28 across the metrics), followed by the Perspective models (0.41 to 0.67). The most fair model is R5-T with Demographic Parity Ratio of 0.90 and Equalized Odds Ratio of 0.77. However, the overall performance of the emoji-aware models is higher (see Fig. 2): for every subgroup, R8-T has higher accuracy, precision and recall, and lower false positive and negative rates. Thus, the marginally worse performance by between-group fairness metrics is paired with a better ability to protect all these subgroups against emoji-based hate.

Table 9: Between-group fairness metrics by model.

	Demographic Parity Ratio	**Equalized Odds Ratio**
P-IA	0.668	0.430
P-TX	0.611	0.405
B-D	0.174	0.138
B-F	0.276	0.257
R5-T	**0.898**	**0.767**
R6-T	0.818	0.711
R7-T	0.848	0.667
R8-T	0.832	0.600

Abstract

Borrowing ideas from *Production functions* in micro-economics, in this paper we introduce a framework to systematically evaluate the performance and cost trade-offs between machine-translated and manually-created labelled data for task-specific fine-tuning of massively multilingual language models. We illustrate the effectiveness of our framework through a case-study on the TyDIQA-GoldP dataset. One of the interesting conclusions of the study is that if the cost of machine translation is greater than zero, the optimal performance at least cost is always achieved with at least some or only manually-created data. To our knowledge, this is the first attempt towards extending the concept of production functions to study data collection strategies for training multilingual models, and can serve as a valuable tool for other similar cost vs data trade-offs in NLP.

1 Introduction

Transformer based Massively Multilingual Language Models (MMLMs) such as mBERT (Devlin et al., 2019) , XLM-RoBERTa (Conneau et al., 2020) and mT5 (Xue et al., 2021) are surprisingly effective at zero-shot cross-lingual transfer (Pires et al., 2019; Wu and Dredze, 2019). However, while zero-shot transfer is effective, often the performances across different languages is not consistent. Low-resource languages (Wu and Dredze, 2020) and the languages that are typologically distant from the pivot language (Lauscher et al., 2020) are known to benefit the least from zero-shot transfer, which can often be mitigated by using target-language specific labelled data for the task during fine-tuning.

One common approach for collecting such data in the target language is to translate the training data available for the pivot-language to the target by using an off-the-shelf Machine Translation (MT) system. This is usually referred to as the *translate-train* setup (Hu et al., 2020; Turc et al., 2021). Few-shot transfer is another alternative; as shown by Lauscher et al. (2020), a few labelled examples in the target language, that can be obtained cheaply, can lead to substantial improvements over the zero-shot performance.

However, there has not been much work on comparing the performance across these two strategies. In one such study, Hu et al. (2020) compare the performance of *translate-train* with *few-shot* transfer on TyDIQA-GoldP (Clark et al., 2020) dataset, but they only evaluate the few-shot case with 1000 examples, which does not provide any insight into how the performance varies with increasing dataset sizes for these two approaches. Additionally, there are trade-offs related to the data acquisition costs as well. The cost per training instance is expected to be much smaller for an MT-based approach than manual translation or labeling of examples. However, depending on the nature of task, language, and quality of the MT output, the amount of data required to achieve the same performance through these two approaches can be drastically different. More importantly, fine-tuning the MMLMs with a combination of the data from the two strategies could be the cheapest alternative for achieving a target accuracy, which, to the best of our knowledge, has not been explored yet.

Inspired by the above observations and gaps, in this paper, we ask the following question: Given a pre-determined budget to fine-tune a multilingual model on a task for which some data is available in a pivot language, what is the best achievable accuracy on a target language by (a) training the model on the pivot-language data, (b) different amounts of machine-translated and (c) manually-collected data in the target language. Solving this requires an understanding of the exact nature of the performance and cost trade-offs between the two kinds of target language datasets and their relative costs of acquisition, apart from factors such as the amount of pivot language data, the task, the MMLM, and

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1369 - 1384
July 10-15, 2022

the languages concerned.

This problem of modeling and measuring the trade-offs between different input factors and their costs is well-studied in the field of microeconomics. A sophisticated machinery has been developed in the form of *Production Functions* and allied analytical methods (Miller and Blair, 2009; Cobb and Douglas, 1928), in order to solve the following generic problem: with the best available technology, how are the inputs to a production process (eg. *Labor* and *Capital*) related to its output, that is the quantity of goods produced. In this paper, we adapt this framework to address the aforementioned question of MMLM fine-tuning trade-offs.

The key contributions of our work are *threefold*. 1. We extend the idea of production functions to *performance functions* that model the relationship between input data sizes and performance of a system; we propose a possible analytical form for this function and derive the performance trends and optimal data collection strategies under fixed costs. 2. We illustrate the usefulness of this framework through a case study on a Q&A task – TyDIQA–GoldP (Clark et al., 2020) and systematically study the various trade-offs for 8 languages. 3. Our study provides several important insights such as (a) if the cost of MT data creation is non-zero, then the optimal performance under a fixed budget is always achieved with either only manually-created data or a combination of the two; (b) the ratio of the two datasets for the least cost combination usually remains constant at different levels of performance.

To the best of our knowledge, this is the first work that applies the idea of production functions to analyze the cost-performance trade-offs of MMLM fine-tuning. The proposed framework can be extended to a multitude of NLP problems where the trade-offs similar to the ones discussed above, are common (e.g., pre-training vs. fine-tuning data). To encourage reproducible research, we have made our code, the performance data, and a detailed list of the results publicly available [1].

2 Theoretical Foundations

One of the foundational pillars of neoclassical economics is the idea of *Production Functions*. Simply put, a production function is a mathematical formalization of the relationship between the output of a firm (industry, economy) and the inputs that have been used in obtaining it (Khatskevich and Pranevich, 2018; Miller and Blair, 2009). A multifactor production function is defined as a map

$$Q : \mathbf{x} \rightarrow f(\mathbf{x}), \quad \forall \mathbf{x} \in \mathbb{R}^{+n} \tag{1}$$

where $Q \in \mathbb{R}^+$ is the quantity of output, n is the number of the inputs, the non-negative function f is continuously differentiable for all $\mathbf{x} = (x_1, \ldots, x_n)$ when $x_i \in \mathbb{R}^+$. A sophisticated and extensive set of analytical machinery has been developed over the years in microeconomics theory that allows one to closely model and analyze not only the relationship between the inputs and outputs[2] of a firm, but also the interdependence between the inputs (i.e., x_is). Thus, one can efficiently compute and clearly visualize the various trade-offs and optimal configurations of the production system.

Production functions have been extensively used to model and study systems as diverse as education (Bettinger et al., 2020; Bowles, 1970), environment (Lu et al., 2019; Halicioglu and Ketenci, 2018), sustainability (Yankovyi et al., 2021), cognition (Todd and Wolpin, 2003) and of course, different types of industries (Husain et al., 2016; Batiese, 1992). Along similar lines, in this work we develop the concept of *Performance Function* that models the performance of an MMLM given the amount of translated and manually labeled data. In this section, we begin by formalizing the notations and defining some key concepts from microeconomics, appropriately adapted to our context. Then we present the functional form of the performance function, and discuss certain practical constraints and assumptions that we will make in our formulation.

2.1 Notation and Definitions

Consider a multilingual model $\mathcal{M}$ pre-trained on a set of languages $\mathcal{L}$, which is to be fine-tuned for a task $\mathfrak{T}$, for which P labelled examples are available in a pivot language $p \in \mathcal{L}$. Some or all of the P pivot language examples can be automatically translated to a target language $l \in \mathcal{L}$ through an MT system to obtain $T(\leq P)$ examples. Further, let M be the amount of examples for l that have been labelled or translated manually.

Definition 1 Performance Function, $\Pi = \pi(T, M|l, p, P, \mathcal{M}, \mathfrak{T})$, *denotes the* best *possible performance (as per the current state-of-the-art) of*

---

[1] github.com/kabirahuja2431/PerformanceFunctionAnalysis

[2] Production functions can also be defined when there are m outputs i.e. $Q \in \mathbb{R}^m$ and $f : \mathbb{R}^n \rightarrow \mathbb{R}^m$.

a system in language l for a task $\mathfrak{T}$, that has been built on top of a pre-trained MMLM $\mathcal{M}$, P labelled examples in language $p \neq l$, T translated examples by an MT system, and M manually created examples.

Here, $\Pi \in [0, 1]$ is any appropriate and accepted measure of performance, such as accuracy or F1-score. To simplify the notation we will often drop the given conditions from the equation and denote $\Pi = \pi(T, M)$. The conditional factors, whenever not obvious from the context, will be explicitly stated. Note that T and M are respective equivalents of K and L of the neoclassical Capital-Labor production functions. Capital investment in technology or mechanization is similar to *machine*-translated data, whereas manual dataset creation would require investment on labor.

Definition 2 **Total cost of operation** *(or simply the cost), $\kappa(T, M) = \kappa_t(T) + \kappa_m(M)$, is the total cost of procuring translated and manually created datasets for l for the task $\mathfrak{T}$.*

We further assume that the translation and manual collection costs are scalar multiples of the unit costs, i.e. $\kappa_t(T) = c_t T$ and $\kappa_m(M) = c_m M$, where $c_t > 0$ is the cost of translating a single example from P into language l automatically, while $c_m > 0$ is the cost of collecting one training example in l manually. Therefore,

$$C = \kappa(T, M) = c_t T + c_m M \tag{2}$$

Usually, $c_m > c_t$. Also, note that we are ignoring the costs of pivot data collection and computational costs of pre-training and fine-tuning, partly because we are interested in studying the trade-off between T and M. Also, P is useful for any target language, and therefore, the amortized cost of creating P tends to zero as the number of target languages increases. Similarly the amortized cost of pre-training tends to zero as the number of tasks grows. The task-specific training cost is proportional to training data-size, $P + T + M$, and therefore, can be partially consumed in c_t and c_m.

Definition 3 **Isoperf** *curves are the contours of the performance function that represent the relationship between T and M for a fixed performance value Π_c.*

Definition 4 **Isocost** *curves are the contours of the cost function that represent the different possible combinations of T and M that result in equal overall costs.*

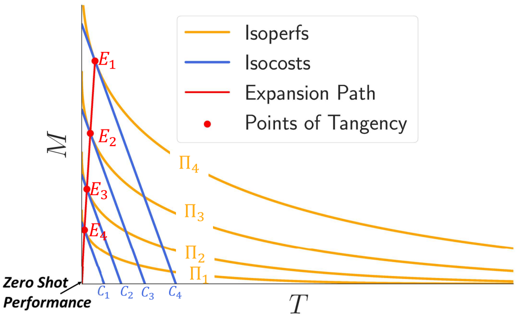

Figure 1: Hypothetical T-M diagram illustrating *isoperfs*, *isocosts*, *points of tangency* and *expansion path*.

Both isoperfs and isocosts are drawn on a T-M diagram (K-L diagram in micro-economics), which is illustrated in Fig. 1. The x and y axis represent the input factors T and M, respectively. The orange curves are the hypothetical isoperfs, known as *isoquants* in economics. As the name suggests, each point on these curves represents T-M combinations that result in the same (*iso*) performance (*perf*), denoted in the diagram by Π_1, Π_2, etc. Intuitively, it can be seen that two isoperfs never intersect; as we move towards right and up, Π increases because either T or M or both increase. Thus, $\Pi_1 < \Pi_2 < \Pi_3 < \Pi_4$. The origin, $T = 0,\ M = 0$, represents an isoperf corresponding to the *zero-shot* performance on l when $\mathcal{M}$ is fine-tuned only on P.

The blue lines represent the isocosts. Considering the nature of the cost function defined, the isocost curves will be straight lines parallel to each other with slope $-\frac{c_t}{c_m}$. Like isoperfs, the cost of operation increases for the isocosts as we move towards right and top in the T-M diagram.

Definition 5 **Least Cost Operating Point** *on an isoperf refers to the (possibly multiple) point where the total cost of operation is lowest for a given performance.*

Under the assumption of smooth and convex isoperfs,[3] the isocost corresponding to the least cost of operation will be a *tangent* to the isoperf, and the optimal allocation of the T and M is given by the *point of tangency*. The isocosts shown in Fig. 1

---

[3] Isoperfs are convex for declining marginal rate of technical substitution.

correspond to the least cost curves for respective isoperfs, and the points of tangency are represented by the points E1, E2, etc.

Definition 6 Expansion path *is a path connecting the point of tangency of different isoperf and isocost curves, tracing out the cost minimizing combination of the data resources with increasing performance and costs.*

Expansion paths are important in determining resource allocations strategies. For instance, when a higher budget is available for dataset expansion in a particular language, should one invest more in translation or in manually collected data? And how does this equation change in the long run, as the system moves towards higher performances?

Thus, isoperfs and isocosts when studied collectively can help determine the allocation of the amount of translation and manual data for a desirable performance value that minimizes the cost of operation.

2.2 Selecting a Functional Form for π

In production analysis, one of the difficult problems is to decide on the functional form of the production function that can on one hand accurately represent the input-output relationship, and on the other, is amenable to close-formed analysis (Griffin et al., 1987). Clearly, a linear production function would be an inappropriate choice for $\pi(T, M)$, as T and M are not perfect substitutes of each other. A popular choice in such case is the Cobb-Douglas performance function (Cobb and Douglas, 1928), which is of the form $T^{\alpha}M^{\beta}$. However, the two datasets do not have multiplicative, but rather an additive effect. Therefore, we propose the following performance function:

$$\Pi = \pi(T, M) = a_{zs} + a_t T^{\alpha_t} + a_m M^{\alpha_m} \quad (3)$$

where $a_{zs}, a_t, a_m \geq 0$ and $0 \leq \alpha_t, \alpha_m \leq 1$. The positive coefficients of the input factors are motivated by assuming that under a reasonable translation and manual annotation quality, the addition of data from these sources should not hurt the zero-shot performance which is given by a_{zs} (when $T = M = 0$). Bounding the exponents below 1 ensures that the performance is not allowed to increase linearly with increasing data in one of these sources, as we always see diminishing returns with respect to data for any machine learning model.

The commonly used training setups can be obtained as special cases of the above equation. The translate-train setup, can be obtained by setting $T = P$ and $M = 0$ in the equation, giving $\Pi_{TT} = a_{zs} + a_t P^{\alpha_t}$. Similarly, $\Pi_{FS} = a_{zs} + a_m k^{\alpha_m}$ gives the few-shot setup with k examples. We denote this functional form as AMUE (Additive Model with Unequal Elasticities).

The expression for tangency point can be derived by setting $dM/dT|_{\Pi=\Pi_c}$ to the slope of the isocost, $-c_t/c_m$, which gives the following equation for the *expansion path*.

$$M = \left(\frac{c_t a_m \alpha_m}{c_m a_t \alpha_t}\right)^{\frac{1}{1-\alpha_m}} T^{\frac{1-\alpha_t}{1-\alpha_m}} \quad (4)$$

Thus, M/T (also called the labor-to-capital ratio) increases with performance if $\alpha_m > \alpha_t$, remains fixed when $\alpha_m = \alpha_t$, and decreases with performance when $\alpha_m < \alpha_t$. Similarly, the ratio of costs of acquiring manually created data to translated data, Mc_m/Tc_t is proportional to $a_m M^{\alpha_m}/a_t T^{\alpha_t}$, which is the ratio of the contributions of the two datasets to the performance Π.

More often than not, actual production systems are too complex to be modeled accurately with simple functional forms. We expect a similar situation, where AMUE might be well suited for modeling and visualizing the trends. However, to obtain the actual operating cost and expansion path that are practically useful, one would need to model the behavior of the performance function more accurately. To this end, we also experiment with Gaussian Process Regression (GPR) for defining the performance function. As we shall see in the next section, GPR is able to fit the data more effectively, though we shall stick to AMUE as the two show identical trends and the latter also allows us to gain deeper insights and richer visualizations.

2.3 Some Practical Considerations

Definition 7 Cost Ratio, *defined as* $c_{t/m} = \frac{c_t}{c_m}$, *is the relative cheapness of the translation data, when compared to the cost of obtaining a manually created data point.*

We expect the cost ratio to be much smaller than 1. However, both translation and manual annotation costs vary according to the complexity (in case of translation, just the lengths of sentences) of the task at hand. c_m might also vary with the choice of the target language l, while c_t can be assumed to be uniform across the languages supported by the commercial MT systems like Google or Bing. In the experiments for our case study, we calculate the expansion paths for different values of $c_{t/m}$ to systematically study the nature of the trade-offs between the two sources of data.

Realizable region: The forms of the performance function as well as cost function defined above do not place any constraint on the values that the input factors, i.e. T and M, can take, which means that the amount of data can be increased indefinitely in order to improve the performance. However, we are aware that the amount of translated data is upper bounded by the amount of pivot data available, i.e. $T \leq P$. While this constraint can be explicitly worked out into the equations (by replacing T with $\min(T, P)$), we stick to the original forms to preserve the smoothness of AMUE . Instead, we define a realizable region $\mathcal{R} : T \leq P$, and if a tangency point lies outside $\mathcal{R}$ we explicitly search for the minimum cost point on the part of the isoperf curve that lies in the realizable region. Note that, in such cases the isocost curves corresponding to the minimum cost point will no longer be tangents to the corresponding isoperfs, and will usually lie at the boundary between the realizable and non-realizable regions.

3 Case-Study on TyDiQA-GoldP

In order to understand the efficacy of the proposed framework, we conduct a case-study on a popular multilingual Question Answering task (cf. $\mathfrak{T}$) using TyDiQA-GoldP (Clark et al., 2020) dataset and consider mBERT as the MMLM $\mathcal{M}$. In the following subsections, we provide the details of the task and training setup for generating the performance Π for different combination of the input factors, the procedure for estimating the parameters of the performance functions, and the findings.

3.1 Task and Dataset

We consider the Minimum Answer Span Task from the Typologically Diverse Question Answering benchmark or TyDiQA-GoldP for conducting the experiments. The choice of this particular dataset stems from two main properties of the benchmark. First, question-answering tasks are amenable to translation. Secondly, TyDiQA-GoldP is comprised of manually labelled datasets for nine typologically diverse languages. This enables us to study the effect of different amounts of manually-created data M on the performance of the MMLM. The amount of M varies significantly from language to language with 1.6k examples for Korean to 15k examples in Arabic. 3.7k examples are available for English which we shall consider as the pivot language p in all the experiments. We use Azure Translator[4] to obtain the translated data T in eight target languages. The answer span alignment between English and the translated languages are obtained based on the technique described in Hu et al. (2020). We measure the performance Π as the average F1-score between the predicted and actual answer-spans for the test examples.

3.2 Fine-tuning Setup

We fine-tune mBERT on the TyDiQA-GoldP dataset with different values of the input factors, T and M, for each target language, along with the amount of English pivot data, P. Different values of T are chosen by translating 0%, 10%, 40% , 70% or 100% of the English pivot data. Eleven different values in the range $[0, |\mathcal{D}_l|]$ ($\mathcal{D}_l$ is the size of the available training data in l) and seven values between 0 and 3.7k are selected for M and P, respectively. Considering eight different target languages, this results in 3080 different fine-tuning configurations. In each configuration, we use 3 different random seeds and train for 5 epochs with a learning rate of 2e-5 and a batch size of 32. The models are also jointly trained[5]. We use XTREME repository (Hu et al., 2020) and the Hugging Face Transformer Library (Wolf et al., 2020) to conduct all our experiments.

3.3 Parameter Estimation of the Performance Function

Upon estimating the performance values for the various fine-tuning configurations, we formulate the parameter estimation for the performance functions π as a regression task, with T and M as inputs and Π as the output. we use a Non Linear Least Squares algorithm (Levenberg, 1944) to fit the AMUE functional form (cf. Equation (5)), while specifying the bounds on the function parameters. For GPR, we use an RBF Kernel added with a White Kernel to model the noise in the observations, and the kernel parameters are optimized using L-BFGS-B optimization algorithm (Byrd et al., 1995) with 10 restarts. Note that, we fit different

performance functions for each combination of l and P. Additionally, we also conducted several experiments with other functional forms including Cobb-Douglas, linear, log-linear and polynomial functions (> 1 degree) which either showed higher margins of error or over-fitting.

3.4 Results

First, we evaluate how well the two proposed performance functions are able to predict the performance for different fine-tuning configurations. For this, we split the 3080 different training configurations into training (80%) and test (20%) sets. The test root mean squared error (RMSE) and coefficient of determination (r^2) values for AMUE and GPR were found to be 5.84, 0.90 and 2.43, 0.98 respectively. Thus, both the models can fit the data reasonably well, though as expected, GPR provides a better fit. Check Appendix for more details.

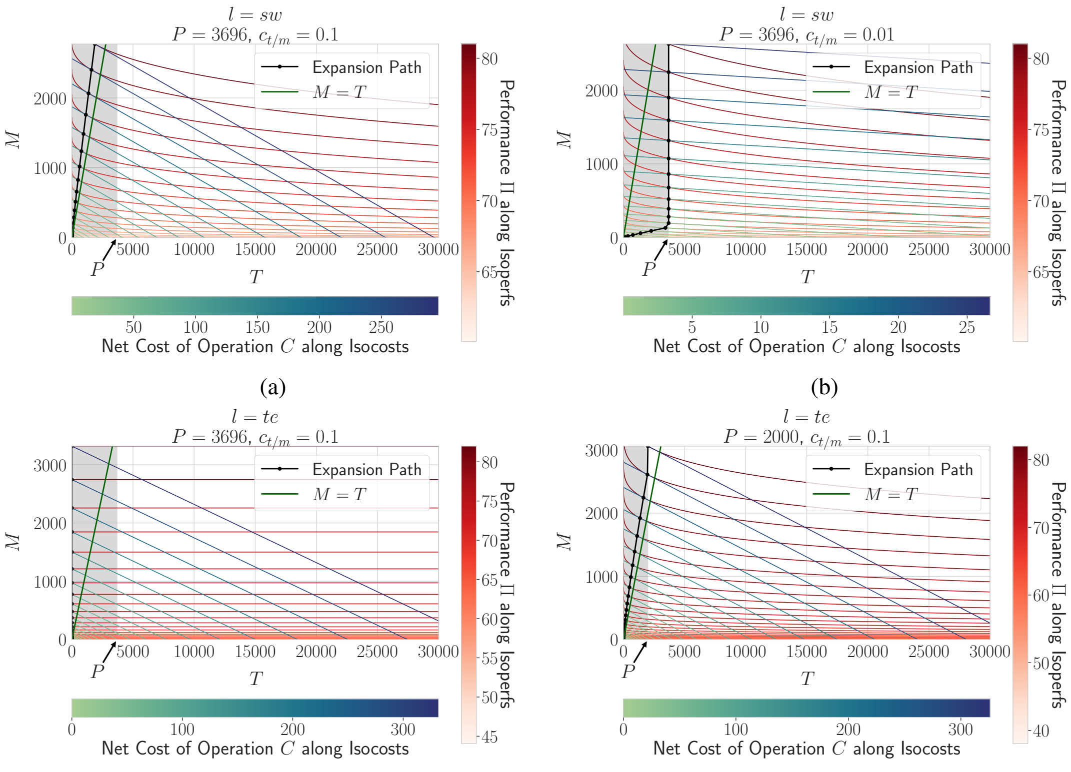
Expansion Paths: Table 1 shows the estimated values of the AMUE parameters for different languages and pivot sizes. For all the languages, a_m is greater than a_t by at least an order of magnitude, meaning that the manually collected data ends up having a significantly higher contribution towards the model's performance. For $P = 2000$, we see comparatively higher values of a_t (though still $< a_m$). This indicates that the machine-translated data might be more beneficial when there is a paucity of training data available in the pivot language, and thus a lower zero-shot performance to begin with.

For $P = 3696$, Arabic, Indonesian and Korean has $\alpha_m > \alpha_t$ and therefore, the corresponding expansion curves (Eqn 4) will have an increasing M/T ratio with increasing Π. On the other hand for Swahili, Telugu and Finnish, $\alpha_m < \alpha_t$, and hence the expansion curves will bend towards the x-axis in the T-M diagram, indicating a declining M/T ratio. In such cases, as we continue to increase the performance at the minimum cost, the optimum strategy would be to collect higher and higher amount of translation data as compared to manually labelled data.

However, notice that the α_m and α_t are close to each other for majority of the cases resulting in nearly linear expansion paths, a situation that is often encountered in economics whenever the production function is *homogenous*. We did not start with a homogenity assumption on $\pi(M, T)$; rather, the estimated parameters indicate so. This has two interesting implications: 1) M/T remains nearly uniform at the different levels of performance; 2) the slope of the expansion path is approximately $(\frac{c_t a_m}{c_m a_t})^{\frac{1}{1-\alpha_m}}$ (by setting $\alpha_m = \alpha_t$ in Eqn 4), meaning if the cost ratio $\frac{c_t}{c_m}$ is greater than $\frac{a_t}{a_m}$, the optimal strategy would be to collect more manually labelled data (since $\frac{1}{1-\alpha_m} > 1$ by definition) and vice-versa. Thus, by just looking at the value of these parameters we can gain key insights about the optimal data allocation strategies.

These strategic insights can also be clearly visualized through the isoperf, isocost and expansion path curves on the T-M diagrams, as shown in Fig. 2. Due to paucity of space, we show the diagrams for two languages – Swahili (sw) and Telugu (te) – with two different cost ratios for the former (Fig. 2a and 2b), and two different pivot sizes for the latter (Fig. 2c and 2d). Refer appendix (6,7, 8, 9) for rest.

For $c_{t/m} = 0.1$, l =sw (Fig. 2a), the expansion path follows a straight line roughly with a slope $(\frac{c_t a_m}{c_m a_t})^{\frac{1}{1-\alpha_m}} = 3.2$. This indicates that even though M is 10 times more expensive than T, the optimal allocation policy is to still collect about thrice as much amount of M as T. However, for $c_{t/m} = 0.01$, which is less than $\frac{a_t}{a_m}$, the slope of the expansion path drops to ≈ 0.08, as demonstrated



(a)

(b)

(c)

(d)

Figure 2: M-T diagrams showing expansion paths obtained through AMUE for Swahili and Telugu for different values of P and $c_{t/m}$. The shaded region represents $\mathcal{R}$ (cf. Sec.2.3).

by the theoretical expansion path on the right side of the $M = T$ line in Fig. 2b. This suggests that we can rely on collecting a higher amount of translation data to increase the performance in this case because the manually collected data is much more expensive. As we move to the performance values > 70, we reach at the boundary of the realizable region (marked by translucent gray rectangle), and can no longer keep on collecting more translation data to increase the performance as by definition $T \leq P$. Beyond this point, to increase the performance, collecting higher amounts of manual data becomes inevitable.

For Telugu, we study the effect of two different values of P and keep $c_{t/m}$ fixed at 0.1. At $P = 3696$, the isoperfs are nearly parallel to x-axis with the expansion path lying along the line $T = 0$ (Fig. 2c), which is expected as $\frac{a_t}{a_m} \approx 0$ in this case (see Table 1). This particular expansion path indicates that data obtained by translating English examples into Telugu does not have any notable performance improvement, though demands additional cost. The optimal strategy in this case is to only collect manually annotated data. This is not entirely surprising; the translate-train setup in Hu et al. (2020) also shows low F1-scores for Telugu than the zero-shot setup.[6] Interestingly, when $P = 2000$ (Fig. 2d), T provides non-trivial performance gains. The expansion curve is bent slightly to the left of the $M = T$ line, similar to Fig. 2a. This trend of higher a_t/a_m for lower P is observable for all languages (Table 1).

Performance and Cost Trade-off: Fig. 3 plots the cost vs the performance value traced out by the expansion paths for the 8 target languages. To calculate the total cost, we assume $c_t = 0.007$, which was estimated according to the standard translator Pricing offered by Azure[7], and consider $c_{t/m} = 0.01$. For all the languages, we observe a declining slope as we increase the value of C. Thus, it becomes increasingly more expensive to improve the performance of the models as we move to the higher values of Π (*law of diminishing returns*).

Comparing AMUE isoperfs with GPR isoperfs:

---

[6] Note that this does not invalidate the assumption we made in section 2.2. Hu et al. (2020) fine-tuned their models only on translated data, while we do train them with English Data as well and observe similar performance as zero-shot for Telugu.

[7] `https://azure.microsoft.com/en-us/pricing/details/cognitive-services/translator/`

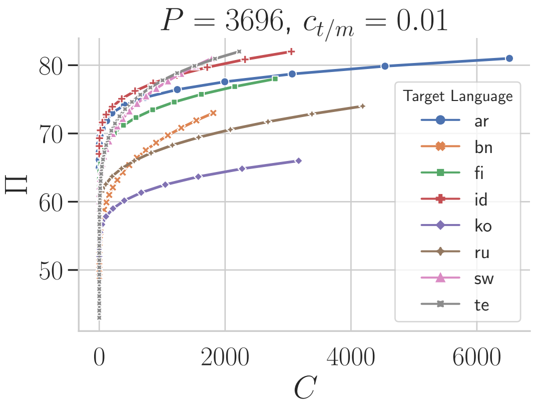


Figure 3: Performance vs the minimum costs for different languages. The performance function considered is AMUE . For $c = 0.1$ case refer to Fig. 10 in appendix.

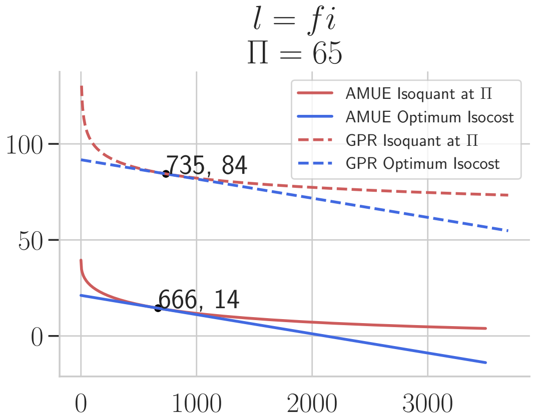

Figure 4: Comparing the Isoperfs and their corresponding optimum isocosts for AMUE and GPR production functions.

Figure 4 displays the isoperfs and the corresponding optimum isocosts obtained using AMUE and GPR based performance functions. As can be observed, both functions predict similar trends across their isoperfs; however, as expected, the curves are shifted due to different margin of errors for the two models.

4 Discussion and Conclusion

In this work, we have proposed a micro-economics inspired framework to study the performance and cost trade-offs between manually annotated and machine-translated data for training multilingual models, and demonstrated its efficacy through a case-study on the TyDiQA-GoldP dataset. The key findings from this case-study are: 1. Some amount of manually collected data in a target language is crucial to attain optimal performance at minimum cost irrespective of how much cheaply MT data can be procured, as long as the cost is non-zero. 2. The ratio of manually collected and machine-translated data at least cost operating point remains nearly uniform at the different levels of performance 3. The usefulness of translated data is higher when the amount of pivot language data is less. There are several other insights that can be drawn from the T-M diagrams and other plots, which could not be presented here due to the paucity of space.

This work can be expanded in several ways. In the current work we considered a single-pivot and single-target case. Generalizing this to the case where the model is allowed to be trained on multiple pivot languages and then be evaluated on multiple targets is of considerable interest. This implies extension to multiple-output production functions with multiple (> 2) input factors.

Here, we have not considered the effect of *multiple technology* on the isoperfs. For our problem, multiple technologies may correspond to the different MMLMs such as mBERT, XLMR and mT5, different MT systems, and even different training curricula. Identifying the optimal allocation policy considering the presence of such multiple technological alternatives would be an interesting exercise. In particular, it will be interesting to explore the impact of translation quality on the trade-offs. An important limitation of the current framework is that it presumes availability of certain amounts of M and T datasets such that the performance function can be estimated. However, in practice, one would like to understand the trade-offs before collecting the data. Recently, Srinivasan et al. (2021) showed that it is possible to predict the zero-shot and few-shot performance of MMLMs for different languages using linguistic properties and their representation in the pre-training corpus. Understanding if there exists a similar dependence of the performance trade-offs with the linguistic properties of different languages can help us generalize our framework to the new languages without the need for explicit data collection.

Finally, we believe that performance function-based analysis can be applied to a multitude of three-way trade-offs among technology, cost and data that are commonly encountered in the NLP world. The economics of language data can be a new direction of study with important practical and theoretical applications.

A Appendix

A.1 Derivations

Here we derive the expression for the curve traced by the expansion path as given in equation 4. As described in section 2.2 AMUE performance function is given by:

$$\pi(T, M) = a_{zs} + a_t T^{\alpha_t} + a_m M^{\alpha_m}$$

Setting $\pi(T, M) = \Pi_c$ i.e. a constant value, we can obtain an analytic expression for the isoperf curves from this functional form, which is given by:

$$M = \left(\frac{\Pi_c - a_{zs} - a_t T^{\alpha_t}}{a_m}\right)^{\frac{1}{\alpha_m}} \tag{5}$$

Since the expansion path is the locus of the points of tangency between isoperf and isocost curves, we can compute the slope of the isoperf curve and set them equal to each other. The slope for isoperf curve can be computed as:

$$\begin{aligned} M^{\alpha_m} &= \left(\frac{\Pi_c - a_{zs} - a_t T^{\alpha_t}}{a_m}\right) \\ \alpha_m M^{\alpha_m - 1}\frac{\mathrm{d}M}{\mathrm{d}T} &= -\frac{\alpha_t a_t}{a_m} T^{\alpha_t - 1} \\ \frac{\mathrm{d}M}{\mathrm{d}T} &= -\frac{\alpha_t a_t}{\alpha_m a_m}\frac{T^{\alpha_t - 1}}{M^{\alpha_m - 1}} \end{aligned}$$

The slope of the isocost curve is simply $-\frac{c_t}{c_m}$, equating them we get:

$$\begin{aligned} \frac{c_t}{c_m} &= \frac{\alpha_t a_t}{\alpha_m a_m}\frac{T^{\alpha_t - 1}}{M^{\alpha_m - 1}} \\ M^{\alpha_m - 1} &= \frac{\alpha_t a_t c_m}{\alpha_m a_m c_t} T^{\alpha_t - 1} \\ M &= \left(\frac{c_t a_m \alpha_m}{c_m a_t \alpha_t}\right)^{\frac{1}{1-\alpha_m}} T^{\frac{1-\alpha_t}{1-\alpha_m}} \end{aligned}$$

A.2 Training Setup

We typically run the fine-tuning experiments on NVIDIA-P100 GPUs with 16 GB of memory. A fine-tuning job with 3 random seeds typically takes 2 hours to run on the specified compute. Having access to 64 of such GPUs we ran multiple jobs in parallel. For fitting performance functions and doing analysis on expansion paths CPU only compute of Intel(R) Xeon(R) CPU E5-2690 was utilized.

We use mBERT configuration bert-base-multilingual-cased for fine-tuning, which supports 104 languages and has around 178 million parameters.

A.3 Goodness of Fit

Table 2 shows the train and test RMSE and r^2 for GPR and AMUE . For training set we also compute the errors corresponding to different fine-tuning setups like translate-train , few-shot etc, which indicates that our models can accurately fit different regions of the performance landscape. The point is again illustrated in Figure5 which compares the predictions of AMUE and GPR with the actual F1-scores for different values of the amount of manual data (i.e. M), keeping T, P, and p as fixed.

		AMUE		GPR	
Data Split	Fine-tune setup	RMSE ↓	r^2 ↑	RMSE ↓	r^2 ↑
Train	Zero-Shot	4.19	0.95	4.43	0.95
	Translate-Train	5.10	0.93	3.68	0.96
	Few-Shot	5.75	0.90	1.63	0.99
	Few-Shot + Translate-train	4.71	0.93	1.53	0.99
	Overall	5.04	0.93	1.86	0.99
Test	Overall	5.84	0.90	2.43	0.98

Abstract

Paraphrase generation is an important language generation task attempting to interpret user intents and systematically generate new phrases of identical meanings to the given ones. However, the effectiveness of paraphrase generation is constrained by the access to the golden labeled data pairs where both the amount and the quality of the training data pairs are restricted. In this paper, we propose a new weakly supervised paraphrase generation approach that extends the success of a recent work that leverages reinforcement learning (RL) for effective model training with data selection. While data selection is privileged for the target task which has noisy data, developing a reinforced selective learning regime faces several unresolved challenges. In this paper, we carry on important discussions about the above problem and present a new model that could partially overcome the discussed issues with a model-based planning feature and a reward normalization feature. We perform extensive evaluation on four weakly supervised paraphrase generation tasks where the results show that our method could significantly improve the state-of-the-art performance on the evaluation datasets.

1 Introduction

Paraphrase generation is an important natural language generation task which aims to generate a target sentence that encapsulates the meaning of a given source sentence while conforming to the style of some desired exemplar. It plays an essential role in many real-world applications for natural language processing, such as semantic parsing (Berant and Liang, 2014; Wu et al., 2021), machine translation (Resnik et al., 2010; Mallinson et al., 2017), recommend system (Falke et al., 2020) and question answering (Fader et al., 2013; Rinaldi et al., 2003; Duboué and Chu-Carroll, 2006). Different from other controllable text generation tasks where golden labelled data pairs are accessible and often being readily available, for paraphrase generation tasks, large scale of parallel paraphrase samples are often extremely hard to collect because generating them would often consume extensive domain knowledge or the generation could hardly be standardized. Therefore, the chance of performing supervised learning in real life scenarios would be considerably limited.

To overcome the data unattainable issue, unsupervised and semi-supervised approaches have achieved growing attention in the recent decade. Generally, the unsupervised approaches adopt sampling-based or editing-based techniques (Bowman et al., 2016; Miao et al., 2019) to remedy golden standard knowledge but they generally result in less coherent or controllable target phrases due to their lose of supervision. Therefore, in our paper, we focus on weakly-supervised paraphrase generation which has demonstrated great effectiveness in many major natural language processing tasks (Dehghani et al., 2017; Sun et al., 2020). Although weakly-supervised approaches have successfully pushed forward the state-of-the-art performance standard for the language-based tasks, when employed for paraphrase generation, they still face the challenge of how to acquire high-quality paired paraphrase data and therefore lead to noisy data pairs which might bring negative effect to the downstream task of training paraphrase generation models.

To overcome the aforementioned challenge and effectively train paraphrase generation models from noisy and not equally informative paraphrase pairs, we adopt a *learning to selectively learn* approach. That is, a meta model is learned to select intuitive paraphrase pairs while eliminating the low quality ones. Thus the paraphrase generation model which is jointly learned with the meta data selector model could achieve better performance through the carefully specified selective learning process. Nonetheless, it is impossible for learning an effec-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1385 - 1395
July 10-15, 2022

tive meta data selection policy to be a supervised learning task due to the missing of optimal target selection policy. To overcome this issue, we adopt a reinforcement learning-based approach to learn effective selection policy without supervised signal. To this end, we extend the success of previous reinforcement learning-based approach for data selection (Ding et al., 2021). However, formulating a Markov decision process (MDP) for the paraphrase learning process is a non-trivial task. In previous works, several important parts of their MDP formulation, such as the design of reward signal, are in need of further investigation (Yoon et al., 2019; Ding et al., 2021) and there also lacks in depth discussion on the challenge of solving the reinforcement learning problem. In this paper, we are motivated to extend this important line of using reinforcement learning to perform selective learning in weakly-supervised paraphrase generation problems and thus overcoming the data unattainable issue. Overall we present several key insights into formulating the MDP for the selective learning problem as well as developing a model-based reinforcement learning framework to effectively solving the MDP.

This paper has three main contributions:

- We present a novel model-based reinforcement learning approach for effectively training paraphrase generation models under weakly supervised regime, where our proposed reinforcement learning approach could effectively overcome some of the major limitations of the existing works for data selection.
- We present an in-depth discussion on the challenges and the potential ways to formulate the selective weakly supervised paraphrase generation tasks with reinforcement learning, which sheds light on the important direction of developing more sophisticated reinforcement learning frameworks for weakly supervised paraphrase generation.
- We present extensive empirical evaluation results on four evaluation datasets where the weakly supervised datasets are generated from supervised or unsupervised manner. The evaluation results show that our proposed method could lead to substantially better performance than all the considered baseline approaches over all the evaluation datasets.

2 Related Work

Paraphrase Generation has long been an important research problem for the natural language processing community. Traditional methods solve this problem by exploiting linguistic knowledge (Wubben et al., 2010; McKeown, 1979) or utilizing statistical machine translation (Quirk et al., 2004; Dolan et al., 2004). As being a sequence generation task, most of recently emerged approaches are framed as instances of the deep neural networks-based sequence-to-sequence (seq2seq) models (Prakash et al., 2016; Chen et al., 2020). Early works are mostly developed under a supervised setting while discarding the noise in the datasets. Two representative examples are the Residual LSTM (Prakash et al., 2016) and BERT (Chen et al., 2020). Later on, researchers start to work on improving the quality of the paraphrases, such as leveraging retrieval augmented (Kazemnejad et al., 2020; Lewis et al., 2020b; Hashimoto et al., 2018) or syntactic structure-based (Iyyer et al., 2018; Chen et al., 2019) approaches to produce better paraphrases. Besides the aforementioned approaches, there are also another lines of methods that attempt to alleviate the labeling cost with attempts like unsupervised learning (Bowman et al., 2016; Fu et al., 2019; Bao et al., 2019; Miao et al., 2019; Wang et al., 2020) as well as simulated annealing (Liu et al., 2020b) and reinforcement learning (Siddique et al., 2020). Compared to the conventional reinforcement learning methods which consider the generators as the policy models, our work models the policy as a meta learner to accomplish a data selection objective. Our work is mostly related to (Ding et al., 2021), but we adopt a very different reinforcement learning approach which is the key for effective selective learning.

Selective Learning refers to the case of selecting items, e.g., features or data points, to learn from among other items. It motivates many important fields in machine learning, such as active learning (Cohn et al., 1996; Settles, 2009; Xu et al., 2013; Fan et al., 2019; Liu et al., 2020a) and robust machine learning (Hendrycks et al., 2018; Reed et al., 2015; Mirzasoleiman et al., 2020). Our work is motivated by the existing instance-wise active data/feature acquisition approaches. One typical example is the conventional linear model that poses sparsity inducing prior distribution to the model (Tibshirani, 1996) and thus actively selects important features to the model. Recently, there also emerged approaches that adopt reinforcement learning to actively find optimal feature subsets (Yoon et al., 2019; Shim et al., 2018; Zannone et al., 2019). Though such attempts have demonstrated certain efficacy in handling instance-wise feature selection, they only deal with non time-series data in non NLP domains, while the focus of our work is to deal with noisy labeled pairs in paraphrase generation tasks. Our work is mostly related to the instance-level active data acquisition approaches (Yoon et al., 2020; Ding et al., 2021), which are mostly adopted under the circumstances of data efficient or cost-sensitive learning or when dealing with noisy data. Yoon et al. (2020) and Ding et al. (2021) are formulation-wise identical while Yoon et al. (2020) is among the very first model for active data selective learning, whereas Ding et al. (2021) applies it on the task of paraphrase generation. Our work extends this important direction to perform selective learning but we formulate a new model-based reinforcement learning method which aims to overcome partial limitations for the existing work and is empirically proven to be more effective than it on all the experimental domains.

3 Reinforced Selective Learning for Paraphrase Generation

We present the general formulation for reinforcement learning-based selective weakly-supervised paraphrase generation problems.

3.1 Weakly-Supervised Paraphrase Generation Problem

Paraphrase generation is a sequence-to-sequence natural language generation problem. Formally, given a set of N source sentences $\mathcal{X} = \{\mathbf{x}_i\}_{i=1}^{N}$, where each sentence X_i is a set of discrete tokens, i.e., $\mathbf{x}_i = \{o_j\}_{j=1}^{T}$, paraphrase generation aims to obtain a non-parallel output sentences $\mathcal{Y} = \{\mathbf{y}_i\}_{i=1}^{N}$, where each y_i encapsulates identical meaning to x_i but comes in the form following some desired exemplars. When training paraphrase generation model, obtaining golden labeled target $\mathcal{Y}$ is a critical challenge. Therefore, we consider a weakly-supervised paraphrase generation regime, forming a set of pseudo labeled pairs termed as $\mathcal{D}_{pseudo} = \{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^{N}$. When training models under the weakly-supervised regime, our work adopts a commonly taken assumption in weakly-supervised learning works. That is, the model has access only to a small set of high-quality parallel sentences $\mathcal{D}_{dev} = \{\mathbf{x}_i, \mathbf{y}_i\}_{i=1}^{L}$ $(L << M)$ which could be considered as golden labeled pairs.

To generate high-quality target for the pseudo labeled pairs, retrieval-based expansion approach is adopted to generate paraphrase $\{\mathbf{y}_i\}_{i=1}^{N}$ which has recently demonstrated great effectiveness in text generation tasks (Kazemnejad et al., 2020; Lewis et al., 2020b). Specifically, for each source sentence $\mathbf{x}_i$, BM25 (Robertson and Zaragoza, 2009) is first adopted as an effective retriever. Then we use Elastic Search (Gormley and Tong, 2015) to create search indexes for fast searching similar sentences to $\mathbf{x}_i$. The benefit of using such a combination is that the method provides flexibility for weak supervision while being training-free. Though there are considerable possibilities for adopting alternative approaches such as training-based methods for generating paraphrases, we demonstrate that our adopted method already yields promising performance.

Given the training data $\mathcal{D}_{pseudo}$ and $\mathcal{D}_{dev}$, the paraphrase generation model is optimized by Maximum Likelihood Estimation (MLE), i.e.,

$$\mathcal{L}(\psi) = \sum_{(x,y)\sim\mathcal{D}_{pseudo}} -\log p_{\psi}(y|x). \qquad (1)$$

3.2 Markov Decision Process

Reinforcement learning is an area of machine learning concerned with how to learn sequential/non-sequential decision making policies for the problems formulated as Markov Decision Processes.

Formally, a Markov Decision Process is formulated as a tuple $< S, A, P, R, \gamma >$, where S is a set of *states*, A is a set of *actions*, P is a *transition probability matrix*, R is the reward function applied upon a state-action pair, and γ is a *discount factor*. Among the transition probability matrix, each of its entry determines the probability of transiting from one state to another. In the reinforcement learning environment, actions are executed state by state, forming time sequences. At each time step, the agent observes a *state*, determines an *action* to be issued under the *state*, and receives a *reward* from the environment suggesting the or optimality of the *action* given the *state*. The state is *Markovian*, which means that the decision could be solely determined by the presented *state* and not on its preceding states. The objective of reinforcement learning is to maximize the cumulative rewards received by the agent.

3.3 Reinforced Paraphrase Generation

We now present a detailed discussion on how to technically combine reinforcement learning with paraphrase generation and devise a reinforcement learning-based selective learning paradigm.

Given the training regime with noisy labeled data, evaluating the value of the data would be a fundamental problem. To tackle this problem, we target at utilizing reinforcement learning techniques to learn an adaptive data valuator model $M_\phi(\cdot)$ which could be jointly updated with the paraphrase generator model and intuitively give value evaluation over the pseudo paraphrase pairs. Generally, $M_\phi(\cdot)$ could be considered as a reinforcement learning agent that we train to maximize the reward signal which is quantitatively represented as improvement achieved by the generator throughout the model training period. With this regard, we present how to formulate the Markov Decision Process (MDP) from corresponding state, action and reward for the selective learning of paraphrase generation task in the following section. We also discuss the challenges of MDP formulation in selective learning and potential ways to improve it.

STATE The state refers to what the agent observe for decision making. It is the representation of the informative features for an instance or a group of data instances to be evaluated. Ideally, the information conveyed by a *state* should dynamically change throughout the learning process. With end-to-end RL, the *state* could be represented by low-level raw features, such as image pixels. It is privileged to use high-level representations for *state* which could potentially ease the policy learning. In our case, we adopt a very common representation for the*state* sentences, which is extracted from a pretrained language model. Generally it reflects the static importance of data to the task without detailed modeling on the learning process. However, the importance values for the data inferred by our model are dynamic due to the dynamic updates of model parameters.

ACTION In selective learning, the way we could model *action* is relatively fixed. That is, an *action* needs to tell the *decision* about whether a data point or a group of pints need to be selected or not. In this paper, we model the action as a Bernoulli variable over each data point. There is generally less space to improve the action modeling part in the reinforced paraphrase generation process.

REWARD The reward signal is designated to tell the benefit of selecting a data instance to update the model over its paraphrase generation quality. It is also the most problematic item to model in the MDP. While the data valuator model is jointly trained with the generator model, it is impossible to obtain a golden standard reward signal to tell the importance of data for the dynamic learning environment. Most of the existing selective learning approach model the reward from the improvement of the downstream task performance before and after the model is updated by the data instance placed in a mini batch of samples. However, such performance score-based reward modeling has the following two major limitations: (1) it generates a reward over a group of mini batch samples and thus could not yield precise term over each independent data point; (2) the reward score has a changing distribution whose scale keeps decreasing and eventually converges to 0, which could bring difficulty to the policy learning (upon convergence the performance would no more increase and therefore lead to a mean of 0 over the reward). Most of the existing works consider the performance score-based reward modeling only without compensating its scaling or independence issue. We develop a method with model-based and scaling flavour to partially overcome the aforementioned challenges.

4 MB-RPG: Model-based Reinforced Paraphrase Generation Framework

In this section, we introduce our proposed Model-based Reinforced Paraphrase Generation framework (MB-RPG). The overview of MB-RPG is shown in Figure 1. The essences of MB-RPG can be summarised as two points. One, MB-RPG adopts model-based planning attempting to perform decision making based on multi-step look-ahead. This way, we can address the first limitation, namely, the short-slightness brought by the conventional score-based approach, one-step look-ahead. Two, MB-RPG adopts a reward scaling module to normalize the reward as a fixed distribution to overcome the stochasticity of reward distribution.

4.1 Model-based Planning

We present a sophisticated method where the decision making system is developed to learn the policy based on long term effects, in order to overcome the

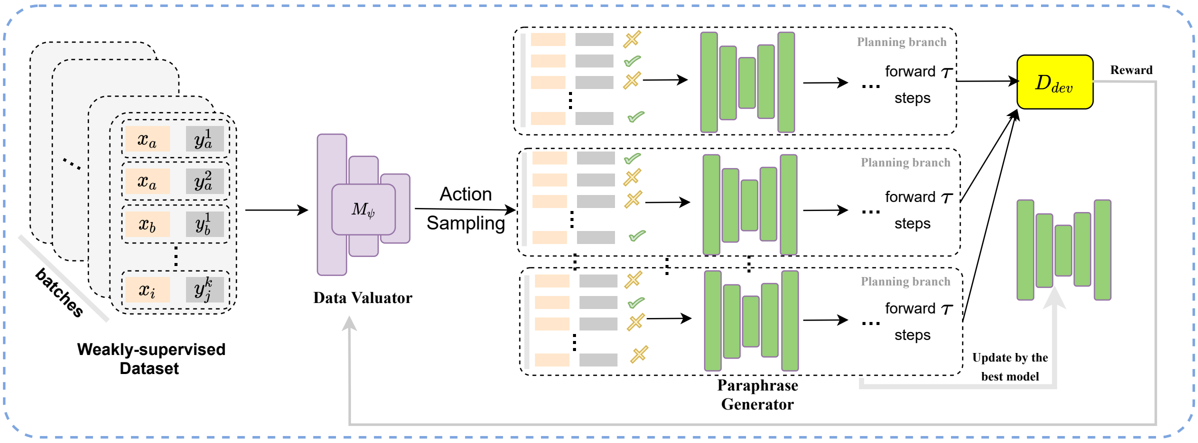

Figure 1: Overview to our proposed Model-Based Reinforced Paraphrase Generation (MB-RPG) framework. Our method takes weakly-supervised dataset obtained from a retrieval-based method as its training data. At each time step, model-based planning is performed which expands the forward direction along multiple action directions and then perform multi-step look ahead. Then the generator is updated by the best model after the τ-step planning.

limitation of the existing works where the reward is inferred from short-term noisy prediction loss-based metrics. In fact, the model-based planning method has been long studied and been proved effective in the reinforcement learning literature (Oh et al., 2015; Wang and Ba, 2020). Unlike model-free reinforcement learning approaches where the agent experiences single-length trajectory, at each time step the episodes expand along one of the action directions instead. Accordingly, the resulting single chain enables our model-based approach to expand future trajectories through multiple action directions and perform the decision making based on the planned roll-outs. Let τ be the planned future steps, i.e., at each time step, the policy network makes decision based on the planned τ-step future states along multiple (e.g., all) action directions. Then the multi-step reward for each action direction can be formulated as follows:

$$\mathcal{R}(s_j, a_j) = \mathbb{E}\Big[\sum_{t=j}^{j+\tau} r(s_t, a_t)\Big], \quad \text{where } s_{t+1} \sim \Psi(s_{t+1}|s_t, a_t), \quad (2)$$

where $\Psi(\cdot)$ is the learned model of the environment (e.g., one-step transition model). In our case, as the environment is only determined by the parameter value for the generator model, we specify one independent generator model at each planning direction. That is, over the N action directions, we will reserve one model to expand each action direction. After planning, the decision of which sample to use is made deterministic by selecting $\operatorname{argmax}_k R(s_j, a_k)$. The aggressive planning scheme enables the decision making to consider prioritizing the actions with better long-term effect. This would typically significantly accelerate the exploration efficiency for the policy training. Such planning would only take effect on the action sampling part, i.e., which samples to be activated to choose would be determined by planning. With this design, the learning part is unaffected and conveniently inherits a model-free nature.

4.2 Reward Scaling

One problem in our prediction-loss based reward modeling is that the reward signal would have a noisy distribution whose mean would gradually decay and eventually converge to 0. In order to resolve it, inspired by many principled reinforcement learning methods such as Actor-critic (Konda and Tsitsiklis, 1999) and PopArt (Hessel et al., 2019), we propose a simple yet effective reward scaling approach to normalize the reward signal to a static distribution. To this end, our normalization method stores the scalar reward signals within a recent window, which would typically consume very minimal amount of memory. Then when we update the policy model, we normalize the reward signal for each transition in the following manner,

$$\hat{R}_j = \frac{R_j - R^{min}}{R^{max} - R^{min}} \quad (3)$$

where R_j and $\hat{R}_j$ are the raw and normalized reward signals, R^{min} and R^{max} are the minimal and maximal values obtained from the window of rewards. With the normalized reward signal, the data

        $g_\theta(y|x)$.
while not done do
    Sample N mini-batches of data $\mathcal{D}_B^{1..N}$
      from $\mathcal{D}_{pseudo}$
    /* Model-based Look-ahead      */
    for $agent \leftarrow 1, N$ do
        $g_\theta^{agent} \leftarrow g_\theta$
        for $step \leftarrow 1, N$ do
            /* Data selection         */
            Compute state representation $s_t$
            Compute selection probabilities
            Sample $a_t$ for each instance
            /* Generator look ahead  */
            Update $g_\theta^{agent}$ with the samples
        end
    end
    Compute reward using validation data
      for each agent model;
    /* Generator greedy update     */
    Update $g_\theta(y|x)$ with the agent with
      maximum reward;
    /* Valuator update (RL)        */
    Update RL selector $p_\theta(s|x)$ with the
      reward.
end
```

selection policy could be optimized by the REINIFORCE algorithm (Sutton et al., 1999). We present the pseudocode for MB-RPG in Algorithm 1.

5 Experiments

In this section, we present extensive empirical evaluation results on comparing our method with its various counterparts on four commonly used paraphrase generation datasets[1].

5.1 Experimental Setting

Evaluation Datasets. For comparison, we consider to adopt both supervised and unsupervised datasets. Note that our method adopts a semi-supervised setting where the target paraphrases are generated following a retrieval-based method introduced in Section 3.1 and thus alleviates the need for golden labeled target data. Overall, we experiment with the following four datasets. The first two datasets for supervised setting and the last two for unsupervised scenario:

- **Quora-s**: corresponds to the Quora Question Pairs (QQP) dataset[2] which consists of 400,000 question pairs and each pair comes with a binary tag telling whether that pair is paraphrase or not. To split the dataset for training and testing, we follow the existing works (Li et al., 2018; Kazemnejad et al., 2020; Ding et al., 2021) and use randomly sampled non-overlapping parallel pairs with sizes 100K, 3K and 30K for training, validation and testing, respectively.

- **Twitter**: is the Twitter News URL Corpus[3] proposed by Lan et al. (2017). The dataset is created by large-scale sentential paraphrases from Twitter by linking tweets through shared URL. Following (Li et al., 2018; Kazemnejad et al., 2020; Ding et al., 2021), we randomly sample 110K instances from automatically labelled data as our training dataset and two non-overlapping datasets of sizes 1K and 5K from the human-annotated data to form the validation set and the testing set, respectively.

- **Quora-U**: is the unsupervised version of Quora-s. To make a fair comparison, we follow the settings of the works (Miao et al., 2019; Liu et al., 2020b) and use two sets of 3K and 20K non-overlapping pairs as the validation set and the testing set, respectively.

- **MSCOCO**: is the COCO image captioning dataset[4]. It consists of over 500K captioning paraphrase pairs for more than 120K images. To create the datasets for training and testing we follow Lin et al. (2014) to split the dataset and adopt an identical evaluation protocol presented in Liu et al. (2020b).

Implementation. We adopt a pretrained transformer encoder-decoder (sequence-to-sequence) WS-BART (Lewis et al., 2020a) as the backbone of the generator in our proposed method MB-RPG.

Table 1: Performance scores for our method MB-RPG as well as all the baseline methods on four paraphrasing datasets under supervised or unsupervised learning setting.

To improve the efficiency of reinforcement learning, we model the reinforced data valuator model M_ψ as a pretrained BERT followed by two fully-connected trainable layers as the head for policy output. BERT serves as a feature extractor and is kept fixed during policy learning. We present other details for our method in appendix.

Baseline Methods. We compare our method with twelve benchmark approaches including the state-of-the-art method. In general, the baselines come from the following three categories: (i) *supervised* methods that are trained with high-quality supervised target paraphrases, i.e., **Transformer** (Vaswani et al., 2017), **RbM** (Li et al., 2018), **Residual LSTM** (Prakash et al., 2016) and two retrieval-based methods **FSET** (Kazemnejad et al., 2020) and **RaE** (Hashimoto et al., 2018); (ii) *unsupervised* methods that do not have access to the parallel data, including Constrained sentence Generation with Metropolis-Hastings (**CGMH**) (Miao et al., 2019) **VAE** (Bowman et al., 2016), Unsupervised Paraphrase generation with Simulated Annealing (**UPSA**) (Liu et al., 2020b) and Progressive Unsupervised Paraphrasing (**PUP**) (Siddique et al., 2020), Dynamic Blocking (**DBlock**) (Niu et al., 2020); (iii) *semi-supervised* methods including *WS-BART* (Lewis et al., 2020a) which corresponds to BART trained upon the weakly-supervised data and Learning To Selectively Learn (**LTSL**) (Ding et al., 2021) which is the most closely related method to ours. **LTSL** also adopts reinforcement learning for selective learning and our approach is a model-based improved version over its vanilla policy gradient formulation. Also note that both **LTSL** and **MB-RPG** adopts BART as the pretrained generator.

5.2 Benchmark Results

We present the benchmark results on all the compared methods on the four evaluation datasets in Table 1. Note that our proposed method is denoted as MB-RPG. Overall, we could conclude that MB-RPG outperforms all its baselines with significant margins in terms of BLEU scores and ROUGE scores across the four evaluation datasets.

From the results, we could notice that under the *supervised* setting, most methods, such as Transformer and FSET, could significantly outperform most of the results obtained from the *unsupervised* setting (e.g., CGMH and VAE). Compared with the *supervised* methods, even though our method does not touch the supervised labels, it could still outperform the *supervised* methods by noticeable margins. This further indicates that our method is promising to be adopted in many real life applications where there is rather limited access to the golden labelled paraphrase pairs.

Compared to the *unsupervised* approaches, MB-RPG is also superior especially in terms of the iBLEU and BLEU metrics. The main reason might be that the word editing or sampling attempts proposed in the *unsupervised* baselines yield less desirable target paraphrases and thus makes the performance of the model trained under the *unsupervised*

Method	Quora-S			
	BLEU-2	BLEU-4	ROUGE-1	ROUGE-2
WS-BART	44.19	31.18	58.69	33.39
w/o planning	50.67	38.29	64.12	41.28
w/o rew norm	51.26	42.32	66.25	40.23
LTSL	49.18	36.05	63.06	39.71
MB-RPG	**54.88**	**41.56**	**67.66**	**43.98**

Table 2: Ablation study results for the planning and reward normalization components on **Quora-s**.

data fall far below our method and various *supervised* baselines. The inferior performance of the *unsupervised* methods has also been empirically evaluated and discussed by Niu et al. (2020).

From Table 1, we could notice that the performance of MB-RPG is much better than its closest counterpart LTSL, while LTSL is also a reinforcement learning-based selective learning method. In both supervised and unsupervised scenarios, MB-RPG could outperform LTSL consistently by a noticeable margins. The average improvements on BLEU-2 and BLEU-4 scores are 4.02 and 3.57 respectively. On each BLEU or ROUGE metrics, MB-RPG achieves better scores than LTSL. This shows that our proposed method MB-RPG achieves state-of-the-art method on various paraphrase generation benchmark datasets. It also shows that using model-based planning and refining the noisy reward could bring considerable benefit to the data valuation process. Such result sheds lights to the research of refining the formulation for the Markov Decision Process and coming up with more adequate reinforcement learning frameworks to facilitate better data valuation. The results reveals that the performance of the vanilla WS-BART is inferior than LTSL or MB-RPG, both of which adopt WS-BART as their generators' backbone.

5.3 Ablation Study

To thoroughly evaluate the effect of the individual components we proposed upon the vanilla policy gradient method, we present an ablation study to evaluate the individual effect of such components. Specifically, we consider three ablated baselines: 1) *w/o planning*: our model without the model-based planning module; 2) *w/o rew norm*: our model without the reward normalization module; 3) LTSL: without both planning and reward normalization modules. We present the results in Table 2. From the results, we notice that the baseline *w/o rew planning* achieves similar results with LTSL which is not comparable to our proposed method. It verifies the importance of leveraging the model-based planning to reduce the noise among the short-term one-step reward signals. From the results shown in Table 2, we also notice that the baseline *w/o rew norm* achieves better results than LTSL, but not as good as the full version of our method. This shows that reward normalization is an essential step to train the Markov Decision Process formulated for selective paraphrase generation. The aforementioned results also reveal that the model-based planning module and the reward normalization module are two modules with relatively parallel effects of each other without much conflicting situations. Lastly, we wish to highlight that the WS-BART without reinforcement learning-based selective learning essentially performs very outstanding by itself. However, leveraging reinforcement learning-based selective learning could result in significant boost to the performance of WS-BART. This shows that reinforced selective learning is a promising direction to consider for improving the SOTA performance in paraphrase generation or other generation tasks.

6 Conclusion

Our work tackles an important problem of leveraging reinforcement learning-based selective learning techniques to effectively deal with the noisy label issue in paraphrase generation tasks. We introduce a model-based framework which performs planning to capture the long-term effects for efficient exploration so as to overcome the noisy short-term reward issue experienced by most of the existing approaches. We also propose an effective reward normalization approach which could normalize the noisy reward signal to a distribution with a fixed zero-mean. We demonstrate that our proposed method could outperform baseline approaches with significant margins on the testified domains. Future work includes refining the *state* and *reward* terms in the Markov Decision Process for better data valuation or feature selections. One ongoing work is to integrate MB-RPG into our previous feature exploration work in video recommendation (Li et al., 2020) to improve feature quality. Another one is to employ MB-RPG in our RL-based coreference resolution to filter out irrelevant features (Fei et al., 2019). In addition, we could consider constructing the policy model upon alternative generator backbone. Also, we could consider inferring the *reward* from different sources, such as incorporating auxiliary language models in the training.

Abstract

Despite the progress in machine translation quality estimation and evaluation in the last years, decoding in neural machine translation (NMT) is mostly oblivious to this and centers around finding the most probable translation according to the model (MAP decoding), approximated with beam search. In this paper, we bring together these two lines of research and propose *quality-aware decoding* for NMT, by leveraging recent breakthroughs in reference-free and reference-based MT evaluation through various inference methods like N-best reranking and minimum Bayes risk decoding. We perform an extensive comparison of various possible candidate generation and ranking methods across four datasets and two model classes and find that quality-aware decoding consistently outperforms MAP-based decoding according both to state-of-the-art automatic metrics (COMET and BLEURT) and to human assessments. Our code is available at `https://github.com/deep-spin/qaware-decode`.

1 Introduction

The most common procedure in neural machine translation (NMT) is to train models using maximum likelihood estimation (MLE) at training time, and to decode with beam search at test time, as a way to approximate maximum-a-posteriori (MAP) decoding. However, several works have questioned the utility of model likelihood as a good proxy for translation quality (Koehn and Knowles, 2017; Ott et al., 2018; Stahlberg and Byrne, 2019; Eikema and Aziz, 2020). In parallel, significant progress has been made in methods for quality estimation and evaluation of generated translations (Specia et al., 2020; Mathur et al., 2020b), but this progress is, by and large, not yet reflected in either training or decoding methods. Exceptions such as minimum risk training (Shen et al., 2016; Edunov et al., 2018) come at a cost of more expensive and unstable training, often with modest quality improvements.

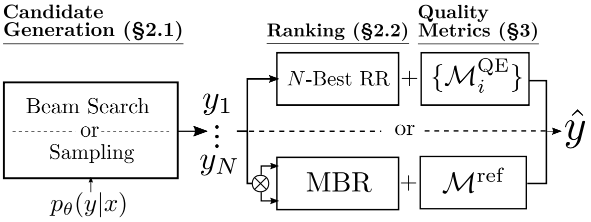

Figure 1: Quality-aware decoding framework. First, translation candidates are *generated* according to the model. Then, using reference-free and/or reference-based MT metrics, these candidates are *ranked*, and the highest ranked one is picked as the final translation.

An appealing alternative is to modify the decoding procedure only, separating it into two stages: *candidate generation* (§2.1; where candidates are generated with beam search or sampled from the whole distribution) and *ranking* (§2.2; where they are scored using a quality metric of interest, and the translation with the highest score is picked). This strategy has been explored in approaches using N-best reranking (Ng et al., 2019; Bhattacharyya et al., 2021) and minimum Bayes risk (MBR) decoding (Shu and Nakayama, 2017; Eikema and Aziz, 2021; Müller and Sennrich, 2021). While this previous work has exhibited promising results, it has mostly focused on optimizing lexical metrics such as BLEU or METEOR (Papineni et al., 2002; Lavie and Denkowski, 2009), which have limited correlation with human judgments (Mathur et al., 2020a; Freitag et al., 2021a). Moreover, a rigorous apples-to-apples comparison among this suite of techniques and their variants is still missing, even though they share similar building blocks.

Our work fills these gaps by asking the question:

> "*Can we leverage recent advances in MT quality evaluation to generate better translations? If so, how can we most effectively do so?*"

To answer this question, we systematically explore

---

* Equal contribution.

July 10-15, 2022

NMT decoding using a suite of ranking procedures. We take advantage of recent state-of-the-art learnable metrics, both reference-based, such as COMET and BLEURT (Rei et al., 2020a; Sellam et al., 2020), and reference-free (also known as *quality estimation*; QE), such as TransQuest and OpenKiwi (Ranasinghe et al., 2020; Kepler et al., 2019). We compare different ranking strategies under a unified framework, which we name **quality-aware decoding** (§3). First, we analyze the performance of decoding using N-best reranking, both *fixed* according to a single metric and *learned* using multiple metrics, where the coefficients for each metric are optimized according to a reference-based metric. Second, we explore ranking using reference-based metrics directly through MBR decoding. Finally, to circumvent the expensive computational cost of the latter when the number of candidates is large, we develop a two-stage ranking procedure, where we use N-best reranking to pick a subset of the candidates to be ranked through MBR decoding. We explore the interaction of these different ranking methods with various candidate generation procedures including beam search, vanilla sampling, and nucleus sampling.

Experiments with two model sizes and four datasets (§4) reveal that while MAP-based decoding appears competitive when evaluating with lexical-based metrics (BLEU and ChrF), the story is very different with state-of-the-art evaluation metrics, where quality-aware decoding shows significant gains, both with N-best reranking and MBR decoding. We perform a human-study to more faithfully evaluate our systems and find that, while performance on learnable metrics is not always predictive of the best system, quality-aware decoding usually results in translations with higher quality than MAP-based decoding.

2 Candidate Generation and Ranking

We start by reviewing some of the most commonly used methods for both candidate generation and ranking under a common lens.

2.1 Candidate Generation

An NMT model defines a probability distribution $p_\theta(y|x)$ over a set of hypotheses $\mathcal{Y}$, conditioned on a source sentence x, where θ are learned parameters. A translation is typically predicted using MAP decoding, formalized as

$$\hat{y}_{\mathrm{MAP}} = \arg\max_{y \in \mathcal{Y}} \; \log p_\theta(y|x). \tag{1}$$

In words, MAP decoding searches for the most probable translation under $p_\theta(y|x)$, *i.e.*, the mode of the model distribution. Finding the exact $\hat{y}_{\mathrm{MAP}}$ is intractable since the search space $\mathcal{Y}$ is combinatorially large, thus, approximations like **beam search** (Graves, 2012; Sutskever et al., 2014) are used. However, it has been shown that the translation quality *degrades* for large values of the beam size (Koehn and Knowles, 2017; Yang et al., 2018; Murray and Chiang, 2018; Meister et al., 2020), with the empty string often being the true MAP hypothesis (Stahlberg and Byrne, 2019).

A stochastic alternative to beam search is to *draw samples* directly from $p_\theta(y|x)$ with ancestral sampling, optionally with variants that truncate this distribution, such as top-k sampling (Fan et al., 2018) or p-**nucleus sampling** (Holtzman et al., 2020) – the latter samples from the smallest set of words whose cumulative probability is larger than a predefined value p. Deterministic methods combining beam and nucleus search have also been proposed (Shaham and Levy, 2021).

Unlike beam search, sampling is not a search algorithm nor a decision rule – it is not expected for a single sample to outperform MAP decoding (Eikema and Aziz, 2020). However, samples from the model can still be useful for alternative decoding methods, as we shall see. While beam search focus on high probability candidates, typically similar to each other, sampling allows for more *exploration*, leading to higher candidate *diversity*.

2.2 Ranking

We assume access to a set $\bar{\mathcal{Y}} \subseteq \mathcal{Y}$ containing N candidate translations for a source sentence, obtained with one of the generation procedures described in §2.1. As long as N is relatively small, it is possible to (re-)rank these candidates in a post-hoc manner, such that the best translation maximizes a given metric of interest. We highlight two different lines of work for ranking in MT decoding: first, N**-best reranking**, using reference-free metrics as features; second, **MBR decoding**, using reference-based metrics.

2.2.1 N-best Reranking

In its simplest form (which we call *fixed* reranking), a *single* feature f is used (*e.g.*, an estimated quality score), and the candidate that maximizes this score is picked as the final translation,

$$\hat{y}_{\text{F-RR}} = \underset{y \in \bar{\mathcal{Y}}}{\arg\max} \;\; f(y). \tag{2}$$

When *multiple* features $[f_1, \ldots, f_K]$ are available, one can tune weights $[w_1, \ldots, w_K]$ for these features to maximize a given reference-based evaluation metric on a validation set (Och, 2003; Duh and Kirchhoff, 2008) – we call this *tuned* reranking. In this case, the final translation is

$$\hat{y}_{\text{T-RR}} = \underset{y \in \bar{\mathcal{Y}}}{\arg\max} \;\; \textstyle\sum_{k=1}^{K} w_k f_k(y). \tag{3}$$

2.2.2 Minimum Bayes Risk (MBR) Decoding

While the techniques above rely on *reference-free* metrics for the computation of features, MBR decoding uses *reference-based* metrics to rank candidates. Unlike MAP decoding, which searches for the most probable translation, MBR decoding aims to find the translation that maximizes the expected *utility* (equivalently, that minimizes *risk*, Kumar and Byrne 2002, 2004; Eikema and Aziz 2020). Let again $\bar{\mathcal{Y}} \subseteq \mathcal{Y}$ be a set containing N hypotheses and $u(y^*, y)$ a utility function measuring the similarity between a hypothesis $y \in \mathcal{Y}$ and a reference $y^* \in \bar{\mathcal{Y}}$ (*e.g*, an automatic evaluation metric such as BLEU or COMET). MBR decoding seeks for

$$\hat{y}_{\text{MBR}} = \underset{y \in \bar{\mathcal{Y}}}{\arg\max} \;\; \underbrace{\mathbb{E}_{Y \sim p_\theta(y|x)}[u(Y, y)]}_{\approx \; \frac{1}{M} \sum_{j=1}^{M} u(y^{(j)}, y)}, \tag{4}$$

where in Eq. 4 the expectation is approximated as a Monte Carlo (MC) sum using model samples $y^{(1)}, \ldots, y^{(M)} \sim p_\theta(y|x)$.[1] In practice, the translation with the highest expected utility can be computed by comparing each hypothesis $y \in \bar{\mathcal{Y}}$ to all the other hypotheses in the set.

3 Quality-Aware Decoding

While recent works have explored various combinations of candidate generation and ranking procedures for NMT (Lee et al., 2021; Bhattacharyya et al., 2021; Eikema and Aziz, 2021; Müller and Sennrich, 2021), they suffer from two limitations:

- The ranking procedure is usually based on simple lexical-based metrics (BLEU, chrF, METEOR). Although these metrics are well established and inexpensive to compute, they correlate poorly with human judgments at segment level (Mathur et al., 2020b; Freitag et al., 2021c).
- Each work independently explores N-best reranking or MBR decoding, making unclear which method produces better translations.

In this work, we hypothesize that using more powerful metrics in the ranking procedure may lead to better quality translations. We propose a unified framework for ranking with both reference-based (§3.1) and reference-free metrics (§3.2), independently of the candidate generation procedure. We explore four methods with different computational costs for a given number of candidates, N.

Fixed N-best Reranker. An N-best reranker using a single reference-free metric (§3.2) as a feature, according to Eq. 2. The computational cost of this ranker is $\mathcal{O}(N \times C_{\mathcal{M}^{\text{QE}}})$, where $C_{\mathcal{M}^{\text{QE}}}$ denotes the cost of running an evaluation with a metric $\mathcal{M}^{\text{QE}}$.

Tuned N-best Reranker. An N-best reranker using as features *all* the reference-free metrics in §3.2, along with the model log-likelihood $\log p_\theta(y|x)$. The weights in Eq. 3 are optimized to maximize a given reference-based metric $\mathcal{M}^{\text{ref}}$ using MERT (Och, 2003), a coordinate-ascent optimization algorithm widely used in previous work. Note that $\mathcal{M}^{\text{ref}}$ is used for tuning only; at test time, only reference-free metrics are used. Therefore, the decoding cost is $\mathcal{O}(N \times \sum_i C_{\mathcal{M}_i^{\text{QE}}})$.

MBR Decoding. Choosing as the utility function a reference-based metric $\mathcal{M}^{\text{ref}}$ (§3.1), we estimate the utility using a simple Monte Carlo sum, as shown in Eq. 4. The estimation requires computing pairwise comparisons and thus the cost of running MBR decoding is $\mathcal{O}(N^2 \times C_{\mathcal{M}^{\text{ref}}})$.

N-best Reranker → MBR. Using a large number of samples in MBR decoding is expensive due to its quadratic cost. To circumvent this issue, we explore a *two-stage* ranking approach: we first rank all the candidates using a tuned N-best reranker, followed by MBR decoding using the top M candidates. The computational cost becomes $\mathcal{O}(N \times \sum_i C_{\mathcal{M}_i} + M^2 \times C_{\mathcal{M}^{\text{ref}}})$. The first ranking stage *prunes* the candidate list to a smaller, higher quality subset, making possible a more accurate estimation of the utility with less samples, and potentially allowing a better ranker than *plain* MBR for almost the same computational budget.

---

[1] We also consider the case where $y^{(1)}, \ldots, y^{(M)}$ are obtained from nucleus sampling or beam search. Although the original MC estimate is unbiased, these ones are biased.

3.1 Reference-based Metrics

Reference-based metrics are the standard way to evaluate MT systems; the most used ones rely on the lexical overlap between hypotheses and reference translations (Papineni et al., 2002; Lavie and Denkowski, 2009; Popović, 2015). However, lexical-based approaches have important limitations: they have difficulties recognizing correct translations that are paraphrases of the reference(s); they ignore the source sentence, an important indicator of meaning for the translation; and they do not always correlate well with human judgments, particularly at segment-level (Freitag et al., 2021c).

In this work, apart from BLEU (computed using SacreBLEU[2] (Post, 2018)) and chrF, we use the following state-of-the-art trainable reference-based metrics for both ranking and performance evaluation of MT systems:

- BLEURT (Sellam et al., 2020; Pu et al., 2021), trained to regress on human direct assessments (DA; Graham et al. 2013). We use the largest multilingual version, *BLEURT-20*, based on the RemBERT model (Chung et al., 2021).
- COMET (Rei et al., 2020a), based on XLM-R (Conneau et al., 2020), trained to regress on quality assessments such as DA using both the reference and the source to assess the quality of a given translation. We use the publicly available model developed for the WMT20 metrics shared task (*wmt20-comet-da*).

These metrics have shown much better correlation at segment-level than previous lexical metrics in WMT metrics shared tasks (Mathur et al., 2020b; Freitag et al., 2021c). Hence, as discussed in §2.2, they are good candidates to be used either *indirectly* as an optimization objective for learning the tuned reranker's feature weights, or *directly* as a utility function in MBR decoding. In the former, the higher the metric correlation with human judgment, the better the translation picked by the tuned reranker. In the latter, we approximate the expected utility in Eq. 4 by letting a candidate generated by the model be a reference translation – a suitable premise *if* the model is good in expectation.

3.2 Reference-free Metrics

MT evaluation metrics have also been developed for the case where references are not available – they are called *reference-free* or *quality estimation* (QE) metrics. In the last years, considerable improvements have been made to such metrics, with state-of-the-art models having increasing correlations with human annotators (Freitag et al., 2021c; Specia et al., 2021). These improvements enable the use of such models for ranking translation hypotheses in a more reliable way than before.

In this work, we explore four recently proposed reference-free metrics as features for N-best reranking, all at the sentence-level:

- COMET-QE (Rei et al., 2020b), a reference-free version of COMET (§3.1). It was the winning submission for the QE-as-a-metric subtask of the WMT20 shared task (Mathur et al., 2020b).
- TransQuest (Ranasinghe et al., 2020), the winning submission for the sentence-level DA prediction subtask of the WMT20 QE shared task (Specia et al., 2020). Similarly to COMET-QE this metric predicts a DA score.
- MBART-QE (Zerva et al., 2021), based on the mBART (Liu et al., 2020) model, trained to predict both the *mean* and the *variance* of DA scores. It was a top performer in the WMT21 QE shared task (Specia et al., 2021).
- OpenKiwi-MQM (Kepler et al., 2019; Rei et al., 2021), based on XLM-R, trained to predict the *multidimensional quality metric* (MQM; Lommel et al. 2014).[3] This reference-free metric was ranked second on the QE-as-a-metric subtask from the WMT 2021 metrics shared task.

4 Experiments

4.1 Setup

We study the benefits of quality-aware decoding over MAP-based decoding in two regimes:

- A high-resource, unconstrained, setting with *large* transformer models (6 layers, 16 attention heads, 1024 embedding dimensions, and 8192 hidden dimensions) trained by Ng et al. (2019) for the WMT19 news translation task (Barrault et al., 2019), using English to German (EN → DE) and English to Russian (EN → RU) language pairs. These models were trained on

---

[2] `nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.0.0`

[3] MQM annotations are expert-level type of annotations more fine-grained then DA, with individual errors annotated.

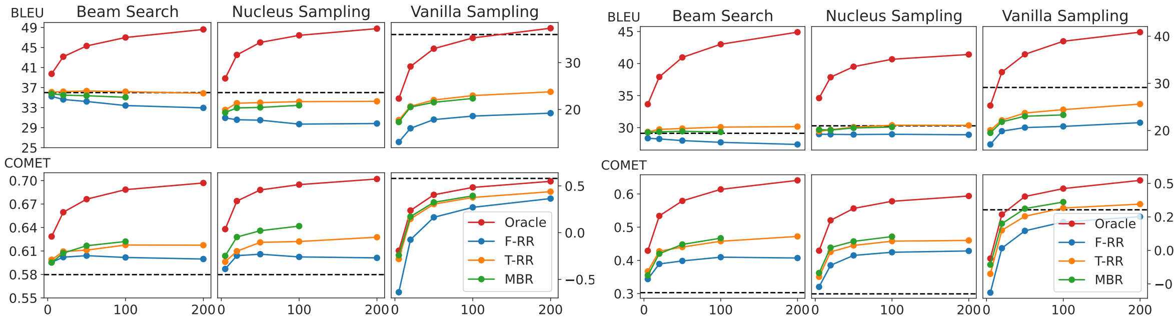

Figure 2: Values for BLEU (top) and COMET (bottom) for EN → DE as we increase the number of candidates for different generation and ranking procedures, as well as oracles with the respective metrics, for the *large* (left) and *small* (right) models. Baseline values (with beam size of 5) are marked with a dashed horizontal line.

over 20 million parallel and 100 million back-translated sentences, being the winning submissions of that year's shared task. We consider the non-ensembled version of the model and use *newstest19* for validation and *newstest20* for testing.

- A more constrained scenario with a *small* transformer model (6 layers, 4 attention heads, 512 embedding dimensions, and 1024 hidden dimensions) trained from scratch in *Fairseq* (Ott et al., 2019) on the smaller IWSLT17 datasets (Cettolo et al., 2012) for English to German (EN → DE) and English to French (EN → FR), each with a little over 200k training examples. We chose these datasets because they have been extensively used in previous work (Bhattacharyya et al., 2021) and smaller model allows us to answer questions about how the training methodology affects ranking performance (see § 4.2.2). Further training details can be found in Appendix A.

We use beam search with a beam size of 5 as our decoding baseline because we found that it resulted in better or similar translations than larger beam sizes. For tuned N-best reranking, we use Travatar's (Neubig, 2013) implementation of MERT (Och, 2003) to optimize the weight of each feature, as described in §3.2. Finally, we evaluate each system using the metrics discussed in §3.1, along with BLEU and chrF (Popović, 2015).

4.2 Results

Overall, given all the metrics, candidate generation, and ranking procedures, we evaluate over 150 systems per dataset. We report subsets of this data separately to answer specific research questions, and defer to Appendix B for additional results.

4.2.1 Impact of Candidate Generation

First, we explore the impact of the candidate generation procedure and the number of candidates.

Which candidate generation method works best, beam search or sampling? We generate candidates with beam search, vanilla sampling, and nucleus sampling. For the latter, we use $p = 0.6$ based on early results showing improved performance for all metrics.[4] For N-best reranking, we use up to 200 samples; for MBR decoding, due to the quadratic computational cost, we use up to 100.

Figure 2 shows BLEU and COMET for different candidate generation and ranking methods for the EN → DE WMT20 and IWSLT17 datasets, with increasing number of candidates. The baseline is represented by the dashed line. To assess the performance *ceiling* of the rankers, we also report results with an *oracle* ranker for the reported metrics, picking the candidate that maximizes it. For the *fixed* N-best reranker, we use COMET-QE as a metric, albeit the results for other reference-free metrics are similar. Performance seems to scale well with the number of candidates, particularly for vanilla sampling and for the *tuned* N-best reranker and MBR decoder. (Lee et al., 2021; Müller and Sennrich, 2021). However, all the rankers using vanilla sampling severely under-perform the baseline in most cases (see also §4.2.2). In contrast, the rankers using beam search or nucleus sampling are competitive or outperform the baseline in terms of BLEU, and greatly outperform it in terms of COMET. For the larger models, we see that the performance according to the lexical metrics degrades with more candidates. In this scenario, rankers us-

---

[4] We picked nucleus sampling over top-k sampling because it allows varying support size and has outperformed top-k in text generation tasks (Holtzman et al., 2020).

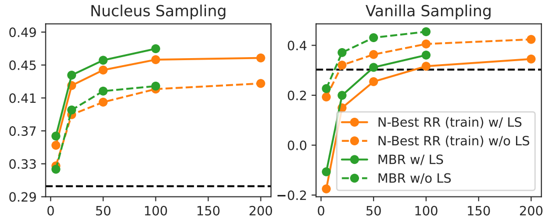

Figure 3: COMET scores for EN → DE (IWSLT17) for models trained with and without label smoothing.

ing nucleus sampling seem to have an edge over the ones that use beam search for COMET.

Based on the findings above, and due to generally better performance of COMET over BLEU for MT evaluation (Kocmi et al., 2021), in following experiments we use nucleus sampling with the *large* model and beam search with the *small* model.

4.2.2 Impact of Label Smoothing

How does label smoothing affect candidate generation? Label smoothing (Szegedy et al., 2016) is a regularization technique that redistributes probability mass from the gold label to the other target labels, typically preventing the model from becoming overconfident (Müller et al., 2019). However, it has been found that label smoothing negatively impacts model fit, compromising the performance of MBR decoding (Eikema and Aziz, 2020, 2021). Thus, we train a small transformer model without label smoothing to verify its impact in the performance of N-best reranking and MBR decoding. Figure 3 shows that disabling label smoothing really helps when generating candidates using vanilla sampling. However, the performance *degrades* for candidates generated using nucleus sampling when we disable label smoothing, hinting that the pruning mechanism of nucleus sampling may help mitigate the negative impact of label smoothing in sampling based approaches. Even without label smoothing, vanilla sampling is not competitive with nucleus sampling or beam search with label smoothing, thus, we do not experiment further with it.

4.2.3 Impact of Ranking and Metrics

We now investigate the usefulness of the metrics presented in §3 as features and objectives for ranking. For N-best reranking, we use all the available candidates (200) while, for MBR, due to the computational cost of using 100 candidates, we report results with 50 candidates only (we found that ranking with *tuned* N-best reranking with $N = 100$ and MBR with $N = 50$ takes about the same time). We report results in Table 1, and use them to answer some specific research questions.

Which QE metric works best in a fixed N-best reranker? We consider a *fixed* N-best reranker with a single reference-free metric as a feature (see Table 1, second group). While none of the metrics allows for improving the baseline results in terms of the lexical metrics (BLEU and chrF), rerankers using COMET-QE or MBART-QE outperform the baseline according to BLEURT and COMET, for both the *large* and *small* models. Due to the aforementioned better performance of these metrics for translation quality evaluation, we hypothesize that these rankers produce better translations than the baseline. However, since the sharp drop in the lexical metrics is concerning, we will verify this hypothesis in a human study, in §4.2.4.

How does the performance of a tuned N-best reranker vary when we change the optimization objective? We consider a *tuned* N-best reranker using as features *all* the reference-free metrics in §3.2, and optimized using MERT. Table 1 (3rd group) shows results for EN → DE. For the *small* model, all the rankers show improved results over the baseline for all the metrics. In particular, optimizing for BLEU leads to the best results in the lexical metrics, while optimizing for BLEURT leads to the best performance in the others. Finally, optimizing for COMET leads to similar performance than optimizing for BLEURT. For the *large* model, although none of the rerankers is able to outperform the baseline in the lexical metrics, we see similar trends as before for BLEURT and COMET.

How does the performance of MBR decoding vary when we change the utility function? Table 1 (4th group) shows the impact of the utility function (BLEU, BLEURT, or COMET). For the *small* model, using COMET leads to the best performance according to all the metrics except BLEURT (for which the best result is attained when optimizing itself). For the *large* model, the best result according to a given metric is obtained when using that metric as the utility function.

How do (tuned) N-best reranking and MBR compare to each other? Looking at Table 1 we see that, for the *small* model, N-best reranking seems to perform better than MBR decoding in all the evaluation metrics, including the one used as the utility function in MBR decoding. The picture is less clear for the *large* model, with MBR decoding

	Large (WMT20)				Small (IWSLT)

Table 1: Evaluation metrics for EN → DE for the *large* and *small* model settings, using a *fixed* N-best reranker (F-RR), a *tuned* N-best reranker (T-RR), MBR decoding, and a two-stage approach. Best overall values are **bolded** and best for each specific group are underlined.

achieving best values for a given fine-tuned metric when using it as the utility; this comes at the cost of worse performance according to the other metrics, hinting at a potential "*overfitting*" effect. Overall, N-best reranking seems to have an edge over MBR decoding. We will further clarify this question with human evaluation in § 4.2.4.

Can we improve performance by combining N-best reranking with MBR decoding? Table 1 shows that, for both the *large* and the *small* model, the two-stage ranking approach described in §3 leads to the best performance according to the fine-tuned metrics. In particular, the best result is obtained when the utility function is the same as the evaluation metric. These results suggest that a promising research direction is to seek more sophisticated pruning strategies for MBR decoding.

4.2.4 Human Evaluation

Which metric correlates more with human judgments? How risky is it to optimize a metric and evaluate on a related metric? Our experiments suggest that, overall, *quality-aware* decoding produces translations with better performance across most metrics than *MAP-based* decoding. However, for some cases (such as fixed N-best reranking and most results with the *large* model), there is a concerning "metric gap" between lexical-based and fine-tuned metrics. While the latter have shown to correlate better with human judgments, previous work has not attempted to explicitly optimize these metrics, and doing so could lead to ranking systems that learn to exploit "pathologies" in these metrics rather than improving translation quality. To investigate this hypothesis, we perform a human study across all four datasets. We ask annotators to rate, from 1 (no overlap in meaning) to 5 (perfect translation), the translations produced by the 4 *ranking* systems in §3, as well as the baseline translation and the reference. Further details are in App. C. We choose COMET-QE as the feature for the fixed N-best ranker and COMET as the optimization metric and utility function for the tuned N-best reranker and MBR decoding, respectively. The reasons for this are two-fold: (1) they are currently the reference-free and reference-based metrics with highest reported correlation with human judgments (Kocmi et al., 2021), (2) we saw the largest "metric gap" for systems based on these metrics, hinting of a potential "overfitting" problem (specially since COMET-QE and COMET are similar models).

Table 2 shows the results for the human evaluation, as well as the automatic metrics. We see that, with the exception of T-RR w/ COMET, when fine-tuned metrics are explicitly optimized for, their correlation with human judgments decreases and they are no longer reliable indicators of system-level ranking. This is notable for the fixed N-best reranker with COMET-QE, which outperforms the baseline in COMET for every single scenario, but leads to markedly lower quality translations. However, despite the potential for overfitting these metrics, we find that *tuned* N-best reranking, MBR, and their combination consistently achieve better

translation quality than the baseline, specially with the small model. In particular, N-best reranking results in better translations than MBR, and their combination is the best system in 2 of 4 LPs.

4.2.5 Improved Human Evaluation

To further investigate how *quality-aware* decoding performs when compared to *MAP-based* decoding, we perform another human study, this time based on expert-level multidimensional quality metrics (MQM) annotations (Lommel et al., 2014). We asked the annotators to identify all errors and independently label them with an error category (*accuracy*, *fluency*, and *style*, each with a specific set of subcategories) and a severity level (*minor*, *major*, and *critical*). In order to obtain the final sentence-level scores, we require a weighting scheme on error severities. We use weights of 1, 5, and 10 to *minor*, *major*, and *critical* errors, respectively, independently of the error category. Further details are in App. D. Given the cost of performing a human study like this, we restrict our analysis to the translations generated by the large models trained on WMT20 (EN → DE and EN → RU).

Table 3 shows the results for the human evaluation using MQM annotations, including both error severity counts and final MQM scores. As hinted in §4.2.4, despite the remarkable performance of the F-RR with COMET-QE in terms of COMET (see Table 2), the quality of the translations decreases when compared to the baseline, suggesting the possibility of *metric overfitting* when evaluating systems using a single automatic metric that was directly optimized for (or a similar one). However, for both language pairs, the T-RR with COMET and the two stage approach (T-RR + MBR with COMET) achieve the highest MQM score. In addition, these systems present the smallest number of errors when combining both major and critical errors.

Although the performance of all systems is comparable for EN→DE, both the T-RR and the T-RR+MBR decoding markedly reduce the number of grammatical register errors related to using pronouns and verb forms that are not compliant with the register required for that translation, at the cost of increasing the number of lexical selection errors (see Figure 4). For EN→RU, however, the number of lexical selection errors produced when using the T-RR or the T-RR+MBR decoding is approximately a half of the ones produced by the baseline (see Figure 5). In this case, this comes at apparently almost no cost in other error types, leading to significantly better results, as shown in Table 3.

5 Related Work

Reranking. Inspired by the work of Shen et al. (2004) on discriminative reranking for SMT, Lee et al. (2021) trained a large transformer model using a reranking objective to optimize BLEU. Our work differs in which our rerankers are much simpler and therefore can be tuned on a validation set; and we use more powerful quality metrics instead of BLEU. Similarly, Bhattacharyya et al. (2021) learned an energy-based reranker to assign lower energy to the samples with higher BLEU scores. While the energy model plays a similar role to a QE system, our work differs in two ways: we use an existing, pretrained QE model instead of training a dedicated reranker, making our approach applicable to any MT system without further training; and the QE model is trained to predict human as-

sessments, rather than BLEU scores. Leblond et al. (2021) compare a reinforcement learning approach to reranking approaches (but not MBR decoding, as we do). They investigate the use of reference-based metrics and, for the reward function, a reference-free metric based on a modified BERTScore (Zhang et al., 2020). This new multilingual BERTScore is not fine-tuned on human judgments as COMET and BLEURT and it is unclear what its level of agreement with human judgments is. Another line of work is *generative reranking*, where the reranker is not trained to optimize a metric, but rather as a generative noisy-channel model (Yu et al., 2017; Yee et al., 2019; Ng et al., 2019).

Minimum Bayes Risk Decoding. MBR decoding (Kumar and Byrne, 2002, 2004) has recently been revived for NMT using candidates generated with beam search (Stahlberg et al., 2017; Shu and Nakayama, 2017) and sampling (Eikema and Aziz, 2020; Müller and Sennrich, 2021). Eikema and Aziz (2021) also explore a two-stage approach for MBR decoding. Additionally, there is concurrent work by Freitag et al. (2021b) on using neural metrics as utility functions during MBR decoding: however they limit their scope to MBR with reference-based metrics, while we perform a more extensive evaluation over ranking methods and metrics. Amrhein and Sennrich (2022) also concurrently explored using MBR decoding with neural metrics, but with the purposes of identifying weaknesses in the metric (in their case COMET), similarly to the *metric overfitting* problem we discussed in §4.2.4. A comparison with N-best re-ranking was missing in these works, a gap our paper fills. A related line of work is *minimum risk training* (MRT; Smith and Eisner 2006; Shen et al. 2016), which *trains* models to minimize risk, allowing arbitrary non-differentiable loss functions (Edunov et al., 2018; Wieting et al., 2019) and avoiding exposure bias (Wang and Sennrich, 2020; Kiegeland and Kreutzer, 2021). However, MRT is considerably more expensive and difficult to train and the gains are often small. Incorporating our quality metrics in MRT is an exciting research direction.

6 Conclusions and Future Work

We leverage recent advances in MT quality estimation and evaluation and propose *quality-aware decoding* for NMT. We explore different candidate generation and ranking methods, with a comprehensive empirical analysis across four datasets and two model classes. We show that, compared to MAP-based decoding, quality-aware decoding leads to better translations, according to powerful automatic evaluation metrics and human judgments.

There are several directions for future work. Our ranking strategies increase accuracy but are substantially more expensive, particularly when used with costly metrics such as BLEURT and COMET. While reranking-based pruning before MBR decoding was found helpful, additional strategies such as caching encoder representations (Amrhein and Sennrich, 2022) and distillation (Pu et al., 2021) are promising directions.

Supplemental Material

A Training Details

For the experiments using IWSLT17, we train a *small* transformer model (6 layers, 4 attention heads, 512 embedding dimensions, and 1024 hidden dimensions) from scratch, using *Fairseq* (Ott et al., 2019). We tokenize the data using SentencePiece (Kudo and Richardson, 2018), with a joint vocabulary with 20000 units. We train using the Adam optimizer (Kingma and Ba, 2015) with $\beta_1 = 0.9$ and $\beta_2 = 0.98$ and use an inverse square root learning rate scheduler, with an initial learning rate of 5×10^{-4} and with a linear warm-up in the first 4000 steps. For models trained with label smoothing, we use the default value of 0.1.

B Additional Results

For completeness, we include in Table 4 results to evaluate the impact of the metrics presented in §3 as features and objectives for ranking using the other language pairs: EN → RU (large model) and EN → FR (small model).

C Human Study

In order to perform human evaluation, we recruited professional translators who were native speakers of the target language on the freelancing site Upwork.[5] 300 sentences were evaluated for each language pair, sampled randomly from the test sets after a restriction that sentences were no longer than 30 words. All translation hypotheses for a single source sentence were first deduplicated, and then shown to the translator side-by-side in randomized order to avoid any ordering biases.

Sentences were evaluated according to a 1-5 rubric slightly adapted from that of Wieting et al. (2019):

1. There is no overlap in the meaning of the source sentence whatsoever.
2. Some content is similar but the most important information in the sentence is different.
3. The key information in the sentence is the same but the details differ.
4. Meaning is essentially equal but some expressions are unnatural.
5. Meaning is essentially equal and the sentence is natural.

---

[5] `https://upwork.com`. Freelancers were paid a market rate of 18-20 US dollars per hour, and finished approximately 50 sentences in one hour.

D MQM Framework

Human evaluations were performed by Unbabel's PRO Community, made of professional translators and linguists with relevant experience in linguistic annotations and translation errors annotations. In order to properly assess translations quality, annotators must be native speakers of the target language and with a proven high proficiency of the source language, so that they can properly capture errors and their nuances. The systems' outputs were evaluated by using the annotation framework adopted internally at Unbabel, which is an adaptation of the MQM Framework (Lommel et al., 2014).

We asked the annotators to identify all errors and independently label them with an error category and a severity level. We consider **three categories** (each of them containing a set of different subcategories) that may affect the quality of the translations:

- *Accuracy*, if the target text does not accurately reflect the source text (*e.g.*, changes in the meaning, addition/omission of information, untranslated text, MT hallucinations);
- *Fluency*, if there are issues that affect the reading and the comprehension of the text (*e.g.*, grammar and spelling errors);
- *Style*, if the text has stylistic problems (*e.g.*, gramatical and lexical register).

Additionally, each error is labeled according to **three severity levels** (*minor*, *major*, and *critical*), depending on the way they affect the accuracy, the fluency, and the style of the translation. The final sentence-level score is obtained using a weighting scheme where minor, major, and critical errors are weighted as 1, 5, and 10, respectively.

Figures 4 and 5 show the counts of errors breakdown by typology and severity level for EN→DE and EN→RU, respectively.

Figure 4: Error typology and severity level breakdown for WMT20 (large models) EN→DE.

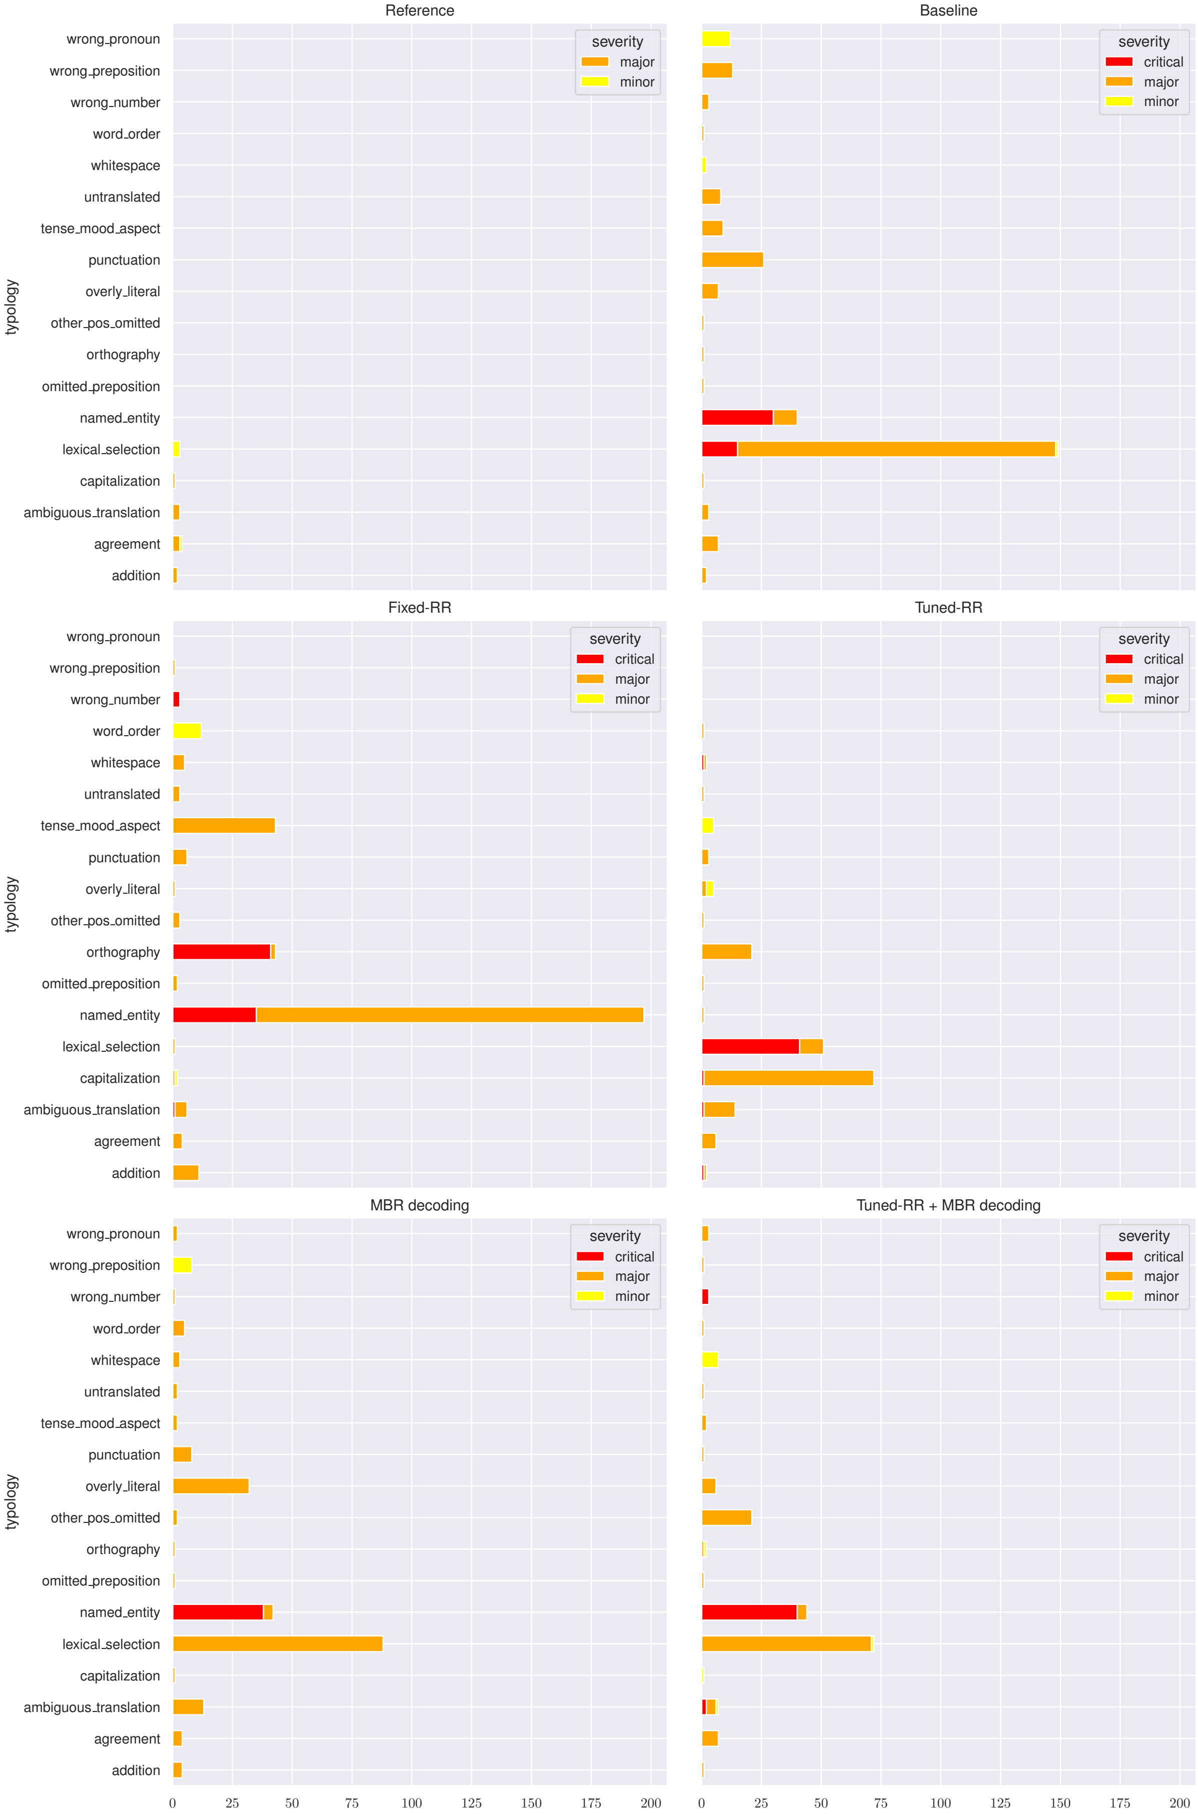

Figure 5: Error typology and severity level breakdown for WMT20 (large models) EN→RU.

Pretrained Models for Multilingual Federated Learning

Abstract

Since the advent of Federated Learning (FL), research has applied these methods to natural language processing (NLP) tasks. Despite a plethora of papers in FL for NLP, no previous works have studied how multilingual text impacts FL algorithms. Furthermore, multilingual text provides an interesting avenue to examine the impact of non-IID text (e.g. different languages) on FL in naturally occurring data. We explore three multilingual language tasks, language modeling, machine translation, and text classification using differing federated and non-federated learning algorithms. Our results show that using pretrained models reduces the negative effects of FL, helping them to perform near or better than centralized (no privacy) learning, even when using non-IID partitioning.[1]

1 Introduction

Federated learning (FL) is a machine learning technique that trains a model across multiple distributed clients holding local data samples, without ever storing client data in a central location (Konečný et al., 2016; McMahan et al., 2017). These techniques are appealing for those who wish to learn from data in a privacy-preserving way, without ever transmitting the data off of a client device. FL becomes essential when data is especially sensitive, as is the case at hospitals, legal firms, financial institutions, or in countries that enact legislation concerning data privacy (such as the EU's GDPR or the US's HIPAA).

FL has been applied to problems in natural language processing (NLP) since its inception, particularly in use of the language modeling task (Yang et al., 2018; Hard et al., 2018; Ramaswamy et al., 2019; Chen et al., 2019a; Ji et al., 2019; Stremmel and Singh, 2020). Another large area of FL research is focused on analyzing performance when the data is non identically independently distributed (non-IID). In these cases, many works have shown that FL performance is sub-par with respect to centralized learning methods (Konečný et al., 2016; Hard et al., 2018; Lin et al., 2021).

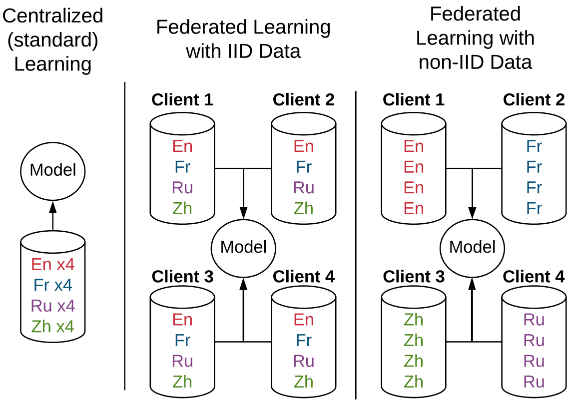

Figure 1: A depiction of different learning strategies with Federated Learning (FL) and multilingual data, with 4 clients and 16 instances from En, Fr, Ru, and Zh in this toy example. Black lines indicate gradient flow. Centralized learning is the standard training method (no privacy), FL with IID data partitions the data into IID data subsets for each client, while FL with non-IID data has the languages separated across clients.

Despite the large amount of research in FL for NLP, how different languages impact the FL training process has yet to be explored (Liu et al., 2021). Furthermore, multilingual FL provides an interesting and natural setting to explore non-IID data, of which different languages are an obvious example.

In this work, we explore multilingual federated learning across three multilingual language tasks and different stages of model pretraining. Our results show that fine-tuning pretrained models with FL can perform similarly to pretrained models fine-tuned with the standard centralized method (the

July 10-15, 2022

no privacy setting), despite having completely non-IID language partitioned data. This finding shows that pretrained models provide an effective way for practitioners (and consumers) of multilingual data to gain the privacy benefits of FL at little or no cost to the final task performance.

2 Background and Related Work

The term *Federated Learning* was first proposed in McMahan et al. (2017), who applied the `FederatedAveraging` algorithm to the tasks of language modeling and image classification. Since then, much of the theoretical and applied work in FL (e.g. Chen et al. (2019b); Wu et al. (2020) among many others) has considered language modeling as a key task or benchmark.

Concurrent with the growing interest in Federated Learning, NLP has rapidly shifted toward the use of pretrained language models (PLMs) (e.g., BERT Devlin et al. 2019; T5 Raffel et al. 2019; GPT-3 Brown et al. 2020). These PLMs are used for both the core task of next word prediction and as a starting point for learning other downstream NLP tasks. This *pretrain-and-fine-tune* paradigm has since become ubiquitous in modern NLP and has inspired a large and active area of research in model pretraining. Multilingual versions of these pretrained models have since been developed and are often used with transfer learning techniques to increase performance for tasks where data is limited (e.g. mBERT from Devlin et al. 2019).

The intersection of distributed learning from private data partitions and PLMs is still a nascent area. Several works have explored more efficient methods of federated communication with the purpose of enabling these larger NLP models for production situations (Sui et al., 2020; Wu et al., 2021). Our work is orthogonal to these (and could be combined in future work), as we explore the effects of multilingual data on PLM FL, rather than creating methods to enable their use. Other papers focus on the gap between federated learning performance and centralized performance, evaluating on a wide variety of English NLP tasks (Liu and Miller, 2020; Lin et al., 2021; Chen et al., 2021). Although they focus on differential privacy (DP) rather than FL, Li et al. (2021) find that direct PLM training is difficult with standard DP methods, but that fine-tuning PLMs on English data is possible with private learning techniques. We differ from all these works by studying private learning, specifically FL, for PLMs in the novel multilingual setting.

3 Experimental Design

3.1 Federated Learning Methods

We use `FederatedAveraging` as the primary learning algorithm (McMahan et al., 2017). `FederatedAveraging` was introduced alongside the term Federated Learning and has been studied in both learning theory research (Stich, 2019) and applied work (Hard et al., 2018; Lin et al., 2021). In this algorithm, each client runs stochastic gradient descent (SGD) on its local data. After a specified number of steps, the client transmits its local model to the server, which averages these updates into a single centralized set of parameters. The server then broadcasts the centralized parameters to each client and the process repeats.

3.2 Client Partitioning

We consider three different training settings: standard training with no FL (e.g. *centralized* or *C*), FL with IID data (*FL IID* or *I*), where the data for each client is sampled randomly from all data, and FL with non-IID data (*FL non-IID* or *N*) where each client only sees data for one language (or for MT, one direction). See Figure 1 for a visual depiction of these three client partitioning schemes.

3.3 Data

We study three multilingual language tasks, due to their common use in the community: language modeling (LM), machine translation (MT), and text classification (TC). We note that the data we use for training is relatively small; however, this mirrors pratical FL, as each client will not have a large amount of data. We measure scores using perplexity (PPL) for LM, BLEU (Papineni et al., 2002) for MT, and accuracy for TC.

Europarl We use the Europarl corpus (Koehn et al., 2005) taken from transcripts of European Union meetings. We sample data from eight languages: English, Spanish, Portuguese, French, German, Finnish, Polish, Lithuanian, and Czech. We sample 20k of each language for training and 5k for validation/testing, and use it for the LM task.

MTNT We use the Machine Translation of Noisy Text (MTNT) dataset (Michel and Neubig, 2018), which was the testset for the 2019 WMT robustness challenge. MTNT was gathered from user

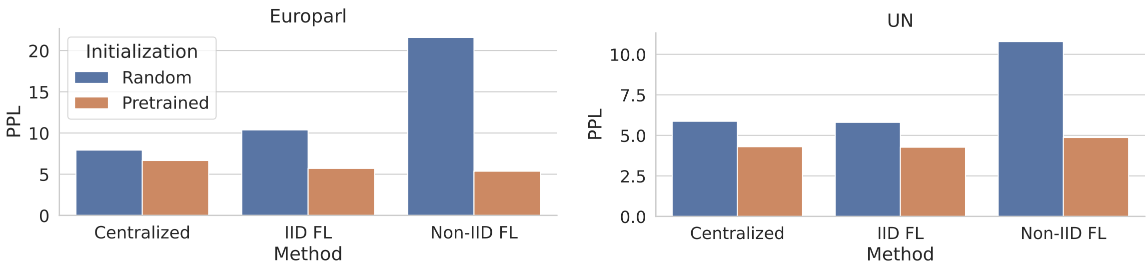

Figure 2: An overview of the language modeling results. Bars indicate the average language perplexity (PPL) over 8 languages for the Europarl dataset and 6 languages for the UN corpus. Lower is better.

Table 1: Results for FL experiments on the LM task. Bold scores indicate the best in the column for the given section. Scores are measured in perplexity (lower is better). The top row (B) is a baseline using the pretrained model with no fine-tuning. The middle rows are trained from *randomly-initialized* models while the bottom rows tune the pretrained model on task data. Due to space we abbreviate: C for Centralized, I for IID FL, and N for non-IID FL. We sample the mask distribution with 5 seeds and report the mean (standard deviations can be found in the Appendix, Tables 4 and 5). Asterisks indicate scores within 2 standard deviations of the best.

comments on Reddit discussion threads and contains noisy text including typos, casual language, and niche terminology. The dataset contains two non-English languages that we use: En → Fr and En → Ja. This dataset has been used to test MT systems for robustness to domain shift (Li et al., 2019) and is suitable for our experiments since FL deals with client data that is uniquely shifted from centralized data. For more details on MTNT data preprocessing for M2M-100, see Appendix C.

UN Corpus The UN Corpus (Ziemski et al., 2016) consists of official records from the UN proceedings over the years 1990 to 2014, in six languages: English, French, Spanish, Russian, Chinese, and Arabic. We use this data for LM (with 50k instances of training data per language and 5k for validation/testing) as well as three MT directions covering 6 languages (En → Fr, Ar → Es, Ru → Zh). Following previous work in MT adaption (see MTNT above) we sample 10k in each direction for training and 5k each for evaluation sets.

NC Corpus For text classification we use the News Classification (NC) dataset from the XGLUE benchmark for cross-lingual language understanding (Liang et al., 2020). This is a classification problem with 10 classes across 5 languages: English, Spanish, French, German, and Russian. We predict the article category given the article title and body (e.g. finance, sports, travel). Since only 10k annotated examples are available for each language (excluding the official test set), we sample 8k instances for training and 1k for evaluation sets. Note that although XGLUE is made for cross-lingual evaluation, we use it for multilingual evaluation.

3.4 Modeling

For language modeling and text classification, we examine two different initialization settings: (1) fine-tuning from a pretrained multilingual model or (2) training the same multilingual model architecture but doing so with randomly initialized weights. For the MT experiments, we omit the *randomly-initialized* results as MT systems generally need large amounts of data to produce good results (see Appendix B for more details).

Our base model for the LM task is a distilled version of the mBERT model (134M parameters),

	MTNT			UN

Table 3: Results for FL experiments on the Text Classification task. Bold scores indicate the best in the column, while asterisks indicate scores within two standard deviations of the best. Scores are the mean of training with 3 different seeds, ± denotes the standard deviation. Scores are measured with accuracy, higher is better. The top rows are trained from random initialization while the bottom rows initialize from the pretrained model.

shown to perform well across many languages (Sanh et al., 2019; Devlin et al., 2019) while being smaller than the full mBERT.[2] For MT, we use the M2M-100 model (Fan et al., 2020) with 418M parameters, a many-to-many MT model that can translate between any pairing of 100 languages. For text classification, we use the XLM-RoBERTa base sized model (270M parameters). We note that although there are other PLMs to consider, we focus on testing a varied set of commonly used, high-performing PLMs.

3.5 Training

We use the Flower framework (Beutel et al., 2020) for federated training and evaluation due to its ease of use and strong community support. We use Hugging Face's *transformers* library (Wolf et al., 2019) for loading pretrained models and PyTorch as the underlying differentiation framework (Paszke et al., 2019). We train each LM model for 100 epochs if pretrained or 200 epochs if randomly initialized. For MT, we train for 25 epochs and for TC we train for 10 epochs if pretrained and 50 epochs if randomly initialized. For other hyperparameters and compute settings, see Appendix A.

4 Results

Language Modeling In Figure 2 we see the overall results of the language modeling task across the two datasets. As expected, the randomly initialized models perform much worse than the pretrained models. The gap between between FL and centralized methods is smaller when using pretrained models, indicating that pretrained models are an effective initialization for federated learning.

In Table 1 we show results broken down by language. Since the fine-tuning task is the same as the pretraining objective (masked language modeling), we can use the pretrained model as a baseline (top row, B). In the randomly initialized category, the centralized model is the same or better than the FL methods in every single language, across both datasets. In the pretrained section the results are more mixed, with the centralized model winning or tying in 5 of the 8 Europarl languages and obtaining similar scores on the UN corpus. We also see that the randomly initialized non-IID model appears to diverge for some of the Europarl languages.

---

[2] We note that mBERT uses masked language modeling (MLM) instead of standard language modeling, however, for the purposes of our analysis (as we do not seek to compare direct scores to previous work) MLM suffices. Furthermore, most multilingual PLMs train via some version of MLM.

Examining the difference between IID FL and non-IID FL, we see that IID FL performs better on average in three of the four settings. However, when initializing with a pretrained model, the performance gap narrows.

Machine Translation Table 2 exhibits results on tuning a machine translation model on a domain specific dataset. We see that on the MTNT dataset, both FL algorithms actually outperform centralized learning (24.4 avg. BLEU for IID FL vs 23.6 for Centralized). The scores on Japanese are very similar for all models, possibly reflecting the difficulty of the task. On the UN corpus, we see again that the IID FL model performs best.

Since the fine-tuning task matches the original M2M-100 task, we can use the pretrained model directly as a baseline. In all cases, fine-tuning shows an improvement (first row, No Training baseline). Note that our scores are not directly comparable to other work as we use a smaller training set.

Text Classification Table 3 shows results on text classification. We see that when initialized randomly, non-IID FL shows a large drop in performance compared to the two other methods (i.e. more than 5 points worse than the Centralized method). Initializing with the pretrained model yields a modest though consistent improvement for all three models (80.4% accuracy vs 88.3% accuracy for Centralized).[3] Furthermore, with a pretrained initialization the non-IID FL method scores become significantly closer to the other two methods, with less than a two point difference between them (86.7% non-IID FL vs 88.3% IID FL).

Discussion Our examination of multilingual FL indicates that performance is similar when pretrained models are used. Despite the fact that local models are averaged together, non-IID data partitioning (where each client sees only one language) has only a small impact on final multilingual performance, when using pretrained models. These findings suggest that, when possible, practitioners who need multilingual federated learning should employ pretrained models in order to gain the privacy benefits of federated learning, without taking much (if any) of a performance loss to do so.

In several cases, we found that IID FL or non-IID FL could even outperform centralized learning. We leave investigation of this phenomena for future work but note a couple of possible explanations. First, FL with `FederatedAveraging` may have similar implicit regularization effects to checkpoint averaging, a common technique when using transformer models (noted in Vaswani et al. 2017, Edunov et al. 2018, etc.). Furthermore, there may be other regularization effects during federated fine-tuning, as transformer training is known to be unstable and sensitive to optimization choices (Mosbach et al. 2020, Nguyen and Salazar 2019).

Overall, our analysis shows that our conclusions hold for different multilingual models, on disparate NLP tasks, and across 13 different languages. We acknowledge that the languages used in this study are generally considered higher-resource, but expect that these conclusions will continue to hold as long as the pretrained model is effective on the target language (or language pairs, for MT).

5 Conclusion

In this work we provided the first analysis of multilingual language data on federated learning algorithms. We found that fine-tuning a pretrained model with FL methods can yield similar performance to centralized learning, even when clients are partitioned by language (non-IID FL). However, models trained from random initializations still show a large gap between centralized and federated learning. Our results suggest that learning on private partitioned data is possible without having to incur a large performance penalty. We hope that these results will aid practitioners in using FL (and also downstream consumers) and inspire the broader community to consider multilingual data in future federated learning research for natural language processing.

A Hyperparameters

Each LM experiment ran for approximately a day each on a 6 GPU cluster of RTX 6000 GPUs with 24GB of memory per GPU. The MT experiments took approximately 12 hours each and the TC experiments took around 3 hours each, all on the same cluster.

We use the AdamW optimizer (Loshchilov and Hutter, 2017; Kingma and Ba, 2014) for all experiments (shown to be effective for FL in Lin et al. 2021). Each client goes through a full epoch of local learning before synchronizing with the server.

For MT, we report results using the 5e-5 learning rate, as we found in initial results (as have others also, see Appendix B of Stickland et al. (2020) as one example) that MT experiments are generally consistent over learning rates when fine-tuning. For language modeling and text classification, we use three different learning rates (1e-4, 5e-5, 1e-5). All models were selected using the best performing version on the validation set, for the given model and training setting. For both tasks, we use early stopping (5 epochs of no improvement for MT and TC, 10 epochs for LM).

We use the standard `sacreBLEU` settings: nrefs:1, mixed case, eff:no, tok:13a, smooth:exp, and version 2.0.0. For Ja and Zh we use their respective tokenizers.

B Randomly Initialized MT

We do not report results for randomly initialized training of MT systems, as large neural MT systems generally need large amounts of data to be effective. We ran experiments for the MTNT dataset from random initializations, running for twice as many epochs. Resulting models appeared to converge by loss but had extremely low BLEU scores. Thus, we only include pretrained results in Table 2.

C MTNT Data Preprocessing for M2M-100

M2M-100 was trained using scripts that removed input with “excess punctuation." We follow this in preparing MTNT training data. We use all En → Ja data (consisting of approximately 6k instances) and take the corresponding En → Fr instances, randomly sampling additional instances until there are the same number of instances in each direction. We sample an equal number of training instances as we are testing the effects of multilingual data, rather than unequal dataset sizes. We then remove the training instances with excess punctuation (or sentences less than 3 characters) following the M2M-100 script. This leaves 5605 instances in each direction for training. We use the standard MTNT dev and test sets, as-is, consisting of approximately 1k data points.

D Full LM Results

We show the full results of the LM experiments, with standard deviations over five random seeds in Tables 4 and 5.

Abstract

While pre-trained language model (PLM) fine-tuning has achieved strong performance in many NLP tasks, the fine-tuning stage can be still demanding in labeled data. Recent works have resorted to active fine-tuning to improve the label efficiency of PLM fine-tuning, but none of them investigate the potential of unlabeled data. We propose AcTune, a new framework that leverages unlabeled data to improve the label efficiency of active PLM fine-tuning. AcTune switches between data annotation and model self-training based on uncertainty: it selects high-uncertainty unlabeled samples for active annotation and low-uncertainty ones for model self-training. Under this framework, we design (1) a region-aware sampling strategy that reduces redundancy when actively querying for annotations and (2) a momentum-based memory bank that dynamically aggregates the model's pseudo labels to suppress label noise in self-training. Experiments on 6 text classification datasets show that AcTune outperforms the strongest active learning and self-training baselines and improves the label efficiency of PLM fine-tuning by 56.2% on average. Our implementation is available at `https://github.com/yueyu1030/actune`.

1 Introduction

Fine-tuning pre-trained language models (PLMs) has achieved much success in natural language processing (NLP) (Devlin et al., 2019; Liu et al., 2019; Brown et al., 2020). One benefit of PLM fine-tuning is the promising performance it offers when consuming only a few labeled data (Bansal et al., 2020; Gao et al., 2021). However, there are still significant gaps between few-shot and fully-supervised PLM fine-tuning in many tasks. Besides, the performance of few-shot PLM fine-tuning can be sensitive to different sets of training data (Bragg et al., 2021). Therefore, there is a crucial need for approaches that make PLM fine-tuning more label-efficient and robust to selection of training data, especially for applications where labeled data are scarce and expensive to obtain.

Towards this goal, researchers have recently resorted to *active fine-tuning* of PLMs and achieved comparable performance to fully-supervised methods with much less annotated samples (Ein-Dor et al., 2020; Margatina et al., 2021a,b; Yuan et al., 2020). Nevertheless, they usually neglect unlabeled data, which can be useful for improving label efficiency for PLM fine-tuning (Du et al., 2021). To incorporate unlabeled data into active learning, efforts have been made in the semi-supervised active learning literature (Wang et al., 2016; Rottmann et al., 2018; Siméoni et al., 2020). However, the query strategies proposed in these works can return highly redundant samples due to limited representation power, resulting in suboptimal label efficiency. Moreover, they usually rely on pseudo-labeling to utilize unlabeled data, which requires greater (yet often absent) care to denoise the pseudo labels, otherwise the errors could accumulate and hurt model performance. This issue can be even more severe for PLMs, as the fine-tuning process is often sensitive to different weight initialization and data orderings (Dodge et al., 2020). Thus, it still remains open and challenging to design robust and label efficient method for active PLM fine-tuning.

To tackle the above challenges, we propose AcTune, a new method that improves the label efficiency and robustness of active PLM fine-tuning. Based on the estimated model uncertainty, AcTune tightly couples *active learning* with *self-training* in each learning round: (1) when the average uncertainty of a region is low, we trust the model's predictions and select its most certain predictions within the region for self-training; (2) when the average uncertainty of a region is high, indicating inadequate observations for parameter learning, we actively annotate its most uncertain

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1422 - 1436
July 10-15, 2022

samples within the region to improve model performance. Different from existing AL methods that only leverage uncertainty for querying labels, our uncertainty-driven self-training paradigm gradually leverages unlabeled data with low uncertainty via self-training, while reducing the chance of error propagation triggered by highly-uncertain mislabeled data.

To further boost model performance for ACTUNE, we design two techniques to improve the query strategy and suppress label noise, namely region-aware sampling (RS) and momentum-based memory bank (MMB). Inspired by the fact that existing uncertainty-based AL methods often end up with choosing uncertain yet repetitive data (Ein-Dor et al., 2020; Margatina et al., 2021b), we design the region-aware sampling technique to promote both diversity and representativeness by leveraging the representation power of PLMs. Specifically, we first estimate the uncertainties of the unlabeled data with PLMs, then cluster the data using their PLM representations and weigh the data by the corresponding uncertainty. Such a clustering scheme partitions the embedding space into small sub-regions with an emphasis on highly-uncertain samples. Finally, by sampling over multiple high-uncertainty regions, our strategy selects data with high uncertainty and low redundancy.

To rectify the erroneous pseudo labels derived by self-training, we design a simple but effective way to select low-uncertainty data for self-training. Our method is motivated by the fact that fine-tuning PLMs suffer from instability issues — different initializations and data orders can lead to large variance in model performance (Dodge et al., 2020; Zhang et al., 2020b; Mosbach et al., 2021). However, previous approaches only select pseudo-labeled data based on the prediction of the current round and are thus less reliable. In contrast, we maintain a dynamic memory bank to save the predictions of unlabeled samples for later use. We propose a momentum updating method to dynamically aggregate the predictions from preceding rounds (Laine and Aila, 2016) and select low-uncertainty samples based on aggregated prediction. As a result, only the samples with high prediction confidence over multiple rounds will be used for self-training, which mitigates the issue of label noise. We highlight that our active self-training approach is an efficient substitution to existing AL methods, requiring little extra computational cost.

Our key contributions are: (1) an active self-training paradigm ACTUNE that integrates self-training and active learning to minimize the labeling cost for fine-tuning PLMs; (2) a region-aware querying strategy to enforce both the informativeness and the diversity of queried samples during AL; (3) a simple and effective momentum-based method to leverage the predictions in preceding rounds to alleviate the label noise in self-training and (4) experiments on 6 benchmarks demonstrating ACTUNE improves the label efficiency over existing self-training and active learning baselines by 56.2%.

2 Uncertainty-aware Active Self-training

2.1 Problem Formulation

We study active fine-tuning of pre-trained language models for text classification, formulated as follows: Given a small number of labeled samples $\mathcal{X}_l = \{(x_i, y_i)\}_{i=1}^{L}$ and unlabeled samples $\mathcal{X}_u = \{x_j\}_{j=1}^{U}$ ($|\mathcal{X}_l| \ll |\mathcal{X}_u|$), we aim to fine-tune a pre-trained language model $f(\boldsymbol{x};\theta) : \mathcal{X} \rightarrow \mathcal{Y}$ in an interactive way: we perform active self-training for T rounds with the total labeling budget b. In each round, we aim to query $B = b/T$ samples denoted as $\mathcal{B}$ from $\mathcal{X}_u$ to fine-tune a pre-trained language model $f(\boldsymbol{x};\theta)$ with both $\mathcal{X}_l, \mathcal{B}$ and $\mathcal{X}_u$ to maximize the performance on downstream text classification tasks. Here $\mathcal{X} = \mathcal{X}_l \cup \mathcal{X}_u$ denotes all samples, and $\mathcal{Y} = \{1, 2, \cdots, C\}$ is the label set where C is the number of classes.

2.2 Overview of ACTUNE Framework

We now present our active self-training paradigm ACTUNE underpinned by estimated uncertainty. We begin the active self-training loop by fine-tuning a BERT $f(\theta^{(0)})$ on the initial labeled data $\mathcal{X}_L$. Formally, we solve the following optimization problem

$$\min_{\theta} \frac{1}{|\mathcal{X}_L|} \sum_{(\boldsymbol{x}_i, y_i) \in \mathcal{X}_L} \ell_{\text{CE}}\left(f(\boldsymbol{x}_i; \theta^{(0)}), y_i\right). \quad (1)$$

In round t ($1 \leq t \leq T$) of active self-training, we first calculate the uncertainty score based on a given function $a_i^{(t)} = a(\boldsymbol{x}_i, \theta^{(t)})$ [1] for all $\boldsymbol{x}_i \in \mathcal{X}_u$. Then, we query labeled samples and generate pseudo-labels for unlabeled data $\mathcal{X}_u$ simultaneously to facilitate self-training. For each sample $\boldsymbol{x}_i$, the pseudo-label $\widetilde{y}$ is calculated based on the current

---

[1] Note that ACTUNE is agnostic to the way uncertainty score $a_i^{(t)}$ is computed.

Algorithm 1: Training Procedures of ACTUNE.
Input: Initial labeled samples $\mathcal{X}_l$; Unlabeled samples
    $\mathcal{X}_u$; Pre-trained LM $f(\cdot;\theta)$, number of active
    self-training rounds $T$.
// Fine-tune the LM with initial labeled data.
1. Calculate $\theta^{(0)}$ based on Eq. (1).
2. Initialize the memory bank $g(\boldsymbol{x};\theta^{t})$ based on the
   current prediction.
// Conduct active self-training with all data.
for $t = 1, 2, \cdots, T$ do
    1. Run weighted K-Means (Eq. (3), (4)) until
       convergence.
    2. Select sample set $\mathcal{Q}^{(t)}$ for AL and $\mathcal{S}^{(t)}$ for
       self-training from $\mathcal{X}_u$ based on Eq. (11) or (13).
    3. Augment the labeled set $\mathcal{X}_L = \mathcal{X}_L \cup \mathcal{Q}^{(t)}$.
    4. Obtain $\theta^{(t)}$ by finetuning $f(\cdot;\theta^{t})$ with $\mathcal{L}_{\mathrm{ST}}$ (
       Eq. (14)) using AdamW.
    5. Update memory bank $g(\boldsymbol{x};\theta^{t})$ with Eq. (10)
       or (12).
Output: The final fine-tuned model $f(\cdot;\theta^{T})$.
```

model's output:

$$\widetilde{y} = \underset{j \in \mathcal{Y}}{\operatorname{argmax}} \left[f(\boldsymbol{x};\theta^{(t)}) \right]_j, \tag{2}$$

where $f(\boldsymbol{x};\theta^{(t)}) \in \mathbb{R}^C$ is a probability simplex and $[f(\boldsymbol{x};\theta^{(t)})]_j$ is the j-th entry. The procedure of ACTUNE is summarized in Algorithm 1.

2.3 Region-aware Sampling for Active Learning on High-uncertainty Data

After obtaining the uncertainty for unlabeled data, we aim to query annotation for high-uncertainty samples. However, directly sampling the most uncertain samples gives suboptimal results as it tends to query repetitive data (Ein-Dor et al., 2020) that represent the overall data distribution poorly.

To tackle this issue, we propose region-aware sampling to capture both *uncertainty* and *diversity* during active self-training. Specifically, in the t-th round, we first conduct the weighted K-means clustering (Huang et al., 2005), which weights samples based on their uncertainty. Denote by K the number of clusters and $\boldsymbol{v}_i^{(t)} = \mathrm{BERT}(\boldsymbol{x}_i)$ the representation of $\boldsymbol{x}_i$ from the penultimate layer of BERT. The weighted K-means process first initializes the center of each each cluster $\boldsymbol{\mu}_i (1 \leq i \leq K)$ via K-Means++ (Arthur and Vassilvitskii, 2007). Then, it jointly updates the centroid of each cluster and assigns each sample to cluster c_i as

$$c_i^{(t)} = \underset{k=1,\ldots,K}{\operatorname{argmin}} \left\| \boldsymbol{v}_i - \boldsymbol{\mu}_k \right\|^2, \tag{3}$$

$$\boldsymbol{\mu}_k^{(t)} = \frac{\sum_{\boldsymbol{x}_i \in \mathcal{C}_k^{(t)}} a(\boldsymbol{x}_i, \theta^{(t)}) \cdot \boldsymbol{v}_i^{(t)}}{\sum_{\boldsymbol{x} \in \mathcal{C}_k^{(t)}} a(\boldsymbol{x}_i, \theta^{(t)})} \tag{4}$$

where $\mathcal{C}_k^{(t)} = \{\boldsymbol{x}_i^{(t)} | c_i^{(t)} = k\} (k = 1, \ldots, K)$ stands for the k-th cluster. The above two steps in Eq. (3), (4) are repeated until convergence. Compared with vanilla K-Means method, the weighting scheme increases the density of the samples with high uncertainty, thus enabling the K-Means methods to discover clusters with high uncertainty. After obtaining K regions with the corresponding data $\mathcal{C}_k^{(t)}$, we calculate the uncertainty of each region as

$$u_k^{(t)} = U(\mathcal{C}_k^{(t)}) + \beta I(\mathcal{C}_k^{(t)}) \tag{5}$$

where

$$U(\mathcal{C}_k^{(t)}) = \frac{1}{|\mathcal{C}_k^{(t)}|} \sum_{\boldsymbol{x}_i \in \mathcal{C}_k^{(t)}} a(\boldsymbol{x}_i, \theta^{(t)}), \tag{6}$$

is the average uncertainty of samples and

$$I(\mathcal{C}_k^{(t)}) = -\sum_{j \in C} f_j^{(t)} \log f_j^{(t)} \tag{7}$$

is the inter-class diversity within cluster k and $f_j^{(t)} = \frac{\sum_i \mathbb{1}\{\widetilde{y}_i = j\}}{|\mathcal{C}_k^{(t)}|}$ is the frequency of class j on cluster k. Notably, the term $U(\mathcal{C}_k^{(t)})$ assigns higher score for clusters with more uncertain samples, and $I(\mathcal{C}_k^{(t)})$ grants higher scores for clusters containing samples with more diverse predicted classes from pseudo labels since such clusters would be closer to the decision boundary.

Then, we rank the clusters in an ascending order in $u_k^{(t)}$. A high score indicates high uncertainty of the model in these regions, and we need to actively annotate the member instances to reduce uncertainty and improve the model's performance. We adopt a hierarchical sampling strategy: we first select the M clusters with the highest uncertainty, and then sample $b' = \lfloor \frac{B}{M} \rfloor$ data with the highest uncertainty to form the batch $\mathcal{Q}^{(t)}$.[2]

$$\mathcal{K}_a^{(t)} = \underset{k \in \{1,\ldots,K\}}{\text{top-M}} \; u_k^{(t)},$$
$$\mathcal{Q}^{(t)} = \bigcup_{k \in \mathcal{K}_a^{(t)}} \mathcal{C}_{a,k}^{(t)} \text{ where } \mathcal{C}_{a,k}^{(t)} = \underset{\boldsymbol{x}_i \in \mathcal{C}_k^{(t)}}{\text{Top-b}'} a(\boldsymbol{x}_i, \theta^{(t)}). \tag{8}$$

We remark that such a hierarchical sampling strategy queries most uncertain samples from *different* regions, thus the uncertainty and diversity of queried samples can be both achieved.

---

[2] If the number of samples in the i-th cluster $\mathcal{C}_i$ is smaller than b', then we sample all the data within $\mathcal{C}_i$ and increase the budget for the $(i+1)$-th cluster by $b' - |\mathcal{C}_i|$.

2.4 Self-training over Confident Samples from Low-uncertainty Regions

For self-training, we aim to select unlabeled samples which are *most likely* to have been correctly classified by the current model. This requires the sample to have low uncertainty. Therefore, we select the top k samples from the M lowest uncertainty regions to form the acquired batch $\mathcal{S}^{(t)}$:

$$\begin{aligned} \mathcal{C}_s^{(t)} &= \bigcup_{k\in\mathcal{K}_s^{(t)}} \mathcal{C}_k^{(t)} \text{ where } \mathcal{K}_s^{(t)} = \underset{k\in\{1,\dots,K\}}{\text{bottom-M}}\, u_k^{(t)}, \\ \mathcal{S}^{(t)} &= \underset{\boldsymbol{x}_i\in\mathcal{C}_s^{(t)}}{\text{bottom-k}}\, a(\boldsymbol{x}_i,\theta^{(t)}). \end{aligned} \tag{9}$$

Momentum-based Memory Bank for Self-training. As PLMs are sensitive to the stochasticity involved in fine-tuning, the model suffers from the instability issue — different weight initialization and data orders may result in different predictions on the same dataset (Dodge et al., 2020). Additionally, if the model gives inconsistent predictions in different rounds for a specific sample, then it is potentially uncertain about the sample, and adding it to the training set may harm the active self-training process. For example, for a two-class classification problem, suppose we obtain $f(\boldsymbol{x};\theta^{(t-1)}) = [0.65, 0.35]$ for sample $\boldsymbol{x}$ the round $(t-1)$ and $f(\boldsymbol{x};\theta^{(t)}) = [0.05, 0.95]$ for the round t. Although the model is quite 'confident' on the class of $\boldsymbol{x}$ when we only consider the result of the round t, it gives contradictory predictions over these two consecutive rounds, which indicates that the model is actually uncertain to which class $\boldsymbol{x}$ belongs.

To effectively mitigate the noise and stabilize the active self-training process, we maintain a dynamic memory bank to save the results from previous rounds, and use momentum update (He et al., 2020; Laine and Aila, 2016) to aggregate the results from both the previous and current rounds. Then, during active self-training, we will select samples with the highest aggregated score. In this way, only those samples that the model is certain about over all *previous rounds* will be selected for self-training. We design two variants for the memory bank, namely *prediction-based* and *value-based* aggregation.

Prediction based Momentum Update. We adopt an exponential moving average approach to aggregate the prediction $g(\boldsymbol{x};\theta^{(t)})$ on round t as

$$g(\boldsymbol{x};\theta^{(t)}) = m_t f(\boldsymbol{x};\theta^{(t)}) + (1-m_t) g(\boldsymbol{x};\theta^{(t-1)}), \tag{10}$$

where $m_t = (1-\frac{t}{T})m_L + \frac{t}{T}m_H$ $(0 < m_L \le m_H \le 1)$ is a momentum coefficient. We gradually increase the weight for models on later rounds, since they are trained with more labeled data thus being able to provide more reliable predictions. Then, we calculate the uncertainty based on $g(\boldsymbol{x};\theta^{(t)})$ and rewrite Eq. (9) and (2) as

$$\begin{aligned} \mathcal{S}^{(t)} &= \underset{\boldsymbol{x}_i\in\mathcal{C}_s^{(t)}}{\text{bottom-k}}\, a\left(\boldsymbol{x}_i, g(\boldsymbol{x};\theta^{(t)}), \theta^{(t)}\right) \\ \widetilde{y} &= \underset{j\in\mathcal{Y}}{\text{argmax}} \left[g(\boldsymbol{x};\theta^{(t)})\right]_j, \end{aligned} \tag{11}$$

Value-based Momentum Update. For methods that do not directly use prediction for uncertainty estimation, we aggregate the uncertainty value as

$$g(\boldsymbol{x};\theta^{(t)}) = m_t a(\boldsymbol{x};\theta^{(t)}) + (1-m_t) g(\boldsymbol{x};\theta^{(t-1)}). \tag{12}$$

Then, we use Eq. (12) to sample low-uncertainty data for self-training as[3]

$$\begin{aligned} \mathcal{S}^{(t)} &= \underset{\boldsymbol{x}_i\in\mathcal{C}_s^{(t)}}{\text{bottom-k}}\, g(\boldsymbol{x}_i,\theta^{(t)}), \\ \widetilde{y} &= \underset{j\in\mathcal{Y}}{\text{argmax}} \left[f(\boldsymbol{x};\theta^{(t)})\right]_j. \end{aligned} \tag{13}$$

By aggregating the prediction results over previous rounds, we filter the sample with inconsistent predictions to suppress noisy labels.

2.5 Model Learning and Update

After obtaining both the labeled data and pseudo-labeled data, we fine-tune a new pre-trained BERT model $\theta^{(t+1)}$ on them. Although we only include low-uncertainty samples during self-training, it is difficult to eliminate all the wrong pseudo-labels, and such mislabeled samples can still hurt model performance. To suppress such label noise, we use a threshold-based strategy to further remove noisy labels by selecting samples that agree with the corresponding pseudo labels. The loss objective of optimizing $\theta^{(t+1)}$ is

$$\begin{aligned} \mathcal{L}_{\text{ST}} =& \frac{1}{|\mathcal{L}^{(t)}|} \sum_{\boldsymbol{x}_i\in\mathcal{L}^{(t)}} \ell_{\text{CE}}\left(f(\boldsymbol{x}_i;\theta^{(t+1)}), y_i\right) \\ &+ \frac{\lambda}{|\mathcal{S}^{(t)}|} \sum_{\widetilde{\boldsymbol{x}}_i\in\mathcal{S}^{(t)}} \omega_i \ell_{\text{CE}}\left(f(\widetilde{\boldsymbol{x}}_i;\theta^{(t+1)}), \widetilde{y}_i\right), \end{aligned} \tag{14}$$

where $\mathcal{L}^{(t)} = \mathcal{X}_L \cup \mathcal{Q}^{(t)}$ is the labeled set, λ is a hyper-parameter balancing the weight between clean and pseudo labels, and $\omega_i = \mathbb{1}\{[f(\boldsymbol{x}_i;\theta^{(t+1)})]_{\widetilde{y}_i} > \gamma\}$ stands for the thresholding function.

Complexity Analysis. The running time of AcTune is mainly consisted of two parts: the inference time $O(|\mathcal{X}_u|)$ and the time for K-Means clustering $O(dK|\mathcal{X}_u|)$, where d is the dimension of the BERT feature $\boldsymbol{v}$. For self-training, the size

---

[3] Other choices such as soft pseudo label (Xie et al., 2020; Liang et al., 2020) is also applicable.

Dataset	Label Type	# Class	# Train	# Dev	#Test
SST-2	Sentiment	2	60.6k	0.8k	1.8k
AG News	News Topic	4	119k	1k	7.6k
Pubmed	Medical Abstract	5	180k	1k	30.1k
DBPedia	Wikipedia Topic	14	280k	1k	70k
TREC	Question	6	5.0k	0.5k	0.5k
Chemprot	Medical Abstract	10	12.8k	0.5k	1.6k

Table 1: Dataset Statistics. For DBPedia, we randomly sample 20k sample from each class due to the limited computational resource.

of the memory bank $g(\boldsymbol{x};\theta)$ is proportional to $|\mathcal{X}_u|$, while the extra computation of maintaining this dictionary is *ignorable* since we do not inference over the unlabeled data for multiple times in each round as BALD (Gal et al., 2017) does. The running time of ACTUNE will be shown in section C.

3 Experiments

3.1 Experiment Setup

Tasks and Datasets. In our main experiments, we use 4 datasets, including *SST-2* (Socher et al., 2013) for sentiment analysis, *AGNews* (Zhang et al., 2015) for news topic classification, *Pubmed-RCT* (Dernoncourt and Lee, 2017) for medical abstract classification, and *DBPedia* (Zhang et al., 2015) for wikipedia topic classification. For weakly-supervised text classification, we choose 2 datasets, namely *TREC* (Li and Roth, 2002) and *Chemprot* (Krallinger et al., 2017) from the WRENCH benchmark (Zhang et al., 2021) for evaluation. The statistics are shown in Table 1.

Active Learning Setups. Following (Yuan et al., 2020), we set the number of rounds $T = 10$, the overall budget for all datasets $b = 1000$ and the initial size of the labeled $|\mathcal{X}_l|$ is set to 100. In each AL round, we sample a batch of 100 samples from the unlabeled set $\mathcal{X}_u$ and query their labels. Since large development sets are impractical in low-resource settings (Kann et al., 2019), we keep the size of development set as 1000, which is the same as the labeling budget[4]. For weakly-supervised text classification, since the datasets are much smaller, we keep the labeling budget and the size of development set to $b = 500$.

Implementation Details. We choose RoBERTa-base (Liu et al., 2019) from the HuggingFace codebase (Wolf et al., 2020) as the backbone for ACTUNE and all baselines except for Pubmed and Chemprot, where we use SciBERT (Beltagy et al., 2019), a BERT model pre-trained on scientific corpora. In each round, we train from scratch to avoid overfitting the data collected in earlier rounds as observed by Hu et al. (2019). More details are in Appendix B.

Hyperparameters. The hyperparameters setting is in Appendix B.5. In the t-th round of active self-training, we increase the number of pseudo-labeled samples by k, where k is 500 for TREC and Chemprot, 3000 for SST-2 and Pubmed-RCT, and 5000 for others. For the momentum factor, we tune m_L from $[0.6, 0.7, 0.8]$ and m_H from $[0.8, 0.9, 1.0]$ and report the best $\{m_L, m_H\}$ based on the performance of the development set.

Baselines.

Self-training Methods: (1) **Self-training (ST, Lee (2013))**: It is the vanilla self-training method that generates pseudo labels for unlabeled data. (2) **UST** (Mukherjee and Awadallah, 2020; Rizve et al., 2021): It is an uncertainty-based self-training method that only uses low-uncertainty data for self-training. (3) **COSINE** (Yu et al., 2021): It uses self-training to fine-tune LM with weakly-labeled data, which achieves SOTA performance on various text datasets in WRENCH benchmark (Zhang et al., 2021). Note that for these two baselines, we *randomly sample* b labeled data as the initialization.

Active Learning Methods: (1) **Random**: It acquires annotation randomly, which serves as a baseline for all methods. (2) **Entropy** (Holub et al., 2008): It is an uncertainty-based method that acquires annotations on samples with the highest predictive entropy. (3) **BALD** (Gal et al., 2017): It is also an uncertainty-based method, which calculates *model uncertainty* using MC Dropout (Gal and Ghahramani, 2015). (4) **BADGE** (Ash et al., 2020): It first selects high uncertainty samples then uses KMeans++ over the gradient embedding to sample data. (5) **ALPS** (Yuan et al., 2020): It uses the masked language model (MLM) loss of BERT to query labels for samples. (6) **CAL** (Margatina et al., 2021b) is the most recent AL method for pretrained LMs. It calculates the uncertainty of each sample based on the KL divergence between the prediction of itself and its neighbors' prediction.

Semi-supervised Active Learning (SSAL) Methods: (1) **ASST** (Tomanek and Hahn, 2009; Siméoni et al., 2020) is an active semi-supervised learning method that jointly queries labels for AL and samples pseudo labels for self-training. (2) **CEAL** (Wang et al., 2016) acquires annotations on informative samples, and uses high-confidence

---

[4] This is often neglected in previous low-resource AL studies, and we highlight it to ensure the true low-resource setting.

samples with predicted pseudo labels for weights updating. (3) **BASS** (Rottmann et al., 2018) is similar to CEAL, but use MC dropout for querying labeled sample. (4) **REVIVAL** (Guo et al., 2021) is the most recent SSAL method, which uses an adversarial loss to query samples and leverage label propagation to exploit adversarial examples.

Our Method: We experiment with both Entropy and CAL as uncertainty measures for ACTUNE. Note that when compared with active learning baselines, we do not augment the train set with pseudo-labeled data (Eq. (9)) to ensure fair comparisons.

3.2 Main Result

Figure 1 reports the performance of ACTUNE and the baselines on 4 benchmarks. From the results, we have the following observations:

- ACTUNE consistently outperforms baselines in most of the cases. Different from studies in the computer vision (CV) domain (Siméoni et al., 2020) where the model does not perform well in the low-data regime, pre-trained LM has achieved competitive performance with only a few labeled data, which makes further improvements to the vanilla fine-tuning challenging. Nevertheless, ACTUNE surpasses baselines in more than 90% of the rounds and achieves 0.4%-0.7% and 0.3%-1.5% absolute gain at the end of AL and SSAL respectively. Figure 3 quantitatively measures the number of labels needed for the most advanced active learning model and self-training model (UST) to outperform ACTUNE with 1000 labels. These baselines need >2000 clean labeled samples to reach the performance as ours. ACTUNE saves on average **56.2%** and **57.0%** of the labeled samples than most advanced active learning and self-training baselines respectively, which justifies its promising performance under low-resource scenarios. Such improvements show the merits of two key designs under our active self-training framework: the region-aware sampling for active learning and the momentum-based memory bank for robust self-training, which will be discussed in the section 3.5.
- Compared with the previous AL baselines, ACTUNE can bring consistent performance gain, while previous semi-supervised active learning methods cannot. For instance, BASS is based on BALD for active learning, but sometimes it performs even worse than BALD with the same number of labeled data (see Fig. 1(b) and Fig. 1(f)). This is mainly because previous methods simply combine noisy pseudo labels with clean labels for training without explicitly rectifying the wrongly-labeled data, which will cause the LM to overfit these hazardous labels. Moreover, previous methods do not exploit momentum updates to stabilize the learning process, as there are oscillations in the beginning rounds. In contrast, ACTUNE achieves a more stable learning process and enables an active self-training process to benefit from more labeled data.
- The self-training methods (ST & UST) achieve superior performance with limited labels. However, they mainly focus on leveraging unlabeled data for improving the performance, while our results demonstrate that adaptive selecting the most useful data for fine-tuning is also important for improving the performance. With a powerful querying policy, ACTUNE can improve these self-training baselines by 1.05% in terms of accuracy on average.

3.3 Weakly-supervised Learning

ACTUNE can be naturally used for weakly-supervised classification, where $\mathcal{X}_l$ is a set of noisy labels derived from linguistic patterns or rules. Since the initial label set is noisy, the model trained with Eq. (1) can overfit the label noise (Zhang et al., 2022a), and we can actively query labeled data to refine the model. We conduct experiments on the TREC and Chemprot dataset[5], where we first use Snorkel (Ratner et al., 2017) to obtain weak label set $\mathcal{X}_l$, then fine-tune the pre-trained LM $f(\theta^{(0)})$ on $\mathcal{X}_l$. After that, we adopt ACTUNE for active self-training.

Fig. 2 shows the results of these two datasets[6]. When combining ACTUNE with CAL, the performance is unsatisfactory. We believe it is because CAL requires clean labels to calculate uncertainties. When labels are inaccurate, it will prevent ACTUNE from querying informative samples. In contrast, ACTUNE achieves the best performance over baselines when using Entropy as the uncertainty measure. The performance gain is more notable on the TREC dataset, where we achieve 96.68% accuracy, close to the fully supervised performance (96.80%) with only ∼6% of clean labels.

3.4 Combination with Other AL Methods

Fig. 5(a) demonstrates the performance of ACTUNE combined with other AL methods (e.g. BADGE, ALPS) on SST-2 dataset. It is clear that even if the AL methods are not uncertainty-based

---

[5] Details for labeling functions are in Zhang et al. (2021).

[6] We omit AL methods since they perform worse than SSAL methods on these datasets in general.

Figure 2: The comparison of AcTune and baselines on weakly-supervised classification tasks.

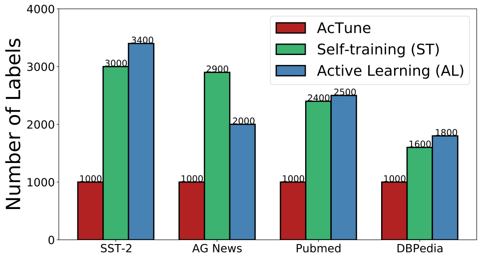

Figure 3: The label-efficiency of AcTune compared with AL and self-training baselines. According to Fig. 1, the best AL method is Entropy for DBPedia and CAL for others.

(e.g. BADGE), when using the *entropy* as an uncertainty measure to select pseudo-labeled data for self-training, AcTune can further boost the performance. This indicates that AcTune is a general active self-training approach, as it can serve as an efficient plug-in module for existing AL methods.

3.5 Ablation and Hyperparameter Study

The Effect of Different Components in AcTune. We inspect different components of AcTune, including the region-sampling (RS), momentum-based memory bank (MMB), and weighted clustering (WClus)[7]. Experimental results (Fig. 5(b)) shows that all the three components contribute to the final performance, as removing any of them hurts the classification accuracy. Also, we find that when removing MMB, the performance hurts most in the beginning rounds, which indicates that MMB effectively suppresses label noise when the model's capacity is weak. Conversely, removing WClus hurts the performance on later rounds, as it enables the model to select most informative samples.

Hyperparameter Study. We study two hyperparameters, namely β and K used in querying labels. Figure 4(a) and 4(b) show the results. In general, the model is insensitive to β as the performance difference is less than 0.6%. The model cannot perform well with smaller K since it cannot pinpoint to high-uncertainty regions. For larger K, the performance also drops as some of the high-uncertainty regions can be outliers and sampling from them would hurt the model performance (Karamcheti et al., 2021).

A Closer Look at the Momentum-based Memory Bank. To examine the role of MMB, we show the overall accuracy of pseudo-labels on AG News dataset in Fig. 4(c). From the result, it is clear that the momentum-based memory bank can stabilize the active self-training process, as the accuracy of pseudo labels increases around 1%, especially in

---

[7] For models w/o RS, we directly select samples with highest uncertainty during AL. For models w/o MMB, we only use the prediction from the current round for self-training. For models w/o WClus, we cluster data with vanilla K-Means.

later rounds. Fig 4(d) and 4(e) illustrates the model performance with different m_L and m_H. Overall, we find that our model is robust to different choices as AcTune outperform the baseline without momentum update consistently. Moreover, we find that the larger m_H will generally lead to better performance in later rounds. This is mainly because in later rounds, the model's prediction is more reliable. Conversely, at the beginning of the training, the model's prediction might be oscillating on unlabeled data. In this case, using a smaller m_L will favor samples with consistent predictions to improve the robustness of active self-training.

Another finding is that for different AL methods, the optimal memory bank can be different. For Entropy, probability-based memory bank leads to a better result, while for CAL, simple aggregating over uncertainty score achieves better performance. This is mainly because the method used in CAL is more complicated, and using probability-based memory bank may hurt the uncertainty calculation.

3.6 Case Study

We give an example of our querying strategy on AG News dataset for the 1st round of active self-training process in figure 6. Note that we use t-SNE algorithm (Van der Maaten and Hinton, 2008) for dimension reduction, and the black triangle stands for the queried samples while other circles stands for the unlabeled data. We can see that the existing uncertainty-based methods such as Entropy and CAL, are suffered from the issue of limited diversity. However, when combined with AcTune, the diversity is much improved. Such results, compared with the main results in figure 1, demonstrate the efficacy of AcTune empirically.

4 Related Work

Active Learning. Active learning has been widely applied to various NLP tasks (Yuan et al., 2020; Shelmanov et al., 2021; Karamcheti et al., 2021). So far, AL methods can be categorized into uncertainty-based methods (Gal et al., 2017; Margatina et al., 2021a,b), diversity-based methods (Ru et al., 2020; Sener and Savarese, 2018) and hybrid methods (Yuan et al., 2020; Ash et al., 2020). Ein-Dor et al. (2020) offer an empirical study of active learning with PLMs. Very recently, there are also several works attempted to query labeling functions for weakly-supervised learning (Boecking et al., 2020; Hsieh et al., 2022; Zhang et al., 2022b). In our study, we leverage the power of unlabeled instances via self-training to further promote the performance of AL.

Semi-supervised Active Learning (SSAL). Gao et al. (2020); Guo et al. (2021) design query strategies for specific semi-supervised methods, Zhang et al. (2020a); Jiang et al. (2020) combine active learning with data augmentation and Tomanek and Hahn (2009); Rottmann et al. (2018); Siméoni et al. (2020) exploit the most-certain samples from the unlabeled with pseudo-labeling to augment the training set. So far, most of the SSAL approaches are designed for CV domain and it remains unknown how this paradigm performs with PLMs on NLP tasks. In contrast, we propose AcTune to effectively leverage unlabeled data during finetuning PLMs for NLP tasks.

Self-training. Self-training is one of the earliest and simplest approaches to semi-supervised learning (Lee, 2013). It first generates pseudo labels for high-confidence samples, then fits a new model on pseudo labeled data to improve the generalization ability. However, it is known to be vulnerable to error propagation (Arazo et al., 2020; Rizve et al., 2021; Zuo et al., 2021). To alleviate this, we adopt a simple momentum-based method to select high confidence samples, effectively reducing

Figure 6: Visualization of the querying strategy of AcTune. Black dots stand for the queried data points. Different colors indicates different categories.

the pseudo labels noise for active learning. Note that although Mukherjee and Awadallah (2020); Rizve et al. (2021) also leverage uncertainty information for self-training, their focus is on developing better self-training methods, while we aim to jointly query high-uncertainty samples and generate pseudo-labels for low-uncertainty samples. The experiments in Sec. 3 show that with appropriate querying methods, AcTune can further improve the performance of self-training.

5 Conclusion and Discussion

In this paper, we develop AcTune, a general active self-training framework for enhancing both label efficiency and model performance in fine-tuning pre-trained language models (PLMs). We propose a region-aware sampling approach to guarantee both the uncertainty the diversity for querying labels. To combat the label noise propagation issue, we design a momentum-based memory bank to effectively utilize the model predictions for preceding AL rounds. Empirical results on 6 public text classification benchmarks suggest the superiority of AcTune to conventional active learning and semi-supervised active learning methods for fine-tuning PLMs with limited resources.

There are several directions to improve AcTune. First, since our focus is on fine-tuning pre-trained language models, we use the representation of `[CLS]` token for classification. In the future work, we can consider using prompt tuning (Gao et al., 2021; Schick and Schütze, 2021), a more data-efficient method for adopting pre-trained language models on classification tasks to further promote the efficiency. Also, due to the computational resource constraints, we do not use larger pre-trained language models such as RoBERTa-large (Liu et al., 2019) which shown even better performance with only a few labels (Du et al., 2021). Moreover, we can explore more advanced uncertainty estimation approach (Kong et al., 2020) into AcTune to further improve the performance. Last, apart from the text classification task, we can also extend our work into other tasks such as sequence labeling and natural language inference (NLI).

A Datasets Details

A.1 Data Source

The seven benchmarks in our experiments are all publicly available. Below are the links to downloadable versions of these datasets.

◇ *SST-2*: We use the datasets from `https://huggingface.co/datasets/glue`.

◇ *AGNews*: We use the datasets from `https://huggingface.co/datasets/ag_news`.

◇ *Pubmed-RCT*: Dataset is available at `https://github.com/Franck-Dernoncourt/pubmed-rct`.

◇ *DBPedia*: Dataset is available at `https://huggingface.co/datasets/dbpedia_14`.

For two weakly-supervised classification tasks, we use the data from WRENCH benchmark (Zhang et al., 2021).

◇ *TREC*: Dataset is available at `https://drive.google.com/drive/u/1/folders/1v55IKG2JN9fMtKJWU48B_5_DcPWGnpTq`.

◇ *ChemProt*: The raw dataset is available at `http://www.cbs.dtu.dk/services/ChemProt/ChemProt-2.0/`. The preprocessed dataset is available at `https://drive.google.com/drive/u/1/folders/1v55IKG2JN9fMtKJWU48B_5_DcPWGnpTq`.

A.2 Train/Test Split

For all the datasets, we use the original train/dev/test split from the web. To keep the size of the development set small, we randomly sample 1000 data for *SST-2, AGNews, Pubmed-RCT, DBPedia* and randomly sample 500 samples for *TREC, ChemProt*.

B Details on Implementation and Experiment Setups

B.1 Computing Infrastructure

System: Ubuntu 18.04.3 LTS; Python 3.6; Pytorch 1.6.
CPU: Intel(R) Core(TM) i7-5930K CPU @ 3.50GHz.
GPU: NVIDIA 2080Ti.

B.2 Number of Parameters

ACTUNE and all baselines use Roberta-base (Liu et al., 2019) with a task-specific classification head on the top as the backbone, which contains 125M trainable parameters. We do not introduce any other parameters in our experiments.

B.3 Experiment Setups

Following (Ein-Dor et al., 2020; Yuan et al., 2020; Margatina et al., 2021b), all of our methods and baselines are run with 3 different random seed and the result is based on the average performance on them. This indeed creates 4 (the number of datasets) $\times$ 3 (the number of random seeds) $\times$ 11 (the number of methods) $\times$ 10 (the number of fine-tuning rounds in AL) = 1320 experiments for fine-tuning PLMs, which is almost the limit of our computational resources, not to mention additional experiments on weakly-supervised text classification as well as different hyper-parameter tuning. We have show both the mean and the standard deviation of the performance in our experiment sections. All the results have passed a paired t-test with $p < 0.05$ (Dror et al., 2018).

B.4 Hyper-parameters for General Experiments

We use AdamW as the optimizer, and the learning rate is chosen from $1 \times 10^{-5}, 2 \times 10^{-5}\}$. A linear learning rate decay schedule with warm-up 0.1 is used, and the number of training epochs is 15 for fine-tuning. For active self-training & SSAL baselines, we tune the model with 2000 steps, and evaluate the performance on the development set in every 50 steps. Finally, we use the model with best performance on the development set for testing.

B.5 Hyper-parameters for ACTUNE

Although ACTUNE introduces several hyper-parameters including K, M, m_L, m_H, β,γ, λ, most of them are keep fixed during our experiments, thus it does not require heavy hyper-parameter tuning. All results are reported as the average over three runs.

In our experiments, we keep $\beta = 0.5$, $\lambda = 1$ for all datasets. For other parameters, we use a grid search to find the optimal setting for each datasets. Specifically, we search γ from $[0.5, 0.6, 0.7]$, m_L from $[0.6, 0.7, 0.8]$, m_H from $[0.8, 0.9, 1]$. For ACTUNE with Entropy, we use probability based aggregation and for ACTUNE with CAL, we use value

Hyper-parameter	**SST-2**	**AG News**	**Pubmed**	**DBPedia**	**TREC**	**Chemprot**
Dropout Ratio	0.1					
Maximum Tokens	32	96	96	64	64	128
Batch Size for $\mathcal{X}_l$	8					
Batch Size for $\mathcal{X}_u$ in Self-training	32	48	48	32	16	24
Weight Decay	10^{-8}					
Learning Rate	2×10^{-5}					
β	0.5					
M	25	30	30	40	40	40
K	5	10				
γ	0.7	0.6				
m_L	0.8	0.9	0.7	0.8	0.8	0.8
m_H	0.9	0.9	0.8	0.9	0.9	1.0
λ	1					

Table 2: Hyper-parameter configurations. Note that we only keep certain number of tokens.

Method	Dataset	
	Pubmed	DBPedia
Finetune (Random)	<0.1s	<0.1s
Entropy (Holub et al., 2008)	461s	646s
BALD (Gal et al., 2017)	4595s	6451s
ALPS (Yuan et al., 2020)	488s	677s
BADGE (Ash et al., 2020)	554s	1140s
CAL (Margatina et al., 2021b)	493s	688s
REVIVAL (Guo et al., 2021)	3240s	OOM
ACTUNE + Entropy	477s	733s
w/ RS for Active Learning	15.8s	44.9s
w/ MMB for Self-training	0.12s	0.18s
ACTUNE + CAL	510s	735s
w/ RS for Active Learning	16.6s	46.4s
w/ MMB for Self-training	0.12s	0.18s

Table 3: The running time of different baselines. Note that for ASST, CEAL and BASS, they directly use existing active learning methods so we do not list the running time here.

based aggregation by default.

C Runtime Analysis

Table 3 shows the time in one active learning round of ACTUNE and baselines. Here we highlight that the additional time for region-aware sampling and momentum-based memory bank is *rather small* compared with the inference time. Also, we find that BALD and REVIVAL are not so efficient. For BALD, it needs to infer the uncertainty of the model by passing the data to model with multitple times. Such an operation will make the total inference time for PLMs very long. For REVIVAL, we find that calculating the adversarial gradient needs extra forward passes and backward passes, which could be time-consuming for PLMs with millions of parameters[8].

---

[8] The original model is proposed with CV tasks and they use ResNet-18 as the backbone which only contains 11M parameters (around 10% of the parameters of Roberta-base).

Label Anchored Contrastive Learning for Language Understanding

Zhenyu Zhang, Yuming Zhao, Meng Chen, Xiaodong He
JD AI, Beijing, China
`{zhangzhenyu47,zhaoyuming3,chenmeng20,xiaodong.he}@jd.com`

Abstract

Contrastive learning (CL) has achieved astonishing progress in computer vision, speech, and natural language processing fields recently with self-supervised learning. However, CL approach to the supervised setting is not fully explored, especially for the natural language understanding classification task. Intuitively, the class label itself has the intrinsic ability to perform hard positive/negative mining, which is crucial for CL. Motivated by this, we propose a novel label anchored contrastive learning approach (denoted as LaCon) for language understanding. Specifically, three contrastive objectives are devised, including a multi-head instance-centered contrastive loss (ICL), a label-centered contrastive loss (LCL), and a label embedding regularizer (LER). Our approach does not require any specialized network architecture or any extra data augmentation, thus it can be easily plugged into existing powerful pre-trained language models. Compared to the state-of-the-art baselines, LaCon obtains up to 4.1% improvement on the popular datasets of GLUE and CLUE benchmarks. Besides, LaCon also demonstrates significant advantages under the few-shot and data imbalance settings, which obtains up to 9.4% improvement on the FewGLUE and FewCLUE benchmarking tasks.

1 Introduction

In recent years, contrastive learning (CL) has been widely applied to self-supervised representation learning and led to major advances across computer vision (CV) (He et al., 2019; Chen et al., 2020b), speech (Saeed et al., 2021; Chen et al., 2021), and natural language processing (NLP) (Fang and Xie, 2020; Gao et al., 2021; Yan et al., 2021). The basic idea behind these works is to pull together an anchor and a "positive" sample in the embedding space, and to push apart the anchor from many "negative" samples. Since no labels are available, a positive pair often consists of data augmentations of the sample (a.k.a "views"), and negative pairs are formed by the anchor and randomly chosen samples from the mini-batch. In visual representations, an effective solution to generate data augmentations is to take two random transformations of the same image (e.g., cropping, flipping, distortion and rotation) (Chen et al., 2020b; Grill et al., 2020; Chen et al., 2020c). For natural language, similar approaches are adopted such as word deletion, reordering, substitution, and back-translation etc. (Fang and Xie, 2020; Wang et al., 2021) However, data augmentation in NLP is inherently difficult because of its discrete nature. Therefore, some previous works (Gao et al., 2021; Yan et al., 2021) also use dropout technique (Srivastava et al., 2014) to obtain sentence augmentations.

Unlike self-supervised setting, some researchers propose supervised contrastive learning (SCL) (Khosla et al., 2020; Gunel et al., 2021; Suresh and Ong, 2021) which can construct positive pairs by leveraging label information. Examples from the same class are pulled closer than the examples from different classes, leveraging the semantics of labels to construct negatives and positives rather than shallow lexical information via data augmentation. Despite the aforementioned advantages brought by SCL, we argue that CL under supervised learning is not fully explored because the label information can be better utilized. On the one hand, labels are usually not merely categorical indices in the label vocabulary, but also contain specific semantic meanings, especially in the language understanding tasks. Thus labels can be used as positive/negative samples or anchors when calculating contrastive loss. On the other hand, label embedding enjoys a built-in ability to leverage alternative sources of information related to labels, such as class hierarchies or textual descriptions. Once we obtain representative label embeddings, they can be utilized to enhance the image/text representations, and finally facilitate the classification task. Previous la-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1437 - 1449
July 10-15, 2022 ©2022 Association for Computational Linguistics

bel embedding based classification models (Wang et al., 2018; Xiao et al., 2019) have demonstrated the effectiveness of leveraging label information.

Motivated by above analysis, we propose a novel label anchored supervised contrastive learning approach (denoted as LaCon), which combines the advantages of both contrastive learning and label embedding techniques. Specifically, we have the following three novel designs: 1) Instance-centered contrastive loss (ICL), which uses the InfoNCE (van den Oord et al., 2018) to encourage each text representation and its corresponding label representation to be closer while pushing far away mismatched instance-label pairs. We further apply a multi-head mechanism to catch different aspects of text semantics. 2) Label-centered contrastive loss (LCL), which takes label as anchor, and encourages the label representation to be more similar to the corresponding instances belonging to the same class in a mini-batch than the instances with different labels. 3) Label embedding regularizer (LER), which keeps the inter-label similarity as low as possible thus the feature space of each class is more dispersed to prevent representation degeneration. By combining above three losses, LaCon can learn good semantic representations within the same space for both input instances and labels. It's also well aligned with the two key properties related to CL: alignment and uniformity (Wang and Isola, 2020), where alignment favors encoders that assign similar features to similar samples. Uniformity prefers a feature distribution that preserves maximal information, i.e., the uniform distribution on the unit hypersphere.

To validate the effectiveness of LaCon, we perform extensive experiments on eight language understanding tasks. We take the popular pre-trained language model BERT-base (Devlin et al., 2019) as text encoder without loss of generality. For simplicity, we predict the classification label by matching the instance representation with label embeddings directly. Since our approach does not require any specialized network architecture or any extra data augmentation, LaCon can be easily plugged into other pre-trained language models. Additionally, we also explore the capability of LaCon under more difficult task settings, including few-shot learning and data imbalance situations.

To summarize, our contributions are as follows:

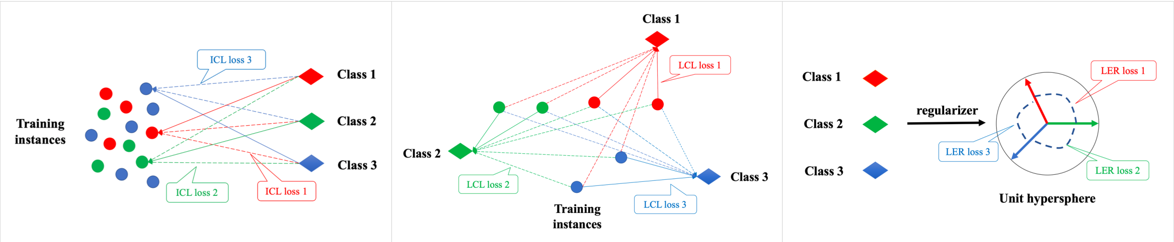
- We propose a novel label anchored contrastive learning approach for language understanding, which is equipped with a multi-head instance-centered contrastive loss, a label-centered contrastive loss, and a label embedding regularizer. All three contrastive objectives help the model learn the joint semantic representations for both input instances and labels.
- We conduct extensive experiments on eight public language understanding tasks from GLUE (Wang et al., 2019) and CLUE (Xu et al., 2020) benchmarks, and experimental results show the competitiveness of LaCon. Additionally, we also experiment on more difficult settings including few-shot learning and data imbalance situations. LaCon experimentally obtains up to 9.4% improvement over BERT-base on FewGLUE (Schick and Schütze, 2021) and FewCLUE (Xu et al., 2021) benchmark tasks.
- We analyze the contribution of each ingredient of LaCon, and also visualize the learned instance and label representations, showing the necessity of each loss component and the advantage of LaCon on representation learning over BERT fine-tuned with cross entropy.

2 Model

In this section, we introduce the details of LaCon. We focus on the language understanding classification tasks. For a multi-class classification problem with C classes, we work with a batch of training examples $\{x_i, y_i\}$, where $1 \leq i \leq N$ and $1 \leq y_i \leq C$. Our target is to learn discriminative representations for both instances and class labels. As Figure 1 shows, we propose three supervised CL based objectives, including the instance-centered contrastive loss, the label-centered contrastive loss, and the label embedding regularizer loss.

2.1 The Input Encoder

The input of LaCon contains two parts consisting of the text and all the labels for the task. Since SOTA language understanding classification models follow the "pre-training then fine-tuning" two-stage paradigm, here we take the prevalent pre-trained language model (PtLM) as input encoder. In this paper, we select BERT-base (Devlin et al., 2019) as the backbone for PtLM (denoted as f) without loss of generality. Given a text $\mathbf{x} = \{w_1, w_2, ..., w_M\}$ containing M tokens, the output of PtLM (i.e. BERT) is $\mathbf{E} = f_{PtLM}([CLS], w_1, ..., w_M)$ where



(a) Instance-centered Contrastive Loss **(b) Label-centered Contrastive Loss** **(c) Label Embedding Regularizer Loss**

Figure 1: Overview of LaCon. The full line is the similarity between a instance and corresponding label, and the dash line is the similarity between the mismatched instance and label. The lines with the same color denote the per-instance or per-label loss.

the $[CLS]$ token is the inserted sentence representation token and $\mathbf{E} \in R^{(M+1)\times d}$. d is the dimension of the model. We use the first token output $E_{[CLS]} \in R^d$ to represent the whole input text. We then apply a projection head (denoted as g) that is a 3-layer MLP with ReLU activation function for each hidden layer to the $E_{[CLS]}$, where the dimension of the g is also d. For a mini-batch X with N training samples, the text representations can be obtained as Equation 1.

$$\begin{gathered} H = g \circ f_{PtLM}(X), \text{ where} \\ X = x_1, x_2, ..., x_N \ and \ H \in R^{N\times d} \end{gathered} \tag{1}$$

Along with each mini-batch, LaCon also maps the C classes into C label embeddings. For simplicity, we look up in a learnable weight matrix W_{emb} and map the k^{th} label into the k^{th} row of W_{emb}, where the W_{emb} is randomly initialized. The dimension d is the same as PtLM. We then normalize the vectors for both L and H using the l_2 norm.

$$\begin{gathered} L = lookup([1, 2, ..., C], W_{emb}) \\ \text{where } L \in R^{C\times d} \ and \ W_{emb} \in R^{C\times d} \end{gathered} \tag{2}$$

2.2 Instance-centered Contrastive Loss

Given a mini-batch of input text and corresponding label (x_i, y_i), as shown in Figure 1 (a), the instance-centered contrastive loss (ICL) takes each instance x_i as anchor, and mines positive and negative samples from class labels. ICL aims to encourage each text representation and corresponding label representation to be closer while pushing far away mismatched instance-label pairs. As shown in Equation 3, we modify the InfoNCE (van den Oord et al., 2018) to calculate the loss. Here we leverage the cosine similarity function as the distance metric sim. τ is the temperature hyper-parameter, which can be tuned to improve the performance. Lower temperature increases the influence of examples that are harder to separate, effectively creating harder negatives. Similar to the self-supervised CL, ICL also takes only one positive and many negatives. Differently, the positive is not generated from data augmentation, and the negatives are not randomly sampled from the same mini-batch. By treating the class labels as data samples, ICL can mine better positive and negatives with the supervision signal. By minimizing the ICL, the instance representation is aligned to its label representation in the same semantic space, which encourages the model to learn a more representative embedding for each class label.

$$\mathcal{L}_{ICL} = -\frac{1}{N}\sum_{x_i, y_i} log \frac{exp(sim(H_{x_i}, L_{y_i})/\tau)}{\sum_{1\leq p\leq C} exp(sim(H_{x_i}, L_p)/\tau)} \tag{3}$$

Inspired by the image-augmented views proposed in CV (He et al., 2019; Chen et al., 2020b,c; Grill et al., 2020), we also leverage the multi-head mechanism proposed in Transformer (Vaswani et al., 2017) to compute the ICL for each head representation with smaller representation dimension. Each head can be regarded as a clipped local view of the instance or label representation. Suppose we have m heads for both instance representation and label representation, then for the k_{th} head, the corresponding representations for training sample (x_i, y_i) are $h^k_{x_i}$ and $l^k_{y_i}$, and the dimension of each vector becomes $d' = d/m$. Then, we apply the contrastive loss for each head by following Equation 4. Compared with InfoNCE, $\mathcal{L}_{ICL}$ and $\mathcal{L}'_{ICL}$ do not suffer from small batch size issue (He et al., 2019; Chen et al., 2020c) because we only need to contrast the instance representation with corresponding label representation for per example loss.

$$\mathcal{L}'_{ICL} = -\frac{1}{N}\sum_{k=1}^{m}\sum_{x_i, y_i} log \frac{exp(sim(h^k_{x_i}, l^k_{y_i})/\tau)}{\sum_{1\leq p\leq C} exp(sim(h^k_{x_i}, l^k_p)/\tau)} \tag{4}$$

2.3 Label-centered Contrastive Loss

As shown in Figure 1 (b), we can take the class label in a mini-batch as anchor, and mine positive/negative samples from corresponding instances. Suppose there are $|P|$ classes in the batch, where $P = \{p|1 \leq p \leq C \wedge |A(p)| > 0\}$. We define that $A(p)$ denotes the set of indices of all positive instances whose label is p, i.e. $A(p) = \{x_i|y_i = p\}$. And $B(p)$ represents the set of negative instances whose label is not p, i.e. $B(p) = \{x_j|y_j \neq p\}$. Then we can calculate the label-centered contrastive loss (LCL) as Equation 5, which promotes the instances of a specific label to be more similar than the others for each label. Similar to the previous SCL (Khosla et al., 2020; Gunel et al., 2021), LCL also contains many positives per anchor and many negatives. Different from SCL which sums up all the softmax scores among all pairs of instances of the same class in a batch, LCL is based on comparing a specific label representation with corresponding instances (i.e. $A(p)$). LCL is more stable as the label representation serves as the anchor which can be stably updated.

$$\mathcal{L}_{LCL} = -\frac{1}{|P|} \sum_{p \in P} \sum_{a \in A(p)} log \frac{exp(sim(L_p, H_a)/\tau)}{\sum_{b \in B(p)} exp(sim(L_p, H_b)/\tau)} \quad (5)$$

ICL and LCL are complementary to each other and more computationally efficient than previous SCL. We conduct the detailed theoretical analysis in Appendix A.3 due to space limitation.

2.4 Label Embedding Regularizer

Recent researches (Wang and Isola, 2020) demonstrate that it is common and useful to add a regularization term during training to eliminate the anisotropy problem. Inspired by this, We devise a label embedding regularizer as shown in Equation 6 to promote the uniformity of our model and prevent model degeneration. As illustrated in Figure 1 (c), the label embedding regularizer (LER) encourages the label representations to be dispersed in the unit hypersphere uniformly. The LER loss is the exponential mean of the cosine similarity for all pairs of label representations. As $-1 \leq sim(L_i, L_j) \leq 1$, it is quite sensitive to the loss change as the gradient is larger than 1 for $exp(x)$ w.r.t $x \geq 0$. Thus, we add 1.0 to the cosine similarity so that the value of LER varies from 0 to e^2 - 1.

$$\mathcal{L}_{LER} = avg(\sum_{i \neq j}(exp(1.0 + sim(L_i, L_j)) - 1.0) \quad (6)$$

Finally, the overall loss function of LaCon is summarized as follows:

$$\mathcal{L} = \mathcal{L}'_{ICL} + \mathcal{L}_{LCL} + \lambda * \mathcal{L}_{LER} \quad (7)$$

where λ is a hyper-parameter to balance the influence of our regularization term.

2.5 Matching based Class Prediction

Since LaCon is capable of learning instance and label representations jointly, we can predict the class by matching the instance representation to all label representations directly during inference, just as shown in Equation 8. We denote this simple and direct approach as **LaCon-vanilla**. H_x is the instance representation and L_j is the label representation of Class j. sim denotes the cosine similarity and $1 \leq j \leq C$ denotes the corresponding label. The advantage of LaCon-vanilla is that it does not require any complicated network architecture and can be easily plugged into the mainstream PtLMs. As a result, our inference-time model contains exactly the same number of parameters as the model using the same encoder but trained with cross entropy loss.

$$pred = \arg_{max}(j)\{score_j|sim(H_x, L_j)\} \quad (8)$$

2.6 LaCon with Label Fusion

Previous researches (Akata et al., 2016; Wang et al., 2018; Xiao et al., 2019; Pappas and Henderson, 2019; Miyazaki et al., 2020) have proved that incorporating the label semantics into the sentence representation can improve the model performance because the label information can highlight the alignment of input tokens and label information via carefully designed fusion mechanism. Inspired by LEAM (Wang et al., 2018), here we design a fusion block to enhance the instance representations by utilizing the learnt discriminative label embeddings. We firstly calculate the cosine similarity interaction matrix G between words and labels, and then apply a convolution then max-pooling layer ($conv_{max}$) to measure the attention score (β_i) for each word attending the instance representation. The fusion process is illustrated as Equation 9. Then the fused vector z is fed into the projection head g to get the enhanced instance representation.

$$\begin{aligned} m &= conv_{max}(G), \text{ where } G_{ij} = \frac{< L_i, E_j >}{||L_i|| \cdot ||E_j||} \\ z &= \sum_i \beta_i E_i, \text{ where } \beta = softmax(m) \end{aligned} \quad (9)$$

To distinguish with the vanilla model above, we name this approach as **LaCon-fusion**. Please note that the fusion block is just applied between the text encoder and projection head, so the class prediction keeps the same as the LaCon-vanilla. Since the fusion block is not the main focus of this paper, we leave exploring more advanced fusion networks to future work.

3 Experiments

3.1 Experimental Setup

Datasets. We experiment on 8 public datasets listed in Table 1. which are from GLUE (Wang et al., 2019), CLUE (Xu et al., 2020), DBpedia, and Yelp Dataset Challenge 2015. They cover five representative tasks including sentiment analysis (senti), genre classification (genre), paragraph identification (PI), natural language inference (NLI) and linguistic acceptability (LA). To improve the comparability and experiment confidence of the models, we follow the experimental setup in (Chen et al., 2020a) and use part of the training sets via sampling and the full original test sets for evaluation. We randomly sample without replacement at most 5K (binary-class) / 1K (multi-class) training instances per class from the whole datasets except for MRPC, RTE, and CoLA. We use the wilcoxon rank test (Wilcoxon, 1945) to check the statistic significance. The results of 10 runs are reported for each dataset in the format as "avg$\pm std.dev$".

Training & Evaluation. During training, we run experiments for MRPC, RTE and CoLA with 10 random seeds on the whole training datasets and run the sampling strategy with 10 repeats for the remaining datasets. The average evaluation metrics are reported to avoid the noise and unstable randomness of a single run. We use the AdamW optimizer with initial learning rate as {1e-5, 2e-5, 3e-5} with linear learning scheduler, 6% of warm-up steps of total optimization steps, and batch size as {8,16,32,64,96}, where the hyper-parameters are tuned for different datasets. For evaluation, we leverage accuracy (ACC), Macro-F1 score and Matthew's corr (M' corr) metrics to evaluate the performance. We run 10 epochs for all the datasets[1] and then evaluate the models on dev set. Our implementation is based on Huggingface Transformers[2].

3.2 Baselines

Since LaCon is based on CL and label embedding technique, we compare with several SOTA models in language understanding including BERT-base fine-tuned with cross-entropy (CE) loss, label embedding based models, and self-supervised CL and supervised CL models.

- **CE**: we directly follow the instructions of original paper (Devlin et al., 2019) to finetune BERT for both English and Chinese langauge understanding tasks.
- **LEAM**: Wang et al. (2018) apply cosine similarity to get matching scores between words and labels and use CNN on the matching matrix to get the label-aware attention weighted text representation for classification.
- **LSAN**: Xiao et al. (2019) propose a label specific attention network that leverages label-attention and self-attention mechanism with an adaptive attention fusion strategy for multi-label classification. We use *softmax* instead of *sigmoid* for the model output due to our multi-class classification setting.
- **CE+CL**: Yan et al. (2021) propose to learn sentence representations by joint fine-tuning PtLM with InfoNCE and cross-entropy based on feature augmentation. Here we leverage the framework of ConSERT (Yan et al., 2021) and the feature augmentation in SimCSE (Gao et al., 2021) to finetune and evaluate the PtLM on classification datasets.
- **CE+SCL**: Gunel et al. (2021) propose to boost sentence representation learning by fine-tuning PtLM with both supervised contrastive learning loss (Khosla et al., 2020) and cross entropy loss. We follow the instructions in (Gunel et al., 2021) to set hyper-parameters.

---

3.3 Main Results

We report the experimental results of eight language understanding tasks in Table 2. It's observed that, LaCon-vanilla outperforms all the baselines in 7 datasets except MRPC, and LaCon-fusion achieves the best performance across all datasets. Specifically, 1) LaCon-vanilla outperforms BERT fine-tuned with CE by 4.1%, 2.3%, 1.9%, and 1.5% on RTE, Tnews, MRPC, and CoLA respectively, which indicates our proposed novel CL approach can facilitate the representation learning; 2) Compared with previous supervised contrastive learning method (CE+SCL), LaCon-fusion can still obtain very exciting improvements of 3.1%, 2.1%, 1.7%, 1.2% points on RTE, Tnews, YelpRev, QQP, which demonstrates the label fusion block can enhance the instance representations effectively; 3) Compared to previous label embedding methods (LEAM and LSAN) which are also equipped with the label fusion block, LaCon-fusion outperforms them with a large margin, which proves that LaCon can learn more discriminative joint representations for both labels and instances.

3.4 Ablation Study

In this section, we conduct three groups of ablation studies to investigate the contribution of each component in LaCon. We only conduct experiments on MRPC, RTE, and CoLA datasets due to space limitation. The experimental results are shown in Table 3. First, we replace the multi-head ICL with single head version (LaCon w/ $\mathcal{L}_{ICL}$). Table 3 shows the performance drops on all three datasets. We conjecture that the multi-head version can learn different parts of the local features of the representation, which can catch the text semantics in more fine-grained granularity. Second, we remove each of our proposed CL loss separately, and the results in the second part of Table 3 demonstrate that ICL plays a more important role while LCL and LER are complementary to further improve the performance. We also try to add each CL loss in an accumulative way, please refer to Appendix A.1 for more details. Finally, we try to remove the projection head g from LaCon and the performance degrades significantly, which indicates g is critical in CL. Previous researches (Chen et al., 2020c) also find the projector head can eliminate the non-task relevant features of the encoder in CL and benefit the downstream tasks. Meanwhile, Table 3 shows that it is basically useless by adding g to BERT directly (BERT w/ g), indicating that the projector head needs to be used with CL.

4 Discussion

In this section, we conduct further experiments under more challenging few-shot and data imbalance settings. We also discuss the hyper-parameter tuning and the impact of class number on LaCon.

4.1 LaCon for Few-shot Learning

Few-shot learning is critical for applications of language understanding models because the high-quality human annotated datasets are usually costly and limited. Previous researches (Liang et al., 2021; Gunel et al., 2021; Aghajanyan et al., 2021) find that fine-tuning PtLM with cross entropy loss in NLP tends to be unstable across different runs especially when supervised data is limited. This limitation can result in model degeneration and model shift. Besides, some researches (Müller et al., 2019) also demonstrate that the cross-entropy optimization goal is not reachable due to the bounding of the gradient, which can also easily result in overfitting. Since LaCon is equipped by CL, it's interesting to validate if LaCon can overcome the shortcomings of CE under few-shot learning settings.

Model	**YelpRev**	**Tnews**	**EPRSTMT**	**BUSTM**
CE	59.0	52.5	84.4	65.6
LaCon	**65.0**	**55.8**	**90.6**	**75.0**
Model	**QNLI**	**RTE**	**MRPC**	**QQP**
CE	73.0	54.0	65.8	64.0
LaCon	**76.0**	**60.0**	**69.0**	**71.0**

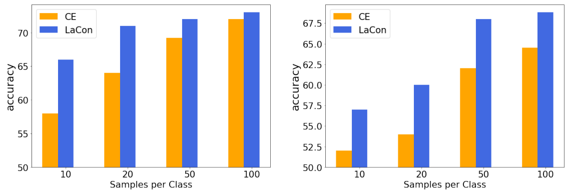
Table 4: Performance under few-shot learning settings.

We conduct further experiments with vanilla LaCon on 5 public English datasets from FewGLUE (Schick and Schütze, 2021) and 3 public Chinese datasets (Tnews, EPRSTMT and BUSTM) from FewCLUE (Xu et al., 2021). We build all the few-shot learning datasets by sampling **20 samples** for each class to form training set. We also held out the same amount of samples for validation set but keep the whole test set unchanged. We train the model for 20 epochs and select the best model based on validation set. Table 4 shows that LaCon significantly outperforms the BERT-base fine-tuned with CE loss with a huge margin. Specifically, we observe 9.4%, 7%, and 6.2% absolute improvement on BUSTM, QQP, and EPRSTMT.

Additionally, we also conduct more strict experiments by changing the number of samples per class from $\{10, 20, 50, 100\}$. Figure 2 demonstrates that the smaller the sample size per class is, the larger gain the model obtains. All above results indicate that the similarity-based CL losses in LaCon are able to hone in on the important dimensions of the multidimensional hidden representations hence lead to better and more stable few-shot learning results when fine-tuning PtLM.

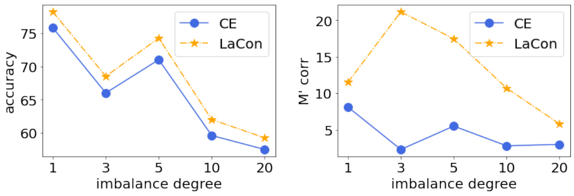
4.2 LaCon for Data Imbalance Setting

The real-world datasets are usually imbalanced for different classes (Cao et al., 2019; Bao et al., 2020), where several dominant classes contain most of the samples while the rest minority classes only hold a handful of samples. In this section, we conduct experiments to validate the capacity of LaCon under data imbalance setting. We follow the previous research (Cao et al., 2019) to construct imbalanced classification training datasets with different imbalance degree ($\rho = |class_{max}|/|class_{min}|$, where $|class_{max}|$ / $|class_{min}|$ denotes number of samples in maximum / minimum class). For space limitation, we conduct experiments with vanilla LaCon on QNLI and CoLA. The minority class contains 32 samples and the majority class contains $32 \times \rho$ in our experiments. As shown in Figure 3, we vary the imbalance degree (ρ) from $\{1, 3, 5, 10, 20\}$ and observe that LaCon outperforms BERT with CE consistently, demonstrating that LaCon also has advantage on the data imbalance setting.



(a) QQP (b) RTE

Figure 2: Few-shot learning with different number of training samples.



(a) QNLI (b) CoLA

Figure 3: LaCon with Different Imbalance Degree (ρ).

	QNLI		**CoLA**	
Methods	**minor**	**major**	**minor**	**major**
CE	43.4	71.8	2.3	81.3
LaCon	56.1	74.0	12.9	82.2

Table 5: F1 score for both majority and minority classes. Due to space limitation, we show results of $\rho = 10$.

We argue that LaCon may alleviate data imbalance issue on two aspects: 1) For the infrequent classes, treating labels as anchor or positive/negative may mitigate the data insufficient issue to some extent. 2) Label representations are shared across the whole dataset during training, which may transfer the knowledge from frequent classes to infrequent classes. To validate above conjecture, we present the performance on the test sets for majority and minority classes separately.

Table 5 shows that LaCon outperforms the baseline on both majority and minority classes and the gain on minority class is much larger.

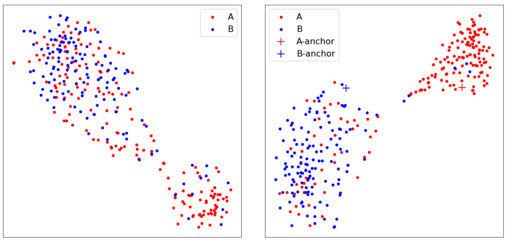
4.3 Visualization

To demonstrate the effectiveness of LaCon on representation learning, we visualize the learned instance representations of LaCon and CE on the MRPC and CoLA dataset. In Figure 4, we use t-SNE (Van der Maaten and Hinton, 2008) to visualize both the high dimensional representations of the instances and labels on a 2D map. Different classes are depicted by different colors. As shown in Figure 4 (a), the instances of class A and class B are sparsely located and overlapped in a large area, making it hard to find a hyper-plane to separate them. However, in Figure 4 (b), the instances gather into two compact clusters and the instances stay close to the corresponding class. For CoLA, Figure 4 (c) and (d) show the similar trends. It indicates that LaCon can learn more discriminative instance representations than CE. Besides, in Figure 4 (b), the instances are near the corresponding label anchor, proving that LaCon can also learn a representative label embedding for each class.

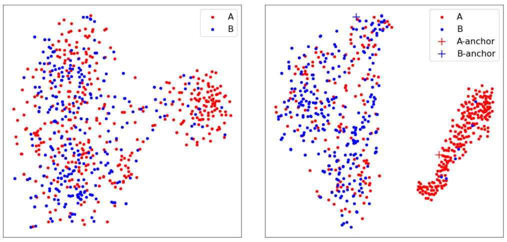
4.4 Hyper-parameter Tuning

In this section, we take the RTE dataset as an example for illustrating the hyper-parameter tuning process. The similar hyper-parameter tuning strategy is applied for other datasets. The tuning scripts will be released in our source code. Figure 5 shows the influence of different hyper-parameters.

For each experiment, we conduct a grid-based hyper-parameter sweep for τ between 0.05 and 0.5 with step 0.05, λ between 0.1 and 1.0 with step 0.1, and select the best hyper-parameter for the given dataset. The τ is the most influential hyper-parameter that needs to be tuned carefully with minimum step 0.05. Larger τ results in lower accuracy in LaCon and the recommended value is around 0.1 and 0.2. Figure 5 (b) illustrates that the optimal number of heads in Equation 4 is 6 and both the most and fewest heads result in low accuracy while heads with middle sizes get relatively better accuracy scores. Small number of head shows little diversity in feature clipping while larger one results in very short vectors with poor representation capacity. The label embedding regularizer weight λ in Figure 5(c) can be set in a wide range, where either without $\mathcal{L}_{LER}$ or large λ will result in poor performance.



(a) CE (b) LaCon



(c) CE (d) LaCon

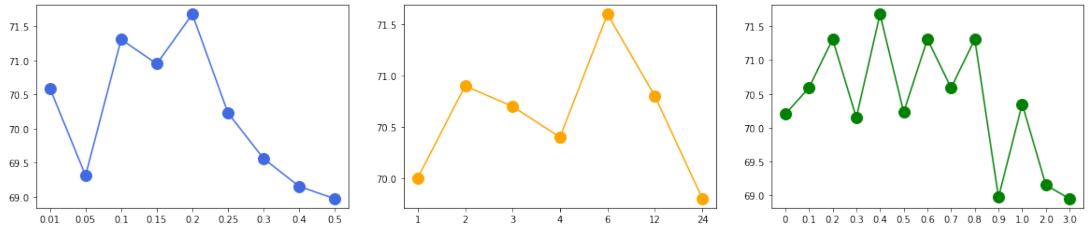
4.5 The Impact of Class Number

As the number of classes influence the difficulty of classification task directly, in this section, we discuss the impact of class number on our proposed model LaCon. We pick the DBPedia dataset for experiment. The original DBPedia dataset includes 14 labels. We gradually increase the label number from 2 to 14 and randomly select 1000 samples for each label in our experiment as training set. Meanwhile, we keep the whole samples for the chosen labels in the evaluation set unchanged. Figure 6 demonstrates that with the increase of the labels, the performance of all models degrades as the task becomes more difficult. However, LaCon-fusion outperforms CE+SCL consistently on different number of labels, which shows the advantage of leveraging labels as anchors or positive/negative samples during contrastive learning.

5 Related Work

5.1 Contrastive Learning

Contrastive Learning has become a rising domain and achieved significant success in various CV, speech and NLP tasks (He et al., 2019; Chen et al., 2020b; Fang and Xie, 2020; Han et al., 2021; Saeed et al., 2021; Gunel et al., 2021; Gao et al., 2021; Yan et al., 2021). There are two kinds of CL approaches, which are self-supervised CL and supervised CL. The self-supervised CL contrasts a



(a) τ (b) $heads$ (c) λ

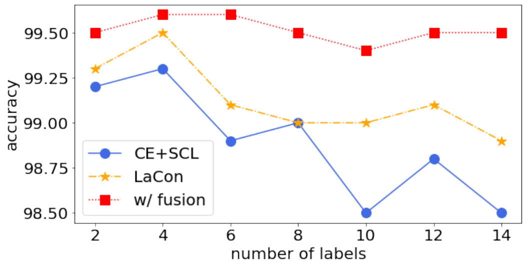

Figure 6: The impact of class number on LaCon. Experiments were conducted on DBPedia.

single positive for each anchor (i.e., an augmented version of the same image) against a set of negatives consisting of the entire remainder of the batch. However, due to the intrinsic discrete nature of natural language, data augmentations are less effective than that in CV. Recently, researchers (Khosla et al., 2020; Gunel et al., 2021) propose supervised CL, which contrasts the set of all samples from the same class as positives against the negatives from the remainder of the batch. Suresh and Ong (2021) propose label-aware SCL method via assigning weights to instances of different labels, which treats the negative samples differently.

LaCon belongs to the scope of supervised CL. Different from (Khosla et al., 2020; Gunel et al., 2021), LaCon can take the labels as anchors or mine negative/positive from labels, which does not need to construct positive pairs from the data augmentation. Meanwhile, Gunel et al. (2021) combine CL and CE losses at the same time, but LaCon is purely equipped with three CL objectives, including the instance-centered contrastive loss, the label-centered contrastive loss and the label embedding regularizer.

5.2 Label Representation Learning

Label representation learning aims to learn the embeddings of labels in classification tasks and has been proven to be effective in various CV (Frome et al., 2013; Akata et al., 2016) and NLP tasks (Tang et al., 2015; Pappas and Henderson, 2019; Nam et al., 2016; Zhang et al., 2018; Wang et al., 2018; Xiao et al., 2019; Miyazaki et al., 2020). In this work, we compare with two representative label embedding based models, which are LEAM (Wang et al., 2018) and LSAN (Xiao et al., 2019). Both learn label embeddings and sentence representations in a joint space based on attention mechanism and fuse them to improve the classification. Differently, LaCon learns the label and instance representations jointly via purely supervised contrastive learning. Besides, our experiments also verify that after obtaining the discriminative label and instance representations, even simple fusion block can facilitate the language understanding tasks.

6 Conclusions

In this paper, we proposed a novel supervised contrastive learning approach for language understanding. To utilize the class labels sufficiently, we devise three novel contrastive objectives, including a multi-head instance-centered contrastive loss, a label-centered contrastive loss, and a label embedding regularizer. Extensive experiments were conducted on eight public datasets from GLUE and CLUE benchmarks, showing the competitiveness of LaCon against various strong baselines. Besides, we also demonstrate the strong capacity of LaCon on more challenging few-shot and data imbalance settings, which leads up to 9.4% improvement on the FewGLUE and FewCLUE benchmarks. LaCon does not require any complicated network architecture or any extra data augmentation, and can be easily plugged into mainstream pre-trained language models. In the future, we will explore more advanced representation fusion approaches to enhance the capability of LaCon and plan to extend LaCon to the computer vision and speech fields.

A Appendix

A.1 Accumulative Ablation Study

In this section, we supplement more ablation results by adding each proposed CL loss cumulatively. We conduct experiments on MRPC, RTE, and CoLA datasets and keep the setting consistent with Section 3.4. Table 6 demonstrates that the contribution of each component in more details.

A.2 Experimental Results of More Datasets

We supplement more experimental results on the remaining datasets of GLUE and CLUE benchmarks. We follow the same experimental setup with Section 3.1. Please note that SST-B is a regression task that is beyond the capacity of the proposed LaCon. The official CLUE benchmark has replaced CMNLI with OCNLI dataset, and the CSL dataset is a keyword recognition task, which is not suitable for our proposed model. Thus, we omit the experiments on above three datasets and report the performance on the remaining language understanding tasks including SST-2, MNLI, AFQMC, OCNLI and IFLYTEK.

Methods	MRPC	RTE	CoLA
$\mathcal{L}_{ICL}$	86.2±1.5	67.8±1.1	61.2±0.9
$\mathcal{L}'_{ICL}$	86.9±1.1	68.2±0.7	61.2±1.5
$\mathcal{L}_{LCL}$	87.0±1.7	68.3±1.0	61.1±1.3
$\mathcal{L}'_{ICL} + \mathcal{L}_{LCL}$	87.3±1.1	70.2±1.3	62.2±1.6
$\mathcal{L}'_{ICL} + \mathcal{L}_{LER}$	87.1±0.6	70.5±0.8	61.2±1.1
LaCon-vanilla	**87.5±0.8**	**71.4±0.7**	**62.4±1.1**

Table 6: Ablation study via adding losses cumulatively.

Table 7 shows that, LaCon-vanilla consistently outperforms BERT fine-tuned with CE, and LaCon-fusion still beats the baselines among all datasets, which further demonstrates the superiority of our proposed method.

A.3 Theoretical Analysis

In this section, we conduct the theoretical analysis to prove the rationality and necessity of our proposed ICL and LCL losses. We also explain why these two losses are complementary. Finally, we analyze the computational efficiency of ICL and LCL compared to InfoNCE (van den Oord et al., 2018) and SCL (Khosla et al., 2020).

The recent researches (Li et al., 2020; Gao et al., 2019) reveal that the anisotropy problem of pre-trained language models, which shows that the learnt embeddings occupy a narrow cone in the dense vector space, harming the uniformity of the models and limiting the representation capacity. The singular values of the contextual embeddings decay drastically with most of them nearly zeros (Wang and Isola, 2020). CL is proposed to eliminate the long-tail distribution problem of singular values, aiming to enhance the representation capacity (Gao et al., 2021; Yan et al., 2021; Gunel et al., 2021). From the spectrum perspective (Wang et al., 2020; Wang and Isola, 2020) that analyzes the distribution and uniformity of the learned embedding space, CL flattens singular values of the embeddings thus improves the capacity of language

Methods	**SST-2**	**MNLI**	**AFQMC**	**OCNLI**	**IFLYTEK**
Baseline*	91.4±0.3	73.1±0.3	74.5±0.3	68.3±0.7	61.5±0.5
CE	91.2±0.1	72.5±0.3	70.9±0.5	66.8±0.4	60.6±0.2
LaCon-vanilla	91.4±0.3	73.3±0.4	72.5±0.3	67.4±0.3	60.9±0.2
LaCon-fusion	**92.5±0.2**	**73.9±0.3**	**74.8±0.5**	**69.1±0.6**	**63.5±0.7**

Table 7: Performance on the remaining datasets of GLUE and CLUE. Baseline* means the best performance of our baselines. The evaluation metrics are the same as the official GLUE (Wang et al., 2019) and CLUE (Xu et al., 2020) benchmarks (all with significance value $p < 0.05$).

models.

$$\begin{aligned}\mathcal{L}_{ICL} &= -\frac{1}{\tau}E_{(x,y)\sim A(y)}(H_x L_y)\\ &+E_{x\sim A(y)}[logE_{y^-\notin A(y)}(e^{H_x L_{y^-}/\tau})]\end{aligned} \tag{10}$$

$$\begin{aligned}&E_{x\sim A(y)}[logE_{y^-\notin A(y)}(e^{H_x L_{y^-}/\tau})]\\ &=\frac{1}{N}\sum_{i=1}^{i=N} log(\frac{1}{C-1}\sum_{j\neq i}^{1\leq j\leq C} e^{H_{x_i}L_{y_j}/\tau})\\ &\geq \frac{1}{N(C-1)\tau}\sum_{i=1}^{i=N}\sum_{j=1,j\neq i}^{j=C} H_x L_{y^-}\end{aligned} \tag{11}$$

Therefore, we can form an asymptotic equivalent objective of the $\mathcal{L}_{ICL}$ (Equation 3) as Equation 10. $(x, y) \sim A(y)$ denotes instances (i.e. x) with corresponding label (i.e. y) and y^- denotes the label that is different from y. The first item keeps instances and corresponding labels similar and the second item pushes the mismatched instances and labels apart. We can further derive Equation 11 using Jensen's inequality because $e(.)$ is convex. Therefore, minimizing the $\mathcal{L}_{ICL}$ equals to minimization of summation of all elements in $HL^T \in R^{N\times C}$. Because both H and L are normalized, $tr(H^T L)$ is a constant due to all diagonal elements are ones. $sum(HL^T)$ is an upper bound of the largest singular value (Merikoski, 1984) and minimization of the $sum(HL^T)$ will flatten the singular values distribution of HL^T. As the HL^T is a non-squared matrix, we need to optimize both the left and right singular values using HL^T and LH^T in order to effectively eliminate the anisotropy and promote the uniformity of pre-trained language models in classification tasks to enhance the model capacity. Thus, we also need to optimize the label-centered contrastive loss $\mathcal{L}_{LCL}$ at the same time. From above analysis, we can see that $\mathcal{L}_{ICL}$ and $\mathcal{L}_{LCL}$ are complementary to each other. Similarly, we can derive that minimizing $\mathcal{L}_{LCL}$ results in the minimization of $sum(LH^T) \in R^{C\times N}$.

Although both ICL and LCL calculate the $N \times C$ similarity scores for a mini-batch, they are different. The ICL is the average of the instance-level per sample loss while the LCL is the per label loss. The ICL intends to align each instance to corresponding label correctly. The LCL makes the instances of different labels far away from each other and instances of the same label more compact. They consider different aspects of instance and label representation through operating the $N \times C$ similarity scores differently according to Equation 3 and 5.

Compared to InfoNCE, ICL improves the computational efficiency from $O(N^2)$ to $O(NC)$ because we only need to contrast the instance representation with corresponding label representations for per example loss, which is extremely useful for language understanding tasks (Wang et al., 2019; Xu et al., 2020) that commonly consist of 2 or 3 labels. Similarly, LCL is also more computationally efficient as it only contrasts one label representation to several instances rather than computes all pairs of instances belonging to a given label in the mini-batch. Thus it improves the complexity from $O(N^2)$ to $O(CN)$ compared with SCL too.

Go Back in Time:
Generating Flashbacks in Stories with Event Temporal Prompts

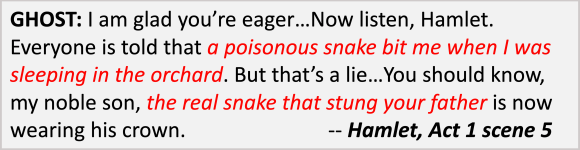
Abstract

Stories or narratives are comprised of a sequence of events. To compose interesting stories, professional writers often leverage a creative writing technique called *flashback* that inserts past events into current storylines as we commonly observe in novels and plays. However, it is challenging for machines to generate *flashbacks* as it requires solid understanding of event **temporal order** (e.g. *feeling hungry* ⟨*before*⟩ *eat*, not vice versa), and the creativity to arrange storylines so that earlier events do not always appear first in **narrative order**. Two major issues in existing systems exacerbate the challenges: 1) temporal bias in pretraining and story datasets that leads to monotonic event temporal orders; 2) lack of explicit guidance that helps machines decide where to insert *flashbacks*. We propose to address these issues using structured storylines to encode events and their pair-wise temporal relations (⟨*before*⟩, ⟨*after*⟩ and ⟨*vague*⟩) as **temporal prompts** that guide how stories should unfold temporally. We leverage a Plan-and-Write framework enhanced by reinforcement learning to generate storylines and stories end-to-end. Evaluation results show that the proposed method can generate more interesting stories with *flashbacks* while maintaining textual diversity, fluency and temporal coherence.[1]

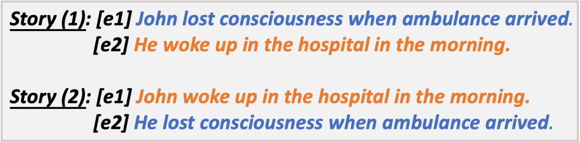
1 Introduction

Flashback is a popular creative writing technique that brings the readers from the present moment to the past via inserting earlier events in order to provide background or context of the current narrative (Pavis, 1998; Kenny, 2004; Gebeyehu, 2019). For example, in Figure 1a, the "GHOST" in Shakespeare's play *Hamlet* instruments a *flashback* by interrupting the main narrative and describing a historical event to the audience that *Hamlet*'s father was killed by the current king rather than a snake.



GHOST: I am glad you're eager…Now listen, Hamlet. Everyone is told that *a poisonous snake bit me when I was sleeping in the orchard*. But that's a lie…You should know, my noble son, *the real snake that stung your father* is now wearing his crown. -- ***Hamlet, Act 1 scene 5***

(a) A *flashback* example from William Shakespeare's famous play *Hamlet* (in plain English). Red text indicates past events.



Story (1): ***[e1]*** ***John lost consciousness when ambulance arrived.***
[e2] ***He woke up in the hospital in the morning.***

Story (2): ***[e1]*** ***John woke up in the hospital in the morning.***
[e2] ***He lost consciousness when ambulance arrived.***

(b) Two-sentence stories with the same event **temporal order** but different **narrative order**. The second one with a flashback is intuitively more interesting than the first one.

Figure 1: (a) *flashback* (b) temporal v.s. narrative order.

Flashback, by manipulating the event temporal orders in narrative structure, can arouse readers' emotions such as surprise, suspense, and curiosity (Brewer and Lichtenstein, 1981, 1982). These emotions stimulate readers' interests and eventually contribute to the satisfaction of reading (Tan, 1996; Alwitt, 2002), which improves the **interest level** of a story. The example in Figure 1a injects historical events in the middle of the narrative. This arrangement of events can surprise readers and therefore, makes the story more interesting than a straightforward storyline where the past events are shown in the beginning.

Similarly, consider the pair of two-sentence stories in Figure 1b. Both stories are composed of the same events with the **temporal order** *"lost consciousness"* ⟨*before*⟩ *"woke up in the hospital."* In Story (1), seeing **[e1]**, readers can make a relatively easy educated guess of **[e2]**, but it is more subtle in Story (2) as there are many different ways to end up in a hospital. By showing the ending event first, the *flashback* in Story (2) creates suspense that makes the following sentences less predictable, and thus arouses readers' curiosity and makes the reading more interesting.

While human writers are capable of maneuver-

---

ing event temporal orders to compose coherent and interesting stories, it remains challenging for machines. The challenge is partially attributed to data bias. Ning et al. (2018a) shows that the pattern in Story (1) is dominant in human-written texts, where neighboring events with $\langle$*before*$\rangle$ temporal relations (i.e., **narrative order** indicates **temporal order**) occur $60-70\%$ of the time. This is also manifested in our experiments with vanilla language models amplifying this ratio and producing more than 80% $\langle$*before*$\rangle$ relations for neighboring events in the generated stories. Furthermore, current state-of-the-art story generation systems that incorporate event representations usually assume event **temporal order** follows **narrative order** (Goldfarb-Tarrant et al., 2020; Lin et al., 2021). There are no explicit prompts in these systems that help determine when *flashback* should be used, leaving models to produce dull stories consisting of event sequences with monotonic $\langle$*before*$\rangle$ relations.

To facilitate more effective *flashback*, we propose to incorporate **temporal prompts** in an end-to-end story generation framework inspired by the Plan-and-Write paradigm (Yao et al., 2019; Xu et al., 2020; Goldfarb-Tarrant et al., 2020), where machines first learn to plot a storyline, and then generate the story based on the storyline. Specifically, we encode predefined event **temporal prompts** in structured storylines. As the bottom block of Figure 2 shows, a structured storyline contains two components: 1) **event representations** where an event trigger ("grabbed") and two arguments ("she" and "the dog") are extracted from the original story sentences; and 2) **temporal prompts**: the temporal order between neighboring events, e.g. event 1: ("she", "grabbed", "the dog") is $\langle$*after*$\rangle$ event 2: ("white snow", "blanketed", "the ground"). By training our storyline generation model with these predefined pair-wise temporal relations, models capture how neighboring events are temporally related to each other; while during storyline decoding, supplying predefined **temporal prompts** can guide models to generate reasonable narratives with desirable event temporal orders.

Prior works (Fan et al., 2019; Goldfarb-Tarrant et al., 2020) build the storyline and story models separately, which creates a discrepancy where gold storylines are used during training, but predicted storylines are used during inference. To mitigate this training-inference discrepancy, we leverage reinforcement learning (RL) to train our systems end-to-end. It enables the story model to train on generated storylines and updates the storyline model with the feedback from the story model. Our experimental results show that the RL-based models can leverage **temporal prompts** more effectively, resulting in more effective *flashback* generation and more interesting stories.

We summarize the contributions of this paper as follows: 1) To facilitate effective *flashback*, we propose to leverage structured storylines with **temporal prompts** to arrange events in story generation. 2) We integrate reinforcement learning in our story generation pipeline, which can help models better leverage **temporal prompts**. 3) We test our framework on two open-domain story datasets and show more effective *flashbacks* and increased **interest level** while maintaining fluency and temporal commonsense in the generated stories. To our best knowledge, this is a pioneering study on *flashbacks* in *neural story generation*.

2 Background and Task Definitions

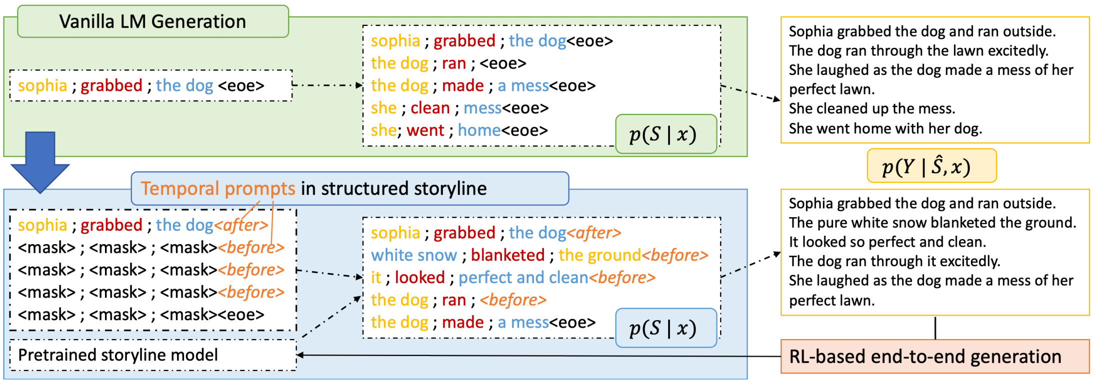
In this section, we describe the key components: **events** and **temporal prompts** in our proposed structured storylines, and then define the Plan-and-Write generation task.

Event Representation. Following the definitions of ACE (2005), we define an event as a trigger word and its arguments. In this work, we simplify the representation by leveraging semantic role labeling (SRL) tools (Shi and Lin, 2019) to parse two arguments as shown in Figure 2. We only consider one event per story sentence and denote the k-th event in story i as $e_{i,k}$. We leave more complicated representations for future study.

Temporal Prompts. Let $\boldsymbol{r}_i = \{r_{i,k}\}$ denotes the set of temporal relations between the k-th and the $(k+1)$-th event in story i. If k indexes the last event, $r_{i,k}$ is not defined. Following the event relation definition of (Ning et al., 2018b), we use events' *start time* to evaluate temporal order.

Structured Storyline. Figure 2 provides a storyline consisting of five event representations extracted from our data. More formally, let $\mathcal{S}_i = \{e_{i,1}, e_{i,2}, ...e_{i,k}, ...e_{i,n}\}$ indicates a storyline with n events. Encoding **temporal prompts**, $\mathcal{S}_i$ becomes $\mathcal{S}_i^r = \{e_{i,1}, r_{i,1}, e_{i,2}, r_{i,2}...e_{i,k}, r_{i,k}, ...e_{i,n}\}$. Note that in this work, $\boldsymbol{r}_i$ **is provided as predefined prompts** rather than predicted as $e_{i,k}$.

Story. Our ultimate goal is to generate *flashbacks* in stories. We denote the story associated with the



Sophia grabbed the dog and ran outside.
The dog ran through the lawn excitedly.
She laughed as the dog made a mess of her perfect lawn.
She cleaned up the mess.
She went home with her dog.

Sophia grabbed the dog and ran outside.
The pure white snow blanketed the ground.
It looked so perfect and clean.
The dog ran through it excitedly.
She laughed as the dog made a mess of her perfect lawn.

Figure 2: An illustration of our overall model. Here we use the first sentence of the story (and its associated event representation) as input $\boldsymbol{x}$. The upper block shows the vanilla implementation of the Plan-and-Write workflow. The bottom block is our core novel design by leveraging **temporal prompts** in structured storylines to generate *flashbacks*. For illustration purposes, we re-order the triggers and arguments, and storylines are ground-truths (i.e. not predicted by models). Our final model uses reinforcement learning to implement end-to-end training.

storyline $\mathcal{S}_i$ as $\mathcal{Y}_i$.

Plan-and-Write is a two-stage framework that first generates storyline $\hat{\mathcal{S}}_i$ given some input $\boldsymbol{x}$ (e.g. title, leading sentence), and then generate $\hat{\mathcal{Y}}_i$ based on $\hat{\mathcal{S}}_i$. Again, $r_{i,k}$ are given as *predefined* prompts whereas $e_{i,k}$ are to be predicted as part of the storyline generation shown in Figure 2.

3 Framework for FlashBack Generation

In this section, we first provide an overview of the Plan-and-Write story generation system and introduce a vanilla version of the end-to-end training method. Then we describe the details of our key contribution of leveraging event **temporal prompts** to generate *flashbacks*. After that, we discuss pretraining structured storylines with self-labeled data and incorporating reinforcement learning to jointly train our end-to-end models.

3.1 Plan-and-Write Models

In order to provide better explainability and controllability over the machine generated stories, recent research efforts (Yao et al., 2019; Xu et al., 2020; Goldfarb-Tarrant et al., 2020) explore dividing story generation into two steps: 1) from input or prefix, $\boldsymbol{x}$, we first produce a storyline, $\mathcal{S}_i$; 2) based on the storyline, we generate a story, $\mathcal{Y}_i$. We describe the details below.

Storyline Model. Let α denote the parameters of the storyline model, per sample training loss can be computed as $\mathcal{L}_\alpha = -\log p\left(\mathcal{S}_i|\boldsymbol{x}_i, \alpha\right)$.

Story Model. Let β denote the parameters of the story model, per sample training loss can be computed as $\mathcal{L}_\beta = -\log p\left(\mathcal{Y}_i|\boldsymbol{x}_i, \mathcal{S}_i, \beta\right)$.

Inference. Note that $\mathcal{S}_i$ above is the gold storyline extracted from $\mathcal{Y}_i$. At the inference time, we do not have $\mathcal{S}_i$, and have to replace it with $\hat{\mathcal{S}}_i$, the predicted storyline. This results in a discrepancy between the training and inference time.

End-to-end Training. Instead of using gold storyline $\mathcal{S}_i$ to train a story model, we can take $\hat{\mathcal{S}}_i$ as its input. Now the per sample training loss for the story model becomes $\mathcal{L}_\theta = -\log p\left(\mathcal{Y}_i|\boldsymbol{x}_i, \hat{\mathcal{S}}_i, \theta\right)$, where θ indicates the end-to-end story model parameters. End-to-end training can alleviate the gap between the training and inference time, and potentially lead to more consistent stories [2].

3.2 Structured Storyline Construction

As Figure 2 shows, for a story sentence, we first use the SRL tool to parse its trigger $t_{i,k}$ and two arguments $a^1_{i,k}$ and $a^2_{i,k}$. We then convert this representation into a textual form: "$t_{i,k}$; $a^1_{i,k}$; $a^2_{i,k}\langle eoe\rangle$", where ";" separates two event components, and $\langle eoe\rangle$ indicates event ending. For example, the parsed $t_{i,k}$, $a^1_{i,k}$ and $a^2_{i,k}$ in the story sentence "she grabbed the dog and ran outside" are "grabbed," "she" and "the dog" respectively. They are concatenated into a final textual representation as "grabbed ; she ; the dog$\langle eoe\rangle$."

Depending on the experimental setup, we may use no or only the leading event as input, $\boldsymbol{x}$. Inspired by the mask prediction design in Devlin et al. (2019); Liu et al. (2019); Lewis et al. (2020), we represent the remaining missing events in the inputs as "⟨mask⟩ ; ⟨mask⟩ ; ⟨mask⟩ ; $\langle eoe\rangle$," where ⟨mask⟩ indicates either event trigger word or argu-

---

[2] End-to-end training may have small coverage of the generated events in stories, which we address in Appendix F.

    Generate $\hat{S}_i^r$ from storyline model ($\alpha$)
    $\mathcal{L}_\theta = -\log p\left(\mathcal{Y}_i|\boldsymbol{x}_i, \hat{\mathcal{S}}_i^r, \theta\right)$
    $\nabla J_\alpha = R_i \cdot \nabla \log\left(p(S_i|\boldsymbol{x}_i, \boldsymbol{r}_i, \alpha)\right)$
    $\alpha = \alpha - \nabla J_\alpha$
    $\theta = \theta - \nabla \mathcal{L}_\theta$
end for
```

ments to be predicted by the storyline model.

3.3 Temporal Prompt Encoding

Temporal prompts are used to generate *flashbacks*. As we mentioned in Section 2, we encode a sequence of *predefined* event **temporal prompts** $\boldsymbol{r}_i = \{r_{i,k}\}$ in storyline for $k \in \{1, n-1\}$ to help models determine whether the next event mention (in narrative order) should start earlier or later than its preceding event mention. We use temporal relation extraction tools to annotate all $r_{i,k}$ in our experimental data. Specifically, we use ECONET (Han et al., 2021b) finetuned on the MATRES dataset (Ning et al., 2018b) to predict the temporal relation between neighboring events.[3] The context and the locations of a pair of event trigger words are fed into ECONET to predict their temporal order. The **temporal prompt** set consists of $\langle$*before*$\rangle$, $\langle$*after*$\rangle$ and $\langle$*vague*$\rangle$ (capturing undetermined temporal order), and are fixed in S_i^r. Note that $\langle$*vague*$\rangle$ indicates undetermined temporal order due to the ambiguity of the context (Cassidy et al., 2014; Ning et al., 2018b) and it does not suggest the context is poor or the relations are wrong. As shown in Figure 2, we replace the end-of-event token $\langle eoe \rangle$ with **temporal prompts** in storylines, except for the last event which does not have a next event. With the prompt-augmented storylines, S_i^r, we can re-write the storyline loss as $\mathcal{L}_\alpha = -\log p\left(\mathcal{S}_i^r|\boldsymbol{x}_i, \boldsymbol{r}_i, \alpha\right)$, and story loss as $\mathcal{L}_\theta = -\log p\left(\mathcal{Y}_i|\boldsymbol{x}_i, \hat{\mathcal{S}}_i^r, \theta\right)$.

3.4 Storyline Pretraining

Using intermediate pretraining to adapt original pretrained language models has been shown to be effective for a variety of downstream tasks such as information extraction (Joshi et al., 2020), question-answering (Khashabi et al., 2020; Garg et al., 2020) and commonsense reasoning (Zhou et al., 2021). To capture more diverse event sequences and facilitate better story generation, we explore pretraining storyline model with SRL extracted storyline from BookCorpus dataset (Zhu et al., 2015), and use learned α to initialize storyline models.

3.5 RL-based End-to-end Model

The end-to-end model described in Sec. 3.1 allows the story model to train with the generated storylines and hence alleviate the gap between training and inference. However, this workflow still lacks a mechanism that enables the storyline model to adjust with the feedback from the story model. The challenges of training storyline and story models jointly originate from decoding storylines as inputs for the story model, which involves non-differentiable token selections. Thus, the final loss L_θ cannot be directly back-propagated into the storyline model.

To overcome this barrier, we adopt reinforcement learning (RL), specifically, the REINFORCE algorithm (Williams and Peng, 1991) in our end-to-end training. Let $R_i = R(\boldsymbol{x}_i, \boldsymbol{r}_i)$. The expected reward with respect to the storyline model can be written as $\mathbb{E}_\alpha\left[R_i\right] = \mathbb{E}\left[R_i \cdot \log\left(p(S_i^r|\boldsymbol{x}_i, \boldsymbol{r}_i, \alpha)\right)\right]$. The gradient to update the storyline model is $\nabla J_\alpha = \mathbb{E}\left[R_i \cdot \nabla \log\left(p(S_i^r|\boldsymbol{x}_i, \boldsymbol{r}_i, \alpha)\right)\right]$, which can be approximated with sampling techniques. Motivated by Xu et al. (2018), we use negative loss of the story model to construct rewards, that is, $R = -\mathcal{L}_\theta$.[5] In other words, smaller loss from the story model is associated with larger reward. Algorithm 1 summarizes the overall method.

4 Experimental Setup

In this section, we start by describing our research objectives, then we describe our data, evaluation metrics, experimental designs and implementation details aiming to achieve these objectives.

The overall research objective is to measure the impact of using **temporal prompts** in structured storylines. Specifically, can $\langle$*after*$\rangle$ successfully induce *flashbacks*? If so, does that contribute to the interest level of the generated stories while maintaining the overall quality of the texts?

4.1 Datasets.

ROCStories (Mostafazadeh et al., 2016a) and WritingPrompts (Fan et al., 2018) are our experimental datasets. We ensured all reported results using the same test data as the baseline systems (Xu et al., 2020) and (Goldfarb-Tarrant et al., 2020). For

---

[3] The ECONET tool is available here: `https://github.com/PlusLabNLP/ECONET`.

[5] We do not use baseline reward as we found this simple reward design works effectively in our experiments.

pretraining data, we use BookCorpus (Zhu et al., 2015). Appendix B shows all details of data splits and pre-processing process.

4.2 Temporal Prompts Constructions

ECONET was finetuned three times with different random seeds, so we take the consensus vote from three models. If there is any disagreement, we label the temporal order as $\langle$*vague*$\rangle$. We benchmark ECONET's annotation performances in Appendix G, which shows it provides highly accurate temporal relations. For human evaluations specifically, we consider two prompt settings in order to gauge different impacts of $\langle$*after*$\rangle$. 1) for ROCStories, all structured storylines consist of exactly four *predefined* **temporal prompts** created following Sec 3.3. We randomly sample stories with one $\langle$*after*$\rangle$ prompt from the test data. We will show later in the analysis that vanilla language models would generate more than 80% event pairs with $\langle$*before*$\rangle$ relations for ROCStories; $\langle$*after*$\rangle$ prompt should bring this ratio down if it is effective. 2) for WritingPrompts, since the number of events is not fixed, we randomly sample test stories generated with $\langle$*after*$\rangle$ prompts for evaluation.

4.3 Automatic Evaluation Metrics

We use automatic metrics to evaluate the textual quality of stories. We report **Ref. PPL**: reference stories' perplexity in our models and **Gen. PPL**: generated stories' perplexity scored by GPT-2 (Radford et al., 2019). For diversity, we report **Distinct Ratio** (%): overall vocabulary:token number ratio. We also report standard **BLEU-3** and **ROUGE**$_L$.

4.4 Human Evaluation Metrics

We rely on human annotators to analyze the effectiveness of *flashback* generations. We request 18 MTurkers who succeeded in our previous annotation tasks (Han et al., 2021a) to evaluate stories produced by our compared models. We host a small qualification round followed by a large annotation task. Only 10 workers are qualified, and we only consider their annotations. Eventually, we collect 106 and 77 sets of valid annotations for ROCStories and WritingPrompts.

Temporal diversity. The dominance of $\langle$*before*$\rangle$ relation in our data can make models biased toward generating stories with more $\langle$*before*$\rangle$ relations. Therefore, we are interested to see how inserting an $\langle$*after*$\rangle$ prompt can help **increase** the percentage of non-$\langle$*before*$\rangle$ event relations in the generated stories. Let $\hat{R}_r$ indicate the percentage of a particular relation annotated by MTurkers. We calculate the entropy of the set $\{\hat{R}_r\}, \forall r \in \{\langle before\rangle, \langle after\rangle, \langle vague\rangle\}$ to measure temporal diversity.

Accuracy measures the percentage of $\langle$*after*$\rangle$ being correctly incorporated in the generated stories labeled by human annotators. We used a relaxed version by counting annotated $\langle$*vague*$\rangle$ as correct too, as $\langle$*vague*$\rangle$ can potentially be $\langle$*after*$\rangle$. Both **accuracy** and **temporal diversity** can show the effectiveness of generating *flashbacks* using $\langle$*after*$\rangle$.

Temporal coherence indicates if the event sequence in a generated story aligns with an annotator's **temporal commonsense**.[6] 1 and 0 correspond to yes and no, respectively.

Interest level. Precisely defining interest level is difficult as it is a broad concept. So we focus on the *unexpectedness* component of cognitive interest. As pointed out by Behrooz (2019), *unexpectedness* can be further explained as how predictive an event is, which is closely related to *flashback* generation. Therefore, we define an *interesting* event as 1) being unexpected or surprising and 2) being logical according to the context and general commonsense.[7]

For the compared models, we ask annotators to provide ranks between 1 to K for the generated stories, with K indicating the most interesting story and 1 indicating the least interesting one. We encourage workers to provide different scores for all compared stories, but equal scores are allowed. The max score K depends on the number of compared models, 5 for ROCStories and 4 for WritingPrompts. We provide detailed instructions in the interface shown in the appendix. Crucially, **interest level** is separately annotated from other metrics and we ensure annotators do not see the same set of stories in both tasks.

4.5 Compared Models

Baselines. Xu et al. (2020), denoted as MEGATRON, is chosen as the baseline as it outperforms previous systems such as Guan et al. (2020) on ROCStories. We also compare with TEMPORAL-BART (Lin et al., 2021) as it is pretrained with temporal ordering and event infilling tasks. For WritingPrompts, we compare with CONTENTPLANNING (Goldfarb-Tarrant et al., 2020) as it also

---

[6] interface with detailed instructions and examples can be found in Figure 7 of the appendix.

[7] the second definition is not identical to the temporal coherence above. Events contradicting general commonsense can still be temporally coherent (see Figure 7) for examples.

	Automatic Evaluation					Human Evaluation			
Models	Ref. PPL(↓)	Gen. PPL(↓)	Distinct Ratio(↑)	BLEU (↑)	ROUGE$_L$ (↑)	Temporal Diversity(↑)	Accuracy (↑)	Temporal Coherence (↑)	Interest Level (↑)
Temporal-BART	24.65	19.47	4.10	5.01	19.12	-	-	-	-
MEGATRON	-	34.14	**4.57**	2.57	15.23	**1.21***	-	0.78	2.69
Vanilla-Gen	27.30	19.29	3.99	5.13	19.29	0.88	-	**0.88**	2.95
+ Structured-Prompt	22.85	19.94	4.09	5.07	19.39	1.09	55.75	0.82	3.03
+ Pretrained	21.16	**19.25**	4.01	5.06	19.44	1.07	52.21	0.84	2.96
+ RL	**15.45**	19.42	4.17	**5.20**	**19.49**	1.14	**56.64**	0.86	**3.06**

Table 1: Evaluation results for ROCStories. All values in the bottom block are averaged over three runs. MEGATRON's **Ref. PPL** is missing as it is not reported in the paper and the model is not publicly available. MEGATRON and Vanilla-Gen do not use any **temporal prompts**, so **accuracy** is not applied. MEGATRON's **temporal diversity*** is high due to large amount of ⟨*vague*⟩ annotations in its generated stories.

Input prompt	[s1] my favorite class was english literature. ⟨*before*⟩ ⟨***after***⟩ ⟨*before*⟩ ⟨*before*⟩
baseline	[s2] i was in english class for the first time. [s3] i had to take a class with my local author this semester. [s4] i decided to ask him to speak to me at a local book festival. [s5] he said that he was really good and i liked him.
Vanilla	[s2] one day, i decided to go to the library. [s3] i found a book that i really liked. [s4] i read the whole book in one day. [s5] i was so happy that i went back to school.
RL	[s2] i would go to the library to read all the books. [s3] i had never been to a library before. [s4] i was so excited to go. [s5] i ended up spending a lot of time in the library.
Input prompt	[s1] tom was excited to go on a date. ⟨***after***⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*before*⟩
baseline	[s2] he went to his favorite restaurant to pick up his date. [s3] the date went well and then tom got drunk. [s4] he told his date they were going to a comedy show. [s5] the date went on and they had a great time at the movie.
Vanilla	[s2] he was going to take his girlfriend to the movies. [s3] they went to the movie theater. [s4] they had a great time. [s5] tom couldn't wait to go back again.
RL	[s2] he had been looking forward to it for months. [s3] he went to the mall and bought a new dress. [s4] he wore it to his date's house. [s5] his date loved it and they had a great time.

Table 2: Generated stories by our compared models. baseline: MEGATRON, Vanilla-Gen and RL-based. end-to-end. Input is the first sentence. Highlighted sentences contain an event that started earlier than the preceding event.

adopts the Plan-and-Write workflow as well as structured event representations. Appendix D describes more details of baseline systems.

We describe our own model variants below,

1. Vanilla-Gen uses the parameters of a pretrained language model (LM), specifically BART-base (Lewis et al., 2020), to initialize both the storyline and story models. Its workflow is illustrated in the upper block of Figure 2. Since no information other than the prefix (first sentence, prompt, etc.) is used to generate the story, we denote this model as vanilla LM generation or Vanilla-Gen.

2. Structured-Prompt enhances Vanilla-Gen by using a structured storyline of events to encode **temporal prompts**, which is associated with the workflow of the bottom block of Figure 2.

3. Pretrained. For ROCStories data only, we initialize the storyline model of Structured-Prompt with the pretrained parameters.

4. RL uses the same inputs as Structured-Prompt. The difference is that reinforcement learning is used to train storyline and story models jointly. As Algorithm 1 shows, RL-based model is trained following the same forward workflow as Structured-Prompt, but during backpropagation, the storyline models' parameters are updated.

5 Results and Analysis

The main results for ROCStories and WritingPrompts are shown in Table 1 and Table 3 respectively. Examples of generated stories can be found in Table 2 and Table 6 for ROCStories and Table 11 in the appendix for WritingPrompts. We organize our discussions and analysis in the following sections by answering the four research questions. **Q1)** Can our proposed models (with **temporal prompts**) produce stories with good **textual quality**? **Q2)** Are our proposed models effective at generating *flashbacks*? **Q3)** Can our proposed models maintain event **temporal coherence** in stories? **Q4)** How do our proposed models contribute to stories' **interest levels**?

5.1 Textual Quality

We measure the textual quality of stories using a wide range of automatic evaluation metrics.

Perplexity. For ROCStories, all three model variants can improve **Ref. PPL** against Vanilla-Gen and Temporal-BART while maintaining good **Gen. PPL**. The weak **Gen. PPL** of MEGATRON may be attributed to its sentence-by-sentence generation pipeline, whereas our models generate an entire story in an integrated step. For WritingPrompts, both model variants improve **Gen. PPL** over Vanilla-Gen and ContentPlanning while maintaining good **Ref. PPL**.

Token Diversity. For ROCStories, RL-based model improves the Vanilla-Gen by 0.18 per

Models	Ref. PPL (↓)	Gen. PPL (↓)	Distinct Ratio (↑)	BLEU (↑)	ROUGE$_L$ (↑)	Tok. Len. (↑)	Pearson Corr. (↑)	Temporal Coherence (↑)	Interest Level (↑)
ContentPlanning	-	25.52	1.80	**3.46**	**14.40**	**252.3**	0.04	**0.57**	2.20
Vanilla-Gen	31.04	11.17	**3.50**	0.67	9.43	160.2	0.09	0.52	2.49
+ Structured-Prompt	**30.77**	**9.30**	2.86	1.44	10.95	208.6	0.56	0.49	2.49
+ RL	30.98	9.50	2.83	1.39	10.78	203.8	**0.57**	0.55	**2.62**

Table 3: Evaluation results for WritingPrompts. Pearson correlation approximates the effectiveness of prompts.

Distinct Ratio. MEGATRON achieves the highest token diversity as it incorporates external knowledge-bases that make the generated stories contain novel tokens. For WritingPrompts, we observe longer stories are associated with poorer scores. However, the large increases in **Distinct Ratio** suggest that the token usages in our proposed models are diverse.

BLEU and ROUGE$_L$. For ROCStories, the proposed models perform on-par with Vanilla-Gen and Temporal-BART while outperforming MEGATRON, which generates the shortest stories among all compared models. For WritingPrompts, ContentPlanning performs the best partially due to its usage of BART-large models.

The overall performances across these three types of automatic metrics suggest that using **temporal prompts** in the Plan-and-Write framework can produce stories with high textual quality.

5.2 Effectiveness on Flashback Generation

The second research question probes the effectiveness of using **temporal prompts** on generating *flashbacks*. For ROCStories, all models can generate stories with the same number of events/sentences as the gold stories. This allows annotators to judge pairwise event relations in the generated stories and help us check whether the generated events have relations truthfully reflecting the **temporal prompts** used. **Accuracy** is the perfect metric for this. As Table 1 shows, the final RL-based model achieves the highest score, which indicates the strongest effectiveness of generating *flashbacks*.

However, **temporal prompts** are not used in the baselines and Vanilla-Gen. So we compute an approximate measures of effectiveness, **temporal diversity**, which indicates how many non-$\langle$*before*$\rangle$ relations $\langle$*after*$\rangle$ prompt can induce. Table 1 shows that Structured-Prompt, Pretrained and RL-based models can help improve Vanilla-Gen with more than 80% generated $\langle$*before*$\rangle$ relations. MEGATRON achieves the highest score due to the largest amount (29%) of $\langle$*vague*$\rangle$ relations (complex or undetermined) annotated by MTurkers shown in Figure 3, which is associated with its lowest **temporal coherence** score.

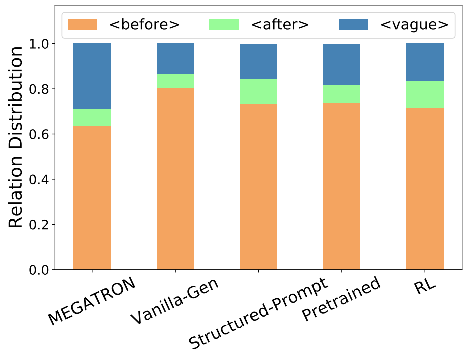

Figure 3: Relation annotation distribution by MTurkers for compared models trained on ROCStories.

For WritingPrompts, stories are long and can contain dialogues or short phrases without events at all. These make the sentence or event alignments between the gold and generated stories worse than ROCStories, i.e. $e_{i,k}, r_{i,k}$ may not correspond to the k-th sentence in $\mathcal{Y}_i$. Therefore, **accuracy** cannot be computed. To obtain an approximate metric, we use the tool described in Sec. 3.3 to annotate neighboring event temporal relations in the *generated* test stories for all the compared models. Slightly different from **temporal diversity**, we calculate the total number of machine annotated $\langle$*after*$\rangle$ relations, denoted as $\hat{N}_{i,A}$ in each $\hat{\mathcal{S}}'_i$. Let $\{N_{i,A}\}$ denote the number of $\langle$*after*$\rangle$ **temporal prompts** extracted in gold stories. We compute the **Pearson correlation** (Benesty et al., 2009) between the sets $\{\hat{N}_{i,A}\}$ and $\{\hat{N}_{i,A}\}$ as the measure.

As Table 3 shows, for ContentPlanning and Vanilla-Gen without **temporal prompts**, the correlations are weak; whereas when **temporal prompts** are used in both Structured-Prompt and RL-based models, the correlations are strong. Although using models' temporal annotations for the generated stories is not as precise as human annotations, the large differences in correlation provide another piece of evidence that our proposed methods are effective at generating *flashbacks*.

5.3 Temporal Coherence

Generating *flashbacks* requires a system to disrupt the monotonic $\langle$*before*$\rangle$ sequence, which is the dominant temporal pattern generated by Vanilla-Gen (see Figure 3). In other words, *flashbacks* with at least one $\langle$*after*$\rangle$ are minor patterns that can be hard to learn in our data, which may result in event sequences violating our temporal commonsense. Thus, we need to check that stories generated with *flashbacks* maintain good **temporal coherence**. As shown in Table 1 and 3, our proposed models with **temporal prompts** can achieve on-par or slightly lower scores, suggesting little trade-off of **temporal coherence** in generating *flashbacks*. We will discuss this more in the error analysis (Sec. 6).

5.4 Contributions to the Interest Level

As we can observe in Table 1, the impact of **temporal diversity** and **coherence** on the **interest level** appears to be complex. To better understand the dynamics among these metrics, we run ordinary least square regressions (OLS) (Kenney and Keeping, 1965) by setting **interest level** as the target variable and **temporal diversity**, **coherence** and the number of ⟨*after*⟩s as predictors. Since all of these metrics apply to each of the compared stories, the total instances are 530 and 308 for ROCStories and WritingPrompts, respectively.

As Table 4 shows, for ROCStories, holding other metrics constant, adding 1 unit to **temporal coherence** and **diversity** leads to a 0.609 increase and 0.532 decrease of the **interest level**. The former result implies that a story lacking event temporal coherence tends to be less interesting. The latter result suggests that increasing **temporal diversity** may lead to less interesting stories, which we hypothesize could be attributed to two factors: 1) ⟨*before*⟩ is dominant in ROCStories, and by using ⟨*after*⟩ as prompt, we force models to generate relations less seen in data. 2) Figure 3 shows **temporal diversity** can increase with more ⟨*vague*⟩ relations. Since ⟨*vague*⟩ is an undetermined temporal relation even for our annotators, it could make the storyline confusing and thus lead to less interesting stories. The coefficient for the number of ⟨*after*⟩ indicators is positive with strong statistical significance. It suggests that holding the other two metrics constant, adding the number of ⟨*after*⟩ indicators by 1 contributes to 0.387 increases of the **interest level**.

For WritingPrompts, although we are not able to conclude that the estimates are statistically significant, the coefficients have the same signs as ROCStories. Also, we observe that the p-value of the number of ⟨*after*⟩ indicators is much lower than the other two variables, which implies a relatively stronger (positive) impact.

Since **temporal prompts** in human evaluations all contain at least one ⟨*after*⟩, these results show that when ⟨*after*⟩ prompt successfully produces event pairs with ⟨*after*⟩ relation in the final stories, it makes stories more interesting. Now, we can answer the final research question: improving **temporal diversity** can help **interest level** when ⟨*after*⟩ prompts are effective at generating ⟨*after*⟩ relations in stories; that is, when *flashbacks* truly work, stories become more interesting.

	ROCStories		**WritingPrompts**	
	Coef.	**p-value**	**Coef.**	**p-value**
Temporal Coherence	0.609	0.000*	0.006	0.963
Temporal Diversity	−0.532	0.004*	−0.279	0.410
# ⟨*after*⟩ prompt	0.387	0.000*	0.034	0.238

Table 4: OLS regression results on temporal coherence, diversity and number of ⟨*after*⟩ indicators. The coefficients for the intercept are omitted. * means statistically significant with 99% confidence.

6 Error Analysis

In Table 1, we observe that our final models cannot outperform VANILLA-GEN for **Temporal Coherence** and fall behind MEGATRON for **Temporal Diversity**. We show examples below to provide feasible explanations.

Temporal Coherence. Table 5 shows three comparisons between our final RL-based model and the VANILLA-GEN baseline. In all three pairs, human evaluators mark VANILLA-GEN's generated stories as temporally coherent but not for RL's stories. As we can see in these examples, the red highlighted events temporally contradict the preceding context. In Input 1, the context shows "I have listened to the new album" so "can't wait to listen to the new album" shouldn't follow the former event. For Input 2, if "Anna had gotten her hair permed," it does make sense that the event "went to apply it (the perm)" follows. In Input 3, if the officer "gave [a] ticket" already, it does quite make sense to give "a warning" afterward as it is a weaker penalty than a "ticket." However, we observe that in all three cases, ⟨*after*⟩ relations are successfully reflected (*flashback*). Since stories with ⟨*after*⟩ relations are minority cases in the data, we hypothesize that they have not been perfectly learned by our proposed models. We leave more rigorous investigation for future research efforts.

Temporal Diversity. Table 10 in the appendix shows three comparisons between our final RL-based model and the MEGATRON baseline. In all three pairs, MEGATRON's generated stories are more temporally diverse based on the **predicted relations** provided by human evaluators. However, MEGATRON's stories are either contradic-

Input 1 prompt	[s1] the new album from my favorite pop star came out today. ⟨***after***⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*before*⟩
VANILLA	[s2] i was so excited to listen to it. [s3] i listened to it all day long. [s4] i couldn't believe how good it was. [s5] red i can't wait to listen again.
RL	[s2] i had never heard the album before. [s3] i went to the store and bought the album. [s4] when i got home, i listened to the whole thing. [s5] i can't wait to listen to the new album.
Input 2 prompt	[s1] anna had just gotten her hair permed. ⟨*before*⟩ ⟨*before*⟩ ⟨***after***⟩ ⟨*before*⟩
VANILLA	[s2] she was excited to see how it looked. [s3] but then she saw that her hair had grown out. [s4] anna was horrified! [s5] she had to go to the salon to get it fixed.
RL	[s2] she was excited to see how it looked. [s3] but when she went to apply it, it was terrible. [s4] her hair had grown way too long! [s5] anna had to go to the salon to get her hair fixed.
Input 3 prompt	[s1] last week we saw a police car in front of a parked car. ⟨***after***⟩ ⟨*before*⟩ ⟨*before*⟩ ⟨*before*⟩
VANILLA	[s2] the police officer pulled over the car. [s3] he asked the driver if he had insurance. [s4] the driver said he did not. [s5] the officer gave him a ticket.
RL	[s2] the car was parked in the parking lot. [s3] the police officer pulled over the car. [s4] he gave the driver a ticket. [s5] the officer gave him a warning.

Table 5: Examples from our RL-based model that are not as temporally coherent as examples generated by the VANILLA-GEN model. Highlighted sentences contain an event that started earlier than the preceding event. Red text indicates temporal incoherence.

tory (Input 1), incoherent (Input 2) or repetitive (Input 3), resulting in higher ambiguous event relations, i.e. ⟨*vague*⟩ annotations (consistent with Figure 3). Therefore, despite lower temporal diversity, our proposed models can still produce stories with higher quality, which is demonstrated via other metrics such as **Temporal Coherence** and **Interest Level**.

7 Related Work

Generating flashbacks has been studied in a few prior works. Bae and Young (2008) is one of the early efforts proposing a planning-based approach to generate flashbacks to evoke surprise in the readers. Follow-up works proposed a cognitive-based model that finds the best location in the original stories to insert a past event (Wu et al., 2016). Our work differs from this line of research by using temporal prompts with pretrained language models to generate integrated *flashback* in stories. Hoek et al. (2014) studies *flashback* in game narrative generation, which is remotely related to our work.

Plan-and-Write framework has been shown to be an effective method to enhance the explainability and controllability of story generation. Yao et al. (2019) enables machines to produce a sequence of keywords prior to generating stories. Follow-up works leverage commonsense or external knowledge to enhance the quality of stories (Guan et al., 2020; Xu et al., 2020; Tan et al., 2021). Goldfarb-Tarrant et al. (2020) is one of our compared works that incorporates SRL extracted event representations in storylines and train models with several event-related decoding objectives. Our work differs from it by explicitly encoding **temporal prompts** in event plots that facilitates *flashback*.

Structured representation such as discourse structure (Guan et al., 2021), story keywords (Peng et al., 2018; Goldfarb-Tarrant et al., 2019) and event/plot graph (Ammanabrolu et al., 2019, 2021) have been widely used in story generation to enable models to output diverse stories, but they are remotely related to our *flashback* generation task.

Reinforcement learning has also been explored in two-stage story generation such as Xu et al. (2018) and Tambwekar et al. (2019). Our motivation of using RL-based generation is to enhance the effectiveness of **temporal prompts**.

Event temporal reasoning helps the construction of the **temporal prompts**. It has been studied in story understanding (Han et al., 2019b), information extraction (Ning et al., 2017; Han et al., 2019c,a, 2020; Ma et al., 2021), QA (Ning et al., 2020; Zhou et al., 2019), and event generation (Lin et al., 2021; Li et al., 2021). Our proposed method is the pioneer work to introduce event **temporal prompts** in *flashback* generation.

8 Conclusions

We propose to generate *flashbacks* in stories by encoding temporal prompts in structured storylines. Experimental and evaluation results show our proposed systems can produce fluent, temporally coherent, and more interesting stories. Future work can focus on improving temporal prompts so that they handle minority cases (i.e. prompts with one or more ⟨*after*⟩ indicators) more effectively. Designing more powerful rewards in reinforcement learning is another promising research direction.
