Abstract

Recently, several studies on propaganda detection have involved document and fragment-level analyses of news articles. However, there are significant data and modeling challenges dealing with fine-grained detection of propaganda on social media. In this work, we present TWEETSPIN, a dataset containing tweets that are weakly annotated with different fine-grained propaganda techniques, and propose a neural approach to detect and categorize propaganda tweets across those fine-grained categories. These categories include specific rhetorical and psychological techniques, ranging from leveraging emotions to using logical fallacies. Our model relies on multi-view representations of the input tweet data to (a) extract different aspects of the input text including the context, entities, their relationships, and external knowledge; (b) model their mutual interplay; and (c) effectively speed up the learning process by requiring fewer training examples. Our method allows for representation enrichment leading to better detection and categorization of propaganda on social media. We verify the effectiveness of our proposed method on TWEETSPIN and further probe how the implicit relations between the views impact the performance. Our experiments show that our model is able to outperform several benchmark methods and transfer the knowledge to relatively low-resource news domains.

1 Introduction

Propaganda refers to any idea or information, that is often false or exaggerated, and is used to promote or publicize a particular cause or point of view. In recent years, there has been a surge in research and development of methods to detect propaganda from text. For example, some of the earlier works like (Rashkin et al., 2017a) and (Barrón-Cedeno et al., 2019) released a corpus of news articles containing coarse-grained document-level annotation of propaganda. Da San Martino et al. (2019b) described a corpus of news articles containing annotations of 18 fine-grained propaganda techniques. Following this work, two subtasks were presented as a part of NLP4IF workshop (Da San Martino et al., 2019a) that focused on the identification of propagandist text units at fragment and sentence level.

We believe that the challenge for this task lies in the varied nature of propaganda techniques, including cognitive and information distortion and logical fallacies. The challenges are further exacerbated in the social media setting, which has become a key battleground in the spread of propaganda. Research on propaganda detection in social media platforms like Twitter has been limited by the: (a) lack of sufficiently annotated social media propaganda data, (b) idiosyncratic nature of the content on social media, (c) difficulty in modeling the social context in which propaganda is disseminated, and (d) varying propaganda techniques that require factual knowledge, structural relationships, and reasoning abilities.

In this work, we address a subset of both the data and modeling challenges. First, we introduce TWEETSPIN, a corpus of tweets containing weak labels of fine-grained propaganda techniques. We accomplish this through a data collection pipeline that incorporates keyword-based search and users calling out propaganda techniques publicly on Twitter (see Figure 1 for examples). Next, we present a transformer-based multi-view propaganda detection model, MV-PROP, that identifies varied aspects of the textual data using multi-view contextual embeddings and captures their interaction via pairwise cross-view transformers. The main contributions of this work are described as follows:

(1) Creation of the TWEETSPIN corpus containing weak annotations of fine-grained propaganda techniques for tweets.

(2) An end-to-end Transformer-based MV-PROP model augmented with multiple views that infuse context, relational information and external knowl-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3433 - 3448

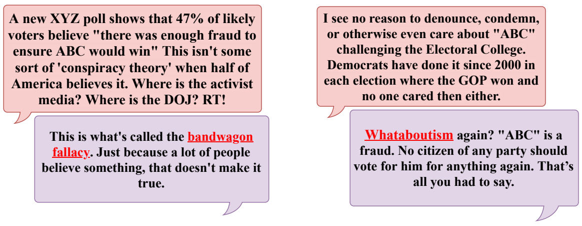

Figure 1: Data from TWEETSPIN where users are being called out for using specific propaganda techniques.

edge into the representation and capture their pairwise interactions through cross-view transformers. To the best of our knowledge, this is the first study that incorporates such multi-view representations for the propaganda detection task.
(3) We conduct experiments using TWEETSPIN to demonstrate the capability of our model in detecting fine-grained propaganda techniques for tweets. We also demonstrate the transferability of our model to data from the news domain.

2 Related Work

This work is closely related to a broad spectrum of topics, including offensive language detection, computational argumentation, and fake news detection. Some of the propaganda techniques might overlap with the categories of argumentation techniques (e.g., strawman argument) or offensive language (e.g., name-calling). However, there are considerable variations in propaganda techniques across different social contexts. Thus, methods used for the detection of offensive language or argumentation techniques may not be directly transferable to fine-grained propaganda detection. In this section, we review the prior researches in two main areas that are relevant to our work – (a) propaganda analyses and detection and (b) multi-view representation learning.

Propaganda Analyses and Detection Research in propaganda detection has primarily focused on document-level analysis. A work by Rashkin et al. (Rashkin et al., 2017b) constructed a corpus of news stories from eight different sources and labeled them with four broad categories – propaganda, hoax, trusted, and satire. Barron et al. (Barrón-Cedeno et al., 2019) addressed some of the limitations of the previous work by obtaining more data using distant supervision. They explored a range of features such as keywords, rich representations, writing styles, and readability level to discern propaganda text from other forms of news stories by casting it as a binary classification problem. More recently, there has been a dedicated line of research aimed at identifying fine-grained propaganda methods at the fragment level (Da San Martino et al., 2019b,a). This involved a manually annotated corpus flagging specific text spans in news articles as containing one of 18 propaganda techniques beyond the binarized setting used earlier. Various text classification models (Da San Martino et al., 2019a; Alhindi et al., 2019) incorporating TF-IDF features (Li et al., 2019) and contextual representations (e.g. BERT (Zellers et al., 2019), RoBERTa and ELMo (Cruz et al., 2019)) have been proposed to handle this fragment-level task. To detect propaganda on social media, many studies (Williamson III and Scrofani, 2019; Caldarelli et al., 2020) utilize datasets that contain propaganda content spread on social media by Russian-based IRA (Farkas and Bastos, 2018; Miller, 2019) or extremists (Johnston and Weiss, 2017; Nizzoli et al., 2019). Subsequent works investigated the influence of propaganda on public opinion (Caldarelli et al., 2020) and the techniques applied to disseminate targeted political agenda (Gorrell et al., 2019). Another recent work (Wang et al., 2020b) leveraged cross-domain learning approach to label propagandistic content. Wang et al. (2020b) implement different classifiers using different informative features and constraints based on labeled documents and sentences from news and tweets to detect propaganda within and across domains. Most of these works either apply bot or troll detection techniques or apply feature engineering methods to conduct binary classification of propagandistic content.

Multi-View Representation Learning Multi-view representation learning has numerous applications involving images, texts, graphs or videos. A line of work in computer vision has extensively studied the benefits of multi-view representation in embedding social images (Gong et al., 2014), object detection (Chen et al., 2017), viewpoint classification (Su et al., 2009), shape/face recognition (Chen et al., 2017; Su et al., 2015; Li et al., 2016), to list a few. However, there has been a limited exploration of multi-view representation explicitly for texts. For instance, the widely used Seq2Seq with attention module (Bahdanau et al., 2014), used in several state-of-the-art NLP tasks, can be seen from the the perspective of multi-view fusion where information from different time-steps are fused and encoded together into a semantic representation.

More recently, a work by (Bian et al., 2020) focused on learning to match a resume with a relevant job using multi-view representation learning approach.

Unlike previous studies that either focused on news articles or individual social media posts, our work performs a fine-grained analysis of propaganda for tweets considering the importance of the discussion context. Furthermore, we collect a weakly-annotated corpus of tweets associated with different propaganda techniques and develop a multi-view learning approach that has not yet to the best of our knowledge been explored for propaganda detection.

3 Problem Definition

Given an input tweet text along with a discussion context, our goal is to predict if the input text exhibits any propaganda techniques. Determining the propaganda technique of the input tweet can be formulated as a multi-class classification problem. In this work, we denote the input tweet text as $T_i = [w_1, w_2, .., w_{N_i}]$, where N_i is the sequence length of the input text. Each tweet text may be accompanied by a context $C_i = [T_1, T_2, ..., T_{i-1}]$, referring to M prior tweets in the discussion thread related to the input tweet T_i. Every input text might not necessarily contain a context (in such a case, $M = 0$). In this task, the target is to develop a model that can learn a mapping function $f : T \mapsto p_k$, where $k \in 1, 2, ..., L$, $p_k \in P$ indicates one of the L propaganda labels and p_1 denotes the special case of non-propaganda category or absence of any propaganda technique.

4 TWEETSPIN

We construct a dataset of English-language tweets, referred to as the TWEETSPIN corpus, containing weak annotations of 18 propaganda techniques same as in (Da San Martino et al., 2019b). Table B1 shows the full statistics of our dataset.

Our data collection pipeline consists of three components: (a) propaganda keyword expansion, (b) keyword-based tweet retrieval, (c) tweet filtration and (d) data augmentation.

Propaganda Keyword Expansion: For each propaganda technique, we select the name of the technique as the initial keyword. This works well for techniques that cannot be easily characterized by specific lexical patterns. Typical examples of such techniques include red herring, obfuscation, causal oversimplification, and strawmen. Additionally, we expand the list of keywords related to some of the propaganda techniques by combining information from publicly available resources including technique-specific phrases, idioms, and examples listed in Table B2.

Keyword-based Tweet Retrieval: We use Twitter's standard search API to ingest tweets based on the keywords identified from the previous step. We enclose the keywords or phrases within quotation marks. We observed that many Twitter users explicitly call out any usage of specific propaganda techniques in their discussions on the platform. Therefore, we select quoted tweets and replies containing keywords related to the propaganda techniques. Additionally, we search for tweets containing both the word "you" along with the identified keywords to capture instances where the users call out the usage of propaganda techniques.

Tweet Filtration: Given the tweets retrieved based on the keywords, we remove tweets that are extremely short (less than 5 words) and those that are replies to tweets from deleted or protected accounts. For the remaining tweets, we collect the discussion thread for each tweet which provide the context for the tweet. Though the tweet threads may involve complex tree structures with different reply branches, we are only interested in the specific branch of the tree that contains the tweet being called out for using specific propaganda techniques. In tweet threads that are long (>50 tweets in a discussion thread), not all tweets in the discussion context might be important for the classification task. Thus, we apply temporal filtering on such discussion threads, where we only retain the source tweet and discussion context that falls in a 7-day window before a particular tweet was being called out as propagandistic.

Data Augmentation: We adopt data augmentation strategies to handle potential data scarcity and also address the problem of overfitting. We employ linguistically informed transformations of text to prevent meaning distortion leading to new misclassification errors (Li et al., 2020). Hence, we randomly select 10% of examples from each class from our training set and perform linguistically informed augmentations using the code from Li et al. (2020).

Manual Validation of TWEETSPIN We randomly sampled 1,000 samples from the TWEETSPIN corpus containing the tweet to be classified, the prior context, and anonymized user information indicating if the text in the discussion context is from the same user or a different user. Three MTurk workers annotated each of these samples with one of the 19 propaganda techniques (18 techniques + 1 for non-propaganda). The definitions of the propaganda techniques were made available to the MTurk workers for reference. The inter-rater reliability as calculated using Fleiss' κ was 0.85, indicating a substantial agreement between the annotators. The agreement between the labels in our corpus and the labels provided by the annotators (through majority agreement) was 89.3%, indicating the relative high fidelity of our corpus, especially given its reliance on a weak-annotation scheme.

5 MV-PROP: Multi-View Propaganda Detection

Here, we describe our proposed model for fine-grained propaganda detection on social media. Unlike the fragment-level classification task used for propaganda detection in news articles, we formulate this problem as a text classification task where we aim to map the input tweet text to one of the several propaganda labels conditioning on the discussion thread context if it exists (as explained in Section 3). Figure 2 illustrates the overview of our model architecture. Inspired from the literature in multi-modal learning (Tsai et al., 2019), we propose a transformer-based multi-view propaganda detection model, MV-PROP, that integrates multi-view contextual embeddings via pairwise cross-view transformers. The main motivation behind such a modeling choice comes from the fact that different propaganda techniques require focus on varying aspects of the data. For example, propaganda techniques like loaded language can be identified from the usage of specific words or phrases, while repetition or red herring necessitates a contextual understanding of the tweet. Similarly, most propaganda techniques can benefit from word sense disambiguation and entity information that can be accumulated from external knowledge sources. Thus, the fine-grained differences between these propaganda techniques call for multi-view representations that can unravel such variations in the data. Our MV-PROP model comprises the following components:

Multi-View Encoding Layer, which computes multi-view representation from input tweet T_i and context C_i.

Cross-View Transformer, that reinforces representations obtained from a specific view with those computed from another view. We compute this for all pairs of such cross-view transformers.

Classification Layer, which fuses the embeddings from the previous step and computes the likelihood of the input tweet with the given context belonging to a particular propaganda label.

5.1 Multi-View Encoding Layer

In this work, we compute three different views: (a) context-aware semantic view, which derives semantic representation from text and context by leveraging a pre-trained language model, (b) relationship structure view, that calculates a relational representation by applying relation-based graph neural network on dependency graph and speaker-dependent context graph, and (c) knowledge-enriched view, which enriches the input tweet embedding with different kinds of knowledge. We discuss them in detail in subsequent sections.

5.1.1 Context-Aware Semantic View

The accompanying discussion context of a tweet can significantly shift how the tweet is perceived and hence plays a critical role in determining the propaganda technique used in the given tweet. Therefore, we employ a hierarchical incremental transformer encoder to obtain a context-aware semantic representation of the tweet text. Inspired from some of the existing hierarchical approaches (Zhang et al., 2019; Liu and Lapata, 2019), we implement a two-level transformer encoding process: (a) a tweet encoder f_T that operates at the word-level to transform each tweet into an embedding including those in the discussion thread and (b) a context encoder f_C that enriches the input tweet representation by capturing the influence of the previous tweets in the discussion thread relevant to our classification task. Thus, we learn a context-aware semantic view of the given input tweet.

We utilize a BERT-based pretrained language model (Devlin et al., 2018) as our tweet encoder, f_T. Each tweet $T_j = [w_1, w_2, ...w_{N_j}]$ is fed to the wordpiece tokenization algorithm. Here N_j is the number of words in the tweet text. We add special tokens $[CLS]$ and $[SEP]$ at the start and end of the tokenized tweet token list. We feed each tweet text into the BERT model and produce contextual word embedding as:

$$\hat{H}_j = [\hat{h}_j^1, \hat{h}_j^2, ..., \hat{h}_j^{N_j}] = f_T(T_j) = BERT(T_j) \qquad (1)$$

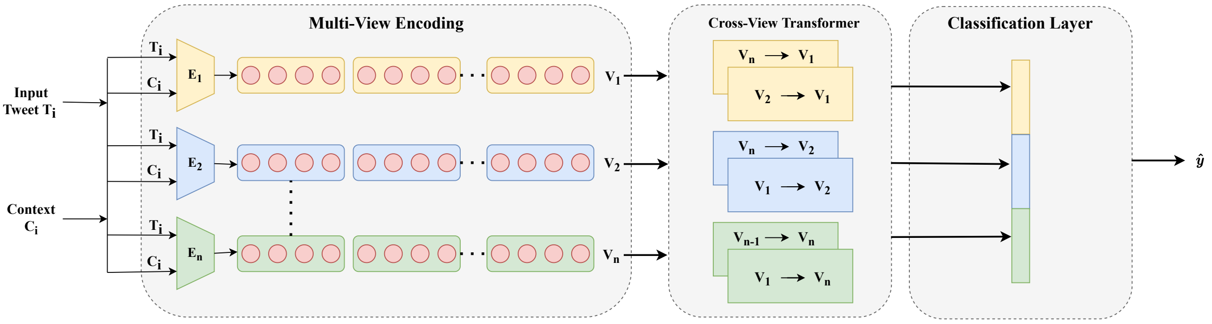

Figure 2: Illustration of our MV-PROP model.

We obtain an overall tweet embedding by performing a maxpool operation on the contextual word embeddings intended primarily to retain the important information in each dimension:

$$h_j^s = maxpool(\hat{H}_j) \tag{2}$$

The choice of maxpool was made after considering other options like average pooling and $[CLS]$ token representation. We found the maxpool worked best for our classification task.

Given an input tweet T_i and its prior context $\{T_k\}_{k=1}^{i-1}$, we account for the sequence information in the discussion context by performing an element-wise summation of the tweet embedding h_j^s with the positional embedding p_k. We compute the position incorporated tweet context embeddings as:

$$C^{(<i)} = [h_1^s, h_2^s, ..., h_{i-1}^s] \odot [p_1, p_2 ..., p_{i-1}] \tag{3}$$

Since our goal is to detect the propaganda technique used in the input tweet by conditioning on the prior context, we enrich the input tweet embedding using the information from the computed context embeddings $C^{(<i)}$. This is done by feeding the input tweet and the context representations to a context encoder, f_C, comprising N_C transformer encoding layers. However, we introduce an additional context-attention sub-layer in the transformer layer that integrates discussion context into the encoder. This is implemented as:

$$\begin{gathered} U^{(l)} = \textsc{MhAtt}(\hat{H}_i^{(l-1)}, \hat{H}_i^{(l-1)}, \hat{H}_i^{(l-1)}) \\ V^{(l)} = \textsc{MhAtt}(U^{(l)}, C^{(<i)}, C^{(<i)}) \\ H_i^{(l)} = FFN(V^{(l)}) \\ H_{cas} = H_i^{(N_C)} \end{gathered} \tag{4}$$

where l refers to the l^{th} context encoding layer, $l \in 1, 2, ..., N_C$, MHATT and FFN refer to the multi-head attention step and feed-forward network in each transformer encoding layer and $H_i^1 = \hat{H}_i$, $C^{(<t)}$ is the prior discussion context embedding as computed in Equation 3 and $H_i^{(l)}$ is the embedding of the input tweet at the l^{th} layer. The output from the N_C-th layer is the final context-aware semantic view H_{cas} of the input tweet T_i.

5.1.2 Relationship Structure View

The goal of this view is to compute a hierarchical relational embedding that captures two main aspects: (a) dependency graph-based structural information from individual tweets and (c) speaker-dependent structural relationships from the discussion context. First, we intuit that a representation that encapsulates the syntactic structures explicitly and learns relationships between specific words and phrases can better guide the propaganda detection model. We explain the reason as follows. Certain words can express an attitude or sentiment towards specific key terms or entities in the sentence. Despite the advantages of using flat attention-based models, the limitations of assigning higher attention scores to irrelevant words or wrong associations can lead to performance degradation. Additionally, we differentiate between the input tweet user's previous tweets and the other users' tweets in the discussion context. We believe that self-dependency (relationship between input tweet user's previous tweets in the context) and inter-speaker dependency (relationship between input tweet with other users' tweets in the context) can be critical to understanding the speaker motivation (or intention) or attitudinal/sentiment shifts in the conversation. Therefore, both these aspects require the extraction of some form of structural relationship. Recently, graph neural networks (Scarselli et al., 2008; Schlichtkrull et al., 2018; Kipf and Welling, 2016; Veličković et al., 2017) have been applied to tackle challenges in effective representation of nodes from graph-structured data and have proven effective in a number of NLP applications such as aspect-level sentiment analysis (Huang and Carley, 2019; Wang et al., 2020a), reading comprehension (Tu et al., 2019; Zhang, 2020; Song et al., 2018) and relation extraction (Fu et al., 2019; Zhang et al., 2018). However, most of the models like graph-convolution networks (GCN) (Kipf and Welling, 2016) or graph attention networks (GAT) (Veličković et al., 2017) operate on homogeneous links or edges. In our work, we introduce a hierarchical relation-based graph neural network that can aggregate incoming information from neighbors depending on the edge type.

First, we perform coreference resolution[1] given the discussion context tweets and replace the mentions with proper entity information. Next, We apply a dependency parser from (Kong et al., 2014; Liu et al., 2018) to transform a tweet text into a dependency parse graph $\mathcal{G}$. This graph is denoted as $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{R})$ where a node refers to a word in the tweet text ($v_k \in V$) and a labeled edge indicating a dependency relation between two words $(v_k, r, v_m) \in \mathcal{E}$, where $r \in \mathcal{R}$ is a relation type. Each tweet T_j is converted into a graph $\mathcal{G}_j$. Since the traditional GAT model fails to consider different relation types into consideration, there is a significant loss of crucial dependency information. Following some of the prior work on relation-based graphical propagation of information (Busbridge et al., 2019; Veličković et al., 2017; Ishiwatari et al., 2020), we aggregate embeddings of the k^{th} node, $\bar{h}_k^{(l)}$, using varied relation-specific influences of the relation-specific neighborhood nodes $\mathcal{N}_k^r$ computed using an attention mechanism. Stacking N_S layers allows information from nodes N_S-hops away to propagate to a particular node. Therefore, we implement a relational graph attention network (R-GAT) that intuitively aggregates the incoming information from different relations with varying influences. These steps are defined by:

$$\begin{gathered}\bar{h}_k^{(l)} = \textstyle\sum_{r=1}^{R} \bar{h}_{kr}^{(l-1)} \\ \bar{h}_{kr}^{(l-1)} = \textstyle\sum_{m \in \mathcal{N}_k^r} \beta_{kj}^{r(l-1)} W_r^{(l-1)} \bar{h}_m^{(l-1)} \\ \beta_{km}^{r(l-1)} = attention(\bar{h}_k^{(l-1)}, \bar{h}_m^{(l-1)}) \\ \bar{H}_j = [\bar{h}_1^{N_S}, \bar{h}_2^{N_S}, ..., \bar{h}_{N_j}^{N_S}]\end{gathered} \tag{5}$$

where $\beta_{kj}^{r(l-1)}$ denotes the normalized attention coefficient calculated using dot-product mechanism for the node k based on its neighborhood node m under relation type r. Additionally, we compute multi-head attention and concatenate its outputs. We also incorporate relational position embeddings as in (Ishiwatari et al., 2020). At $l = 1$, $\bar{h}_j^1$ is assigned to the contextual word embeddings obtained in Equation 1. Similar to Equation 2, we obtain a structural information enriched tweet embedding h_j^{rel} for a tweet T_j using maxpool operation on $\bar{H}_j$.

For the input tweet T_i, we differentiate discussion context tweets into two types: (i) T^A: tweets that are produced by the same user as the input tweet and (ii) T^B: tweets that are produced by all users other than the input tweet user. Using the computed tweet-level structural embedding h_j^{rel}, we construct a graph to account for speaker-dependent structural relationships (An example is shown in Figure B1). This includes two labeled edges indicating how the input tweet T_i is influenced by T^A (self-dependency) and T^B (inter-speaker dependency). Once the graph is constructed, we run R-GAT as in equations 5. Finally, we obtain relationship structure view of the input tweet T_i as:

$$H_{rel} = \bar{H}_i^{(N_R)} \tag{6}$$

where N_R refers to the number of layers in the speaker-dependent relationship extraction layer.

5.1.3 Knowledge-Enriched View

Some of the propaganda techniques involve distortion of facts and data to promote their cause or point of view. Thus, we intuit that models which infuse external knowledge could potentially improve the overall performance in our task. Therefore, the primary aim of the knowledge-enriched view is to compute a text representation by enriching them with different kinds of knowledge. We leverage K-ADAPTER$(F + L)$ (Wang et al., 2020c) that combines both factual knowledge and linguistic knowledge to derive the knowledge-enriched view. K-ADAPTER acquires factual knowledge from the relationships among entities in text by training on a large scale alignment dataset between Wikipedia abstracts and Wikipedia triples. We modify the input by concatenating the context C_i and input tweet T_i: "<SEP> context</SEP>input tweet</SEP>" and use the embedding of the first token to get the knowledge-enriched view. This is given as:

$$\widetilde{H}_{know} = \text{K-ADAPTER}(T_i, C_i) \tag{7}$$

5.2 Cross-View Transformer

First, we fuse the cross-view information between any two views A and B using an additional multi-attention sub-layer as in Equation 4. We denote the three views as S, R, K. Next, we introduce a

---

[1] https://spacy.io/universe/project/neuralcoref

transformer encoder layer on top of the cross-view transformer layer. Finally, we perform a maxpool operation on the output from the previous transformer layer. These steps are defined by:

$$\begin{aligned} H_{R \mapsto S} &= \text{MH-ATT}(Query_S, Key_R, Value_R) \\ H_{K \mapsto S} &= \text{MH-ATT}(Query_S, Key_K, Value_K) \\ z_S &= maxpool(Transformer([H_{R \mapsto S}; H_{K \mapsto S}])) \end{aligned} \tag{8}$$

Similarly, we compute z_R, z_K and feed the concatenated outputs to the final classification layer.

5.3 Classification Layer

We calculate the probability that the input tweet uses a particular propaganda technique using a softmax layer, where f_p is a fully-connected layer, and z is the embedding produced by concatenating the outputs from the previous layer as:

$$z = z_S || z_R || z_K q = softmax(f_p(z)) \tag{9}$$

6 Training & Implementation Details

We optimize the categorical cross-entropy loss between the predicted and true propaganda labels as in Equation 10, where L is the total number of propaganda labels, q_j is the predicted distribution that the input tweet falls under propaganda technique j, and $p_j \in \{0, 1\}$ denotes the ground-truth of whether the input tweet can be categorized under the j^{th} propaganda label.

$$L_{CE} = \textstyle\sum_{j=1}^{L} -p_j log(q_j) \tag{10}$$

We use the publicly released default pre-trained model parameters for the BERT variants used. We perform a grid-search and optimize the hyperparameters using the validation set: $N_C = 3, N_S = N_R = 2$. We used Adam with a learning rate of α=2e-5 and a warmup proportion of 0.1 for optimization. To account for randomness, we report the numbers which are the mean of five experimental runs with different random seeds. To alleviate the problem of unbalanced datasets, we utilize class weights in categorical cross-entropy loss based on the training and validation sets. See Appendix A for details on the hardware.

7 Experiments

Our experiments are designed to investigate the following research questions:

RQ1: How well does our MV-PROP model perform compared to the other baselines in the propaganda detection task on social media data?

RQ2: What are the influences of different views and their interactions on the overall performance?

RQ3: Can our model be applied to detect propaganda on in-domain and cross-domain datasets?

7.1 Dataset

We run experiments using TWEETSPIN dataset containing 210,392 tweets labeled with 19 propaganda types (referring to 18 propaganda techniques and 1 non-propaganda label). Due to the imbalance of the TWEETSPIN dataset, we divide our TWEETSPIN dataset into training (70%), validation (10%), and test (20%) sets using a stratified shuffle split[2].

7.2 Baselines

We use the following baselines in our experiments:

BERT FT (Devlin et al., 2018) is a fine-tuned version of BERT$_{base}$ model on the input tweets with and without considering the discussion context.

ROBERTA FT (Liu et al., 2019) is a fine-tuned version of ROBERTA$_{base}$ model on the input tweets conditioning on the discussion context tweets.

LATEXPRO (Wang et al., 2020d) leverages the declarative knowledge expressed in both first-order logic and text. We reimplement a variant of this model without the token-level loss to suit the sentence-level classification task. We further investigate the importance of the discussion context.

7.3 Model Variants

We investigate the importance of different modeling components by introducing variants to our proposed model and evaluating their performance on the TWEETSPIN validation set. These variants assess the influence of critical aspects: (a) discussion context, (b) different views, and (c) different fusion techniques. Depending on the fusion technique, we replace the cross-view transformer with simple late fusion techniques involving concatenation, mean, and sum of embeddings obtained from multiple views. View-specific variants include:

MV-PROP, which refers to our full model comprising all the three views as shown in Section 5.

MV-PROP-K, which integrates semantic and relational views while removing the knowledge-enriched view from our model.

MV-PROP-R, which combines semantic and knowledge-enriched views while removing the relationship structure view from our model.

---

[2] In this paper, we performed the stratified shuffle split using Python's Scikit-learn module

MV-PROP	**70.17**	**59.63**	**64.47**

Table 2: Ablation study on the TWEETSPIN validation set. We observe that the performance degrades when a specific view is removed or the cross-view transformer is replaced with other fusion techniques.

MV-PROP-S, which computes knowledge and relational views while removing the context-aware semantic view from our model.

7.4 Results

We report the precision, recall, micro-averaged F1 scores and standard deviation of the computed F1 scores across five runs. in Table 1. Notably, the context plays a critical role in determining the propaganda label. This is evident from an average $\sim 17.8\%$ drop in F1 without the context information in the baseline methods. We also find that the context information reduces the sensitivity of the models as indicated by a diminished standard deviation value whenever context comes into play. The results in Table 1 also demonstrate the ability of our multi-view representations to surpass the other baseline models by a large margin.

7.4.1 Effect of Multi-view Representations

In addition to experiments that emphasize the importance of the context in Table 1, we study the necessity of each view by discarding one view at a time and reporting the relative impact on the performance. It is clear from Table 2 that removal of each view leads to a significant drop in performance with knowledge-enriched view diminishing the performance by $\sim 14\%$. Since K-Adapter model injects additional knowledge into a pre-trained language model, it retains the benefits of the semantic representation obtained from the language model and also additionally incorporates both factual knowledge and entity information into the embedding. Therefore, discarding this component leads to a significant loss of information. This is the same reason why the drop in performance is relatively smaller when the context-aware semantic view is removed. The embedding from the knowledge-enriched view partially compensates for the information loss when the semantic view is discarded. We also highlight that the relationship structure view has a noticeable effect on the recall. We show sample tweets that were misclassified by our variants compared to our full model in Table B3 to further illustrate the importance of our views.

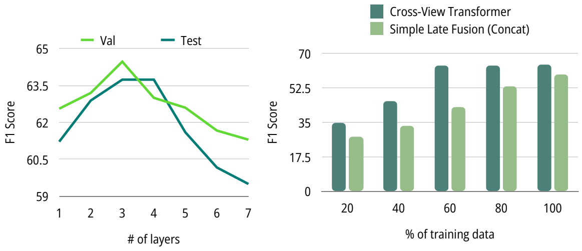

Figure 3: Analysis of cross-view transformer on TWEETSPIN. Left: Effect of number of cross-view transformer layers on performance. Right: Impact of cross-view transformers over simple late fusion method (concatenation) by varying the proportion of training samples.

7.4.2 Effect of Cross-View Transformer

To study the effect of the cross-view transformer, we analyze the following: (a) effect of number of cross-view transformer layers, (b) impact of cross-view transformers over simple late fusion methods such as concat, mean, and sum of embeddings obtained from different views. Figure 3 (left) shows model performance with varying number of layers. The performance improves initially with the increase in number of layers and then drops beyond a point. The optimal number of layers on the validation and test datasets is 3. Moreover, Table 2 reports the performance for model variants involving simple late fusion techniques instead of the cross-view transformers. Visibly, the best performing late fusion technique (concat) lags behind the full MV-PROP model containing cross-view transformer layers. With a performance drop of $\sim 8\%$, it is evident that the cross-view transformer efficiently

Models	F1
LR*	81.7
SVM*	79.5
LSTM*	80.7
LSTMR*	78.9
MV-PROP	84.36

Table 3: Evaluations results on the TWE dataset. * indicates the scores reported in the original paper (Wang et al., 2020b).

computes the interaction between multi-view representations. Further, we vary the proportion of the training data and evaluate the potential impact of the cross-view transformer. We observe that our model with the cross-view transformer allows for quicker learning than the simple concatenation-based late fusion strategy. Figure 3 (right) shows that our full MV-PROP model plateaus closer to the best F1 score with $\sim 60\%$ of the training data.

7.5 Performance on Unseen In-Domain dataset

Wang et al. (2020b) constructed a TWE dataset by combining two pre-existing datasets, the Twitter IRA corpus (Edgett, 2017) and the "twitter7" data from SNAP (Yang and Leskovec, 2011) as propagandistic and non-propagandistic data respectively. However, this dataset doesn't contain the discussion context that is critical to exploit the full potential of our MV-PROP model. Table 3 shows evaluations on the TWE dataset. Though certain views like the relationship structure view may not be utilized to their capabilities due to the lack of the discussion context, our MV-PROP model is able to significantly outperform the baselines used in the original work. Notably, our trained MV-PROP model performs well on the unseen in-domain dataset.

7.6 Performance on Cross-Domain Dataset

We hypothesize that our full model trained on the TWEETSPIN dataset is transferable to a cross-domain dataset like news articles. To verify this, we conduct an experiment on the Propaganda Techniques Corpus (PTC) (Da San Martino et al., 2019b), which is a manually annotated dataset for propaganda detection. Given that our model detects propaganda at the tweet level, we perform the sentence level propaganda detection (SLC) task from Da San Martino et al. (2019b) that determines whether a given sentence from a news article is propagandistic. We train a zero-shot (MV-PROP (ZS)) variant of our model that directly takes the input from the PTC dataset and outputs the likelihood of it being propagandistic. With a threshold of 0.6, our model performs comparably to the fine-tuned BERT model, showing that our model demonstrates transfer capability to a similar task in the news domain. Further, we fine-tune our MV-PROP model (MV-PROP (FT)) using the PTC training set and observe that we outperform other benchmarks for the SLC task. Results are shown in Table 4.

Models	P	R	F1
Random	30.48	51.04	38.16
All-Propaganda	30.54	100.00	46.80
Fine-tuned BERT*[1]	63.20	53.16	57.74
BERT-Joint*[1]	62.84	55.46	58.91
MGN*[1]	60.41	61.58	60.98
Proper Gander*[2]	56.50	70.10	62.56
LatexPRO*[3] (L)	56.53	73.17	63.79
LatexPRO*[3] (L+T)	59.04	71.66	64.74
MV-PROP (ZS)	54.08	62.75	58.09
MV-PROP (FT)	**64.35**	**84.58**	**73.09**

Table 4: Evaluation results on the test set of PTC dataset for the sentence level propaganda classification (SLC) task.* refers to the scores reported from their original work. 1 refers to (Da San Martino et al., 2019b), 2 refers to (Madabushi et al., 2020), 3 refers to (Wang et al., 2020d). ZS refers to zero-shot and FS to fine-tuned variants of our model. All-Propaganda model always classifies the input text as propagandstic.

8 Conclusion

We introduced TWEETSPIN, a corpus of tweets containing weak labels of fine-grained propaganda techniques. Next, we presented a transformer-based multi-view propaganda detection model, MV-PROP, that integrates multi-view contextual embeddings via pairwise cross-view transformers. We demonstrate how the semantic, relational, and knowledge view enrichment of the input tweet text leads to significant performance improvement over other baseline methods. Our experiments also demonstrated the transferability of our trained model to propaganda detection for news articles. The main limitation of our work is the reliance on weak annotations of Twitter data, which is unavoidable given the scale of our dataset. Future work could investigate leveraging the multi-view representations for span-level detection of fine-grained propaganda techniques.

9 Ethics Statement

Social media has become a battleground for propaganda and influence campaigns. This paper is an attempt to provide a dataset and models for detecting various propaganda techniques on Twitter to aid with the fight against this scourge on society. We release TWEETSPIN, a Twitter corpus containing weak-annotations of fine-grained propaganda. Consistent with Twitter TOS, TWEETSPIN contains only tweet IDs (with code provided to hydrate them) and no identifying information. Given the nature of the task the dataset contains potentially offensive and hateful language which should be taken into consideration. Additionally it is possible that our models, analyses, and dataset can potentially be used to create more advanced and harder to detect propaganda techniques. Though we should be aware of this possibility it is imperative that we in the research community stay ahead of miscreants by actively pushing this field forward. Finally, our models can lead to false positives where a user is falsely accused of spreading propaganda. Thus, it is important that the techniques presented here be used as a part of a larger effort to combat propaganda with humans in the loop for checks and balances.

TWEETSPIN was validated using MTurk. The annotators were paid 0.08 USD per task which took on average 30 seconds, for an hourly rate of 9.6 USD, above the federal and our state's minimum wage.

A Experiment Platform

All the experiments were conducted on a Ubuntu 20.04 system, with 2.10GHz Intel(R) Xeon(R) CPU and 8-core NVIDIA GeForce GTX 1080Ti/11GB. Our models were implemented using Pytorch 1.4 with CUDA 10.1.

B Additional Information and Examples

Table B1 shows the statistics of the TWEETSPIN dataset. Table B2 lists the common phrases related to different propaganda techniques used in our data collection process. Table B3 shows sample tweets that were misclassified by our model variants in comparison to our full MV-PROP model. Finally, Figure B1 illustrates the speaker dependency graph related to a sample tweet thread.

Dataset Statistics	
#Total Propaganda Tweets	157,327
#Total Non-Propaganda Tweets	53,165
% of tweets with discussion context	59.06
Avg. discussion context length	3.15
Avg. #users in discussion context	2.26

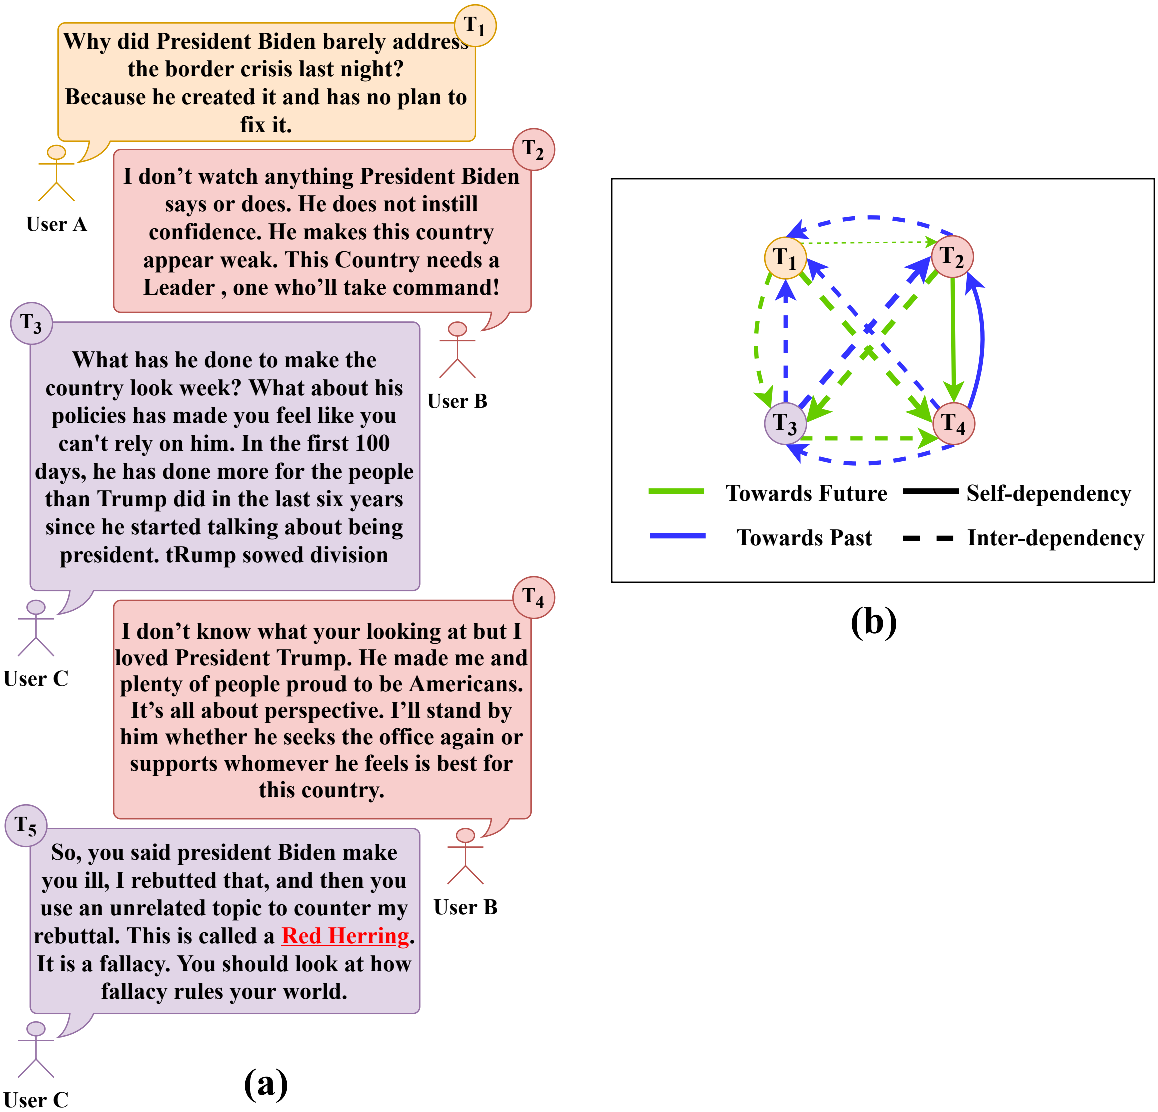
Tweet	True Label	Model	Predicted Label
Context: A discussion about AR15 Guns for hunting And no one needs a BMW o a$1000 suit or a Rolex instead of a Timex. It's what one wants, not needs. Many people want an AR15...You remind me of an unelected bureaucrat in a position of power,...	Straw man	MV-PROP-S	[Loaded language, Whataboutism]
		MV-PROP	[Straw man, Whataboutism]
Context: A discussion about student loans You're right. Being able to sign away your life & go to war & die is definitely less that debt.	Red Herring	MV-PROP - R	[Straw man, Exaggeration]
		MV-PROP	[Red Herring, Straw man]
Context: A discussion about Presidential Elections 2020 This is 'Democracy', Venezuela-style. Or Cuba. Or China. Or the Soviet Union. Or a certain Central European country in the 1930's.	Reductio Ad Hitlerum	MV-PROP - K	[Non Propaganda, Red Herring]
		MV-PROP	[Reductio Ad Hitlerum, Straw man]

Table B3: Sample tweets which were misclassified by our model variants in comparison to our full MV-PROP model. We report the top 2 ranked predictions.



Why did President Biden barely address the border crisis last night? Because he created it and has no plan to fix it.

I don't watch anything President Biden says or does. He does not instill confidence. He makes this country appear weak. This Country needs a Leader , one who'll take command!

What has he done to make the country look week? What about his policies has made you feel like you can't rely on him. In the first 100 days, he has done more for the people than Trump did in the last six years since he started talking about being president. tRump sowed division

I don't know what your looking at but I loved President Trump. He made me and plenty of people proud to be Americans. It's all about perspective. I'll stand by him whether he seeks the office again or supports whomever he feels is best for this country.

So, you said president Biden make you ill, I rebutted that, and then you use an unrelated topic to counter my rebuttal. This is called a Red Herring. It is a fallacy. You should look at how fallacy rules your world.

Figure B1: (a) Sample tweet thread where speaker dependencies can determine the propaganda technique; (b) Speaker-dependent structural relationship for the discussion thread in (a).

UserIdentifier: Implicit User Representations for Simple and Effective Personalized Sentiment Analysis

Abstract

Global models are typically trained to be as generalizable as possible. Invariance to the specific user is considered desirable since models are shared across multitudes of users. However, these models are often unable to produce personalized responses for individual users, based on their data. Contrary to widely-used personalization techniques based on few-shot and meta-learning, we propose UserIdentifier, a novel scheme for training a single shared model for all users. Our approach produces personalized responses by prepending a fixed, user-specific non-trainable string (called "user identifier") to each user's input text. Unlike prior work, this method doesn't need any additional model parameters, any extra rounds of personal few-shot learning, or any change made to the vocabulary. We empirically study different types of user identifiers (numeric, alphanumeric, and also randomly generated) and demonstrate that, surprisingly, randomly generated user identifiers outperform the prefix-tuning based state-of-the-art approach by up to 13%, on a suite of sentiment analysis datasets.

1 Introduction

Personalization arises in applications where different clients need models specifically customized to their environment and user profiles (Yang and Eisenstein, 2017; Mazaré et al., 2018; Flek, 2020). This need for customization stems from the inherent heterogeneity existing in the data and the labels, especially when the task is classification (Kulkarni et al., 2020; Wang et al., 2018). Fig. 1 shows an example of the sentence "That is just great!". This sentence could carry a positive sentiment, a neutral apathetic sentiment, or even a completely negative sentiment. A non-personalized model cannot correctly predict the label for different users.

Most techniques for personalization generally involve two phases: first, a shared, global model is built between all users, and then, it is personalized for each client using their data (Kulkarni et al., 2020; Schneider and Vlachos, 2019; Lee et al., 2021). In such cases, each user has either an entirely separate model, or additional personal parameters, causing significant overheads, both in terms of storage of the large models, and the computation complexity of training separate models for each user. UserAdapter (Zhong et al., 2021), the state-of-the-art in personalized sentiment analysis, takes a prefix-tuning based approach (Li and Liang, 2021), as shown in Fig. 1. In the first phase, a global model is trained in a user-agnostic way on a large dataset. In the second phase, each user u is assigned their own prefix vector, p_1^u, which is fine-tuned separately for them, on their own data. If there are N users, there would be N separate rounds of fine-tuning, producing N vectors. During this prefix-tuning phase, the underlying transformer-based classification model is frozen and shared between users,

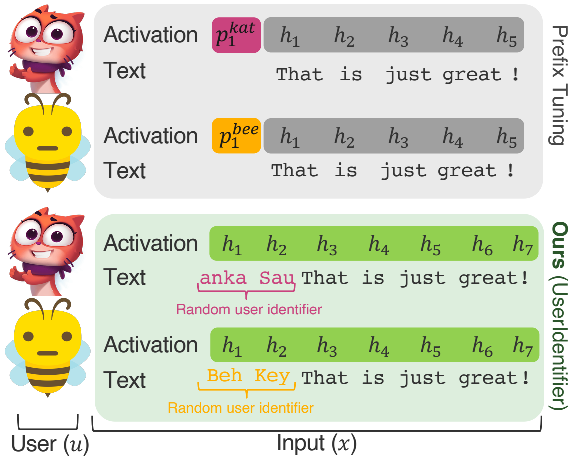

Figure 1: An overview of the proposed method, UserIdentifier, compared to its prefix-tuning counterpart. p_1^{kat}, p_1^{bee} denote the trainable prefix vector for users kat and bee, in the prefix tuning method (Zhong et al., 2021). UserIdentifier, on the other hand, does not have trainable user-specific parameters and uses random per-user (UID) strings ("`anka Sau`" and "`Beh KY`"), to condition a shared model, for each user.

---

and the final N vectors are stored for inference.

To alleviate these training and storage costs and also improve overall performance, we propose training a single, shared personalized model, which can capture user-specific knowledge by conditioning on a unique, user-specific sequence of tokens from the classifier's vocabulary. We name this sequence "user identifier", and dub the underlying method of adding user identifiers to the input UserIdentifier. This is shown in Fig. 1, where we add the randomly generated, and non-trainable user identifiers "`anka Sau`" and "`Beh KY`" to each user's sample, and then train the transformer classifier model, on these augmented samples. The user identifiers just use the underlying model's vocabulary and embeddings and do not add any tokens nor any user embeddings to the model. They are also static over time, and unique to each user, which means the user "bee" in Fig. 1 will have "`Beh KY`" pre-pended to all their samples, and no other user has this identifier. This is similar to the prompting of models like GPT-3 (Brown et al., 2020), however, here the prompt is fixed and used as data augmentation during training, and the model is not generative. As such, we only do training once and have one set of shared parameters for all users. The approach is similar in essence to those of Daumé III (2009); Kocoń et al. (2021); Kocoń et al. (2021), which augments each individual feature with domain annotations.

We experiment with different types of strings for user identifiers, such as real usernames from the dataset, consecutive numbers, random digits, random non-alphanumeric tokens, and random tokens (all types), and observe that, surprisingly, random identifiers, sampled from all possible tokens in the vocabulary perform best, providing $1.5\% - 13\%$ classification accuracy improvement on average, over the prefix-tuning based method UserAdapter (Zhong et al., 2021). We also study different lengths of identifiers. We report our results on three different sentiment analysis datasets (Sentiment 140, IMDB, and Yelp). We also show that UserIdentifier is effective in a federated learning setup (Appendix A.1), which is a real-world application of such personalization (Kulkarni et al., 2020).

2 UserIdentifier

In this section, we first explain how UserIdentifier operates, then we go over the parameterization and learning procedure.

2.1 Method

UserIdentifier is a data augmentation method which consists of adding a sequence of user-specific tokens (user identifier, u_{id}, drawn from the tokenizer's vocabulary) to each sample, x, to provide user-related cues to the model and help it learn individual user behaviour and preferences, all in one shared model. Figure 1 shows how this augmentation works. Each utterance is appended by the user identifier to create the augmented sample $[u_{id}; x]$, and then used as input to the model, for the training stage.

There is no restriction on what the make-up or the length of the user identifier sequence can be (as long as it is not longer than the maximum sequence length the model can input). However, we propose randomly generating each user's identifying sequence, through uniformly sampling from the tokenizer vocabulary, for a given length L, which we ablate in section 4.2. This random sampling step creates a diverse while unique set of user identifiers, potentially allowing the model to distinguish different users more efficiently.

2.2 Parameterization

For parameterizations of the user identifiers, we use parameter tying (He et al., 2019), where the user identifiers use the same set of parameters for their embeddings as the rest of the user utterance. In other words, in this setup the user embedding parameters are tied to the embedding parameters of the main transformer classification model, parameterized by θ. This form of parameterization is both simpler and has highere performance (we try separate parametrization in our experiments and show its inferior performance).

2.3 Learning

The training stage doesn't change compared to the original fine-tuning process, with parameters θ of the transformer model being trained to minimize the cross-entropy loss for the classification (Devlin et al., 2018):

$$\mathcal{L}_{\mathrm{CE}}(x,u_{id},y;\theta) = -\log \Pr(y|[u_{id};x];\theta) \qquad (1)$$

$$\theta = \underset{\theta}{\operatorname{argmin}}\, \mathcal{L}_{\mathrm{CE}}(x,u,y;\theta) \qquad (2)$$

Where x denotes the input utterance, $u_i d$ denotes the user identifier for the user to whom utterance x belongs, and y is the class label for x.

Table 1: Dataset specifications

Dataset	# Users	# Samples	# Classes
IMDB	1,012	137,710	10
Yelp	4,460	428,369	5
Sent140	1,100	56,557	2
Sent140 (skewed)	473	23,155	2

3 Experimental Setup

3.1 Tasks, Datasets, and Models

We evaluate the proposed method on the task of sentiment analysis. Table 1 shows a summary of the datasets used in our experiments. We use the IMDB (Diao et al., 2014) and Yelp (Tang et al., 2015) datasets for comparison with the UserAdapter method (Zhong et al., 2021) and for the ablation studies. Each user's data is split into train, test, and validation sets, with 0.8, 0.1, and 0.1 ratios. For comparison purposes, we are using a subset of the available users, i.e. those with fewer than 50 samples, as done by Zhong et al. in support of few-shot learning, for reporting test accuracy. We use the RoBERTa-base model for this set of experiments.

In addition to IMDB and Yelp, we also report the performance of the proposed method on the Sentiment140 dataset citesent140, caldas2018leaf, which is a set of Tweets collected from Twitter and labeled positive or negative based on the emojis in each Tweet. For this dataset, We use the methodology provided by Li et al. (2019) to preprocess and partition this dataset. We create a second version of this dataset, and mark it as "skewed". For this skewed data, the users have been selected such that their sentiments are mostly skewed, i.e. we only include users with 80% or more positive or negative Tweets. We do this to create a setup where data is more heterogeneously distributed. We use BERT-base-uncased for evaluations on the Sentiment140 dataset.

3.2 Baselines

Conventional Training. Conventional finetuning of the pre-trained transformer model on the full dataset, without personalization.

UserAdapter. In UserAdapter, the work closest to ours, a per-user embedding is learned through few-shot learning and stored. These personal vectors are prepended to the users' data to create personal responses. This work proposes prefix-tuning (Li and Liang, 2021) on a user-level. Unlike our method, UserAdapter consists of two phases, as discussed in the introduction.

Trainable User Embeddings. UserIdentifier uses the same set of parameters (BERT embeddings) for embedding both the sample content and the user identifiers. In other words, the text and user embedding parameters are tied. To untie these parameters, we introduce a third baseline, with trainable user embeddings. In this setup, while the tokens used for the user identifier are still drawn from the pre-trained model's tokenizer vocabulary, we're creating and training a separate set of global parameters for the user embedding, instead of using the pre-trained model's embedding. These extra embedding parameters are placed in parallel to the model's existing embedding layer. Each input sequence is partitioned to the content and the UID, the content is fed to the model's existing embedding layer and the UID is fed to the new embedding.

3.3 Types of User Identifiers

We investigate five scenarios (types of sequences) for the user identifiers. The length of the user identifier sequences can vary in terms of the number of tokens (L) for the last three of these scenarios.

Default (Def.): This scenario uses the real user id (e.g., username) of that user, when provided by the dataset and if they are not private. We only have this option available for the Sentiment140 dataset.

Consecutive Numbers (Num.): We assign each user a unique number, from 1 to N, representing each user (up to N users).

Random sequence of digits (Rand. Dig.): In this scenario, L independent and identically distributed (i.i.d) samples from the set of digits (0 to 9) are drawn, creating a sequence of length L for each user.

Random sequence of tokens with non-alphanumeric characters (Rand. Non.): L i.i.d samples are drawn from a subset of tokens (with size 400) that contain non-alphanumeric characters, e.g., the token `Ã""`. The motivation for this scenario is that such user identifiers might be easier for the model to distinguish from the text (if we make sure the textual content in the sample has no overlapping tokens with the identifier).

Random sequence of all tokens (Rand. All): This scenario draws L i.i.d samples from the set of all available tokens in the tokenizer vocabulary.

4 Results

Apart from the evaluations here, We have also provided evaluations of applying our method to federated learning in Appendix A.1, and applying it to new unseen user samples in 4.4.

Table 2: Comparison of sentiment classification accuracy of UserIdentifier, with the baselines of Section 3.2. Num., Def. and Rand. refer to the different types of user identifiers introduced in Section 3.3.

	Dataset	Conventional	UserAdapter	Trainable User Emb.			UserIdentifier		
				Num.	Def.	Rand. All	Num.	Def.	Rand. All
RoBERTa	IMDB	45.1	46.2	45.5	–	48.9	50.1	–	**52.5**
	Yelp	68.3	70.2	68.3	–	70.6	69.5	–	**71.3**
BERT	Sent140	84.7	–	84.7	86.3	86.5	84.9	87.1	**87.1**
	Sent140 (Skewed)	86.3	–	87.2	89.3	90.0	87.5	90.3	**90.4**

Table 3: Classification accuracy vs the length (#tokens) and type (Section 3.3) of user identifier sequence)

	Seq. Len.	Rand. Dig	Rand. Non.	Rand. All
IMDB	5	48.8	51.3	52.2
	10	47.4	51.7	52.5
	20	47.1	50.2	51.1
	50	46.5	48.7	50.8
	200	33.3	32.8	40.1
Yelp	5	68.6	69.3	70.8
	10	68.7	69.6	71.3
	20	68.4	68.6	71.0
	50	67.8	69.0	70.6
	200	63.2	60.2	65.1

4.1 Comparison with Baselines

A comparison of UserIdentifier with the state-of-the-art UserAdapter method, and the other baselines is presented in Table 2. For the **Num.** (consecutive numbers) and **Def.** (default username) scenarios, as detailed in Section 4.2, the length of the user identifier sequences depends solely on the tokenization process. For the case of **Rand. All** (randomly sampled from all vocabulary tokens), however, it is shown that the sequence length of 10 tokens provides the best performance through the ablation study, therefore the results are reported for this length. Since the default usernames for IMDB and Yelp datasets are not provided, the corresponding results are not reported here.

It is shown that UserIdentifier with randomly generated identifiers outperforms all baselines, in all tasks. Our intuition is that UserIdentifier outperforms UserAdapter because of collaborative learning and personalization happening simultaneously, unlike in the case of UserAdapter where personalization is performed separately for each user. The performance of trainable user embeddings appears inferior to that of UserIdentifier, which could be attributed to the parameter tying used in UserIdentifier. This parameter tying couples the learning problems for both domains (user identifier and text) and allows us to jointly learn from the full data, as in (He et al., 2019). For the Sentiment140 dataset, we can see that increasing the heterogeneity or skew in the dataset boosts the benefits brought about by UserIdentifier. This shows that the proposed method performs better in setups where personalization is actually needed (Deng et al., 2020).

4.2 Ablation Studies

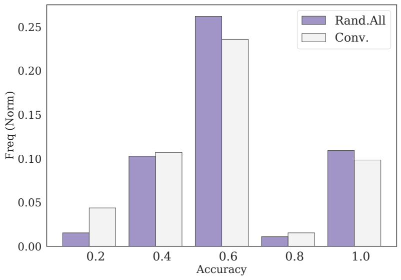
Table 3 shows our ablation study into the length and the type of the user identifier sequence, for IMDB and Yelp datasets. The most evident trend is that performance significantly degrades in both datasets when the length of the user identifier sequence exceeds 20 tokens, holding for all identifier types. This is because the length of the input text itself is essentially decreased (the maximum sequence length for RoBERTa is 512, and the textual content of the sample is truncated to fit the user identifier) when increasing the length of the identifier. This decreases the useful information which could be used to infer sentiment, and in turn, it has an adverse effect on accuracy.

A rather surprising observation is that randomly sampling from the tokenizer's entire vocabulary outperforms sampling only from digits or from the non-alphanumeric tokens. This can be attributed to the different sizes of the sampling spaces for these three types, and the probability of overlap in user identifier from user to user. For the random digits (**Rand. Dig.**) the sample space size for each token position is 10, the number of possible digits. For the non-alphanumeric tokens, we have limited them to 400, and for the token type all (**Rand. All**), the possible sample space is 47,400. This means that the probability of having token overlaps in user identifiers is much much smaller in the last scheme than it is for the other two, or in other words, the hamming distance between different user identifiers is higher with this method.

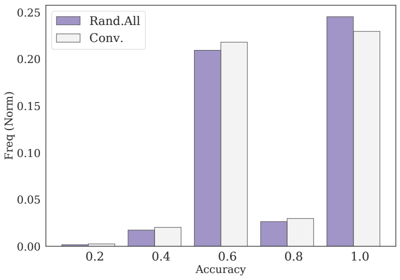
One hypothesis that might explain the success of random user identifiers: random user identifiers are similar to random feature projections (Rahimi et al., 2007), but, in contrast with learnable embeddings, they are defined in terms of the pre-trained model's original token embeddings. This may have a positive effect on optimization during fine-tuning.

4.3 User-level Study Accuracy

Figure 2 shows the distribution of test-accuracy changes across users, for conventional training (Conv.) and the Rand. All scheme from UserIdentifier. We have chosen the best version of our model from Table 2 for this figure. We can see that the number of users with low accuracy decreases in both datasets. Also, the standard deviation of accuracy across users decreases compared to conventional training when using UserIdentifier, it drops from 27.0% to 25.6% for IMDB, and from 21.2% to 21.0% for Yelp. We provide more plots and analysis on this in A.2.



(a) IMDB



(b) Yelp

Figure 2: Distribution of test accuracy across users.

4.4 Performance on Unseen Users

To measure how robust the proposed method is to new users that have never been seen before, we run an evaluation on new users and report the results in Table 4. For this experiment, we have used the best models from Tables 2, and tested them on samples from new users, without appending any user identifiers. It is noteworthy that there is some distribution shift between these unseen users and the seen users from Table 2, especially for Yelp, as we used samples that were not used in the original training/test/val setup (this test set contains 5000 samples for Yelp and 1357 samples for IMDB).

Table 4: Evaluation results on unseen users.

	UserIdentifierAccuracy (%)	Conventional Model Accuracy (%)
IMDB	50.4	50.9
Yelp	50.1	49.8

The UserIdentifier column refers to the accuracy of those datapoints on models trained with user identifiers, and the conventional column shows the accuracy but on a conventionally trained model, which would be the baseline. We can see that both models behave similarly, which suggests that for unseen data points, the UserIdentifier trained model falls back to a conventional model, and does not behave even worse.

5 Conclusion

In this work, we present a novel approach for learning global models, producing personalized classification responses. This method which doesn't require model extensions or specialized training algorithms, consists of appending a fixed, non-trainable, unique identifier string to each sample during training and inference.

Acknowledgments

The authors would like to thank the anonymous reviewers and meta-reviewers for their helpful feedback. We also thank Huseyin Inan and Guoqing Zheng for insightful discussions and Wanjun Zhong for helping with datasets. Additionally, we thank our colleagues at the UCSD and Microsoft for their helpful comments and feedback.

Ethical Considerations

Our proposed model is intended to be used for addressing the problem of personalization, by learning one shared model for all users, and querying it using a personal identifier. One potential measure that needs to be taken for deployment of such technology is to setup proper authentication tools, so that each user can only query with their own identifier and prevent users from breaching privacy by querying other users' models. However, this could be a concern in other personalization setups too.

The datasets used in our experiments are all publicly available (Yelp, IMDB and Sentiment 140), and we have not collected any information about the users who have contributed their data beyond what is originally provided in the dataset, which is only the user-based partitioning of the data.

A Appendix

A.1 Federated Learning as an Application

Federated learning is a form of distributed learning where data never leaves each user's device (Wang et al., 2021; Konečný et al., 2018; Mireshghallah et al., 2020). Instead, the user trains a model on their device locally and then shares the gradients (model updates) with a centralized server, which aggregates the gradients from different users and sends the updated model back to all of them, for further training. We target this setup since it is a good candidate for personalization, given how a conventionally trained global model often fails to accommodate all users (Kulkarni et al., 2020; Mansour et al., 2020). Table 5 shows the performance gain of applying UserIdentifier, in a federated setup. UserIdentifier can be readily applied in federated learning, by assigning identifiers to each user and then asking them to append it to all their samples. We have used the Rand. All type of user identifier for this experiment, since we observed in previous sections that it was the most effective. In general, the baseline performance and the performance gain in the federated setup is slightly lower than in centralized learning, which is due to the distributed nature of FL, and the fact that only the average of multiple gradient updates are shared with the server for aggregation.

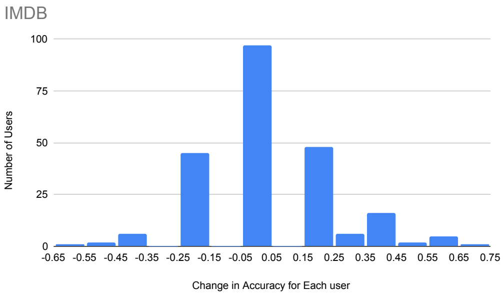
Table 5: Performance of UserIdentifier for sentiment classification in a federated learning setup.

	Dataset	Conventional	User Identifier
RoBERTa	IMDB	44.30	47.23
	Yelp	68.40	70.60
BERT	Sent140	84.40	86.30
	Sent140 (Skewed)	86.50	90.00

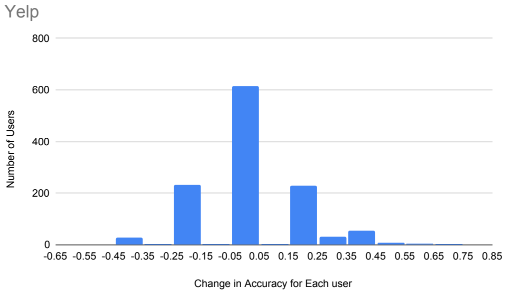
A.2 Further User-level Accuracy Studies

Figure 3 shows the change in user accuracy, when we use UserIdentifier for training, instead of conventional training for each user. In other words, the horizontal axis shows $conventional_{acc} - UID_{acc}$ for each user, and the vertical axis shows the count of users.

As the plots show, on average across the two datasets, 32.1% of the users see improvements in accuracy, whereas 54.2% don't see any change.



(a) IMDB



(b) Yelp

Figure 3: Distribution of test accuracy **change** across users.

A.3 Maximally Distant User Identifiers

To better understand the effect of edit distance between user identifiers, We also experimented with **maximally distanced** identifiers (for the Rand. All setup), where the maximum distance would be the length of the identifier here since each token in the identifier can take a substantially large number of values. For this experiment, we used rejection sampling for user ids, as in if a new random sample had any token overlaps with existing user ids, we would reject it and sample a new one. We observed results very similar to the ones with the random identifiers, which we hypothesize is because the random identifiers are already highly distanced and rarely overlap (less than 10% of the users have non-maximal distance).

Improving Neural Models for Radiology Report Retrieval with Lexicon-based Automated Annotation

luyao.shi@ibm.com {stf, tbaldwin}@us.ibm.com

Abstract

Many clinical informatics tasks that are based on electronic health records (EHR) need relevant patient cohorts to be selected based on findings, symptoms and diseases. Frequently, these conditions are described in radiology reports which can be retrieved using information retrieval (IR) methods. The latest of these techniques utilize neural IR models such as BERT trained on clinical text. However, these methods still lack semantic understanding of the underlying clinical conditions as well as ruled out findings, resulting in poor precision during retrieval. In this paper we combine clinical finding detection with supervised query match learning. Specifically, we use lexicon-driven concept detection to detect relevant findings in sentences. These findings are used as queries to train a Sentence-BERT (SBERT) model using triplet loss on matched and unmatched query-sentence pairs. We show that the proposed supervised training task remarkably improves the retrieval performance of SBERT. The trained model generalizes well to unseen queries and reports from different collections.

1 Introduction

Electronic health record (EHR) retrieval is important for clinicians, staff and researchers. The tools for performing clinically relevant searches could aid in many use cases such as clinical decision support (Syeda-Mahmood, 2010), auditing, revenue cycle management, and cohort selection for clinical studies. Frequently, these searches involve retrieval of patients based on clinical findings that are often captured in unstructured textual reports such as radiology reports, encounter notes, etc. Unlike structured query-based lookup of EHR, retrieval of unstructured (free-text) EHRs is much more challenging, requiring a semantic understanding of the underlying clinical conditions present or absent. Conventional exact or approximate term-based retrieval methods such as BM25 (Robertson and Zaragoza, 2009) often perform poorly in response to ad-hoc queries (Chamberlin et al., 2020), as these methods lack the ability of semantic understanding of the clinical as well as language context. With the emergence of deep learning encoding models, new retrieval methods have emerged with studies showing BERT-based neural methods outperforming BM25 on multiple retrieval benchmarks (Yilmaz et al., 2019a; Chang et al., 2020; Nogueira and Cho, 2019; Yilmaz et al., 2019b; Qiao et al., 2019). The BERT-based retrieval methods can be classified into two categories: the cross-attention (or interaction-based) models (Yilmaz et al., 2019a; Nogueira and Cho, 2019; Yilmaz et al., 2019b) and the embedding-based (or representation-based) models (Chang et al., 2020; Reimers and Gurevych, 2019). While the BERT-style cross-attention models are very successful, they cannot be directly applied to large-scale retrieval problems because computing the similarity score for every possible query-document pair during inference can be prohibitively expensive. Therefore, they were often used as a re-ranker after a initial candidate retrieval round using BM25. The embedding-based methods can pre-encode the documents, and only the queries need to be encoded upon retrieval. Retrieval can be achieved via approximate nearest-neighbor search in the embedding space very efficiently (Johnson et al., 2021). In this study, we focus on the embedding-based retrieval BERT models. Specifically, we adopted the sentence-level retrieval setting, as studies suggested that the "best" sentence in a document provides a good proxy for document relevance (Yilmaz et al., 2019a).

Different pre-training tasks were used to train the BERT-based models for retrieval. The pre-training tasks range from masked language modelling (MLM) over unlabeled free-text to supervised training on labeled datasets such as STS (Cer et al., 2017), MS MARCO (Nguyen et al., 2016) or TREC Microblog track (Lin et al., 2014). How-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3457 - 3463
July 10-15, 2022 ©2022 Association for Computational Linguistics

ever, MLM is not tailored for the purpose of information retrieval (IR), and labeled datasets are usually small and not easily accessible. Recently, pre-trained models on biomedical corpora such as BioClinicalBERT (Alsentzer et al., 2019) and BioBERT (Lee et al., 2020) can obtain embeddings with medical-domain-specific knowledge, but they were still trained with MLM.

Early studies (Natarajan et al., 2010) showed that most clinical queries are actually short queries (e.g. a disease or a syndrome). We found that the existing BERT models pre-trained with MLM performed poorly on short queries as well as negative queries (i.e. queries asking for lack of a finding). Ideally, if a retrieval system could be trained by matched and unmatched query-sentence pairs, in both positive and negated instances, we can expect a higher precision and recall in retrieval. However, manually labeling a large dataset is impractical, particularly for the medical domain where the number of clinical findings is very large. Training neural IR models using weak supervision has been previously investigated (Dehghani et al., 2017; MacAvaney et al., 2019). These methods use unsupervised methods (e.g. BM25) or article headings to provide pseudo labels. However, these pseudo labels usually are imprecise and do not consider negative queries. Moreover, the article headings are not always available.

Motivated by these challenges, we present a hybrid approach where we combine automated clinical finding detection with supervised query-sentence pair learning. Specifically, we use an automatic lexicon-driven concept detection method to detect relevant positive or negative chest X-ray (CXR) findings in sentences. These findings paired with the sentences containing them serve as weakly labeled training data for Sentence-BERT (SBERT) (Reimers and Gurevych, 2019). The resulting approach avoids manual annotation and can be scaled for training on a large number of query-sentence pairs. We show that the proposed training task remarkably improves the retrieval performance of SBERT on datasets with automatic annotations and human annotations.

2 Methods

2.1 Fine-grained concept extraction

The algorithm for extracting findings from sentences in reports uses a vocabulary-driven approach. Specifically, a domain-specific CXR finding lexicon was used. This lexicon captures the name of finding along with its potential variants and synonyms mined from over 200,000 chest radiology reports. To spot the occurrence of a finding lexicon phrase within reports, a string matching algorithm called the *longest common subfix (LCF)* algorithm was used. To determine if a core finding is positive or negative (e.g. "no pneumothorax"), a two-step approach that combines language structuring and vocabulary-based negation detection is used. The method is reported to be highly accurate ($<3\%$ errors) compared with human labels. More details are described in (Syeda-Mahmood et al., 2020).

2.2 Labeled data generation

In this paper, we focus on "anatomical findings" as well as "disease concepts" as those are the most commonly searched in EHR (Natarajan et al., 2010). We use these finding modifiers as surrogates for queries. For each sentence S_j in our data collection, we have a set with K_j labeled data entries $I_j = \{(S_j, N_{j,i}, M_{j,i})\}_{1 \leq i \leq K_j}$. For each labeled entry $(S_j, N_{j,i}, M_{j,i})$, $M_{j,i}$ is the i-th finding for S_j, and $N_{j,i} = yes|no$ indicates a positive or ruled out finding. By using the findings as query surrogates, we can designate a query $Q_{j,i} = (N_{j,i}, M_{j,i})$ paired with S_j: if $N_{j,i}$ equals to yes, $Q_{j,i}$ is a positive query, otherwise $Q_{j,i}$ is a negative query. For example, $(yes,\ vascular\ congestion)$ and $(no,\ pulmonary\ edema)$ are two queries for the sentence "lungs: central vascular congestion without overt edema." The actual queries can be more properly phrased for data augmentation in training, such as "presence of M" or "M is observed" for a positive query and "no evidence of M" or "absence of M" for a negative query, where M is a finding. In this study, however, we only consider the simple form of "M" and "no M" as positive and negative queries, in both training and evaluation.

Since we labeled all the sentences in our training dataset extensively with all the finding types we summarized, we can create a dictionary using each unique query $Q = (N, M)$ as the key and the list of all the sentences that contain that query as the dictionary value. Any sentence in the list is considered as a matched sentence for that query, whereas other sentences are considered as unmatched sentences.

2.3 Model

We used SBERT as our retrieval model. MEAN-pooling was used to derive a fixed size sentence embedding (for either a query or an EHR sentence).

We used the triplet objective function (Reimers and Gurevych, 2019) to train our model. A diagram of the training objective function is shown in Figure 1. Given a query q, a matched sentence m and an unmatched sentence u, the triplet loss tunes the network such that the distance between the embeddings of q and m is smaller than the distance between the embeddings of q and u by a margin ϵ:

$$max(\|e_q - e_m\| - \|e_q - e_u\| + \epsilon, 0) \qquad (1)$$

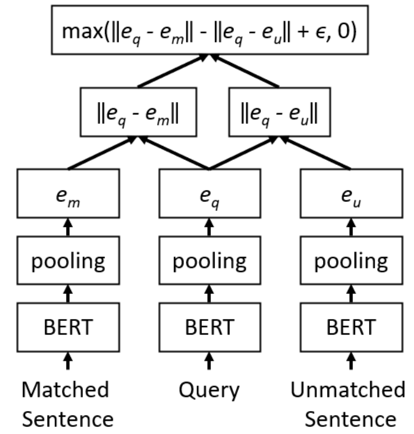

Figure 1: SBERT architecture with the triplet training objective function. The three BERT networks share the same weights.

where e_q, e_m and e_u are the sentence embeddings for q, m and u, respectively. $\|\cdot\|$ is a distance metric. We used the cosine distance and $\epsilon = 0.5$.

To improve training, we further used hard-sampling (HS) to mine the hardest unmatched sentence for the triplet loss within a training batch. To be specific, we performed inference within a batch beforehand to find the unmatched sentence with the highest cosine similarity score (the most confusing unmatched sentence) for each query. We further applied mega-batching (MB) (Wieting and Gimpel, 2018) to encourage the model to learn to distinguish "harder" unmatched sentences by increasing the batch size.

At inference, the cosine similarity between the query embedding and the report sentence embedding is used to determine the level of relevance.

3 Experiments and Results

3.1 Datasets

The experiments in Section 3.1-3.4 were carried out on two public collections of radiology reports provided by Indiana University (Demner-Fushman et al., 2016) and NIH (Wang et al., 2017). After pruning for duplicates and applying our labeled data generation algorithm described in Section 2.2, a total of 21,612 labeled entries were generated for the Indiana dataset, which include 10,363 unique sentences, 200 positive queries and 75 negative queries. For the NIH dataset, 17,047 labeled entries were generated, including 9,091 unique sentences, 250 positive queries and 30 negative queries.

3.2 Sensitivity analysis and parameter tuning

We first run a sensitivity analysis on the Indiana dataset (IND) to investigate how much improvement hard-sampling (HS) and mega-batching (MB) can bring over random-sampling (RS, randomly select unmatched sentence within a batch) and normal-batching (NB, size 32). We randomly split the IND dataset into two halves with non-overlapping findings with the constraint that they should roughly have equal number of labeled entries. After the split, the two sets have 117/44 and 83/31 positive/negative queries, respectively. We performed a 2-fold cross-validation and reported the average of the two test results regarding mean Average Precision (mAP). This allows us to evaluate the model performance on unseen queries. The evaluation was performed over positive queries (Pos. Q.), negative queries (Neg. Q.) and all queries (All Q.) separately.

The results in Table 1 shows that the combination of HS and MB achieved the best results. Increasing the mega-batching size to 128 resulted the best performance, but further increasing the batch size slightly degraded the performance. The remarkable improvent of SBERT over the baseline BioClinical-BERT also suggests that the proposed model can generalize well to unseen queries.

Model	**mean Average Precision (mAP)**		
	Pos. Q.	**Neg. Q.**	**All Q.**
BioClinicalBERT	0.213	0.254	0.224
SBERT/RS/NB(32)	0.353	0.312	0.349
SBERT/HS/NB(32)	0.384	0.334	0.371
SBERT/HS/MB(64)	0.388	0.318	0.369
SBERT/HS/MB(128)	**0.399**	**0.392**	**0.397**
SBERT/HS/MB(256)	0.392	0.352	0.381
SBERT/HS/MB(512)	0.380	0.344	0.370

Table 1: Sensitivity analysis on the Indiana dataset. The analysis was performed for positive queries (Pos. Q.), negative queries (Neg. Q.) and all queries (All Q.) separately.

Model	mean Average Precision (mAP)			mean Recall (mR)		
	Pos. Q. IND / NIH	Neg. Q. IND / NIH	All Q. IND / NIH	Pos. Q. IND / NIH	Neg. Q. IND / NIH	All Q. IND / NIH
BM25	0.39 / **0.46**	0.34 / 0.32	0.38 / 0.44	0.36 / **0.43**	0.30 / 0.27	0.35 / 0.42
BERT	0.14 / 0.16	0.21 / 0.23	0.16 / 0.17	0.12 / 0.15	0.19 / 0.23	0.14 / 0.16
BERT (fine-tuned)	0.20 / 0.23	0.22 / 0.23	0.21 / 0.23	0.19 / 0.21	0.21 / 0.21	0.19 / 0.21
BioClinicalBERT	0.16 / 0.28	0.21 / 0.25	0.17 / 0.27	0.14 / 0.27	0.19 / 0.22	0.15 / 0.26
SBERT (MS MARCO)	0.40 / 0.44	0.35 / 0.36	0.39 / 0.43	0.37 / 0.40	0.31 / 0.31	0.35 / 0.39
SBERT (ours)	**0.48** / 0.45	**0.42 / 0.56**	**0.46 / 0.47**	**0.44** / 0.42	**0.39 / 0.47**	**0.42 / 0.43**

Table 2: Cross-dataset evaluation. The dataset name in the heading means the model was tested on that dataset and trained on the other dataset. The evaluation results are reported for positive queries (Pos. Q.), negative queries (Neg. Q.) and all queries (All Q.) separately.

3.3 Cross-dataset study

We also trained on the IND dataset and tested on the unique sentences in the NIH dataset and vice versa to investigate whether a trained model can generalize well to a different dataset. The best SBERT model from Table 1 was used here. We further included Okapi BM25 (k_1=1.5, b=0.75), the pre-trained BERT (Huggingface "BERT-base-uncased"), the fine-tuned BERT (trained on the EHR sentences using MLM, without using our generated annotations), the BioClinicalBERT and SBERT pre-trained on MS MARCO dataset for comparison. More details about these models are given in the appendix. In addition to mAP, mean Recall (over all the queries) was also reported, where Recall was defined as the ratio of the number of correctly retrieved sentences to the size of the query's ground truth list.

Table 2 shows that our fine-tuned SBERT performs very well on the dataset from another collection regarding both mAP and mR, and outperformed the other BERT/SBERT models by large margins. The baseline BERT without pre-training over medical texts obtained the worst results. The results for BERT (fine-tuned) and BioClinicalBERT suggest that MLM training over the texts from the same domain can lead to some improvements but is still not ideal for direct use of retrieval. SBERT pre-trained on MS MARCO dataset showed significant improvements over BERT trained with MLM, but lacks domain-specific knowledge and shows performance drop on negative queries. BM25 performs well on positive queries with performance degradation on negative queries as well, because negation is not always explicitly expressed in EHR.

3.4 Embedding separation analysis

Because we have the negation labels, we can also create opposite-negation queries. For example, the opposite-negation query for "no opacity" would be "opacity". Ideally, with a high-precision retrieval system, for a given sentence, the similarity score between the matched query and sentence should be higher than that between the opposite-negation query and the sentence. We reported (Table 3) the differences (mean±std) between these two scores for all the entries in each dataset with all the BERT embedding-based methods. Our trained SBERT showed a clear separation in the embedding space. The distances for the other BERT models are all around zero with even negative distances, suggesting poor negation awareness.

Model	IND	NIH
BERT	-0.04±0.06	0.01±0.07
BERT (fine-tuned)	0.03±0.09	0.05±0.08
BioClinicalBERT	0.01±0.05	0.01±0.03
SBERT (MS MARCO)	0.01±0.01	0.02±0.01
SBERT (ours)	0.42±0.36	0.56±0.34

Table 3: Embedding space separation analysis.

3.5 Evaluation on human-annotated data

We also evaluated our model on a separate human-annotated dataset. The radiology reports used in this section are private anonymized data obtained from our collaborative partners. HIPPA was fully enforced and all data were handled according to the Declaration of Helsinki. All reports were written in the English language. 206 CT reports and 120 chest X-ray (CXR) reports were annotated for various disease findings on the sentence level by 3 radiologists using the brat rapid annotation tool (available at `https://brat.nlplab.org/`). Majority voting was used to handle disagreements. This resulted in 2,990 unique sentences/8 queries for CT reports and 1,810 unique sentences/18 queries for CXR reports. Note that the candidate sentences for retrieval also include those sentences without any our interested disease findings. For

Model	mAP	mR
	CT / CXR	**CT / CXR**
BM25	0.34 / 0.34	0.39 / 0.31
BioClinicalBERT	0.32 / 0.28	0.34 / 0.26
SBERT (MS MARCO)	0.35 / 0.39	0.40 / 0.37
SBERT (trained on IND)	**0.59 / 0.66**	**0.57 / 0.60**
SBERT (trained on NIH)	0.52 / 0.57	0.50 / 0.54

Table 4: Evaluation on human-annotated datasets.

the CT reports, the annotation was based on the presence or absence of 4 diseases (resulting in 8 queries): thoracic aneurysm, abdominal aneurysm, lung nodule and pulmonary embolism. The average number of matched sentences for each query is 42±33. For the CXR reports, the annotation was based on 10 diseases (resulting in 18 queries, as 2 negative queries do not have the corresponding matched sentences): pulmonary embolism, airspace opacity, lung nodule, emphysema, pneumothorax, abdominal aortic aneurysm, thoracic aortic aneurysm, rib fracture, scapula fracture and spine fracture. The average number of matched sentences for each query is 18±16. It it worth noting that some of the diseases are not even used as queries in the IND/NIH training data, including thoracic aneurysm, abdominal aneurysm and spine fracture.

Table 4 shows that our SBERT fine-tuned on either IND or NIH dataset outperforms the other compared methods by large margins.

4 Discussion

In this paper we demonstrated that the proposed supervised pre-training tasks with automated annotation can greatly improve the IR performance of SBERT on short and negative queries. The proposed labeled data generation method can also be used to train the cross-attention BERT models for further improvement when computation speed is not the bottleneck.

We focused on short queries in this study, and BM25 still performs well on positive queries. The embedding-based BERT models are expected to show more advantages over BM25 on complicated queries that require semantic understanding. Having the comprehensive negation and finding labels for each sentence also allows us to assemble more complicated queries that include more than one finding, such as "A and B" or "A without C" where A, B and C represent three different findings. These more challenging tasks can be explored in the future work. The label generation tool can also be extended to training IR models in domains other than medical domain, such as finance, law, or retail, provided with the corresponding lexicons.

In this study we did not evaluate retrieval on the report-level because we have the sentence-level annotations, which enable fine-grained evaluation. The report-level evaluation can be included in the future work.

5 Conclusion

In this work we proposed to generate query-sentence pairs automatically using a CXR lexicon for training embedding-based BERT models on the EHR retrieval problem. We showed that the fine-tuned SBERT obtained a substantial performance gain over the other pre-trained models. The trained model can also generalize well to unseen queries and data from another source. The proposed method can be especially helpful in training and evaluating neural IR models in domains with limited human-labeled data.

A Appendix: Model training details

Here we provide more details on the models used in Section 3. We used the Huggingface "BERT-base-uncased" model (pre-trained on BookCorpus and English Wikipedia, availabel at: `https://huggingface.co/bert-base-uncased`) as our BERT model for comparison. The BERT (fine-tuned) model was fine-tuned on the EHR text (Indiana or NIH dataset) using MLM for 5 epochs based on the "BERT-base-uncased" model. The pre-trained BioClinicalBERT (Alsentzer et al., 2019) (availabel at: `https://github.com/EmilyAlsentzer/clinicalBERT`) was initialized with BioBERT (Lee et al., 2020) and fine-tuned on clinical notes.

Our SBERT model was initialized with the BioClinicalBERT. We fine-tuned SBERT using the triplet loss for 10 epochs for all datasets in this study. We used AdamW optimizer with the learning rate 2e-5, weight decay 0.01 and a linear learning rate warm-up of 100 steps.

The SBERT model used as comparison was pre-trained on 500K (query, answer) pairs from the MS MARCO dataset. This pre-trained model (msmarco-bert-base-dot-v5) was one of the recommended sentence embedding models from the official SBERT webpage (`https://www.sbert.net/docs/pretrained_models.html`). Among all the pre-trained models, we picked this one because it is the only pre-trained model based on "BERT-base" model, to be consistent with all the other models (all based on "BERT-base") in our experiments. Since this model was tuned to be used with dot-product, we used dot-product to calculate similarity scores only for this model in the retrieval experiments in Table 2. For all the other models, cosine-similarity was used to calculate scores. However, for the embedding separation analysis in Table 3, cosine-similarity was used for SBERT (MS MARCO) as well so that the scale of the similarity scores is comparable to the others.

Transparent Human Evaluation for Image Captioning

Abstract

We establish THumB, a rubric-based human evaluation protocol for image captioning models. Our scoring rubrics and their definitions are carefully developed based on machine- and human-generated captions on the MSCOCO dataset. Each caption is evaluated along two main dimensions in a tradeoff (*precision* and *recall*) as well as other aspects that measure the text quality (*fluency*, *conciseness*, and *inclusive language*). Our evaluations demonstrate several critical problems of the current evaluation practice. Human-generated captions show substantially higher quality than machine-generated ones, especially in coverage of salient information (i.e., recall), while most automatic metrics say the opposite. Our rubric-based results reveal that CLIPScore, a recent metric that uses image features, better correlates with human judgments than conventional text-only metrics because it is more sensitive to recall. We hope that this work will promote a more transparent evaluation protocol for image captioning and its automatic metrics.[1]

1 Introduction

Recent progress in large-scale training has pushed the state of the art in vision-language tasks (Li et al., 2020; Zhang et al., 2021, *inter alia*). One of these tasks is image captioning, whose objective is to generate a caption that describes the given image. The performance in image captioning has been primarily measured in automatic metrics (e.g., CIDEr, Vedantam et al., 2015; SPICE, Anderson et al., 2016) on popular benchmarks, such as MSCOCO (Lin et al., 2014) and Flickr8k (Hodosh et al., 2013). Use of these metrics is justified based on their correlation with human judgments collected in previous work (Hodosh et al., 2013; Elliott and Keller, 2014; Kilickaya et al., 2017, *inter alia*).

Machines	P	R	CIDEr
A red fire hydrant spewing water on a street.	5	3	139.2
A red fire hydrant spraying water on a street.	5	3	205.2
Human			
A busted red fire hydrant spewing water all over a street creating a rainbow.	5	5	120.5

Figure 1: These machine captions are *precise* (in the scale of 1–5) but lose points in recall (i.e., coverage of salient information); they both ignore the rainbow in the picture. Automatic metrics, such as CIDEr, do not capture this failure.

Continuous use of these previous human judgments, however, raises significant concerns for development of both captioning models and automatic metrics because of their lack of transparency. In previous work, annotators (crowdworkers, typically) rate image captions directly (Hodosh et al., 2013), pairwise (Vedantam et al., 2015), or along multiple dimensions such as thoroughness (Aditya et al., 2015) and truthfulness (Yatskar et al., 2014). These scoring judgments depend highly on individual annotators' discretion and understanding of the annotation scheme (Freitag et al., 2021; Clark et al., 2021), making it difficult to decompose, interpret, and validate annotations. This lack of transparency also makes it difficult to interpret evaluation results for downstream applications where some aspects are particularly important (e.g., accessibility for people with visual impairments; Gleason et al., 2019, 2020). Further, these annotations were done only on relatively old models (e.g., MSCOCO leaderboard submissions in 2015; Anderson et al.,

2016). Correlations of automatic metrics with human judgments can break down especially when model types change (Callison-Burch et al., 2006), or generation models become increasingly powerful (Ma et al., 2019; Edunov et al., 2020). We thus develop an up-to-date, transparent human evaluation protocol to better understand how current models perform and how automatic metrics are correlated when applied to current models.

At the core of our rubrics are two main scores in a tradeoff: *precision* and *recall* (Fig. 1). The former measures accuracy of the information in a caption, and the latter assesses how much of the salient information in the image is covered. We then penalize a caption if we find a problem in *fluency*, *conciseness*, or *inclusive language*. Two or more authors evaluate every instance and collaborate to resolve disagreements, ensuring high quality of the annotations. We assess outputs from four strong models as well as human-generated reference captions from MSCOCO. We call our scores THUMB 1.0 (**T**ransparent **Hum**an **B**enchmark), and release them publicly.

Key Findings We made several key observations from the evaluations.

- Machine-generated captions from recent models have been claimed to achieve superhuman performance using popular automatic metrics (human performance is ranked at the 250th place in the MSCOCO leaderboard),[2] but they still show substantially lower quality than human-generated ones.

- Machines fall short of humans, especially in recall (Fig. 1), but most automatic metrics say the opposite. This finding is consistent with prior work that showed that machines tend to produce less diverse captions than humans (van Miltenburg et al., 2018).

- Human performance is underestimated in the current leaderboard paradigm, and there is still much room for improvement on MSCOCO captioning.

- CLIPScore and RefCLIPScore (Hessel et al., 2021), recently proposed metrics that use image features, improve correlations particularly in recall. While they fail to score human generation much higher than machine one, they capture an aspect that is less reflected in text-only metrics.

- Currently available strong captioning models generate highly fluent captions. Fluency evaluation is thus no longer crucial in ranking these models.

2 Evaluation Protocol

We establish a transparent evaluation protocol for English image captioning models. Our rubrics and rules are developed through discussions among all annotators (first four authors of this paper) and designed to increase the reliability of evaluation (Jonsson and Svingby, 2007)

2.1 Evaluation Setups and Quality Control

We used images from the test data in the standard *Karpathy split* (Karpathy and Fei-Fei, 2015) of the MSCOCO dataset (Lin et al., 2014). The dataset consists of 113K, 5K, and 5K train/dev./test everyday-scene photos sampled from Flickr. We randomly sampled 500 test images and prepared one human- and four machine-generated captions for every image (§2.3). We first performed developmental evaluations of 250 captions for 50 images and created rubrics. We then proceeded with the rest of the captions. For every image, captions were shuffled, and thus annotators did not know which caption corresponded to which model, thereby avoiding a potential bias from knowledge about the models. We conducted two-stage annotations: the first annotator scores all captions for given images, and the second annotator checks and modifies the scores when necessary. After the developmental phase, the κ coefficient (Cohen, 1960) was 0.86 in precision and 0.82 in recall for the rest of the evaluated captions (§2.2.1).[3] The first four authors of this paper conducted all evaluations; none of them are color blind or low vision, two are native English speakers, and one is a graduate student in linguistics. We finally ensured that at least one native speaker evaluated the fluency of every caption (§2.2.2), meaning that if a caption is annotated by the two non-native speakers, one native speaker checks the fluency in an additional round.

---

[2] `https://competitions.codalab.org/competitions/3221#results`.

[3] Furthermore, we found that a third annotator did not change the scores for all 100 captions randomly sampled for meta-evaluations, confirming the sufficiently high quality of our two-stage annotations. Disagreement in ratings can also result from a certain degree of subjectivity (Misra et al., 2016).

2.2 THumb 1.0

Similar to the framework of the automatic SPICE metric (Anderson et al., 2016), we base our manual evaluations on two main scores: **precision** and **recall**. We also consider three types of penalty: **fluency**, **conciseness**, and **inclusive language**. The overall score is computed by averaging precision and recall and deducting penalty points.

2.2.1 Main Scores

The two main scores are assessed in the scale of 1–5. They balance information accuracy and coverage.

Precision Precision (P) measures how precise the caption is given the image. For instance, Caption 1-B in Table 1 is perfectly precise, while 1-A (*dog* vs. *otter*, *one* vs. *two frisbees*) and 1-C (*three* vs. *two frisbees*) are not precise. Precision guards against hallucinations from the language model (*table* in 2-B) that are known to be common failures of image captioning models (Rohrbach et al., 2018). The score of 4 is reserved for relatively minor issues, such as attributes that are almost correct (e.g., *pink* vs. *red* in 4-C, Table 1) or cases where the caption does not contradict the image but is not guaranteed to be true (e.g., it is unclear whether the girl is sitting on a couch in 3-B). In addition to objects themselves, precision deals with information like properties, attributes, occasions, locations, and relations between objects (e.g., *in a red suitcase* vs. *on a red suitcase* in 4-A).

Recall Recall (R) measures how much of the salient information (e.g., objects, attributes, and relations) from the image is covered by the caption. This includes color (e.g., color of the frisbees in 1-A, 1-B, and 1-C) and guards against generic, uninformative captions that machines tend to produce (Wang et al., 2020). For instance, an otter is a *small animal*, and thus *small animal* is *precise* (1-C); however, it is much less informative (and less natural; Ordonez et al., 2013) than saying an otter. Similarly, Caption 5-B only says a woman is standing behind a counter at a donut shop, but she is selling donuts, not buying or looking at donuts, which is salient information from the picture. We do not take a point off if missing information is already expected from the caption (e.g., a double-decker bus is typically red). We often find it useful to take a generative approach when evaluating recall: *what image does the caption lead us to imagine?* When the caption entails many potential images that substantially diverge from the given image, the recall score should be low.[4]

2.2.2 Penalties

Fluency Fluency (Flu.) measures the quality of captions as English text regardless of the given image. Initially, we scored fluency in the scale of 1–5, similar to P and R, but we found most captions from modern neural network models were highly fluent. Thus, we instead decided to take points off from the average of P and R if there's a fluency problem to account for minor issues that are much less problematic than losing one P/R point. The four annotators had extensive discussions and developed rubrics for fluency. Similar to recent work on professional evaluations for machine translation (Freitag et al., 2021), we evaluated under the following principle: if a fluency problem is expected to be easily corrected by a text postprocessing algorithm (e.g., grammatical error correction: Yuan and Briscoe, 2016; Sakaguchi et al., 2017), the penalty should be 0.1. This includes obvious misspellings or grammatical errors (e.g., *A otter* in 1-B) and missing determiners/hyphens (*multi colored* in 2-C). 0.5+ points were subtracted for more severe problems, such as duplication (e.g., *A display case of donuts and doughnuts*), ambiguity (e.g., *A cat is on a table with a cloth on **it***), and broken sentences (e.g., *A large concrete sign small buildings behind it.*). See Table 6 in §A.1 for more extensive fluency rubrics. Note that the average fluency penalty was 0.01; this confirms that fluency is no longer crucial in ranking models for MSCOCO captioning and contrasts with human evaluations previously done for older captioning models.

Conciseness The scores so far do not take into account conciseness of captions. Specifically, a model could simply increase all scores by describing every detail in a picture. For instance, the following caption is overly repetitive: *a woman lying on her back with knees bent on a beach towel under a multicolored, striped beach umbrella, surrounded by sand, and with clear blue sky above*. We subtract 0.5 points for these captions. Note that most machine captions were short, and this penalty was only applied to two human-generated captions. It might become more crucial for future models

---

[4] Prior work found recall (or *specificity*) can vary across cultures or languages (van Miltenburg et al., 2017). We focus on the English language in this work.

Image	Caption	P	R	Flu.	Total
	**1-A**: Up-Down ***A dog playing with a frisbee on the ground.***	3	4	0	3.5
	1-B: VinVL-base ***A otter is laying on the sand next to two frisbees.***	5	4	0.1	4.4
	1-C: VinVL-large ***A small animal laying on a rock with three frisbees.***	4	3	0	3.5
	**2-A**: Up-Down ***A close up of a plate of broccoli.***	5	3	0	4
	2-B: Unified-VLP, VinVL-base, VinVL-large ***A plate of pasta and broccoli on a table.***	4	4	0	4
	2-C: Human ***A multi colored dish with broccoli and white twisted pasta in it.***	5	5	0.1	4.9
	**3-A**: Unified-VLP ***A little girl holding a video game controller.***	3	4	0	3.5
	3-B: VinVL-large ***A little girl is blow drying her hair on a couch.***	4	5	0	4.5
	3-C: Human ***A little girl holding a blow dryer next to her head.***	5	5	0	5
	**4-A**: Up-Down ***A black cat laying in a red suitcase.***	3	5	0	4
	4-B: Unified-VLP, VinVL-base, VinVL-large ***A black cat sitting on top of a red suitcase.***	5	5	0	5
	4-C: Human ***A large black cat laying on top of a pink piece of luggage.***	4	5	0	4.5
	**5-A**: Up-Down, Unified-VLP ***A man standing in front of a display of donuts.***	3	2	0	2.5
	5-B: VinVL-large ***A woman standing behind a counter at a donut shop.***	5	3	0	4
	5-C: Human ***Woman selling doughnuts with doughnut stock in the background.***	5	5	0.3	4.7

Table 1: Example evaluations of machine- and human-generated captions. None of these captions get penalties in conciseness and inclusive language. Evaluated captioning models are described in §2.3. All MSCOCO images are provided under a Creative Commons Attribution 4.0 License (Lin et al., 2014).

with a more powerful object detection module that catches many objects in the picture.

Inclusive Language We found that some instances substantially diverge from inclusive language when humans are described (van Miltenburg, 2020), raising a concern for downstream applications. In these cases, we added a penalty: 0.5 points were deducted for a subjective comment about appearance (e.g., *very pretty girl*), and 2 points for more severe problems (e.g., *beautiful breasts*).

2.2.3 Rules of THumb

In our development phase, we established the following additional rules to clarify our annotation scheme.

Avoiding Double Penalties When an error is accounted for in precision, we correct the error before scoring the recall, thereby avoiding penalizing the precision and recall for the same mistake. For example, P=3 is given to Caption 1-A in Table 1 because of its wrong detection (*dog* vs. *otter*; *one* vs. *two frisbees*), but we score the recall assuming that the caption is now *an **otter** playing with two frisbees on the ground*. This ensures that a generic, useless caption, such as *there is something on something* (P=5, R=1), would be ranked considerably lower than *a dog on the beach with two pink and yellow frisbees* (P=3, R=5). Similarly, the wrong detection in 5-A (*man* vs. *woman*) is handled only in precision. Note that such error correction is not applicable to hallucinations because there is no alignment between a part of the image and a hallucinated object (e.g., *table* in 2-B). This rule departs from the definition of recall in SPICE (Anderson et al., 2016), an automatic metric that measures the

F_1 score in scene graphs predicted from reference and generated captions; their alignment is limited to WordNet synonyms (Miller, 1995). This means that classifying an otter as a dog or even a small animal would result in cascading errors both in precision and recall, overrating captions that completely overlook the otter or ones that make a more severe classification error (e.g., miscategorize the otter as a car, compared to a dog).

Object Counts as Attributes All counts are considered as object attributes, and wrong counts are handled in precision. This simplifies the distinction between precision and recall. For instance, both *a frisbee* (1-A) and *three frisbees* (1-C) are precision problems, while saying *some frisbees* would be a recall problem when it is clear that there are exactly two frisbees. Note that this is in line with SPICE, which treats object counts as attributes in a scene graph, rather than duplicating a scene graph for every instance of an object (Anderson et al., 2016).

Black and White Photo MSCOCO contains black and white or gray-scale pictures. Some captions explicitly mention that they are black and white, but we disregard this difference in our evaluations. The crowdsource instructions for creating reference captions do not specify such cases (Chen et al., 2015). Further, we can potentially run postprocessing to determine whether it is black and white to modify the caption accordingly, depending on the downstream usage.

Text Processing Image captioning models often differ slightly in text preprocessing. As a result, we found that generated captions were sometimes slightly different in format (e.g., tokenized or detokenized; lowercased or not). For better reproducibility, we follow the spirit of SACREBLEU (Post, 2018), which has become the standard package to compute BLEU scores for machine translation: all evaluations, including automatic metrics, should be done on clean, untokenized text, independently of preprocessing design choices. We apply the following minimal postprocessing to the model outputs and human captions.

- Remove unnecessary spaces at the start or end of every caption.
- Uppercase the first letter.
- Add a period at the end if it doesn't exist, and remove a space before a period if any.

We keep the postprocessing minimal for this work and encourage future model developers to follow the standard practice in machine translation: every model has to output clean, truecased, untokenized text that is ready to be used in downstream modules. This also improves the transparency and reproducibility of automated evaluations (Post, 2018).

2.3 Evaluated Captions

We evaluated the following four strong models from the literature as well as human-generated captions. They share similar pipeline structure: object detection followed by crossmodal caption generation. They vary in model architecture, (pre)training data, model size, and (pre)training objective. Evaluating captions from them will enable us to better understand what has been improved and what is still left to future captioning models.

- **Up-Down** (Anderson et al., 2018) trains Faster R-CNN (Ren et al., 2015) on the Visual Genome datset (Krishna et al., 2016) for object detection. It then uses an LSTM-based crossmodal generation model.
- **Unified-VLP** (Zhou et al., 2020) uses the same object detection model as Up-Down. The transformer-based generation model is initialized with base-sized BERT (Devlin et al., 2019) and further pretrained with 3M images from Conceptual Captions (Sharma et al., 2018).
- **VinVL-base** and **VinVL-large** (Zhang et al., 2021) train a larger-scale object detection model with the ResNeXt-152 C4 architecture (Xie et al., 2017) on ImageNet (Deng et al., 2009). The transformer generation model is initialized with BERT and pretrained with 5.7M images.
- **Human** randomly selects one from the five human-generated reference captions in MSCOCO. Those captions were created by crowdworkers on Amazon Mechanical Turk (Chen et al., 2015).

Further details are described in §A.3 of Appendix.

3 Results and Analysis

We present results and analysis from our evaluations. Our transparent evaluations facilitate assessments and analysis of both captioning models (§3.1) and automatic metrics (§3.2).

3.1 Comparing Models

Seen in Table 2 (left section) is the model performance that is averaged over the 500 test images and broken down by the rubric categories. Overall, Human substantially outperforms all machines in the

	THumB 1.0						**Automatic Metrics**						
Model	P↑	R↑	Flu.↓	Con.↓	Inc.↓	Total↑	BLEU	ROUGE	BERT-S	SPICE	CIDEr	CLIP-S	RefCLIP-S
Human	4.82	4.35	0.019	0.02	0.00	$\mathbf{4.56}^{+0.03}_{-0.03}$	26.2	50.4	0.938	23.7	111.5	0.791	0.834
VinVL-large	4.54	3.97	0.005	0.00	0.00	$4.25^{+0.04}_{-0.04}$	33.3	56.5	0.946	26.4	141.8	0.784	0.834
VinVL-base	4.47	3.95	0.001	0.00	0.00	$4.21^{+0.04}_{-0.04}$	32.3	55.9	0.945	25.6	138.4	0.779	0.830
Unified-VLP	4.35	3.77	0.004	0.00	0.00	$4.06^{+0.04}_{-0.04}$	31.6	55.8	0.945	24.3	128.5	0.771	0.821
Up-Down	4.29	3.50	0.014	0.00	0.00	$3.88^{+0.05}_{-0.05}$	28.4	52.2	0.939	21.0	110.7	0.746	0.803

Table 2: Performance of image captioning models with respect to THumB 1.0 (left) and automatic metrics (right). All scores are averaged over 500 images randomly sampled from the Karpathy test split. P: precision; R: recall; Flu.: fluency; Con.: conciseness; Inc.: inclusive language. 90% confidence intervals for total scores are calculated by bootstrapping (Koehn, 2004). All reference-based metrics take as input the same four crowdsourced captions that are not used in Human for fair comparisons. **THumB 1.0 scores Human substantially higher than the machines, unlike all automatic metrics.**

P, R, and total scores. In particular, we see a large gap between Human and the machines in recall (e.g., Human 4.35 vs. VinVL-large 3.97). This contrasts with the automatic metric-based ranking of the MSCOCO leaderboard, where Human is ranked at the 250th place.[5] This result questions claims about human parity or superhuman performance on MSCOCO image captioning. The four machine captioning models are ranked in the expected order, though the small difference between VinVL-large and VinVL-base suggests that simply scaling up models would not lead to a substantial improvement. We see that the three models that are initialized with pretrained BERT (VinVL-large/base, Unified-VLP) are particularly fluent, but the problem is small in the other models as well.

While we compute representative, total scores, our transparent rubrics allow for adjusting weighting of the categories depending on the application of interest. For instance, in the social media domain, recall can be more important than precision to make captions engaging to users (Shuster et al., 2019). To assess the models independently of these aggregation decisions, we count the number of times when each model outperforms/underperforms all the others both in P and R (*strictly* best/worst, Table 3). We see patterns consistent with Table 2. For example, Human is most likely to be strictly best and least likely to be strictly worst. This suggests that machine captioning models would still fall short of crowdworkers in a wide range of downstream scenarios.

Model	Human	Vin-large	Vin-base	U-VLP	Up-Down
# Best ↑	**327**	180	161	112	74
# Worst ↓	**65**	128	150	190	269

Table 3: # times when each captioning model is *strictly* best/worst in the caption set (i.e., best/worst both in precision and recall).

3.2 Comparing Automatic Metrics

While carefully-designed human judgments like ours should be considered more reliable, automatic metrics allow for faster development cycles. Our transparent evaluations can also be used to analyze how these automatic metrics correlate with different aspects of image captioning. Table 2 (right section) shows automatic scores of the captioning models over 7 popular metrics for image captioning. CLIP-S (Hessel et al., 2021) is a *referenceless* metric that uses image features from CLIP (Radford et al., 2021), a crossmodal retrieval model trained on 400M image-caption pairs from the web. RefCLIP-S augments CLIP-S with similarities between the generated and reference captions. All other metrics, such as SPICE (Anderson et al., 2016) and CIDEr (Vedantam et al., 2015), only use reference captions without image features.

These automatic metrics generally agree with our evaluations in ranking the four machines, but completely disagree in the assessment of Human. Most metrics rank Human near the bottom, showing that they are not reliable in evaluating high-quality, human-generated captions. The two metrics with powerful image and text features (CLIP-S and RefCLIP-S) give high scores to Human compared to the other metrics, but they still fail to score Human substantially higher than VinVL-large. This suggests that automatic metrics

---

[5] The official leaderboard ranks submissions using CIDEr (Vedantam et al., 2015) with 40 references on the hidden test data. We use the public Karpathy test split instead, but we suspect the same pattern would hold on the hidden data as well, given the large gap between machines and Human.

should be regularly updated as our models become stronger (and perhaps more similar to humans), and raises a significant concern about the current practice that fixes evaluation metrics over time (Kasai et al., 2022).

	w/o Human			w/ Human		
Metric	P	R	Total	P	R	Total
RefCLIP-S	0.34	**0.27**	**0.44**	0.31	0.26	$\mathbf{0.41}^{+0.05}_{-0.05}$
RefOnlyC	**0.42**	0.14	0.41	**0.37**	0.11	$0.34^{+0.04}_{-0.05}$
CLIP-S	0.18	**0.27**	0.32	0.17	**0.28**	$0.32^{+0.05}_{-0.05}$
CIDEr	0.27	0.18	0.33	0.21	0.11	$0.23^{+0.04}_{-0.04}$
BERT-S	0.27	0.18	0.33	0.20	0.10	$0.21^{+0.04}_{-0.04}$
SPICE	0.26	0.15	0.30	0.20	0.09	$0.21^{+0.04}_{-0.04}$
ROUGE-L	0.26	0.17	0.31	0.18	0.07	$0.18^{+0.04}_{-0.04}$
BLEU	0.21	0.13	0.25	0.15	0.04	$0.13^{+0.04}_{-0.04}$

Table 4: Instance-level correlations of automatic evaluation scores. RefCLIP-S and CLIP-S use image features unlike the others, and all but CLIP-S require references. All of these reference-based metrics use the same subset of four captions as in Table 2 that exclude Human. All metrics had correlations lower than 0.1 for fluency.

Seen in Table 4 are instance-level Pearson correlation scores between automatic scores and our evaluations.[6] We also add an ablation study: RefOnlyC removes image features from RefCLIP-S to quantify the effect of image features. We consider two types of scenarios: one *with* Human and one *without*. Correlations drop from the latter to the former for all metrics and aspects except CLIP-S, again showing that the metrics are not reliable in assessing human-generated captions. Interestingly, CLIP-S correlates best in recall (0.28 w/ Human) but suffers in precision (0.17 w/ Human). RefOnlyC, in contrast, achieves the best correlations in P at the expense of R. RefCLIP-S balances the two and achieves the best correlation in total scores. This indicates that the CLIP image features particularly help assess coverage of salient information that can be ignored in some reference captions from crowdworkers.[7] Prior work (Hessel et al., 2021) found that SPICE can still improve correlations when combined with CLIP-S, even though CLIP-S better correlates with human judgments than SPICE. This implies that image-based and reference-only metrics capture different aspects of image captioning. Our analysis indeed agrees with their finding and, further, identifies that recall is one such aspect. For an extensive description of these metrics and their configurations, see §A.2.

3.3 Score Distributions

Seen in Fig. 2 are distributions of precision and recall scores for human and machine-generated captions. We see that the precision distribution looks similar between Human and machines, but not recall. This provides further support for our claim that current machines fall short of humans particularly in recall.

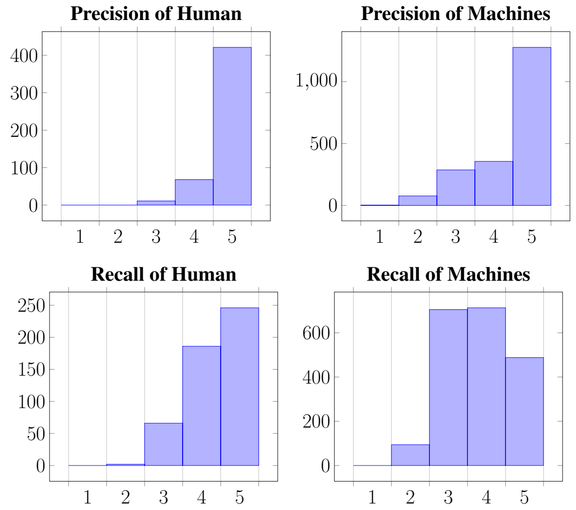

Figure 2: Precision/recall histograms for human- and machine-generated captions.

3.4 Machine vs. Human Examples

Table 5 provides examples that contrast machine- and human-generated captions. We see that machine-generated captions ignore salient information or make critical errors for these images. These problems often occur in relatively rare cases: a tennis player is showing excitement rather than hitting a ball; a bride and groom are cutting a wedding cake; a boy is wearing a tie without a shirt; a man is putting clothing and a tie on a dummy instead of a person. But these situations are exactly the most important information because of their *atypicality* (Feinglass and Yang, 2021). This illustrates fundamental problems of current image

---

[6] Instance-level Pearson correlations with human judgments were often computed in prior work to compare automatic metrics for image captioning (e.g., Hessel et al., 2021). An alternative is system-level correlations, but they would be uninformative with five systems only.

[7] The low recall correlations of reference-only metrics can be partly because the maximum (as opposed to minimum or average) is typically taken over multiple reference captions (e.g., BERTScore, Zhang et al., 2020). Nevertheless, this alone does not explain the recall gap from image-based metrics because RefCLIP-S also takes the maximum score over all references. Future work can explore the relation between precision/recall and different treatments of multiple references.

Image	Caption	P	R	Flu.	Total
	**6-A**: Up-Down *A man holding a tennis racquet on a tennis court.*	5	3	0	4
	6-B: Unified-VLP, VinVL-base, VinVL-large *A man holding a tennis racket on a tennis court.*	5	3	0	4
	6-C: Human *A tennis player shows controlled excitement while a crowd watches.*	5	5	0	5
	**7-A**: Up-Down *A person cutting a cake with a knife.*	3	3	0	3
	7-B: Unified-VLP *A person cutting a wedding cake with a knife.*	3	5	0	4
	7-C: VinVL-base *A couple of cakes on a table with a knife.*	5	3	0	4
	7-D: VinVL-large *A woman cutting a cake with a knife.*	3	3	0	3
	7-E: Human *Bride and grooms arms cutting the wedding cake with fruit on top.*	5	5	0.1	4.9
	**8-A**: Up-Down *A young boy wearing a blue shirt and a blue tie.*	3	3	0	3
	8-B: Unified-VLP *A young boy wearing a shirt and a tie.*	3	3	0	3
	8-C: VinVL-base *A young boy wearing a tie standing in front of a lamp.*	5	3	0	4
	8-D: VinVL-large *A young man wearing a tie and a shirt.*	3	3	0	3
	8-E: Human *A man wearing only a tie standing next to a lamp.*	4	5	0	4.5
	**9-A**: Up-Down *A couple of men standing next to each other.*	2	2	0	2
	9-B: Unified-VL *Two men standing in a room.*	2	2	0	2
	9-C: VinVL-base *A couple of men standing in a room.*	2	2	0	2
	9-D: VinVL-large *Two men standing next to each other in a room.*	2	2	0	2
	9-E: Human *A man standing next to a dummy wearing clothes.*	5	3	0	4

Table 5: Examples that contrast machine- and human-generated captions. All machine-generated captions overlook or misinterpret salient information: the excitement the tennis player expresses, the bride and groom cutting a wedding cake, the boy not wearing a shirt, and the man putting a tie on a dummy. None of these captions are penalized for conciseness or inclusive language. See §A.4 in Appendix for more examples.

captioning models that are left to future work.

4 Related Work

Human Evaluations for Image Captioning Several prior works conducted human evaluations for image captioning with varying models, datasets, and annotation schemes. Much work used crowdworkers from Amazon Mechanical Turk on Flickr-based datasets, including the PASCAL (Rashtchian et al., 2010), Flickr8k/30k (Hodosh et al., 2013; Young et al., 2014), and MSCOCO datasets. Annotators scored the overall quality directly (Kulkarni et al., 2011; Hodosh et al., 2013), pairwise (Vedantam et al., 2015), or along multiple dimensions, such as truthfulness/correctness (Yatskar et al., 2014; Anderson et al., 2016), thoroughness (Aditya et al., 2015), relevance (Yang et al., 2011; Li et al., 2011), and grammaticality/readability (Mitchell et al., 2012; Elliott and Keller, 2013). There are similarities between our rubrics and previous annotations, but our framework defines every dimension in a decomposable way through discussions among all annotators, while focusing on outputs from strong models currently available. Apart from these conventional Flickr-based datasets, some other work evaluated image captions for social media (engagingness, Shuster et al., 2019; accessibility for Twitter users with vision impairments, Gleason et al., 2019, 2020) and news articles (Biten et al., 2019). Our transparent evaluations would enable us to adjust the aggregation method based on the nature of downstream applications. More specializing categories can be added for these applications in later versions (e.g., THUMB 2.0).

Human Evaluations for Other Generation Tasks Much previous work explored human evaluations for other language generation tasks than image captioning. The WMT shared task (Akhbardeh et al., 2021) conducts human evaluations of state-of-the-art machine translation systems every year; participants or crowdworkers directly rate a translation in a 100-point scale, which is a method developed by Graham et al. (2013, 2014, 2017). GENIE takes a similar approach but hosts human evaluations in leaderboards for machine translation, summarization, and commonsense reasoning (Khashabi et al., 2021). Kryscinski et al. (2019) and Fabbri et al. (2021) assessed many summarization models in a similar annotation scheme to the DUC 2006/2007 evaluations (Dang, 2006). Our transparent evaluation framework is inspired by rubric-based machine translation judgments by professional translators (Freitag et al., 2021), which resulted in different system rankings than the WMT evaluations. As top-performing models and automatic metrics are becoming increasingly similar across various natural language generation tasks, our findings on image captioning may be useful for other generation tasks as well.

5 Conclusion

We developed THUMB 1.0, transparent evaluations for the MSCOCO image captioning task. We refined our rubrics through extensive discussions among all annotators, and ensured the high quality by two-stage annotations. Our evaluations demonstrated critical limitations of current image captioning models and automatic metrics. While recent image-based metrics show promising improvements, they are still unreliable in assessing high-quality captions from crowdworkers. We hope that our annotation data will help future development of better captioning models and automatic metrics, and this work will become a basis for transparent human evaluations for the image captioning task and beyond.

Acknowledgments

We thank Jack Hessel, Daniel Khashabi, Rowan Zellers, Noriyuki Kojima, Desmond Elliott, and Koji Shiono as well as the anonymous reviewers for their helpful feedback on this work. We also thank Jack Hessel, Xiujun Li, Ani Kembhavi, Eric Kolve, and Luowei Zhou for their help with captioning models and automatic evaluation metrics. This work was supported in part by the DARPA MCS program through NIWC Pacific (N66001-19-2-4031) and Google Cloud Compute.

A Appendix

A.1 Fluency Rubrics

Table 6 presents our fluency rubrics. They were developed by the first four authors (two of whom were native English speakers, and one was a graduate student in linguistics). Generally, if a fluency problem is expected to be easily corrected by a text postprocessing algorithm, the penalty is 0.1. More severe errors (e.g., broken sentence and ambiguity) are penalized more.

A.2 Automatic Metrics

Here we discuss details and configurations of the automatic metrics used in §3.2. CLIPScore and RefCLPScore use image features from CLIP (Radford et al., 2021), a crossmodal retrieval model trained on 400M image-caption pairs from the web. All the other five metrics only use reference captions.

BLEU BLEU (Papineni et al., 2002) is a precision-oriented metric and measures n-gram overlap between the generated and reference captions. We use the SacreBLEU implementation of BLEU-4 and get sentence-level scores (Post, 2018).[8]

ROUGE ROUGE (Lin, 2004) measures the number of overlapping n-grams between the generated and reference captions. We use the rouge-score implementation of ROUGE-L.[9]

CIDEr CIDEr (Vedantam et al., 2015) measures the cosine similarity between the n-gram counts of the generated and reference captions with TF-IDF weighting. We use the implementation from the pycocoevalcap package.[10]

SPICE SPICE (Anderson et al., 2016) predicts scene graphs from the generated and reference captions using the Stanford scene graph parser (Schuster et al., 2015). It then measures the F_1 score between scene graphs from the generated and reference captions. WordNet Synsets are used to cluster synonyms (Miller, 1995). We again use the implementation from the pycocoevalcap package.

BERTScore BERTScore (Zhang et al., 2020) aligns tokens between the generated and reference captions using contextual word representa-

[9] `https://pypi.org/project/rouge-score/`.

[10] `https://github.com/salaniz/pycocoevalcap`.

Fluency Error Type	Penalty	Example
Obvious spelling error, one vs. two words	0.1	*cel phone*, *surf board*
Grammatical error that can be easily fixed	0.1	*a otter*
Casing issue	0.1	*tv*, *christmas*
Hyphenation	0.1	*horse drawn carriage*
Interpretable but unnatural wording	0.1	*double decked bus*
Non-trivial punctuation	0.2	*A bird standing in the wooded area with leaves all around.*
Misleading spelling error	0.5	*A good stands in the grass next to the water.* (good→goose)
Duplication	0.5	*A display case of donuts and doughnuts.*
Ambiguity	0.5	*A cat is on a table with a cloth on it.*
Awkward construction	0.1–0.5	*There is a freshly made pizza out of the oven.*
Broken sentence	0.5+	*A large concrete sign small buildings behind it.*

Table 6: Fluency penalty rubrics.

tions from BERT (Devlin et al., 2019). We use the HuggingFace implementation (Wolf et al., 2020) and compute the F_1 score. As in Zhang et al. (2020), we take the maximum score over all reference captions.

CLIPScore CLIPScore (Hessel et al., 2021) is the only *referenceless* metric out of the 7 metrics. It measures the cosine similarity between the generated caption and given image using the representations from CLIP. It is shown to correlate better with human judgments from prior work, compared to previous reference-based metrics (Hessel et al., 2021). We use the official implementation by the authors.[11]

RefCLIPScore RefCLIPScore augments CLIPScore with the maximum similarity between the generated and reference captions. We again use the official implementation.

A.3 Evaluated Captions

We evaluated the following four strong models from the literature as well as human-generated captions. They share similar pipeline structure but vary in model architecture, (pre)training data, model size, and (pre)training objective. Evaluating captions from them will enable us to better understand what has been improved and what is still left to future captioning models.

Up-Down The bottom-up and top-down attention model (Up-Down, Anderson et al., 2018) performs pipelined image captioning: *object detection* that finds objects and their corresponding image regions and *crossmodal generation* that predicts a caption based on the features from object detection. The bottom-up attention finds salient image regions during object detection, and the top-down one attends to these regions during crossmodal generation. Up-Down uses Faster R-CNN (Ren et al., 2015) and LSTMs (Hochreiter and Schmidhuber, 1997) for object detection and crossmodal generation respectively. Faster R-CNN is trained with the Visual Genome dataset (Krishna et al., 2016), and the crossmodal generation model is trained on the MSCOCO dataset. We generate captions for the test data with a model optimized with crossentropy.[12]

Unified-VLP Unified-VLP (Zhou et al., 2020) also runs a pipeline of object detection and crossmodal generation. Faster R-CNN and the transformer architecture (Vaswani et al., 2017) are used for object detection and crossmodal generation respectively. Similar to Up-Down, the Faster R-CNN object detection model is trained with the Visual Genome dataset. The transformer generation model, on the other hand, is initialized with base-sized BERT (Devlin et al., 2019) and pretrained on the Conceptual Captions dataset (3M images, Sharma et al., 2018) with the masked and left-to-right language modeling objectives for the captions. The crossmodal generation model is then finetuned on the MSCOCO dataset. We apply beam search of size 5 to the model with CIDEr optimization.

VinVL-base, VinVL-large VinVL with Oscar (Li et al., 2020; Zhang et al., 2021) performs a similar pipeline of object detection, followed by crossmodal generation. The crossmodal model is initialized with BERT (Devlin et al., 2019) as in

---

[11] `https://github.com/jmhessel/pycocoevalcap`.

[12] `https://vision-explorer.allenai.org/image_captioning`.

Unified-VLP but uses detected object tags to encourage alignments between image features and word representations. The object detection model with the ResNeXt-152 C4 architecture (Xie et al., 2017) is pretrained with ImageNet (Deng et al., 2009) and trained on 2.5M images from various datasets. The transformer-based crossmodal generator is initialized with BERT, pretrained with 5.7M images, and finetuned for MSCOCO captioning. We use VinVL-base and VinVL-large that are both finetuned with CIDEr optimization[13] and generate captions with beam search of size 5.

Human In addition to machine-generated captions from the four models, we assessed the quality of human-generated reference captions from MSCOCO. This will allow us to understand the performance gap between machines and humans, as well as the quality of crowdsourced captions. Human-generated captions were created using Amazon Mechanical Turk (Chen et al., 2015). Crowdworkers were only given the following instructions (Chen et al., 2015):

- Describe all the important parts of the scene.
- Do not start the sentences with "There is."
- Do not describe unimportant details.
- Do not describe things that might have happened in the future or past.
- Do not describe what a person might say.
- Do not give people proper names.
- The sentences should contain at least 8 words.

Every image has five human-generated captions, and we randomly selected one for each to evaluate. We found, however, a non-negligible number of noisy captions in the MSCCOCO dataset from annotation spammers. We often find subjective adjectives (e.g., *very nice/clean/cute*) or words that diverge from *inclusive language* in reference captions, probably because crowdworkers increased the number of words in captions effortlessly (see the last instruction item that says captions have to have 8+ words). To better estimate the performance of a human that invests reasonable effort into the captioning task, we resampled a caption for 13% of the test images, which would have been given a total score lower than 4.0.

A.4 Additional Machine vs. Human Examples

Table 7 provides an additional example that contrasts machine- and human-generated captions. All machines generate generic captions and ignore the most important information that a traditional Thanksgiving dinner is being served on the table.

---

[13] `https://github.com/microsoft/Oscar/blob/master/VinVL_MODEL_ZOO.md#Image-Captioning-on-COCO`.

Image	Caption	P	R	Total
	**10-A**: Up-Down ***A table that has some food on it.***	5	2	3.5
	10-B: Unified-VLP ***A table with plates of food on a table.***	5	2	3.5
	10-C: VinVL-base ***A red table topped with plates of food and bowls of food.***	4	2	3
	10-D: VinVL-large ***A table with a turkey and other food on it.***	5	3	4
	10-E: Human ***A table set for a traditional Thanksgiving dinner.***	5	5	5

Table 7: Additional example that contrasts machine- and human-generated captions. Similar to Table 5, machine-generated captions ignore the most salient information: Thanksgiving dinner. Note that this case is specific to North America; such salient information can vary across cultures or languages (van Miltenburg et al., 2017). None of these captions are penalized for fluency, conciseness, or inclusive language.

Lifting the Curse of Multilinguality by Pre-training Modular Transformers

Abstract

Multilingual pre-trained models are known to suffer from *the curse of multilinguality*, which causes per-language performance to drop as they cover more languages. We address this issue by introducing language-specific modules, which allows us to grow the total capacity of the model, while keeping the total number of trainable parameters per language constant. In contrast with prior work that learns language-specific components post-hoc, we pre-train the modules of our **Cross**-lingual **Mod**ular (**X-MOD**) models from the start. Our experiments on natural language inference, named entity recognition and question answering show that our approach not only mitigates the negative interference between languages, but also enables positive transfer, resulting in improved monolingual and cross-lingual performance. Furthermore, our approach enables adding languages post-hoc with no measurable drop in performance, no longer limiting the model usage to the set of pre-trained languages.

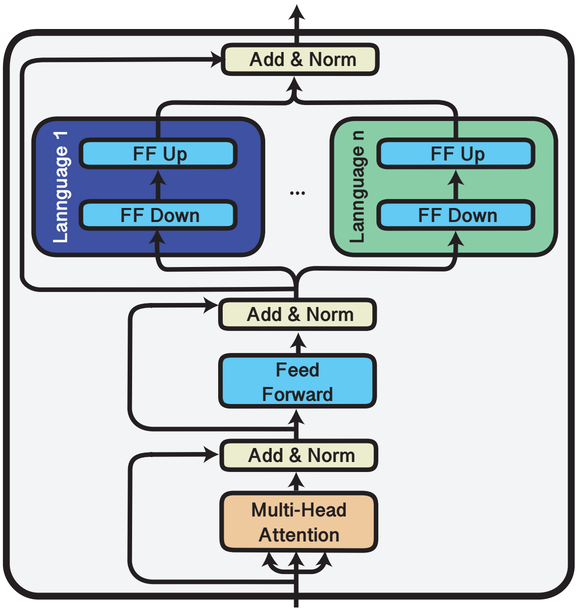

Figure 1: A transformer layer of our proposed modular architecture. The dark blue and green components illustrate the modular layers, which are language specific. The Multi-Head Attention and Feed-Forward components are shared by all languages.

1 Introduction

Recent work on multilingual NLP has focused on pre-training transformer-based models (Vaswani et al., 2017) on concatenated corpora of a large number of languages (Devlin et al., 2019; Conneau et al., 2020). These multilingual models have been shown to work surprisingly well in cross-lingual settings, despite the fact that they do not rely on direct cross-lingual supervision (e.g., parallel data or translation dictionaries; Pires et al., 2019; Wu and Dredze, 2019; Artetxe et al., 2020; Hu et al., 2020; K et al., 2020; Rust et al., 2021).

However, recent work has uncovered fundamental limitations of multilingual transformers. Conneau et al. (2020) observe that pre-training a model with a fixed capacity on an increasing amount of languages only improves its cross-lingual performance up to a certain point, after which performance drops can be measured—a phenomenon known as *the curse of multilinguality* (Figure 2). As such, prior work had to find a trade-off between supporting more languages and obtaining better performance on a smaller set of languages.

In this work, we address this problem by introducing language-specific, modular components during pre-training (Figure 1). Our **Cross**-lingual, **Mod**ular (**X-MOD**) language model shares the majority of the transformer parameters between all pre-training languages, while providing each language with individual capacity to learn idiosyncratic information without increasing the total number of trainable parameters per language. While previous adapter-based approaches (Figure 3a) extend pre-trained multilingual language models (LMs) with modular components *after* pre-training, we add modular components *during* pre-training, thereby

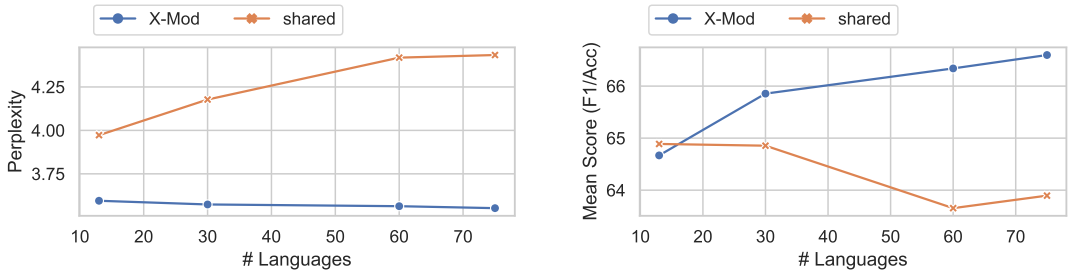
July 10-15, 2022



(a) Mean Perplexity. (b) Mean Performance on XNLI and NER.

Figure 2: Average (a) perplexity and (b) transfer performance on XNLI and NER across pre-trained languages when training on an increasing number of languages. Each model has seen the **same amount of examples** in each language. Lower perplexity and higher downstream score indicate better performance. Refer to Figure 4 for per-task performance, and Appendix A for per-language performance.

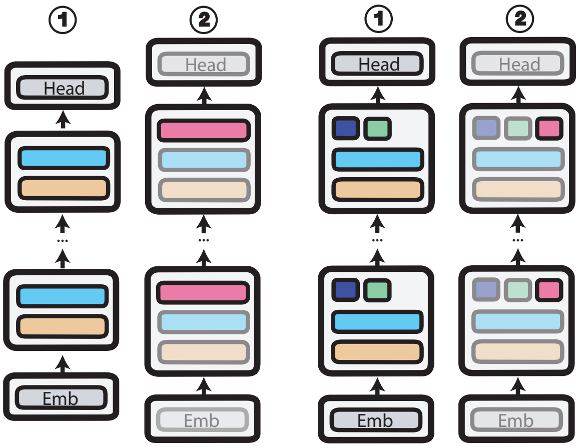
preparing the model to be extended to new languages post-hoc. Our experiments on natural language inference (NLI), named entity recognition (NER), and question answering (QA) demonstrate that our modular architecture not only is effective at mitigating interference between languages, but also achieves positive transfer, resulting in improved monolingual and cross-lingual performance. In addition, we show that X-Mod can be extended to unseen languages, with no measurable drop in performance, by learning its corresponding modules and leaving the shared parameters frozen. All in all, we propose a multilingual architecture that can scale to a large number of languages without any loss in performance, and can be further extended to new languages after pre-training.[1]

2 Background and related work

We provide a background on multilingual and modular language modelling, as well as approaches that extend LMs to new languages.

2.1 Multilingual transformers

Recent LMs (Devlin et al., 2019; Conneau et al., 2020), based on transformer architectures (Vaswani et al., 2017) and pre-trained on massive amounts of multilingual data, have surpassed (static) cross-lingual word embedding spaces (Ruder et al., 2019; Glavas et al., 2019) for cross-lingual transfer in NLP (Pires et al., 2019; Wu and Dredze, 2019; Wu et al., 2020; Hu et al., 2020; K et al., 2020). Transformer-based models are **1)** pre-trained on textual corpora using Masked Language Modelling (MLM). They are then **2)** fine-tuned on labelled data of a downstream task in a *source* language and **3)** directly applied to perform inference in a *target* language (Hu et al., 2020).



(a) Adapter-based (b) X-Mod

Figure 3: Our proposed architecture in comparison to adapter-based approaches. (a) Previous approaches ① utilize non-modular pre-trained transformer models and ② extend them with modular adapter components. (b) We ① pre-train the transformer with modular units from the get-go, *preparing* the model to be ② extended with additional modular units later on. Yellow and light blue components indicate standard Multi-Head Attention and Feed-Forward layers. The remaining (non-gray) components are bottleneck (modular) units. Grayed-out components are frozen.

2.2 Modular language models

Modular approaches have a long standing history in NLP, preceding pre-trained models (Andreas et al., 2016). They have recently re-gained interest for transformer-based models, where mix-

---

[1] Code and pre-trained models are available at: https://github.com/pytorch/fairseq/tree/main/examples/xmod.

ture of experts (MoE; Shazeer et al., 2017) approaches have enabled training trillion parameters models in a distributed fashion (Fedus et al., 2021). More recently modular MoE approaches have been shown to improve domain-specific pretraining of LMs (Gururangan et al., 2021). In a similar trend, 'expert' modules have been added to (non-modular) pre-trained LMs post-hoc, predominantly referred to as adapters (Rebuffi et al., 2017, 2018; Houlsby et al., 2019). Next to being extremely parameter (Houlsby et al., 2019; Mahabadi et al., 2021a; He et al., 2022) and training efficient (Pfeiffer et al., 2020a; Rücklé et al., 2021), these modular approaches allow models to be extended to new data settings (Chen et al., 2019; Rücklé et al., 2020), where newly learned knowledge can be combined (Stickland and Murray, 2019; Wang et al., 2021a; Pfeiffer et al., 2021a; Lauscher et al., 2020a; Mahabadi et al., 2021b; Poth et al., 2021), or stacked for combinatory cross-lingual (Pfeiffer et al., 2020b, 2021b; Üstün et al., 2020; Vidoni et al., 2020; Ansell et al., 2021b,a; Wang et al., 2021b) as well as NMT scenarios (Bapna and Firat, 2019; Philip et al., 2020; Chronopoulou et al., 2020; Le et al., 2021; Üstün et al., 2021; Stickland et al., 2021; Garcia et al., 2021).

2.3 Weaknesses, improvements, and extensions of language models

Next to the *curse of multilinguality*, recent works have shown substantially reduced cross-lingual and monolingual abilities of models for low-resource languages with smaller pre-training data (Wu and Dredze, 2020; Hu et al., 2020; Lauscher et al., 2020b; Artetxe et al., 2020; Pfeiffer et al., 2020b, 2021b; Chau et al., 2020b; Ponti et al., 2020).

K et al. (2020); Artetxe et al. (2020) show that a shared vocabulary is not necessary for cross-lingual transfer. Chung et al. (2021) demonstrate that decoupling the input embeddings from the prediction head improves the performance on a number of downstream tasks. Dufter and Schütze (2020) show that the number of parameters and training duration is interlinked with the model's multilingual capability. Chung et al. (2020); Rust et al. (2021) show that the tokenizer plays an important role in the per-language downstream task performance, which Clark et al. (2022); Xue et al. (2022); Tay et al. (2021) take to the extreme by proposing tokenizer-free approaches.

To extend a monolingual LM to other languages, Artetxe et al. (2020) train a new embedding layer with a corresponding target-language tokenizer, while freezing the pre-trained transformer weights. Tran (2020) extend a monolingual model to new languages using bilingual corpora. Wang et al. (2020); Chau et al. (2020a) extend the vocabulary of multilingual models with a small number of target-language tokens, to improve the performance in the target language. Muller et al. (2021) propose a transliteration based approach, Vernikos and Popescu-Belis (2021) propose subword mappings, and Pfeiffer et al. (2020b, 2021b); Vidoni et al. (2020); Ansell et al. (2021b) propose adapter-based approaches to extend multilingual models to unseen languages.

While these approaches achieve considerable performance gains over unseen languages, they are outperformed by standard full fine-tuning methods for seen languages. One can further argue that, as the pre-trained models have already been cursed by multilinguality, the adapter-based approaches build upon sub-optimal parameter initializations.[2] In our work, we consequently aim to **1)** modularize the model from the start to prepare the model to be **2)** extendable to new languages post-hoc.

3 Proposed approach

We propose X-MOD, a modular multilingual architecture that combines shared and language-specific parameters. In contrast to prior work, we pretrain modular models from the get-go. Our models can be extended to new languages after pretraining, and used for cross-lingual transfer learning in downstream tasks.

Architecture. As illustrated in Figure 1, we extend the transformer-based architecture from mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) by incorporating language-specific modules—bottleneck feed-forward layers—at every transformer layer. We learn a separate module for each language, whereas the attention and feed-forward components are shared. While the total number of parameters of the model grows linearly with the number of languages, the training and inference cost does not increase (as measured in FLOPs), as only the module in the relevant language is used for each input. Inspired by the adapter[3] architecture of Pfeiffer et al. (2021a) we

---

[2] We investigate this claim further in §6.2.

[3] The term 'adapter' refers to newly introduced layers within a pre-trained (frozen) model. These layers *adapt* the

place our 'modules' after the LayerNorm of the feed-forward transformer block, and the residual connection is placed after the LayerNorm;[4] the LayerNorm before and after the modular component is shared.[5]

Pre-training procedure. Similar to Conneau et al. (2020), we pre-train our model on MLM on combined monolingual corpora in multiple languages. Examples of each language are passed through the shared embedding matrix as well as the multi-head attention and feed-forward components at each layer. As each layer contains a language-specific modular component, the examples are routed through the respective designated modular bottleneck layer. Given that each example only requires access to a single module, modules can be efficiently stored on only a subset of GPUs in distributed training.

Extending to new languages. The modular design of our model allows us to extend it to new languages after pre-training. To that end, we learn new embeddings and adapter modules for the target language through MLM, while the rest of the components are frozen.[6] Consequently, we are able to extend the model to a new language by learning a small number of new parameters, without affecting performance in the set of pre-trained languages. Following Pfeiffer et al. (2021b), we learn a new subword vocabulary for the added languages, and initialize the embeddings of lexically overlapping tokens from the original embedding matrix.

Fine-tuning on downstream tasks. To transfer the models to cross-lingual downstream tasks, we fine-tune the shared weights only on the source language data, while keeping the modular components and the embedding layer frozen. We follow the standard fine-tuning procedure of adding a prediction head on top of the CLS token. We then replace the source language modules (as well as embedding layer for *added* languages) with the target language parameters, passing the text of the target language through the model.[7]

4 Experimental design

We detail the baseline and models (§4.1), and their training (§4.2) and evaluation settings (§4.3).

4.1 Model variants

We pre-train separate models for all combinations along the following axes:

X-MOD vs. SHARED. To evaluate the effectiveness of our X-MOD model, we aim to compare ourselves to a conventional non-modular architecture. However, simply removing the modular component would be unfair, as the number of FLOPs and trainable parameters per language would not be the same—both in terms of pre-training, as well as fine-tuning. Consequently, for our baseline model—where all parameters should be *fully* shared between all languages—we include a single bottleneck layer right after the Feed-Forward component. Effectively, this is the same architecture as our X-MOD model, just with a single module that is shared by all languages. We refer to this as the SHARED model throughout this paper.[8] To extend the SHARED model to unseen languages, we follow Artetxe et al. (2020) and only learn a new embedding layer, freezing the transformer parameters. To fine-tune the SHARED model on a downstream task, we freeze the embedding layer, as well as the (single) module, thereby fine-tuning an equal amount of parameters on the downstream task as the X-MOD model.[9]

13 vs. 30 vs. 60 vs. 75 languages. So as to understand how each approach is affected by the curse of multilinguality, we pre-train the X-MOD and SHARED models on 4 increasing sets of languages. We start with an *initial* set of 13 typologically diverse languages that we evaluate on, and add additional languages for larger sets of 30, 60, and 75 languages. In addition, we keep a set of 7 held-out languages that we extend the pre-trained models to. Table 1 lists the specific languages in each

---

representations of the pre-trained mode; we train these modular components together with the transformer weights, and therefore refer to them as modules.

[4] We find that the residual connection proposed by Pfeiffer et al. (2021a) results in training instabilities when trained together with the transformer weights.

[5] Preliminary results showed that sharing the LayerNorm results in better cross-lingual transfer performance.

[6] Following Artetxe et al. (2020) we train positional embeddings.

[7] We initially also experimented with stacking adapters on top of the language modules similar to Pfeiffer et al. (2020b, 2021b). While this approach is considerably more parameter efficient, we find that fine-tuning all shared weights slightly outperformed the adapter-based approach.

[8] Extending the **total** number of shared parameters would be unfair, as X-MOD and SHARED would not have the same FLOPs nor the same number of trainable parameters when fine-tuning.

[9] Adapter-based approach such as MAD-X (Pfeiffer et al., 2020b) would be an alternative. However, this would require training on languages twice—once during pre-training, and once when adding adapters—which is not directly comparable to X-MOD. Nonetheless, we report results in §6.2.

Pre-trained languages	13-LANGS	***en***, ***ar***, **fr**, ***hi***, ko, ***ru***, ***th***, ***vi***, ta, id, fi, **sw**, ka
	30-LANGS	13-LANGS + cs, eu, hr, hu, hy, it, lt, ml, mn, ms, pl, ro, si, sk, sq, sv, tl

Table 1: **Selection of languages.** We pre-train different models on 4 sets of languages, and further extend them to a set of held-out languages post-hoc. We evaluate on XNLI (languages in **bold**), NER (underlined languages) and XQuAD/MLQA (languages in *italic*). For more details about the language selection, see Appendix C.

group. The selection and split of *initial* as well as *added* languages is motivated by typological and geographical diversity, as well as the availability of downstream task evaluation data.

Controlling for total vs. per-language updates. Conneau et al. (2020) investigated the effect of adding more languages during pre-training, while training on an equal number of update steps. However, increasing the number of languages while keeping the number of updates constant results in the model seeing less data in each individual language. As such, it remains unclear if the curse of multilinguality happens because of negative interference, or simply because the number of updates for each specific language is smaller. So as to understand this, we compare (1) training on an equal number of *update steps* and (2) training on an equal number of *seen examples* per language. We start with the set of 13 languages (Table 1) and train the respective models for 125k update steps. When adding more languages, we compare (1) training models on each set of languages for 125k update steps, and (2) increasing the number of update steps such that the models are trained on the same number of examples in each of the initial 13 languages. For the latter, this amounts to training for 195k, 265k and 269k update steps, respectively.

4.2 Training details

Data and hyperparameters. We sample languages with $\alpha = 0.7$ and train our models with a batch size of 2048 across 64 V100 GPUs on the CC100 dataset (Conneau et al., 2020) using fairseq (Ott et al., 2019). All our models extend the *base* transformer architecture, with 12 layers and 768 dimensions. Modules are implemented with a bottleneck size of 384. The shared transformer weights account for 270M parameters, whereas each individual module accounts for 7M parameters. We train our models with a linear learning rate decay peaking at $7e{-}4$ during pre-training and $1e{-}4$ when adding languages.

Vocabulary. As we aim to identify the impact of *modularity* on the curse of multilinguality, we control for consistent tokenization across the different axes. We therefore tokenize using the XLM-R vocabulary for all our pre-training experiments.[10] However, for languages added post-hoc, we learn a *new* SentencePiece tokenizer for each of the target language,[11] as the languages potentially use scripts unseen by the original tokenizer.

4.3 Evaluation

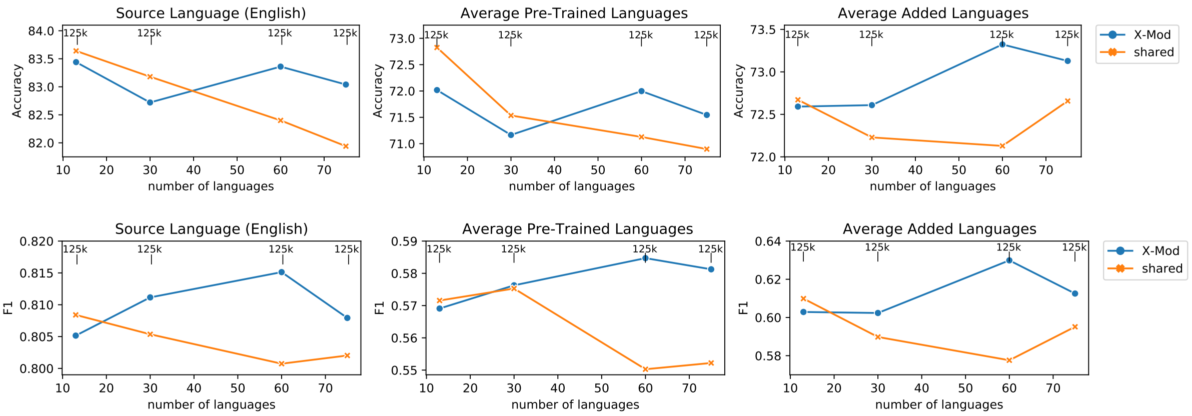
We conduct experiments on NLI, NER, and QA. In all cases, we fine-tune the model on English and measure the zero-shot transfer performance in other languages. For NLI we train on MultiNLI (Williams et al., 2018) and evaluate on XNLI (Conneau et al., 2018). For QA, we train on SQuAD (Rajpurkar et al., 2016) and evaluate on XQuAD (Artetxe et al., 2020) and MLQA (Lewis et al., 2020). For NER, we use WikiANN (Pan et al., 2017; Rahimi et al., 2019). We experiment with learning rates $1e{-}4$, $3e{-}4$, and $5e{-}4$ and train for 3 or 5 epochs for QA and 5 or 10 epochs for NER and NLI. For NER and NLI we take the hyperparameter setting performing best on the development sets, averaged across the pre-trained languages (Table 1). For SQuAD we take the best performing checkpoint evaluated on the English development set, and report the cross-lingual test set results.[12] All results are averaged across 5 random seed runs.

---

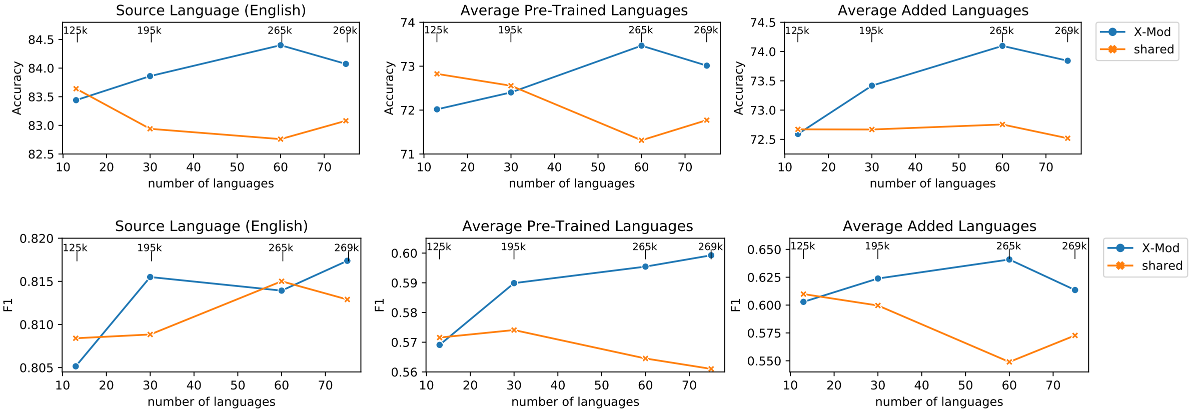
[10] Rust et al. (2021) have previously demonstrated the impact of the multilingual tokenizer on the downstream task performance: languages underrepresented in the sub-word vocabulary exhibit considerable performance drops when compared to vocabularies dedicated to the respective language.

[11] We train the new tokenizers for a vocabulary size of 30k.

[12] In contrast to NER and NLI, the cross-lingual evaluation benchmarks of SQuAD do not provide a development set for each target language on the basis of which the best checkpoint can be selected. Consequently, we select the checkpoint based



(a) All models are trained for 125k update steps. Models trained on **more languages** have seen **less examples** in each language.



(b) Models trained on more languages are trained longer. All models have seen the **same amount of examples** in each language.

Figure 4: Test set results on XNLI (top) and NER (bottom) for models trained on different numbers of languages. *Source Language (English)* only includes scores of the source language. *Average Pre-Trained Languages* includes all evaluation languages that the model was pre-trained on. *Average Added Languages* includes all languages that were added to the model after pre-training. Scores are averaged across all languages and random seeds.

5 Results and discussion

We present results for pre-trained languages in §5.1 and added languages in §5.2.

5.1 Pre-trained languages

In Figure 4 we plot downstream task results of models pre-trained on different amounts of languages. Table 2 reports the individual language performance for the models trained on 60 languages.

The Curse of Multilinguality. Conneau et al. (2020) showed that multilingual LMs trained on *increasing* amounts of languages, while *maintaining* the number of update steps, exhibit drops in downstream task XNLI performance. We reproduce these results, both in terms of language modelling perplexity (Figure 2a),[13] as well as downstream task performance on XNLI *and* NER (Figure 4a). We further find that the curse of multilinguality does not *only* happen *because* the total number of update steps per language decreases, but *also* when all SHARED models are trained on the *same* number of examples per language (Figure 4b). This confirms that fully shared architectures suffer from negative interference.

Lifting the Curse. While for the SHARED model we witness negative interference between languages in terms of perplexity, the X-MOD model is able to *maintain* performance, and even improves for a subset of languages. We observe similar patterns in the downstream task performance: In both our experimental setups—(1) we control for the number of update steps (Figure 4a); (2) we control for the number of per-language seen examples (Figure 4b)—our X-MOD model—in contrast to the SHARED model—is able to maintain, or

---

on the best performance on the English development set.

[13] For per-language perplexity see Appendix A.

even outperform model variants trained on less languages. These results demonstrate that the added per-language capacity is sufficient for the model to adequately represent all languages.

Surprisingly, X-MOD not only maintains performance, but actually slightly improves while we increase the number of languages we pre-train on. This is even the case for settings where the model sees *less* examples in the target language. This suggests that increasing the language diversity can have a positive impact on the model's cross-lingual representation capability.

X-MOD vs SHARED. Overall, the X-MOD model pre-trained on 60 languages achieves the best cross-lingual performance.[14] Our results on XNLI, NER, MLQA, and XQuAD in Table 2 demonstrate consistent performance gains over the SHARED model for every task and across (almost) all high- as well as low-resource languages.

5.2 Extending to unseen languages

We further evaluate the cross-lingual performance of languages added in the second step; (1) on the architectural side—comparing the SHARED with the X-MOD modelling variant—and (2) by comparing the performance when *pre-training* on the language, vs. when *adding* the language post-hoc.

Modular vs Shared. We evaluate if the additional per-language capacity improves the extendability of the X-MOD model. On the right in Figure 4a we plot the results for added languages on XNLI (top) and NER (bottom). Similarly, we plot the results for the models where we control for the number of seen examples per target language in Figure 4b. We find that the X-MOD model consistently outperforms the SHARED model, with a peak performance when pre-training on 60 languages, demonstrating that the language specific capacity is beneficial for adding new languages post-hoc. We report results for the 60 language versions in Table 3, demonstrating the consistent advantage of the X-MOD over the SHARED model.

Pre-training vs Adding Languages. To evaluate if there is a measurable difference on downstream performance for languages that we *pre-train* on vs. those we *add post-hoc*, we train 2 models on *different* initial sets of languages, adding the respectively missing ones in the second step. So as to understand if the typological similarity of languages has impact on the downstream task performance, we split the *initial* and *added* languages (Table 1) of our previous experiments into two parts. The *first* split consists of languages where the model was pre-trained on at least one language of the same language family (e.g. English vs. German). The *second* split consists of languages that are part of a **unique** language family, i.e. the model was **not**

---

[14] We find that the X-MOD model trained on 75 languages is less stable than the versions trained on less languages. We think that this can be attributed to the 15 added languages being extremely low resource—we only train for an additional 4k update steps—resulting in the respective randomly initialized modules being updated very infrequently. This variance could potentially be mitigated by training for longer.

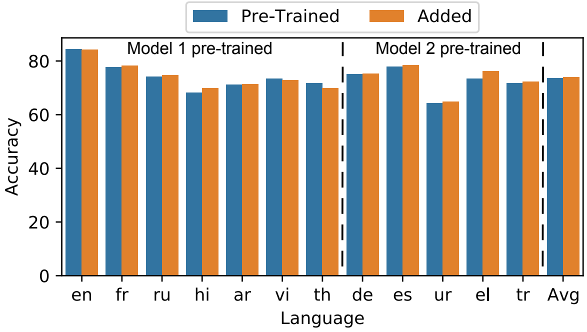

Figure 5: XNLI test set accuracy of X-MOD models pre-trained on different languages in comparison to those added post-hoc (Table 4).

Table 4: Selection of 2 sets of languages that we either pre-train on, or add post-hoc. The last 6 languages in the list are part of language families which are *unique* in the total list of languages we pre-train on (Table 1), i.e. none of our models was pre-trained on a language of the same family.

pre-trained on a language of the same family (Table 4). Consequently, we pre-train two models on two sets of languages, adding the respective other set post-hoc.[15]

Our XNLI results (Figure 5) demonstrate that the per-language performance is on par when pre-training vs. when adding the language post-hoc.[16] We also find that the family does not have a measurable effect on the performance of the language. Our results therefore suggest that it is sufficient to train X-MOD on only a subset of languages for which sufficient pre-training data exists. Essentially, X-MOD has the potential to cover all languages of the world, as the model has the capability to be adapted to new languages post-hoc.

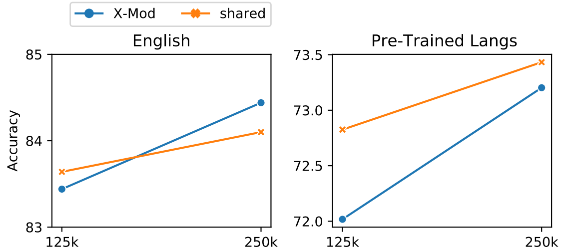

Figure 6: Results on XNLI when when pre-training on 13 languages for 125k and 250k update steps.

6 Further analysis

We further analyze the impact of the number of update steps on X-MOD (§6.1) and compare our method to adapter-based approaches (§6.2).

6.1 The importance of update steps

In Figure 4 we have witnessed a slight edge of the SHARED model over the X-MOD model, when training on only 13 languages and only training for 125k update steps. Dufter and Schütze (2020) found that it requires a large number of update steps for a model pre-trained on multiple languages to become multilingual; with the added per-language capacity we hypothesize that update steps also play an important role for modular models. We compare the downstream task performance of models pre-trained on 13 languages, when training for 125k with 250k update steps in Figure 6. When training for longer we find that the X-MOD model begins to outperforms the SHARED model in the source language, while almost closing the gap in the cross-lingual setting. This supports the hypothesis that the X-MOD model requires more update steps when training only on a small number of languages, in order for modularity to "kick-in".

6.2 X-MOD vs. Adapters

As illustrated in Figure 3, from an architecture perspective X-MOD is similar to previously proposed multilingual Adapter-based methods (MAD-X; Pfeiffer et al., 2020b). MAD-X utilizes a pre-trained massively multilingual transformer-based model and fine-tunes newly introduced adapter weights on languages the model has seen during pre-training, and ones the model has not been

---

[15] In previous experiments, the modular model trained on 60 languages achieved the best performance. Therefore, the models in these experiments are also trained on 60 languages. Both models are trained on the same additional languages, i.e. the 60-LANGS of Table 1, where only the 13-LANGS differ.

[16] The models have seen an equal amount of examples in the respective languages in each case.

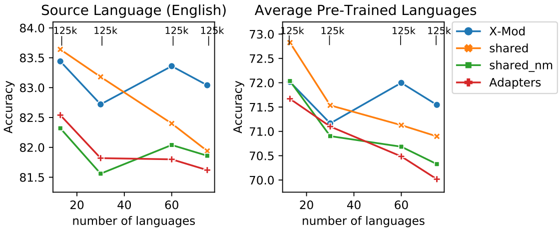

Figure 7: Comparison on XNLI of X-MOD and *shared* models with an Adapter baseline, all models are pre-trained for 125k update steps.

trained on. For a fair comparison in terms of *seen examples* and *number of update steps* we train a transformer model without module components (*shared_nm*) for 100k update steps on the respective languages (Table 1). We subsequently train adapters on each of the target languages for another 25k update steps.[17] We report results in comparison to X-MOD in Figure 7, here results for *shared_nm* are for a model that was trained for 125k update steps to instantiate a fair comparison.

Our results demonstrate that the additional capacity of adapters added *after* pre-training is not able to mitigate the curse of multilinguality which has already had a catastrophic impact on the shared transformer weights; the performance of the adapters strongly correlates with the performance of the corresponding fully shared model *shared_nm*. Consequently, adding language-specific capacity *during* pre-training is important, as the curse of multilinguality cannot be lifted post-hoc.

7 Conclusions

In this paper, we have evaluated the effectiveness of modular multilingual language modelling across multiple axes. We have demonstrated that by providing additional per-language capacity, while maintaining the total number of trainable parameters per language, we are not only able to mitigate negative interference between languages, but additionally achieve positive transfer. Our results suggest that it is sufficient to train our proposed X-MOD model only on a subset of languages for which sufficient amounts of textual data is available. Unseen languages can be added post-hoc, with no measurable drop in performance on XNLI. By *pre-training* the model in a modular fashion, we thus mitigate negative interference of idiosyncratic information, while simultaneously preparing the model to be extendable to unseen languages.

While in this work we have simulated language adding scenarios with a held out set of languages, in future work we aim to evaluate the performance on truly low-resource languages such as MasakhaNER (Adelani et al., 2021) and AmericasNLI (Ebrahimi et al., 2021). We further aim to evaluate the cross-lingual transfer performance from typologically more diverse source languages, besides English.

Acknowledgments

We thank Samuel Broscheit for insightful feedback and suggestions on a draft of this paper, as well as the ARR reviewers and meta-reviewers for their valuable comments.

[17] We follow Pfeiffer et al. (2020b) and train adapter weights with a learning rate of 0.0001. While they have found that cross-lingual transfer performance of adapters converges at ∼20k update-steps, we would like to stress that our experimental setup is only **one** of multiple different valid versions. A more thorough investigation to find the optimal number of update steps for pre-training and subsequent adapter training is necessary, which was out of scope for this work.

A Additional results

We report MLQA and XQuAD results on pre-trained languages in Tables 5 and 6, respectively, and MLQA results on added languages in Table 7. Table 8 report NER results on more languages.

Figures 9, 10 and 11 report per-language results as we increase the amount of languages on language modeling perplexity, XNLI and NER, respectively.

B Intermediate checkpoints

Our results in §6.1 suggest that, when the number of languages is small, X-MOD becomes more competitive with SHARED as the number of training steps increases. So as to understand if this behavior also holds for models covering more languages, we evaluate intermediate checkpoints for the 60-LANG model on XNLI. As shown in Figure 8, we find that the X-MOD model continuously outperforms the SHARED model. This suggests that the SHARED model immediately suffers from negative interference between languages, while the added, language-specific components of the X-MOD model are able to mitigate the curse of multilinguality, resulting in considerable performance gains at all evaluated checkpoints.

C Language selection

We provide more details about our selection of languages in Table 9.

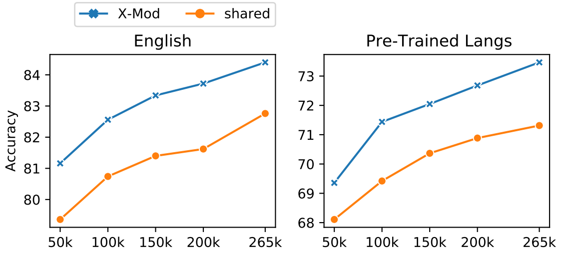

Figure 8: Results on XNLI using intermediate checkpoints of the models trained on 60 languages.

	en F_1 / EM	ar F_1 / EM	hi F_1 / EM	vi F_1 / EM	*avg* F_1 / EM
X-MOD	**80.1 / 66.9**	**58.6 / 38.9**	**60.7 / 42.4**	**67.5 / 46.1**	**66.7 / 48.6**

Abstract

Despite extensive research on parsing of English *sentences* into Abstract Meaning Representation (AMR) graphs, *full-document* parsing into a unified graph representation lacks well-defined representation and evaluation. Taking advantage of a super-sentential level of AMR coreference annotation from previous work, we introduce a simple algorithm for deriving a unified graph representation, avoiding the pitfalls of information loss from over-merging and lack of coherence from under-merging. Next, we describe improvements to the Smatch metric to make it tractable for comparing document-level graphs, and use it to re-evaluate the best published document-level AMR parser. We also present a pipeline approach combining the top performing AMR parser and coreference resolution systems, providing a strong baseline for future research.

1 Introduction

Abstract Meaning Representation (AMR) is a formalism that represents the meaning of a text in the form of a directed graph, where nodes represent concepts and edges are labeled with relations (Banarescu et al., 2013). Until recently, the annotated corpora for AMR only provided sentence-level annotations. As a result, AMR parsing research has been limited to sentence-level parsing. A unified document-level AMR graph representation can be quite useful for applications that require document-level understanding, such as question answering and summarization.

The most recent release of AMR annotations (AMR 3.0) includes a multi-sentence AMR corpus (MS-AMR; O'Gorman et al., 2018) that provides cross-sentential coreference information for AMR graphs. These annotations connect multiple sentence-level graphs via coreference chains, implicit relations and bridging relations. However, an adequate representation of this multi-sentence information in the form of an AMR graph has yet to be decided upon. The initial proposal (O'Gorman et al., 2018), to merge all nodes in a coreference chain into one node, suffers from significant information loss. Without a consistent multi-sentence graph representation, AMR's standard Smatch metric (Cai and Knight, 2013) cannot be used for evaluation and comparison. The Smatch scores differ greatly depending on how the coreference information is added to the AMR graphs. Additionally, the Smatch algorithm is exceedingly slow in its original form when run over multi-sentence graphs. These limitations in multi-sentence AMR graph representation and evaluation get in the way of research efforts in this area. Without a consistent representation and evaluation mechanism, it is impossible to draw meaningful comparisons between different approaches on the task. In this work, we present a simple and non-lossy multi-sentence AMR graph representation as well as a modification of the Smatch algorithm that allows efficient and consistent evaluation.[1]

Our chief contributions are:

- A standard for merging sentence-level AMR graphs into a single document-level graph based on MS-AMR coreference annotations (DocAMR; §3.3)
- A faster implementation of the Smatch metric suitable for evaluating document-level AMR parsers (§4.1)
- A metric, based on Smatch, for specific evaluation of coreference in document-level AMR graphs (§4.3)
- A baseline system for document-level AMR parsing and its evaluation (§5)

2 Multi-Sentence AMR Corpus

Multi-Sentence AMR corpus (henceforth MS-AMR) is part of AMR3.0 release and was introduced by O'Gorman et al. (2018). While a number of works have used document-level AMR graph creation for downstream tasks such as summarization (Liu et al., 2015; Lee et al., 2021), it is the only dataset currently with manual annotations of AMR document graphs. It contains 284 documents in its train split and 9 documents on test split, annotated over 8027 gold AMRs in total. Out of the 284 train documents, 43 are annotated twice; in this work we refer to these double annotation documents as our development set.

Coreference chains were annotated as clusters of coreferent nodes in gold AMR graphs, rather than as coreferent spans of text: this is what allows evaluation with Smatch. Such an annotation also precludes evaluation of system predictions using more traditional coreference evaluations, as there is no notion of mention spans to use when comparing mentions.

The MS-AMR corpus also annotated implicit relations, as shown in the blue `ARG4` edge in figure 1, whenever a numbered argument of a predicate was semantically identifiable in another sentence. Similarly, the MS-AMR corpus annotates bridging mentions, such as part-whole or set-member relations. Both implicit relations and bridging relations can be seamlessly added as cross-sentential edges.

Coreference chains form the majority of cross-sentential relations annotated in MS-AMR. Unlike implicit and bridging relations, there is no straight forward way of incorporating coreference chains into a multi-sentence AMR graph. Next section discusses the challenges involved and proposes a solution.

3 Document-level AMR Representation

As discussed in the past section, majority of MS-AMR annotations take the form of coreference chains over sentence-level gold AMR graphs. In this work, we propose a representation DOCAMR that incorporates these chains into multi-sentence AMR graphs. The motivation for having such a representation is two-fold. First, representing a multi-sentence document as a single AMR graph will allow downstream applications to treat the whole document as single entity, much like the AMR graphs for sentences. Second, it is crucial to have a consistent representation for the purpose of evaluating MS-AMR predictions. Smatch – the standard evaluation metric for AMR – operates over graphs. We can use this metric for MS-AMR evaluation only if the system outputs and the gold graphs adhere to the same document-level graph representation.

Intrasentential coreferences in *sentence-level* AMR are annotated with what one might call *manual full merge* – i.e., given multiple mentions in the same sentence (such as a named entity and a pronoun), a human annotator would pick a single informative mention, and merge all other information into the root of the subgraph representing that mention. Language being efficient, it is very rare for multiple non-reduced mentions to occur in the same sentence, therefore it was a trivial task for human annotators. MS-AMR human annotations do not perform manual merge – they only indicate the nodes in multiple existing sentence-level graphs that participate in a coreference cluster.

3.1 Why Not Merge All Coreferent Nodes?

The pioneering work on MS-AMR (O'Gorman et al., 2018) that introduced the annotations, also

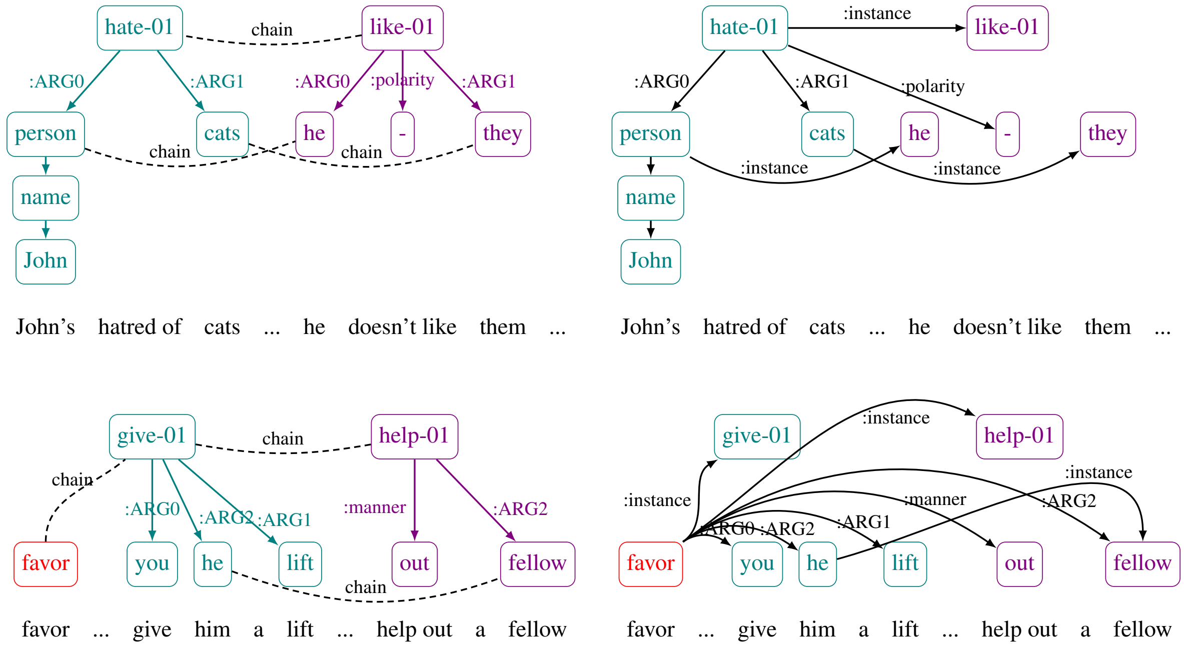

Figure 2: Two examples of merge operations that result in loss or distortion of information. Nodes of the same color belong to the same sentence-level AMR. Dashed lines indicate the identity chain links. In the top example, the merged node representation (right) reverses the meaning of the first sentence because of the negative `:polarity` node migrating from the merged node `like-01`. In the bottom example, the non-predicate node `favor` has received a bunch of `ARG` nodes from the fellow coreference nodes. Moreover, the merged-in predicate nodes `give-01` and `help-01` have lost association with their arguments. For example, the sentence "you help the fellow lift [something]" will be consistent with this graph.

proposed a way to represent MS-AMR in the form of a graph. This approach essentially merges all coreferent nodes from a chain into one node that inherits all the parents and children of the original nodes. Furthermore, if the lexical form of the merged nodes are different, each distinct form is added as an additional instance of the merged node connected via an `:instance` edge. Figure 1 shows a simple example of this merge operation.

This representation has a desirable property in that it treats cross sentential coreference information in a manner similar to sentence-level reentrancies. Another advantage of node merging is that a single node represents each entity/event, thus a document representation can be viewed as a mini Knowledge Base for the document. Moreover, this highly connected representation is consequential for Smatch: if a gold document has a cluster of ten mentions and a system incorrectly splits that cluster into six and four mentions, then the optimal one-to-one Smatch alignment will consider all links to the smaller cluster wrong.

However, merging coreference nodes at the document level is not trivial. Automatic indiscriminate merging of all coreference clusters has serious limitations. Without manual curation of potentially conflicting referential expressions or situations, it can end up merging conflicting information, particularly with event coreference: e.g., “his hatred of cats” and “John doesn’t like cats” would be merged into the AMR equivalent of “John+he does not (like + hate) cats”. It does not preserve the semantics of the original AMR graphs. Figure 2 shows examples of merge operations that either lose or distort the meaning of the text.

Moreover, the proposed method of (O’Gorman et al., 2018) assumes that a node can have multiple `:instance` edges – however existing AMR tools (including the Smatch implementation) do not allow multiple `:instance` edges on a node. In the hand full of previous works on MS-AMR, edge labels other than `:instance` are used to connect additional forms of a node. One node becomes privileged over others under the proposed approach – as a result, a system that selects the privileged node differently will be unnecessarily penalized.

We wish to avoid the above pitfalls while still retaining the advantages of node merging. The next section discusses the principles considered while formulating the DOCAMR representation.

3.2 Considerations

Our primary consideration while designing DOCAMR has been to preserve the meaning of the underlying text as encoded by the combination of sentence-level graphs and MS-AMR annotations. Whenever a secondary consideration led towards a lossy representation, we decided in favor of meaning preservation. In addition, we considered the following principles:

1. *Be consistent with AMR's treatment of within-sentence coreference.* In sentence-level AMRs, pronominal concepts are only used in the absence of a contentful antecedent. Pronouns don't contribute enough meaning beyond referential information. Therefore, only those pronouns are kept whose antecedent is unspecified. Furthermore, in sentence-level AMRs all coreferent nodes are merged so they share the same variable. We stick to these principles except in the cases where they can potentially cause information loss.
2. *Do not place more weight on any particular representative member of a coreference chain.* It would be artificial to represent the cluster as pairwise mention-mention links, e.g. by privileging one mention as the primary representative of the cluster. Instead, coref chains should be represented in a way that the non-pronominal ways of referring to the entity/event in different sentences are on equal footing.
3. *Systems should not get too much credit for superficial decisions* (like merely creating a concept for a pronoun, or detecting the name string and entity type on every mention of the name). This can be achieved by merging the nodes whenever it can be done safely without loss of information. The effect is that the scoring places more weight on detection of coreference.
4. *The representation should support comparison via Smatch* (without unnecessary computational overhead) for document-level parsers given the same document as input.[2]
5. *The edges between the nodes in a coref cluster and their sentence-level neighbours should be kept intact*, so that when evaluated with Smatch, at least one mention in a chain of correctly predicted entity mentions will get full credit even if the coreference is missed.
6. Finally, *the representation should not rely on complicated heuristics or new manual annotations.* For example, we considered and ultimately rejected the possibility of merging coreferent non-name nodes, which would have required heuristics for choosing one representative concept from among multiple distinct concepts from different mentions (and also would have violated principle #2).

3.3 Proposed Approach (DOCAMR)

We propose DOCAMR, an extension of AMR to the document level. In this representation, the entity and event coreference annotations from (O'Gorman et al., 2018) are properly assimilated into a single graph representing the meaning of the document. It completely preserves the semantic information while trying to stay close to the sentence-level AMR conventions.

The basic idea is that a new node with concept `coref-entity` is added for each identity chain of nodes – all nodes participating in the chain are then connected to this node via a `:coref` relation. Figure 3 shows an example of this. In addition to the base method of using `coref-entity` nodes, we introduce two exceptions. First, all the **named entities** within an identity chain are merged into one named entity. Second, all **pronominal nodes** participating in a chain are dropped. Both these exceptions are consistent with the treatment of coreferent named entities and pronouns in sentence-level AMR annotations. Further details of these two exceptions are outlined below:

Treatment of Named Entities: All the named entities (that is, AMR nodes with a `:name` relation) participating in an identity chain cluster are merged into one named entity. The structure of named entities is quite consistent and usually all the named entities participating in a chain match exactly. Occasionally, a cluster may contain named entities that differ in their type, wiki link or form of the name. In such cases, all unique forms of the name and all unique wikis are kept under a common variable. If types are different, the most specific type becomes the root and remaining types are connected to it with the new relation `:additional-type`.[3] If nodes to be merged have modifier roles other than `:name` and `:wiki`, they are gathered under the merged entity node.

---

[2] We do not consider here how to measure similarity between *comparable* documents.

[3] We use the AMR types ontology to decide which type is the most specific. If a cluster contains types that are not in the AMR ontology, then the ones from the ontology are considered for root position; and if none belong to the ontology, the most frequent type from the within the cluster becomes the root. Frequency ties are broken by picking the first mention.

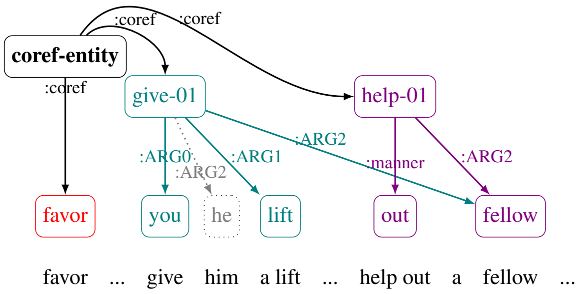

Figure 3: Our proposed DocAMR representation applied to the bottom example from Figure 2. For the identity chain between `he` and `fellow`, the pronoun is dropped indicated in dotted gray and the links are transferred to the non-pronominal node. For the identity chain between `favor`, `give-01` and `help-01`, merging is deemed potentially lossy – instead a `coref-entity` node is introduced and all nodes in the chain are linked to it via `:coref` edge. This not only preserves the meaning without loss but also avoids preferential treatment of any content node in the chain.

You appear to have done the maths and ...

(b)

Bilal Khar was arrested in 2002 ...
Khar was eventually cleared of the attack.

(c)

I can say it is a decent book.

You are a crack up!
Cola, now you see why it is sucha good book.

Figure 4: Various scenarios of merge operations in DocAMR: (a) Merging first and second person pronouns in a dialogue into `interlocutor-entity` (b) Merging named entities with multiple forms, keeping all distinct forms under separate `name` nodes (c) Dropping pronominal nodes and replacing them with the named entity in the chain Nodes of the same color belong to the same sentence-level AMR. Dotted gray indicates dropped nodes and edges.

Treatment of Pronominal Nodes: Sentential AMR incorporates pronouns as concepts only as a fallback if there is no contentful antecedent within the same sentence. We extend this philosophy to pronominal nodes whose antecedent can be found in another sentence. That is, all pronominal nodes participating in an identity chain cluster with an antecedent are replaced by the `chain-entity` node, removing the pronominal concepts from the graph. Pronominal concepts are retained only if there is no content antecedent to be found. For an identity chain with exclusively pronominal nodes, no `chain-entity` node is needed; they are simply merged into one node, which is labeled with the most specific pronoun concept in the chain (e.g., "he" is considered more specific than "someone"). As a special case, if a heterogeneous pronoun chain (with multiple pronouns) refers to a participant in a dialogue – indicated by the concept `i` or `you` – a new `interlocutor-entity` node is introduced and all pronouns are merged into that to account for different perspectives taken in different utterances.

A notable consequence of discarding pronoun concepts is that, correct antecedent resolution is required in order for any roles in which the pronominal mention participates, to be counted as correct. Systems could struggle with long chains of pronouns, especially if the first in the chain is resolved to the wrong antecedent and this causes cascading errors. That said, we believe representing the wrong substantive entity as participating in a relation is a serious error, no less so when a system correctly clusters a group of pronouns but fails to resolve their antecedent correctly.

Discard Single Node Clusters: After creating a document-level graph per the rules outlined above, we perform a final step of removing any `coref-entity` nodes with one `:coref` edge, and replace references to that node with its only member node. This can happen if there is a cluster with one non-pronominal concept and one or more pronouns

	Train	Dev1	Dev2
Nodes in chains	12513	1241	1141
Pronouns in chains	4456	433	423
↪ Pronoun	1029	141	121
↪ Interlocutor-entity	773	66	90

↪ Coref-entity	1160	86	94
NEs in chains	2917	224	205
NEs merged	903	85	84

Table 1: Statistics on DocAMR merge operations. Top row shows the total number of un-merged nodes in all identity-chains. Middle section shows the total number of pronominal nodes in identity-chain and the numbers of different target node types they are merged into. Most pronouns are dropped only about one fourth – in pronoun-only chains – are merged into one of the pronouns in the chain. Bottom sections shows number of Named Entities in chains before and after merging.

that got deleted. It can also happen if a cluster had multiple names that were merged. This simplification will discard superfluous `coref-entity` nodes. It would make alignment faster for Smatch that uses surface form matching during initialization.

3.4 The Roads not Taken

In an attempt to adhere to the sentence-level AMR conventions (principle 1 in §3.2) to a greater extent, we considered merging all non-predicate nodes participating in a cluster – keeping the most specific one. This required heuristics and even manual input on deciding the most specific instances, we therefore did not take that route.

A less complicated version of this would have been merging only those nodes that have the same concept. However, even if a concept recurs, the different mentions may have different modifiers/arguments that may collide and make merging problematic. Merging only concepts with the same modifiers could place outsize importance on the attachment of modifiers by the parser. We opted for the simplest approach of not performing any merging of non-name, non-pronominal nodes.

We also considered an alternative representation where, similar to DocAMR, all nodes participating in a coreference cluster are connected to a `coref-entity` – but unlike DocAMR, the parents of all participating nodes now point to the `coref-entity`. In other words, all mention nodes are clustered (via `:coref` edge without any merge) under `coref-entity` along with their descendent sub-graphs, but the `coref-entity` nodes sit between the mention nodes and their sentence-level parents. This flipped version of DocAMR makes dense connections at document level making Smatch more sensitive to coreference errors. However, this often results in multiple similar or identical sub-graphs collected under `coref-entity` – with no connection to the corresponding sentences. Merging these sub-graphs based on the similarity of their structure will make the final representation highly dependent on small modifier level differences. Another significant side effect of this approach is that due to lack of connection with original sentence level graphs, the Smatch algorithm (as given in §4.1) cannot benefit from sentence alignments and becomes prohibitively inefficient.

4 DocAMR Evaluation

DocAMR represents MS-AMR annotations of multiple sentences in the form of one AMR graph. Ideally, the quality of this graph should be assessed as single unified entity. Traditional measures of coreference, such as MUC, CEAF etc., try to align the gold coreference chains with the predicted ones based on the shared mentions. In the case of text based coreference resolution, identifying shared mentions is trivial since the mentions are anchored in the input text. AMR, by contrast, is not anchored in the text – the nodes of AMR graphs are not aligned to words. As a result, traditional coreference measures can be applied to AMR only if the graphs are either identical to the gold graphs or have been aligned at the node level.

The Smatch algorithm used for evaluation of AMR parsers is a randomly initialized, greedy, hill-climbing algorithm. Due to the greedy nature of the algorithm, multiple random restarts are needed to get a stable matching score. Moreover, the problem itself is NP-complete and even its greedy implementation becomes prohibitively slow as the size of graph increases. As a result, Smatch in its original form is quite inefficient for document-level AMR evaluation.

4.1 Smatch Evaluation

Smatch (Cai and Knight, 2013) views an AMR graph as a set of triples, where each triple comprises of either a pair of nodes with a relation label (i.e. edges in the graph) or one node with an attribute and its value (i.e. concepts and attributes).

Given the set of triples for a source and a target graph and an *optimal* alignment between their nodes, the metric computes the precision, recall and F-score over triples between the two graphs. An *optimal* alignment is the one that will maximize the F-score. Cai and Knight (2013) provide a greedy implementation of Smatch that uses a combination of a 'smart initialization' and greedy hill-climbing steps to get closer to an optimal mapping. Each greedy step needs to evaluate $m(n-1)$ options where m and n are the numbers of nodes in the two graphs being matched. Therefore, Using this implementation of Smatch at the document-level is very slow.

4.2 Document-level Smatch

The sentence-level Smatch implementation[4] relies on a pool of candidate node-mappings to efficiently select the next greedy step. The pool includes all the node mappings that can possibly add to the triple F-score. We can restrict this candidate pool further for document-level Smatch if the source and target documents are aligned at the sentence level. More specifically, we can forbid any source to target node alignments where the sentence(s) of the source node is(are) not aligned with the sentence(s) of the target node. Note, that in DOCAMR graphs, certain nodes can belong to multiple sentences such as `coref-entity` or a merged node.

We propose an implementation of Smatch (DOCSMATCH) that assumes alignment between the roots of sentence-level subgraphs of a pair of document-level AMR graphs. Nodes are first categorised by sentences with each node possibly assigned to multiple sentences. Next, the candidate mappings pool is constructed respecting the sentence-level alignments. In particular, a node in one AMR cannot be mapped to a node in the other AMR if none of their assigned sentences are aligned (see appendix A for details). For instance, consider the example in figure 4(c) – the node for the concept **`now`** must be aligned to a node in the third sentence in a target graph, whereas the **`person`** node, merged from mentions in all 3 original sentences, is not constrained.[5]

DOCSMATCH allows us to evaluate the DOCAMR development set comprising of 42 documents in roughly 4 minutes with the default four random-restarts. This is a manageable time frame for the purpose of parser comparisons. The original Smatch evaluation for the same setup ran out-of-memory (with up-to 200GB allocation) without a result. Table 3 compares the Smatch scores and the runtimes of our implementation with those of the original Smatch with 1 random restart.

4.3 Coreference Subscore

A side effect of representing and evaluating the document AMR as a single unified graph is that we can not analyze the coreference performance of the parser separately. To mitigate this, we propose and implement a breakdown of Smatch that provides a separate coreference subscore. For the purpose of coreference subscore, all nodes connected to multiple sentences are considered coreferent nodes. Incoming edges for each coreferent node are counted as a part of the coreference subscore, as well as bridging relations and nodes with the labels `coref-entity` or `interloculor-entity`. Note, in the case of merged nodes, their incoming edges count towards the coreference scores, however the node themselves (i.e. their instance triples) are not counted towards the coreference score.

Since what is considered a coreference depends on the graph structure, the edges and nodes that are considered coreferent in the gold graph might be different from those in the predicted graph. Therefore, to calculate F1 for the coreference subscore, we consider an edge or node to be a correct match if (1) it has a matching node or edge according to the standard Smatch score, and (2) the node or edge is part of coreference in both the gold and predicted graph. Recall is calculated as a percentage of gold coreference nodes/edges, precision is a percentage of predicted coreference nodes/edges, and F1 is taken as the harmonic average.

5 Experiments and Results

We use DOCAMR along with our efficient implementation of Smatch to assess the quality of two document-level AMR parsing systems. First, we develop a pipeline system combining a top-performing AMR parser (Zhou et al., 2021) and a state-of-the-art coreference resolution system

---

[4] `https://amr.isi.edu/evaluation.html`

[5] Note that there could be a case where the predicted parse of sentence 2 resembles the correct parse of sentence 1 and vice versa without any coreference link between the two—then the proposed constraint would prevent finding the optimal alignment. However, this happens quite infrequently. Moreover, we argue that accidental mapping of triples between graphs of entirely unrelated sentences should not be rewarded. Note also that for the border case where all nodes are connected with all sentences, the constrained version will be same as the original Smatch.

MS-AMR Splits		Double Anno. (Dev1)			Double Anno. (Dev2)			Test		
AMR	Coref	Smatch	Coref	Reent	Smatch	Coref	Reent	Smatch	Coref	Reent
Gold	None	87.6	0	72	88.6	0	73	86.4	0	72

S-BART	AllenNLP	**69.4**	**33**	**59**	**69.8**	**34**	**59**	**72.0**	**50**	**65**

Table 2: Document-level Smatch, coreference sub-scores (Coref) and reentrancy scores (Reent) on MS-AMR double annotations (Dev1 and Dev2) and test splits – using various combinations of gold and predicted AMR graphs with predicted coreferences from CoreNLP (Clark and Manning, 2016) and AllenNLP (Joshi et al., 2020).

Impl.		Original		DocSmatch	
Split	R	Time	Smatch	Time	Smatch
Dev1	4	-	-	244	69.4
Dev2	4	-	-	136	69.8
Test	4	-	-	417	72.0
Dev1	1	927	69.5	66	69.3
Dev2	1	945	69.8	41	69.7
Test	1	1314	71.3	104	72.0

Table 3: Comparison of Smatch scores and runtimes (in seconds) between the original Smatch implementation (Original) and our proposed implementation (DocSmatch). All results are on our best performing pipeline system. R is the number of random restarts. 'Original' Smatch runs out of memory for R>1.

(Joshi et al., 2020). We also provide the pipeline results with CoreNLP's neural coreference resolution system (Clark and Manning, 2016) v4.3.2 for additional point of comparison. Second, we reevaluate the past best system of Anikina et al. (2020) – this is also a pipeline approach combining AMR parser of (Lindemann et al., 2019) with AllenNLP coreference resolution system.[6]

5.1 Our Pipeline Approach

We use the BART-based structured transformer model of Zhou et al. (2021) to produce sentence-level AMR graphs. In particular, we use the StructBART-S version of their system referred to as S-BART in table 2. This parser produces node-to-token alignments as part of its output – we use these alignments to match coreference systems' outputs with AMR graphs. Text-based coreferences are obtained using the systems of Joshi et al. (2020) and Clark and Manning (2016). Coreference chains are computed from these prediction files.[7]

In order to incorporate this coreference information into the AMR graphs, we first convert node-to-token alignments into node-to-span alignments. The span of a node is defined as the smallest text span containing all the tokens aligned to any of its descendants (to avoid loops, re-entrant edges are removed keeping only the first). With node-to-span alignments, a predicted mention is assigned to the node with the shortest span containing the mention. If there is more than one candidate node, the one with the greatest height, subsuming the other candidates is selected. Instances of coreference within a sentence are ignored assuming that the sentence-level parser has already taken care of them.

5.2 Results

Table 2 shows the results on MS-AMR double annotation documents (used here as development set) and its test split. Both gold and predicted AMR graphs are converted to DocAMR before running Smatch evaluation. All numbers are produced using document-level Smatch with 4 random restarts.

Our pipeline approach outperforms the previous best system by a large margin, providing a strong baseline for future research on this task. This is due mainly to difference in quality of the underlying sentence-level parsers.

---

[6] We obtained the document-level graphs before merge operations from Anikina et al. (2020) for the purpose of re-evaluation in DocAMR format.

[7] Using the package `https://github.com/boberle/corefconversion`

Dev1	Smatch	Time (s)
No-Merge	93.3	66
Merge-NE	92.8	66
DocAMR	87.6	90
Merge-All	82.4	153

Table 4: Impact of representation on evaluation scores and runtimes. Comparing double-annotation gold documents (Dev1) with and without coreference links in different document-level representations.

Note that significant improvements in coreference quality result in only small improvements in overall Smatch score – showing that a separate coreference subscore is essential for assessing a system's performance on cross-sentential relations. We also report reentrancy scores (Damonte et al., 2017) for comparison. While the performance gap is more pronounced in reentrancy scores compared to overall Smatch, the gains are best highlighted in coreference subscore. For instance, reentrancy scores improves by up to 2 points from CoreNLP to AllenNLP in all settings – coref subscores, on the other hand, shows up to 7 points improvement giving a finer range for coreference evaluation.

Impact of Representation on Smatch: To highlight how document-level representation can affect Smatch scores and efficiency, we compare the gold double-annotation development set with and without coreference links. In addition to DocAMR we consider three representations: 1) No-Merge: where all coreference nodes are linked via coref-entity without any merging 2) Merge-NE: where only Named Entities are merged and 3) Merge-All: where all coreference nodes in a chain are merged (O'Gorman et al., 2018). One of our aims for DocAMR was to ensure that the lack of coreference links is visible in the overall Smatch score. Table 4 shows that DocAMR makes this gap bigger without losing efficiency or semantic information.

6 Related Work

MS-AMR Annotations MS-AMR annotations by O'Gorman et al. (2018) include coreference chains, implicit roles and bridging relations. In the context of AMR-based summarization, Lee et al. (2021) present a novel dataset consisting of human-annotated alignments between the nodes of paired documents and summaries to evaluate merge strategies for merging individual AMR graphs into a document graphs. However, they sought out the merge operations that can serve as cross sentential coreference in the absence of any annotations – they only merge nodes with same surface forms, except for 'person' nodes. Our work, on the other hand, outlines a representation for already available gold annotations, where nodes' surface forms don't match in a large number of cases.

MS-AMR Evaluations and Models O'Gorman et al. (2018) proposes Smatch as primary method for scoring MS-AMRs. They also report CoNLL-F1 relying on Smatch alignments. Adopting the methods from O'Gorman et al. (2018), Anikina et al. (2020) presented a comparative evaluation of various coreference resolution systems over MS-AMR test sets and document-level Smatch evaluations of machine generated sentence-level AMRs augmented with coreference predictions from various systems. The best approach from their study is incorporated as a baseline in §5. Fu et al. (2021) introduce an AMR coreference resolution system that uses graph neural network to model gold sentence-level AMR graphs for coreference predictions. This system assumes gold graphs and is not comparable with document-level parsing systems. Use of gold graphs also alleviates the need for alignments between gold and predicted graphs for the purpose of evaluation. Bai et al. (2021) constructed dialogue-level AMR graphs from multiple utterance level AMRs by incorporating inter-sentence coreference, speaker and identical concept information into sentence-level AMRs.

7 Conclusion

We have presented DocAMR, a graph representation for document-level AMR graphs based on coreference annotations. Relative to the original sentence-level graphs, DocAMR removes redundancy without information loss. We modified the implementation of Smatch to take advantage of sentence provenance to efficiently search for node alignments when comparing two document-level graphs. Finally, we reported results for a document-level parsing pipeline that can serve as a strong baseline for future work on this task.

Abstract

Pretrained language models (PLMs) have made remarkable progress in text generation tasks via fine-tuning. While, it is challenging to fine-tune PLMs in a data-scarce situation. Therefore, it is non-trivial to develop a general and lightweight model that can adapt to various text generation tasks based on PLMs. To fulfill this purpose, the recent prompt-based learning offers a potential solution. In this paper, we improve this technique and propose a novel prompt-based method (PTG) for text generation in a transferable setting. First, PTG learns a set of source prompts for various source generation tasks and then transfers these prompts as target prompts to perform target generation tasks. To consider both task- and instance-level information, we design an adaptive attention mechanism to derive the target prompts. For each data instance, PTG learns a specific target prompt by attending to highly relevant source prompts. In extensive experiments, PTG yields competitive or better results than fine-tuning methods. We release our source prompts as an open resource, where users can add or reuse them to improve new text generation tasks for future research. Code and data can be available at `https://github.com/RUCAIBox/Transfer-Prompts-for-Text-Generation`.

1 Introduction

In natural language processing (NLP), text generation is an important research topic that aims to automatically produce understandable text in human language from input data (Li et al., 2022). In recent decades, various approaches have been widely applied to a variety of text generation tasks (Li et al., 2019; Gehring et al., 2017; Li et al., 2021a), especially the emergence of pretrained language models (PLMs) (Li et al., 2021c). By involving large-scale parameters pretrained on massive general corpora, PLMs such as GPT-3 (Brown et al., 2020) have achieved substantial progress in text generation. Through the *fine-tuning* paradigm, PLMs can adapt to various text generation tasks by directly adjusting the model parameters with labelled datasets.

However, in real-world scenarios, we are inevitably confronted with tasks having only limited labelled data (*e.g.,* new domains). It is often difficult to fine-tune text generation models in a data-scarce situation (Chen et al., 2020; Li et al., 2021b). Although the input and output formats are different for various text generation tasks, these tasks essentially adopt similar learning and generation mechanism (*e.g.,* Seq2Seq (Sutskever et al., 2014)). Furthermore, the success of PLMs sheds light on the possibility of developing general or transferable text generation models. For example, Radford et al. (2019) framed generation tasks as language modeling by predicting the next token given previous tokens. Based on these studies, we aim to devise a general and lightweight text generation approach that can effectively adapt to various new tasks and datasets, based on PLMs.

To fulfill this purpose, the recently proposed *prompt-based learning* offers a potential technical solution (Liu et al., 2021b). In this paradigm, a text generation task can be solved with the help of a *prompt* containing task-specific information. For example, T5 (Raffel et al., 2020) framed summarization and question answering into a text-to-text format by utilizing prompts "`summarize:`" and "`answer the question:`". Based on learned or manually designed prompts, PLMs can be leveraged to perform existing or new generation tasks without being tuned (Brown et al., 2020; Li and Liang, 2021), which provides a unified approach to utilizing PLMs for various generation tasks. Furthermore, to quickly adapt PLMs to new NLU tasks, several works directly used a soft prompt learned from source NLU tasks to initialize the prompt for a target NLU task (Vu et al., 2021; Su et al., 2021).

Inspired by these studies, we aim to apply prompt-based methods to data-scarce text generation tasks in a transferable setting.

Despite promising, there are still two major challenges for transferring prompts in text generation. Firstly, it has been found that prompts are highly task-specific (Gao et al., 2020), and it is difficult to effectively transfer or reuse existing prompts for new tasks. Second, for a single task, even a well-learned prompt may not be suitable for all the data instances from a large population (Scao and Rush, 2021), and hence it is non-trivial to design effective transferring strategy considering both task- and instance-level characteristics.

To address the above issues, we propose **PTG**: **P**rompt **T**ransfer for **T**ext **G**eneration, a novel prompt-based transfer learning approach for text generation. PTG is built upon a transfer learning setting. Specifically, we learn *source prompts* from a number of representative source generation tasks and then transfer these prompts as *target prompts* to perform target generation tasks. The core idea is that these learned source prompts serve as representation bases (*i.e., value vectors* in self-attention mechanism). For each data instance from a new task, we learn a specific target prompt by attending to highly relevant source prompts. To support such an approach, we construct a multi-key memory network storing both source prompts and prompt clusters for key-value prompt finding, and then design an adaptive attention mechanism considering both task- and instance-level information to derive the target prompt. Instead of using a fixed prompt for a new task, our approach is able to effectively learn the most suitable prompt representation from source prompts for a specific data instance. Such an adaptive mechanism considers the specific instance-level features, making our approach more flexible to transfer to new text generation tasks.

To the best of our knowledge, we are the first to introduce the idea of prompting in transfer learning to address text generation tasks. For evaluation, we test PTG on 14 datasets from three sets of text generation tasks: i) *compression* to express salient information in concise text such as summarization; ii) *transduction* to transform text while preserving content precisely such as style transfer; and iii) *creation* to produce new content from input context such as story generation. In both fully-supervised and few-shot experiments, PTG yields competitive or better results than fine-tuning PLMs.

Besides performance benefits, more importantly, we release our source prompts to serve as an open-source prompt library. Researchers can train new task prompts added to our library and reuse these learned prompts to improve unseen text generation tasks. Our library can further act as an analysis tool, such as analyzing what factors influence prompts' transferability across generation tasks and interpreting the task similarity by measuring the corresponding prompt similarity.

2 Related Work

Prompt-based Language Models. Prompt-based learning is a way of leveraging PLMs by prepending task-specific instructions to the task input when feeding into PLMs. Early approaches mainly utilized hand-crafted prompts to adapt to different generation tasks (Brown et al., 2020; Raffel et al., 2020; Zou et al., 2021). However, manually designed prompts are not flexible and cannot be applied to more kinds of new tasks. Thus, recent works have focused on automating the learning of discrete prompts (Shin et al., 2020; Gao et al., 2020). However, learning prompts over discrete space is hard to optimize and likely to be sub-optimal. To address these problems, many works proposed to optimize continuous prompts (Liu et al., 2021c; Li and Liang, 2021), which are more flexible to many kinds of tasks. Among these studies, prefix-tuning (Li and Liang, 2021) prepended a sequence of vectors to the input for text generation tasks. By contrast, we utilize soft prompts to investigate transfer learning for text generation and demonstrate that generation tasks can often help each other via prompt transfer.

Transferability of Natural Language Processing. We are also closely related to existing works on transfer learning in NLP tasks (Jeong et al., 2020; Wiese et al., 2017; Liu et al., 2019). Prior studies have shown that cross-task transfer can address the data scarcity issue (Wiese et al., 2017), enhance the ability to complex reasoning and inference (Jeong et al., 2020), or learn effective word representations (Liu et al., 2019). Efforts to transfer prompts for addressing NLU tasks have also been developed (Vu et al., 2021; Su et al., 2021). As a representative work, Vu et al. (2021) used the learned prompt to directly initialize the prompt for a target task while not considering the specific input. Our work focuses on challenging text generation tasks by utilizing prompts to extract implicit task-related knowledge and considering specific model inputs for the most helpful knowledge transfer.

3 Preliminary

3.1 Problem Formulation

Generally, the objective of text generation is to model the conditional probability $\Pr(y|x)$, where $x = \langle w_1, \dots, w_n \rangle$ and $y = \langle z_1, \dots, z_m \rangle$ denote the input text and output text respectively and consist of sequences of tokens from a vocabulary $\mathcal{V}$.

Prompting is a technique for injecting extra task information to PLMs as a condition during the generation of output text (Brown et al., 2020). Typically, prompting is conducted by prepending a series of tokens (discrete prompts) or continuous vectors (continuous prompts) to the input x. In our paper, we adopt continuous prompts. Specifically, given a series of n input tokens, $x = \langle w_1, \dots, w_n \rangle$, we first utilize PLM to embed the tokens, forming a matrix $\boldsymbol{E}_x \in \mathbb{R}^{n \times e}$, where e is the dimension of the embedding space. Then, our continuous prompt p is represented as a parameter matrix $\boldsymbol{E}_p \in \mathbb{R}^{l \times e}$, where l is the number of prompt vectors. The prompt p is then prepended to the embedded input forming a single matrix $[\boldsymbol{E}_p; \boldsymbol{E}_x] \in \mathbb{R}^{(l+n) \times e}$ which is encoded by PLMs as an ordinary sequence, such that the model maximizes the likelihood of the ground-truth y, *i.e.*, $\Pr(y|[p; x])$.

3.2 Prompt-based Transfer Learning

In a general transfer learning framework, we define a set of source generation tasks $\mathcal{S} = \{\mathcal{S}_1, \dots, \mathcal{S}_T\}$, where the t-th task $\mathcal{S}_t = \{(x_i^t, y_i^t)\}_{i=1}^{n_t}$ contains n_t tuples of the input text $x_i^t \in \mathcal{X}$ and its corresponding output text $y_i^t \in \mathcal{Y}$. For a target generation task $\mathcal{T}$, the goal of transfer learning is to use the previously learned task-specific knowledge of the source tasks $\mathcal{S}$ to help improve the performance of a learned model f_θ (parameterized by θ) in the target task $\mathcal{T}$.

In this paper, we consider a new transfer learning setting based on prompting. Specifically, the parameters of the underlying PLM are frozen, and the text generation tasks have to be fulfilled by prepending prompts (continuous vectors) to input as described in Section 3.1. Formally, we will learn an independent *source prompt* p_t for each source generation task $\mathcal{S}_t$ based on a shared frozen PLM by maximizing the likelihood $\Pr(y_i^t|[p_t; x_i^t])$. Our core idea is to transfer these learned source prompts to a new (target) text generation task, such that the target generation task can be performed in zero or few shot settings.

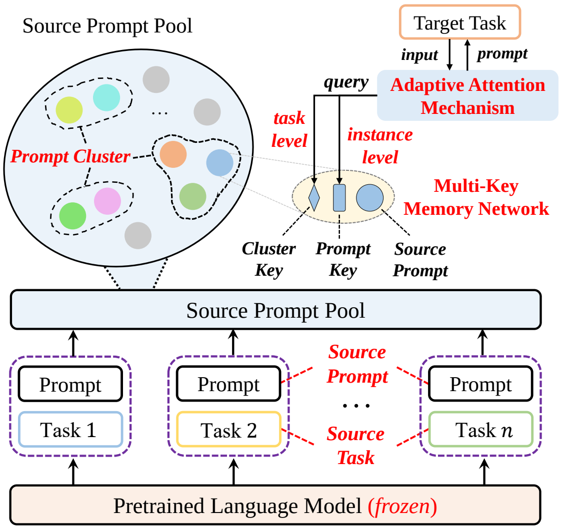

Figure 1: Overview of our proposed model PTG.

4 Approach

Our proposed method, Prompt Transfer for Text Generation (PTG), is depicted in Figure 1. Our approach first learns a number of source prompts for various representative source generation tasks, and then derive the prompt for the target generation task with a novel adaptive attention mechanism. Next we will describe each part in detail.

4.1 Learning Transferable Source Prompts

To extract task-related knowledge from source generation tasks, we learn a set of source prompts and store them in a *source prompt pool*. The motivations for introducing the prompt pool are twofold. First, we expect to identify the similarity between source generation tasks. Second, the pool stores task-specific prompts for every source task, which can be shared by all target tasks.

Constructing Source Prompt Pool. For each source generation task $\mathcal{S}_t$, we aim to learn a source prompt p_t given its training data $\{(x_i^t, y_i^t)\}_{i=1}^{n_t}$. Following the learning steps in Section 3.1, we learn an independent source prompt p_t for each source task $\mathcal{S}_t$ based on a shared frozen PLM, *i.e.*, BART. These source prompts are stored in a prompt pool $\mathcal{P} = \{p_1, \dots, p_t, \dots, p_T\}$, where T is the total number of source text generation tasks.

To construct the source prompt pool, a key point lies in the selection of source text generation tasks. According to the literature (Deng et al., 2021), text generation tasks can be categorized as performing compression, transduction, or creation based on changes in conveyed information from input to output. Moreover, recent studies have shown that few but diverse source tasks/domains also lead to remarkable transfer learning performance (Friedman et al., 2021; Zhuang et al., 2021). Therefore, we select six text generation tasks (including 14 public datasets) within the three types of generation tasks for learning their corresponding source prompts.

Clustering Source Prompts. As described above, the source tasks are diverse in the prompt pool. It is challenging for PLMs to effectively transfer or reuse existing prompts for new tasks. Thus, to identify the similarity between source tasks (prompts), we construct a source prompt pool for more effective cross-task knowledge transfer. In particular, via spectral clustering algorithm (Ding et al., 2001), we group these source prompts into several prompt clusters. Under this algorithm, each prompt p_t is regarded as a node in a weighted undirected graph $\mathcal{G}$. The similarity degree (weight) between node (prompt) p_i and p_j is computed via the position-agnostic Euclidean distances (Su et al., 2021):

$$w_{i,j} = \frac{1}{1 + \frac{1}{l^2}\sum_{k_1=1}^{l}\sum_{k_2=1}^{l}||p_{i,k_1} - p_{j,k_2}||}, \tag{1}$$

where p_{i,k_1}, p_{j,k_2} denote the k_1-th and k_2-th vector of prompt p_i and p_j, respectively. We then adopt the min-max cut strategy (Ding et al., 2001) to partition the graph $\mathcal{G}$ into several subgraphs representing different prompt clusters $\mathcal{C} = \{\mathcal{C}_1, \dots, \mathcal{C}_m\}$, where m is the total number of clusters. When transferring the source prompts, it will be better to identify the suitable prompt cluster and select the most relevant source prompt. By contrast, previous works considered each source prompt equally and ignore the differences between different tasks (Vu et al., 2021; Su et al., 2021).

Multi-Key Memory Network. With source prompts encoding task-related knowledge, the second motivation is to share them with every target generation task. To facilitate the prompt transfer from source tasks to target tasks, we build a multi-key memory network to store these clustered prompts. Specifically, for a source prompt p_t from the prompt cluster $\mathcal{C}_z$, *i.e.,* $p_t \in \mathcal{C}_z$, it is associated with a learnable cluster key $\boldsymbol{k}_z^c$ and a learnable prompt key $\boldsymbol{k}_t^p$, as follows:

$$\tilde{\mathcal{P}} = \{\mathcal{C}_z : \langle \boldsymbol{k}_z^c, \boldsymbol{k}_t^p, p_t\rangle\}_{z=1}^{m}, \tag{2}$$

where $\boldsymbol{k}_z^c, \boldsymbol{k}_t^p \in \mathbb{R}^d$, and d is the key embedding size. In our memory network, these learned source prompts serve as representation bases, *i.e.,* value vectors, which can be transferred to target generation tasks through key-value prompt finding.

4.2 Transferring Instance Adaptive Prompts

Previous works (Li and Liang, 2021; Vu et al., 2021) usually consider only the task information but ignore the specific input data when deriving prompts. However, for a single task, even a well-learned prompt may not be suitable for all the data instances (Scao and Rush, 2021), and thus it is non-trivial to design effective transferring strategy considering both task- and instance-level characteristics. In our model, we design an adaptive attention mechanism to incorporate the instance feature for constructing the target prompt.

Adaptive Attention Mechanism. Specifically, for an instance (x, y) of the target task $\mathcal{T}$, we use both task-level and instance-level queries to adaptively lookup and select the source prompts for transferring the previously learned task-related knowledge. The task-level query aims to select the overall information related to the specific target task, which is defined as a learnable task query vector $\boldsymbol{q}^{task} \in \mathbb{R}^d$. However, the source prompts in the pool are diverse but limited, thus the task-level prompt may not well adapt to all the data instances of the target generation task. Therefore, we design an instance-level query to learn the target prompt by attending to the highly relevant source prompts to help improve the model performance in specific instances. The instance-level query is computed as the input encoding $\boldsymbol{q}^{ins} \in \mathbb{R}^d$ through a frozen PLM such as BERT (Devlin et al., 2019):

$$\boldsymbol{q}^{ins} = \text{Average}(\text{BERT}(x)), \tag{3}$$

where we average the top-layer representations of every input tokens encoded by BERT.

For a source prompt $p_t \in \mathcal{C}_z$, we use $\boldsymbol{q}^{task}$ and $\boldsymbol{q}^{ins}$ to lookup its corresponding cluster key and source key respectively, following multi-head attention (Vaswani et al., 2017). Thus, the final matching score between the instance x and prompt p_t is calculated as:

$$s_t = \text{softmax}(\lambda \cdot \boldsymbol{q}^{task\top}\boldsymbol{k}_z^c + (1-\lambda)\cdot \boldsymbol{q}^{ins\top}\boldsymbol{k}_t^p), \tag{4}$$

where λ is a hyper-parameter. Finally, according to the weight score, the selected source prompt is computed as: $\tilde{p} = \sum_{t=1}^{T} s_t \cdot p_t$.

Compared to other prompt-based transfer learning methods that used only a fixed prompt for a new task (Vu et al., 2021; Li and Liang, 2021), our adaptive attention mechanism is able to effectively learn the most suitable prompt representation from source prompts for a specific data instance. Such a mechanism makes our model more flexible to transfer to new text generation tasks.

Prompt-based Text Generation. Based on the above adaptive attention mechanism, we retrieve the prompt $\tilde{p}$ encoding the most useful and relevant knowledge to help the model perform the specific generation instances. As described in Section 3.1, we prepend the prompt $\tilde{p}$ to the input embedding of x, which then flows through a generative PLM such as BART (Lewis et al., 2020) for generating text. The generative PLM is optimized via maximum likelihood estimation (MLE) as:

$$\mathcal{L}_{\text{MLE}}(\theta) = \mathbb{E}_{(x,y)\sim(\mathcal{X},\mathcal{Y})} \log \Pr(y|[\tilde{p}; x]). \quad (5)$$

During the learning process of the target task, the retrieved prompt $\tilde{p}$ is adaptive to different instances and is frozen because it encodes the previously *learned* task-related knowledge.

4.3 Model Discussion

For prompt-based transfer learning in text generation, the key point lies in how to effectively transfer or reuse existing prompts (encoding task-specific knowledge) for new generation tasks considering both task- and instance-level characteristics.

To achieve this goal, we first learn a set of source prompts encoding task-specific knowledge from a number of representative source text generation tasks (Section 4.1). These source prompts serve as representation bases, *i.e.,* value vectors in the multi-key memory network. Moreover, we design an adaptive attention mechanism considering both task- and instance-level information for constructing the target prompt (Section 4.2). Each data instance from a new generation task can learn a specific prompt by attending to the most highly relevant source prompts.

Compared with typical transfer learning methods, our model utilizes a lightweight technique, *i.e.,* prompting, to learn task-specific knowledge from source tasks. Our pretrained source prompts can help PLMs perform more effective and useful knowledge transfer.

5 Experiments

In this section, we first set up the experiments, and then report the results and analysis.

5.1 Experimental Setup

Datasets. We select 14 public datasets divided into three types of text generation tasks: i) *compression* to express salient information in concise text including summarization (CNN/Daily Mail (See et al., 2017), XSum (Narayan et al., 2018), MSNews (Liu et al., 2021a), Multi-News (Fabbri et al., 2019), NEWSROOM (Grusky et al., 2018)) and question generation (SQuAD (Rajpurkar et al., 2016)); ii) *transduction* to transform text while preserving content precisely including style transfer (Wiki Neutrality (Pant et al., 2020)) and text paraphrase (Quora (Wang et al., 2017)); and iii) *creation* to produce new content from input context including dialog (PersonaChat (Zhang et al., 2018), TopicalChat (Gopalakrishnan et al., 2019), DailyDialog (Li et al., 2017), DSTC7-AVSD (Alamri et al., 2019), MultiWOZ (Budzianowski et al., 2018)) and story generation (WritingPrompts (Fan et al., 2018)). Dataset statistics are in Appendix A.

Baselines. We compare our proposed PTG to the following baselines:

- **GPT-2** (Radford et al., 2019), **BART** (Lewis et al., 2020), and **T5** (Raffel et al., 2020): These are three representative PLMs for text generation, where all pretrained parameters are fine-tuned on each target task dataset separately. We adopt the LARGE version of these PLMs.
- **PREFIXTUNING** (Li and Liang, 2021): It is the recent state-of-the-art prompt-based PLM for text generation by concatenating a sequence of vectors and the input, which keeps PLM parameters frozen but optimizes a set of continuous prefix vectors.
- **SPOT** (Vu et al., 2021): It also adopts a prompt-based transfer learning method which first trains a prompt on source tasks and then uses the resulting prompt to initialize the prompt for a target task.
- **MULTI-TASK MODELTUNING**: This strong multi-task baseline first fine-tunes **BART** on the same source tasks used for PTG and then fine-tunes on each target task dataset individually.

We conduct all methods in the same setting to obtain their results without special tricks such as label smoothing. Compared with other baselines, our model is extremely lightweight, *i.e.,* when solving target generation tasks, we freeze the transferred

Table 2: Cross-dataset transferability performance comparisons of different methods in fully-supervised setting.

target prompt and parameters of the backbone PLM but only tune the multi-head attention parameters in adaptive attention mechanism (Eq. 4).

In particular, we adopt BART-LARGE to learn a set of source prompts. The length of prompt is set to 200 and the learning rate is set to 1×10^{-3}. For the target generation task, we utilize BART-LARGE as the generation backbone and frozen BERT-LARGE to obtain the instance-level query $\boldsymbol{q}^{ins}$. The dimension d is set to 1024, which is the same as the embedding size e of the BERT/BART-LARGE. The multi-head attention in adaptive attention mechanism has 16 heads. During fine-tuning, the learning rate of BART is set to 3×10^{-5} and the learning rate of cluster key $\boldsymbol{k}^c$, prompt key $\boldsymbol{k}^p$, task key $\boldsymbol{q}^{task}$ and multi-head attention is set to 1×10^{-3}. The value of λ is set to 0.5 based on the performance in validation set. The training details of baselines can be found in Appendix B.

Evaluation Metrics. For performance comparison, we adopt three automatic evaluation metrics widely used by previous works, *i.e.,* BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) and Distinct (Li et al., 2016). Specifically, BLEU-n measures the ratios of the co-occurrences of n-grams between the generated and real text; ROUGE-n measures the text quality by counting the overlapping n-grams between the generated and real text; and Distinct-n measures the degree of diversity by calculating the number of distinct n-grams in generated text.

5.2 Fully-Supervised Setting

Table 1 and Table 2 present the fully-supervised results of cross-task and cross-dataset transferability, respectively, for our model and baselines. In fully-supervised setting, we use all training instances of the target task to train our model.

For the *cross-task* experiment, we consider two pairs of source and target tasks transfer: 1) the tar-

Table 4: Cross-dataset transferability performance comparisons of different methods in few-shot setting.

get task is summarization (CNN/Daily Mail), and the source tasks are the mixture of other five tasks; and 2) the target task is dialog (PersonChat), and the source tasks are other five tasks. For the *cross-dataset* experiment, we consider datasets within summarization and dialog. For summarization, the target dataset is CNN/Daily Mail or XSum, and the source datasets are the mixture of other four summarization datasets. For dialog, the target dataset is PersonaChat or DailyDialog, and the source datasets are other four dialog datasets.

First, by transferring prompts from source tasks to the target task, PTG outperforms GPT-2, BART, T5 and PREFIXTUNING. The results suggest that prompt transfer in PTG provides an effective means of improving the performance of typical fine-tuning and prompt methods since our method utilizes the knowledge learned from source tasks.

Second, PTG performs better than the prompt-based transfer method, SPoT. While transferring prompts, SPoT considers each source task equally and ignored the specific instance information. And SPoT only learns a common prompt for source tasks to directly initialize the target prompt. By constrast, PTG clusters diverse source prompts and uses an adaptive attention mechanism considering both task- and instance-level characteristics.

Finally, PTG produces competitive performance or even exceeds the strong MULTI-TASK MODELTUNING. Different from most NLU tasks sharing some common knowledge to understand the semantics and syntax of surface words, text generation tasks need to generate diverse text based on different input data, thus having large task boundaries. Thus, in cross-task transfer, simply tuning PLMs on a mixture of tasks without considering the task similarity leads to a performance decrease. While, our prompt-based transfer learning approach can still achieve the best performance, showing that PTG improves stability across tasks and datasets.

5.3 Few-Shot Setting

In few-shot setting, we only sample a handful of training instances of the target task to train our model. Specificlly, we subsample the target task dataset to obtain small training datasets of size {50, 100, 200, 500}. For each size, we sample 5 different datasets and average over 2 training random

Target Task	SUMMARIZATION (CNN/Daily Mail)			DIALOG (PersonaChat)			
Model	ROUGE-1	ROUGE-2	ROUGE-L	BLEU-1	BLEU-2	Distinct-1	Distinct-2
PTG w/o Prompt Pool	41.46	20.40	38.40	39.70	24.45	0.77	4.00
PTG w/o Prompt Cluster	42.10	21.15	38.86	44.63	29.20	1.34	7.78
PTG w/o Multi-Key Memory	42.12	21.14	38.85	44.67	29.34	1.42	8.23
PTG w/o Instance-level Query	42.16	21.22	38.93	44.74	29.28	1.36	7.80
PTG	42.40	21.35	39.14	45.46	29.52	1.46	8.43

Table 5: Ablation analysis on cross-task transferability experiments.

seeds. Thus, we average over 10 models for each few-shot setting. In few-shot setting, we adopt the same cross-task and cross-dataset experiments with the fully-supervised setting. Table 3 and 4 shows the few-shot results of our model and baselines.

We can clearly see that PTG achieves competitive (underline fonts) or better performance (**bold** fonts) than the strong baseline (*i.e.,* MULTI-TASK MODELTUNING) in most low-data regimes, but the gap narrows as the training dataset size increases. In addition, our model outperforms most of vanilla PLMs in most cases. The reason behind this might be that large PLMs can easily suffer from overfitting during few-shot learning due to their massive parameters (Gao et al., 2020). While, in our framework, we adopt a lightweight technique, *i.e.,* prompting, to learn source prompts, which can provide the previously learned knowledge in source tasks to PLMs and serve as a better starting point when solving the target tasks.

5.4 Effectiveness of Core Designs

We further conduct ablation studies to demonstrate the effectiveness of the core designs of PTG.

Source Prompt Pool. To confirm the importance of the prompt pool, we design a counterpart of our method with only training a sharing prompt for all source tasks. From Table 5 (row 1), we can see that PTG significantly outperforms its counterpart with a single prompt, suggesting that the prompt pool encodes task-specific knowledge well.

Source Prompt Cluster. We remove the step of grouping source prompts into different clusters and directly lookup source prompts based on queries (see in Table 5 row 2). The decrease in performance demonstrates that when tasks are diverse, clustering task prompts can identify the similarity between source tasks, thus promoting effective knowledge transfer.

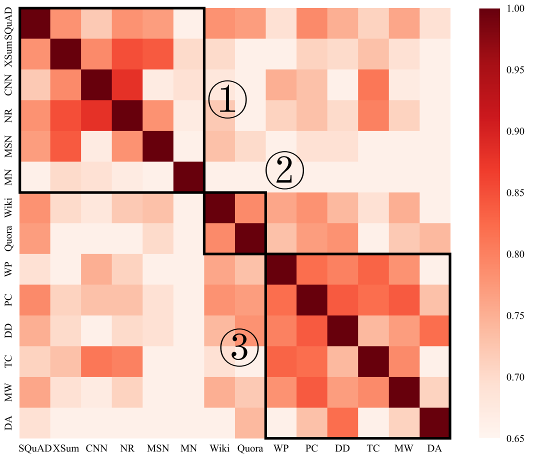

Figure 2: Similarity analysis of 14 datasets within our six generation tasks.

Multi-Key Memory Network. We remove the learnable key vector associated with prompts and directly transfer the mean of the source prompts to the target task. From Table 5 (row 4), we can see this results in a significant drop, demonstrating the importance of introducing learnable keys to dynamically select prompts through query-key matching.

Instance-level Query. The instance-level query is used in adaptive attention mechanism. When we remove it (Table 5 row 3), we only use the task-level query to select source prompts. The declined performance demonstrates that incorporating the instance-level features can indeed help to transfer the most helpful knowledge to the specific instances in target tasks.

5.5 Task Similarity Analysis

Figure 2 shows a clustered heatmap of cosine similarities between the source prompts of the 14 public datasets within our six text generation tasks using the position-agnostic Euclidean distances defined by Eq. 1. We can clearly observe that our learned 14 source prompts are roughly grouped into three clusters. Similar tasks and datasets are grouped together into clusters in this heatmap, and these clusters capture many intuitive task relationships. Specifically, these three clusters mainly focus on *compression*, *transduction*, and *creation* tasks respectively. For example, story generation (WritingPrompts) and dialog (PersonaChat) are grouped together into the third cluster. This observation further verifies our conclusion that text generation tasks can help each other within our approach by learning task-specific prompts and then transferring them to the target task. The results also suggest that our method can serve as an effective means of predicting task transferability.

6 Conclusion

This paper presented a prompt-based transfer learning approach for text generation. We learn a set of prompts from a number of representative source generation tasks and then transfer these prompts as target prompts to perform the target generation tasks. In our model, we design an adaptive attention mechanism considering both task- and instance-level information to construct the target prompts. Experiments in fully-supervised and few-shot settings demonstrate the effectiveness of our prompt-based transfer learning model. In future work, we will consider incorporating more kinds of text generation tasks.

7 Ethical Concerns

Text generation techniques has been applied to a wide range of meaningful applications for society, such as game narrative generation, news report generation, and weather report generation. However, this technique may be potentially utilized for harmful applications. Our work improves the quality of generated text compared with traditional methods. Thus, the high-quality text generated by our work makes it difficult to distinguish synthetic text from human-written text, such as fake news and stories. Here we are primarily concerned with two potential ethical issues: the possibility of deliberate misuse of our methodology and the issue of bias.

First, it is somewhat challenging to anticipate the harmful usages of our method since they often involve repurposing our model in a totally different setting or for an unexpected purpose than we planned. To alleviate this issue, we can ask for the assistance of classic security risk assessment frameworks such as detecting threats. Second, biases in training data may cause our model to generate stereotyped or prejudiced texts. This is a worry since the model bias has the potential to hurt some persons in relevant groups in unforeseen ways. To avoid prejudice, it may be useful to develop a common vocabulary that connects the normative, technological, and empirical difficulties of bias reduction for our model.

Appendix

We provide some experiment-related information as supplementary materials. The appendix is organized into three sections:

- Statistics of each dataset are presented in Appendix A;
- Training settings of baselines and our model PTG are presented in Appendix B.

A Statistics of Datasets

The detailed information of the dataset for each task is listed in Table 6, including summarization (CNN/Daily Mail, XSum, MSNews, Multi-News and NEWSROOM), question generation (SQuAD), style transfer (Wiki Neutrality), text paraphrase (Quora), dialog (PersonaChat, TopicalChat, DailyDialog, DSTC7-AVSD and MultiWOZ) and story generation (WritingPrompts). These datasets are utilized under MIT license.

B Configuration of Models

The learning rate of other baselines is set to 3×10^{-5}, which is the same as our backbone BART. The other settings of baselines and our model are set the same for fair comparison. And we do not utilize special tricks such as label smoothing, warm-up learning rate and length penalty. We apply the Adam optimizer and set $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 1 \times 10^{-6}$. We set the accumulated batch size of each model to 96 using accumulated gradients. Furthermore, we use the model with the best performance on validation set for generation. During inference, we apply the beam search method with a beam size of 5 and a no repeat ngram size of 3. We train our models using NVIDIA A100 GPUs and PyTorch 1.9.0 upon Ubuntu 20.04.2 LTS.

Dataset	#Train	#Valid	#Test	#Input	#Output

Abstract

Nowadays, pretrained language models (PLMs) have dominated the majority of NLP tasks. While, little research has been conducted on systematically evaluating the language abilities of PLMs. In this paper, we present a large-scale empirical study on genEral language ability evaluation of PLMs (**ElitePLM**). In our study, we design four evaluation dimensions, *i.e.*, memory, comprehension, reasoning, and composition, to measure ten widely-used PLMs within five categories. Our empirical results demonstrate that: (1) PLMs with varying training objectives and strategies are good at different ability tests; (2) fine-tuning PLMs in downstream tasks is usually sensitive to the data size and distribution; (3) PLMs have excellent transferability between similar tasks. Moreover, the prediction results of PLMs in our experiments are released as an open resource for more deep and detailed analysis on the language abilities of PLMs. This paper can guide the future work to select, apply, and design PLMs for specific tasks. We have made all the details of experiments publicly available at `https://github.com/RUCAIBox/ElitePLM`.

1 Introduction

Recent years have featured a trend towards Transformer (Vaswani et al., 2017) based pretrained language models (PLMs) in natural language processing (NLP) systems. By being pretrained on massive unlabeled text, PLMs can be directly fine-tuned on downstream tasks, entirely removing the need for task-specific architectures (Radford et al., 2018). This paradigm has led to significant progress on many challenging NLP tasks such as reading comprehension (Devlin et al., 2019) and text generation (Brown et al., 2020).

With rising new state-of-the-art results that approach or surpass human performance on several tasks, it is a non-trivial research topic about how to systematically evaluate the language abilities of PLMs from a wide range of perspectives. Given a wide range of publicly released PLMs, it is particularly useful to derive principles or guidelines for selecting suitable PLMs for specific downstream tasks. However, existing works either target some single ability (Talmor et al., 2020; Zhou et al., 2020), or consider a simple mixture of multiple (small-scale) tasks that lack a comprehensive design and test (Wang et al., 2019b; Liang Xu, 2020). There has been no detailed and systematic analysis of PLM's abilities in large-scale NLP tasks. To fill the gap of PLMs evaluation, we introduce the genEral language ability evaluation (**ElitePLM**) for empirically and systematically assessing the general language abilities of PLMs.

The ideal goal behind PLMs is to create a human-like machine learner where it can understand the language and then perform any specific task related to language. In cognitive science, Wechsler Adult Intelligence Scale (WAIS) (Kaufman and Lichtenberger, 2005) is the most commonly used intelligence quotient (IQ) test for measuring the intelligence and cognitive ability of humans. This test would assess the level of individuals on verbal comprehension, perceptual reasoning, working memory, and processing speed. Thus, by imitating the intelligence test on humans, we design four evaluation dimensions in ElitePLM for measuring the abilities of PLMs, including *memory*, *comprehension*, *reasoning*, and *composition*. Following previous works (Zhou et al., 2020; Wang et al., 2019b), for each ability in ElitePLM, we elaborate and select multiple representative tasks (*e.g.*, question answering for the comprehension ability) and commonly-used benchmarks (*e.g.*, GLUE and SQuAD) to quantitatively evaluate the performance of PLMs. These results can serve as numerical explanations of PLMs at a specific ability.

In human intelligence tests, the background of participants (*e.g.*, gender, race, and occupation)

July 10-15, 2022

should be as much as diverse. Thus, in ElitePLM, we select a diversity of PLMs to conduct generalized and meaningful comparisons. According to training objectives, PLMs can be divided into three types: bidirectional LMs (*e.g.,* BERT (Devlin et al., 2019)) for natural language understanding (NLU), unidirectional LMs (*e.g.,* GPT (Radford et al., 2019)) for natural language generation (NLG), and hybrid LMs (*e.g.,* UniLM (Dong et al., 2019)) for combining these two paradigms. Furthermore, knowledge-enhanced LMs (*e.g.,* ERNIE (Zhang et al., 2019)) and text-to-text LMs (*e.g.,* T5 (Raffel et al., 2020)) also emerge as important branches of PLMs. Considering the variety, we finally select ten widely-used PLMs within the above five categories and evaluate their abilities on four dimensions. We show the comparisons of these PLMs in Table 7 of Appendix A.

From the ability test results, we have three salient findings. First, PLMs with varying pretraining objectives and strategies are good at different kinds of downstream tasks. Specifically, we observe that bidirectional LMs like BERT and pretraining strategies like larger training batches in RoBERTa are helpful for memorizing pretraining corpora; permutation language modeling in XLNet is beneficial for modeling the bidirectional context in language comprehension; inter-sentence coherence objective in ALBERT is suitable for sentence-level reasoning tasks; text-to-text LMs using denoising objective like BART perform better in short text generation. Second, when fine-tuning PLMs in downstream tasks, their performance is typically sensitive to the data distribution in fine-tuning stage, which can be addressed by incorporating intermediate datasets or tasks to alleviate such a discrepancy. Third, PLMs have excellent transferability between similar tasks, especially reasoning tasks. This finding will inspire future researchers to leverage data-rich tasks for improving data-scarce tasks. For more clarity, we illustrate the impact level of each factor for PLMs' abilities in Table 8 of Appendix A.

Besides ElitePLM being an evaluation benchmark of PLMs' language ability, more importantly, the predicted results of ElitePLM can be used as an open resource for more depth and granularity in analyzing PLMs performance on each ability. For example, we further analyze the comprehension test results of PLMs across answer types in QA tasks. The analysis shows that PLMs are good at simple single-token answers such as dates but more challenged on intricate phrase answers. Moreover, by analyzing human test and Turing test results on composition, we observe that summaries with high accuracy are more likely to pass the Turing test while rich information is more important for story generation. Overall, ElitePLM can act as an analysis tool to gain more insight into PLMs. We show the details of our used datasets and predicted outputs of PLMs in Appendix B.

This paper is intended to help establish sound principles for choosing, applying, interpreting and designing PLMs for NLP tasks in practical settings. We have released the code and predicted results of each ability experiment, providing the research and industry community with off-the-shelf tools to evaluate and analyze their PLMs.

2 ElitePLM

In this section, we will detail these four kinds of language abilities, *i.e.,* memory, comprehension, reasoning, and composition, in ElitePLM.

Memory Ability. Memory is the most basic ability of humanity, involved in how much information we recall throughout our lives (Miyake and Shah, 1999). By analogy, ElitePLM will measure how much knowledge and language patterns PLMs have memorized in pretraining, as assessed by tests of recalling words based on contexts. Based on the memorized information, PLMs can effectively adapt to downstream tasks for understanding and reasoning about the similar context in a specific text. On the other hand, efficiency is also a critical aspect of memory ability for PLMs learning from new data distribution in the fine-tuning stage. Thus, besides recalling words, we also compare the memory efficiency of PLMs in terms of memorizing the given new information.

Comprehension Ability. Comprehension is an intricate and multifaceted ability. It typically consists of understanding a text's vocabulary, background knowledge of a specific topic, and comprehension of its linguistic structures like grammar (Cain and Oakhill, 2008). In particular, background (prior) knowledge is used to comprehend a special situation, lesson, or text. For example, readers should be aware of the background knowledge of dog behavior when reading a text about dog training. In ElitePLM, we will assess PLMs' comprehension ability from three aspects, *i.e.,* vocabulary, background knowledge, and linguistic structures.

Reasoning Ability. Based on the comprehension of a text, reasoning ability refers to the power of the processes and strategies used in drawing inferences, reaching conclusions, arriving at solutions, and making decisions (Kyllonen and Christal, 1990). In ElitePLM, we mainly focus on three types of reasoning abilities. In detail, commonsense reasoning requires PLMs to draw inferences using commonsense knowledge about the world, like the fact that "*matches*" plus "*logs*" usually equals "*fire*" (Sap et al., 2020); Note that subtle differences exist between commonsense knowledge and background knowledge in comprehension ability. Commonsense knowledge is broadly defined as the total accumulation of facts and information that a person has gained from previous experiences. Deductive reasoning involves PLMs drawing conclusions from a set of given premises in the form of categorical syllogisms (*e.g.,* all x are y) or symbolic logic (*e.g.,* if p then q) (Johnson-Laird, 1999); Abductive reasoning involves reaching the most likely explanation for a set of facts, such as a scientific theory to explain a set of empirical findings (Walton, 2014).

Composition Ability. In the literature (Connors, 1997), composition is a highly intelligent and synthetic process where a writer assembles words and sentences to create a coherent and meaningful work (*e.g.,* poem, music, and novel) from scratch, which closely resembles to the text generation task in NLP (Berninger, 1999). Therefore, in ElitePLM, we introduce several text generation tasks to evaluate the composition ability of PLMs, including story generation, text summarization, and question generation. Note that, story generation is a representative composition task which needs PLMs to not only comprehend the given story background, but also reason about and create reasonable and coherent story endings (Fan et al., 2018). During the composition process, PLMs should include a good vocabulary, grammar, spelling, and punctuation knowledge, and deliberate the text structure.

3 Experiments

In this section, we first set up baselines, and then report the results and analysis on four ability tests.

3.1 Models

As mentioned before, we compare the performance of ten publicly released PLMs from five categories: (1) *Bidirectional LMs*: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b), and ALBERT (Lan et al., 2020); (2) *Unidirectional LMs*: GPT-2 (Radford et al., 2019); (3) *Hybrid LMs*: XLNet (Yang et al., 2019) and UniLM (Dong et al., 2019); (4) *Knowledge-enhanced LMs*: ERNIE (Zhang et al., 2019); (5) *Text-to-Text LMs*: BART (Lewis et al., 2020), T5 (Raffel et al., 2020), and ProphetNet (Qi et al., 2020). We implement these models and ability tests mostly on huggingface (Wolf et al., 2020), fairseq (Ott et al., 2019), and jiant (Phang et al., 2020). To reflect the true level of language abilities, we adopt the best hyper-parameter values reported in their original papers for each PLM.

3.2 Memory Tests

Datasets and Metrics. The goal of memory tests is to assess how much knowledge and language patterns PLMs have memorized during pretraining. For this purpose, we adopt two datasets for evaluation, *i.e.,* LAMA (F. Petroni and Riedel, 2019) and English Wikipedia (2,500M words). Specifically, LAMA is a knowledge probe corpus containing a set of knowledge facts, where facts are either subject-relation-object triples or question-answer pairs. Each fact is converted into a cloze statement where the subject or object entity is masked. Wikipedia is one of the widely-used pretraining corpora for our selected PLMs (except GPT-2 and T5). Therefore, to conduct a fair comparison, we continuously train GPT-2 and T5 on Wikipedia using their pretraining objectives. Similar to LAMA, we randomly sample 100,000 texts from Wikipedia and then mask a proportion of 15% tokens following BERT. By querying PLMs with the missing tokens on Wikipedia and LAMA, we can test the language patterns and factual knowledge in PLMs' memory. For metrics, we use *Mean Precision at One* ($P@1$) of predicting missing tokens. For efficiency, we measure it as the performance *w.r.t.* the number of training epochs: the more efficient a model is, the fewer epochs to achieve a reference performance.

Results and Analysis. To evaluate how much text PLMs have recalled in pretraining, we directly test PLMs using Wikipedia and LAMA without fine-tuning, similar to zero-shot learning. The results on $P@1$ metric are shown in Table 1. Compared with bidirectional and hybrid LMs (*e.g.,* BERT and XLNet), GPT-2 uses auto-regressive self-attention where every token can only attend to the context to

Models	Bidirectional			Uni.	Hybrid		KE	Text-to-Text

Figure 1: Memory efficiency ($P@1$) of five PLMs on Google-RE and T-REx datasets.

its left. This unidirectional training objective naturally limits the performance of GPT-2 in terms of memorizing information. It has been previously reported that PLMs can remember more information by scaling up the model size (Brown et al., 2020). However, in our tests, BART-large (400M) achieves worse results than RoBERTa-base (125M) with the same training corpus and similar vocabulary sizes (50,295 vs 50,265). During pretraining, RoBERTa adopts bidirectional objectives and novel strategies like larger training batches. It can be concluded that, as opposed to model size, **training objectives and strategies reflect the way that PLMs memorize information, making significant impacts on PLMs' memory ability**. Besides, we can clearly observe that all PLMs achieve their best results in T-REx (created from Wikipedia triples) among LAMA, and perform relatively well on Wikipedia. This implies that PLMs indeed remember a large proportion of knowledge and language patterns from pretraining corpora.

To test the memory efficiency, we fine-tune five models, BERT, ALBERT, GPT-2, BART, and XLNet, for several epochs. As shown in Figure 1, to achieve a reference performance, the bidirectional training objective like BERT needs fewer epochs than other kinds of objectives. This further implies that the bidirectional training objective is also helpful to facilitate the memory efficiency since bidirectional language modeling can make PLMs more quickly capture the language patterns.

Based on the memory test results, we further analyze how to effectively elicit the information from PLMs' memory. LAMA hand-crafts templates to test PLMs by filling the `[MASK]` token. Therefore, we conduct a pilot study on designing different templates for two relations in Google-RE. Table 2 shows that different templates can result in substantial differences in eliciting PLMs' memory. The bidirectional LMs, *e.g.,* BERT, show relatively adaptability to varying templates, further verifying their strength in memory ability. Therefore, with large-scale knowledge stored in PLMs, how to derive an effective and appropriate method to provoke them is a key challenge.

3.3 Comprehension Tests

Datasets and Metrics. In comprehension tests, we take into account three aspects of comprehension ability, including vocabulary, background knowledge, and linguistic structures. Therefore, we employ five datasets for comprehension tests, *i.e.,* GLUE (Wang et al., 2019b), SuperGLUE (Wang et al., 2019a), SQuAD v1.1 (Rajpurkar et al., 2016), SQuAD v2.0 (Rajpurkar et al., 2018), and RACE (Lai et al., 2017). Among these datasets, GLUE and SuperGLUE are two widely-used comprehension benchmarks. Several tasks, like word sense disambiguation and coreference resolution, can assess PLMs' understanding of vocabulary meaning and grammatical structure of a text. By contrast, SQuAD v1.1&v2.0, and RACE are three popular question answering datasets. To answer the natural language questions, PLMs should be aware of the background knowledge about some particular topic. For example, to answer the question "*what can be used as rewards for dog training?*", the background knowledge "*dogs like bones*" will be helpful for PLMs to answer "*bones*". For evaluation, we report the corresponding metrics results for each task, such as the *Matthews corr.* metric for CoLA.

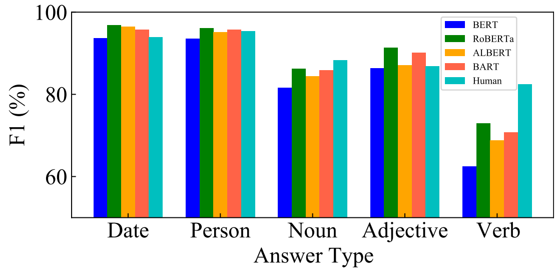

Figure 3: PLMs Performance on SQuAD v1.1&v2.0 stratified by five types of answer.

Results and Analysis. Table 3 presents the results of comprehension test in GLUE dataset (results in other four datasets can be found in Appendix D). The last column in this table indicates the average overall performance across all tasks. Interestingly, the models behaving well in memory tests (*e.g.,* RoBERTa and XLNet) also present good results in many comprehension tasks. The results indicate that **the improvement on memory ability is beneficial for the performance of comprehension ability**, which is in line with our intuition. Compared with bidirectional language modeling in

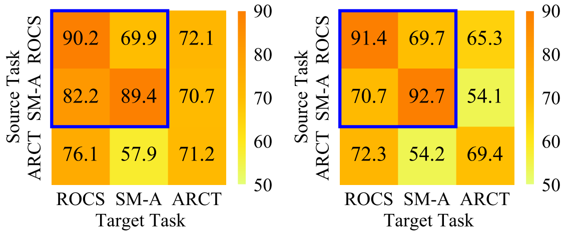
Table 4: Reasoning tests results on seven datasets (test set). CQA is short for CommonsenseQA. SM-A and SM-B denote the Task A and Task B of Sense Making, respectively. We report the results of LARGE version for each model in this table and more results can be found in the Appendix E.

BERT, permutation language modeling (relying on all permutations of the factorization order) used in XLNet enables PLMs to learn more context for enhancing PLMs' understanding of text, which seems to be effective for good comprehension ability.

Among these tasks, we observe a significant performance drop in the linguistic acceptability task (CoLA) since it has different data distribution from the pretraining corpora (Wang et al., 2021). This kind of sensitiveness to unfamiliar tasks is also reflected in Figure 2, where the model performance on CoLA shows a more volatile fluctuation (ranging from 10 to 35) than QNLI (ranging from 15 to 20). It indicates that **the performance of PLMs is closely related to the similarity of data distributions in pretraining and fine-tuning**. To solve this challenge, it will be better to adopt intermediate fine-tuning, which involves first fine-tuning PLMs on an intermediate dataset similar to the final target dataset and then transferring tuned PLMs to the final dataset.

To gain more insights into PLMs' comprehension ability, we choose four representative PLMs (*i.e.,* BERT, RoBERTa, ALBERT, and BART) and humans to analyze their performance across the answer types of SQuAD v1.1&v2.0. The results in Figure 3 show that PLMs perform well on simple answers such as dates and persons. For these categories of answers, there are usually only a few plausible candidates and most answers are single tokens. The models are more challenged on other intricate answer types (*e.g.,* noun and verb phrases) because there are many more plausible candidates and multiple tokens. Thus, improving PLMs' understanding of intricate named entities during the pretraining phase will possibly benefit PLMs' comprehension ability later.



(a) BERT$_{\text{LARGE}}$ (b) T5$_{\text{LARGE}}$

Figure 4: Heatmaps of two-stage transfer learning.

3.4 Reasoning Tests

Datasets and Metrics. In reasoning tests, we mainly consider three forms of reasoning, *i.e.,* commonsense reasoning, deductive reasoning, and abductive reasoning, focusing on commonsense utilization, conclusion induction, and reason derivation, respectively. For evaluation, we choose six reasoning datasets, namely CommonsenseQA (Talmor et al., 2019), ROCStories (Mostafazadeh et al., 2016), SWAG (Zellers et al., 2018), HellaSwag (Zellers et al., 2019), Sense Making (Wang et al., 2019c), and ARCT (Habernal et al., 2018). Specifically, CommonsenseQA requires PLMs to reason about commonsense knowledge in human experience of everyday life (Liu and Singh, 2004). ROCStories, SWAG, HellaSwag, and Sense Making Task A are concerned with deriving the conclusions of stories and events, while Sense Making Task B and ARCT focus on identifying the reason behind a statement. For evaluation, we report the *Accuracy* results for each dataset.

Results and Analysis. Table 4 shows the model performances in reasoning ability. It can be clearly observed that performing well in comprehension tests, ALBERT and RoBERTa also achieve stronger performance in almost all reasoning tasks. In pre-

Models	CNN/DailyMail			GigaWord			SQuAD			WritingPrompts

ProphetNet	**44.20**	21.17	**41.30**	**39.51**	**20.42**	**36.69**	14.20	23.97	35.99	19.31	2.59	7.19

Table 5: Composition tests results on four datasets. R-1, R-2, R-L are short for ROUGE-1, ROUGE-2, ROUGE-L respectively. B-4 and MT denote BLEU-4 and METEOR, respectively. We report the result of LARGE version for each model in this table and more results can be found in the Appendix F.

training, ALBERT introduces an inter-sentence coherence objective to capture the relationship among sentences, which is helpful for the sentence-level reasoning ability of PLMs. It has been found that the next sentence prediction (NSP) loss in BERT might hurt the performance of PLMs in sentence-level tasks of downstream datasets (Liu et al., 2019b). Interestingly, despite being the best in comprehension tests, XLNet does not perform as well as we expected in reasoning tests. We speculate that the permutation operation in XLNet disturbs the semantic relationship between sentences, thus leading to poor reasoning ability. **To improve PLMs' reasoning ability, it would be useful to design sentence-level reasoning objectives like inter-sentence coherence loss in ALBERT**. Moreover, despite incorporating knowledge, ERNIE still shows mediocre performance in knowledge-related datasets such as CQA. A possible reason might be that ERNIE only uses trained KB embeddings to enhance semantic representations but ignores the reasoning structure of KBs. This inspires us that designing appropriate and effective fusion methods to integrate knowledge is more important.

To further analyze the transferability of PLMs' reasoning ability, we conduct a two-stage study on three task datasets, *i.e.,* ROCStories, SM-A, and ARCT. We first train PLMs on source tasks with full data and then fine-tune PLMs on target tasks with ten instances. In Figure 4, it can be observed that **PLMs have better reasoning transferability between similar tasks** such as deductive reasoning tasks (ROCStories and SM-A). This shows that model performance on data-scarce reasoning tasks can be improved by incorporating additional training on data-rich similar tasks (Wang et al., 2021).

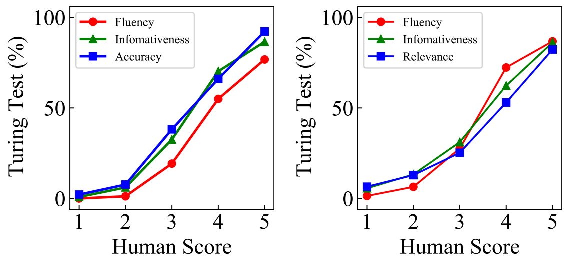
Table 6: Turing test (TT) and human scores on the test set of GigaWord and WritingPrompts. Flu., Info., Acc. and Rel. denote fluency, informativeness, accuracy and relevance respectively. We report the result of LARGE version for each model in this table and more results can be found in the Appendix F.

3.5 Composition Tests

Datasets and Metrics. Composition is similar to the text generation task, aiming at generating new content from scratch. Therefore, we use four text generation benchmarks for composition tests, *i.e.,* WritingPrompts (Fan et al., 2018) on story generation, CNN/Daily Mail (Hermann et al., 2015) and GigaWord (Rush et al., 2015) on text summarization, and SQuAD v1.1 (Rajpurkar et al., 2016) on question generation. According to the length of the target text, text summarization and question generation is short text generation, while story generation is long text generation. For evaluation, we adopt three automatic metrics, *i.e.,* BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), and METEOR (Banerjee and Lavie, 2005). Besides, following (Zou et al., 2021), we conduct human test from five aspects, *i.e., Fluency*, *Informativeness*, *Accuracy*, *Relevance* and *Overall*. The overall score is rated from 1 to 10, while the others are rated from 1 to 5. Inspired by Turing (2009), we further de-



(a) GigaWord (b) WritingPrompts

Figure 5: Impact factors of Turing Test.

sign a Turing test to assess the generation ability of PLMs, where a human interrogator is requested to distinguish whether the given text is generated by a human. From the generated texts of each model and gold texts, we randomly select 500 texts scored by judges. More details of human test and Turing test are shown in Appendix F.

Results and Analysis. Table 5 and Table 6 present the automatic evaluation and human evaluation results on composition ability, respectively. We can observe that ProphetNet and BART achieve great performance on short text generation, while GPT-2 and T5 show better results on long text generation. Specifically, BART employs denoising objectives for reconstructing the corrupted original text, and ProphetNet adopts future n-gram prediction, which is flexible for modeling the semantic relations between tokens and phrases in short texts. However, in long texts, a small ratio of masked tokens (*i.e.,* 15%) might be not effective in capturing the complex long-range dependency. By comparison, the left-to-right prediction objective in GPT-2 can be more suitable to model the long-range semantic continuity in long texts, and T5 has the largest model size to achieve a strong composition ability. For composition ability, we conclude that **the denoising objective is helpful for short text composition, while the left-to-right objective is more powerful for long text composition**. Besides, the model size is also an important factor in improving PLMs' composition ability.

To further investigate what factors affect the pass rate of the Turing test, we deeply analyze the intermediate scoring results in the human test and Turing test. As shown in Figure 5, we calculate the pass rate of the Turing test for each human test metric across 1 to 5 scale. Moreover, we compute the Pearson correlation coefficient between the pass rate and each metric. In story generation (WritingPrompts), the coefficients for *Fluency*, *Informativeness*, and *Relevance* are 96.63, 97.93, 96.44, respectively. While, in text summarization (GigaWord), the coefficients for *Fluency*, *Informativeness*, and *Accuracy* are 96.08, 97.67, 98.38, respectively. From these analysis results, we can conclude that *Informativeness* is more important for story generation, while *Accuracy* is more influential in text summarization. Besides, we compute the text similarity between the generated texts from different PLMs, which is shown in Appendix F.

4 Discussion

Based on the above four ability tests, we intend to provide a guideline for helping researchers choose, apply, interpret and design PLMs for NLP tasks.

In section 3.3, we observe that the improvement in memory ability is likely to be helpful for the performance of comprehension ability. Hence, designing PLMs with special objectives like bidirectional language modeling in BERT and strategies like larger training batches in RoBERTa for larger memory capacity will further benefit PLMs in the downstream comprehension tasks. Besides, when applying PLMs to downstream tasks, the similarity of data distribution between pretraining and fine-tuning has a great impact on PLMs performance. Possible solutions such as introducing intermediate tasks or datasets can alleviate such a discrepancy. Moreover, we further find some limitations in PLMs' comprehension ability, where PLMs are good at simple single-token answer types in QA such as dates but perform worse in complex phrase answers.

Compared to comprehension, reasoning in section 3.4 is much more intricate and usually involves inferring the semantic relationships among multiple sentences. Therefore, PLMs such as ALBERT trained with sentence-level objectives can be more suitable for conducting reasoning tasks. Intuitively, incorporating sentence-level objectives during pretraining will help PLMs learn the correlation among different sentences. Note that PLMs have better reasoning transferability between similar tasks, thus data-scarce reasoning tasks can be improved by first training on data-rich tasks.

For composition ability, PLMs with denoising training objectives perform much better on short text composition, while PLMs with left-to-right objectives or larger model size are more suitable for long text composition. This might be because

PLMs with different training objectives can finally capture different ranges of semantic dependency between tokens and phrases. Moreover, to obtain a higher pass rate of Turing test, different text generation tasks will be concerned with varying factors, such as informativeness is much more critical for story generation.

5 Related Work

Pretrained Language Models. Owing to the great achievements Transformer (Vaswani et al., 2017) has made, the paradigm of pretrained language models (PLMs) is thriving (Radford et al., 2019; Devlin et al., 2019; Liu et al., 2019b; Lewis et al., 2020; Raffel et al., 2020). It is widely recognized that PLMs can learn massive knowledge from corpora (Li et al., 2021c), leading to significant progress in various language tasks (Li et al., 2021a,b). With such encouraging results in extensive NLP tasks, it is a non-trivial topic to systematically evaluate the abilities of PLMs, which can further deepen our understanding of PLMs and facilitate their application to more fields.

Language Model Evaluation. Many efforts have studied the evaluation of language model performance. Liu et al. (2019a) evaluate BERT (Devlin et al., 2019), GPT (Radford et al., 2018), and ELMo (Peters et al., 2018) on a variety of linguistics tasks. Their findings indicate that the features generated by PLMs are sufficient for good performance on a board set of tasks but fall short on tasks requiring fine-grained linguistic knowledge. Tenney et al. (2019) evaluate similar models on a range of sub-sentence linguistic analysis tasks, showing that PLMs encode both syntax and semantics into parameters. Zhou et al. (2020) also report that PLMs can learn rich knowledge but focus on evaluating the commonsense. However, these studies only look at one dimension of PLMs ability evaluation. Other work such GLUE (Wang et al., 2019b) and CLUE (Liang Xu, 2020) just consider a simple mixture of multiple tasks lacking comprehensive evaluation. To the best of our knowledge, this is the first work to systematically evaluate PLMs by defining various kinds of language abilities and performing extensive comparison.

6 Conclusion

This paper investigates the general language ability evaluation of pretrained language models. We design four kinds of language abilities of PLMs, including memory, comprehension, reasoning, and composition, and measure ten widely-used PLMs within five categories. For each language ability, we select multiple representative tasks to quantitatively evaluate the performance of PLMs. Our experimental results demonstrate that PLMs with varying objectives and strategies are good at different ability tests. Note that our final predicted outputs of PLMs can also be reused as an open resource for more depth and granularity in analyzing PLMs' language abilities. As a result, it is believed that this study will benefit future work about choosing or designing suitable PLMs for the target NLP tasks based on their properties.

Supplementary Material for *ElitePLM*

We give some experiment-related information as supplementary materials. The appendix is organized into six sections:

- Configurations and pretraining setting comparisons for selected models are presented in Appendix A;
- Data statistics of each test are presented in Appendix B;
- Full results for memory tests are presented in Appendix C;
- Full results for comprehension tests are presented in Appendix D;
- Full results for reasoning tests are presented in Appendix E; and
- Full results for composition tests are presented in Appendix F.

A Configurations of Pretrained Language Models

The selected ten PLMs within five categories and the comparisons of these PLMs in configuration and pretraining setting have been shown in Table 7. The effect extent of each factor for PLMs abilities in Table 8.

B Data Statistics

Memory Tests. The data statistics of LAMA and Wikipedia of each model are presented in Table 9. Due to the differences of each PLM, we drop the data that are not in the vocabulary.

Comprehension Tests. The data statistics of GLUE, SuperGLUE, SQuAD and RACE are presented in Table 10.

Reasoning Tests. The data statistics for commonsense reasoning, deductive reasoning and abductive reasoning are presented in Table 11.

Composition Tests. The data statistics for text summarization, question generation and story generation are presented in Table 12. For the first three datasets, we truncate the source text considering the input length of PLMs during training. And for WritingPrompts, we reconstruct the original dataset and discard examples where text contains more than 512 tokens.

C Memory Tests

Full results on LAMA and Wikipedia datasets are presented in Table 13.

D Comprehension Tests

Full results on SuperGLUE, SQuAD and RACE are presented in Table 14 and Table 15.

E Reasoning Tests

Full results on CommonsenseQA, ROCStories, SWAG, HellaSwag, Sense Making, and ARCT are presented in Table 16.

F Composition Tests

For automatic metrics, BLEU-n and ROUGE-n compute the ratios of overlapping n-grams between generated and real text, while METEOR measures word-to-word matches based on WordNet between generated and real text. For the human test, *Fluency* evaluates whether the text is well-formed and logical to read; *Informativeness* measures whether the text contains useful information; *Accuracy* tests whether the text describes the given content accurately; *Relevance* measures whether the text is relevant to the given context; *Overall* evaluates the overall quality of the text.

In the human test, we ramdomly select 500 generated texts for each PLM and 500 gold text. Therefore, there are 3000 texts totally. The judges are all PhD students which do not know about where each text comes from. Each text will be scored by two judges from the above five aspects, and the final score is the average of the two scores. In the Turing test, each text will also be distinguished by two judges. Only when two judges make the same decisions that the text is generated by human, we will consider the text is true.

Full results on CNN/Daily-Mail, GigaWord, SQuAD, and WritingPrompts are presented in Table 17. Turing test results are presented in Table 6. We also show some summaries and stories generated by different PLMs in Table 19, Table 20, and Table 21.

Type	Models	Configurations		Pretraining Setting	
		Size	#Parameter	Corpus	Size
Bidirectional	BERT	base/large	110M/340M	BooksCorpus, English Wikipedia	16GB
	RoBERTa	base/large	125M/355M	BooksCorpus, CC-News, WebText, Stories	160GB
	ALBERT	xlarge/xxlarge	60M/235M	BERT Corpus	16GB
Unidirectional	GPT-2	small/medium	117M/345M	WebText (removing Wikipedia)	40GB
Hybrid	XLNet	base/large	110M/340M	BooksCorpus, English Wikipedia, Giga5, ClueWeb, Common Crawl	158GB
	UniLM	base/large	110M/340M	BERT Corpus	16GB
Knowledge-Enhanced	ERNIE	base	114M	English Wikipedia, Wikipedia	17GB
Text-to-Text	T5	base/large	220M/770M	Colossal Clean Crawled Corpus	745GB
	BART	base/large	140M/400M	RoBERTa Corpus	160GB
	ProphetNet	large	373M	RoBERTa Corpus	160GB

Table 7: Configurations and pretraining setting comparisons for our selected models.

Ability	MA	DD	MS	PO	PS
Memory	★★	★	★	★★★	★★★
Comprehension	★★	★★	★	★★	★★★
Reasoning	★	★★★	★	★★★	★★★
Composition	★	★★★	★★★	★★★	★

Table 8: The impact extent of each factor for four language abilities of PLMs. MA, DD, MS, PO, and PS are short for model architecture, data distribution, model size, pretraining objective, and pretraining strategy, respectively

	G-RE	T-REx	ConceptNet	SQuAD	Wikipedia
#Origin	6,106	34,014	14,878	305	100,000
#Relation	3	41	16	-	-
BERT / UniLM	5,527	34,014	11,658	305	85,836
RoBERTa	4,618	29,500	12,505	286	85,862
ALBERT	5,469	33,636	12,389	291	86,533
ERNIE	1,900	9,071	11,649	173	-
BART	4,618	29,500	12,505	286	85,862
T5	4,256	25,850	10,905	230	78,069
GPT-2	4,618	29,500	7,477	196	1,184
XLNet	5,202	32,293	12,080	279	85,228
ProphetNet	5,527	34,014	12,506	305	87,516
The Predicted Outputs	The predicted token of "`[MASK]`" in each template.				

Table 9: Statistics of datasets in memory tests, including LAMA and Wikipedia. #Origin and #Relation denote the number of examples and relations in original dataset, and the number of each model denotes the number of examples after selected. The predicted outputs is the intermediate result resources we provide.

Corpus		**#Train**	**#Valid**	**#Test**	**The Predicted Outputs**
GLUE	**CoLA**	8,551	1,043	1,063	The predicted binary class whether a sentence is grammatical.
	SST-2	67,349	872	1,821	The predicted sentiment (positive/negative) of a sentence.
	MRPC	3,668	408	1,725	The predicted binary class whether two sentences are semantically equivalent.
	QQP	363,846	40,430	390,965	
	STS-B	5,749	1,500	1,379	The predicted similarity score (1-5) of two sentences.
	MNLI -M.	392,702	9,815	9,796	The predicted relation (entailment/contradiction/neutral) between two sentences.
	MNLI -MM.		9,832	9,847	
	QNLI	104,743	5,463	5,463	The predicted relation (entailment or not) between two sentences.
	RTE	2,490	277	3,000	
	WNLI	635	71	146	
Super GLUE	**BoolQ**	9,427	3,270	3,245	The predicted answer (yes/no) to the passage-based question.
	CB	250	57	250	The predicted relation (entailment/contradiction/neutral) between two sentences.
	COPA	400	100	500	The predicted cause or effect of the premise from two choices.
	MultiRC	5,100	953	1,800	The predicted answer choice to the passage-based question.
	Wic	6,000	638	1,400	The predicted binary class whether a word is used with the same sense in two sentences .
	WNLI	635	71	146	The predicted relation (entailment or not) between two sentences.
	WSC	554	104	146	The predicted noun phrase referrent of the pronoun from among the provided choices.
SQuAD	**v1.1**	88,567	10,790	-	The predicted answer span to the passage-based question.
	v2.0	131,924	12,165	-	
RACE	**all**	25,137	1,389	1,407	The predicted answer choice to the passage-based question.
		87,866	4,887	4,934	
	middle	6,409	368	362	
		25,421	1,436	1,436	
	high	18,728	1,021	1,045	
		62,445	3,451	3,498	

Table 10: Statistics of datasets in comprehension tests including GLUE, SuperGLUE, SQuAD and RACE. #Train, #Valid and #Test denote the number of instances in train, valid and test set, respectively (the same as below). MNLI-M. and MNLI-MM. denote MNLI-match and MNLI-mismatch, respectively. SQuAD doesn't have test set, and we utilize the valid set as the test set. The predicted outputs is the intermediate result resources we provide.

Reasoning Task	**Corpus**	**#Train**	**#Valid**	**#Test**	**The Predicted Outputs**
Com.sense	**CQA**	9,741	1,221	1,140	The predicted answer choice to a commonsense question.
Deductive	**ROCS.**	1,257	314	1,571	The predicted ending choice based on the context.
	SWAG	73,546	20,006	20,005	The predicted answer choice based the grounded situation.
	HellaS.	39,905	10,042	10,003	
	SM-A	10,000	1,000	1,000	The predicted valid sentence between two sentences.
Abductive	**SM-B**	10,000	1,000	1,000	The predicted reason choice why the sentence is invalid.
	ARCT	1,210	316	444	The predicted warrant choice that justifies reason and claim.

Table 11: Statistics of datasets in reasoning tests, including commonsense reasoning, deductive reasoning and abductive reasoning. CQA is short for CommonsenseQA. SM-A and SM-B denote the Task A and Task B of Sense Making, respectively. The Predicted outputs is the intermediate result resources we provide.

Task	Corpus	#Train	#Valid	#Test	#Input	#Output	The Predicted Outputs
TS	**CNN/ DailyMail**	287,113	13,368	11,490	822.3	57.9	The generated summary given a news.
	Gigaword	3,803,957	189,651	1,951	33.7	8.7	The generated headline given a paragraph and corresponding Turing test and aspect scores.
QG	**SQuAD**	75,722	10,570	11,877	149.4	11.5	The generated question given a passage and corresponding answer.
SG	**Writing Prompts**	67,765	3,952	3,784	30.2	281.2	The generated story given a prompt and corresponding Turing test and aspect scores.

Table 12: Statistics of datasets in composition tests, including text summarization (TG), question generation (QG) and story generation (SG). #Input and #Output denote the average number of tokens in the input text and output text. The Predicted outputs is the intermediate results and human evaluation resources we provide.

Prompts	[WP] You have a very shitty type of precognition .
GPT-2$_{\text{MEDIUM}}$	<newline>“ I’m sorry, ” I said. “ I don’t know what you’re talking about. ” I looked around the room, trying to find the source of the noise. “ What do you mean? ” I asked. “ It’s not like I’ve never heard it before. ” He looked at me, confused. “ No, ” he said, “ it’s never happened to me before. I ’d be surprised if it ever did. ” “ What’s that supposed to mean? You’re telling me that I can’t remember anything before? ” “ No. ” he replied. “ That’s exactly what it means. You’ve always been precognitions, and you ’ll never be able to remember anything. ”
UniLM$_{\text{LARGE}}$	i’m not sure what i’ve done wrong. i’d rather not be able to do it. i don’t know what i have done wrong, i don’t know what it has done. i have been told that i have n’ve been wrong. <newline ><new york. <york ><yoline >i’ll never forget that day. «new >«line >the day i was born. the day that i was raised. the one that i never forget. the time that i first met her. the moment that i met her, the time when i first saw her. <nowline >my life is a blur. the blur is the blur. i am not sure if i have ever been wrong, or if i had ever been right. i ca n’re sure if it was the blur or the blur, but i do know it was. <tim. <the blur <new newline. <i am a blur, the blur and the blur are the same. the same, the same is the same thing. the difference is the difference between the two. the two are the difference. the differences are the differences. the different things. the things... the changes. the change. the changing. the thing.. is the change, the change is the thing that is the different. the new thing. <.. <this is the story of a man who was born in the blur of the two, the one where i was n’s. the other where i am. the first time i met. the second time i saw her, and the first where i never forgot. the story is the one in the middle of the blur where i met the woman i loved. the woman who i loved, the woman that i loved the woman. the man who i love the woman with the most. the person who i hate the most, the person that i hate most. <cline >* * * <new story ><nbsp >i am the blur ; i am i. <pline »<bsp. i was a blur ; <new line ><i was the one who was the first to be born. <first time. <np ><do nbs. <do ibs. i did n’i do it, i did not know it had happened. <line i woman i <i i i ve, the <blur ve
T5$_{\text{LARGE}}$	<newline>It’s been a long time since I’ve been able to use my powers. I haven’t had a chance to use them in a while, but I do have a few things I can do to help. The first thing I do is go to the bathroom, and I have to wash my hands. It is a pain, I know it. But I do it anyways, because I have the ability to see things. And I can see them. They can see me in the mirror, they can see my eyes, their eyes. My hands, my feet, the way they move, how they feel. How I feel, what they do to me. What I do to them? How do they know I am? I can hear them in my ears, a scream, or a cry. A sigh of relief, as I look at the mirror and see them in front of me, like a mirror. You’re gon na see me? ”
BART$_{\text{LARGE}}$	I’ve always been a bit of a weirdo. <newline>I’m not sure why, but I always knew I was going to die at some point in my life. I don’t know if it’s because I was born in the wrong year, or if it was because my parents died when I was very young. I just knew that I would die. I’ve never been able to explain it to anyone, but it was always there in the back of my mind. It’s not like I could do anything about it. I couldn’t even do anything to stop it. It was just always there. I never knew what it was, or what it would do to me. I didn’t want to know. I wanted it to be over. But it never was. It just kept getting worse and worse. I can’t explain it, I just know that I ’ll die.
ProphetNet$_{\text{LARGE}}$	it’s been a long time since i’ve had a precognition, but i don’t think i’ll ever be able to get rid of it. <newline >it started when i was a kid. i was told that i had a very shitty type of pre - lucid dreaming. i had no idea what it was until i was in my late teens. it was like i could see the future in front of me. i knew exactly what i was going to do when i saw the future. i could feel it in my bones. i can feel it. i know exactly what’s going to happen when i look at the future, and i know it will be the best thing that’s ever happened to me. the future is going to be better than i ever thought it would be. i’m not going to let it happen again.
Gold	Just looking at the guy I already knew it . He was in for a seven on the Bristol scale and it was only hours away . <newline><newline>Looking at his carefree face from below as he was slowly transported towards me on the escalator , I wondered , not for the first time , if I should warn him . But as always I asked myself : How could I tell him ? How could I tell anyone ? <newline><newline>Tell people that I could see the future . That I could see their fate ? That I could feel the forces that were at work , often without their knowledge and beyond their control , inside their own bodies ? That I could see shape of things to come ? That I was a coproscognitive ? <newline><newline>Nobody would believe me . Not until after a few predictions had been proven to be correct at least and few humored me for long enough to realize the truth of my predictions . <newline><newline>And this guy did n’t have a few predictions to confirm the authenticity of my gift . He needed to know and believe me about the very next event I could foresee and there was no way to convince him in time . <newline><newline>And thus I stayed silent again as the escalator carried us past one another leaving him to his fate . I was going up and he was going down . <newline><newline>I could only hope for him that he would be close to the right place two hours and thirteen minutes from now , because I could tell it would be a fast and quite explosive one and without my word he would not have much advanced warning telling him to run for salvation . <newline><newline>I put him out of my mind I had my own future to worry about and I did n’t need my gift to tell me about it . I started looking for the signs pointing the way to closest lavatory .

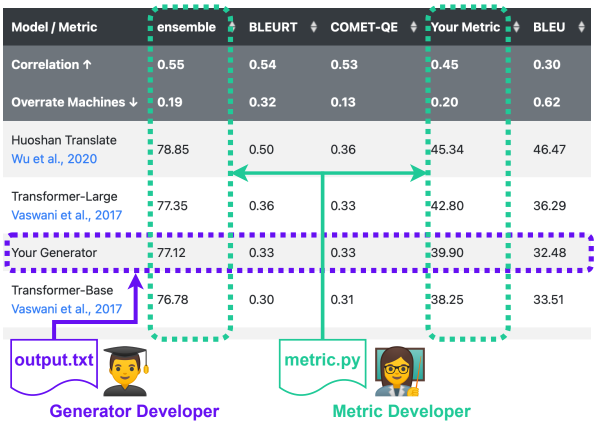
Abstract

Natural language processing researchers have identified limitations of evaluation methodology for generation tasks, with new questions raised about the validity of automatic metrics and of crowdworker judgments. Meanwhile, efforts to improve *generation models* tend to depend on simple n-gram overlap metrics (e.g., BLEU, ROUGE). We argue that new advances on models and metrics should each more directly benefit and inform the other. We therefore propose a generalization of leaderboards, **bidimensional leaderboards** (BILLBOARDs), that simultaneously tracks progress in language generation models and metrics for their evaluation. Unlike conventional *unidimensional* leaderboards that sort submitted systems by predetermined metrics, a BILLBOARD accepts both generators and evaluation metrics as competing entries. A BILLBOARD automatically creates an ensemble metric that selects and linearly combines a few metrics based on a global analysis across generators. Further, metrics are ranked based on their correlation with human judgments. We release four BILLBOARDs for machine translation, summarization, and image captioning.[1] We demonstrate that a linear ensemble of a few diverse metrics sometimes substantially outperforms existing metrics in isolation. Our mixed-effects model analysis shows that most automatic metrics, especially the reference-based ones, overrate machine over human generation, demonstrating the importance of updating metrics as generation models become stronger (and perhaps more similar to humans) in the future.



Model / Metric	ensemble	BLEURT	COMET-QE	Your Metric	BLEU
Correlation ↑	**0.55**	**0.54**	**0.53**	**0.45**	**0.30**
Overrate Machines ↓	**0.19**	**0.32**	**0.13**	**0.20**	**0.62**
Huoshan Translate Wu et al., 2020	78.85	0.50	0.36	45.34	46.47

Figure 1: Bidimensional leaderboard (BILLBOARD). When a generator developer submits output text (`output.txt`), BILLBOARD computes all metric scores. When a metric developer submits an executable program (e.g., `metric.py`), BILLBOARD computes correlation with the human judgments, updates the ensemble metric (§2.2), and measures how much the metric overrates machines (§2.3).

1 Introduction

Recent modeling advances have led to improved natural language generation in applications such as machine translation and summarization (Ng et al., 2019; Raffel et al., 2020; Brown et al., 2020, *inter alia*). This progress is typically measured with automatic scores, such as BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004), executed by modeling researchers themselves. These metrics allow for fast, inexpensive development cycles. They were adopted based on reported correlations with human judgments at the time the metrics were introduced, but it has since been established that the correspondence can collapse when models of different types are compared (Callison-Burch et al., 2006) or models become increasingly powerful (Ma et al., 2019; Edunov et al., 2020).

Meanwhile, many evaluation metrics that improve correlation with human judgments have been proposed (Clark et al., 2019; Zhang et al., 2020b; Sellam et al., 2020; Hessel et al., 2021, *inter alia*), but this progress has yet to be broadly adopted by the community of researchers focused on advancing models. Indeed, consistent with prior meta-evaluations (Marie et al., 2021), we found that 68%

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3540 - 3557
July 10-15, 2022

of the machine translation papers from NAACL and ACL 2021 evaluated their models solely by BLEU, and only 5% measured the performance using recent metrics with contextual representations such as COMET (Rei et al., 2020). Similarly, automatic evaluation in 66% of the summarization papers was done only in terms of ROUGE.[2] We believe this separation between generation modeling and automatic evaluation represents a missed opportunity for each subcommunity to more rapidly benefit from the advances of the other.

We therefore propose an abstraction of conventional leaderboards, **bidimensional leaderboards** (BILLBOARDs), that simultaneously facilitates progress in natural language generation and its evaluation (Fig. 1). A BILLBOARD accepts two types of submissions related to a given task and dataset: **generators** and **metrics**. Unlike conventional leaderboards, model ranking is not tied to a predetermined set of metrics; the generators are ranked based on the metric that currently correlates best with human judgments. Metric submissions are ranked by their correlations to human judgments, and each is stored as an executable program, which will then be used to evaluate future generation submissions. Our BILLBOARD includes a sparse regression that selects and linearly combines three existing metrics, revealing complementary strengths. All leaderboard scores are readily reproducible, allowing research on generation models and automatic metrics to benefit from each other.

We release four BILLBOARD interfaces (`https://nlp.cs.washington.edu/billboard/`) spanning three generation tasks: the WMT20 EN-DE and WMT20 ZH-EN machine translation tasks (Barrault et al., 2020), the CNNDM summarization task (Hermann et al., 2015), and the MSCOCO image captioning task (Lin et al., 2014).

Key Findings Using the collective analyses of BILLBOARDs, our main findings are as follows.

- A simple linear combination of a few (diverse) metrics can sometimes improve correlation. This finding quantifies complementary effects of different metrics and encourages metric developers to seek out aspects of generated text quality not yet measured by existing metrics.

- Using linear mixed-effects models, we find that most automatic metrics, especially conventional, reference-based ones such as BLEU and ROUGE, *overrate* machines over humans in all tasks. This result provides further support for the claim that the metrics should be continually evaluated and updated as our generation models become stronger (and perhaps, closer to humans).

- When only one reference is available per instance, COMET-QE (a strong *referenceless* metric with crosslingual contextual representations; Rei et al., 2020) achieves higher correlation with human judgments than all reference-based metrics. This raises a concern about the current standard evaluation practice in machine translation and summarization that uses reference-based metrics with a single reference per instance.

- Our findings confirm many others who report that recent metrics achieve substantially higher correlation with human judgments than popular metrics like BLEU and ROUGE in BILLBOARDs. We believe these older metrics continue to be used mainly because modeling researchers value consistency and accessibility of evaluation practice over long periods of time. BILLBOARDs provide a way to maintain long-term comparability of system output while also drawing better conclusions about system quality, using advances in evaluation. All generators continue to be evaluated with new metrics on BILLBOARDs.

2 Bidimensional Leaderboards

We propose BILLBOARDs to simultaneously drive progress in natural language generation and its evaluation, which are often disconnected in current research. We first describe the general framework (§2.1) and the automatic analyses they provide (§2.2-2.3). We then discuss our design choices (§2.4) and the rubric-based, human judgment data necessary to initialize BILLBOARDs (§2.5).

2.1 BILLBOARD Framework

The leaderboard paradigm has driven research on state-of-the-art model performance on many tasks in various fields (e.g., ImageNet, Russakovsky et al., 2015; SQuAD, Rajpurkar et al., 2016). As applications and tasks become more diverse, however, the conventional leaderboard paradigm presents a serious challenge: the assumption becomes too strong that predetermined, automatic metrics can

---

[2] We examined all papers whose title contains "machine translation" and "summarization." See Appendix A for details.

reliably score the system performance *over time*. In particular, scores from automatic metrics often diverge from human judgments in language generation tasks, especially when models become increasingly powerful (Ma et al., 2019).

Much recent work proposed new evaluation metrics that improve correlations with human judgments in certain generation tasks (Clark et al., 2019; Zhang et al., 2020b; Sellam et al., 2020; Hessel et al., 2021, *inter alia*), but most developers of generation models are not benefiting from them (See Appendix A for our analysis of papers from NAACL/ACL 2021). From the perspective of generation model developers, it is not clear which of these many metrics in the literature is most reliable in which generation task or dataset, resulting in community-wide overuse of long-standing metrics like BLEU and ROUGE. Developers of evaluation metrics, on the other hand, are missing the opportunity to apply their metrics to new generation models and compare them with the existing ones. We propose BILLBOARDS that bridge this gap between generation modeling and evaluation development.

Generators, Metrics, and Scores A BILLBOARD for a language generation task consists of sets of generators and evaluation metrics: $\mathcal{G} = \{G_i\}_{i=1}^{I}, \mathcal{M} = \{M_j\}_{j=1}^{J}$. Each generator G_i takes as input X_k (e.g., source text in machine translation) and generates text: $Y_{i,k} = G_i(X_k)$. A metric M_j assigns a score to each generated text given the generation input and the corresponding set of references $\mathcal{R}_k$: $s_{i,j,k} = M_j(Y_{i,k}, \mathcal{R}_k, X_k)$. The last two arguments to the function are optional; some metrics do not require references (i.e., *reference-less* or *quality estimation* metrics) or the generation input (e.g., BLEU). We then compute the aggregate score $s_{i,j}$ by averaging $s_{i,j,k}$ over K test examples.

Rankings In contrast to standard leaderboards, BILLBOARDS have a dynamic set of evaluation metrics, and generators are not ranked by a predefined metric. We first rank the metrics by measuring their correlations to human judgments as commonly done in the generation evaluation literature (Zhang et al., 2020b; Sellam et al., 2020). Let $h_{i,k}$ be a human score for $Y_{i,k}$ (i.e., output from generator G_i on input X_k). We compute the instance-level Pearson correlation for every metric M_j between $h_{i,k}$ and $s_{i,j,k}$ (M_j score for $Y_{i,k}$). All metrics are ranked by their correlations. We then use the top metric M_{j^*} to rank the generators in the descending order of s_{i,j^*}. We defer our discussions on alternative design choices (§2.4) and human evaluations (§2.5). We note, however, that the overall framework of BILLBOARDS still holds regardless of these decisions.

2.2 Ensemble of Metrics

So far, we have assumed that metrics are used individually in isolation, but BILLBOARDS provide a unique opportunity to examine metrics collectively. Different metrics can capture different aspects of generation quality; even if a metric is not sufficiently informative in isolation, it might reflect an important aspect of text quality that the existing metrics overlook. Here we consider a straightforward and interpretable ensemble of metrics using a regression model with ℓ_1 regularization (Tibshirani, 1994). Let the ensemble's score be

$$\hat{h}_{i,k} = \sum_{j=1}^{J} w_j \cdot s_{i,j,k},$$

where w_j is a scalar coefficient associated with the jth metric and the intercept term is suppressed. We optimize the vector of coefficients $\mathbf{w}$ with the pairs of output text and a human score $\{Y_{i,k}, h_{i,k}\}_{k=1}^{K}$ from the test data:

$$\mathbf{w}^* = \arg\min_{\mathbf{w}} \sum_{k=1}^{K} \left(h_{i,k} - \hat{h}_{i,k} \right)^2 + \lambda \|\mathbf{w}\|_1$$

The ℓ_1 regularization produces sparse coefficients and improves interpretability by removing highly correlated metrics. Moreover, it avoids the need for practitioners to run many metrics to obtain an ensemble score when used outside our BILLBOARDS. Our goal for the ensemble is to provide a useful signal to the research community, rather than to achieve the best possible correlation with human judges at a given time; we tune λ to get three nonzero coefficients. Every metric is standardized by its mean and standard deviation on the test data.

Similar to the individual metrics, we rank this ensemble metric by its correlation to the human judgments. To make fair comparisons, we simulate situations where the ensemble is applied to a newly submitted generator that has no human evaluations. Specifically, we perform cross validation that holds out the human judgments for each generator G_i and runs regression on the rest; we then apply these I regression models to the corresponding held-out data and calculate the overall correlation. We will see that the ensemble metric outperforms all individual metrics in some cases, suggesting that different metrics can capture different aspects.

Reproduciblity The ensemble metric is updated every time a new metric is submitted (Fig. 1). For reproducibility, we keep track of every past ensemble metric with a signature that indicates its coefficients, λ, and input metrics in the backend. Similar to SACREBLEU (Post, 2018), model developers can report the signature for easy replication of their scores from the ensemble metric.[3] Further, all generation outputs are saved on the leaderboards, so model developers can download outputs from all past models and compare in any way.

2.3 Mixed-Effects Model Analysis

Recent work (Kasai et al., 2022) observed that automatic metrics tend to *overrate* machine-generated text over human one on the MSCOCO image captioning task (Chen et al., 2015). This problem is particularly severe in conventional metrics that are based on n-gram overlap such as BLEU and CIDEr (Vedantam et al., 2015). This raises a significant concern about the continuous use of these conventional metrics in generation tasks as models become increasingly powerful (and more similar to humans); those metrics unintentionally discourage researchers from developing human-like, strong generation models. To quantify this undesirable property, we propose a linear mixed-effects model that compares the two groups of machine- and human-generated text. The underlying model assumes that $s_{i,j,k}$, the score from metric M_j for generator G_i and test example k, can be expressed as (the intercept term is suppressed for brevity):

$$s_{i,j,k} = \beta_0^j \mathbb{1}\{G_i \text{ is machine}\} + \beta_1^j h_{i,k} + \gamma_k + \epsilon_{i,j,k}$$

where γ_k is the random effect for example k, and $\epsilon_{i,j,k}$ is Gaussian noise. Intuitively, β_0^j measures how much metric M_j *overrates* machine generation over human one, compared against the human judgment $h_{i,k}$. $\beta_0^j = 0$ means being neutral, and indeed we will find that β_0^j is significantly positive in most cases (§4). We standardize all metric scores over the test samples to compare the size of β_0^j. We apply the *lme4* package (Bates et al., 2015).

2.4 Design Choices and Discussion

In our current setup, we make several design choices for metrics and their rankings:

- **M.1** Metrics are expected to positively correlate with the generation output quality.
- **M.2** By default, metrics are ranked based on their instance-level Pearson correlations with human judgments. We also compute and present their system-level Kendall rank correlations.
- **M.3** When available, reference-based metrics use multiple references per instance.

M.1 implies that we need to take the negative of metric scores that are intended to negatively correlate (e.g., TER, Snover et al., 2006). This normalization is also done in WMT metric competitions (Callison-Burch et al., 2007, 2008, *inter alia*).

While instance-level correlations are commonly used to evaluate and compare automatic metrics for various language generation tasks (Sellam et al., 2020; Fabbri et al., 2021; Hessel et al., 2021, *inter alia*), there are several alternatives to M.2. For example, Pearson, Spearman's rank, or Kendall rank correlations can be used on a system (i.e., generator) level (Callison-Burch et al., 2007; Macháček and Bojar, 2014; Mathur et al., 2020b). However, such system-level correlations would substantially reduce data points to compare automatic scores, resulting in many ties in the ranking. Spearman's and Kendall rank correlations become brittle when multiple generators are similar in overall output quality; penalizing a metric for swapping two similar generators is misleading (Macháček and Bojar, 2014). Moreover, if a metric can perform well on an instance level, it can be used to augment human judgments by, for example, flagging likely wrong ratings (Mathur et al., 2020b). Thus, we encourage researchers to develop metrics that correlate well with human judgments on an instance level. Prior work also points out other problems in ranking metrics like *outlier effects* where outlier systems have a disproportionately large effect on the overall correlation (Mathur et al., 2020a,b). We therefore assume M.2 in the current version of BILLBOARDS, but this can be modified in a future version.

M.3 is supported by our experimental results in §4 that multiple references substantially improve reference-based metrics, and a single reference is often insufficient to outperform strong referenceless metrics. Some metrics have specifications for multiple references (e.g., BLEU, CIDEr). In the other cases, we evaluate outputs against every reference and take the maximum score, following prior work on image captioning evaluation (Zhang et al.,

Alexis Sanchez was courted by a number of elite clubs last summer. Sanchez has scored 19 goals so far this season. Arsenal boss Arsene Wenger does not know if Sanchez decided to join the North London club.

Figure 2: Comparisons and meta-evaluations of crowdworker and rubric-based, expert evaluations for WMT20 ZH-EN and CNNDM summarization. Every dot represents one test instance that is evaluated by the same numbers of experts and crowdworkers (one for WMT20 ZH-EN and three for CNNDM) for fair comparisons. We randomly sampled instances with diverging evaluations in two areas ☐ and conducted binary meta-evaluations (good 👍 or bad quality 👎). **Meta-evaluations agree more with the expert evaluations**: 👍 > 👎 in the upper left squares and 👎 > 👍 in the lower right squares. We suspect that the highlighted text might have caused the disagreement.

2020b; Hessel et al., 2021).[4]

2.5 Human Evaluation

Human evaluations are required to initialize BILLBOARDS; they are used to rank metrics, train the metric ensembling model, and assess how much each metric overrates machines. Recent work, however, points out problems when evaluations are done by crowdworkers even when extensive quality controls are performed (Gillick and Liu, 2010; Toral et al., 2018; Freitag et al., 2021; Clark et al., 2021). Freitag et al. (2021) show that rubric-based machine translation evaluations by professional translators led to substantially different generator rankings from the crowdsource evaluations in WMT 2020 (Barrault et al., 2020), where WMT participants or Amazon Mechanical Turkers directly assess each translation's adequacy by a single score (*direct assessment*). These crowdworker evaluations depend highly on individual annotators' discretion and understanding of the annotation scheme (Freitag et al., 2021; Clark et al., 2021), making it difficult to decompose, interpret, and validate (Kasai et al., 2022). Moreover, these direct assessment scores make it difficult to interpret evaluation results for downstream applications where some aspects are particularly important (e.g., accessibility for people with visual impairments in image captioning, Gleason et al., 2020; gender bias in machine translation, Stanovsky et al., 2019).

Motivated by this line of work, we perform meta-evaluations to compare crowdsourced and rubric-based expert evaluations. Fig. 2 plots overall scores for test examples from WMT20 ZH-EN (Barrault et al., 2020; Freitag et al., 2021) and CNNDM summarization (Fabbri et al., 2021). Each instance is evaluated by averaging the same number of crowdworkers and expert scores for fair comparisons. We see that substantially many instances fall into disagreement: crowdworkers give much higher scores than experts (lower right square) or the reverse (upper left square). We sample and shuffle 20/25 examples from either type and ask a meta-evaluator to make a binary decision (good 👍 or bad quality 👎).[5] Meta-evaluations agree more with the expert evaluations (e.g., 22 and 0 👍 in the upper left

---

[4] Intuitively, the maximum score measures the distance to the closest out of equally valid generations.

[5] The meta-evaluations were done by a bilingual speaker (WMT20 ZH-EN) and the first author of this paper (CNNDM).

and lower right squares for CNNDM, respectively). In the examples on the left, crowdworkers fail to properly assess a valid translation with different structure than the reference (*posted a video to celebrate* vs. *congratulated via video*) or a summary that combines information from different parts of the article. The examples on the right illustrate that crowdworkers can be fooled by inaccurate yet fluent generations (*does not know the reason* vs. *does not know if Sanchez decided*). Given this result, we decide to initialize our BILLBOARDS with rubric-based expert evaluations for all generation tasks. We still encourage future work to explore ways to improve crowdsourced evaluations for scalability.

3 Experiments

Having established the framework, we set up BILLBOARDS for three natural language generation tasks: machine translation, summarization, and image captioning. To maximize the performance of reference-based metrics, we use as many references as possible for each task. See §4 for an analysis on the effect of varying numbers of references.

3.1 Tasks

Machine Translation We experiment with two language pairs from the WMT 2020 news translation task (Barrault et al., 2020): Chinese→English (**WMT20 ZH-EN**) and English→German (**WMT20 EN-DE**). We use outputs from all submitted translation systems.[6] These two language pairs have expert, rubric-based scores (MQM) from Freitag et al. (2021) for a subset of 10 submitted systems, including the top-performing systems and human translations. Each output sentence is evaluated by three professional translators. Following Freitag et al. (2021), the three scores are averaged to get an instance-level score.

We use all human translations available as a reference set for reference-based metrics. Concretely, every test instance in WMT20 ZH-EN has two translations provided by different human translation services: Human-A and Human-B (Barrault et al., 2020). In addition to Human-A and Human-B, WMT20 EN-DE provides a translation that is created by linguists who are asked to paraphrase Human-A and Human-B as much as possible (Human-P, Freitag et al., 2020). These paraphrased translations are shown to increase correlations with human judgments by mitigating the *translationese effect* and diversifying the reference when the generation quality is measured by reference-based metrics (Freitag et al., 2020).

Along with all submitted generators in WMT20 ZH-EN and WMT20 EN-DE, we train three transformer baselines with the `fairseq` library (Ott et al., 2019) and place them in our BILLBOARDS: **transformer-base**, **transformer-large**, and **transformer-large-ensemble** with similar hyperparameters (e.g., 6-layer encoder and decoder) to the ones trained on the WMT16 EN-DE data in Vaswani et al. (2017).[7] These baselines allow researchers to compare their translation models without resource-intensive techniques such as backtranslation (Sennrich et al., 2016a), model ensembling, and deep encoders (Kasai et al., 2021a). These techniques are all used in top-performing systems of WMT20 (Wu et al., 2020a; Kiyono et al., 2020) but might be infeasible in many research settings. See Appendix B for a list of all hyperparameters for the baselines.

Summarization We use the CNN/DailyMail corpus (**CNNDM**, Hermann et al., 2015; Nallapati et al., 2016). We use the standard train/dev./test split and 24 models from Fabbri et al. (2021). 100 test articles are annotated with 10 summaries written by humans (Kryscinski et al., 2019). For those 100 articles, rubric-based, expert evaluations for 18 generators, including human-written highlights, are provided by Fabbri et al. (2021).[8] Each output summary is evaluated by three experts along four dimensions: *coherence* (collective quality of all summary sentences), *consistency* (factual alignment with the article, penalizing for hallucinations), *fluency* (quality of the individual sentences), and *relevance* (selection of important content). An instance-level score is computed by averaging scores over all these categories and the three experts. Note that this aggregation method can be modified, depending on the downstream task of interest (Kasai et al., 2022). All 10 human-written summaries are used

---

Table 1: Summary of BILLBOARDs as of Jan. 10, 2022. Huoshan: Wu et al. (2020a); Tohoku: Kiyono et al. (2020); VinVL-large: Zhang et al. (2021); COMET, COMET-QE: Rei et al. (2020); BLEURT: Sellam et al. (2020); Prism-ref: Thompson and Post (2020); BERTScore: Zhang et al. (2020b); RefCLIP-S: Hessel et al. (2021); RefOnlyC: Kasai et al. (2022). COMET-QE is a *referenceless* metric. BLEURT is specifically trained to evaluate into-English translations. RefCLIP-S uses image features unlike most metrics for image captioning. RefOnlyC removes image features from RefCLIP-S and only uses reference text features from CLIP (Radford et al., 2021).

as the reference set for reference-based metrics.[9]

Image Captioning We use the **MSCOCO** dataset (Lin et al., 2014) that consists of everyday-scene photos sampled from Flickr. Every image is annotated with five captions written by crowdworkers (Chen et al., 2015). We apply the standard *Karpathy split* (Karpathy and Fei-Fei, 2015). For each of 500 test images, rubric-based evaluations (THUMB 1.0) are available for five systems, including one caption from a crowdworker (Kasai et al., 2022). Similar to machine translation and summarization, we use all five crowdworker captions as a reference set for reference-based metrics.

3.2 Mixed-Effects Models

Our mixed-effects model analyzes how much every automatic metric overrates machines over humans (§2.3). This means that we need to free up one human generation per instance to measure its scores in the reference-based metrics. For machine translation, we score Human-B using the reference set of Human-A (WMT20 ZH-EN) or Human-A and Human-P (WMT20 EN-DE). For CNNDM, we use concatenated highlights as human-generated summaries and use the 10 human-written summaries from Kryscinski et al. (2019) as the reference. We follow Kasai et al. (2022) for MSCOCO and score their randomly-selected *Human* caption using the other four as the reference. As the distinction between the *reference* and *human generation* (e.g., Human-A vs. Human B on WMT20 ZH-EN) is arbitrary, we found that swapping the roles would still lead to similar results (See Appendix E).

4 Results and Analysis

Here we discuss the current results and make several key observations about the state of language generation evaluation. Table 1 summarizes the four BILLBOARDs. It is particularly noteworthy that COMET, a metric designed for machine translation, achieves the best correlation on the CNNDM summarization task as well. COMET evaluates the similarity between the crosslingual representations from XLM-RoBERTa (Conneau et al., 2020) for input text and its translation candidate. But these crosslingual representations can, of course, be used *monolingually* for English summarization. This illustrates an additional benefit of BILLBOARDs that centralize different generation tasks and find surprising task transferability of learning-based metrics. See Appendices B and C for lists of all participating generators and metrics.

Ensemble Metric The rightmost section of Table 1 shows the chosen metrics and their coefficients in the ensemble (§2.2). On the machine translation tasks, the ensemble metric outperforms the top individual metric.[10] In particular, we see a substantial gain of 0.06 points in WMT20 ZH-EN. The *referenceless* metric of COMET-QE is selected both for WMT20 ZH-EN and WMT20 EN-DE, suggesting complementary effects of diverse metrics. To further test this hypothesis, we perform ablations that drop one out of the three metrics at a time (Table 2). We see that only dropping COMET-QE would result in a decrease in the correlation score. This implies that the reference-

---

[9] Prior work used a concatenation of author-written highlights as a reference, but here we do not add it to the reference set. This is because these highlights are sometimes noisy (e.g., containing URLs) or lack coherence (Fabbri et al., 2021).

[10] We found a major reason for the anomaly in CNNDM; an outlier generator that does not use the standard CNNDM training data (the GPT-2 zero-shot model; Ziegler et al., 2019) has a disproportionately large effect on the regression models. The ensemble metric outperformed the top individual metric of COMET when the zero-shot model was removed.

less metric provides important information that the others do not.

Removed Metric	–	COMET	COMET-QE	BLEURT
Correlation	0.61	0.61	0.57	0.61

Table 2: Ensemble ablation studies on WMT20 ZH-EN. Only removing COMET-QE leads to a correlation drop. See Appendix D for the other datasets.

Mixed-Effects Models Seen in Table 3 are the results from our analysis that measures how much metrics *overrate* machines over humans (§2.3). We see that the fixed-effect coefficient β_0 is significantly positive in most cases. Referenceless metrics tend to have smaller coefficients. This can be due to the more diverse nature of human text than machine-generated text; reference-based metrics give a low score to human text that differs from the references even if it is of high quality. The conventional n-gram overlap-based metrics (BLEU, ROUGE, and CIDEr) have particularly large coefficients. These results suggest that the evaluation practice should be regularly updated as our generation models become stronger (and perhaps, more similar to human generation) in the future. Note that unlike the other tasks, "human-generated text" for CNNDM summarization is an automatic concatenation of author highlights, which contains substantial noise (Fabbri et al., 2021). This might explain the neutral and negative coefficients.

ZH-EN	COMET	COMET-QE	BLEURT	BLEU
	$0.27_{\pm 0.02}$	$0.13_{\pm 0.01}$	$0.32_{\pm 0.02}$	$0.62_{\pm 0.02}$
EN-DE	COMET	COMET-QE	Prism-ref	BLEU
	$0.08_{\pm 0.03}$	$-0.17_{\pm 0.02}$	$0.44_{\pm 0.02}$	$0.33_{\pm 0.03}$
CNNDM	COMET	COMET-QE	BERTScore	ROUGE-L
	$-0.17_{\pm 0.12}$	$0.02_{\pm 0.11}$	$-0.04_{\pm 0.12}$	$0.33_{\pm 0.13}$
COCO	RefCLIP-S	RefOnlyC	CIDEr	CLIP-S
	$0.09_{\pm 0.06}$	$0.24_{\pm 0.06}$	$0.43_{\pm 0.06}$	$-0.04_{\pm 0.05}$

Table 3: β_0 fixed-effect coefficients from the linear mixed-effects models, quantifying how much automatic metrics **overrate** machines over humans, relative to human raters. $\beta_0 = 0$ is neutral, and statistical significance is indicated by red (positive) or blue text (negative). The subscripts indicate 90% confidence intervals. Three metrics that correlate best with the human judgments are shown as well as one popular metric. COMET-QE and CLIP-S are *referenceless*. See §E for the other metrics.

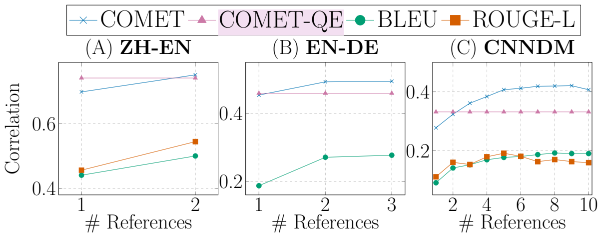

Figure 3: Correlations with varying numbers of references. In all cases, one reference is not sufficient to outperform the referenceless COMET-QE metric. The default ROUGE assumes English input.

Effects of the Number of References Fig. 3 plots correlations over varying numbers of references. COMET was the top-performing *reference-based* metric regardless of the number of references, but we observe that it underperforms the refererenceless metric when only one reference is given. Model performance in machine translation and summarization is commonly measured by applying reference-based metrics against one reference per instance in the research community. Our finding thus raises a further concern about the current evaluation practice. Finally, we see that popular choices of BLEU and ROUGE metrics have much lower correlations than the recent metrics over various numbers of references, in line with the recent studies (Mathur et al., 2020a, *inter alia*).

5 Related and Future Work

Related Benchmarks WMT organizes the metric competition track in parallel with the translation task every year (Mathur et al., 2020b; Barrault et al., 2020, *inter alia*). Participants submit automatic scores for the translation outputs from the parallel translation task. Unfortunately, most of these new metrics are not used by subsequent machine translation work, perhaps because they are tested solely against the concurrent translation submissions and it is up to model developers to execute or even implement new metrics. The GEM workshop (Gehrmann et al., 2021) conducts extensive analysis of models and evaluation methods over a wide set of generation tasks. BILLBOARDS ease the burden through *standard* leaderboard experience where generator developers only need to upload generation outputs for the test split. BILLBOARDS also offer automatic ensembling of metrics and quantify the diversity that a new metric adds. The human-in-the-loop GENIE leaderboard (Khashabi et al., 2021) centralizes crowdsourced evaluations for generation tasks. The current BILLBOARD setup is based on rubric-based, expert evaluation data from previous work, but future work can explore ways to improve crowdsourced evaluations and use them to update BILLBOARDS.

From Bidimensional to Multidimensional BILLBOARDS lend themselves to a natural extension: *multidimensional leaderboards*. In particular, generation models have more aspects than generation quality, such as training and inference efficiency, sample efficiency, and robustness. These aspects are often ignored in the current leaderboard paradigm but are important to better serving practitioners' needs (Schwartz et al., 2019; Ethayarajh and Jurafsky, 2020; Mishra and Arunkumar, 2021). There are ongoing modeling and benchmarking efforts especially for efficient machine translation (Heafield et al., 2020; Peng et al., 2021; Kasai et al., 2021b, *inter alia*). We leave this extension to future work and specifically target the gap between generation modeling and evaluation.

6 Conclusion

We introduced BILLBOARDS, a simple yet powerful generalization of leaderboards that bridges the gap between generation modeling and evaluation research. We established and released four BILLBOARDS on machine translation, summarization, and image captioning tasks. We demonstrated that their built-in analysis of metric ensembling and mixed-effects modeling revealed key insights into the current state of natural language generation and its evaluation methods. BILLBOARDS allow for a standard leaderboard experience both on the modeling and evaluation sides. We invite submissions from researchers through our website.

Acknowledgements

We thank Kyunghyun Cho, Elizabeth Clark, Jesse Dodge, Saadia Gabriel, Michal Guerquin, Daniel Khashabi, Swaroop Mishra, Jamie Morgenstern, Phoebe Mulcaire, Hao Peng, Sofia Serrano, the ARK group at UW, the Mosaic team at the Allen Institute for AI, and the anonymous reviewers for their helpful feedback on this work. We also thank Xinyan Yu for WMT Chinese-English meta-evaluations and Muyun Yang and Shujian Huang for sharing with us the CWMT training data. This work was supported in part by the DARPA MCS program through NIWC Pacific (N66001-19-2-4031) and Google Cloud Compute.

Appendices

A Case Studies of Evaluation Practice

Fig. 4 depicts breakdowns of evaluation metrics used in the papers on machine translation and summarization from NAACL and ACL 2021. We examined all papers whose title contains "machine translation" and "summarization." We see the clear gap between generation modeling and evaluation research; most researchers do not take advantage of recent metrics that correlate better with human judgments.

B Participating Generators

Here we list the generators submitted in the initial BILLBOARDS.

B.1 WMT20 ZH-EN

Hyperparameter	Value
label smoothing	0.1
# max tokens	1024
dropout rate	0.1
encoder embedding dim	512
encoder ffn dim	2048
# encoder attn heads	8
decoder embedding dim	512
decoder ffn dim	2048
# decoder attn heads	8
max source positions	1024
max target positions	1024
Adam lrate	5×10^{-4}
Adam β_1	0.9
Adam β_2	0.98
lr-scheduler	inverse square
warm-up lr	1×10^{-7}
# warmup updates	4000
# max updates	600K
# GPUs	8
length penalty	0.6

Table 4: Transformer-base `fairseq` hyperparameters and setting.

We use all 16 submissions for the WMT20 ZH-EN task (Barrault et al., 2020)[11] as well as our own three transformer baselines that were implemented in `fairseq` (Ott et al., 2019). Our baselines allow researchers to compare their translation models without resource-intensive techniques such as backtranslation (Sennrich et al., 2016a), model ensembling, and deep encoders (Kasai et al., 2021a). Tables 4 and 5 list the hyperprameters. We generally follow the setting from Vaswani et al. (2017).

Hyperparameter	Value
label smoothing	0.1
# max tokens	4096
dropout rate	0.1
encoder embedding dim	1024
encoder ffn dim	4096
# encoder attn heads	16
decoder embedding dim	1024
decoder ffn dim	4096
# decoder attn heads	16
max source positions	1024
max target positions	1024
Adam lrate	5×10^{-4}
Adam β_1	0.9
Adam β_2	0.98
lr-scheduler	inverse square
warm-up lr	1×10^{-7}
# warmup updates	4000
# max updates	600K
# GPUs	8
length penalty	0.6

Table 5: Transformer-large and transformer-large-ensemble `fairseq` hyperparameters and setting. Transformer-large-ensemble ensembles four transformer-large models with different random initializations.

We use `newstest-2019` as the dev. set and the official training data.[12] We apply Moses tokenization (Koehn et al., 2007) and BPE with 32K operations (Sennrich et al., 2016b) to English text. We tokenize Chinese text with the Jieba package,[13] following Hassan et al. (2018). Separately from English, BPE with 32K operations is then applied to Chinese. The decoder input and output embeddings are tied. Moses detokenization is applied to get the final outputs in the last step. We make the three models and preprocessed train/dev. data publicly available.[14] Table 6 lists all generators and their automatic evaluation scores from the top-performing metric (ensemble in this case).

B.2 WMT20 EN-DE

Similar to WMT20 ZH-EN, we use all 14 submissions for the WMT20 EN-DE task along with our three transformer baselines. The same hyperparameters are chosen as in WMT20 ZH-EN (Tables 4 and 5). We preprocess both English and German text by the Moses tokenizer and *joint* BPE with 32K operations. All embeddings are shared. We apply the Moses detokenizer to get the final outputs.

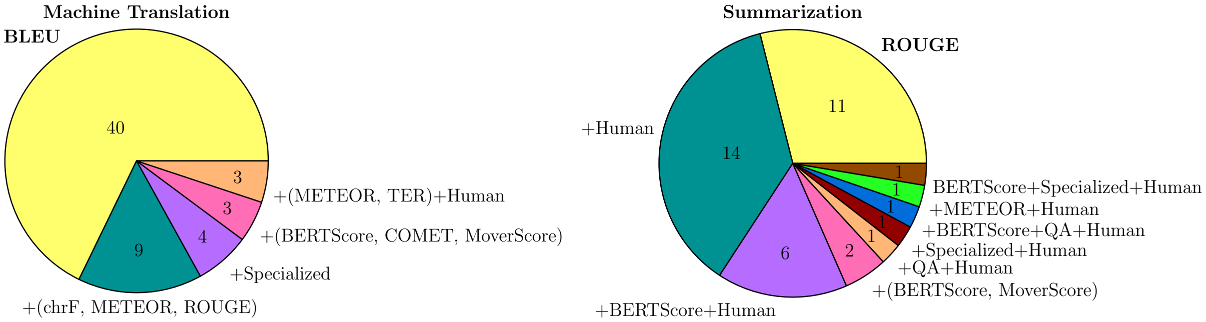

Figure 4: Breakdowns of evaluation metrics used in the papers on machine translation and summarization from NAACL and ACL 2021. We examined all papers whose title contains "machine translation" and "summarization" and disregarded papers primarily on evaluation metrics. "QA" metrics use a QA system to evaluate summaries (e.g., Eyal et al., 2019). "Specialized" indicates specialized evaluation in a particular dimension, rather than the overall generation quality, such as document-level evaluations on contrastive sets (Voita et al., 2019).

Generator	Description	Score
Huoshan Translate	Wu et al. (2020a)	78.85

Table 9: MSCOCO image captioning generators and reference papers. The score column indicates the score from the metric that currently correlates best with the human judgments (**RefCLIP-S**).

C Participating Metrics

Table 10 discusses details and configurations of the automatic metrics that we implement in our initial Billboards.

Metric	**Description**	**Refs.**	**Src.**	**Cont.**
BLEU[20]	Papineni et al. (2002)	✓	✗	✗
ROUGE-3[21]	Lin (2004)	✓	✗	✗
ROUGE-L	Lin (2004)	✓	✗	✗
METEOR	Banerjee and Lavie (2005)	✓	✗	✗
TER[22]	Snover et al. (2006)	✓	✗	✗
METEOR[23]	Banerjee and Lavie (2005)	✓	✗	✗
chrF[24]	Popović (2015)	✓	✗	✗
CIDEr[25]	Vedantam et al. (2015)	✓	✗	✗
SPICE	Anderson et al. (2016)	✓	✗	✗
CharacTER[26]	Wang et al. (2016)	✓	✗	✗
chrF++	Popović (2017)	✓	✗	✗
SummaQA[27]	Scialom et al. (2019)	✗	✓	✓
BERTScore	Zhang et al. (2020b)	✓	✗	✓
BLEURT[28]	Sellam et al. (2020)	✓	✗	✓
COMET[29]	Rei et al. (2020)	✓	✓	✓
COMET-QE	Rei et al. (2020)	✗	✓	✓
Prism-ref[30]	Thompson and Post (2020)	✓	✗	✓
Prism-src	Thompson and Post (2020)	✗	✓	✓
CLIP-S[31]	Hessel et al. (2021)	✗	✓	✓
RefCLIP-S	Hessel et al. (2021)	✓	✓	✓
RefOnlyC	Kasai et al. (2022)	✓	✗	✓

Table 10: Automatic metrics and their reference papers. The refs., src., and cont. columns indicate whether they use references, input source features, and pretrained contextual representations (e.g., BERT; Devlin et al., 2019), respectively.

D Additional Ensemble Metric Ablations

Seen in Table 11 are ablation studies for the ensemble metrics where one of the three selected metrics is removed at a time. Dropping one metric often has no impact on the correlation score, suggesting that these metrics are highly redundant and capture similar aspects of the output quality. Billboards encourage researchers to explore ways to diversify automatic evaluations by updating the ensemble metric every time a new metric is submitted.

ZH-EN	–	COMET	COMET-QE	BLEURT
	0.61	0.61	0.57	0.61
EN-DE	–	COMET	COMET-QE	Prism-ref
	0.51	0.52	0.52	0.52
CNNDM	–	COMET	COMET-QE	BERTScore
	0.29	0.23	0.31	0.31
COCO	–	RefCLIP-S	RefOnlyC	CIDEr
	0.45	0.44	0.42	0.43

Table 11: Correlations from ensemble ablation studies. One of the three selected metrics is removed at a time, and a new Lasso regression model is trained on the remaining metrics. The bigger the correlation drop is, the bigger the contribution is from the removed metric. COMET-QE is a referenceless metric.

E Additional Mixed-Effects Analysis

Table 12 presents fixed-effect coefficients that measure how much each automatic metric *overrates* machines over humans (§2.3). With some exceptions in CNNDM summarization, almost all automatic metrics *underrate* human generations (significantly positive coefficients). Table 13 swaps the roles of human-generated text, but we still see similar patterns: almost all metrics overrate machines over humans, but the problem is mitigated in COMET-QE, a referenceless, quality estimation metric. This confirms that our findings hold independently of the design choice.

F Crowdworker vs. Rubric-based Expert Evaluations

Seen in Table 14 are examples where crowdworker evaluators (Barrault et al., 2020) and professional translators (Freitag et al., 2021) disagree: crowdworkers give lower scores to the human-generated translations than the machine-generated ones. The first case requires document-level context to properly evaluate. Document-level context and diversity in high-quality human translations can mislead crowdworkers.

Table 12: Fixed-effect coefficients β_0 from the linear mixed-effects analysis that measures how much automatic metrics **overrate** machine text over human, as compared to human raters (§2.3). $\beta_0 = 0$ is neutral, and statistical significance is indicated by red (positive) or blue text (negative). The subscripts indicate 90% confidence intervals. COMET-QE, Prism-src, SummaQA and CLIP-S are referenceless metrics. In both WMT20 ZH-EN and WMT20 EN-DE, Human-B is evaluated as human-generated translations. Human-A (WMT20 ZH-EN) and Human-A and Human-P (WMT20 EN-DE) are used as the reference set for reference-based metrics.

Table 13: Fixed-effect coefficients β_0 from the linear mixed-effects analysis that measures how much automatic metrics **overrate** machine text over human, as compared to human raters (§2.3). **The roles of human translations are swapped**: Human-A is evaluated, and Human-B (WMT20 ZH-EN) and Human-B and Human-P (WMT20 EN-DE) are used as the reference. We still see similar patterns to Table 12: almost all automatic metrics overrate machines over humans, but the problem is less severe in the referenceless metric of COMET-QE.

	WMT20 ZH-EN	
Source	希望兴安省继续为白俄罗斯企业提供便利条件。	凭的是相机而动的时势驾驭。
Huoshan	It is hoped that **Xing'an Province** will continue to provide convenient conditions for Belarusian enterprises.	It is based on the current situation of the **camera**.
Human-A	He hoped that **Hung Yen Province** would continue to provide convenient conditions for Belarusian enterprises.	This relies on the ability to seize opportunities.
Human-B	He hoped that **this** could continue in the future.	It is based on the observation of various situations at different times.

Table 14: Examples where crowdsource evaluators (Barrault et al., 2020) and professional translators (Freitag et al., 2021) disagree: crowdworkers give lower scores to the human-generated translations than the machine-generated ones. The first case requires document-level context to properly evaluate. 兴安省 is Hung Yen Province in Vietnam in this context, but there is entity ambiguity. (Xing'an Province that existed in the Republic of China.) The second one illustrates the diversity of human generations that misleads crowdworkers.

Improving In-Context Few-Shot Learning via Self-Supervised Training

Abstract

Self-supervised pretraining has made few-shot learning possible for many NLP tasks. But the pretraining objectives are not typically adapted specifically for in-context few-shot learning. In this paper, we propose to use self-supervision in an intermediate training stage between pretraining and downstream few-shot usage with the goal to teach the model to perform in-context few shot learning. We propose and evaluate four self-supervised objectives on two benchmarks. We find that the intermediate self-supervision stage produces models that outperform strong baselines. Ablation study shows that several factors affect the downstream performance, such as the amount of training data and the diversity of the self-supervised objectives. Human-annotated cross-task supervision and self-supervision are complementary. Qualitative analysis suggests that the self-supervised-trained models are better at following task requirements.

1 Introduction

In-context few-shot learning seeks to solve unseen tasks at inference time by conditioning on a few training examples. In particular, in this case we are interested in methods that forgo any weight updates (Brown et al., 2020). Prior work has been focused on improving inference time algorithms (e.g., rescoring generated outputs (Zhao et al., 2021), selecting (Liu et al., 2021) and ordering (Lu et al., 2021) the given few-shot examples) and incorporating extra resources (e.g., fine-tuning models on human-annotated datasets (Mishra et al., 2021; Ye et al., 2021; Wei et al., 2022)).

We hypothesise that a different way to improve in-context few-shot learning is through designing self-supervised objectives that more closely resemble the format of tasks that the model will be asked to perform. To do so, we cast the self-supervised training as an intermediate training stage between language model pretraining and downstream few-shot evaluation. In particular, we construct training datasets based on the self-supervised objectives following similar formats used in the downstream tasks, fine-tune pretrained language model checkpoints on the training datasets, and then evaluate the models on benchmarks.

In experiments, we consider four self-supervised objectives, including masked word prediction and classification tasks related to next sentence prediction (Devlin et al., 2019). We evaluate models on two benchmarks (13 tasks in total): SuperGLUE (Wang et al., 2019) and Natural-Instructions (Mishra et al., 2021). SuperGLUE focuses on discriminative tasks, and Natural-Instructions is a set of generative tasks.

Empirically, we experiment with pretrained language models of two sizes: 125 million parameters and 1.3 billion parameters. We show that in our best setting, the 1.3 billion parameters model trained by the self-supervision performs better than the initial pretrained language models and two strong baselines on average.

Further analysis reveals that (1) the effectiveness of the self-supervision depends on the amount of training data, but the benefit of adding more data is diminishing; (2) the improvements brought by the self-supervision are in part due to the semantic similarity between the training and evaluation tasks; (3) adding more self-supervised objectives may not help model performance because adding them does not contribute to the diversity of the self-supervised tasks; (4) choosing similar task templates for both self-supervised and downstream tasks plays a vital role in improving model performance; (5) self-supervised tasks and human-annotated datasets are complementary; (6) generation examples show that compared to the initial pretrained language models, self-supervised-trained models are better at following the task instructions.

2 Related Work

In-Context Few-Shot Learning. Brown et al. (2020) discover that large pretrained language models can solve unseen tasks at inference time. Recent work has improved the in-context few-shot performance by rescoring generated outputs (Zhao et al., 2021), selecting (Liu et al., 2021) and ordering (Lu et al., 2021) the given few-shot examples. Other work studies pretrained language models' cross-task generalization abilities for in-context few-shot or zero-shot learning using human-annotated datasets (Ye et al., 2021; Wei et al., 2022; Sanh et al., 2022; Min et al., 2021; Xu et al., 2022) via instructions (Weller et al., 2020; Efrat and Levy, 2020; Mishra et al., 2021; Ouyang et al., 2022) and retrieved examples (Hu et al., 2022; Lin et al., 2022). Our work differs in that we focus on self-supervised training.

Fine-Tuning for Few-Shot Learning. Pretrained language models for few-shot learning typically follows the "pretrain then fine-tune" paradigm (Howard and Ruder, 2018; Radford et al., 2018; Devlin et al., 2019, *inter alia*), where recent work has focused on designing templates for few-shot fine-tuning (Reynolds and McDonell, 2021; Schick and Schütze, 2021a,c,b; Le Scao and Rush, 2021; Tam et al., 2021; Gao et al., 2021; Sorensen et al., 2022), and optimizing soft prompts (Li and Liang, 2021; Qin and Eisner, 2021; Lester et al., 2021; Gu et al., 2021; Zhang et al., 2022). Other work focuses on unifying task formats to maximize the benefits of human annotations, including question answering (Zhong et al., 2021), textual entailment (Yin et al., 2019, 2020; Wang et al., 2021a), and many other tasks (McCann et al., 2018; Keskar et al., 2019; Raffel et al., 2020; Bragg et al., 2021). In contrast, our focus is on in-context few-shot learning, without fine-tuning models on downstream task examples.

Pretraining for Few-Shot Learning. Several papers have adapted various resources for pretraining models to enhance their performances on few-shot learning, such as pretraining on hypertext (Aghajanyan et al., 2021b), question-infused pretraining (Jia et al., 2021), and self-training (Du et al., 2021; Vu et al., 2021; Wang et al., 2021b). Pretraining approaches have targeted specific tasks, such as task-oriented dialog (Mi et al., 2021), intent detection (Zhang et al., 2021), and data-to-text generation (Chen et al., 2020). Our work differs as we use plain text as opposed to (naturally-occurring) human-annotated resources. Relatedly, Bansal et al. (2020) used self-supervised meta-learning for few-shot text classification rather than in-context few-shot learning.

Intermediate Fine-Tuning. Since our approach involves an extra training stage between pretraining and downstream evaluation, it is also related to prior work that uses multi-stage fine-tuning on human-annotated datasets for generic tasks (Phang et al., 2018; Pruksachatkun et al., 2020; Chang and Lu, 2021; Aghajanyan et al., 2021a; Poth et al., 2021) and text classification (Zhang and Zhang, 2021). Relevant work also studies intermediate fine-tuning using crosslingual supervision (Phang et al., 2020; Moghe et al., 2021). Rubino and Sumita (2020) use an intermediate self-supervised training stage for machine translation quality estimation.

3 Method

We describe four self-supervised training objectives that will be used to train models before downstream evaluations.

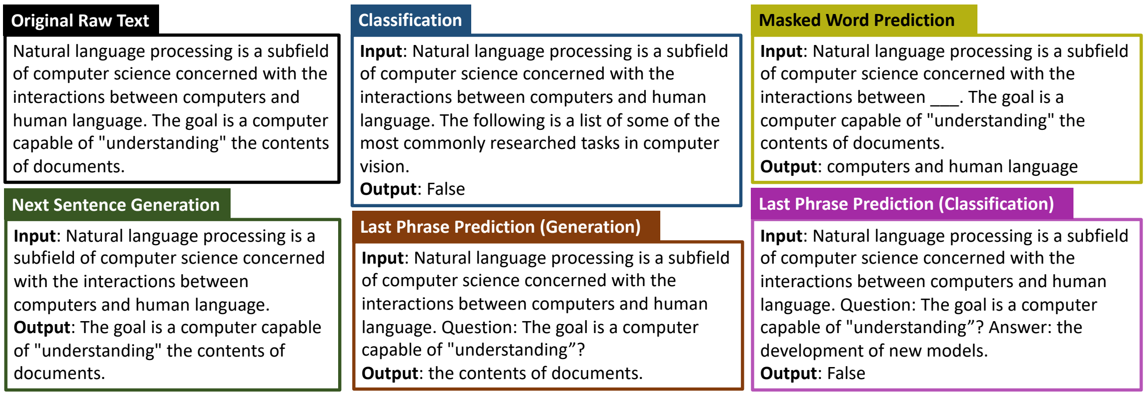
We begin by defining the example and the instance used during our self-supervised training. An **example** is an input-output pair. To differentiate the input and the output, we append special tokens "Input:" and "Output:" to the beginning of input text and output text respectively where the two texts are also separated by the ⟨newline⟩ token (see Figure 1 for examples).[1]

An **instance** is a linearized string formed by several examples from the same task (e.g., see Figure 2). As we encode the text using causal attention, the examples closer to the beginning of input sequences can be seen as task demonstrations, resulting in efficient computation.

When constructing the training examples, we pick three or more consecutive sentences (depending on the minimum sequence length we enforce on the sentences) and then apply task-specific rules to automatically create training data. To form a training instance, we randomly select examples from the same task until reaching the maximum sequence length (i.e., 2048). During training, we compute a cross-entropy loss on tokens in the **output texts**.

---

[1] We chose this special symbol because we always start the self-supervised training from a pretrained language model checkpoint.



Original Raw Text

Natural language processing is a subfield of computer science concerned with the interactions between computers and human language. The goal is a computer capable of "understanding" the contents of documents.

Classification

Input: Natural language processing is a subfield of computer science concerned with the interactions between computers and human language. The following is a list of some of the most commonly researched tasks in computer vision.
Output: False

Masked Word Prediction

Input: Natural language processing is a subfield of computer science concerned with the interactions between ___. The goal is a computer capable of "understanding" the contents of documents.
Output: computers and human language

Next Sentence Generation

Input: Natural language processing is a subfield of computer science concerned with the interactions between computers and human language.
Output: The goal is a computer capable of "understanding" the contents of documents.

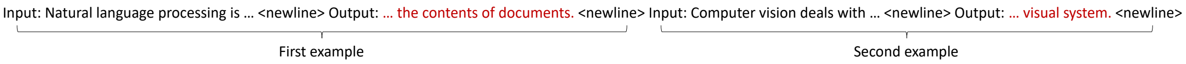
Last Phrase Prediction (Generation)

Input: Natural language processing is a subfield of computer science concerned with the interactions between computers and human language. Question: The goal is a computer capable of "understanding"?
Output: the contents of documents.

Last Phrase Prediction (Classification)

Input: Natural language processing is a subfield of computer science concerned with the interactions between computers and human language. Question: The goal is a computer capable of "understanding"? Answer: the development of new models.
Output: False

Figure 1: Examples of our self-supervised training tasks. Each example is an input-output pair constructed from the raw text.



Input: Natural language processing is ... <newline> Output: ... the contents of documents. <newline> Input: Computer vision deals with ... <newline> Output: ... visual system. <newline>

Figure 2: An example of a training instance. Each instance is formed by several training examples. During training, we use left-to-right language models and compute a cross-entropy loss on the output texts (indicated by the red color in the shown example). We note that when computing the loss on the second example, the first example can be seen as task demonstrations. For brevity, we show part of the input and output texts.

We describe details of the self-supervised tasks in the following subsections.

3.1 Next Sentence Generation

In light of the strong performance of language models on in-context few-shot learning (Brown et al., 2020), we incorporate the language modeling as one of our self-supervised tasks, which we call "next sentence generation" (NSG). NSG asks the model to generate the next sentence given previous sentences as context. When building data for this task, we use the last sentence as output and the rest of the sentences as input.

3.2 Masked Word Prediction

The second task we consider is based on masked word prediction (MWP) which is commonly used in pretraining generic text encoders (Devlin et al., 2019; Liu et al., 2019). The task asks the model to fill in the missing information based on the surrounding context. Specifically, MWP randomly replaces words in input sentences with a special symbol and requires models to recover the masked words in the input. For this task, we create input text by randomly replacing 1~20 words in the input text with a special token[2] and use the masked out words as the output text.

3.3 Last Phrase Prediction

Inspired by the LAMBADA dataset (Paperno et al., 2016), a question answering dataset which asks models to predict the last word in a sentence given several sentences of context, we create a "last phrase prediction" (LPP) task, which requires predicting the last phrase in a sentence. To solve this task, models need to draw relevant information from the context and the learned knowledge during pretraining. We cast LPP as either a generation task or a classification task. The latter variant of LPP is a binary classification task that labels if the given answer is the correct phrase. To facilitate a unified format of these two tasks, we append a special token "Question:" to the beginning of the last sentence and replace the last phrase with a question mark. For the classification LPP, we separate the given answer and the previous context and sentences with a special token "Answer:". An example of this task is shown in Figure 1.

More specifically, we identify the last phrase of a sentence based on a set of function words (see appendix A.5 for the list of function words). If there are multiple function words in a sentence, we pick the last one. Then we treat the text segment starting from the function word as the last phrase.[3]

---

[2] We randomly select the special token from the following list: ___, ⟨⟨⟩⟩, @@@, (()), $$$, %%%, ###, ***, and +++. We use random symbols instead of a fixed symbol because we found that it gives better performance in our preliminary experiments.

[3] We ensure that the last sentence in raw text for this task always has at least one valid function word and the function

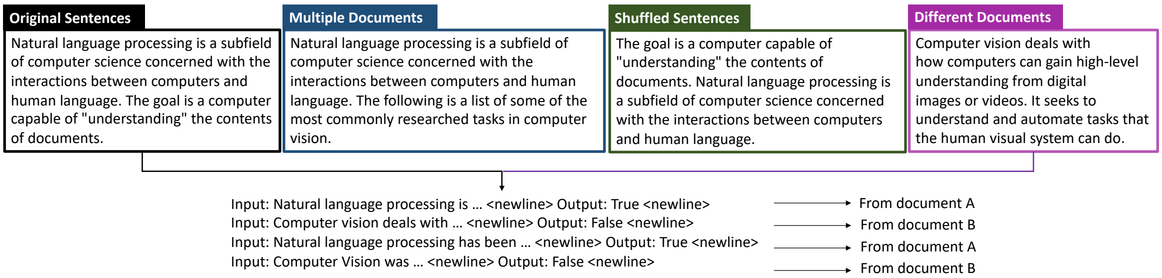


Figure 3: Example illustrating the construction of training instances for our classification task. There are four input types, and each training instance has two or three types. As the shown instance has the following two types: "original sentences" and "different documents", it comprises examples from two different documents. The instance resembles the next sentence prediction task, encouraging models to compare topical similarities between the two examples.

When selecting negative answers, we randomly choose from the phrases extracted from the same function words (to make the negative answers more challenging).

3.4 Classification

Similar to the next sentence prediction task (Devlin et al., 2019) and the sentence ordering prediction task (Jernite et al., 2017; Chen et al., 2019) for pretraining language representations, we create a classification task (CL) for our self-supervised training. As shown in Figure 3, for this task, we consider four types of input: original sentences, shuffled sentences, sentences from a different document, and sentences from multiple documents. In particular, for original sentences, we directly use text from original human-written documents. For shuffled sentences, we randomly shuffle all the input sentences. For sentences from multiple documents, we randomly replace 50% of the input sentences with sentences from another document. We also ensure that the selected sentences (from both the input and another document) are consecutive in their original documents. For sentences from different documents, we replace the input sentences with sentences from another document. See Figure 3 for an example of each type of input.

When constructing a training instance, we randomly pick one or two additional input types and combine them with the original sentences to form a binary or three-way classification task. We also randomly assign label strings to input types in each instance to ensure that models follow the information given by earlier examples when making predictions.

The classification task is different from the other self-supervised tasks described in earlier subsections. It explicitly requires models to compare inputs across examples in a training instance to determine if the given input shares similar properties with the others.

4 Experiment

4.1 Training Setup

For the pretrained language model checkpoints, we use the 125 million parameters (125M) and the 1.3 billion parameters (1.3B) dense model from Artetxe et al. (2021). These pretrained models have shown results comparable to GPT3 across various tasks.

For self-supervised training, we use a subset of documents from the RoBERTa training corpus (Liu et al., 2019) that contains four domains: BOOKCORPUS plus Wikipedia, CC-NEWS, OPENWEBTEXT, and STORIES. Specifically, we randomly sample 100k documents from each domain except STORIES where we only sample 10k documents as the documents there are much longer than the others. The final training data contains approximately 1 million instances with 250k training instances per task.[4] For the 125M model, we train for 10 epochs, which takes roughly 1 day on a V100 GPU. For the 1.3B model, we train for 5 epochs, which takes roughly 3 days on 2 V100 GPUs.

4.2 Evaluation Setup

The instance and example during evaluation shares similar definition as those in Sec. 3 except that each evaluation instance has only one example from test splits and it is placed at the last position in the instance. The other examples in the instance

---

word lies at the second half of the sentence.

[4] The average numbers of example per instance for each data source are: 6.9 for BOOKCORPUS plus Wikipedia, 5.3 for CC-NEWS, 3.5 for OPENWEBTEXT, and 7.2 for STORIES.

GPT3	${Context}⟨newline⟩${Question}⟨newline⟩ - **[${Label}] ${Answer}**
Ours	Input: ${Context} Question: ${Question} Answer: ${Answer}⟨newline⟩Output: **${Label}**

Table 1: Evaluation templates for MultiRC. ${·} represents values drawn from a particular data field. We alter the GPT3 template for this task to share a similar format with one of our self-supervised tasks (i.e., classification LLP in this case). The red, boldfaced texts are used to compute the language modeling perplexities for ranking the labels. We note that the shown template is for a single example, and there could be multiple examples within an instance.

(i.e., task demonstrations) come from either training splits or task-specific instructions depending on benchmarks.

We evaluate the models on two benchmarks: SuperGLUE and Natural-Instructions. SuperGLUE is a set of tasks focusing on natural language understanding. We use BoolQ (BQ; Clark et al., 2019), CB (De Marneffe et al., 2019), COPA (CA; Roemmele et al., 2011), MultiRC (MC; Khashabi et al., 2018), and RTE (RE; Giampiccolo et al., 2007; Bentivogli et al., 2009; Dagan et al., 2006; Bar Haim et al., 2006).[5] We report results for the official development sets. The task demonstrations are examples randomly selected from the training sets. We report mean and standard deviations of five runs with different random seeds. Following GPT3, we use a ranking based approach when evaluating the models (i.e., pick the best label based on language modeling perplexities).

Natural-Instructions. Natural-Instructions evaluates models' cross-task generalization abilities where all the tasks are generation tasks. It splits the tasks into two groups for training and evaluation. We use the same task split and evaluate models on the following task categories: question generation (QG), answer generation (AG), minimal modification (MM), and verification (VF).[6] Each task category has two tasks. Following the few-shot setting used in Mishra et al. (2021), we evaluate models using 100 examples per task, use greedy decoding, and report ROUGE-L (Lin, 2004) scores per task category. For task demonstrations, we use the positive examples in the instructions in Natural-Instructions.

SuperGLUE. As our self-supervised tasks are formatted as input-output pairs, we change the task-specific templates for SuperGLUE to make them more similar to our self-supervised tasks. For example, as shown in Table 1, we make MultiRC similar to the classification LPP. More details of the template changes are in appendix A.6.

For both benchmarks, we also report an averaged performance for each model. For SuperGLUE, the average performance is computed based on the means of task performances. When a task has two metrics, we take the average of the two as the task performance.

More details on the dataset statistics and metrics for each task for both benchmarks are in appendix A.2.

Baselines. We consider four baselines: (1) directly evaluating pretrained language models on the benchmarks (LM) ; (2) performing additional language modeling training on the subset of the original data that is used for constructing the self-supervised tasks (ExtraLM). We use ExtraLM to approximately measure the contribution of additional computation; (3) fine-tuning on training sets for the tasks outside the evaluation sets (CrossTask). We use CrossTask to estimate the performances of cross-task supervision from human-annotated datasets; and (4) fine-tuning on training sets for the tasks in the evaluation sets (SameTask). SameTask serves as an oracle baseline estimating the approximated upperbound performances of cross-task supervision.

Since SuperGLUE does not have an official split for the CrossTask setting, we split the datasets into two groups according to the task category and report the CrossTask results based on "CrossTask (QA→NLI)" and "CrossTask (NLI→QA)".[7] As we alter the task templates, we report results for evaluating the pretrained language model check-

---

[5] We exclude WSC (Levesque et al., 2011) and ReCoRD (Zhang et al., 2018) as pretrained models, including GPT3, require scoring algorithms at inference time to achieve competitive results. We exclude WiC (Pilehvar and Camacho-Collados, 2019) because GPT3-like models, including GPT3 and our models, do not give accuracies significantly better than random baselines.

[6] We discard training tasks that share the same source datasets with evaluation tasks as we found that tasks with the same source dataset may contain leaked labels. We exclude the binary classification tasks because the class labels are severely imbalanced (i.e., more than 80% of the class labels belong to one category).

[7] "QA→NLI" suggests that we train models on the NLI tasks and evaluate on the QA tasks. Similarly, for "NLI→QA", we train models on the QA tasks and evaluate on the NLI tasks.

points using the new templates (NewTemplate) to study the effect of new templates.

4.3 Results

We report the results for SuperGLUE and Natural-Instructions in Table 2 and Table 3. Our findings are as follows:

1. Our proposed self-supervised training achieves the best performance on average for both benchmarks.
2. ExtraLM and NewTemplate show similar performances as the pretrained language model checkpoints, suggesting that the improvements from our self-supervised training is unlikely to come from the additional training on the data and the task template changes.
3. Compared to the pretrained language model checkpoints, CrossTask shows worse performances on both benchmarks, which is likely due to the differences between training tasks and evaluation tasks.

5 Analysis

5.1 Effect of Amount of Data

In Figure 4, we report model performances for the 1.3B model on SuperGLUE and Natural-Instructions with 1%, 10%, 20%, 50%, and 200%

	ALL	ALL+MoreTask
SuperGLUE Results		
125M	51.0	50.9
1.3B	55.6	55.6
Natural-Instructions Results		
125M	30.0	31.7
1.3B	45.5	45.4

Table 6: Average results when adding denoising autoencoding and gap sentence prediction to the self-supervised training. ALL: use all of the self-supervision described in Sec. 3.

	LM	Correct Label	Random Label
SuperGLUE Results			
125M	46.2	51.0	38.2
1.3B	50.7	55.6	42.5
Natural-Instructions Results			
125M	28.6	30.0	19.1
1.3B	43.8	45.5	31.5

Table 7: Average model performance comparing whether we assign random labels to the self-supervised tasks.

of training examples.[8] We train the models for ten epochs.[9] As shown in the figure, when the amount of training data for self-supervised tasks is similar to that for the CrossTask setting (i.e., 1% data), the self-supervised tasks also lead to worse performances. The improvements become clearer when we increase the number of training data, but it begins to plateau at around 100% data. This suggests that one of the advantages of the self-supervised tasks compared to the tasks in the CrossTask setting is the amount of training data. We hypothesize that further increasing the amount of data not being helpful is because the data used for constructing the self-supervised tasks has already been used for language model pretraining. So, our models manage to learn to solve these tasks with a relatively limited amount of data. We have similar observations for the 125M model. See appendix A.8 for more details.[10]

5.2 Effect of Individual Self-Supervised Tasks

We investigate the effect of individual self-supervised tasks by training models with only one task. We report the experiment results in Table 4 and Table 5. More results and discussions are in appendix A.9. Our findings are:

	MS	GPT3 Template	Our Template
LM	125M	48.4	46.2
SelfSup	125M	47.2	51.0
LM	1.3B	51.8	50.7
SelfSup	1.3B	51.1	55.6

Table 8: Average results for SuperGLUE when using different task templates. MS=model size.

Model	MS	QG	AG	MM	VF	Avg.
LM	125M	**33.7**	12.9	53.0	14.7	28.6
CrossTask	125M	22.0	24.8	66.9	17.9	32.9
SelfSup.	125M	16.9	14.6	70.1	**18.9**	30.0
Combined	125M	23.5	**25.2**	**70.3**	18.5	**34.4**
LM	1.3B	40.9	32.5	74.0	27.8	43.8
CrossTask	1.3B	38.1	41.6	69.2	23.0	42.9
SelfSup.	1.3B	**43.9**	37.5	72.3	28.6	45.5
Combined	1.3B	42.1	**42.5**	**74.1**	**28.7**	**46.9**

Table 9: Natural-Instructions results when combining the self-supervised tasks and the tasks in the CrossTask setting. The best performance in each column for each model size is boldfaced. MS=model size.

1. Combining all four self-supervised tasks results in the biggest improvements for most tasks, suggesting that the tasks are complementary.
2. Each self-supervised task improves a few downstream task performances (e.g., NSG helps COPA; CL helps MultiRC and CB). This is likely due to similarities between tasks.
3. It is worth noting that while CL hurts model performances on Natural-Instructions, it helps on the SuperGLUE. We hypothesis that this is because unlike Natural-Instructions, SuperGLUE is ranking based and, therefore, more favorable to classification-related training.
4. It is interesting to see that NSG and CL tasks are the two most beneficial to downstream performance among the four self-supervised tasks. This is likely due to (1) the generic task formulation of NSG, and (2) CL requires different inference abilities compared to the other self-supervised tasks. It is also interesting that training on only one of the self-supervised tasks can hurt the performance on Natural-Instruction.

5.3 Effect of More Self-Supervised Tasks

To investigate the effect of having more self-supervised tasks during training, we add two extra self-supervised tasks to the self-supervised training,

---

[8] We apply the same ratio to all the self-supervised tasks and use the same development sets for each task across these settings.

[9] Upon manual inspection, we found that the development set loss values in these experiments have converged.

[10] Our goal for this analysis is to show the rough trends of model performance when varying the amount of training data, rather than to provide an exact estimate of the training data required for the self-supervised training.

Task Prompt	Task Input	Reference	LM	Self-Supervised
Construct a question from the given fact by a simple rearrangement of words.	Fact: Pollen seeds come from male gametes of plants.	what seeds come from male gametes of plants?	What might cause harm to plants?	What would you use to measure the number of male gametes of plants?
Ask a question on "event duration" based on the provided sentence.	Sentence: At the sight of the great man, Spear flushed crimson, and then his look of despair slowly disappeared; and into his eyes there came incredulously hope and gratitude.	How long did Spear see the great man?	How long did he stay in the Embassy?	How long did it take for Spear to look at the great man?
Answer the given question. Your answer must be a single span in the passage.	Passage: ... The following year he won a scholarship to the Royal Academy of Music, ... The principal of the Academy, Sir Alexander Mackenzie, had forbidden ... Question: What was the full name of the school Sir Alexander Mackenzie was principal of?	Royal Academy of Music.	Oliver.	the Royal Academy of Music.
Answer the given question. Your answer must be a single span in the passage.	Passage: ... Epitaph Records, founded by Brett Gurewitz of Bad Religion, was the base for many future pop punk bands ... The mainstream pop punk of latter-day bands such as Blink-182 is criticized by many punk rock devotees; in critic Christine Di Bella's words ... Question: What is the full name of the person that is very critical of modern mainstream pop punk bands?	Christine Di Bella.	the "Bad Religion".	many punk rock devotees.

Table 10: Generation examples by the 1.3B model. The examples are taken from Natural-Instructions. The first two examples are from QG, and the other two are from AG. We only show part of the passages relevant to the outputs for QA for brevity.

following the same procedure as the other tasks. The additional tasks are: denoising autoencoding (Lewis et al., 2020) and gap sentence generation (Zhang et al., 2020). Denoising autoencoding is the task of reconstructing the original sentences from sentences corrupted by random noises, which has been shown effective for training generic language representations; gap sentence generation is to recover the missing sentence and has been found useful for abstractive summarization.

We report the results in Table 6 where we do not find adding the two tasks improves downstream tasks. This is likely because the two tasks share similarities with our existing tasks (e.g., gap sentence generation shares a similar inference style as MWP). So, adding them does not promote diversity in the self-supervised tasks, leading to the fact that the models are not encouraged to learn different information.

5.4 Effect of Few-Shot Templates

The self-supervised training brings two benefits: making models familiar with the few-shot templates and task semantics. To differentiate the effect of the two, we train models on the self-supervised tasks with random labels. For example, for NSG, we use random sentences as outputs rather than the true next sentences; for the binary classification tasks, we randomly select binary labels. As shown in the results in Table 7, random labels hurt model performances, suggesting that what the models have learned is more than the few-shot templates.

We also investigate the effect of task templates for SuperGLUE by evaluating models using different templates. We report results in Table 8 where we find that having the templates for downstream tasks similar to the ones used for self-supervised training gives the models significantly better performances.

5.5 Zero-Shot vs. One-Shot vs. Few-Shot

We show zero-shot, one-shot, and few-shot performances for the LM and the self-supervised model in Table 11. We find that among the three settings, the self-supervised training is the most helpful in the few-shot setting and does not help in the zero-shot setting, suggesting that the self-supervised training improves the models' in-context learning capabilities.

	Zero-Shot		One-Shot		Few-Shot	
	LM	SS	LM	SS	LM	SS
125M	46.7	44.3	42.6	46.1	46.2	51.0
Δ	(-2.4)		(+3.5)		**(+4.8)**	
1.3B	49.5	49.9	46.5	50.8	50.7	55.6
Δ	(+0.4)		(+4.3)		**(+4.9)**	

Table 11: Average results for SuperGLUE showing the zero-shot, one-shot, and few-shot model performances for the LM and the self-supervised model (SS). The numbers in parenthesis are the performance differences between the LM and the SS with the positive numbers indicating improvements. We boldface the largest improvement for each model.

5.6 Combine Self-Supervision with Cross-Task Human-Supervision

We investigate the relations between the self-supervised tasks and the human-annotated tasks. We combine the tasks from the self-supervision and those from the CrossTask and report the results in Table 9. Interestingly, combining the two kinds of tasks results in better performances on average, showing that they are complementary.

5.7 Generation Examples

We show generation examples in Table 10. In general, we find that compared to the vanilla pretrained language models, the self-supervised models are better at using information from task input following task requirements. Specifically, for the first two examples in Table 10, the LM suffers from more severe semantic drift than the self-supervised model (e.g., “male gametes of plants” is more specific and relevant to the task input than “plants”). We have similar observations for the third example, where “Oliver” is a name from the task demonstration rather than the passage. Interestingly, for the last example, the answer generated by the LM is from the passage but is actually “the base for many future pop punk bands” instead of what the question looks for (i.e., “very critical of modern mainstream pop punk bands”). While the answer generated by the self-supervised model does not exactly match the reference, it is partially correct as the mainstream pop punk “is criticized by many punk rock devotees”.

6 Conclusion

We evaluated four self-supervised objectives on two few-shot benchmarks by casting the self-supervised training as an intermediate training stage between language model pretraining and downstream few-shot evaluation. Empirically, we have shown that the models trained by the self-supervised objectives show the best performances compared to strong baselines on average. Analysis showed that (1) the amount of self-supervised training data and the diversity of the self-supervised tasks can affect the downstream performances.; (2) the self-supervised tasks are complementary to the human-annotated datasets; and (3) the self-supervised-trained models are better at following task requirements.

A Appendix

A.1 Additional Details for LPP and Classification Tasks

The label strings we used for LPP are as follows: Yes and No, Y and N, True and False, and T and F. We randomly choose from Yes, Y, True, and T as the label string for the positive label and use the other one in the selected pair as the negative label.

The label strings we used for the binary classification task are the same as the classification LPP task. For the three-way classification task, we use the following label strings: Positive and Negative and Neutral, True and False and Neither, T and F and N, Yes and No and Unknown, Y and N and U.

A.2 Dataset Statistics

We report dataset statistics for SuperGLUE and Natural-Instructions in Table 12 and Table 13, respectively.

A.3 Training Details

We train our models in PyTorch (Paszke et al., 2017) using FAIRSEQ (Ott et al., 2019).

A.4 More Details for Natural-Instructions

Dataset Sources. CosmosQA (Huang et al., 2019), DROP (Dua et al., 2019), EssentialTerms (Khashabi et al., 2017), MCTACO (Zhou et al., 2019), MultiRC (Khashabi et al., 2018), QASC (Khot et al., 2020), Quoref (Dasigi et al., 2019), ROPES (Lee et al., 2021) and Winogrande (Sakaguchi et al., 2020).

Training Datasets. We used the following 8 datasets when training models in the cross-task setting: subtask026_drop_question_generation, subtask060_ropes_question_generation, subtask028_drop_answer_generation, subtask047_misc_answering_science_questions, subtask061_ropes_answer_generation, subtask059_ropes_story_generation, subtask027_drop_answer_type_generation, subtask046_miscellaenous_question_typing.

Dataset	Task Category	Metrics	#Train	#Test	#Class
BoolQ	Question Answering	Accuracy	9427	3270	2
MultiRC	Question Answering	F1_a/EM	5100	953	2
COPA	Question Answering	Accuracy	400	100	2
RTE	Natural Language Inference	Accuracy	2500	278	2
CB	Natural Language Inference	Accuracy/F1	250	57	3

Table 12: Dataset statistics for SuperGLUE. We use the official development sets as test sets.

Dataset	Task Category	#Train	#Test
subtask003_mctaco_question_generation_event_duration	Question Generation	330	100

A.5 List of Function Words for the Last Phrase Prediction Task

We used the following function words for identifying the last phrase: the, a, an, for, including, and, in, is, are, were, was, neither, or, nor, be, at, in, on, by, to, would, will, before, after, of, about, from, excluding, except, during, under, above, then, into, onto, should, shall, must, may, might, than, with, using, can, could, about, as, from, within, without, have, had, been.

A.6 Templates for SuperGLUE

We show the SuperGLUE templates in Table 14.

A.7 Hyperparameters

We tune the hyperparameters based on development set performances. We tune the learning rate in {1e-7, 5e-7, 1e-6, 3e-6, 5e-6, 8e-6, 1e-5, 3e-5, 5e-5}, and the attention dropout rate in {0.0, 0.1}.

A.8 Effect of Amount of Data

In Figure 5, we report model performances for the 125M and 1.3B models on SuperGLUE and Natural-Instructions with 1%, 10%, 20%, 50%, and 200% of training examples.

A.9 Effect of Individual Self-Supervised Task to Downstream Tasks

We investigate the effect of individual self-supervised task by considering two experiment settings: training models with only one task and training models with one task excluded. We report the experiment results in Table 15, Table 16, Table 17, and Table 18. Our findings are:

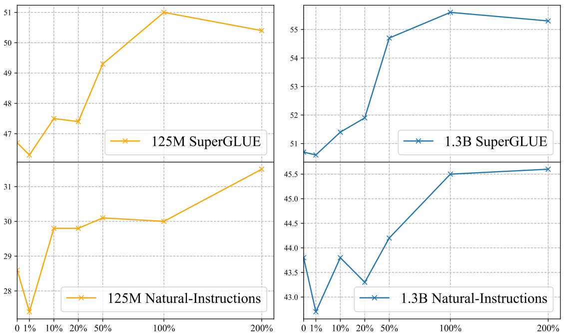

Figure 5: Average results on SuperGLUE and Natural-Instructions when varying number of examples used for training.

1. Combining all the four self-supervised tasks gives the largest improvements for most tasks, suggesting that these tasks are mostly complementary.

2. Each self-supervised task improves a few downstream task performances (e.g., NSG helps COPA; CL helps MultiRC and CB). This is likely due to the semantic similarities between tasks.

3. It is worth noting that (1) while CL hurts model performances on Natural-Instructions, it helps on the SuperGLUE; and (2) excluding NSG hurts the model performances most on Natural-Instructions whereas excluding CL hurts the most on SuperGLUE. This presumably is because SuperGLUE is ranking based and therefore is more favorable to classification-related training, whereas the tasks in Natural-Instructions are generation tasks and thus benefits more from generation-related tasks.

Table 14: Evaluation templates for SuperGLUE. ${·} represents values drawn from a particular data field. We alter the GPT3 templates for these tasks to share similar formats with one of our self-supervised tasks. The red, boldfaced texts are used to compute the language modeling perplexities for ranking the labels. We note that the shown templates are for a single example, and there could be multiple examples within an instance.

Model	**BQ**	**MC**	**CA**	**RE**	**CB**	**Avg.**
LM	52.2	26.6	63.0	50.8	38.3	46.2
SelfSup.	55.7	33.6	67.6	53.0	44.9	51.0
NSG	52.1	25.9	64.0	51.0	41.2	46.9
CL	52.5	26.8	61.4	50.9	48.1	47.9
MWP	51.9	26.3	61.8	50.8	36.1	45.4
LPP	53.5	29.5	61.6	52.0	40.3	47.4

Table 15: SuperGLUE results when training the 125M model with one of the self-supervised tasks.

Model	**QG**	**AG**	**MM**	**VF**	**Avg.**
LM	33.7	12.9	53.0	14.7	28.6
SelfSup.	16.9	14.6	70.1	18.9	30.0
NSG	32.3	12.5	54.0	13.8	28.2
CL	8.3	0.3	1.0	2.7	3.1
MWP	15.2	19.4	50.5	17.8	25.7
LPP	11.3	16.6	49.5	19.9	24.3

Table 16: Natural-Instructions results when training the 125M model with one of the self-supervised tasks.

4. It is interesting to see that among the four self-supervised tasks, NSG and CL tasks are the two most important factors in terms of affecting the downstream performances. This is likely due to (1) the generic task formulation of NSG and it being the only sentence generation tasks; and (2) the drastic differences between CL and the other self-supervised tasks with respect to their inference styles. Unlike NSG/MWP/LPP, which models can rely on input within each example to solve the task, CL require models to make comparisons across examples in a training instance.

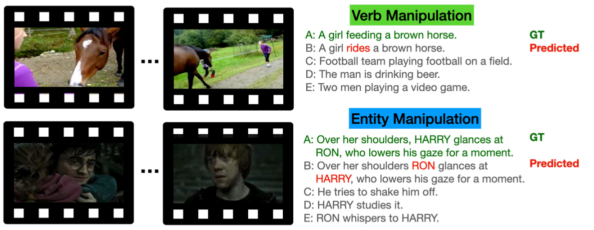
Abstract

Recent video-text models can retrieve relevant videos based on text with a high accuracy, but to what extent do they comprehend the semantics of the text? Can they discriminate between similar entities and actions? To answer this, we propose an evaluation framework that probes video-text models with hard negatives. We automatically build *contrast sets*, where true textual descriptions are manipulated in ways that change their semantics while maintaining plausibility. Specifically, we leverage a pre-trained language model and a set of heuristics to create verb and person entity focused contrast sets. We apply these in the multiple choice video-to-text classification setting. We test the robustness of recent methods on the proposed automatic contrast sets, and compare them to additionally collected human-generated counterparts, to assess their effectiveness. We see that model performance suffers across all methods, erasing the gap between recent CLIP-based methods vs. the earlier methods. [1]

1 Introduction

Relating video and text modalities is one of the important goals in vision and language. Video is a complex signal where people and objects act and interact with each other through space and time. Thus correctly associating a textual description and a video requires understanding of entities, their actions and much more, making it a hard problem.

One of the popular ways of training and evaluating video-text models is via cross-modal matching. Often the task is formulated as a retrieval problem, where the goal is to select the correct match among many (e.g. thousand) candidates, and distractors are picked randomly (Yu et al., 2018). Another way is via multiple-choice prediction, where the goal is to pick the true match out of several (e.g. 5) candidates (Torabi et al., 2016). The latter allows for more controlled choice of negatives, which are typically selected from other videos. Commonly, the retrieval setting is used during training to avoid capturing any specific multiple-choice patterns or biases, while both are used for evaluation.



A: A girl feeding a brown horse.
B: A girl rides a brown horse.
C: Football team playing football on a field.
D: The man is drinking beer.
E: Two men playing a video game.

A: Over her shoulders, HARRY glances at RON, who lowers his gaze for a moment.
B: Over her shoulders RON glances at HARRY, who lowers his gaze for a moment.
C: He tries to shake him off.
D: HARRY studies it.
E: RON whispers to HARRY.

Figure 1: Samples of our video-to-text tasks on the MSR-VTT (Xu et al., 2016) and LSMDC dataset (Rohrbach et al., 2017; Park et al., 2020). A hard negative option is added by manipulating verb (top) and entity (bottom) in the ground truth sentence. Two SOTA methods MMT (Gabeur et al., 2020) and CLIP4CLIP (Luo et al., 2021) incorrectly choose the manipulated sentence (option B) in *both* these cases.

Recent methods that leverage the large-scale CLIP model (Radford et al., 2021) show significant improvement in cross-modal matching, specifically, in the retrieval setting (Fang et al., 2021; Luo et al., 2021). They outperform the prior state-of-the-art methods, often based on the Multimodal Transformer design (Miech et al., 2020; Gabeur et al., 2020; Lei et al., 2021). However, we know that often model performance is "over-estimated" due to the lack of challenging samples in evaluation. For instance, Gardner et al. (2020) show that model performance on several NLP tasks and one image-text task is much lower on *contrast sets*, which are test samples with small perturbation done by human experts in a way that changes the gold label.

In this work, we are investigating whether the video-text models also struggle in an evaluation framework that probes them with hard negatives. Instead of using human-designed contrast sets that are not easily scalable, we propose an automated pipeline that can generate contrast sets via verb and

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3574 - 3586
July 10-15, 2022

human entity manipulation. Our manipulations are carefully designed to preserve fluency but change semantics of the textual descriptions, making them invalid for a given video. We focus on *entities* and *verbs* to evaluate if the model can truly understand "who did what" in a video. Inspired by (Li et al., 2020; Morris et al., 2020), we leverage a generative T5 language model (Raffel et al., 2020) to manipulate the verb phrase and use heuristics to swap person entities. Note that our pipeline does not require a trained video-text model in the loop.

We apply our automatic manipulations to two popular video-text benchmarks, MSR-VTT (Xu et al., 2016) and LSMDC (Rohrbach et al., 2017). We additionally collect human generated contrast sets to compare with our automatic ones. To make sure that our automatic negatives are of high quality, we also confirm that humans can successfully select the correct description for a given video with our hard negatives. Finally, we benchmark several video-text models on our contrast sets. We find that all methods degrade in performance with the introduction of hard negatives in the multiple-choice setting (Figure 1). This includes the recent CLIP-based works that demonstrated large gains in the retrieval setting. This shows that all methods have difficulty discriminating between entities and verbs when the remaining context is unchanged. We observe that model performance drops especially on cases such as verb antonym swaps, where fine-grained action understanding is important.

2 Related Work

Defending and generating adversarial examples (Jia et al., 2019; Jin et al., 2020) have been mostly explored in NLP since the reign of pre-trained language models (LMs) (Devlin et al., 2019). Li et al. (2020); Garg and Ramakrishnan (2020); Morris et al. (2020) show that substituting words in a sentence with masked LMs (Devlin et al., 2019; Liu et al., 2019) can successfully mislead the classification and entailment model predictions to be incorrect. Template-based (McCoy et al., 2019; Glockner et al., 2018) and manually crafted (Gardner et al., 2020) perturbations on evaluation datasets have also been studied for textual entailment. Ribeiro et al. (2020) have curated a list of checklists to reveal bugs present in NLP models.

Language-based adversarial examples can be collected to study the robustness of vision-language models as well. Shekhar et al. (2017) introduces FOIL-COCO dataset to evaluate the vision-language model's decision when associating images with both correct and "foil" captions. Akula et al. (2020) measure the robustness of visual referring expression models by checking if grounding is performed correctly after word manipulation. Hendricks and Nematzadeh (2021) show that vision-language Transformers are worse at verb understanding than nouns. New versions of the VQA dataset (Antol et al., 2015) are proposed to study robustness of VQA models (Shah et al., 2019; Li et al., 2021). Bitton et al. (2021) automatically generate contrast sets from scene graphs to probe compositional consistency of VQA models. Our work is different in that we use pre-trained LMs to introduce perturbations and evaluate robustness of *video*-language models.

3 Designing Contrast Sets

In this section we present our approach to automatically constructing *text-based* contrast sets for video-language tasks. Suppose we are given a video V_i and description s_i. Contrast sets $\hat{C}_i = \{\hat{s_1}, ..., \hat{s_i}\}$ are designed such that $\hat{s_i}$ is semantically inconsistent with V_i and yet models incorrectly select $\hat{s_i}$ over s_i in a video-to-text multiple-choice setting. While there are different ways to create valid $\hat{C}_i$, we investigate manipulating 1) *person entities* and 2) *verb phrases* in the original descriptions. Qualitative examples of $\hat{C}$ are shown in Table 1.

3.1 Contrast Sets for Person Entities

First, we investigate automatically swapping the name (or *identity*) of a person. The LSMDC dataset (Rohrbach et al., 2017; Park et al., 2020) includes movie descriptions with character identities (e.g. *Harry Potter*), and a list of characters present in each movie along with their gender. We replace each character's ID with one from the same movie and with the same gender, to prevent the language statistics alone from detecting the swapped IDs.

For the MSR-VTT dataset (Xu et al., 2016) we do not have the identities; however, 80% of videos have gender cues in the descriptions. Thus the contrast sets are created by swapping the gender of a person mentioned in a sentence and the corresponding pronouns (e.g., *A woman is pushing her stroller* → *A man is pushing his stroller*). This is done with a template that maps gender-sensitive words and pronouns to their counterparts (see Appendix).

Dataset	Original	Person Entity	Verb Phrase
MSRVTT	1. Two men are doing wrestling.	Two women are doing wrestling.	Two men are dancing.
	2. A man in black shirt is talking with his two friends.	A woman in black shirt is talking with her two friends.	A man in black shirt is running with his two friends.
LSMDC-ID	3. His gaze steely, Jenko lowers his gun.	His gaze steely, Schmidt lowers his gun.	His gaze steely, Jenko raises his gun.
	4. Jenko and Schmidt sit in the rear pew.	Zach and Schmidt sit in the rear pew.	Jenko and Schmidt stand in the rear pew.

Table 1: Examples of person entity and verb phrase based contrast sets in MSR-VTT and LSMDC-IDs dataset.

3.2 Language Model Generated Verb Contrast Sets

The above rule-based strategies cannot be directly translated to create contrast sets for verb phrases: 1) a substitute verb phrase is not guaranteed to be inconsistent with a video, and 2) the sentence may look unnatural and no longer be textually plausible. Based on their success in adversarial attack generation (Li et al., 2020; Garg and Ramakrishnan, 2020; Morris et al., 2020), we instead leverage pretrained language models (LMs) to automatically manipulate the verb phrases.

We identify verb phrases in a sentence using Spacy (Honnibal and Montani, 2017), replace them with a mask token [MASK], and select top K phrases that best fit the mask token using probability scores from a LM. Different from prior work (Li et al., 2020), we use T5-base model (Raffel et al., 2020) instead of masked language models (Devlin et al., 2019; Liu et al., 2019) to easily support generating multi-word candidates. We additionally finetune T5 to learn verb phrases in the downstream training data with unsupervised denoising objective (Raffel et al., 2020). This is done to mitigate the possible distribution shift between ground truth and manipulated descriptions, which could be exploited to distinguish between the two.

We then filter the K sentence candidates with the following criteria: 1) There is no verb in the sentence. 2) Verbs are rare or unseen in training descriptions. 3) The sentence has a high perplexity measured by GPT2-XL (Radford et al., 2019) to ensure grammaticality and plausibility (Morris et al., 2020). Lastly, we check that the semantics of a candidate is *inconsistent* with the original sentence. This is when *a)* a candidate verb is an antonym[2] of an original verb, or *b)* a word embedding (Mrkšić et al., 2016) of candidate and original verbs and their sentence encodings (Reimers and Gurevych, 2019) both have low cosine similarity scores. We handle the antonyms separately, as the embedding-based scores do not adequately capture these, i.e., a sentence with an antonym verb may still be considered semantically close to an original sentence.

3.3 Human-Generated Verb Contrast Sets

Are language models capable of generating contrast sets of good quality? To answer this question, we follow the original contrast sets work (Gardner et al., 2020), and also create negatives manually to see if the performance on machine and human generated contrast sets is similar. We use the Amazon Mechanical Turk (AMT) platform and ask workers to modify a verb phrase such that a sentence becomes inconsistent with a video (see Appendix).

4 Experiments

4.1 Datasets and Multiple Choice Design

MSR-VTT (Xu et al., 2016) is composed of 10K YouTube videos each paired with 20 natural descriptions and is typically evaluated on retrieval performance with 1000 video text pairs as candidates in the test set. The multiple choice version (Yu et al., 2018) has 2,990 test videos as queries, and a positive caption with 4 random captions from other videos as 5 answer options. We label this split as the *Random MC*. We design another MC problem by replacing one negative option with one from our contrast sets. In particular, *Gender MC* swaps gender in an original sentence; *Verb*$_{LM}$ *MC* and *Verb*$_{H}$ *MC* include verb-based negatives generated by our approach and by humans.

LSMDC (Rohrbach et al., 2017) includes short movie clips and captions. Characters in these captions are labeled as SOMEONE and we cannot construct contrast sets for person-entities. We instead use captions in (Park et al., 2020) that include

CLIP2Video	**43.3**	98.3	78.5	81.1	79.0
Human	-	-	-	92.7	94.5

Table 2: Method comparison on **MSR-VTT** dataset. Human is majority vote over 3 judges.

Approach	V → T R@1	Random MC	ID MC	Verb$_{\mathrm{LM}}$ MC	Verb$_{\mathrm{H}}$ MC
CLIP zero-shot	4.3	53.3	39.8	38.9	35.7
MMT	17.7	73.2	65.2	56.2	56.9
MMT-CLIP	23.8	**74.8**	**70.1**	**56.9**	**58.7**
CLIP4CLIP	**25.0**	72.9	69.1	54.1	57.5
Human	-	-	-	90.2	92.8

Table 3: Method comparison on **LSMDC-IDs** dataset. Human is majority vote over 3 judges.

the character identities. We create a new split using the same movies in training and test so that the test identities have been seen during training. We call this modified dataset **LSMDC-IDs**. Using this set, *Random MC* is newly defined with 4 negative captions drawn randomly from different clips of the same movie. *ID MC* swaps the character IDs (Section 3.1) as negatives, and *Verb MC* includes the verb contrast sets, as before.

4.2 Video-Text Models and Evaluation

We benchmark Transformer (Vaswani et al., 2017) based video-language models in our experiments. Portillo-Quintero et al. (2021) apply frozen CLIP features (Radford et al., 2021) to perform zero-shot video to text retrieval (CLIP zero-shot). Multi Modal Transformer (MMT) (Gabeur et al., 2020) learns the joint representation between text and multiple modalities in videos. Inspired by Dzabraev et al. (2021), we also extend MMT to take frozen CLIP features as input, denoted as MMT-CLIP. CLIP4CLIP (Luo et al., 2021) and CLIP2Video (Fang et al., 2021) directly finetune CLIP with temporal pooler and are the state-of-the-art in retrieval tasks. ViT-B/32 model is used for all CLIP experiments (see Appendix C for details). We train the above models with a contrastive loss to learn the joint video-text representation. In MC settings, we mark it as correct, if a ground truth sentence is scored the highest. In addition, we also evaluate humans on the MC task. We report video-to-text (V → T) Recall@1 for retrieval evaluation.

4.3 Results

Table 2 shows results on the MSR-VTT dataset. In video-to-text retrieval, we see a significant gap in performance between the CLIP-finetuned models and all other models. Moreover, CLIP zero-shot matches MMT in this metric. Next, we see that *Random MC* is nearly solved by almost all models. However there is a significant drop in performance across all models when evaluated on contrast-set based MC. Interestingly, the performance gap between MMT and the finetuned CLIP models with high retrieval performance (CLIP4CLIP and CLIP2Video) is gone in this setting, meaning stronger retrieval performance does not guarantee robustness to word-level manipulations. We also observe that models with frozen CLIP features perform better on *Gender MC* than *Verb MC*, and fine-tuning the CLIP features on video-language task can make the model less sensitive to gender information. Finally, to verify that the automated verb-based contrast sets are valid, we note that: models on *Verb$_{LM}$ MC* perform on par with the human produced ones *Verb$_{H}$ MC*, and humans maintain accuracy greater than 90% on both contrast sets.[3]

Table 3 presents results on the LSMDC-IDs dataset. We find that distinguishing different clips of the same movie (*Random MC*) is not "solved" by the models unlike the MSR-VTT. We also notice that the ID swaps are significantly easier than the verb swaps, and CLIP features are particularly helpful in distinguishing different character IDs (MMT vs. MMT-CLIP). Table 4 shows that model accuracy drops by at least 13.9% when the "negative" IDs appear more frequently in the training data than the original IDs, meaning the models struggle to identify IDs in the long-tail. The results on verb contrast sets are similar to the MSR-VTT dataset. The performance is much lower on contrast-set MC cases than *Random MC*. There is no significant gap between *Verb$_{LM}$ MC* and *Verb$_{H}$ MC*. Our automated contrast sets are still valid as humans perform above 90% for both cases.

Does Semantic Proximity in Verb Contrast Sets Affect the Model Performance? To answer this, we first considered a subset containing verb antonyms. For the remaining ones, we use the off-the-shelf sentence encoders, SentBERT (Reimers and Gurevych, 2019) and CLIP text transformer

---

[3] We report majority vote over 3 human judges.

Original: A lady is **holding** a taco salad.

Verb Contrast Set: A lady stirs a taco salad.

Original: A woman opening a package and **pulling** something out.

Verb Contrast Set: A woman opening a package and pushing something out.

Original: Helen **wipes** her nose.

Verb Contrast Set: Helen points to her nose.

Original: Todd **raises** an arm victoriously, and so does Olive.

Verb Contrast Set: Todd lowers an arm victoriously, and so does Olive.

Figure 2: Example failure cases where MMT and CLIP4CLIP prefer a negative sentence over an original one. Despite "watching" the video, the models have difficulty distinguishing fine grained actions (e.g. *hold vs. stir*, *wipe vs. point*), and verb antonyms (*pulling vs. pushing*, *raise vs. lower*.

	Overall	Rare	Δ
MMT	65.2	48.4	16.8
MMT-CLIP	70.1	56.2	13.9
CLIP4CLIP	69.1	54.2	14.9

Table 4: Accuracy for *ID MC* in **LSMDC-IDs** dataset. We show the overall accuracy and accuracy when the original ID was more rare than the swapped ID (Rare). Δ is the difference between the two accuracies.

	Verb Antonyms	SentBERT High	SentBERT Low	CLIP-Text High	CLIP-Text Low
CLIP zero-shot	53.8	63.5	76.9	60.4	72.3
MMT	67.6	79.6	95.3	80.2	89.8
CLIP4CLIP	70.6	77.6	95.7	77.0	92.4
Human	92.9	92.2	94.1	91.6	94.3

Table 5: Model accuracy on $Verb_{LM}$ *MC* in **MSR-VTT**. We show contrast sets with verb antonyms, and remaining subsets with the highest (High) and lowest (Low) 15% semantic similarity with the original sentence (High and Low). Similarity scores are calculated using: SentBERT (Reimers and Gurevych, 2019) and CLIP text encoder (Radford et al., 2021).

(Radford et al., 2021), to measure the semantic proximity b.w. the original and negative sentences, and select the ones with the highest and lowest 15% according to these scores (High/Low)[4]. We present the results on MSR-VTT in Table 5. We notice that the models especially struggle with antonyms, such as dropping from 83.7% (in Table 2) to 70.6% for CLIP4CLIP. Humans on the other hand get 92.9% accuracy and show no difference in their performance. The best models achieve high accuracy on par with humans on semantically different examples (Low) as measured by both SentBERT amd CLIP-Text. However, model performance is much lower for contrast sets with high semantic similarity (High), whereas human performance is not as affected (e.g. CLIP4CLIP drops to 77.6% and humans maintain 92.2% accuracy on SentBERT). In Figure 2, we show failure cases where the SOTA models are misled by semantically close sentences and verb antonyms, due to their lack of fine-grained understanding of actions in the video.

5 Conclusion

We present a pipeline to build automatic contrast sets for video and language tasks, focused on manipulating person entities and verb phrases. We show that models struggle on contrast sets compared to random negatives, and stronger retrieval models do not show better robustness to hard negatives. For verb contrast sets, we find that model performance is strongly correlated with semantic proximity, unlike humans. We leave it as future work to use automatic contrast sets in training to improve model robustness, and designing contrast sets for different concepts/parts of speech.

---

[4] These subsets are disjoint from the antonym set to avoid scoring antonyms as semantically similar (see Section 3.2).

6 Ethical Considerations

Our goal is to diagnose performance of video-language models on hard negative samples w.r.t. verbs and person entities. Overall, we envision positive impact from this work, as it aims to expose limitations of the existing models. Some of our entity swaps focus on apparent gender (as described by humans in the video-text datasets), but we do not predict biological sex or gender identity. We construct our verb-focused contrast sets automatically, using a large generative language model, thus potentially some biases present in such a model could propagate into our hard negative samples. Practitioners who wish to use our contrast sets should be mindful of such sources of bias.

Male Nouns	**Female Nouns**
man → woman	woman → man
men → women	women → men, guys
boy → girl	girl → boy, guy
boys → girls	girls → boys, guys
guy → woman, girl	lady → man, guy
guys → women, girls, ladies	ladies → men, guys

Table 6: List of gender sensitive words mapped to a different gender. Note, that singular and plural form is maintained.

A Contrast Set Construction

Here, we provide more details on construction of each contrast set.

A.1 Gender Contrast Sets

Table 6 shows the mapping of gender-sensitive words. We use these rules to swap only a single word in the sentence. This is to guarantee that swapping gender leads to different semantics (e.g. *man and woman walk together → woman and man walk together* both apply to the same video if all words are swapped). If there are more than one possible mappings, we randomly sample one from a uniform distribution. Lastly, we swap all gender-sensitive pronouns that have the same gender as original noun. These contrast sets are used for the MSR-VTT dataset (Xu et al., 2016).

A.2 Person ID Contrast Sets

The first character ID in a sentence is replaced by a different character ID that appears in the same movie and has the same gender. Among all the candidates, the manipulated ID is sampled from a uniform distribution. The following character IDs in the same sentence have uniform chance of being kept or swapped using the same strategy. These contrast sets are used for the LSMDC-IDs dataset.

A.3 Verb Contrast Sets

Attack Selection We use Spacy to get the POS tags, and find verb phrases that match a list of pre-defined patterns (verb; verb + preposition).

Candidate Generation We use T5 model and performed beam search (beam size = 50) to generate $K = 50$ multi-word candidates.

Candidate Constraints We keep a candidate if the lemmatized verbs [5] in it appeared more than 30 times in the training set. For fluency, we calculate perplexity score of original and manipulated sentence using GPT2-XL (Radford et al., 2019), which we call ppl_o and ppl_m. We calculate the normalized difference of perplexity scores $\text{ppl}_{\text{diff}} = \frac{\text{ppl}_o - \text{ppl}_m}{\text{ppl}_o}$ to remove a candidate that is less plausible than the original. Specifically, candidates are kept if $\text{ppl}_{\text{diff}} < 0.6$, or $\text{ppl}_{\text{diff}} < 1.4 \cap \text{ppl}_m < 750$. Lastly, the semantic inconsistency constraints are satisfied if the word embedding (Mrkšić et al., 2016) of the lemmatized verbs in the candidate and original sentence have cosine similarity score lower than 0.4, and the sentence embeddings (Reimers and Gurevych, 2019) have cosine similarity score lower than 0.8.

B Human vs Machine Generated Verb Contrast Sets

Figure 3 shows a distribution of machine and human generated verb contrast sets. Each instance is the number of lemmatized verbs divided by total number of verbs in the contrast sets. We see that machine generated contrast set is more skewed to the left, and doesn't share the same distribution of verbs as in the human generated contrast sets. (e.g. human contrast sets have more occurrences of *cry* and *throw* in MSR-VTT, and *jump* and *drop* in LSMDC-IDs). Despite the difference, note that models have similar performances in both contrast sets.

C Implementation Details

- **MMT** (Gabeur et al., 2020): We use the following features extracted from video[6]: motion from S3D (Xie et al., 2018), audio from VGGish (Hershey et al., 2017), scene embeddings, face, OCR, Speech, and Appearance. We refer to Miech et al. (2018); Gabeur et al. (2020) for more details about the features.

  For MSR-VTT, we use the released checkpoint from their code[7], which is pre-trained on HowTo100M dataset (Miech et al., 2019) and further finetuned on MSR-VTT.

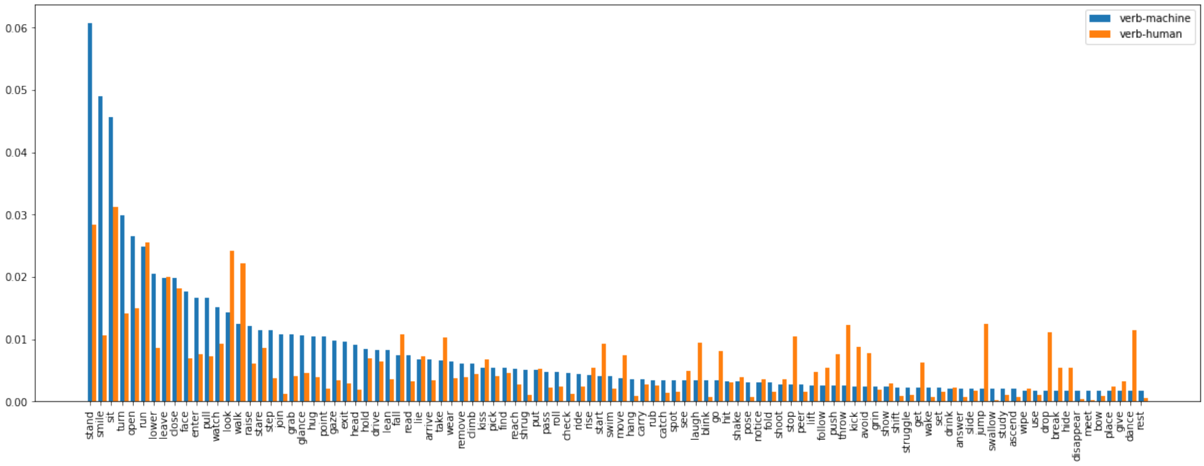
(a) Verb contrast sets in MSR-VTT



(b) Verb contrast sets in LSMDC-IDs

Figure 3: Distribution of machine and human generated verb contrast sets in the MSR-VTT and LSMDC-IDs dataset. Each instance is the ratio of lemmatized verbs within each contrast set.

For LSMDC-IDs which needs re-training, we used their finetuning code for LSMDC dataset (Rohrbach et al., 2017). The model is trained with max margin ranking loss on 1 Nvidia RTX-6000 GPU for 12 hours. Hyperparameter search was done to find margin of 0.05, batch size of 32, and Adam optimizer (Kingma and Ba, 2015) with learning rate $5e^{-5}$. The best model was selected by the video-to-text retrieval performance with Recall@1. We found training from scratch performs better than using pre-trained model. This has been also observed by Gabeur et al. (2020) for the LSMDC dataset.

- **MMT-CLIP**: We replace the appearance features in MMT with frozen CLIP ViTB/32 features and train with the same architecture.
- **CLIP zero-shot:** In (Portillo-Quintero et al., 2021) CLIP(ViTB-32) (Radford et al., 2021) features are aggregated via mean pooling to approximate video representation. This video representation and text embedding from CLIP are combined to perform retrieval and MC in a zero shot manner.
- **CLIP4CLIP** (Luo et al., 2021): We use the hyperparameters from the finetuning code[8] to reproduce their results. We use mean pooling for the similarity calculator and CLIP model is initialized with ViTB-32 weights. The model was trained with 4 Nvidia RTX-6000 GPUs for 5 epochs (48 gpu hours). The best model was selected by using Recall@1 in video-to-text retrieval.

---

[8] `https://github.com/ArrowLuo/CLIP4Clip`

- **CLIP2Video** (Fang et al., 2021): We used the released checkpoint on MSR-VTT using their code base[9]. This model is not used for LSMDC-IDs because finetuning code was not provided. CLIP model is initialized with ViTB-32 weights.

D Multiple Choice Details

Here we provide more details about our evaluation data. Note, that we use 5 text candidates (1 positive and 4 negative) for all multiple choice (MC) settings.

D.1 MSR-VTT

We use the standard train/val/test split in MSRVTT dataset (Xu et al., 2016).

- Retrieval: 1,000 ground truth video-text pairs in the test set (Yu et al., 2018).
- Random MC: 2,990 videos and all negative options are drawn randomly from other videos (Yu et al., 2018).
- Gender MC: 2,477 video-text instances. Using the original descriptions from Random MC, a single negative is drawn from gender contrast sets to replace one of the options in Random MC (the remaining 3 are kept). Note, that not all videos involved people or contained gender-sensitive words in descriptions, hence some instances are filtered.
- Verb$_{LM}$ MC: 2,554 video-text instances. Constructed using the same strategy as in Gender MC but a single negative is drawn from verb contrast sets generated by language models. Instances are filtered when there are no valid verb contrast sets satisfying constraints in Section A.3.
- Verb$_{H}$ MC: 2,554 video-text instances. We use the instances in Verb$_{LM}$ MC, and a negative is drawn from human designed verb contrast sets.

D.2 LSDMC-IDs

We define a new split using LSMDC-ID descriptions with character IDs (proper names) (Park et al., 2020). Note, that Rohrbach et al. (2017); Park et al. (2020) use development and test sets where videos come from distinct movies than the training data, meaning that IDs in test data are not seen in training. To overcome this issue, we split their *training* descriptions into 80%/10%/10%/ ratio to create new training/validation/test sets that *share* the same movies and identities across splits.

- Retrieval: 7,010 ground truth video-text pairs.
- Random MC: 7,010 videos, negative text options drawn randomly from different videos but the same movie.
- ID MC: 7,010 video-text instances. We replace one negative in Random MC with the one from ID contrast sets.
- Verb$_{LM}$ MC: 7,010 video-text instances. We replace one negative in Random MC with one from the language model generated verb contrast sets.
- Verb$_{H}$ MC: 3,500 video-text instances. We replace one negative in Random MC with one from the human designed verb contrast sets (we only crowdsourced 3,500 instances).

E Human Annotation Details

We ran two different human annotations, one to evaluate our Verb$_{\text{LM}}$ MC and another to manually design verb contrast sets. Figures 4 and 5 show the respective HIT UIs. We use Amazon Mechanical Turk interface to get a pool of annotators from native Enlgish speaking countries and with high approval rate, and pay them $15 hour on average which is above a minimum wage.

F Dataset Details

We include additional information on the MSR-VTT (Xu et al., 2016) and LSMDC (Rohrbach et al., 2017) datasets. MSR-VTT contains diverse YouTube videos and corresponding crowdsourced descriptions in English language. LSMDC contains movie clips and associated descriptions from scripts or Audio Description, also in English. Both datasets are distributed for research use. The license, personally identifiable information (PII), and consent details of each dataset are in the respective papers. Since LSMDC contains clips from movies, some may contain nudity or violence, etc.

---

Overview

Thanks for participating in this HIT!

In this HIT, you'll be given an **video** and **5 candidate sentences.** Your task is to select the **best sentence** describing the video.

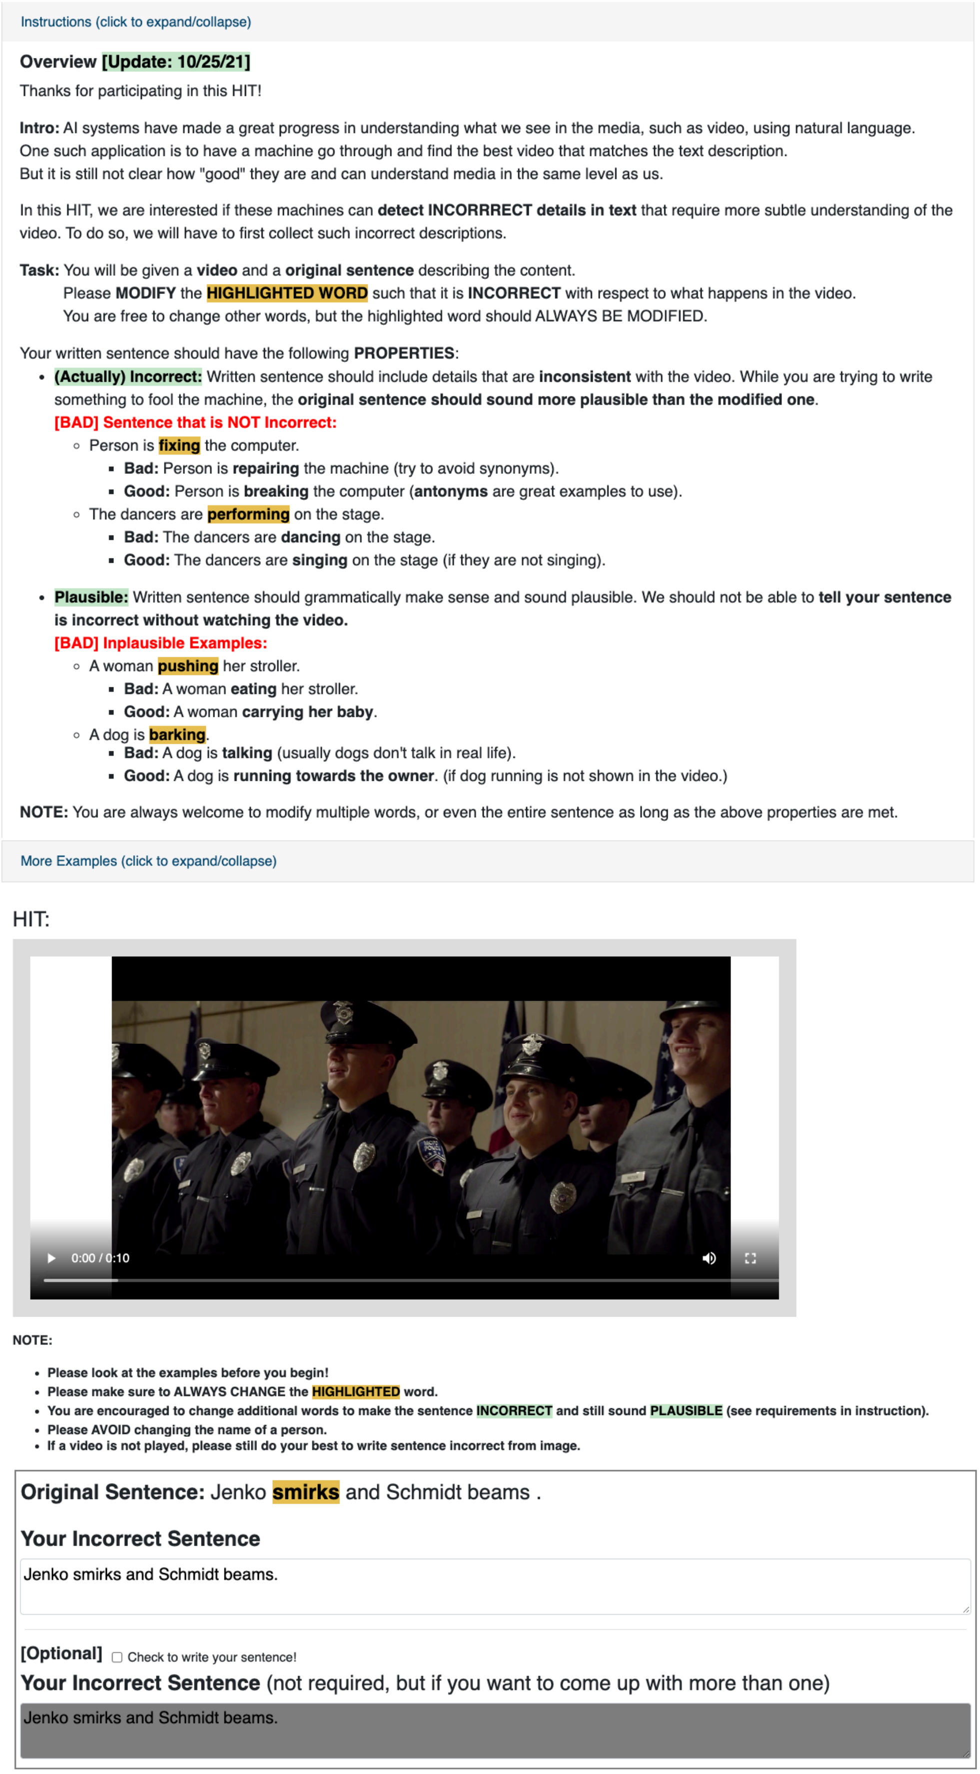
Note:

- Please be forgiving of minor spelling errors.
- There might be more than one statement (or None) that matches the content. Try to do your best to choose the most plausible option.
- **Names** in text correspond to characters in movies, which could be used to disambiguate **different genders**. BUT, we do not expect you to determine if the character is doing the right action, and the correct answer should be clear without knowing the names.
- If you are not sure about your answer for the above reasons, you can check the **"not clear"** box

○ a boy explaining how to plug something into his computer
○ a group is dancing
○ a boy explaining how to edit something into his computer
○ asian man discusses technology in the younger generations
○ two men on wave runner in ocean rescuing a surfer

☐ **Not Clear (More than one or None of the statement applies).**

Figure 4: AMT UI for conducting human evaluation in the MC setting with contrast sets.



Instructions (click to expand/collapse)

Overview **[Update: 10/25/21]**

Thanks for participating in this HIT!

Intro: AI systems have made a great progress in understanding what we see in the media, such as video, using natural language.
One such application is to have a machine go through and find the best video that matches the text description.
But it is still not clear how "good" they are and can understand media in the same level as us.

In this HIT, we are interested if these machines can **detect INCORRRECT details in text** that require more subtle understanding of the video. To do so, we will have to first collect such incorrect descriptions.

Task: You will be given a **video** and a **original sentence** describing the content.
Please **MODIFY** the **HIGHLIGHTED WORD** such that it is **INCORRECT** with respect to what happens in the video.
You are free to change other words, but the highlighted word should ALWAYS BE MODIFIED.

Your written sentence should have the following **PROPERTIES**:

- **(Actually) Incorrect:** Written sentence should include details that are **inconsistent** with the video. While you are trying to write something to fool the machine, the **original sentence should sound more plausible than the modified one**.
  [BAD] Sentence that is NOT Incorrect:
  - Person is **fixing** the computer.
    - **Bad:** Person is **repairing** the machine (try to avoid synonyms).
    - **Good:** Person is **breaking** the computer (**antonyms** are great examples to use).
  - The dancers are **performing** on the stage.
    - **Bad:** The dancers are **dancing** on the stage.
    - **Good:** The dancers are **singing** on the stage (if they are not singing).
- **Plausible:** Written sentence should grammatically make sense and sound plausible. We should not be able to **tell your sentence is incorrect without watching the video.**
  [BAD] Inplausible Examples:
  - A woman **pushing** her stroller.
    - **Bad:** A woman **eating** her stroller.
    - **Good:** A woman **carrying her baby**.
  - A dog is **barking**.
    - **Bad:** A dog is **talking** (usually dogs don't talk in real life).
    - **Good:** A dog is **running towards the owner**. (if dog running is not shown in the video.)

NOTE: You are always welcome to modify multiple words, or even the entire sentence as long as the above properties are met.

More Examples (click to expand/collapse)

HIT:

NOTE:

- **Please look at the examples before you begin!**
- **Please make sure to ALWAYS CHANGE the HIGHLIGHTED word.**
- **You are encouraged to change additional words to make the sentence INCORRECT and still sound PLAUSIBLE (see requirements in instruction).**
- **Please AVOID changing the name of a person.**
- **If a video is not played, please still do your best to write sentence incorrect from image.**

Original Sentence: Jenko **smirks** and Schmidt beams .

Your Incorrect Sentence

Jenko smirks and Schmidt beams.

[Optional] ☐ Check to write your sentence!

Your Incorrect Sentence (not required, but if you want to come up with more than one)

Jenko smirks and Schmidt beams.

Abstract

Poetry generation, and creative language generation in general, usually suffers from the lack of large training data. In this paper, we present a novel framework to generate sonnets that does not require training on poems. We design a hierarchical framework which plans the poem sketch before decoding. Specifically, a content planning module is trained on non-poetic texts to obtain discourse-level coherence; then a rhyme module generates rhyme words and a polishing module introduces imagery and similes for aesthetics purposes. Finally, we design a constrained decoding algorithm to impose the meter-and-rhyme constraint of the generated sonnets. Automatic and human evaluation show that our multi-stage approach without training on poem corpora generates more coherent, poetic, and creative sonnets than several strong baselines.[1]

1 Introduction

A sonnet is a fourteen-line poem with rigorous meter-and-rhyme constraints. In this paper, we aim at generating full-length sonnets that are logically and aesthetically coherent, without training on poetic texts.

There are several challenges for this ambitious goal. First, there are limited number of sonnets available to train a fully supervised model. The only resource is a mere 3,355 sonnets collected by Lau et al. (2018) in Project Gutenberg (Hart, 2004), one of the largest free online libraries for English literature. While it is possible to train on related corpus such as general poems or English lyrics (Ghazvininejad et al., 2016), such approaches are not applicable to many languages for which sizable poetry/lyrics data do not exist. Moreover, even if large-scale creative texts exist, learning from and mimicking existing corpora is *not* creative by definition and is unlikely to result in novel content.

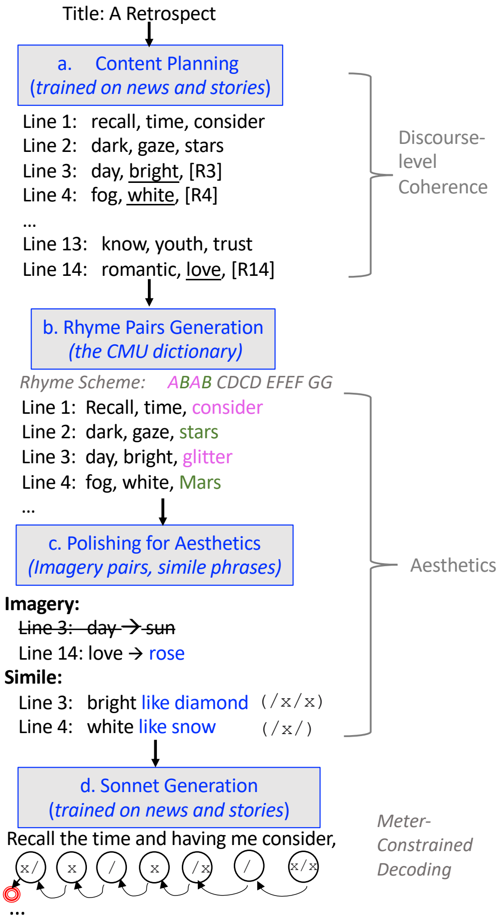

Figure 1: An overview of our approach. The content planning module generates keywords while maintaining discourse-level coherence. The second module form rhyming pairs and the polishing module enrich the imagination and add poetic flavor. (The keywords underlined in the first step have been polished.) Finally, we generate the sonnet with a meter-constrained decoding algorithm. Note that all four steps do not require poem/sonnet data.

Second, coherence remains a known issue among previous works on poetry generation. Existing works mainly focus on conforming to the format constraints (i.e., meter-and-rhyme), or generating a small stanza with a typical length of four (Lau et al., 2018; Liu et al., 2019; Yi et al., 2020). For full-length sonnets, Ghazvininejad et al. (2016) propose to use topical words as rhyme words to

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3587 - 3597
July 10-15, 2022 ©2022 Association for Computational Linguistics

achieve topical relatedness, but the generated sonnets are not discourse-level coherent. They later generate discourse-level coherent English sonnets through French-English translation (Ghazvininejad et al., 2018). Generating logically and aesthetically ordered poems without relying on content translation from other languages remains a challenge.

With all these in mind, we propose **Zest**, a **Ze**ro-shot **s**onne**t** *generation model that does not require training on any poetic data*. Our framework, as is shown in Figure 1, consists of four components: content planning, rhyme pairing, polishing for aesthetics, and final decoding. The first three steps provide salient points for the sketch of a sonnet. The last step is responsible for "translating" the sketch into well-formed sonnets.

To achieve zero-shot generation, the content planning and the final decoding components are both trained on a combination of news and story corpora. The trained planning module is aimed to generate several keywords for each sentence to equip the system with *general world knowledge to construct a coherent text world*. However, the language used by poems is different from that of standard texts because it follows certain rhetorical rhythm and is full of vivid descriptions that appeals to readers' senses and imagination (Gibbs Jr et al., 1994). To this end, in the polishing step we leverage external knowledge and incorporate two figurative speeches (i.e., simile and imagery) into the planned keywords to boost vividness and imagination. The rhyme and final decoding steps are designed to impose the meter-and-rhyme constraints.

While there are previous works on creative generation using the *plan-and-write* paradigm (Wang et al., 2016; Martin et al., 2018; Peng et al., 2018; Yao et al., 2019; Gao et al., 2019; Goldfarb-Tarrant et al., 2019), they all rely on training data from the target task domain (e.g., use story data to train storyline-planning). We on the other hand adopt content planning to disentangle the training from the decoding step to circumvent the shortage of training data for poetry generation. We summarize our contributions as follow:

- We propose **Zest**, a **Ze**ro-Shot **s**onne**t** generation framework, by disentangling training from decoding. Specifically, we first learn to predict context and rhyme words from news and story dataset, and then polish the predicted keywords to promote creativity. A constrained decoding algorithm is designed to impose the meter-and-rhyme constraints while incorporating the keywords.
- We develop two novel evaluation metrics to measure the quality of the generated poems: automatic format checking and novelty evaluation (i.e., diversity and imageability).
- Human evaluation shows that **Zest** generates more discourse-level coherent, poetic, creative, and emotion-evoking sonnets than baselines.

2 Background

In this section, we introduce the characteristics of sonnets in terms of structure, meter and rhyme. We then define important terminologies.

2.1 The Structures of Sonnets

We aim to generate the two most representative sonnets: *Shakespearean* and *Petrarchan*. Sonnets make use of rhymes in a repeating pattern called **rhyme schemes** as shown in Table 1. For example, when writing a Shakespearean sonnet, poets usually adopt the rhyme scheme of ABABCDCDEFEFGG. Although all sonnets have 14 lines, a Petrarchan sonnet consists of an 8-line stanza called an octave followed by a 6-line stanza called a sestet. On the other hand, a Shakespearean sonnet consists of three 4-line quatrains and a 2-line rhyming couplet which leaves the reader with a lasting impression.

	# of Lines	**Iambic Penta**	**Structure**	**Rhyme Scheme**
Shakespearean Sonnet	14	Yes	3 quatrain 1 couplet	ABAB CDCD EFEFGG
Petrarchan Sonnet	14	Yes	1 octave 1 sestet	ABBA ABBA CDECDE

Table 1: Comparison between a Shakespearean sonnet and a Petrarchan sonnet.

2.2 Meter Constraints

Most sonnet conform to iambic pentameter, a sequence of ten syllables alternating between unstressed (`x` or `da`) and stressed syllables (`/` or `DUM`). Strictly speaking, each line reads with the rhythm ($\texttt{da-DUM})^5$, which enhances the tone for the poem and operates like an echo. In reality, there are many rhythmic variations. For example, the first foot is often reversed to sound more assertive, and can be written as ($\texttt{DUM-da} * (\texttt{da-DUM})^4$). Another departure from the standard ten-syllable pattern is to append an addition unstressed syllable to the end, forming feminine rhymes which can be written as ($(\texttt{da-DUM})^5 * \texttt{da}$).

2.3 Rhyme Words, Couplets and Patterns

A pair of **rhyme words** consists of two words that have the same or similar ending sound. A **rhyming couplet** is a pair of rhymed lines. For example, Line 1&3, 2&4 in Figure 1 are two pairs of rhyming couplets. From the CMU pronunciation dictionary (Weide, 1998), we know that “fall" and “thaw" in Figure 1 are *strict* rhyming pairs because they have exactly the same phonetic endings: `"AO L"`. “Leaves" (`"IY V Z"`) and “trees" (`"IY Z"`) are *slant* rhymes, because they have the same stressed vowels, while the ending consonants are similar but not identical.

2.4 Terminology

We formally define the following terms:

- Keywords $\mathcal{K}$: content words and rhyme words combined. They contain main ideas of a poem and define the rhyming pattern.
- Content words $\mathcal{C}$: keywords that do not appear in the end of each line. We target at predicting 2 context words per line, C_{i1} and C_{i2}.
- Rhyme words $\mathcal{R}$: words in the end of each line. For example, in a Shakespearean sonnet with the rhyme scheme ABABCDCDEFEFGG, there are seven pairs of rhyme words: R_1R_3, R_2R_4, ..., and $R_{13}R_{14}$.
- Initial rhyming lines $\mathcal{I}_{Init}$: index of the lines that the first rhyme word in a rhyming couplet appears (e.g., $\mathcal{I}_{Init}$ = [1, 2, 5, 6, 9, 10, 13] for a Shakespearean sonnet and $\mathcal{I}_{Init}$ = [1, 2, 9, 10, 11] for a Petrarchan sonnet).
- Sketch: The sketch of a poem contains three aspects: 1) content words that cover the key concepts or main ideas, 2) the rhyme words to appear at the end of each line, and 3) the modification of keywords for aesthetics.

3 Approach

Overview As is shown in Figure 1, our sonnet generation model can be divided into four steps. At step a, we train a title-to-outline module by finetuning T5 (Raffel et al., 2019) on keywords extracted from news reports and stories. During inference time, we generate a fourteen-line sonnet sketch that contain those content words $\mathcal{C}$ (Section 3.1). At step b, we aim at forming the correct rhyming pairs. We first select the initial rhyme words from $\mathcal{C}_i$ for $i \in \mathcal{I}_{Init}$, and then generate the remaining rhyme words (i.e., for $i \in \overline{\mathcal{I}_{Init}}$) by forcing the decoder to sample from a vocabulary pool that contains strict and slant rhyme words (Section 3.2). At step c, we infuse imagery and simile as two figurative devices to $\mathcal{C}$ (Section 3.3). In the last step, we leverage a fine-tuned language model with constrained decoding algorithm to impose the meter-and-rhyme constraints (Section 3.4).

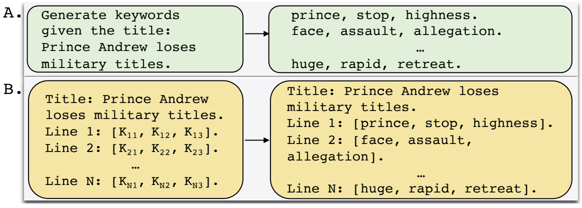

Figure 2: A comparison diagram of two input-output formats to train the first module. While format `A` is most straight-forward, there is no control over the output structure. Therefore, we purposefully design the prompt shown in format `B` to control the number of keywords and the number of lines to be generated. $\mathcal{K}_{ij}$ represents the mask tokens at the i-th sentence.

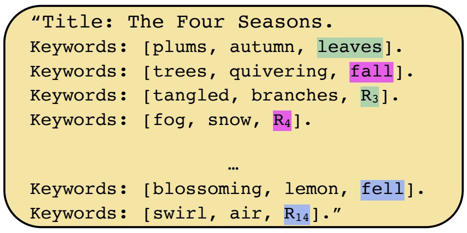
3.1 Content Planning

For each piece of news or stories, we train a title-to-keywords framework that predicts the outline. To this end, we first extract three most salient words per line using the RAKE (Rose et al., 2010) algorithm, which is a domain-independent keyword extraction technique.

Controllable Text Formatting We then leverage the task adaptability of the pretrained T5 (Raffel et al., 2019) to predict the keywords of the whole body. As a unified framework that treats every text processing task as a “text-to-text” problem, T5 can be easily adapted to our task as shown in Figure 2.A, where the input is an instruction to generate the sketch given the title, and the outputs are multiple keywords for each line. However, we need a mechanism to specify the number of lines and keywords to be generated, since we train on prosaic texts with varying formats but infer only on the 14-line sonnets.

To solve this problem and gain control over the poem structures, we format the input and output as shown in Figure 2.B. Specifically, we use [MASK] tokens as placeholders for the keywords. Now that one [MASK] token on the input side corresponds to exactly one word on the output side, we are able to specify the number of lines and keywords during the inference time.



```
"Title: The Four Seasons.
Keywords: [plums, autumn, leaves].
Keywords: [trees, quivering, fall].
Keywords: [tangled, branches, R3].
Keywords: [fog, snow, R4].

                    …
Keywords: [blossoming, lemon, fell].
Keywords: [swirl, air, R14]."
```

Figure 3: An example input to query the remaining rhyme words during the inference time. Rhyme words in the same background color form a rhyming pair.

3.2 Generating Rhyme Words

Our title-to-outline model is trained to generate keywords, regardless of the rhyme constraints. In this section, we describe the procedure to generate rhyme pairs. Specifically, we force the model to generate a 14-line outline, with two or three content words for each line depending on whether the line is an initial rhyming line:

$$\text{Keywords}_i = \begin{cases} [K_{i1}, K_{i2}, K_{i3}]\text{, if } i \text{ in } \mathcal{I}_{Init} \\ [K_{i1}, K_{i2}]\text{, otherwise.} \end{cases} \tag{1}$$

where K_{ij} represents the j-th keyword in the i-th line. Among the three keywords in the initial rhyming lines, we select the last word as the initial rhyme word.

Rhyme Pairs Generation Given the initial rhyme words, we then retrieve all the possible rhyme words $\mathbb{R}$ based on their phonetics information from the CMU prounounciation dictionary (Weide, 1998). This include strict rhymes and slant rhymes. For instance, in Figure 3, the retrieved rhyme word candidates $\mathbb{R}$ for 'leaves' are ['achieves', 'believes', 'Steves', 'trees', ...]. The probability distribution for generating the rhyme word w_R from the candidate list $\mathbb{R}$ is modified as:

$$P'(w_R) = \begin{cases} \frac{p(w_R|\text{context})}{\sum_{x \in \mathbb{R}} p(x|\text{context})} & \text{, if } w_R \in \mathbb{R} \\ 0 & \text{, otherwise.} \end{cases} \tag{2}$$

where $p(w_R|\cdot)$ is the original word probability yielded by the title-to-outline decoder.

3.3 Polishing Context Words for Aesthetics

Now, we have the generated context words and rhyme words that are discourse-level coherent yet less vivid. To this end, we use external knowledge to incorporate two figurative devices into the planned keywords: imagery and simile.

Imagery We leverage the <symbol, imagery> pairs (e.g., <love, rose>) in the ConceptNet knowledge base (Liu and Singh, 2004) and finetune a imagery generation model from a pretrained model called COMmonsEnse Transformer (Bosselut et al., 2019) (COMeT). It is trained on imagery pairs to generate the imagery word given the symbolism word as input. At inference time, we randomly sample multiple nouns from the sketch to predict their imageries, and only make replacement for the two most confident generations. For example in Figure 1, both <day, sun> and <love, rose> are generated, yet we only replace 'love' with 'rose', because the probability of generating the latter pair is much higher than the former pair.

Algorithm 1 Gen Valid Tokens

```
function GEN( $gen_t$, $stress_t$)
Parameter: Int - $t$                          ▷ current time step
Parameter: Int - $N$                          ▷ num of return samples
Parameter: List - $CW$                        ▷ context words yet to include
Input: List of strings - $gen_t$, $stress_t$  ▷ generated beams at time step t and corresponding 0/1 stress series
Output: List of strings - $gen_{t+1}$, $stress_{t+1}$
Initialize $gen_{t+1}$, $stress_{t+1}$ to empty
for $gen$, $stress$ in zip($gen_t$, $stress_t$) do
▷ repeat topk sampling N times and return all generations
    $tokens$ = generate_next($gen$, $N$).to_set()
    for $c$ in $CW$ do
        if $c$ not in tokens then
            $tokens$.append($c$)
    for $t$ in $tokens$ do                    ▷ check for meter constraints
        if satisfy($t$, $stress$) then
            update $gen_{t+1}$, $stress_{t+1}$, $CW$
        else
            continue
    return $gen_{t+1}$, $stress_{t+1}$        ▷ call recursively until 10 or 11 syllables are generated and disregard the metric line unless all three keywords are incorporated.
```

Simile A simile phrase consists of two parts: the adjective and the figurative vehicle. For example, 'sudden like a flash' is a simile phrase where 'a flash' is the figurative vehicle of 'sudden'. We leverage the simile generation model by Chakrabarty et al. (2020) as an off-the-shelf tool[2] to generate simile vehicles from adjectives to extend the sketch keywords. At inference time, we randomly sample multiple adjectives from the sketch to predict their figurative vehicles, and only keep the most confident ones. In addition, we also make sure the generated simile phrase conforms to the iambic-meter constraint. For example in Figure 1, the phrase 'bright like diamond' (/x/x) follows the iambic meter, whereas another phrase such as 'shining like diamond' (/xx/x) will be disregarded.

3.4 Sketch to Sonnet Generation

In order to write fluent and poetic languages that meet the meter-and-rhyme constraints, we make the following adaptations. First, generating the full sonnet requires more powerful pretrained model than generating the outlines. Therefore, we finetune GPT-Neo-2.7B on the same combination of news and stories data as a language model to generate the sonnet. Second, to effectively incorporate the rhyme words at the end of each line, we follow previous methods (Ghazvininejad et al., 2016; Van de Cruys, 2020) and generate the whole sonnet line-by-line *in reverse*, starting from the final rhyme word to the first word. That is to say, our language model is finetuned to generate from right to left to better enforce rhyming. Third, we include the sketch in the prompt, so that the decoder will learn to give higher probability for these keywords. We then use lexically constrained decoding similar to that of Grid Beam Search (Hokamp and Liu, 2017) to incorporate the keywords. In addition, we also include the previously generated lines in the prompt to generate the next line in a sonnet to promote discourse-level coherence. A simile phrase in the sketch is considered fixed that cannot be modified. Namely, we force to generate the whole phrase when the first word in the phrase is decoded. Lastly, we modifies the beam search algorithm to impose the meter-and-rhyme constraint. Algorithm 1 displays the skeleton of our decoding strategy. At each decoding step, we apply rhythm control, so that only those tokens that satisfy the iambic-pentameter and its two variations (listed in Section 2.2) are kept in the beams. We recursively generate the next token until 10 or 11 syllables are generated and make up a metric line where all the context words are incorporated.

4 Experimental Setup

4.1 Dataset

Our approach does not require poem data. The training dataset for the content planing module and the decoding module is a combination of 4,500 CNN news summary (Hermann et al., 2015) and 16,000 short stories crawled from Reddit.[3] We remove those articles that contain conversations, urls, or are too long (>50 lines) or too short (<8 lines). During decoding, we generate sonnets using top-k sampling and set no_repeat_ngram_size to 3 to promote creativity and avoid repetition.

We finetune the pretrained T5 for 10 epochs for the "content planning" component, and finetune GPT-Neo-2.7B for 6 epochs for the decoding component. We use one Nvidia A100 40GB GPU. The average training time is 5∼10 hours for each experiment.

4.2 Baselines

Hafez A program that is trained on lyrics data and generates sonnets on a user-supplied topic (Ghazvininejad et al., 2018). It combines RNNs with a finite state automata to meet the meter and rhyme constraints. Hafez is the state-of-the-art model that generates full-length sonnets but it does not train on standard, non-poetic texts.

Few-shot GPT-3 We utilize the most capable model in the GPT-3 family (Brown et al., 2020), *GPT3-davinci*[4], as a strong baseline to follow instructions and generate sonnets. In the prompt, we provide two examples of standard sonnets and then instruct the model to generate a sonnet given the title. We force the output to be exactly 14 lines.

Ablations of our own model To test the effectiveness of our sketch-before-writing mechanism, we also compare variations of our own model:

Prosaic An stronger version of *nmf* (Van de Cruys, 2020), the first (and only) model to generate rhyming verses from prosaic texts. Topical and rhyme consistency are achieved by modifying the word probability of rhyme and topical words. For fair comparison, we replace the original vanilla encoder-decoder with GPT2 that **Zest** is finetuned on, and force the output to be 14 lines. Model comparison between Prosaic and **Zest** serves as ablations of the keyword-planning component (versus end-to-end generation).

Zest *w/o fig* The model consisting of step a, c, and d as illustrated in Figure 1, but without the polishing the sketch for figurative devices. Our full model consisting of 4 modules is called **Zest**.

4.3 Decoding Strategy

For decoding, we generate sonnets from our models using a top-k random sampling scheme where k is set to 50. At each time step, the GPT2 model generates subwords instead of complete words. In order

---

[2] https://github.com/tuhinjubcse/SimileGeneration-EMNLP2020

[3] https://www.reddit.com/r/shortscarystories/

[4] https://beta.openai.com/docs/engine

to impose the meter and rhyme constraints while decoding for each word, we ask the language model to continue to generate until a complete word is generated as indicated by special space token 'Ġ'. To avoid repetition and encourage creativity, we set no_repeat_ngram_size to 3 and use a softmax temperature of 0.85.

4.4 Automatic Evaluation

It is difficult and thus uncommon to automatically evaluate the quality of poems. For example, Ghazvininejad et al. (2016) and Van de Cruys (2020) exclude automatic evaluation, with the later stating "Automatic evaluation measures that compute the overlap of system output with gold reference texts such as BLEU or ROUGE are of little use when it comes to creative language generation." In addition, Yang et al. (2021) show current metrics have very low correlation with human. Hence, we propose to evaluate the generated poems in two novel aspects: format and novelty.

Format Checking For rhyme checking, we count the percentage of rhyme pairs that belong to strict or slant rhymes. For meter checking, we consider the following most common scenarios mentioned in Section 2.2: the standard Iambic Pentameter; the first foot reversed; and a feminine rhyme. In all scenarios, words that are monosyllables can serve as both stressed and unstressed syllables. For a looser standard, we also calculate the percentage of valid lines that contain either 10 or 11 syllables.

Novelty We follow the settings in exsiting works Yi et al. (2018, 2020) and calculate the Distinct-2 scores (Li et al., 2015) to measure the diversity of generated poems. Besides, imagery is another important feature of poems as pointed out by linguistic studies Kao and Jurafsky (2012); Silk (2006). Here, we calculate *Imageability* score to assess how well a poem invokes mental pictures of concrete objects. Specifically, we extracted the features from the resource by Tsvetkov et al. (2014), who use a supervised learning algorithm to calculate the imageability ratings of 150,114 terms. For each poem, we average the ratings of all its words after removing the stop words.

4.5 Human Expert Judgement

Considering the expertise required to appreciate sonnets, we recruit 6 professionals that hold a bachelor's degree in English literature or related majors as domain experts to annotate the generated sonnets. We provide detailed instructions and ask them to evaluate the each poem on a scale from 1 (not at all) to 5 (very) on the following criteria: **1) Discourse Coherence**: whether the sonnet is well organized, with the sentences smoothly connected and flow together logically and aesthetically, **2) Originality/Creativity**: the usage of original ideas in the poem, including imagination, rhetorical devices, etc., **3) Poetic in language**: how well the poem adopts descriptive and vivid language that often has an economical or condensed usage, **4) Emotion Evoking**: if the poem is emotionally abundant and make the readers emphasize with the writer. At last, we ask the annotators to judge if the sonnet is written by a poet with *serious* goals to write a poem. In total, we evaluate 50 sonnets for each baseline and the gold standard (human) model. Each sonnet is rated by three professionals.

Model Name	**Format Checking**			**Novelty**	
	Rhyme	Meter	Syllable	Dist-2	Img
Hafez	98.3%	76.8%	95.7%	84.8	0.44
Fewshot GPT-3	14.0%	17.6%	30.9%	85.3	0.48
Prosaic	100%	10.1%	19.0%	84.9	0.46
Zest *w/o fig*	100%	77.7%	98.6%	86.6	0.49
Zest	100%	75.6%	98.4%	86.6	0.51
Human	94.6%	70.7%	81.8%	87.4	0.52

Table 2: Automatic evaluation results for rhyme, meter, syllable checking, distinct scores, and imageability (Img in the table). Best machine scores are underlined.

The average inter-annotator agreement (IAA) in terms of Pearson correlation is 0.61 with p-value <0.01, meaning that our collected ratings are highly reliable. We also conduct paired t-test for significance testing. The difference between our best performing model and the best baseline is significant. Considering the expertise required, human evaluators are paid $25 per hour.

5 Results and Analysis

5.1 Results of Automatic Evaluation

Table 2 summarizes the format checking and novelty scores of our model compared to the baselines. We can see that human poets tend to incorporate more variations and do not strictly follow the meter and rhyme constraints, which computers are good at. GPT-3 fails to learn the sonnet formats through massive pretraining and few-shot learning despite its gigantic size. Prosaic falls short of meter-checking because is only trained to generate rhyming verses. Since we utilize the the phonetics

	DC	O	P	E	WH
Hafez	3.09	3.01	3.05	2.95	41.3%
Few-shot GPT3	3.43	3.10	2.86	3.11	52.7%
Prosaic	3.25	2.95	2.97	2.98	46.0%
Zest *w/o fig*	3.57*	3.25	3.35	3.13	58.7%
Zest	3.52	3.41*	3.66*	3.22*	62.0%*
Human	**3.82**	**3.54**	**3.68**	**3.56**	**83.3%**

Table 3: Expert ratings on several criteria to assess sonnet quality: discourse-level coherence (DC), originality/creativity (O), poeticness in language (P), emotion evoking (E), and written by human (WH). We show average scores with 1 denoting the worst and 5 the best. We boldface/underline the best/second best scores. $*$ denotes that paired t-test shows that our model variations (**Zest** *w/o fig*, and **Zest**) outperform the best baseline in all aspects with statistical significance (p-value < 0.05).

information provided in the CMU dictionary, **Zest** achieves 100% success in rhyme words pairing. As for novelty, **Zest** generates most diversely and is best at that arousing mental pictures of concrete objects among machines.

5.2 Results of Human Evaluation

Table 3 presents the performance of the aforementioned evaluation criteria: coherence, originality, poeticness, and emotion-evoking. Our models (**Zest** *w/o fig*, and **Zest**) outperform the baselines in all aspects by a large margin.

Comparison between our own models. Compared with Prosaic which also generates poems from non-poetic texts, our models generates more coherent sonnets with great statistical significance (p-value < 0.01), showing the superiority of explicit sketch planning over generating from scratch (i.e., end-to-end generation).

Zest *w/o fig* generates more coherently than **Zest** (p-value < 0.10). However, **Zest** achieves high scores in originality, poeticness by a large margin (+0.2). Hence, we still consider it as our best model. It is also noteworthy that **Zest** is the most *emotion-evoking* system among all machines even though we do not have explicit sentiment control. Poem theories have shown that emotion appeals lie in the following aspects: the general topic, the word choice, vivid descriptions, figurative language, insights and experience (Scheub, 2002). We posit that aesthetic features in the **Zest** arouse emotion appeals.

Analysis for high poeticness. **Zest** is on par with humans in terms of poeticness score, meaning that our models generate highly descriptive, vivid, and condensed text. With manual examination, we attribute such high poeticness to three aspects. First, the imagery and similes clearly represents traits of poems. Second, in keyword-planning we ensure that at least three concepts will be presented per line, and thus the generation module naturally become economical in word usage to include all the information. Lastly, with the constraint decoding algorithm to insert keywords, we inevitably become less natural (e.g., miss conjunctions and auxiliary verbs). While this can be a drawback in other generation tasks, the occasional omission of such auxiliary words is just opportune for sonnets, and adds to the flavor of a poem. The examples in table 4 helps demonstrate these points.

6 Qualitative Analysis

6.1 Case Study

We conduct case study to better understand the advantages of our model over the baselines. Table 4 lists the generated sonnets by Hafez, Prosaic and **Zest** given the same title: “The Four Seasons".

Problems with the Baselines Hafez chooses words that are related to the title as rhyme words. However, topically related rhyme words are not sufficient for overall coherence. While it is locally understandable, the sonnet generated by Hafez is divergent and disconnected when sentences are put together. On the other hand, Prosaic mimics the rhyme and topical properties of poems, but still generate highly prosaic and colloquial sentences that are not poetic at all.

Advantages of Our Model Thanks to content planning, **Zest** *w/o fig* generates a well-organized sonnet that describes the four seasons from winter to autumn in a logical order. Despite minor grammar errors, the full model **Zest** benefits from vivid descriptions and natural imagery such as ‘whispers rumors of a winter coming’, ‘blossom of the season’, and ‘sudden like a flash’.

6.2 Impact of Keywords

By comparing **Zest** *w/o fig* versus Prosaic, our human evaluation results already show that content planning contributes to discourse-level coherence. In addition, we provide the keywords along with the sonnet generated by **Zest**, and ask human annotators to judge if the sonnet can be condensed into those keywords. Results are shown in Figure 4. We observe that 82% of the time the planed

Hafez	Score	Prosaic	Score
Delightful hours over long ago, Succeed to hang the little hook and light. The darker still and more extended snow, The fresh invention bore the better night.	C: 2.7	The leaves fall and the air is cooler, Were we known with seasons? Spring is coming, Of course there isn't that much humor, And it is now blooming.	C: 3.3
Another party started getting heavy, And never had a little bit of summer. And got a trigger on the finger really, Or something going by the name of winter.	O: 3.0	Even when everyone else's warm, Someone would want to know what we could do in may, else we didn't known – It was the first storm, It's how they used to do every other day.	O: 2.7
Retreat the colors and fun in afternoon And bought the tickets loved a royal song A sacred person join and ride in moon Away the author go and winding long,	P: 3.0	What aren't you looking up Right behind us, no clouds, Just know no one's will ever see the clouds or thunder, And nobody other than the crowds, Before now, we had just started to wonder.	P: 3.0
Oh maybe get a little out of sight, And wounded victim suffered from the site.	E: 3.0	We all aren't sure what we can keep, they couldn't see me, like they were about to reap.	E: 3.3
Zest *w/o fig*	Score	**Zest**	Score
Falling snow, I feel a little cooler, Is a sign of stormy winter coming, Meet the honest friends and gather humor, Happy spring and just admire the blooming.	C: 3.7	The snow is falling, whether getting cooler, Whispers rumors of a winter coming, Gather honest, peace and love and humor, Blossom of the happy season blooming.	C: 3.7
The heat and ocean air becoming warm, Little birds and beautiful songs in May, Leaves and flowers probably just the storm, Among the lunar moons and summer day.	O: 3.3	Wind gets heat and the air becoming warm, The birds enjoy the little lovely may, Beneath the leaves, flowers survive the storm, The moon is shining on a summer day.	O: 4.0
Sudden rain and downpour from the thunder, And summer always fill hotels with crowds, Take a shower and give the spring a wonder, Watch the blue sky and far behind the clouds.	P: 3.3	Sudden like a flash comes rain with thunder, The summer vibes fill the running crowds, Because of shower, spring became a wonder, The sky is high and blue like sea with clouds.	P: 4.0
In months the future vegetables reap, The years and seasons never really keep.	E: 3.0	The coming months are watching future reap, Those years and seasons bring us all to keep.	E: 3.3

Table 4: An example of the generated sonnets from four systems with the same title: "The Four Seasons". The scores are average numbers of three human ratings on the following criteria: coherence (C), originality (O), poetic in language (P), and emotion evokingness (E). We underline the planed keywords and highlight the figurative languages in blue.

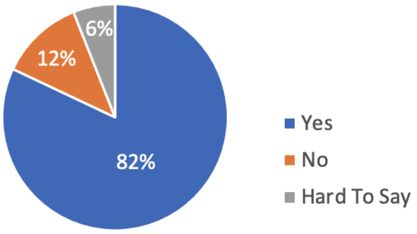


Figure 4: Pie chart showing whether the generated sonnet be condensed into the planed keywords.

keywords successfully guide the generation by providing salient points of the sonnet. We then conduct error analysis on the rest 18%. Top two reasons among the fail cases are: 1) the decoding step generates novel contents that are not represented by the keywords (8%), and 2) the polishing step alters the original meaning of planed keywords (6%).

6.3 Limitation and Future Direction

Sonnets are divided in to multiple stanzas. Lines within a stanza are more interlaced than across stanza, and the start of a new one usually indicates transition to another viewpoint. Our current approach could not capture such structural characteristics during planning and generation, and we hope to investigate these features in future work.

We also plan to extend this poem generation pipeline to other languages. For example, pretrained LMs (e.g. multilingual T5) and existing rhyming resources (r.g. `rhymes.woxikon.com` provides rhymes in 13 languages) already made the first and second component transferable to other languages.

7 Related Work

Poetry Generation Automatic poetry generation before the deep learning age relies heavily on templates, norms, or rule-based approaches (Gervás, 2001; Manurung, 2004; Manurung et al., 2012). Neural approaches to automatic poetry generation pay little attention to the coherence issue of long poems. For example, Wang et al. (2016); Lau et al. (2018); Yi et al. (2018); Liu et al. (2019)

merely target at generating the first stanza (four lines) of a poem. For longer poems such as sonnets, Ghazvininejad et al. (2016) propose to use related words as rhyme words to achieve topical relatedness, and later propose to generate discourse-level coherent English sonnets by French-English translation (Ghazvininejad et al., 2018). Van de Cruys (2020) propose a naive RNN framework to generate rhyming verses from prosaic texts by imposing a priori word probability constraints. We on the other hand achieve discourse-level coherence by learning from standard, non-poetic texts.

Other related works to boost the creativity of generated poems include adding rhetorical (Liu et al., 2019) and influence factors (e.g., historical background) as latent variables (Yi et al., 2020). To the best of our knowledge, we are the first to explore adding both figurative speeches and meter-and-rhyme constraints to poetry generation without relying on poetry data.

Content Planning Content planning for automatic text generation originates in the 1970s (Meehan, 1977). Recently, the *plan-and-write* generation framework has shown to be efficient in creative content generation (Wang et al., 2016; Martin et al., 2018; Peng et al., 2018; Yao et al., 2019; Gao et al., 2019; Goldfarb-Tarrant et al., 2019). The framework employs a hierarchical paradigm and helps to produce more coherent and controllable generation than generating from scratch (Fan et al., 2019; Goldfarb-Tarrant et al., 2020). However, all existing works under this line learn the storyline/plot from the target domain for improved coherence. We on the other hand adopt content planning to disentangle the training from the decoding step which aims at circumventing the shortage of sizable creative contents for training supervised models.

8 Conclusion

We investigate the possibility of generating sonnets without training on poems at all. We propose a hierarchical planning-based framework to generate sonnets which first plans the high-level content of the poem, refine the predicted keywords by adding poetic features, and then achieve decoding-time control to impose the meter-and-rhyme constraints. Extensive automatic and expert evaluation show that our model can generate sonnets that use rich imagery and are globally coherent, poetic, and emotion provoking.

Abstract

There has been a recent wave of work assessing the fairness of machine learning models in general, and more specifically, on natural language processing (NLP) models built using machine learning techniques. While much work has highlighted biases embedded in state-of-the-art language models, and more recent efforts have focused on how to debias, research assessing the fairness and performance of biased/debiased models on downstream prediction tasks has been limited. Moreover, most prior work has emphasized bias along a single dimension such as gender or race. In this work, we benchmark multiple NLP models with regards to their fairness and predictive performance across a variety of NLP tasks. In particular, we assess intersectional bias - fairness across multiple demographic dimensions. The results show that while current debiasing strategies fare well in terms of the fairness-accuracy trade-off (generally preserving predictive power in debiased models), they are unable to effectively alleviate bias in downstream tasks. Furthermore, this bias is often amplified across demographic dimensions. We conclude with implications for future NLP debiasing research.

1 Introduction

As state-of-the-art natural language processing (NLP) language models become increasingly powerful and pervasive, recent progress in NLP has underscored the need for deeper analyses of how such models perform with respect to underrepresented groups. Research on fairness in NLP has shown that distributed representations of words often encode stereotypes - particularly towards different demographic groups (Blodgett et al., 2020; Bender et al., 2021). There is a growing stream of research that looks at mitigating these biases, especially when it manifests in the learned embedding state (Bolukbasi et al., 2016; Zmigrod et al., 2019; Kaneko and Bollegala, 2021). While prior work has undoubtedly moved the needle, recent surveys and research articles have identified several important gaps and issues (Blodgett et al., 2020; Tan and Celis, 2019). First, much of the current work on examining NLP bias (and proposing debiasing strategies) has focused on representational harm - how a model describes certain groups, including stereotyping and other misrepresentations (Blodgett et al., 2020; Suresh and Guttag, 2019). Conversely, there has been far less work exploring *allocational harm in downstream NLP prediction tasks* - when a system distributes resources or opportunities differently (Blodgett et al., 2020; Suresh and Guttag, 2019). Downstream tasks, such as sequence classification, also affect underrepresented groups, as these models show disparate impact on various demographic subsets, including women, African Americans, and the elderly (Blodgett et al., 2020; Bender et al., 2021; Shah et al., 2020).

Second, there has been limited work that examines *intersectional bias across a wide array of relevant charactersitics*, including several demographic dimensions, for a variety of non-debiased and debiased embeddings,[1] on a multitude of downstream tasks. Some work has studied demographic intersections such as young men and old women from a theoretical perspective (e.g., Kearns et al., 2018). Other recent studies have empirically shown that the biases inherent in language models for gender and race intersections might exceed those observed for gender and race alone (Tan and Celis, 2019), and that only debiasing along a single dimension can be problematic (Subramanian et al., 2021). Based on these two gaps, there is a need for a more systematic analysis of how current state-of-the-art language models and mitigation strategies perform with regards to intersectional bias in down-

---

[1] In this work, our scope is debiasing embeddings, not debiasing classifiers. While there is much work in the area of debiasing classifiers, here we restrict our focus to the debiasing of embeddings.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3598 - 3609
July 10-15, 2022

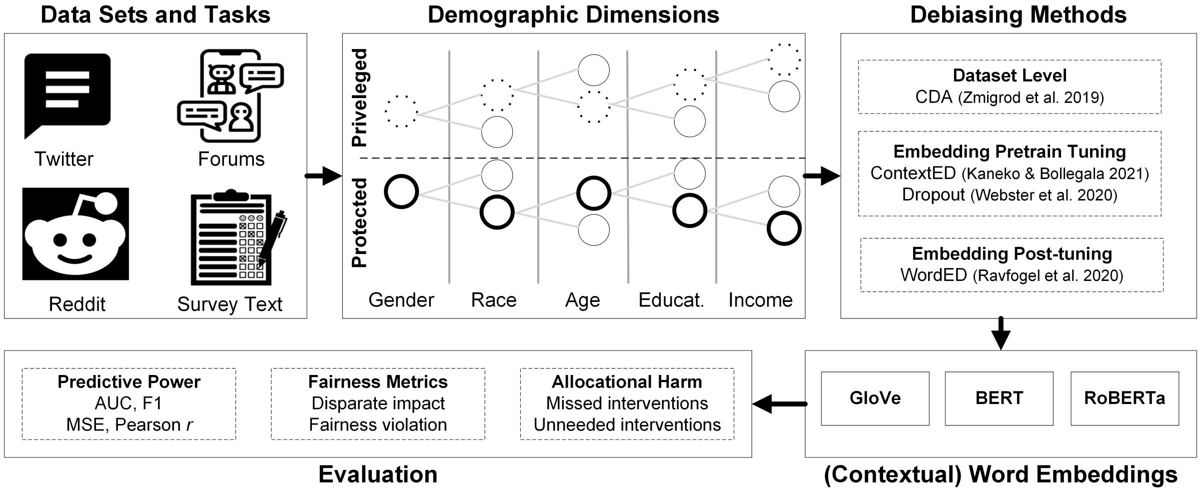

Figure 1: Overview of our fairness benchmarking analyses. We benchmark performance across datasets, models, and debiasing methods for tasks involving multiple demographic variables.

stream tasks.

Accordingly, in this study we perform a broad benchmark analysis of intersectional bias (Figure 1) encompassing the following key characteristics:

- Benchmark analysis on ten downstream sequence classification tasks related to five datasets that span common modes of user-generated content: Twitter, forums, Reddit, and survey responses. For these tasks, we also note the allocational harm implications of disparate impact, namely the harm associated with biased NLP-guided interventions.

- Inclusion of five demographic dimensions: gender, race, age, education, and income. Having three or more dimensions on many of the tasks affords opportunities to examine bias for various demographic intersection subgroups in a more in-depth manner. On four of the datasets, these demographics are self-reported as opposed to being algorithmically or heuristically inferred - an important consideration for debiasing research.

- Evaluation of three prominent word embeddings, BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and GloVe (Pennington et al., 2014), and four state-of-the-art model debiasing methods (Ravfogel et al., 2020; Kaneko and Bollegala, 2021; Zmigrod et al., 2019; Webster et al., 2020). This allows us to draw empirical insights regarding the effectiveness of mitigation strategies for downstream tasks.

Our results show that existing debiasing methods are generally very adept at preserving predictive power in downstream tasks. However, their ability to mitigate intersectional bias in such tasks is limited. In general, debiasing BERT/RoBERTa only incrementally alleviates disparate impact of model classifications. Further, while gender bias alone has disparate impact rates of 5-10% or less on most tasks, the range of bias is amplified for intersections - with unfairness rates often being 20 to 50% higher. On tasks such as inferring personality traits, literacy, or numeracy of users, these debiased models are still outside the fairness ranges recommended by governing bodies (Barocas and Selbst, 2016). Interestingly, these biases are more pronounced in models using GloVe, suggesting that debiased transformer-based models generally have better predictive power, and are fairer.

Our main contributions are two-fold. First, we perform a large-scale examination of intersectional bias across an array of downstream tasks. Our benchmark evaluation offers empirical evidence that the concerns voiced in recent critical surveys about too much emphasis on representational debiasing devoid of explicit normative goals (Blodgett et al., 2020), relative to mitigation of downstream allocational harm, are well-founded. Second, we quantify the size and scope of the intersectional bias problem, and the risks it can introduce for select underprivileged sub-groups when deploying NLP models for sequence prediction tasks. We are hopeful our work will spur future research that further sheds light on intersectional biases in downstream tasks, as well as mitigation strategies for alleviating allocational harm. Towards this goal, the code and data used in this work is publicly available via GitHub.[2]

2 Related Work

2.1 Allocational and Representational Harms

In their survey on bias in NLP, Blodgett et al. (2020) drew a distinction between allocational and representational harms. They found that most papers in NLP describe methods for measuring and mitigating representational harms - when “a system (e.g., a search engine) represents some social groups in a less favorable light than others, demeans them, or fails to recognize their existence altogether” (Blodgett et al., 2020). One well-known example are stereotypes in word embeddings, such as certain ethnic groups being more closely associated with "housekeeper" (Garg et al., 2018).

In contrast, (Blodgett et al., 2020) only found four papers in their survey that were classified as having techniques for measuring/mitigating allocational harms - these “arise when an automated system allocates resources (e.g., credit) or opportunities (e.g., jobs) unfairly to different social groups.” Allocational harm is often aligned with downstream tasks/interventions guided by the NLP model. For instance, all four of the aforementioned allocational harm papers measure and/or mitigate gender bias with respect to an NLP-based occupation classifier (De-Arteaga et al., 2019; Prost et al., 2019; Romanov et al., 2019; Zhao et al., 2020). More specifically, these studies examine the allocational harm of biased occupation classification predictions on decisions that affect humans, specifically whether an HR NLP system scraping web bios classifies individuals as relevant or not for a position. Our work builds on the nascent allocational harm literature by examining ten downstream tasks related to five data sets spanning Twitter, Reddit, forum, and survey response text.

2.2 Intersectional Biases

Intersectional biases arising as a result of interacting demographics have been studied in the broader machine learning literature, either from a theoretical perspective (Kearns et al., 2018; Yang et al., 2020), or in the context of facial recognition (Buolamwini and Gebru, 2018). In NLP, Tan and Celis (2019) evaluate and reveal important intersectional biases in contextualized word embedding models such as BERT and GPT-2. However, in their study, intersectional biases are evaluated using the word association test with an emphasis on representational harm - it remains unclear how intersectional biases affect allocational harm in downstream NLP tasks. Subramanian et al. (2021) looked at intersectional biases of classification models specifically designed for unbiased prediction, but do not evaluate embedding debiasing techniques. We build on the emergent literature on intersectional biases by assessing datasets encompassing up to five demographic dimensions, in conjunction with state-of-the-art word embeddings and debiasing methods, on downstream tasks where biased predictions can lead to allocational harm (§3.1).

2.3 Debiasing

Pretrained word embeddings, including static word embeddings such as GloVe and contextualized word embeddings such as BERT, contain human-like biases and stereotypical associations (Caliskan et al., 2017; Garg et al., 2018; May et al., 2019). A burgeoning body of NLP work has explored debiasing techniques to mitigate biases in pretrained word embeddings. One body of work has focused on debiasing static word embeddings (Bolukbasi et al., 2016; Zhao et al., 2020, 2018; Kaneko and Bollegala, 2019; Ravfogel et al., 2020).

Given the wide adoption of transformer-based contextualized embedding models, recent research has investigated bias mitigation in models such as BERT and RoBERTa (Zmigrod et al., 2019; Webster et al., 2020; Garimella et al., 2021; Kaneko and Bollegala, 2021; Guo et al., 2022). Existing methods for debiasing static and contextualized embeddings have alleviated representational harm along demographic dimensions such as gender. However, Gonen and Goldberg (2019) raised the concern that some debiasing strategies geared towards static word embeddings simply cover up the biases - which can resurface. Moreover, the seemingly debiased static embeddings often do not alleviate biases in downstream NLP prediction tasks (Goldfarb-Tarrant et al., 2021). The extent to which state-of-the-art debiasing methods can mitigate downstream intersectional biases remains unclear. This is precisely one of the gaps our study attempts to shed light on.

3 Data, Models, Experiments

As previously depicted in Figure 1, our experimental setup is as follows. We assess predictive performance and fairness across five datasets spanning ten dependent variables/tasks and five demographic dimensions. We train three models (GloVe, BERT, and RoBERTa) as our prediction and fairness baselines. We then debias the input embeddings for these models (Ravfogel et al., 2020; Zmigrod et al., 2019; Kaneko and Bollegala, 2021) and re-train them to compare the performance. Details of the data, models, and evaluation metrics are below.

3.1 Data

We examine five datasets (Table 1) across several NLP tasks: psychometric dimension prediction, hate speech identification, personality detection, and sentiment analysis. The psychometric data set (Abbasi et al., 2021) consists of free-text responses on four psychometric dimensions: subjective health literacy, numeracy, anxiety, and trust in doctors. These free-text responses were then linked to survey-based psychometric scores also provided by the participants (serving as gold-standard numeric response labels). The data also includes self-reported demographics for each individual: age, race, gender, income, and education level. This data set was collected using crowd workers from Amazon Mechanical Turk and Qualtrics.

Similarly, the Five Item Personality Inventory (FIPI) and Myers–Briggs Type Indicator (MBTI) datasets include free text responses to estimate one of the FIPI or MBTI personality traits (Gjurković et al., 2021). In particular, due to space constraints, we focus on the MBTI traits of perceiving and thinking, and the FIPI traits of extraverted and stable. For FIPI, available demographics are gender, race, age, income, and education. For MBTI, self-reported gender and age are available. The AskAPatient dataset (Limsopatham and Collier, 2016) is taken from web forums and has labeled sentiment, along with gender and age information.

The Multilingual Twitter Corpus (MTC) hate-speech dataset contains labeled Twitter messages for the task of hate speech detection (Huang et al., 2020). The dataset also contains inferred author demographic factors. We use three demographics: gender, race, and age.

The Psychometrics, FIPI, AskAPatient, and MBTI tasks are all relevant from an allocational harms perspective. Biases in predictions for healthcare-related variables (Psychometrics), or personality type variables (MBTI, FIPI) can affect an individual's health care plan, personalized interventions, job prospects, etc. Biased predictions for drug rating sentiment can affect which drugs a future user chooses to take.

3.2 Models and Debiasing Methods

In the experiments, we considered several different text classification models. We used a word convolutional neural network (CNN) model, initialized with GloVe embeddings. We also considered two transformer-based contexualized embedding models: BERT and RoBERTa.

CNN We trained a word convolutional neural network (CNN) model, initialized with GloVE embeddings. The model consists of 3 concatenated CNN layers with kernel size of 1, 2 and 3 respectively. Each layer has a filter size of 256, rectified linear unit (ReLU) activation, L2 regularization (0.001), and global max pooling. The models were trained for 35 epochs with a batch size of 32 and learning rate of $1e^{-4}$.

Debiased-CNN We debiased the GloVe model using (Ravfogel et al., 2020). We kept all parameters the same as in the original paper based on their publically available implementation.[3] The projection matrix was learned over 50 epochs.

BERT and RoBERTa We fine-tuned BERT and RoBERTa on downstream prediction tasks. We used `BERT-base-uncased` and `RoBERTa-base` model loaded from the transformers library. We fine-tuned BERT and RoBERTa model for five epochs using the following hyperparameters: a batch size to 32, learning rate of $1e^{-5}$, weight decay of 0.01. We saved the final model that achieves the lowest loss on validation set.

Debiased-BERT and Debiased-RoBERTa We debiased BERT and RoBERTa using (Kaneko and Bollegala, 2021). We obtained the gender word lists and stereotype word lists[4]. We used News-commentary-v15 corpus[4] as the external corpus to locate sentences where the gender and stereotype words occur and then debias. All BERT or RoBERTa layers are debiased at the token level, and the debiasing loss weight is set to 0.8. The model is fine-tuned for three epochs used the following hyperparameters: a batch size of 32 and learning rate of $5e^{-5}$.

Training Details For each dataset we trained using five-fold cross validation, so that for each example in each dataset, we could generate predictions as unseen test data.Each test fold was then concatenated for a given model for fairness calculations. All models were trained on the same data with hyperparameter tuning. All prediction models, debiasing models are trained on a NVIDIA GeForce RTX 3090 GPU card, with 11.2 CUDA version.

Debiasing Strategy Static word embeddings (GloVe, Pennington et al., 2014) were debiased using WordED (Ravfogel et al., 2020)[5]. This method iteratively learns a projection of embeddings that removes the bias information with minimal impact on embedding distances.

Contextualized word embedding models BERT and RoBERTa were debiased using ContextED (Kaneko and Bollegala, 2021)[6], which has been shown to work well at removing gender-bias encoded in embeddings. This method uses predefined word lists to identify sentences that contain the gendered or stereotype words, and then fine-tunes the pretrained model parameters by encouraging gendered and stereotype words to have orthogonal representations.

We also assessed two alternative debiasing methods for the contextualized word embedding models: counterfactual data augmentation (CDA) (Zmigrod et al., 2019) and Dropout (Webster et al., 2020).[7] CDA augments the training corpora with counterfactual data so that the language model is pretrained on gender-balanced text. Dropout mitigates gender biases by increasing the dropout rate in the pretrained models. Therefore, the debiasing methods in our experiments represent different ways of mitigating biases: dataset level (CDA), debiasing during pretraining (ContextED and Dropout), and post-tuning debiasing (WordED).

3.3 Evaluation

There are several definitions of fairness in the literature (Mehrabi et al., 2021), each with corresponding methods of assessment. In this work we rely on two prior metrics from the literature, and also present a new metric, adjusted disparate impact, to account for base rates in the dataset.

Disparate Impact One of the most common fairness assessments is disparate impact (DI, Friedler et al., 2019). DI measures the inequality of positive cases between privileged and non-privileged groups for a particular demographic. DI comes from from the legal field, where certain regulations require DI be above a threshold of 0.8 (or below 1.2 in the inverse case). For true labels y, predicted labels $\hat{y}$, and relevant demographic group A:

$$DI = \frac{p(\hat{y} = 1|A = 0)}{p(\hat{y} = 1|A = 1)} \tag{1}$$

Where $A = 0$ refers to the protected group and $A = 1$ refers to the privileged group. A DI ratio of 1 indicates *demographic parity*, where the rates of positive predictions are consistent across demographic classes: $P(\hat{y} = 1|A = 0) = P(\hat{y} = 1|A = 1)$ (Mehrabi et al., 2021).

Statistical Parity (SP) Subgroup Fairness Recent theoretical work on intersectional biases also assesses demographic parity, where the score compares group-specific rates to the global rate in the dataset instead of a comparison between privileged and protected classes (Kearns et al., 2018):

$$p(A = g) \times |p(\hat{y} = 1) - p(\hat{y} = 1|A = g)| \tag{2}$$

---

[3] https://github.com/shauli-ravfogel/nullspace_projection

[4] https://github.com/kanekomasahiro/context-debias/

[5] https://github.com/shauli-ravfogel/nullspace_projection

[6] https://github.com/kanekomasahiro/context-debias

[7] https://github.com/google-research-datasets/zari

This value is compared to an acceptability parameter λ to assess fairness. As this method was proposed for the intersectional case, it gives a way to identify the upper-bound of the *fairness violation* in a dataset (Yang et al., 2020):

$$FV = \max_{g \in G_f} |TPR_g - TPR_D| \quad (3)$$

Where G_f is the set of demographic groups under consideration for analysis, TPR_g is the true positive rate of the classifier on the instances in g, and TPR_D is the overall true positive rate for the classifier on the dataset. Prior work considered the average violation across groups (Subramanian et al., 2021), but for the purposes of this study we are interested in a worst case analysis.

Adjusted Disparate Impact We propose reweighting DI to account for differences in base rates. Adjusted DI (ADI) divides DI by the base rate ratio for the protected and privileged groups: $DI^* = \frac{p(y=1|A=0)}{p(y=1|A=1)}$, $ADI = \frac{DI}{DI^*}$

Note that the disparate impact metrics are not defined for cases where there are no positive instances for either the protected or privilege classes in the data, or when there are no positive predictions for the privileged class (due to zero division). Therefore, we use additive smoothing when calculating DI and adjusted DI (Zhai and Lafferty, 2004).

Intersectional Fairness To assess intersectional fairness we enumerated all combinations for each n-demographic scenario (e.g., 2-demographic, 3-demographic, etc.). We set a reference demographic, specifically gender, because of the prior work on debiasing word embeddings for gender (Bolukbasi et al., 2016; Gonen and Goldberg, 2019; Kaneko and Bollegala, 2021). For intersectional cases, we calculated DI and FV for all possible combinations of demographics that included gender. For example, the 2-demographic case for the psychometrics dataset involves calculating DI and FV for the following protected groups: older women, lower education women, lower income women, and non-white women. Our privileged groups are the negations of the protected groups, e.g., for the above case they are younger men, higher education men, higher income men, and white men. By considering disjoint demographic groups, we avoid cumulative effects of merging fairness results from individual demographics during the intersectional phase. We follow the same procedure for enumerating protected groups for the 3- and 4-demographic cases. For 5-demographics we consider all demographics together. For all models and datasets, we calculated fairness and performance metrics. For performance, we report mean squared error (MSE), Pearson's r,[8] F1, and area under the receiver operating curve (AUC). For fairness, we report adjusted DI and fairness violation (FV, §3.3).[9]

4 Results and Discussion

Figure 2 shows the ADI results for BERT and GloVe using ContextED and WordED for debiasing, respectively. In most cases, particularly for BERT, disparate impact scores for gender alone are in a reasonable range (within 10%). For GloVe, we do observe high gender ADI on Anxiety and Thinking. However, as the number of demographics under consideration grows, the range of ADI scores widens. While debiasing the word embeddings typically helps to reduce the unfairness for the target demographic (e.g., gender), in the intersectional cases the model still performs poorly. There are similar trends in FV scores as the number of demographics increases, with the extent of violations often increasing by a factor of 3x to 10x as intersections increase (Table 2).

In some cases the intersectional disparities are extreme. On the BERT models, the ratio of positive Numeracy predictions for the protected class is three-to-one compared to the privileged class. In the other direction, for 3-demographics, hate-speech detection positive predictions are significantly less likely for the protected group than the privileged group. This is consistent with prior hate-speech detection work that has shown large (absolute value) fairness gaps between protected and privileged groups (e.g., Liu et al., 2021).

In most cases, trends are consistent between the BERT and GloVe models (e.g., Extraverted, Numeracy, Perceiving). Some counterexamples are the Trust and Anxiety tasks. Here model choice impacts the direction of bias. As more demographics are considered, the GloVe model skews more unfair against the protected group, while the BERT model remains mostly fair, skewing slightly unfair against the privileged group. Higher trust in physicians is associated with better well-being and lower anxiety when visiting a doctor (Netemeyer et al.,

Table 2: Benchmarking results. For Psychometrics and FIPI, + and ++ indicate 3- and 5-way demographics, respectively. For MTC, AskAPatient, and MBTI, + and ++ indicate 2- and 3-way demographics, respectively. Best performance metrics (lowest for MSE, highest for Pearson r, F1, and AUC) and least fair for fairness metrics (furthest from 1 for DI, highest for FV) are **bolded**.

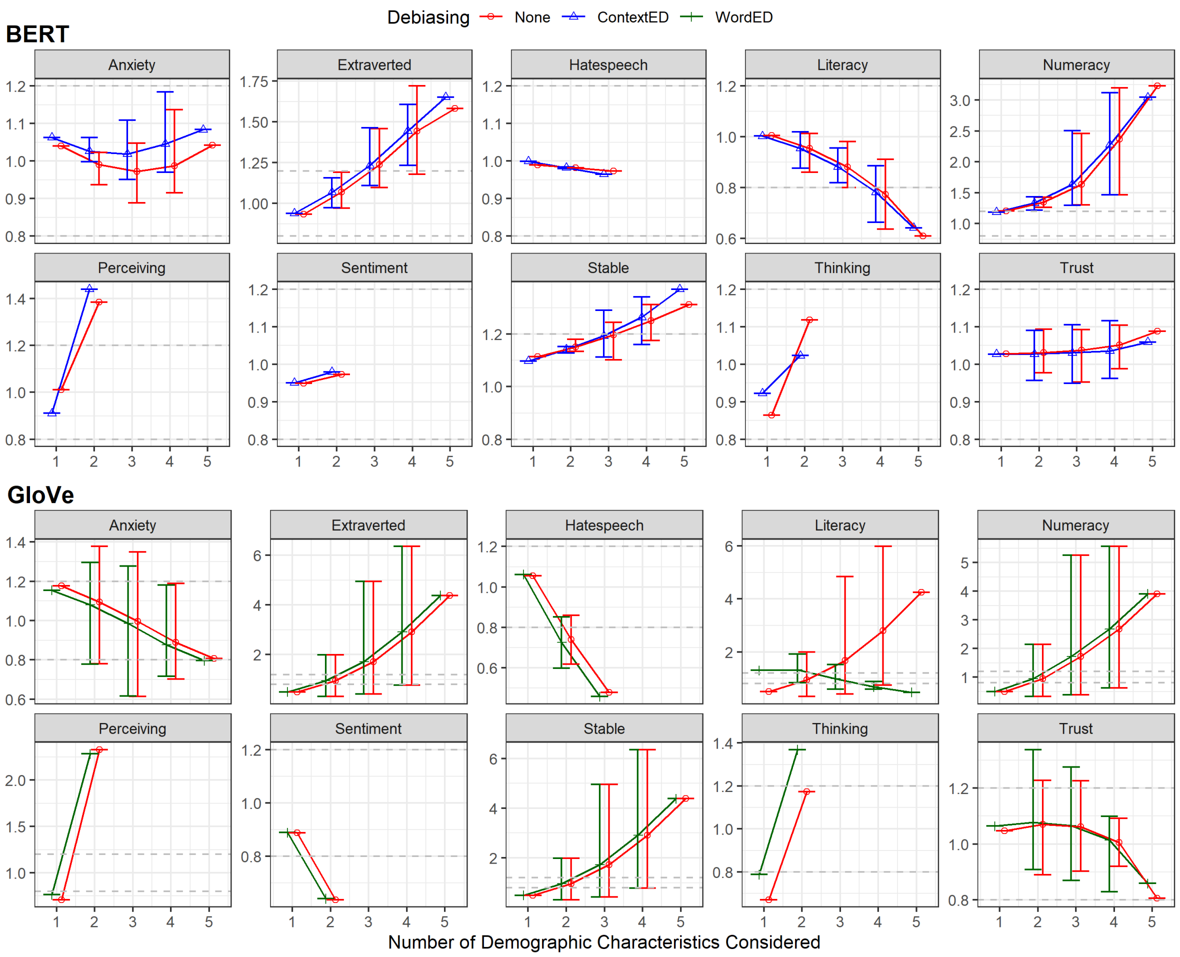

Figure 2: Effect of intersectionality on adjusted disparate impact for BERT and GloVe models. For x-axes with more than one demographic characteristic under consideration, we report the mean ADI and 95% confidence intervals.

2020); disparate predictions can lead to missed interventions for trust-increase and anxiety reduction across demographic groups. Though not depicted in the main paper, plots for RoBERTa show similar trends to those observed for BERT while debiasing with ContextED (see Appendix A).

Results are similar when looking at alternate BERT debiasing methods beyond ContextED, namely CDA and Dropout (Figure 3). These findings on the Anxiety, Literacy, Numeracy, and Trust tasks suggest that debiasing at the dataset, embedding pretraining, and post-tuning levels leads to similar increases in unfairness as the number of demographic intersections considered increases.

Collectively, the results underscore the allocational harm implications of NLP models on several downstream tasks - ones that even well-designed and well-intentioned debiasing strategies cannot overcome. This can be problematic in the era of personalized marketing and precision health, with NLP-based persona-generation playing a bigger role. For tasks like numeracy and literacy, this can affect how a patient is treated by a medical staff during a hospital visit (i.e., a false positive high literacy prediction for a person who has trouble understanding his or her medical record). For the personality indicators, inconsistent predictions may lead to biased decisions in the workplace (e.g., a manager looking to form a team of extroverts).

5 Conclusion

In this work we present a comprehensive benchmarking analysis of fairness for sequence prediction models. We also look at known debiasing methods for these models and show that while the debiased versions maintain predictive performance (as expected), they do not help with mitigating biases. While most models are relatively fair when looking at a single demographic characteristic, accounting for intersectional groups leads to less fair models and wider ranges of bias because of the

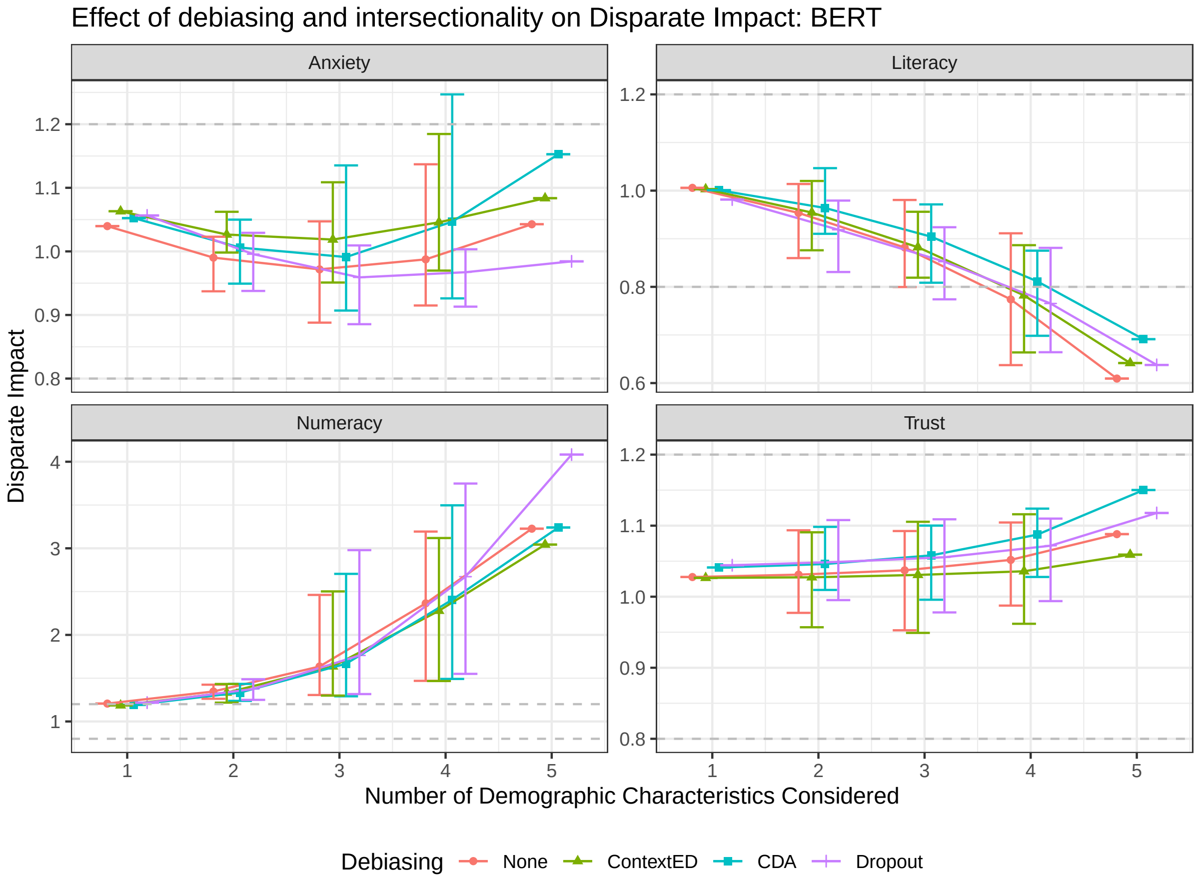

Figure 3: Effect of different debiasing methods on adjusted disparate impact.

combinatorial considerations of the intersectional groups. It is our hope that this benchmarking encourages future work into mitigating intersectional biases, and also to collect more demographic information when creating new datasets.

Abstract

While recent work on multilingual language models has demonstrated their capacity for cross-lingual zero-shot transfer, there is a lack of consensus in the community as to what shared properties between languages enable transfer on downstream tasks. Analyses involving pairs of natural languages are often inconclusive and contradictory since languages simultaneously differ in many linguistic aspects. In this paper, we perform a large-scale empirical study to isolate the effects of various linguistic properties by measuring zero-shot transfer between four diverse natural languages and their counterparts constructed by modifying aspects such as the script, word order, and syntax. Among other things, our experiments show that the absence of sub-word overlap significantly affects zero-shot transfer when languages differ in their word order, and there is a strong correlation between transfer performance and word embedding alignment between languages (e.g., $\rho_s = 0.94$ on the task of NLI). Our results call for focus in multilingual models on explicitly improving word embedding alignment between languages rather than relying on its implicit emergence.[1]

1 Introduction

Multilingual language models like XLM (Conneau et al., 2020a) and Multilingual-BERT (Devlin, 2019) are trained with masked-language modeling (MLM) objective on a combination of raw text from multiple languages. Surprisingly, these models exhibit decent cross-lingual zero-shot transfer, where fine-tuning on a task in a source language translates to good performance for a different language (target).

Requirements for zero-shot transfer Recent studies have provided inconsistent explanations for properties required for zero-shot transfer (hereon, transfer). For example, while Wu and Dredze (2019) conclude that sub-word overlap is vital for transfer, K et al. (2020) demonstrate that it is not crucial, although they consider only English as the source language. While Pires et al. (2019) suggest that typological similarity (e.g., similar SVO order) is essential for transfer, other works (Kakwani et al., 2020; Conneau et al., 2020a) successfully build multilingual models for dissimilar languages.

Need for systematic analysis A major cause of these discrepancies is a large number of varying properties (e.g., syntax, script, and vocabulary size) between languages, which make isolating crucial ingredients for transfer difficult. Some studies alleviate this issue by creating synthetic languages which differ from natural ones only in specific linguistic properties like script (K et al., 2020; Dufter and Schütze, 2020). However, their focus is only on English as a source language, and the scale of their experiments is small (in number of tasks or pre-training corpora size), thus limiting the scope of their findings to their settings alone.

Our approach We perform a systematic study of cross-lingual transfer on bilingual language models trained on a natural language and a systematically *derived* counterpart. We choose four diverse natural languages (English, French, Arabic, and Hindi) and create *derived* variants using four different transformations on structural properties such as inverting or permuting word order, altering scripts, or varying syntax (Section 3.2). We train models on each of the resulting sixteen language pairs, and evaluate zero-shot transfer on four downstream tasks – natural language inference (NLI), named-entity recognition (NER), part-of-speech tagging (POS), and question-answering (QA).

Our experiments reveal the following:

1. Contrary to previous belief, the absence of sub-word overlap degrades transfer when languages

differ in their word order (e.g., by more than 40 F1 points on POS tagging, (§ 4.1)).

2. There is a strong correlation between token embedding alignment and zero-shot transfer across different tasks (e.g., $\rho_s = 0.94, p < .005$ for XNLI, Fig 4).
3. Using pre-training corpora from similar sources for different languages (e.g., Wikipedia) boosts transfer when compared to corpora from different sources (e.g., 17 F1 points on NER, Fig 3).

To our knowledge, we are the first study to quantitatively show that zero-shot transfer between languages is strongly correlated with token embedding alignment ($\rho_s = 0.94$ for NLI). We also show that the current multilingual pre-training methods (Doddapaneni et al., 2021) fall short of aligning embeddings even between simple natural and derived language pairs, leading to failure in zero-shot transfer. Our results call for training objectives that explicitly improve alignment using either supervised (e.g., parallel corpora or bilingual dictionaries) or unsupervised data.

2 Related work

Multilingual pre-training for Transformers The success of monolingual Transformer language models (Devlin et al., 2019; Radford et al., 2018) has driven studies that learn a multilingual language-model (LM) on several languages. Multilingual-BERT (M-BERT) (Devlin, 2019) is a single neural network pre-trained using the masked language-modeling (MLM) objective on a corpus of text from 104 languages. XLM (Conneau and Lample, 2019) introduced translation language-modeling, which performs MLM on pairs of parallel sentences, thus encouraging alignment between their representations. These models exhibit surprising zero-shot cross-lingual transfer performance (Conneau and Lample, 2019; K et al., 2020), a setup where the model is fine-tuned on a source language and evaluated on a different target language.

Analysis of cross-lingual transfer While Pires et al. (2019), Conneau et al. (2020b), and K et al. (2020) showed that transfer works even without a shared vocabulary between languages, Wu and Dredze (2019) discovered a correlation between sub-word overlap and zero-shot performance. Conneau et al. (2020b) and Artetxe et al. (2020a) showed that shared parameters for languages with different scripts were crucial for transfer. Pires et al. (2019) and (Wu and Dredze, 2019) observed that transfer for NER and POS tagging works better between typologically similar languages. However, a study conducted by Lin et al. (2019) showed that there is no simple rule of thumb to gauge when transfer works between languages. Hsu et al. (2019) observed that changing the syntax (SOV) order of the source to match that of the target does not improve performance.

Transfer between real and synthetic Languages K et al. (2020) create a synthetic language by changing English's script and find that transfer between it and Spanish works even without common sub-words. However, they use only English as their source language, test only on two tasks, and use a single natural-synthetic language pair. Dufter and Schütze (2020) study transfer between English and *synthetic* English obtained by changing the script, word order, or model delimiters. However, they use a small corpus (228K words) compared to current standards (we use 3 orders more) and measure only embedding similarity and not zero-shot transfer. A contemporary work (Wu et al., 2022) uses synthetic transformations to modify the GLUE dataset (Wang et al., 2018) and analyze properties required for good zero-shot transfer, but they perform their experiments only on English and do not perform token embedding alignment analysis. We show that the latter is crucial for good transfer.

3 Approach

We first provide some background on bilingual language models (Section 3.1), followed by descriptions of our transformations (Section 3.2), and our training and evaluation setup (Section 3.3).

3.1 Background

Bilingual pre-training The standard setup (Conneau and Lample, 2019) trains a bilingual language model (*Bi-LM*) on raw text corpora from two languages simultaneously. *Bi-LM* uses the masked language-modeling loss ($\mathcal{L}_{\text{MLM}}$) on the corpora from the two languages ($\mathcal{C}_1, \mathcal{C}_2$) separately with no explicit cross-lingual signal:

$$\mathcal{L}^{\theta}_{\text{Bi-LM}}(\mathcal{C}_1 + \mathcal{C}_2) = \mathcal{L}^{\theta}_{\text{MLM}}(\mathcal{C}_1) + \mathcal{L}^{\theta}_{\text{MLM}}(\mathcal{C}_2)$$

A shared byte pair encoding tokenizer (Sennrich et al., 2015) is trained on $\mathcal{C}_1 + \mathcal{C}_2$. A single batch contains instances from both languages, but each instance belongs to a single language.

Transformation	**Instance** (s)	**Transformed instance** ($\mathcal{T}(s)$)
Inversion ($\mathcal{T}_{\textbf{inv}}$)	Welcome to NAACL at Seattle	Seattle at NAACL to Welcome
Permutation ($\mathcal{T}_{\textbf{perm}}$)	This is a conference	a This conference is
Transliteration ($\mathcal{T}_{\textbf{trans}}$)	I am Sam . I am	♣(I) ♡(am) ♢(Sam) ♠(.) ♣(I) ♡(am)
Syntax ($\mathcal{T}_{\textbf{syn}}$)	Sara (S) ate (V) apples (O)	Sara (S) apples (O) ate (V)
	Une table (N) ronde (A)	Une ronde (A) table (N)

Table 1: Examples of our transformations applied to different sentences (without sub-word tokenization). *Inversion* inverts the tokens, *Permutation* samples a random reordering, and *Transliteration* changes the script. We use symbols (♣) to denote words in the new script and mention the corresponding original word in brackets. *Syntax* stochastically modifies the syntactic structure. In the first example for *Syntax*, the sentence in Subject-Verb-Object (SVO) order gets transformed to SOV order, and in the second, the sentence in Noun-Adjective (NA) order gets transformed to the AN order. The examples are high probability re-orderings and other ones might be sampled too.

Zero-shot transfer evaluation Consider a bilingual model (*Bi-LM*) pre-trained on two languages, *source* and *target*. Zero-shot transfer involves fine-tuning *Bi-LM* on downstream task data from *source* and evaluating on test data from *target*. This is considered zero-shot because *Bi-LM* is not fine-tuned on any data belonging to *target*.

3.2 Generating language variants with systematic transformations

Natural languages typically differ in several ways, like the script, word order, and syntax. To isolate the affect of these properties on zero-shot transfer, we obtain *derived* language corpora (hereon, *derived* corpora) from *original* (natural) language corpora by performing sentence level transformations ($\mathcal{T}$) which change particular properties. For example, an "*inversion*" transformation could be used to invert each sentence in the corpus ($Welcome_1$ to_2 $NAACL_3 \Rightarrow NAACL_3$ to_2 $Welcome_1$). Since the transformation ($\mathcal{T}$) is applied on each sentence of the *original* corpus, the size of the *original* and the *derived* corpus is the same. In the following sections, we will use the following notation:

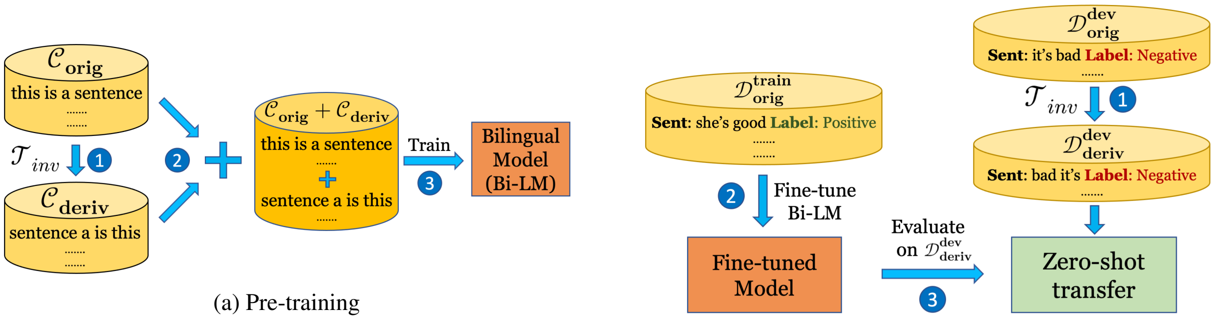
$$\begin{aligned}
\mathcal{C}_{\textbf{orig}} &\equiv \text{Original corpus} \\
&= \{s_i \mid i = 1 : N, s_i = \text{sentence}\} \\
\mathcal{T} &\equiv \text{Sentence-level transformation} \\
\mathcal{C}_{\textbf{deriv}} &\equiv \text{Derived corpus} \\
&= \{\mathcal{T}(\text{sent}) \mid \forall \text{ sent} \in \mathcal{C}_{\textbf{orig}}\}
\end{aligned}$$

Types of transformations We consider four transformations which modify different aspects of sentences (examples in Table 1):

1. **Inversion** ($\mathcal{T}_{\textbf{inv}}$): Invert the order of *tokens* in the sentence, like in Dufter and Schütze (2020). The first token becomes the last, and vice versa.
2. **Permutation** ($\mathcal{T}_{\textbf{perm}}$): Permute the order of tokens in a sentence uniformly at random. For a sentence of n tokens, we sample a random ordering with probability $\frac{1}{n!}$.
3. **Transliteration** ($\mathcal{T}_{\textbf{trans}}$): Change the script of all tokens other than the special tokens (like `[CLS]`). This creates a *derived* vocabulary ($\mathcal{V}_{deriv}$) with a one-to-one correspondence with the original vocabulary ($\mathcal{V}_{orig}$).
4. **Syntax** ($\mathcal{T}_{\textbf{syn}}$): Modify a sentence to match the syntactic properties of a different natural language by re-ordering the dependents of nouns and verbs in the dependency parse. These transformations are stochastic because of the errors in parsing and sampling over possible re-orderings (Wang and Eisner, 2016).

These transformations allow us to systematically evaluate the effect of corresponding properties on zero-shot transfer. We also consider composed transformations (§4.2) which consecutively apply two transformations. We note that while real languages typically differ in more than one or two properties considered in our transformations, our methodology remains useful in isolating crucial properties that enable good transfer and can be extended to more transformations.

Transformations for downstream tasks We obtain the downstream corpus in the *derived* language ($\mathcal{D}_{\textbf{deriv}}$) by applying the same transformation ($\mathcal{T}$) used during pre-training on the *original* downstream corpus ($\mathcal{D}_{\textbf{orig}}$). Unlike pre-training corpora which contain raw sentences, instances in downstream tasks contain one or more sentences with annotated labels. For text classification tasks like



(a) Pre-training

(b) Fine-tuning

Figure 1: **(a)** During pre-training, we ① obtain the *derived* language corpus ($\mathcal{C}_{\text{deriv}}$) by *transforming* the *original* language corpus ($\mathcal{C}_{\text{orig}}$). ② The two corpora are combined and, ③ a bilingual model (*Bi-LM*) is learned using the MLM objective. **(b)** During fine-tuning, we ① obtain the derived dev dataset ($\mathcal{D}^{\text{dev}}_{\text{deriv}}$) by transforming the original dev dataset ($\mathcal{D}^{\text{dev}}_{\text{orig}}$). ② *Bi-LM* is fine-tuned on the original train dataset ($\mathcal{D}^{\text{train}}_{\text{orig}}$), and ③ evaluated on $\mathcal{D}^{\text{dev}}_{\text{deriv}}$, which is the standard zero-shot cross lingual setup.

Evaluation	Corpus source		
	Pre-train	**Fine-tune (train)**	**Fine-tune (dev)**
BZ	$\mathcal{C}_{\text{orig}} + \mathcal{C}_{\text{deriv}}$	$\mathcal{D}_{\text{orig}}$	$\mathcal{D}_{\text{deriv}}$
BS	$\mathcal{C}_{\text{orig}} + \mathcal{C}_{\text{deriv}}$	$\mathcal{D}_{\text{deriv}}$	$\mathcal{D}_{\text{deriv}}$
MZ	$\mathcal{C}_{\text{orig}}$	$\mathcal{D}_{\text{orig}}$	$\mathcal{D}_{\text{deriv}}$

$$\Delta_{(\text{BZ}-\text{BS})} = \left(\textbf{BZ} - \textbf{BS}\right)$$
$$\Delta_{(\text{MZ}-\text{BS})} = \left(\textbf{MZ} - \textbf{BS}\right)$$

Table 2: Summary of evaluation metrics defined in § 3.3. $\mathcal{C}$ and $\mathcal{D}$ denote the pre-training and downstream corpus respectively, and their subscript indicates their source (*original* or *derived*). **BZ** and **MZ** represent bilingual and monolingual zero-shot transfer scores, and **BS** is the supervised learning baseline on *derived*. The differences in the setting of **BZ** and other scores are typeset in blue. We use $\Delta_{(\textbf{BZ}-\textbf{BS})}$ and $\Delta_{(\textbf{MZ}-\textbf{BS})}$ (defined in the last two rows) throughout our paper.

NLI, we apply the transformation on each sentence in every dataset instance. For token classification tasks (e.g., NER, POS), any transformation which changes the order of the tokens also changes the order of the labels. We present the mathematical specification in Appendix A.

3.3 Model Training and Evaluation

We now describe our pre-training and zero-shot transfer evaluation setup. Figure 1 provides an overview of pre-training and fine-tuning, and Table 2 summarizes the evaluation metrics we use.

Pre-training Let $\mathcal{C}_{\text{orig}}$ and $\mathcal{C}_{\text{deriv}}$ be the *original* and *derived* language pre-training corpora. We train two models for each *original-derived* pair:

1. **Bilingual Model (*Bi-LM*)**: A bilingual model pre-trained on the combined corpus ($\mathcal{C}_{\text{orig}}+\mathcal{C}_{\text{deriv}}$) (Figure 1a).
2. **Monolingual Model (*Mono-LM*)**: A monolingual model trained only on $\mathcal{C}_{\text{orig}}$ for the same number of steps as *Bi-LM*'s. *Mono-LM* is used as a baseline to measure zero-shot transfer of a model not pre-trained on *derived*.

Evaluation Let $\mathcal{D}^{\text{train}}_{\text{orig}}$ and $\mathcal{D}^{\text{dev}}_{\text{orig}}$ be the *original* language training and development sets for a downstream task, and $\mathcal{D}^{\text{train}}_{\text{deriv}}$ and $\mathcal{D}^{\text{dev}}_{\text{deriv}}$ be the corresponding *derived* language datasets. For evaluation, we first fine-tune the pre-trained models on a downstream training set and evaluate the resulting model on a development set (Figure 1b). Since our goal is to investigate the extent of zero-shot transfer, we require appropriate lower and upper bounds to make informed conclusions. To this end, we compute three metrics, all on the same development set (summarized in Table 2):

- **Bilingual zero-shot transfer (*BZ*)**: This is the standard zero-shot transfer score (Conneau and Lample, 2019) which measures how well a bilingual model fine-tuned on $\mathcal{D}^{\text{train}}_{\text{orig}}$ zero-shot transfers to the other language ($\mathcal{D}^{\text{dev}}_{\text{deriv}}$).
- **Bilingual supervised synthetic (*BS*)**: This is the supervised learning performance on the *derived* language obtained by fine-tuning *Bi-LM* on $\mathcal{D}^{\text{train}}_{\text{deriv}}$ and evaluating it on $\mathcal{D}^{\text{dev}}_{\text{deriv}}$.
- **Monolingual zero-shot transfer (*MZ*)**: This measures the zero-shot performance of the baseline *Mono-LM*, which is not pre-trained on the *derived* language, by fine-tuning *Mono-LM* on $\mathcal{D}^{\text{train}}_{\text{orig}}$ and evaluating it on $\mathcal{D}^{\text{dev}}_{\text{deriv}}$.

BS uses fine-tuning train data from the *derived* language and serves as an upper-bound on *BZ* and *MZ* which don't use it. *MZ* doesn't pre-train on the *derived* language and serves as a lower-bound on *BZ* which does pre-train on it. For easier comparison of *BZ* and *MZ* with *BS* (upper-bound), we report the following score differences (Table 2), which are both negative in our experiments.

$$\Delta_{(\text{BZ}-\text{BS})} = (\text{BZ} - \text{BS}) \tag{1}$$

$$\Delta_{(\text{MZ}-\text{BS})} = (\text{MZ} - \text{BS}) \tag{2}$$

BZ alone cannot capture the quality of the zero-shot transfer. A large and negative $\Delta_{(\text{BZ}-\text{BS})}$ implies that bilingual zero-shot transfer is much worse than supervised fine-tuning on *derived*. Concurrently, $\Delta_{(\text{BZ}-\text{BS})} \approx \Delta_{(\text{MZ}-\text{BS})}$ implies that *Bi-LM* transfers as poorly as *Mono-LM*. **Thus, good zero-shot transfer is characterized by $\Delta_{(\textbf{BZ}-\textbf{BS})} \approx 0$ and $\Delta_{(\textbf{BZ}-\textbf{BS})} \gg \Delta_{(\textbf{MZ}-\textbf{BS})}$.**

3.4 Experimental Setup

Languages We choose four diverse natural languages: English (Indo-European, Germanic), French (Indo-European, Romance), Hindi (Indo-European, Indo-Iranian), and Arabic (Afro-Asiatic, Semitic), which are represented in the multilingual XTREME benchmark (Hu et al., 2020). For each language, we consider four transformations (Section 3.2) to create *derived* counterparts, giving us 16 different original-derived pairs in total. For the *Syntax* transformation, we use Qi et al. (2020) for parsing. We modify the syntax of FR, HI, and AR to that of EN, and the syntax of EN to that of FR.

Datasets For the pre-training corpus ($\mathcal{C}_{\textbf{orig}}$), we use a 500MB (uncompressed) subset of Wikipedia ($\approx$ 100M tokens) for each language. This matches the size of WikiText-103 (Merity et al., 2016), a standard language-modeling dataset. For downstream evaluation, we choose four tasks from the XTREME benchmark (Hu et al., 2020). Table 4 lists all the datasets and their evaluation metrics.

Implementation Details We use a variant of RoBERTa (Liu et al., 2019) which has 8 layers, 8 heads, and a hidden dimensionality of 512. We train each model on 500K steps, a batch size of 128, and a learning rate of $1e$-4 with a linear warmup of 10K steps. We use an *original* language vocabulary size of 40000 for all the models and train on 8 Cloud TPU v3 cores for 32-48 hours. For fine-tuning, we use standard hyperparameters (Appendix F) from the XTREME benchmark and report our scores on the development sets.

4 Results

Our experiments reveal several interesting findings for bilingual models including the situational importance of sub-word overlap for zero-shot transfer (§ 4.1, 4.2), the effect of domain mismatch between languages (§ 4.3), and correlation of zero-shot performance with embedding alignment (§ 4.4). We connect our findings to zero-shot transfer results between natural languages in Section 4.5.

4.1 Sub-word overlap is not strictly necessary for strong zero-shot transfer

Sub-word overlap is the number of common tokens between two different language corpora. If $\mathcal{E}_1$ and $\mathcal{E}_2$ are sets of tokens which appear in the two corpora, then: Sub-word overlap $= |\mathcal{E}_1 \cap \mathcal{E}_2|/|\mathcal{E}_1 \cup \mathcal{E}_2|$ (Pires et al., 2019). The *Transliteration* transformation ($\mathcal{T}_{\textbf{trans}}$) creates *original-derived* language pairs that have 0% sub-word overlap (equivalently, different scripts), but follow the same word order.

Table 3 displays $\Delta_{(\text{BZ}-\text{BS})}$ scores for $\mathcal{T}_{\textbf{trans}}$, averaged over four languages (Appendix B contains a breakdown). We observe that $\Delta_{(\text{BZ}-\text{BS})} \approx 0$ for all tasks while $\Delta_{(\text{MZ}-\text{BS})}$ is highly negative, implying that zero-shot transfer is strong and on par with supervised learning. This result indicates that zero-shot transfer is possible even when languages with different scripts have similar word orders (in line with K et al. (2020)). However, it is unrealistic for natural languages to differ only in their script and not other properties (e.g., word order).

4.2 Absence of sub-word overlap significantly hurts zero-shot performance when languages differ in their word-orders

To simulate a more realistic scenario, we create *original* and *derived* language pairs which differ both in their scripts (0% sub-word overlap) and in word order. We achieve this by composing two transformations on the *original* language corpus, one of which is *Transliteration* ($\mathcal{T}_{\textbf{trans}}$). We experiment with three different compositions, (a) $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{inv}}$, (b) $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{perm}}$, and (c) $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{syn}}$. Here, $\boldsymbol{\alpha} \circ \boldsymbol{\beta}$ means that transformation $\boldsymbol{\beta}$ is applied before $\boldsymbol{\alpha}$. A composed transformation ($\mathcal{T}_{\textbf{trans}} \circ$

---

[4] XQuAD is a question-answering task where the correct answer is a *contiguous* span. We do not report scores on XQuAD for $\mathcal{T}_{\textbf{perm}}$ and $\mathcal{T}_{\textbf{syn}}$ because they can potentially reorder individual words in the contiguous answer, thus distributing them throughout the transformed sentence and making the question unanswerable. On the other hand, $\mathcal{T}_{\textbf{inv}}$ and $\mathcal{T}_{\textbf{trans}}$ do not have this issue because they maintain the spans.

Table 3: **(1) Evaluation:** We report $\Delta_{(\textbf{BZ}-\textbf{BS})}$ and $\Delta_{(\textbf{MZ}-\textbf{BS})}$ (§ 3.3 and Table 2) for transformations on different tasks, averaged over four languages (EN, FR, HI, AR). We report the breakdown for different languages in Appendix B. *BZ*, the bilingual zero-shot performance, is reported for reference. **(2) Interpreting scores:** Smaller (more negative) $\Delta_{(\text{BZ}-\text{BS})}$ implies worse bilingual zero-shot transfer, whereas $\Delta_{(\text{BZ}-\text{BS})} \approx 0$ implies strong transfer. $\Delta_{(\text{BZ}-\text{BS})} \gg \Delta_{(\text{MZ}-\text{BS})}$ implies that bilingual pre-training is extremely useful. Scores are highlighted based on their value (lower scores have a higher intensity of red). Cases with strong zero-shot transfer ($\Delta_{(\text{BZ}-\text{BS})} \approx 0$) are marked with an asterisk. **(3) Trends:** $\mathcal{T}_{\textbf{trans}}$ exhibits strong transfer on all tasks and languages (high $\Delta_{(\text{BZ}-\text{BS})}$ scores), and bilingual pre-training is extremely useful ($\Delta_{(\text{BZ}-\text{BS})} \gg \Delta_{(\text{MZ}-\text{BS})}$), implying that zero-shot transfer is possible between languages with different scripts but the same word order. $\mathcal{T}_{\textbf{inv}}$ and $\mathcal{T}_{\textbf{perm}}$ suffer on all tasks (small $\Delta_{(\text{BZ}-\text{BS})}$ scores) whereas $\mathcal{T}_{\textbf{syn}}$ suffers significantly lesser, which provides evidence that local changes to the word order made by *Syntax* ($\mathcal{T}_{\textbf{syn}}$) hurts zero-shot transfer significantly lesser than global changes made by *Inversion* ($\mathcal{T}_{\textbf{inv}}$) and *Permutation* ($\mathcal{T}_{\textbf{perm}}$).

Dataset	**Task**	**Metric**
XNLI (Conneau et al., 2018)	NLI	Accuracy
Wikiann (Pan et al., 2017)	NER	F1
UD v2.5 (Nivre et al., 2018)	POS	F1
XQuAD (Artetxe et al., 2020b)	QA	F1

Table 4: XTREME benchmark datasets used for zero-shot transfer evaluation. NLI=Natural Language Inference, NER=Named-entity recognition, POS=Part-of-speech tagging, QA=Question-Answering.

β) differs from its second constituent (β) in that the former produces a *derived* language which has 0% sub-word overlap with the *original* language whereas the latter has a 100% sub-word overlap.

Results Our results (Figure 2, breakdown in Appendix C) show that zero-shot performance is significantly hurt for composed transformations when compared to its constituents. $|\Delta_{(\text{BZ}-\text{BS})}|$ is much larger for $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{inv}}$ when compared to $\mathcal{T}_{\textbf{trans}}$ or $\mathcal{T}_{\textbf{inv}}$ individually. For example, for XNLI, $|\Delta_{(\text{BZ}-\text{BS})}| = 19$ for the composed transformation and just 2 and 3 for $\mathcal{T}_{\textbf{trans}}$ and $\mathcal{T}_{\textbf{inv}}$ individually. $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{perm}}$ is worse by ≈ 20 points on XNLI and NER, and over 40 points on POS when compared to $\mathcal{T}_{\textbf{perm}}$. $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{syn}}$ suffers lesser than the other two composed transformations, but it is still worse than $\mathcal{T}_{\textbf{syn}}$ by 3, 6, and 1 point on XNLI, NER, and POS. In conclusion, the absence of sub-word overlap significantly degrades zero-shot performance in the realistic case of languages with different word orders.

4.3 Data from the same domain boosts bilingual performance

Previously, we considered transformations ($\mathcal{T}$) that modified the *original* pre-training corpus to get a parallel corpus, $\mathcal{C}_{\textbf{deriv}} = \mathcal{T}\,(\mathcal{C}_{\textbf{orig}})$, such that there is a one-to-one correspondence between sentences in $\mathcal{C}_{\textbf{orig}}$ and $\mathcal{C}_{\textbf{deriv}}$ (we call this setting *parallel*). Since procuring large parallel corpora is expensive in practice, we consider two other settings which use different corpora for *original* and *derived*.

Setup Consider two text corpora of the same size, $\mathcal{C}^{\textbf{1}}_{\textbf{orig}}$ and $\mathcal{C}^{\textbf{2}}_{\textbf{orig}}$. We compare two settings: (1) The *parallel* setting pre-trains a bilingual model on $\mathcal{C}^{\textbf{1}}_{\textbf{orig}} + \mathcal{T}(\mathcal{C}^{\textbf{1}}_{\textbf{orig}})$, whereas the (2) *non-parallel* corpus setting uses $\mathcal{C}^{\textbf{1}}_{\textbf{orig}} + \mathcal{T}(\mathcal{C}^{\textbf{2}}_{\textbf{orig}})$. We consider two variants of *non-parallel*, (1) *non-parallel (same)* which uses different splits of Wikipedia data (hence, *same* domain), and (2) *non-parallel (diff)* which uses Wikipedia data for the *original* and common crawl data (web text) for the *derived* language (hence, *diff*erent domain). We use the *Transliteration* transformation ($\mathcal{T}_{\textbf{trans}}$) to generate the *derived* language corpus and report $|\Delta_{(\text{BZ}-\text{BS})}|$ averaged over all languages in Figure 3.

Results We observe consistently on all tasks that the *parallel* setting (blue bar) performs better than both the non-parallel settings. *Non-parallel (same)*

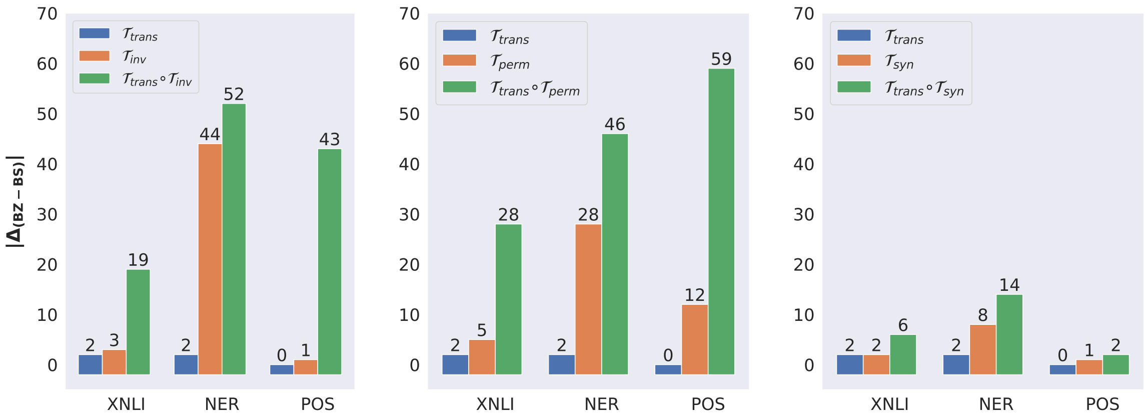

Figure 2: $|\Delta_{(\text{BZ}-\text{BS})}|$ for composed transformations (§ 4.2) applied on EN as the *original* language. Larger scores imply worse zero-shot transfer. $\mathcal{T}_{\textbf{trans}}$ = *Transliteration*, $\mathcal{T}_{\textbf{inv}}$ = *Inversion*, $\mathcal{T}_{\textbf{perm}}$ = *Permutation*, and $\mathcal{T}_{\textbf{syn}}$ = *Syntax*. Sub-word overlap between the *original* and *derived* language is 0% when composed transformations are used (e.g. $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{inv}}$) and 100% when the second constituent is used (here, $\mathcal{T}_{\textbf{inv}}$). We observe that the composed transformations (green bars) do significantly worse than their constituents (blue and orange), showing that $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{inv}}$ is worse than $\mathcal{T}_{\textbf{inv}}$ by over 16 points on XNLI and 42 points on POS, with similar trends for $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{perm}}$. $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{syn}}$ doesn't suffer as much, but its performance degradation when compared to *Syntax* is still large (ranges between 1 point on POS to 6 points on NER). **absence of sub-word overlap significantly hurts performance when languages differ in their word orders.**

performs better than *non-parallel (diff)*, with gains ranging between 2 points on XQuAD to 17 points on NER. This result shows that even for *original* and *derived* language pairs which differ only in their script, having parallel pre-training corpora leads to the best zero-shot transfer. Since large-scale parallel unsupervised data is hard to procure, the best alternative is to use corpora from similar domains (Wikipedia) rather than different ones (Wikipedia v.s. web text).

4.4 Zero-shot performance is strongly correlated with embedding alignment

Our previous results (§ 4.2, 4.3) showed cases where zero-shot transfer between languages is poor when there is no sub-word overlap. To investigate this further, we analyze the static word embeddings learned by bilingual models and find that zero-shot transfer between languages is strongly correlated with the alignment between word embeddings for the *original* and *derived* languages.

Setup The *original* and the *derived* languages have a one-to-one correspondence between their sub-word vocabularies when we use *transliteration* ($\mathcal{T}_{\textbf{trans}}$). For a token embedding in the *original*-language embedding matrix, its alignment score is 100% if it retrieves the corresponding token embedding in the *derived* language when a nearest-neighbor search is performed, and 0% otherwise. We average the alignment score over all the tokens and call it *alignment*.

Results We measure the *alignment* of bilingual models pre-trained on different *original-derived* language pairs created using *transliteration*, namely the composed transformations (§ 4.2), *parallel*, and *non-parallel* (§ 4.3). We plot the *alignment* along with the corresponding $\Delta_{(\text{BZ}-\text{BS})}$ scores for XNLI in Figure 4. Results for other tasks are in Appendix E.

We observe that higher *alignment* is associated with lower $\Delta_{(\text{BZ}-\text{BS})}$, implying better zero-shot transfer. *Alignment* is lower for composed transformations like $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{inv}}$ and $\mathcal{T}_{\textbf{trans}} \circ \mathcal{T}_{\textbf{perm}}$ which have large and negative $\Delta_{(\text{BZ}-\text{BS})}$. *Alignment* also explains the results in Section 4.3, with *non-parallel* variants having lower alignment scores than *parallel*, which is in line with their lower $\Delta_{(\text{BZ}-\text{BS})}$. Overall, we find a strong and significant Spearman's rank correlation between *alignment* and $\Delta_{(\text{BZ}-\text{BS})}$, with $\rho = 0.94, p < .005$ for XNLI, $\rho = 0.93, p < .005$ for NER, and $\rho = 0.89, p < .01$ for POS, indicating that increasing the embedding alignment between languages helps improve zero-shot transfer.

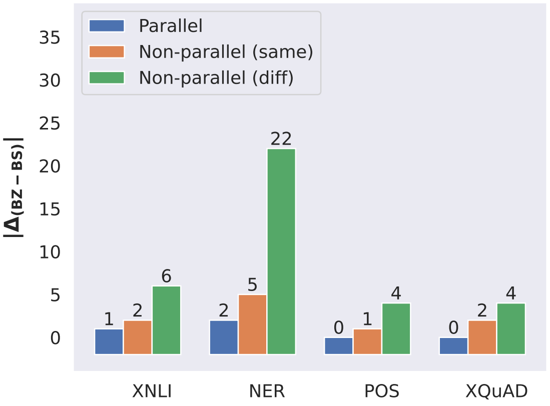

Figure 3: $|\Delta_{(\mathrm{BZ-BS})}|$ for $\mathcal{T}_{\mathbf{trans}}$ under different conditions on the source of *original* and *derived* language pre-training corpora (hereon, corpora) (§ 4.3), averaged over four languages. Larger values imply worse zero-shot transfer. The breakdown of scores for different languages is in Appendix D. (1) *Non-parallel (diff)* (green bar), which uses corpora from different domains is worse than (2) *Non-parallel (same)* (orange bar), which uses different sets of sentences sampled from the same domain, which is in turn worse than (3) *Parallel*, which uses the same sentences. Having pre-training corpora from the same domain like Wikipedia (*Non-parallel (same)*) gives performance boosts between 2 points for QA to 17 points for NER when compared to *Non-parallel (diff)*.

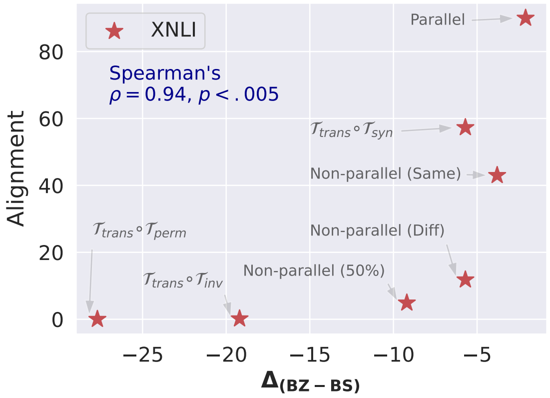

Figure 4: $\Delta_{(\mathrm{BZ-BS})}$ for *Transliteration* ($\mathcal{T}_{\mathbf{trans}}$) variants on XNLI. Larger values (less negative) imply better zero-shot transfer. We see that alignment (§ 4.4) between token embeddings of different languages is correlated with $\Delta_{(\mathrm{BZ-BS})}$, and hence with better zero-shot transfer. For example, $\mathcal{T}_{\mathbf{trans}} \circ \mathcal{T}_{\mathbf{inv}}$ (bottom left) which has poor zero-shot transfer also has lower alignment, whereas *Parallel* (top right) which has strong transfer is accompanied with higher alignment. We find a strong and statistically significant Spearman's correlation of $\rho_s = 0.94, p < .005$ on XNLI, $\rho_s = 0.93, p < .005$ on NER, and $\rho_s = 0.89, p < .01$ on POS. Plots for other tasks are in Appendix E.

4.5 Connections to results on natural language pairs

Effect of sub-word overlap In § 4.2, we showed that when languages have different scripts (0% sub-word overlap), zero-shot transfer significantly degrades when they additionally have different word orders. However, the zero-shot transfer is good when languages differ only in the script and have similar or the same word order. This is in line with anecdotal evidence in Pires et al. (2019), where zero-shot transfer works well between *English* and *Bulgarian* (different script but same subject-verb-object order – SVO), but is poor between *English* and *Japanese* (different script *and* word order – SVO v.s. SOV). Our result also corroborates findings in Conneau et al. (2020b) that artificially increasing sub-word overlap between natural languages (which have different word orders) improves performance (e.g., 3 points on XNLI).

Effect of token embedding alignment In § 4.4, we showed that zero-shot transfer is strongly correlated with word embedding alignment between languages. This explains the usefulness of recent studies which try to improve multilingual pre-training with the help of auxiliary objectives, which improve word or sentence embedding alignment.

DICT-MLM (Chaudhary et al., 2020) and RelateLM (Khemchandani et al., 2021) require the model to predict cross-lingual synonyms as an auxiliary objective, thus indirectly improving word-embedding alignment and the zero-shot performance on multiple tasks. Hu et al. (2021) add an auxiliary objective that implicitly improves word embedding alignment and show that they can achieve performance similar to larger models. Cao et al. (2019) explicitly improve contextual word embedding alignment with the help of word-level alignment information in machine-translated cross-lingual sentence pairs. Since they apply this post hoc and not during pre-training, the improvement, albeit significant, is small (2 points on XNLI). While these studies do not fully utilize word and sentence embedding alignment information, our results lead us to posit that they are a step in the right direction and that baking alignment information more explicitly into pre-training will be beneficial.

5 Conclusion

Through a systematic study of zero-shot transfer between four diverse natural languages and their counterparts created by modifying specific properties like the script, word order, and syntax, we showed that (1) absence of sub-word overlap hurts zero-shot performance when languages differ in their word order, and (2) zero-shot performance is strongly correlated with word embedding alignment between languages. Some recent studies have implicitly or unknowingly attempted to improve alignment and have shown slight improvements in zero-shot transfer performance. However, our results lead us to posit that explicitly improving word embedding alignment during pre-training by using either supervised (e.g., parallel sentences and translation dictionaries) or unsupervised data will significantly improve zero-shot transfer. Although real languages typically differ in more ways than the set of properties considered in our transformations, our methodology is still useful to help isolate crucial properties for transfer. Future work can experiment with more sophisticated transformations and investigate closer connections with human language pairs.

Appendices

A Mathematical Specification for Transformation of Downstream Datasets

Text classification Text classification tasks like news classification or sentiment analysis typically have instances which contain a single sentence and a label. Instances in other classification tasks like natural language inference (NLI) (Bowman et al., 2015) contain two sentences and one label. For such tasks, we apply the transformation ($\mathcal{T}$) on each sentence within every instance, and leave the annotated label as is. Therefore, for a dataset of size n which contains m sentences per instance, we have:

$$\mathcal{D}_{\textbf{orig}} = \{(s_{i1}, \ldots, s_{im}, y_i) \mid i = 1 : N\}$$
$$\mathcal{D}_{\textbf{deriv}} = \{(\mathcal{T}(s_{i1}), \ldots, \mathcal{T}(s_{im}), y_i) \mid i = 1 : N\}$$

Token-classification tasks Tasks like named-entity recognition (NER) and part-of-speech tagging (POS tagging) have labels associated with *each* token in the sentence. For these datasets, we ensure that any transformation ($\mathcal{T}$) that changes the order of the tokens also changes the order of the corresponding labels.

We define a few quantities to express the transformation mathematically. Let $s_i = (w_{i1}, \ldots, w_{ik})$ be a sentence comprised of k tokens and $y_i = (y_{i1}, \ldots, y_{ik})$ be labels corresponding to the tokens in the sentence. We define a new transformation ($\mathcal{T}_{aug}$) which operates on the label augmented sentence, $s_i^{aug} = ((w_{i1}, y_{i1}), \ldots, (w_{ik}, y_{ik}))$. Let $s_i^{aug}[j]$ correspond to the j^{th} element in the sequence, and $s_i^{aug}[j][\texttt{word}]$ and $s_i^{aug}[j][\texttt{label}]$ correspond to the word and label of the j^{th} element. Let $\mathcal{T}_{aug}(s_i^{aug})[j][\texttt{orig}]$ denote the index of the j^{th} element in the transformed sequence with respect to the original sequence s_i^{aug}. Then, the new transformation $\mathcal{T}_{aug}$ is such that,

$$\mathcal{T}_{aug}(s_i^{aug})[j][\texttt{orig}] = \mathcal{T}(s_i)[j][\texttt{orig}]$$
$$\text{Let } \texttt{orig\_j} = \mathcal{T}_{aug}(s_i^{aug})[j][\texttt{orig}]$$
$$\mathcal{T}_{aug}(s_i^{aug})[j][\texttt{label}] = s_i^{aug}[\texttt{orig\_j}][\texttt{label}]$$

We transform the dataset using $\mathcal{T}_{aug}$:

$$\mathcal{D}_{\textbf{orig}} = \{s_i^{aug} \mid i = 1 : N\}$$
$$\mathcal{D}_{\textbf{deriv}} = \{\mathcal{T}_{aug}(s_i^{aug}) \mid i = 1 : N\}$$

B Zero-shot transfer results for different transformations

Table 5 in the appendix is the extended version of Table 3 in the main paper with a breakdown for all languages. It reports $\Delta_{(\text{BZ}-\text{BS})}$, $\Delta_{(\text{MZ}-\text{BS})}$, and *BZ* for different languages and transformations considered.

C Composed Transformations

Table 6 in the appendix presents the breakdown of results in Figure 2 of the main paper. It reports $\Delta_{(\text{BZ}-\text{BS})}$ scores for composed transformations and their constituents.

D Comparing different sources for *original* and *derived* language corpora

Table 8 in the appendix contains the breakdown of results in Figure 3 of the main paper. It reports $\Delta_{(\text{BZ}-\text{BS})}$ for different languages on different tasks for the settings mentioned in Section 4.3.

E Alignment Correlation

We present alignment results (Section 4.4) for all XNLI, NER, and POS in Figure 5. We observe strong correlations between alignment and zero-shot transfer, with $\rho_s = 0.94, p < .005$ on XNLI, $\rho_s = 0.93, p < .005$ on NER, and $\rho_s = 0.89, p < .01$ on POS. We present the raw scores in Table 7.

F Hyperparameters for XTREME

- XNLI: Learning rate – `2e-5`, maximum sequence length – 128, epochs – 5, batch size – 32.
- NER: Learning rate – `2e-5`, maximum sequence length – 128, epochs – 10, batch size – 32.
- POS: Learning rate – `2e-5`, maximum sequence length – 128, epochs – 10, batch size – 32.
- Tatoeba: Maximum sequence length – 128, pooling strategy – representations from the middle layer $\left(\frac{n}{2}\right)$ of the model.
- XQuAD: Learning rate – `3e-5`, maximum sequence length – 384, epochs – 2, document stride – 128, warmup steps – 500, batch size – 16, weight decay – 0.0001.

Table 5: This table is an extended version of Table 3 in the main paper. Smaller (more negative) $\Delta_{(\text{BZ}-\text{BS})}$ implies worse bilingual zero-shot transfer, whereas $\Delta_{(\text{BZ}-\text{BS})} \approx 0$ implies strong transfer. $\Delta_{(\text{BZ}-\text{BS})} \gg \Delta_{(\text{MZ}-\text{BS})}$ implies that bilingual pre-training is extremely useful. Scores are highlighted based on their value (lower scores have a higher intensity of red). **(1) Discussing $\Delta_{(\text{BZ}-\text{BS})}$:** $\mathcal{T}_{\text{trans}}$ exhibits strong transfer on all tasks and languages (high $\Delta_{(\text{BZ}-\text{BS})}$ scores), and bilingual pre-training is extremely useful ($\Delta_{(\text{BZ}-\text{BS})} \gg \Delta_{(\text{MZ}-\text{BS})}$), implying that zero-shot transfer is possible between languages with different scripts but the same word order. $\mathcal{T}_{\text{inv}}$ and $\mathcal{T}_{\text{perm}}$ suffer on all tasks (small $\Delta_{(\text{BZ}-\text{BS})}$ scores) whereas $\mathcal{T}_{\text{syn}}$ suffers significantly lesser, which provides evidence that local changes to the word order made by *Syntax* ($\mathcal{T}_{\text{syn}}$) hurts zero-shot transfer significantly lesser than global changes made by *Inversion* ($\mathcal{T}_{\text{inv}}$) and *Permutation* ($\mathcal{T}_{\text{perm}}$). **(1) Discussing $\Delta_{(\text{MZ}-\text{BS})}$:** $\Delta_{(\text{BZ}-\text{BS})}$ is much larger than $\Delta_{(\text{MZ}-\text{BS})}$ for $\mathcal{T}_{\text{trans}}$, implying that bilingual pre-training (hereon, pre-training) is extremely useful. $\Delta_{(\text{BZ}-\text{BS})}$ and $\Delta_{(\text{MZ}-\text{BS})}$ are similar for $\mathcal{T}_{\text{inv}}$ and $\mathcal{T}_{\text{syn}}$, implying that pre-training is not beneficial for these transformations. $\Delta_{(\text{BZ}-\text{BS})}$ is slightly larger than $\Delta_{(\text{MZ}-\text{BS})}$ for $\mathcal{T}_{\text{perm}}$, which means that pre-training is moderately useful.

$\mathcal{T}$	XNLI		NER		POS	
	BZ	$\Delta_{(\text{BZ}-\text{BS})}$	*BZ*	$\Delta_{(\text{BZ}-\text{BS})}$	*BZ*	$\Delta_{(\text{BZ}-\text{BS})}$

Table 8: $|\Delta_{(\text{BZ}-\text{BS})}|$ for $\mathcal{T}_{\textbf{trans}}$ under different conditions on the source of *original* and *derived* language pre-training corpora (§ 4.3). Larger values imply worse zero-shot transfer. For all languages: (1) *Non-parallel (diff)*, which uses corpora from different domains is worse than (2) *Non-parallel (same)*, which uses different sets of sentences sampled from the same domain, which is in turn worse than (3) *Parallel*, which uses the same sentences.

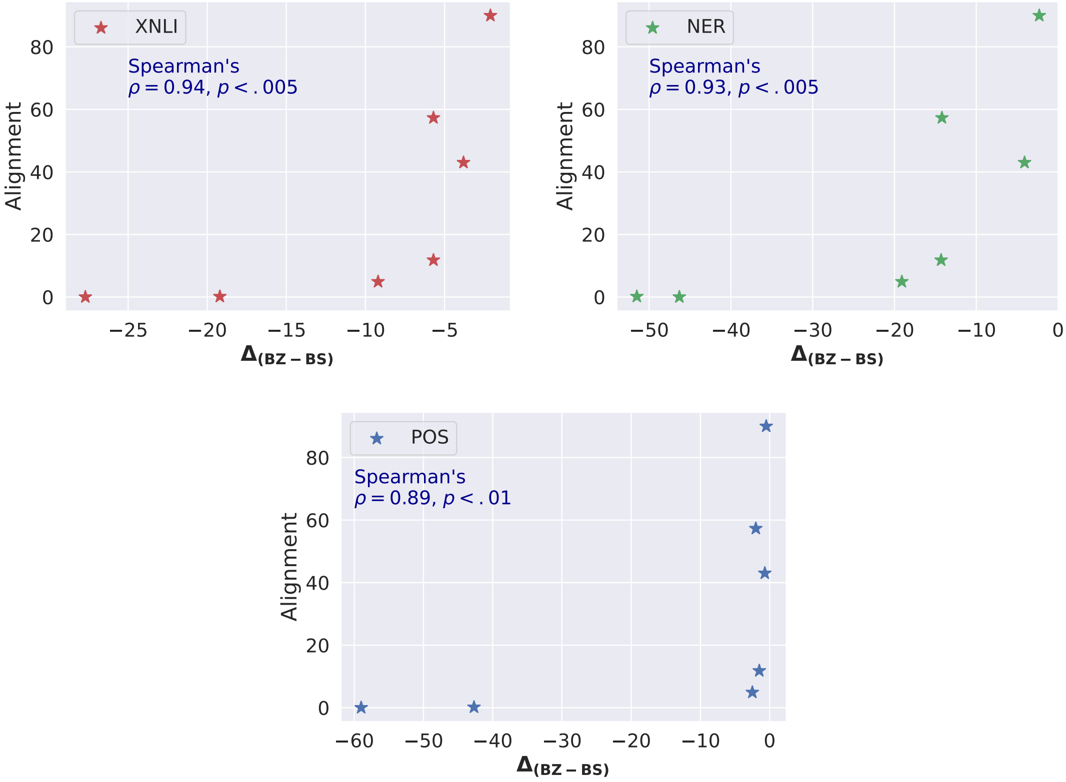

Figure 5: Alignment v.s. $\Delta_{(\text{BZ}-\text{BS})}$ plots for XNLI, NER, and POS. We observe strong correlations between alignment and zero-shot transfer, with $\rho_s = 0.94, p < .005$ on XNLI, $\rho_s = 0.93, p < .005$ on NER, and $\rho_s = 0.89, p < .01$ on POS.

How Conservative are Language Models?
Adapting to the Introduction of Gender-Neutral Pronouns

Stephanie Brandl, Ruixiang Cui, Anders Søgaard
University of Copenhagen, Denmark
`{brandl, rc, soegaard}@di.ku.dk`

Abstract

Gender-neutral pronouns have recently been introduced in many languages to a) include non-binary people and b) as a generic singular. Recent results from psycholinguistics suggest that gender-neutral pronouns (in Swedish) are *not* associated with human processing difficulties. This, we show, is in sharp contrast with automated processing. We show that gender-neutral pronouns in Danish, English, and Swedish are associated with higher perplexity, more dispersed attention patterns, and worse downstream performance. We argue that such conservativity in language models may limit widespread adoption of gender-neutral pronouns and must therefore be resolved.

1 Introduction

Many linguistic scholars have observed how technology in general has altered the course of language evolution (Kristiansen et al., 2011; Abbasi, 2020), e.g., through the influence of social media conventions. Language technologies, in particular, have also been argued to have such effects, e.g., by reducing the pressure to acquire multiple languages.

Gender-neutral pronouns is not an entirely modern concept. In 1912, Ella Flag Young, then superintendent of the Chicago public-school system, said the following to a room full of school principals: "The English language is in need of a personal pronoun of the third person, singular number, that will indicate both sexes and will thus eliminate our present awkwardness of speech." The use of gender-neutral pronouns has become much more popular in recent years (Gustafsson Sendén et al., 2021). In 2013, a gender-neutral pronoun was *politically* introduced in Swedish (Gustafsson Sendén et al., 2015) which can be used for both, people identifying outside the gender dichotomy and as a generic pronoun where information about gender is either unavailable or irrelevant.

In a recently recorded eye-tracking study, Vergoossen et al. (2020a) found no evidence that native speakers of Swedish find it harder to process gender-neutral pronouns than gendered pronouns, an argument often brought up by opponents of gender-inclusive language (Speyer and Schleef, 2019; Vergoossen et al., 2020b). In combination with their increasing popularity, this suggests gender-neutral pronouns have been or will be widely and fully adapted over time (Gustafsson Sendén et al., 2015, 2021). However, since language technology has the potential to alter the course of language evolution, we want to make sure that our NLP models do not become a bottleneck for this positive development.

Contribution We extract stimuli from a Swedish eye-tracking study that has shown no increase in processing cost in humans for the gender-neutral pronoun *hen* compared to gendered pronouns. We translate those stimuli into English and Danish and compare model perplexity across gendered and gender-neutral pronouns for all three languages. Furthermore, we systematically investigate performance differences across pronouns in downstream tasks, namely natural language inference (NLI) and coreference resolution. Across the board, we find that NLP models, unlike humans, are challenged by gender-neutral pronouns, incurring significantly higher losses when gendered pronouns are replaced with their gender-neutral alternatives. We argue this is a problem the NLP community must take seriously.[1]

2 Model perplexity and attention

In this section we introduce a Swedish eye-tracking study and explain how we adapt this study to investigate gender-neutral pronouns in language models.

	0.28	0.33	0.49	0.13	0.17	0.21	0.65	0.72
	0.28	0.33	0.49	0.13	0.17	0.22	0.65	0.72

Table 1: Perplexity scores across pronouns and languages for the eye-tracking stimuli. Correlation between attention flow and perplexity are listed row-wise for layers 1, 6 and 12.

Humans and *hen* Vergoossen et al. (2020a) recently recorded a Swedish eye-tracking study to test the hypothesis whether the gender neutral pronoun *hen* has a higher processing cost during pronoun resolution than gendered pronouns. Participants were reading sentence pairs where the first sentence contained a noun referring to a person and the second sentence contained a pronoun referring to that person either with a gendered pronoun or *hen*, for example:

70-åringen dammsög golvet i vardagsrummet.
Han/Hen skulle få besök på kvällen.

The 70-year-old vacuumed the living room floor.
He/They would have visitors in the evening.

It has recently been shown that attention flow, in contrast to attention itself, correlates with human fixation patterns in task-specific reading (Eberle et al., 2022). We applied a similar analysis pipeline here and extracted all 384 sentence pairs and fed them into the uncased Swedish BERT model.[2] We calculate perplexity values for each sentence pair over word probabilities as given by BERT with the formula proposed by Wang et al. (2019). Furthermore, we calculate attention flow (Abnar and Zuidema, 2020) propagated from layers 1, 6 and 12 and extract attention flow values assigned to the pronoun with respect to the entity. Attention flow considers the attention matrices as a graph, where tokens are represented as nodes and attention scores as edges between consecutive layers. The edge values, i.e., attention scores, define the maximal flow possible between a pair of nodes.

We consider different parameters of human fixation which we assume might be influenced by a change in pronouns, in particular during pronoun resolution, i.e., first and total fixation time on the pronoun and fixation time after the first fixation on the noun. For both attention flow and perplexity, however we could not find any meaningful correlation to those parameters. One reason for that might be that the dataset only contains fixations for the two entities, i.e., pronoun and noun, which makes data comparably sparse and impossible to extract complete reading patterns.

Language models and gender-neutral pronouns We therefore focus on the model-based data alone in order to understand how well language models can deal with gender-neutral pronouns. For this, we consider perplexity values on sentence-level and calculate rank-based Spearman correlation between perplexity and attention flow for the aforementioned layers. Perplexity has been treated as an indicator for model surprisal and language model quality (Goodkind and Bicknell, 2018) thus we argue that it serves as a reasonable indicator for processing difficulty.

With this analysis, we can see if a) gender-neutral pronouns cause a higher sentence perplexity, i.e., a higher *surprisal* and if b) a possible higher surprisal is connected to higher attention flow values on the pronoun with respect to the entity.

We furthermore translate the sentence pairs into English and Danish where we use two sets of gender-neutral pronouns: 3rd person plural (hence: they/de) which are used in both languages as gender-neutral pronouns (Miltersen, 2020) and *neo-pronouns* (xe for English (Hekanaho, 2020) and høn for Danish).[3] For the translation, we use the Google Translate API for Python and manually correct sentences such that semantics agree with the original sentences in Swedish. We apply the same experiments to those translated datasets with uncased Danish BERT[4] and uncased English BERT[5].

Results We show results on perplexity and correlations in Table 1 for Danish, English and Swedish.

[3] `information.dk/kultur/hen-hoen`

[4] `huggingface.co/Maltehb/danish-bert-botxo`

[5] `huggingface.co/bert-base-uncased`

Perplexity values for the datasets with gendered pronouns are set to 1 and we show relative increase for gender-neutral pronouns within a language since perplexity values have been shown to not be comparable across languages (Mielke et al., 2019; Roh et al., 2020). There we can see that perplexity scores for sentences with gender-neutral pronouns are significantly higher (Wilcoxon signed-rank test resulted in p-values < 0.01 for all pair-wise comparisons).

For the correlation between perplexity and attention flow on the Swedish sentence pairs, we can see a clear development between the first layer where there is no correlation ($p > 0.05$) for gender-neutral *hen* and very low correlation for gendered pronouns which changes for the other layers where correlations for *hen* are even higher ($\rho = 0.72$) than for gendered pronouns ($\rho = 0.65$). This suggests that there is some development across layers that is stronger for *hen* than for gendered pronouns. Furthermore, we see a similar evolvement for correlations across layers in English but a much weaker correlation for Danish.

To investigate those effects across layers further, we look at word embeddings for all Swedish pronouns from all 12 layers in BERT and compute pair-wise cosine similarity including the Swedish word for book (*bok*) as a baseline where we expect no specific relation to pronouns. In Figure 1, we see less similarity between *hen* and the other pronouns in the first layer. This changes for layer 6 and 12 where word representations seem to be more similar and the three 3rd person pronouns *hen, han, hon* get closer to each other. This is in line with the literature where it has been found that single attention heads perform better on pronoun resolution than others. In particular middle and deeper layers have shown stronger attention weights between coreferential elements (Vaswani et al., 2017; Webster et al., 2018; Clark et al., 2019). Given that we do not consider individual heads or layers but the entire attention graph it is not surprising that we also see those effects in the top layer as has been shown in the original paper (Abnar and Zuidema, 2020).

3 Downstream Tasks

We also perform downstream task experiments on natural language inference and coreference resolution for both gendered and gender-neutral pronouns to investigate to what extent gender-neutral pronouns influence the performance.

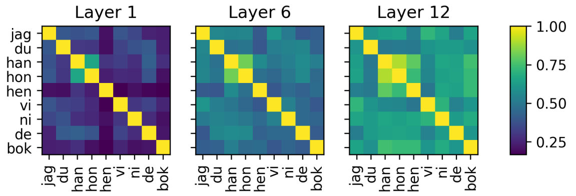

Figure 1: Pair-wise cosine similarity between word representations of all pronouns and the Swedish word *bok* (book) as a baseline for different layers of BERT. We see that gender-neutral *hen* grows from being an outsider (similar to *bok*) in the 1st layer into the cluster of gendered 3rd person pronouns *hon/han* across layers.

Natural Language Inference Natural Language Inference (NLI) is commonly framed as a classification task, which tests a model's ability to understand entailment and contradiction (Bowman et al., 2015). Despite high accuracies achieved by SOTA models, we are yet to know whether they succeed in combating gender bias, especially in cross-lingual settings. We apply two multilingual models mBERT[6] (Devlin et al., 2019) and XLM-R[7] (Conneau et al., 2020) with cross-lingual fine-tuning, i.e., we fine-tune on English and apply both models also on Danish and Swedish. Therefore, mBERT was fine-tuned on the English MNLI train split and evaluated on XNLI. For XLM-R, we apply a model that has been fine-tuned on both MNLI and ANLI (Nie et al., 2020)[8]. For English we test both models on the MNLI test split, for Danish and Swedish we test on the extended XNLI corpus (Singh et al., 2019), the manual translation of the first 15000 sentences of the MNLI corpus (Williams et al., 2018) from English into 15 languages.

Coreference Resolution We also run pronoun resolution experiments on the Winogender dataset (Rudinger et al., 2018) where all 720 English sentences include an *occupation*, a *participant* and a *pronoun*. For each occupation, two similar sentences are composed, one where the pronoun refers to the occupation and one where it refers to the participant. Those sentences are then presented in versions with different pronouns (female, male, singular they). For our experiments, we compare performance for those pronouns and add a version

XLM-R	**95.13**	94.81	94.05	**80.19**	79.18	75.48	**78.79**	78.5	78.58

Table 2: Accuracy [in %] on NLI for English, Danish and Swedish for both models mBERT and XLM-R. Accuracies are calculated on the subset of sentences that contain relevant pronouns (924 for en and 2339 for da/sv). The first column for each language shows the accuracy on the original data, second and third columns show accuracies for respective gender-neutral pronouns. Please note, the total number of label flips in both directions for different pronouns is higher than the performance difference for all pair-wise comparisons. A baseline analysis where we exchanged punctuation ("." for "!") yields similar deviations from the original dataset than the changing pronouns.

for the gender-neutral pronoun *xe*. We run experiments with NeuralCoref 4.0 in SpaCy.[9]. Lauscher et al. (2022) conduct similar experiments in English where all pronouns are exchanged for their POS tag, in contrast to our experiments where we only exchange gendered pronouns and replace them with gender-neutral pronouns.

For Danish, we apply the recently published coreference model (Barrett et al., 2021) to both the corresponding test set from the *Dacoref* dataset and a *gender-neutralized* version where we exchange gendered pronouns *hun/han* for either *høn* or singular *de*.[10]

4 Results

Natural Language Inference Accuracies for all languages and both models are displayed in Table 2. We overall see a very small drop in performance for the datasets with gender neutral pronouns compared to the original sentences. For mBERT we see differences of $0.09 - 1.51\%$, for XLM-R the drop is slightly higher with $0.21 - 4.71\%$. We see the biggest difference for the Danish pronoun *høn* in comparison to the original dataset.

	she	he	they	xe
acc in %	42.92	**43.75**	27.92	0

Table 3: Results for the pronoun resolution task on the English Winogender dataset.

Coreference Resolution Table 3 shows accuracies on the English Winogender corpus for all four pronouns. We see a clear drop in performance from gendered pronouns (*she, he*) to both gender-neutral pronouns (*they, xe*). For *xe*, the model was not able to perform coreference resolution at all. In most cases it was not even recognized as part of a cluster and in the rare cases where it was, it was clustered with the wrong tokens. Please note that since this dataset is not labelled we are only classifying if the pronoun has been clustered with the correct entity.

	orig.	de	høn
F1-score	**0.64**	0.63	0.62
Prec.	**0.70**	0.69	0.69
Recall	**0.59**	0.57	0.56

Table 4: Results for the Danish coreference resolution task. Pronouns in the original dataset (orig.) have been exchanged for singular *de* and gender-neutral *høn*.

Results on the Danish Coref corpus, where we are able to perform a more extensive coreference resolution task are displayed in Table 4. We were able to replicate results from Barrett et al. (2021) (the first column *orig.*) and see small drops in performance for singular *de* and *høn*.

5 Related Work

More eye-tracking studies have been conducted investigating the influence in processing cost for both gender-neutral pronouns and the generic male pronoun. Irmen (2007) and Redl et al. (2021) find male biases when using generic male pronouns in Dutch and generic role nouns in German. The authors of Sanford and Filik (2007) found a clear processing cost when using singular *they* in English, however their stimuli did not include any investigation of how (anti-)stereotypes influence this processing cost and is thus only in parts comparable to other studies. English datasets have been proposed to investigate gender bias in pronoun resolution but have not reported on performance differences between gendered and gender-neutral pronouns (Rudinger et al., 2018; Zhao et al., 2018; Webster et al., 2018). Sun et al. (2021) propose a rewriting task where data is transferred from gendered

---

[9] `github.com/huggingface/neuralcoref`

[10] So far, no Swedish coreference model has been published, we therefore leave this analysis for future work.

to gender-neutral pronouns to train more inclusive language models. Cao and Daumé III (2020) and Dev et al. (2021) discuss the necessity of including non-binary pronouns into NLP research (see also Stanczak and Augenstein (2021)).

6 Discussion

With this paper we provide a first study on how well language can handle gender-neutral pronouns in Danish, English and Swedish for various tasks. We observe an increase in perplexity for gender-neutral pronouns and correlations between perplexity on sentence level and attention flow on the pronoun, in particular for English and Swedish that gets stronger across layers. This indicates that language models indeed struggle with the use of gender-neutral pronouns, even with singular *they*, which has been used for many years as gender-neutral (Saguy and Williams, 2022). The reason for this most likely lies in the sparse representation of gender-neutral pronouns in the training data and the fact that language models, once they are trained and published usually are not updated (Bender et al., 2021). However, Transformer models pre-trained on subword units have been shown to be robust with respect to word frequency (Sennrich et al., 2016) and thus should be able to process unfamiliar gender-neutral pronouns. At the same time, we observe that word representations of all Swedish 3rd person pronouns grow closer in middle and top layers (see Figure 1) which suggests that relevant information is also learned for gender-neutral *hen*.

For NLI, we only see a small drop in performance when exchanging gendered pronouns for gender-neutral pronouns which is in the same range as a baseline analysis where we exchange punctuation ("!" for "."), except for Danish *høn*. We argue that classification in NLI probably does not heavily rely on individual pronouns in most cases. In stark contrast to pronoun resolution where we see a very clear drop in performance for English when applying singular *they* in comparison to both female and male pronouns, again this is surprising since in theory language models should have seen training samples where singular *they* has been used. The small drop in performance for Danish coreference resolution might be because this dataset does not solely focus on pronoun resolution, though further investigation is needed here. We strongly argue that more needs to be done to adapt language models to a more gender inclusive language, initiatives like the rewriting task as proposed by Sun et al. (2021) need to be implemented and extended.

Abstract

Fine-tuning continuous prompts for target tasks has recently emerged as a compact alternative to full model fine-tuning. Motivated by these promising results, we investigate the feasibility of extracting a discrete (textual) interpretation of continuous prompts that is faithful to the problem they solve. In practice, we observe a "*wayward*" behavior between the task solved by continuous prompts and the nearest neighbor discrete projections of these prompts: One can find continuous prompts that solve a task while being projected to an *arbitrary* text (e.g., definition of a different or even a contradictory task) and simultaneously being within a very small (2%) margin of the best continuous prompt of the same size for the task. We provide intuitions behind this odd and surprising behavior, as well as extensive empirical analyses quantifying the effect of design choices. For instance, larger models exhibit higher waywardness, i.e, we can find prompts that more closely map to any arbitrary text with a smaller drop of accuracy. These findings have important implications relating to the difficulty of faithfully interpreting continuous prompts and their generalization across models and tasks, providing guidance for future progress in prompting language models.

1 Introduction

Recent work has shown the surprising power of *continuous prompts* to language models (LMs) for controlled generation and for solving a wide range of tasks (Li and Liang, 2021; Lester et al., 2021; Min et al., 2022). Despite these successes, the resulting continuous prompts are not easy to interpret (Shin et al., 2020). Is it possible to come up with meaningful discrete (textual) interpretations of continuous prompts, especially ones that provide a faithful explanation of the prompt's behavior?

Towards addressing this question, we propose and investigate the *Prompt Waywardness* hypothesis (§3.2), a surprising disconnect between the intended behavior of continuous prompts and their nearest-neighbor discrete (language) representations.[1] In particular, we show that one can find continuous prompts that perform a desired task while, at the same time, project to *any* given target text. This indicates that there is little correspondence between continuous prompts and their discrete interpretation. For instance, a continuous prompt that effectively solves the sentiment classification task in Fig.1, when projected onto discrete space, might appear as the definition of a different task (*"flip the sentiment"*). Intuitively, continuous prompt optimization is a highly non-convex problem with numerous local minima. More surprisingly, many of these prompts (e.g., those near embedded text) are very effective at solving a desired task.

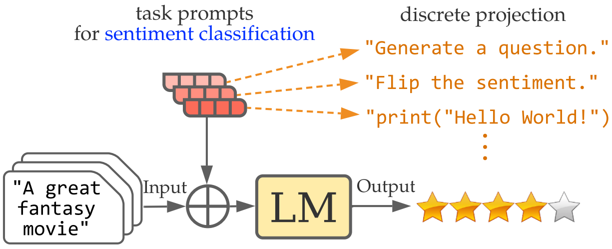

Figure 1: We show that one can find accurate continuous prompts (that do well on a given task, e.g., sentiment classification here) such that they can be projected to any *arbitrary* text, such as the definition of a different task (e.g., generating a question) or even an irrelevant statement (e.g., a piece of code) — suggesting a disconnect between the outcome of continuous prompts and their discrete interpretations.

We conduct extensive analyses showing Waywardness on five classification datasets (§4). Empirically, we find the existence of *wayward* prompts — prompts that solve each of these tasks while pro-

---

[1] Nearest-neighbor projection via dot product has been previously used to study properties of continuous word embeddings (Mikolov et al., 2013; Hashimoto et al., 2016) and is commonly performed in the final layer of modern generative LMs (Radford et al., 2019; Raffel et al., 2020).

jecting to *arbitrary* natural language text. To study a variety of projected text, we experiment with 60+ sentences, either discrete prompts from other tasks (from Mishra et al. 2022b) or random sentences from a large text corpus. We observe that it is possible to find prompts that project to a given discrete prompt (token overlap 94% F1) while scoring within 2% accuracy of the best continuous prompts-based solution for the task. Further analysis shows that the effect of Waywardness gets worse for larger models and longer prompts. We explain this surprising behavior by *relating it to* several structural properties of large language models (§5).

We discuss several social and research implications of prompt waywardness, to help guide future research on prompt based models (§6). First and foremost, despite many promising attributes of continuous prompts, interpreting them is non-trivial and will require further research. In fact, careless interpretation of continuous prompts can result in vulnerabilities against malicious attacks concealed under the guise of benign discrete representation. Further, the loose correspondence between continuous and discrete prompts poses a challenge for future research in *differentiable interpretable-prompt optimization* – optimization in search of human readable discrete prompts through the continuous space. Our work shows that continuous and discrete prompts, despite their seeming similarity, are quite different and the results from one may not always transfer to the other. We hope these findings will motivate further innovations in the prompting literature for NLP models.

2 Related Work

Continuous prompts. There is a line of work focused on tuning continuous prompts (Li and Liang, 2021; Lester et al., 2021; Zhong et al., 2021; Qin and Eisner, 2021; Zhou et al., 2021; Zhong et al., 2021). These works present different approaches to discovering a continuous prompt (which is an array of real numbers) for addressing an end task, though the interpretability of the resulting prompts remains an open question. This paper investigates the feasibility of interpreting a learned continuous prompt and its connection to discrete prompts.

Discrete prompts. The release of GPT-3 (Brown et al., 2020) initiated a body of work on the emergent ability of LMs to follow discrete natural language prompts. Consequently, several follow-up studies have used manually-designed discrete prompts for probing LMs (Petroni et al., 2019; Jiang et al., 2020), improving LMs' few-shot ability (Schick and Schütze, 2021; Gao et al., 2021; Le Scao and Rush, 2021), and their zero-shot ability as well as transferability (Mishra et al., 2022a; Reynolds and McDonell, 2021). Most importantly, discrete prompts have the advantages of being human-readable and thus easily interpretable though we do not have efficient and algorithmic ways of reconstructing them. For example, Shin et al. (2020)'s algorithm discovers discrete prompts, yet the results are not human readable. Prior work also finds that model performance is highly sensitive to small changes in wordings (Mishra et al., 2022a) and that optimization over the discrete prompt space is non-trivial and often highly unstable. Our findings here about the disconnect between continuous prompts and their discrete interpretation provides another perspective on the difficulty of discovering discrete prompts via continuous optimization algorithms that (directly or indirectly) leverage the continuous space (more discussion in §6).

3 Prompt Waywardness

3.1 Preliminaries: Setup and Terminology

We begin with some notation and the setup of our study, starting with the space of discrete and continuous prompts (Fig.2). Let $p_d \in \{0, 1\}^{L \times V}$ denote a discrete prompt represented as an L-length sequence of one-hot vectors over a lexicon of size V (corners of a hyper-cube). Similarly, let $p_c \in \mathbb{R}^{L \times d}$ denote a continuous prompt, represented as a L-length sequence of d-dimensional real vectors.

Projection operators. We define operators that project these two spaces to one another. Define the c-projection as one that maps discrete inputs to a continuous space by multiplying with a fixed (often pre-trained) embedding matrix[2] $E \in \mathbb{R}^{V \times d}$:

$$c\text{-proj}(p_d) = p_d E \in \mathbb{R}^{L \times d}. \tag{1}$$

The d-projection maps the continuous inputs to nearest neighbor discrete elements, where for each position l ($1 \leq l \leq L$), one of the possible (and perhaps most straightforward) methods for interpreting a continuous prompt is defined as a projection

---

[2] In our experiments we use the embedding matrix of the GPT2 family (Radford et al., 2019) which is used for both mapping input text to their embeddings as well as generating text in the output layer.

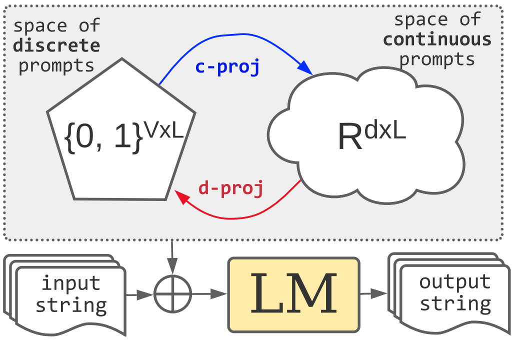

Figure 2: The general problem setup: Similar to Lester et al. (2021)'s setup, each prompt (usually a continuous one) is appended to the given input and fed to a frozen language model.

onto nearest neighbor representations (Mikolov et al., 2013; Hashimoto et al., 2016):

$$d\text{-proj}(p_c) = [\delta_1 \cdots \delta_l \cdots \delta_L] \in \{0,1\}^{L\times V}, \quad (2)$$

where δ_l is a one-hot vector corresponding to the word with the closest (highest dot product) embedding to the l-th position of continuous prompt p_c.

These projections are used in the first and last layer of virtually all modern LMs, such as GPT2.

Solving tasks with continuous prompts. Consider any machine learning model M (typically a pre-trained model) that takes textual input x and produces output y. Normally, the parameters of M are learned so as to optimize behavior on a task with a dataset $\mathcal{D} = \{(x, y)\}$ of input/output pairs. In prompt tuning (Lester et al., 2021), one freezes the parameters of M and instead optimizes for a prompt p that, when fed in conjunction with x, makes M produce the desired output y. Thus, p represents the only learnable parameters in this method. When p is a discrete prompt with k tokens, it can be simply concatenated with x, denoted $p + x$. In our study, p will be a *continuous* prompt (of length equal to the embedding of k tokens). We will concatenate it with the embedding of the input x. For simplicity and with some abuse of notation, we use $p + x$ to denote concatenation in this continuous case as well.

One can quantify the amount of loss incurred when using a continuous prompt p as follows:

$$\ell(p; \mathcal{D}) = \mathbb{E}_{x,y\sim\mathcal{D}} \left[\mathsf{loss}(M(p + x), y)\right], \quad (3)$$

Minimizing this loss function (empirical risk minimization) over p recovers a minimum risk continuous prompt for this dataset:

$$p_c^* = \arg\min_{p_c \in \mathbb{R}^{L\times d}} \ell(p_c; \mathcal{D}^{\text{train}}). \quad (4)$$

Given this prompt, its generalization to the test data can be measured in terms of the loss incurred on the test set: $\ell(p_c^*; \mathcal{D}^{\text{test}})$.

3.2 The Waywardness Hypothesis

How should one interpret the resultant continuous prompt $\tilde{p}_c$? Empirically, one can easily verify that such continuous prompts are not unique (e.g., random initializations lead to different outcomes). Additionally, the resultant prompts get projected to seemingly irrelevant discrete elements. Taking this to an extreme, we hypothesize that next to the continuous projection c-proj(p_d) of any discrete prompt p_d, there exists a variety of continuous prompts p_c that trigger responses from model M that are orthogonal to the intentions described by the discrete prompt p_d. We formalize this idea as the following hypothesis, where $L \in \mathbb{N}$ is the length of the discrete target prompt, M is a prompt-based model, and $\mathcal{D}$ is a dataset for a desired task:

Hypothesis 1 (Prompt Waywardness) *For all $L, M, \mathcal{D}$, there is a small Δ such that for any discrete target prompt p_d with length L, there exists a continuous prompt $\tilde{p}_c \in \mathbb{R}^{L\times d}$ such that:*

1. $\left|\ell(\tilde{p}_c; \mathcal{D}^{test}) - \ell(p_c^*; \mathcal{D}^{test})\right| < \Delta,$ *yet*
2. *d-proj$(\tilde{p}_c) = p_d$.*

In other words, $\tilde{p}_c$ is nearly as effective at making M solve the task as the optimal continuous prompt (Eq.4), and yet it projects to p_d. In this statement, Δ (prompt performance gap relative to the optimal prompt p_c^*) is a function of the prompt length L, the model M (e.g., its embedding size and depth when M is transformer based), and inherent properties of the target dataset $\mathcal{D}$. The analysis in §4.3 will provide an empirical estimate of this gap $\hat{\Delta}$ as a function of various parameters like model size and prompt length.

It is worth emphasizing that the hypothesis is stated for *any* task and any set of discrete prompts, **even if they are irrelevant or contradictory**.[3]

---

[3] While our focus is on the use of continuous prompts for solving datasets (one prompt shared among many instances), one can imagine applications of the same conjecture to special use cases such as controlled generation (Dathathri et al., 2019) with one prompt per instance.

3.3 Finding Wayward Prompts

While the above hypothesis promises the *existence* of $\tilde{p}_c$, it does not say how to discover them. We now discuss a practical method for their discovery.

We learn a continuous prompt p_c using a modification of the prompt tuning objective of Lester et al. (2021). Our modification jointly minimizes the standard downstream task cross-entropy loss $\ell(.)$ for the task (Eq.3) and a distance measure $\mathsf{dist}(.)$ between p_c and the discrete target prompt $p_d \in \{0,1\}^{L\times V}$:

$$\ell'(p_c;\mathcal{D},\gamma) = \ell(p_c;\mathcal{D}) + \gamma\,\mathsf{dist}(p_c,p_d) \quad (5)$$

$$\tilde{p}_c = \underset{p_c\in\mathbb{R}^{L\times d}}{\arg\min}\,\ell'(p_c;\mathcal{D},\gamma), \quad (6)$$

where p_c is the only learnable parameter, and γ is a hyperparameter.

When $\gamma = 0$, the modified objective is reduced to the standard objective (Eq.4), $\ell'(.) = \ell(.)$. We refer to this case and its resulting prompt p_c^* as the *'unconstrained'* setting. A large value of γ will make p_c even closer (possibly identical) to c-$\mathsf{proj}(p_d)$ but lead to poor accuracy on a target dataset. Most of the experiments below are conducted via a range of γ values to better understand the trade off between the two terms in the objective function. In practice, we find $\gamma = 0.01$ to give a reasonable trade-off regardless of the target dataset and the choice of p_d.

There are at least two natural ways to define the distance measure $\mathsf{dist}(p_c, p_d)$ between a continuous prompt p_c and a discrete target prompt p_d, by converting one so that both are in the same space:

$$c\text{-}\mathsf{dist}(p_c,p_d) = \frac{\|p_c - c\text{-}\mathsf{proj}(p_d)\|_2^2}{L} \quad (7)$$

$$d\text{-}\mathsf{dist}(p_c,p_d) = \mathrm{F1}\big(d\text{-}\mathsf{proj}(p_c),p_d\big) \quad (8)$$

The first of these places both p_c and p_d in the continuous space and computes the squared-L^2 norm, normalized by the prompt length. This is used in our training loss (Eq.5) implementation. The second places both in discrete space (text) and computes the standard word-level token overlap F1 score.[4] This is used during our evaluation.

4 Empirical Support of Waywardness

We empirically investigate the Prompt Waywardness hypothesis (§3.2) using our modification (§3.3) of the prompt tuning method from Lester et al. (2021). We show that given an **arbitrary and irrelevant** discrete prompt p_d, it is possible to learn a continuous prompt that is mapped to p_d while retaining its accuracy on a given dataset.[5]

4.1 Setup

Target tasks. Following the setup of Min et al. (2022), we select a diverse set of 5 classification datasets: SST-2 (Socher et al., 2013), SST-5 (Socher et al., 2013), AGNews (Zhang et al., 2015), Subj (Pang and Lee, 2004) and TREC (Voorhees and Tice, 2000). Statistics and the unconstrained accuracy of each dataset are provided in Table 1.

Dataset	Task	$\lvert C\rvert$	Acc
SST-2	Sentiment analysis (movie)	2	92.4
SST-5	Sentiment analysis (movie)	5	50.3
AGNews	News classification (topic)	4	88.1
Subj	Subjectivity classification	2	90.5
TREC	Answer type classification	6	88.0

Table 1: The collection of downstream tasks used in the experiments (§4.1). $|C|$ indicates the output size (number of classes); *Acc* indicates the unconstrained accuracy of a prompt tuning method (Lester et al., 2021) using GPT2 Large, as a reference point.

Discrete Target Projections. We compile two sets of discrete target prompts: (1) 32 target prompts for solving tasks from Natural-Instructions[6] dataset (Mishra et al., 2022b) that are distinct from and intentionally orthogonal to the end tasks considered here. These were chosen by excluding discrete target prompts that have high lexical overlap with other discrete prompts; this is because we found lexically similar prompts are often semantically similar even when written for different subtasks. (2) 30 random sentences from PILE,[7] a large-scale, diverse text corpus used to pretrain GPT-J, the largest public causal language model (Wang and Komatsuzaki, 2021). The sampled sentences were drawn from a Poisson distribution with $\lambda = 14$, which makes the average length of the sentence to be consistent to those in Natural-Instructions. These sentences are selected to have little or no token overlap with the true definition of the target tasks. See Table 3 for a few examples.

Table 2: Main Results: Accuracy of solving five classification datasets, in an unconstrained setting (p_c^*) vs. constrained by the projection to various **irrelevant** pieces of text ($\tilde{p}_c$). Optimization is done using $\gamma = 0.01$ in the objective function (Eq.5). $\hat{\Delta}$ indicates the relative accuracy drop (in %) from unconstrained accuracy. Each reported score (*Accuracy* and *Prompt F1*) are the average over 62 discrete target prompts and 3 random seeds. **Overall, it is possible to achieve $\geq 94\%$ prompt F1 with under 2% drop in accuracy.**

Evaluation metrics. For all experiments, we report two metrics: (1) the task *accuracy*[8] as well as (2) *prompt F1*, the word-level token overlap F1 score computed as in Eq.8, since it easy to interpret and is commonly used for evaluating the textual output of models (Rajpurkar et al., 2016).

Models. For evaluation, we use GPT2 (Radford et al., 2019) an auto-regressive LM which has extensively been used in many NLP applications. Unless otherwise specified, we use a 'large' variant consisting of 774M parameters.

Implementation details. We use a batch size of 8, learning rate 0.01, and 2000 training steps. When experimenting with a discrete target prompt p_d, we initialize the search for continuous prompts (both $\tilde{p}_c$ and p_c^*) using c-proj(p_d).[9] For all experiments, report accuracy averaged over three random seeds.

4.2 Main Results

For each of the 5 tasks T and for each of the 62 discrete target prompts p_d, we use the objective in Eq.5 to find a prompt $\tilde{p}_c$ such that it solves T with a high accuracy while, at the same time, having a discrete projection that is close to p_d. For comparison, we also train unconstrained prompts p_c^* ($\gamma = 0.0$) which solve task T without any projection constraint. To ensure a fair comparison between $\tilde{p}_c$ and p_c^*, we ensure that they have the same size L. In other words, for each $\tilde{p}_c$ (that has the same length as p_d), we train another p_c^* with the same length. We denote the relative accuracy drop from p_c^* to $\tilde{p}_c$ as $\hat{\Delta}$.

Table 2 summarizes the results. Across all datasets, we find that it is possible to learn a continuous prompt p_c whose discrete projection is very close to p_d and mostly retains the task accuracy. There is a trade-off between the task accuracy and prompt F1, which can be controlled by the choice of γ (more extensive ablations in the forthcoming paragraphs (§4.3)). Overall, with $\gamma = 0.01$, it is possible to achieve $\geq 94\%$ prompt F1 with under 2% relative drop in task accuracy. The only outlier is the TREC dataset where we achieved a prompt F1 score of 86% for a $\hat{\Delta} = 2.3\%$ relative drop in accuracy. This might be due to the difficulty of learning effective prompts on TREC (also discussed by Min et al. (2022)).

Example prompts with varying values of prompt F1 scores are shown in Table 3. A prompt F1 $\geq 94\%$ generally indicates one word mismatch with almost no semantically meaningful difference.

4.3 Further Analysis

Effect of Gamma. Fig. 3 shows the trade-off between task accuracy and the prompt F1 when varying γ from 0 to 0.03. As γ increases, the task accuracy goes down while the prompt F1 increases. The drop in task accuracy is relatively minor—it is possible to learn a continuous prompt for which prompt F1 is near 1.00 and the accuracy drop relative to the unconstrained accuracy is less than 1%.

Effect of Prompt Length (L). We randomly sample sentences from The PILE with a constraint that its length must be L (chosen from $\{4, 7, 14, 28, 56\}$). The left and the middle parts of Fig. 4 illustrate the results. We find that when L is very small (e.g., 4) it is relatively difficult to learn a continuous prompt p_c that is close to p_d (F1<60%) while retaining the task accuracy. This is likely be-

---

[8] We did not consider alternatives like Macro-F1 because all datasets are roughly balanced across different classes.

[9] While this is different from prior work (Lester et al., 2021; Min et al., 2022) that uses a random subset of the top-5000 vocabs, we find no meaningful differences in an unconstrained accuracy between two initialization methods.

d-proj(p_c)	*Prompt F1*	*Acc*$(\tilde{p}_c)$
Task: AGNews p_d: Write down the conclusion you can reach by combining the given Fact 1 and Fact 2.

Table 3: Examples of the target prompts p_d and their reconstructions via d-proj(p_c) for different ranges of prompt F1 scores. The first p_d is from Natural-Instructions; the rest two are sampled from The PILE. The mismatches with the original prompt are color-coded.

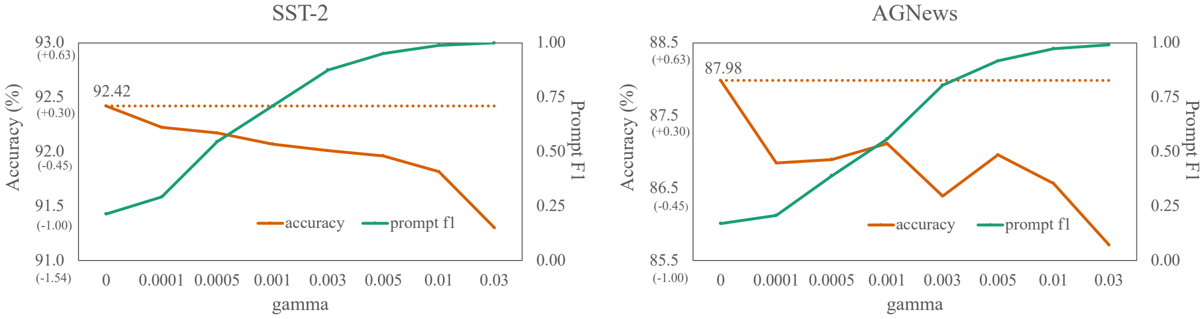

Figure 3: The effect of γ on SST-2 and AGNews. *Accuracy* is the average over 32 discrete target prompts from Natural Instructions and 3 random seeds. A dotted line indicates unconstrained accuracy p_c^* (same as when $\gamma = 0$). Numbers inside parentheses in the y-axis indicate relative drop in accuracy against unconstrained accuracy. **There is a clear trade-off between the task accuracy and the prompt F1.**

cause the prompt being too short significantly hurts the expressivity of the prompt. Nonetheless, when L is reasonably larger, e.g., 14 (the average length of in Natural Instructions) or longer, all cases lead to a continuous prompt with near 1.0 prompt F1 and little accuracy drop.

Effect of Model Size. We vary the size of the GPT2 models—small, medium, large, and XL—with 124M, 355M, 774M, and 1.5B parameters, respectively. Figure 5 (right) reports the result on SST-2. We find that (1) across different sizes of the LM, our findings in learning continuous prompts with the prompt F1 of near 1.0 and little drop in the accuracy generally hold, and (2) in particular, the drop in accuracy is more negligible with larger LMs (0.2% with XL, 0.5–0.7% with medium and large, 1.2% with small).

Projection onto true task definitions. In all our results so far in §4, the target projected text was orthogonal to the tasks being solved. One might naturally wonder whether there is any benefit in projecting continuous prompts to the texts that truly describe the task being solved, i.e., a "true" prompt for the task. To this end, we manually authored 5

Data	Task Accuracy (%)		Prompt
	$\hat{\Delta}_T$	$(\text{Acc}(p_c^*) \to \text{Acc}(\tilde{p}_c))$	F1 (%)
SST-2	1.0	(91.9→ 90.9)	98.5
SST-5	0.9	(51.4 → 50.5)	96.1
AGNews	1.4	(91.8 → 90.4)	95.7
Subj	4.1	(89.8 → 85.6)	100.0
TREC	0.5	(88.6 → 88.1)	99.3

Table 4: Accuracy of solving five classification datasets, unconstrained setting (p_c^*) vs. constrained by the projection to **the true definition of tasks** ($\tilde{p}_c$) using $\gamma = 0.01$ in the objective function (Eq.5). Subscript T in Δ_T denotes this being the case for true task definitions. **Projecting to the true definition of a task does not help continuous prompts solve a task.**

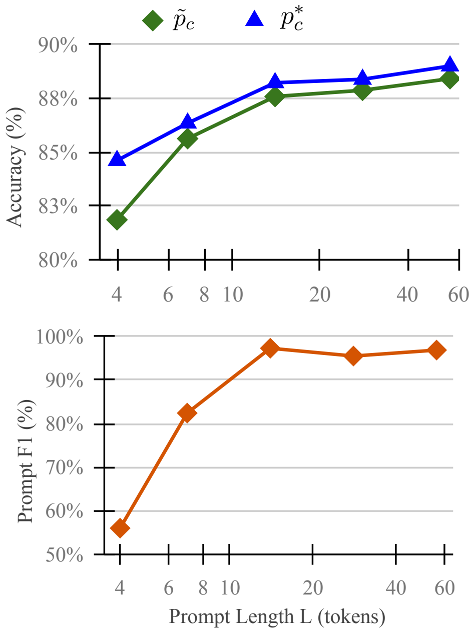

Figure 4: The effect of the length of the prompt (L) on AGNews. Each point computed via the average over 32 discrete target prompts from Natural Instructions and 3 random seeds ($\gamma = 0.01$ used). The corresponding prompt F1 is reported as a orange line. The accuracy of p_c^* and $\tilde{p}_c$ increase as a function of prompt length, however, the gap between them tends to decrease. **The relative accuracy drop is marginal when L is not too small (e.g., 7 or larger).**

"true" prompts for each of the tasks. We then follow the exact same setup used earlier for Table 2 to fine-tune continuous prompts $\tilde{p}_c$ for the task while projecting onto these true task definitions. As before, we fine-tune unconstrained prompts p_c^* of the same length, without any projection requirement.

By design, $\tilde{p}_c$ can be no more effective at solving the task than the unconstrained prompt p_c^* (barring suboptimal search issues), which is what we find in practice. For completeness, we report detailed results for "true" target prompts (analogous to Table 2) in Table 4.

More interestingly, as shown in Table 5, **continuous prompts that project to "true" target prompts are no more effective at solving the task** than continuous prompts that project to the 62 *irrelevant* target prompts considered earlier (Table 2). Specifically, the average performance gap Δ (relative to unconstrained prompts of the same length) is about the same ($\approx 1.5\%$) for continuous prompts that map to true task definitions compared to prompts that map to irrelevant text. This further bolsters the waywardness hypothesis—continuous prompts don't relate to the task being solved.

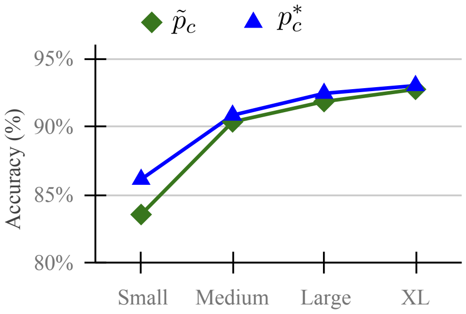

Figure 5: The effect of the size of the model—small, medium, large, and XL—on SST-2. Each point in the experiment is computed by averaging over 30 experiments each with a different discrete target prompt from PILE and 3 random seeds. We vary $\gamma = \{0.01, 0.005, 0.003\}$ and choose the one for which prompt F1 is larger than 0.98. **The relative accuracy drop (gap between the two trends) decreases as models become larger.**

	SST-2	SST-5	AGNews	Subj	TREC	Avg
$\hat{\Delta}_T$	1.0	0.9	1.4	4.1	0.5	1.6
$\hat{\Delta}$	0.6	2.0	0.8	1.5	2.3	1.4

Table 5: Task accuracy gap comparison between unconstrained prompts and those fine-tuned to project to a *true* task definition ($\hat{\Delta}_T$) as reported in Table 4. For comparison, we also show the corresponding performance gaps with *irrelevant* ($\hat{\Delta}$) from Table 2. **The average performance gaps are about the same (around 1.5) for true and irrelevant target prompts**—further evidence that continuous prompts don't relate to the task being solved.

5 Explaining Waywardness

Here we provide intuitions behind the factors that enable Prompt Waywardness.

The mapping between continuous and discrete spaces is not one-to-one. While a discrete target prompt is mapped to exactly one continuous prompt (via its embedding, Eq.1; cf. Fig.2), the reverse is not true. In fact, except for a very small fraction of unnatural or degenerate edge cases,[10] for every target discrete prompt, there are infinitely many continuous prompts that project back to it (via Eq.2). While simple counting-based arguments are insufficient in continuous spaces, we formally prove (Appendix B) that this property holds for all nearest-neighbor projections under any metric distance, and broadly for all but a negligible (measure zero) portion of possible projection operators.

---

[10] Such as using a non-metric distance in nearest-neighbor mapping, or mapping all of $\mathbb{R}^d$ to a single discrete prompt.

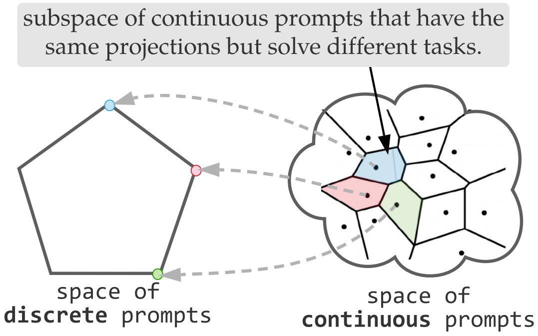

Figure 6: The projection discrete space (Eq.2) induces a clustering (a Voronoi diagram) of the continuous space. Each cluster has infinitely many points that get mapped to the same discrete token.

This intuitively suggests that there is a whole region of continuous prompts that corresponds to a fixed discrete representation (Fig.6). The remaining question is, how is this region able to have a diverse set of prompts that can solve a variety of tasks? This is addressed next.

Deep models give immense expressive power to earlier layers. The deeper a network is, the more expressivity it has with respect to its inputs (Telgarsky, 2016; Raghu et al., 2017). Since continuous prompts reside just before the first layer, they enjoy a lot of expressivity. Therefore, no matter how narrow the regions corresponding to individual tokens are (Fig.6), they are extremely powerful in solving a variety of tasks. Previously in §4.2 we provide an empirical analysis showing evidence that the effect of Waywardness is stronger in deeper models.

6 Implications of Prompt Waywardness

We discuss the implications of these findings on several inter-related lines of research. Note that all the following statements are valid within the boundaries of the existing architectures. Moving beyond these barriers likely requires major innovations in terms of LM architectures or how continuous prompts are optimized.

Faithful interpretation of continuous prompts is difficult. Given the intuitions behind and empirical support for the Waywardness hypothesis (§5), faithful discrete interpretations of continuous prompts via common discrete projections (like nearest-neighbor projection) are unlikely to be robust based on current approaches. It is an open question whether there is a better way of interpreting continuous prompts with human language, or whether explaining and interpreting continuous prompts via human language is inherently impossible because they lie in completely different spaces. Future work may investigate more on this topic in order to improve the interpretability of prompt-based language models.

Risk of interpreting continuous prompts: concealed adversarial attacks. It is not difficult to imagine a future where proprietary model development is driven by fine-tuned continuous prompts. In such a world, not addressing the challenges involved in discrete interpretation of continuous prompts can lead to harmful (and potentially, adversarial) consequences (Slack et al., 2020; Wallace et al., 2021), as discussed below.

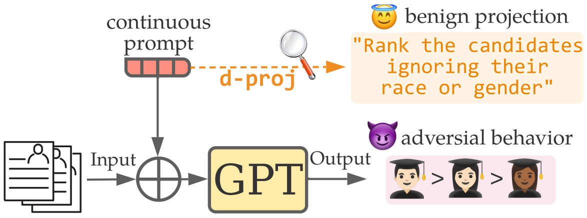

Figure 7: Waywardness implies that continuous prompts can be mapped to seemingly innocuous descriptions while acting maliciously.

We consider the following scenario: a model designer comes up with a set of continuous prompts that solve a target task (e.g., ranking resumes according to each applicant's qualifications and merits). Whether intentionally or not, such prompts may maliciously target, for example, a minority group. To assure their customers, the model designer uses the projection of the prompt that expresses a benign definition for the task, which does not reveal the true nature of the egregious behavior. The customers might even evaluate the prompt on a few instances but not notice this harmful behavior, e.g., when it effects a minority group not in the evaluation set. In a way, the benign discrete projections may provide a false sense of security.

Optimizing discrete prompts through continuous prompts can be degenerate. Manually-written discrete prompts have many nice properties (Schick and Schütze, 2021; Mishra et al., 2022a), yet we do not have an efficient algorithmic way of finding them. One way to operationalize this is to formulate differentiable objective functions via LMs like GPT (Radford et al., 2019). Consider the following problem which is defined in the space of continuous embeddings $p_c \in \mathbb{R}^d$:

$$\max_{p_c \in \mathbb{R}^d} \overbrace{\mathbb{P}\left(\mathcal{D}|p_c\right)}^{\text{utility}} \times \overbrace{\mathbb{P}\left(d\text{-proj}(p_c)\right)}^{\text{readability}}, \tag{9}$$

This a joint optimization towards a *utility* objective (the extent to which it can solve dataset $\mathcal{D}$) and a *human readability* objective. According to the Waywardness hypothesis, there are p_c's that assign high mass to the utility term while also mapping to human interpretable text that is *irrelevant* (or even contradictory) to the task solved by the prompt – hence, *degenerate* solutions.

The same challenge holds if this optimization objective, instead of continuous prompts, is reformulated in terms of word probabilities (e.g., similar to Kumar et al. (2021, Sec 2.2)). This is the case, since searching in the space of word probabilities is analogous to a search in embedding spaces.[11]

In summary, Waywardness presents a challenge for searching effective discrete prompts via continuous optimization. The recent works have used additional signals such as domain-specific constraints (Qin et al., 2020; Khot et al., 2021; Qin et al., 2022) to alleviate these challenges. We hope to see more design innovations in this direction.

Gradients *alone* are insufficient to reverse engineer a model. Suppose we are given a fixed (fine-tuned or otherwise) model M (e.g., an open question-answering model) and an expected output y from this model (e.g., $y =$*"Joe Biden"*). Can we use gradients with respect to an LM's *output* to find a semantically meaningful *input* that makes a frozen model M generate a particular output?

Our findings and the earlier argument about continuous differentiable optimization suggests this may not be feasible with current methods. To see the correspondence to Prompt Waywardness, we can replace $\mathcal{D}$ in Eq.9 with the desired outcome y and run the optimization over word distributions (cf. Footnote 11). While gradients can guide towards *some* input that makes M produce y, their interpretation is likely unfaithful to the task being solved by M. In the context of the above example (M being a QA system), gradients might lead to inputs maximize the probability assigned to *"Joe Biden"*, although this input will likely be neither fluent nor semantically descriptive of *"Joe Biden"*.

Nevertheless, as noted earlier, gradients are still useful when they are applied using domain-specific constraints. For example, one can find local (word-level) perturbations that lead to a certain adversarial outcome, if the perturbations are restricted to well-defined semantic categories (e.g., "blue" can be perturbed to any other color name) (Sha, 2020; Guo et al., 2021; Yuan et al., 2021).

Continuous prompt tuning does not necessitate task-specific initialization. Recent works on continuous prompt-tuning have shown the effectiveness of initialization from embeddings of *random* common words (Lester et al., 2021; Min et al., 2022), despite these words being irrelevant to the task solved by these prompts. This, however, makes sense given the observations made in this work regarding the existence of effective prompts around word embeddings.

7 Conclusion

The prompting literature has seen many parallel developments around continuous and discrete prompts, as efficient alternatives to fine-tuning models with tens of millions of parameters. Our work introduced the Prompt Waywardness hypothesis, which expresses a surprising disconnect between continuous and discrete prompts: given a downstream task, for *any* discrete target prompt p_d, there exists a continuous prompt that projects to p_d while achieving strong performance on the task. We provided empirical evidence for this hypothesis, studied various parameters around it, and ended with several implications of this hypothesis.

While our experiments are done on the GPT family, we expect our findings to apply to a broader set of architectures that, in one way or another, use similar mechanisms for mapping discrete elements to continuous representations and vice versa. Similarly, while our projection to the discrete space (Eq.2) is a popular operator in the field (cf. Footnote 1), the intuition explained in Propositions 1 and 2 of the Appendix suggests similar behavior for a broad class of projection operators.

Prompt Waywardness identifies challenges for future progress on algorithmic methods for the discovery of human readable prompts that are faithful to the task they solve. We hope the observations made in this work motivate architectural innovations that overcome such challenges and guide future steps in the prompting literature.

---

[11] A distribution over words $p \in [0,1]^V$ corresponds to a continuous prompt $p_c = c\text{-proj}(p)$ which is a weighted combination of V-many basis vectors (word embeddings) that form a linear span of $\mathbb{R}^d$.

Supplementary Material

A Additional Experimental Details

Here we include several experimental details (§4) that did not fit in the main text. For the experiments we used A100 GPUs with 40G memory. In terms of the time GPU time of the experiments, each round of training and inference for each seed took about around 6 min. Therefore, the total GPU hours for our main experiment (Table 2) adds up to 93 hours (6 mins × 3 seeds × 5 datasets × 62 prompts = 5580 mins).

B The mapping between continuous and discrete space is not one-to-one

As argued in §5, the mapping between the space of discrete input and that of word embeddings (Fig.2) is not a bijection. While a discrete target prompt is mapped to exactly one continuous prompt (via its embedding, Eq.1), the reverse is not true: except for some unnatural or rare cases (as formalized in the following propositions) there are infinitely many continuous prompts that project back to a fixed discrete target prompt (via Eq.2).

Nearest-neighbor projections are arguably natural, computationally efficient, and useful in practice. Although we have considered them in the Euclidean space so far, they can be defined for an *arbitrary* distance metric[12] m on $\mathbb{R}^d$. As before, consider an embedding of a lexicon of size V into $\mathbb{R}^d$ and the corresponding one-hot vectors in $\{0,1\}^V$. We call d-proj a *nearest-neighbor projection operator w.r.t.* m if it maps each $x \in \mathbb{R}^d$ to the one-hot vector in $\{0,1\}^V$ that corresponds to the lexicon item whose embedding is closest to x under metric m (breaking ties arbitrarily).

Proposition 1 *Every nearest-neighbor projection operator, under any metric, maps infinitely many elements of* $\mathbb{R}^d$*, forming one or more continuous subspaces, to every one-hot vector in* $\{0,1\}^V$.

A proof is included in Appendix B.1. In effect, the projection operators induce a clustering of the space of continuous prompts $\mathbb{R}^{d\times L}$ into regions that have the same discrete projection (Fig.6).

The infinite-to-one mapping aspect is not limited to the class of nearest-neighbor projection operators. It is rather an inherent property of the interaction between continuous and discrete spaces, and holds for a broader family consisting of all but a negligible portion of possible projection operators:

Proposition 2 *Let* $\mathbb{D}$ *denote the space of all projection operators that map* $\mathbb{R}^d$ *to one-hot vectors in* $\{0,1\}^V$*. Let d-proj be a random projection drawn uniformly from* $\mathbb{D}$*. Then, with probability 1, d-proj maps infinite elements of* $\mathbb{R}^d$ *to every one-hot vector in* $\{0,1\}^V$.

B.1 Proofs

Proof of Prop. 1: Let $c_i \in \mathbb{R}^d$ for $i \in \{1,\ldots,V\}$ be fixed vectors (denoting the embedding of words in a lexicon of size V). Let $e_i \in \{0,1\}^V$ denote the one-hot vector with 1 in the i-th position and 0 elsewhere. Since d-proj is a *nearest-neighbor projection operator w.r.t.* m, by definition it maps $x \in \mathbb{R}^d$ to e_i whenever x is closest to c_i, i.e., $i = \arg\min_j m(x, c_j)$ (breaking ties arbitrarily).

Let $S_i \subseteq \mathbb{R}^d$ denote the pre-image of e_i, i.e., the elements that the nearest-neighbor projection d-proj maps to the i-th one-hot vector. By definition, $c_i \in S_i$. Let $d' = \min_j m(c_i, c_j) > 0$ denote the distance of c_i to the nearest c_j w.r.t. the metric m. Consider the subspace $C_i = \{x \mid m(x, c_i) < d'/2\}$. By design, we have $C_i \subseteq S_i$. Further, moving x by some small distance ϵ (w.r.t. m) to another point x' changes its distance to c_i only by at most ϵ (by the triangle inequality property of m). This implies that if ϵ is chosen to be small enough such that $m(x, c_i) + \epsilon < d'/2$, then x' must also be in C_i. In other words, if $x \in C_i$, then, for a small enough ϵ, the entire ϵ-neighborhood of x is also in C_i. It follows that C_i is an open subset of R^d and thus contains infinitely many elements forming a continuous subspace. Hence S_i, which contains C_i,e.g. also has infinite elements in one or more continuous subspaces. $\square$

Proof of Prop. 2: For simplicity, assume $V = 2$. A projection operator d-proj $\in \mathbb{D}$ can then be fully characterized by the subset $S \subseteq \mathrm{R}^d$ that it maps to any one arbitrarily chosen one-hot vector. Choosing d-proj uniformly at random from $\mathbb{D}$ thus amounts to choosing the subset S uniformly at random from $\mathbb{R}^d$. We show that the probability of choosing an S such that $|S|$ is finite, is 0. (The same argument applies to $|\mathbb{R} \setminus S|$ being finite.)

To see this, let $\mathbb{S}_i$ denote the set of all (finite) subsets of $\mathbb{R}^d$ that have size exactly i. First, observe that the probability of choosing an S that lies in $\mathbb{S}_0 \cup \mathbb{S}_1$ (i.e., a subset of $\mathbb{R}^d$ that has at

---

[12] https://en.wikipedia.org/wiki/Metric_(mathematics)

most 1 element) is 0; this is a degenerate case in the underlying continuous probability space. Second, for any $i \geq 2$, $\mathbb{S}_i$ has the same "size" (in the measure theoretic sense) as $\mathbb{S}_1$, because one can construct an injective map from either one to the other—which follows from the fact that they both have the same *cardinality* as the set $\mathbb{R}$.[13] Lastly, the space $\mathbb{S}$ of all finite subsets of $\mathbb{R}^d$ is the countable union $\cup_i \mathbb{S}_i$ of disjoint sets. Therefore, $\Pr[S \in \mathbb{S}] = \sum_i \Pr[S \in \mathbb{S}_i] = 0$. $\square$

---

[13] This can be proved using the rules of cardinal multiplication applied to $\mathbb{S}_i$ viewed as (a subset of) the Cartesian product of $\mathbb{S}_1$ with itself, i times.

Contrastive Representation Learning for Cross-Document Coreference Resolution of Events and Entities

Benjamin Hsu and **Graham Horwood**
AWS AI Labs
`{benhsu, ghorwood}@amazon.com`

Abstract

Identifying related entities and events within and across documents is fundamental to natural language understanding. We present an approach to entity and event coreference resolution utilizing contrastive representation learning. Earlier state-of-the-art methods have formulated this problem as a binary classification problem and leveraged large transformers in a cross-encoder architecture to achieve their results. For large collections of documents and corresponding set of n mentions, the necessity of performing n^2 transformer computations in these earlier approaches can be computationally intensive. We show that it is possible to reduce this burden by applying contrastive learning techniques that only require n transformer computations at inference time. Our method achieves state-of-the-art results on a number of key metrics on the ECB+ corpus and is competitive on others.

1 Introduction

Coreference resolution is the fundamental NLP task of finding all mentions that refer to the same real world entity or event in text. It is an important step for higher level NLP tasks involving natural language understanding, such as text summarization (Azzam et al., 1999), information extraction (Zelenko et al., 2004), and question-answering (Vicedo and Ferrández, 2000). Historically, coreference resolution of entities in the same text document – within document (WD) coreference resolution – has received the most attention, though more recently focus has moved toward cross-document (CD) coreference resolution.

CD coreference resolution has recently gained renewed interest for its application in multi-document analysis tasks. CD coreference resolution presents unique challenges not found in the WD context. Spans of text come from different documents without any inherent linear order, and there is no notion that antecedents for a given expression typically occur before the expression, as in a single document. Coreferent expressions also cannot be assumed to occur near one another. Furthermore, documents are also assumed to be authored independently and about different—though lexically similar—topics. For instance, the event described in the sentences from Topic 19 in Table 1 below are not coreferential, despite their lexical similarity ("killed").

Another important aspect of CD coreference resolution is the potential scale of the problem. In certain applications, the number of documents can be large and ever growing. In particular, for applications that merge information from across documents, such as multi-document summarization (Falke et al., 2017) or multi-hop question answering (Dhingra et al., 2018), the corpus in question can be both large and dynamically increasing in size.

Past methods of CD coreference resolution have treated the problem as a binary classification task: given two pairs of mentions, classify them as referring to the same entity or not (Bejan and Harabagiu, 2010; Yang et al., 2015; Huang et al., 2019; Kenyon-Dean et al., 2018). In more recent works, contextual embeddings using a cross-encoder architecture have been leveraged to obtain state-of-the-art results (Yu et al., 2020; Zeng et al., 2020; Caciularu et al., 2021) on the ECB+ corpus. Despite achieving state-of-the-art results on the benchmark dataset, a shortcoming of these approaches is the fact they use a transformer as a cross-encoder – two sentences are passed to through the transformer network and a label is predicted. For n mentions in a corpus, these approaches require n^2 comparisions at inference time. As Reimers and Gurevych (2019) noted when using BERT in a cross-encoder architecture, finding the most similar pair of sentences in a collection of $n = 10000$ sentences requires $n(n-1)/2 = 49\,995\,000$ inference computations, which they estimated to take 65 hours using a V100

	Yesterday , the *police* explained that officers shot and **killed** a 16-year-old *Kimani Gray* in *Brooklyn* because *he* allegedly pointed a gun at the cops.	Fresh riots were reported in Greece on Saturday December 13 2008 in protest at the **killing** by *police* of a 15-year-old boy, *Alexandros Grigoropoulos*, eight days ago

Table 1: Examples of cross-document coreference clusters from topics 19 of the ECB+ corpus. Bold text indicate events and the same color indicates that they belong in the same coreference cluster. The addition of lexically similar second subtopic (riots in Greece over teenagers death vs riots in Brooklyn over teenagers death) adds an additional challenge to the ECB+ corpus.

GPU.

Others have sought to address the quadratic scaling of these methods. Recently, Allaway et al. (2021); Cattan et al. (2021a) introduced methods that require n transformer passes. In this work, we introduce a method using contrastive learning to generate mention representations that are useful for the coreference resolution problem. Previous attempts along these lines by Kenyon-Dean et al. (2018) introduced clustering-oriented regularization terms in the loss function. Our method improves on these earlier methods on the benchmark dataset, and achieves results competitive with the more expensive methods of Yu et al. (2020); Zeng et al. (2020); Caciularu et al. (2021). We conduct extensive ablations of our model which we discuss in §4.5. We discuss applications to domains outside of the ECB+ corpus in §4.6.

2 Related Work

Most recent work on CD coreference resolution has focused on the ECB+ corpus (Cybulska and Vossen, 2014), which we also use in this work. The ECB+ corpus, which is an extension of the Event Coreference Bank (ECB), consists of documents from Google News clustered into topics and annotated for event coreference (Bejan and Harabagiu, 2010). ECB+ increases the difficulty level of the original ECB dataset by adding a second set of documents for each topic (subtopic), discussing a different event of the same type (e.g. riots in Greece over teenagers death vs riots in Brooklyn over teenagers death; see Table 1) (Cybulska and Vossen, 2014). While relatively small, the corpus is representative of the common cross-document coreference use cases across a restricted set of related documents (i.e. results from a search query).

Most approaches to CD coreference resolution address the problem as a binary classification problem between all pairs of events and entities. Early works utilized hand engineered lexical features (e.g. head lemma, word embedding similarities, etc.) (Bejan and Harabagiu, 2010; Yang et al., 2015). More recent works have relied on neural network methods, utilizing character-based embeddings (Huang et al., 2019; Kenyon-Dean et al., 2018) or contextual embeddings (Yu et al., 2020; Cattan et al., 2020; Zeng et al., 2020; Caciularu et al., 2021; Allaway et al., 2021). Recent approaches by Yu et al. (2020) and Caciularu et al. (2021) leveraging RoBERTa and Longformer transformer models have set strong benchmarks. A drawback of these approaches is the necessity to consider all pairs of n mentions in a corpus in a cross encoder architecture. Each unique pair of entities (separated by a special token) is passed through a transformer to generate a similarity score. This requires n^2 transformer computations.

This can be computationally expensive and several works have sought to address this. Allaway et al. (2021) introduced a model that clusters mentions sequentially at inference time. They achieved competitive results using a BERT-base model and without using a hierarchical clustering algorithm to generate coreference chains. Cattan et al. (2021a) adapted the model of Lee et al. (2017) to the cross-document context. Specifically, they pruned document spans down to the gold mentions and encode each resulting pared document using a RoBERTa-large model. A pairwise (feed-forward network) scorer then generates a score for each pair of spans. They also considered an end-to-end system where they use their model to predict mention spans instead of using gold mentions. In this work, we consider gold mentions only as has been done in earlier works.

In this work, we introduce a method leveraging contrastive learning using a RoBERTa-large model as the base encoder. At inference time, our method requires n passes of the transformer, like earlier methods by Allaway et al. (2021); Cattan et al. (2021a). Our method surpasses their methods on the benchmark ECB+ dataset and is competitive with more expensive cross-encoder approaches of Yu et al. (2020); Zeng et al. (2020); Caciularu et al. (2021).

3 Methodology

3.1 Dataset

We follow earlier works and use the ECB+ corpus, which is an extension of the Event Coreference Bank (ECB), which was discussed in the previous section. Following earlier works by others (Yu et al., 2020; Cattan et al., 2020; Caciularu et al., 2021; Allaway et al., 2021), we follow the setup of Cybulska and Vossen (2015), which was also used by others (Yu et al., 2020; Cattan et al., 2020; Caciularu et al., 2021; Allaway et al., 2021). This setup uses a subset of the annotations which has been validated for correctness and allocates a larger portion of the dataset for training. In this setup, we use topics 1-35 as the train set, setting aside topics 2, 5, 12, 18, 21, 23, 34, 35 for hyperparameter tuning, and 36- 45 as the test set. To preprocess mentions, we utilized the reference implementation from Cattan et al. (2020). The distribution of the train, test, and development sets can be seen in Table 2.

	Train	Dev	Test
# Topics	25	8	10
# Documents	574	196	206
# Event Mentions	3808	1245	1780
# Event Singletons	1116	280	623
# Event Clusters	1527	409	805
# Entity Mentions	4758	1476	2055
# Entity Singletons	814	205	412
# Entity Clusters	1286	330	608

Table 2: Statistics for the ECB+ corpus. We followed the setup of (Cybulska and Vossen, 2015) and used topics 36-45 for our test set and topics 1-35 for training with topics 2, 5, 12, 18, 21, 23, 34, 35 set aside in the development set for hyperparameter tuning.

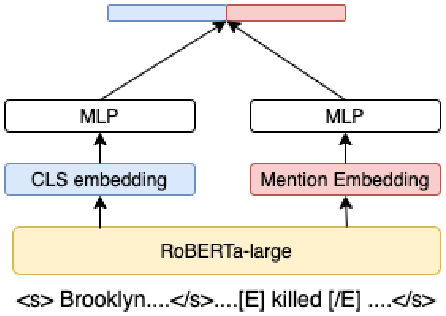

Figure 1: Our encoder takes as input the first two sentences from the document and concatenates it with the sentence containing the mention, taking care to annotate the mention location with tags $[E]$ and $[/E]$.

3.2 Model

We propose a model to learn embeddings useful for clustering events and entities. Our model leverages a Siamese neural network (Bromley et al., 1993) to fine-tune a RoBERTa-large encoder (see Figure 1). We train and evaluate our model using gold mentions as opposed to predicted mentions in order to focus on the cross-document coreference resolution problem. At inference time, our model generates embeddings for the mentions which are then clustered using an agglomerative clustering algorithm as was done previously by Barhom et al. (2019); Yu et al. (2020); Cattan et al. (2020); Caciularu et al. (2021); Zeng et al. (2020). Below we discuss details of our methodology and training procedure.

Document Context Following Caciularu et al. (2021), we use the observation that other parts of the document provide valuable context to the mentions in question. We extract and encode the first two sentences from the document. This takes advantage of the fact that the articles are news articles and in many cases, much of the relevant information is summarized at the beginning of the document. In most cases, these two sentences are the headline and dateline for the article. In cases where the sentence in question is one of the first two sentences, we take the next sentence in the document.

Contextual Embedding In addition to the document context, we also utilize the sentence that the mention appears in and annotate its location in the sentence using $[E]$ and $[/E]$ tokens. The two sequences are concatenated together using a [SEP] token (see Figure 1). In total, we keep 128 word piece tokens and in cases where the combined input exceeds this, we remove tokens from the end of the context before removing tokens from the sentence containing the mention.

This combined sequence is encoded using a RoBERTa-large model (Liu et al., 2019), as shown in Figure 1. We fine-tune all layers of the RoBERTa-large model. RoBERTa will produce a representation vector for each token of the input sequence. We then sum up element-wise the token-level representations of the mention and use this as the representation of the mention, v_e. Additionally, we utilize the first token of the sequence v_{cls} as the embedding for the entire document context and mention embedding. Each of these contextual embeddings are passed separately through a multilayer perceptron (MLP). We found that 1024 for the hidden layer dimension for both MLPs worked well in our experiments.

$$v'_e = MLP_1(v_e); \quad v'_{cls} = MLP_2(v_{cls}) \tag{1}$$

The final representation for the mention i and its context document is given by the concatenation of the two vectors output vectors, indicated by [.; .].

$$v_i = [v'_{cls}; v'_e] \tag{2}$$

At inference time, our model takes in the mention and its context (both the head of the document and its sentence) and generates a 2048 dimensional embedding v_i. A clustering algorithm is applied to embeddings to generate coreference clusters. In order to compare our language model with earlier approaches, we follow earlier works and use an agglomerative clustering model. We use the implementation from scikit-learn[1] and cluster mention representations using the cosine distance metric. Representations within an average threshold distance τ are considered to be in the same cluster (i.e. coreferences).

3.3 Training

To train the model, we consider pairs of sentences – positive samples are pairs of sentences where the mentions are coreferential while negative samples are pairs of sentences where the mentions are not coreferential. Pairs of sentences were chosen from *within* gold topics and were constructed by first computing the similarity between sequences. This focuses our model to learn features to distinguish between the two closely related subtopics, one of the key aspects of the ECB+ corpus. We used SBERT (Reimers and Gurevych, 2019) to embed these sequences initially. Positive pairs were created from sequences that were least similar to one another and negative pairs were selected from the set of pairs most similar to one another, both within a particular subtopic and across subtopics (but still within the same topic). Finally, the negative samples were down-sampled by selecting samples whose similarity was greater than the median similarity among all possible positive sample pairs. The resulting distribution for the pairs can be seen in Table 3.

	Events	**Entities**
# of Pairs	19000	27090
# of Positive	2085	4078
# of Negatives	16915	23012
# of Same Subtopic	13694	18847
# of Different Subtopic	5306	8243
Fraction Positive	0.11	0.15
Fraction Same Subtopic	0.72	0.70
Median pos. similarity score	0.62	0.59
Median neg. similarity score	0.80	0.77

Table 3: Statistics for the contrastive pairs generated. Pairs of sentences were chosen from *within* gold topics and were constructed by first computing the similarity between sequences. Negative samples were down-sampled by selecting samples whose similarity was greater than the median similarity among all possible sample pairs.

The model parameters were then trained using a Siamese network architecture (Chopra et al., 2005) where model weights are shared across both branches. For a given pair of sentences $p = (s_1, s_2)$ and label $y = 1, 0$ where $y = 1$ if the pairs are coreferences and $y = 0$ otherwise, each pair of sentences is encoded using our model. The model was trained by minimizing the contrastive loss, ℓ (Hadsell et al., 2006), as implemented by Reimers and Gurevych (2019),

$$\ell = y * d(i,j)^2 + (1-y) * max(0, m - d(i,j))^2 \tag{3}$$

For our purposes, $d(i,j) = 1 - cos(v_i, v_j)$ is the cosine distance, $m > 0$ is a margin, and y is one if the pairs describe coreferent mentions and zero otherwise. Dissimilar pairs contribute to the loss function only if their distance are within m. The loss pushes the embeddings so that positive pairs are closer together in the embedding space and negative pairs are pushed to be more distant

---

[1] https://scikit-learn.org

than the margin m.

3.4 Hyperparameters

In our experiments, we used the AdamW optimizer without warmup and found that a batch size of 16 worked well. We utilized Ray (Liaw et al., 2018) for hyperparmeter tuning and specifically the Bayesian optimization search algorithm from scikit-optimize.[2] We performed our experiments on a p3dn.24xlarge with 8 V100 Tensor Core GPUs and chose the dropout rate, learning rate, contrastive margin m and clustering threshold τ to optimize the CoNLL F1 score on the development set gold topics. This was done to learn representations that address the lexical ambiguity in the ECB+ corpus topics. Resulting hyperparameters can be found in Table 4.

	Events	Entities
Epochs	100	50
Learning rate	2e-7	2e-7
Batch Size	16	16
Contrastive margin, m	0.40	0.70
Clustering Threshold, τ	0.2	0.2

Table 4: Hyperparameters for our best performing models on events and entities.

4 Results and Discussion

We evaluate our model using four different measures as is common in earlier works. Specifically, we evaluated our model performance using MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), CEAF-e (Luo, 2005), and LEA (Moosavi and Strube, 2016) metrics. We also evaluate our model using the CoNLL F1, the average of the MUC, B^3, and CEAF-e F1 scores. As a baseline, we also show results from a lemma model that takes each span in question and utilizes spaCy[3] to lemmatize each token. Mentions are clustered based on whether their lemmatized tokens are exact matches or not.

Evaluations on ECB+ test corpus are not without controversy, and we discuss these subtleties in detail below. For the reader familiar with these issues, our main results are discussed in §4.2 and §4.3. We also conduct an ablation study with results in §4.5.

4.1 Evaluation Settings

Many earlier methods leveraged an initial document clustering (Yu et al., 2020; Zeng et al., 2020; Caciularu et al., 2021; Allaway et al., 2021). As observed by Barhom et al. (2019); Upadhyay et al. (2016), clustering the documents as a preprocessing step and performing pairwise classification on mentions within each cluster provides a strong baseline. Barhom et al. (2019) introduced a K-Means algorithm to cluster documents using TF-IDF scores of the unigrams, bigrams and trigrams, where K is chosen by utilizing the Silhouette coefficient method (Rousseeuw, 1987). Models are then applied to mentions within each cluster.

However, this approach has come under criticism (Cremisini and Finlayson, 2020; Cattan et al., 2021a,b). Detractors note that, because of the high lexical similarity between documents within the same subtopic, pre-clustering methods are able to produce near perfectly predicted subtopics, especially in the ECB+ corpus, where only a few coreference links are found across different subtopics. Document clustering is not expected to perform as well in realistic settings where coreferent mentions can spread over multiple topics (Cattan et al., 2021a). More importantly, this bypasses the intention behind the inclusion of subtopics in ECB+ and avoids challenging the coreference models on lexical ambiguity (Cybulska and Vossen, 2014).

In our view, evaluation utilizing the original topic clusters ("gold" topics) is more in line with the original intent of Cybulska and Vossen (2014) and more indicative of realistic settings (Cattan et al., 2021b). We discuss results (1) using ECB+ topics ("gold topics" henceforth) as the initial document clustering and (2) using no initial document clustering ("corpus level" henceforth) in section §4.2. We find that our methodology improves on earlier methods (Tables 5 and 9). Finally, because a majority of earlier works evaluate their models using predicted topics, we discuss our model performance under this setting in §4.3. We report results from a single run.

4.2 Gold Topics and Corpus Level

We evaluate our models using the ECB+ topics, in line with the intent of Cybulska and Vossen (2014) and earlier works by Cattan et al. (2021a,b). According to those authors, this setting was designed to approximate an unclustered stream of news articles.

Table 5: Combined within- and cross-document coreference scores for entities and events *without* singletons, using gold mentions. Gold topics use the ECB+ topics as the initial document pre-clustering while corpus level results do not use any document pre-clustering. **Bold** values indicate best overall for a particular data subset.

Additionally, as noted by Cattan et al. (2020, 2021a), the presence of singletons biases the results towards models that perform well on detecting all the mentions instead of predicting coreference clusters. Furthermore, in using gold mentions in the evaluation (like we do here), including singletons artificially inflates performance metrics (Cattan et al., 2021a). We present our results without singletons (Table 5) using the reference implementation of Moosavi and Strube (2016). In Appendix A, we give results *with singletons* in Table 9.

On the gold topic and corpus level subsets, our model performs well. In all cases, we surpass the current state-of-the-art model on the CoNLL F1 metric for both event and entity coreference resolution by large margins without singletons (see Table 5)). We suspect this improvement to be a feature of contrastive learning and methodology we used to choose pairs – coreferential mentions are pushed closer together in the embedding space while mentions that are not coreferences are pushed further apart. We do observe a larger drop in performance in going from gold topics to the corpus level subsets. This is due to the choice in contrastive pairs, where negative examples come from the same gold topic.

Aside from improved performance, our methodology differs in some key aspects to the recent works by Cattan et al. (2021a,b, 2020). Their methodology also leverages a RoBERTa-large model to embed documents, but breaks long documents into 512 word piece token chunks. The authors used as their feature vector for a span in question: the sum of the span embeddings, the embeddings for the span beginning and end, and a vector encoding the span length as their feature vector, which they feed into a pairwise classifier to generate pairwise scores. We on the other hand use the sentences containing the span in question and additional context sentences from the document, keeping a total of 128 word piece tokens. This additional context from the document, despite keeping fewer tokens, accounts for much of the performance gain. This is discussed in further detail in §4.5.

4.3 Predicted Topic Clusters

We compare our model against the majority of earlier works that used predicted topic clusters and gold mentions (see Table 6 and Appendix A Table 8 for more complete results). We used the reference implementation by Pradhan et al. (2014) to score our models *with singletons*. Our model is competitive with earlier approaches (Yu et al., 2020; Zeng et al., 2020; Caciularu et al., 2021), despite using significantly fewer resources at inference time – n transformer computations at inference time as oppose to n^2 transformer computations. We also note that in contrast to our approach, Caciularu et al. (2021) used a total of 600 tokens from each document (most documents are within 512 tokens) whereas we only use 128 tokens. Models by Yu et al. (2020); Zeng et al. (2020) employ a BERT based semantic role labelling (SRL) model. On average, our model lags their models by approximately 1.1 CoNLL F1 points, however, we note that Yu et al. (2020) find that the SRL tagging accounted for roughly 0.4 CoNLL F1 points.

When comparing to other models that are linear in transformer computations, our model does well. Compared to the work by Allaway et al. (2021), our model surpasses their results by 3.7 CoNLL

Table 6: A comparison of methods utilizing contextual embedding models and their performance on the ECB+ test corpus using *predicted* topic clusters of Barhom et al. (2019). We have indicated the scaling at inference time (in terms of transformer computations) above. We have also indicated whether systems utilized adaptive pre-training (Adapt.), fine-tuned encoders (Fine-tuned), or utilized a semantic role labelling model (SRL). To better compare to earlier works, we have included results from using different encoders in our model and indicated which encoders were used in earlier works. Finally, Allaway et al. (2021) used sequential clustering algorithm whereas ours and Cattan et al. (2020) utilized an agglomerative clustering algorithm. **Bold** indicates best overall. Underlined results indicate our best overall.

F1 points on average. We note however, that their model used a BERT-base model and that they also introduced a novel sequential clustering approach. Our methodology used the larger RoBERTa-large model, and we utilized an agglomerative clustering algorithm as in previous works.

Finally, in contrast to earlier works, we note that our model performs equally well when using predicted clusters and ECB+ gold topics. In fact, our model does better (by 0.9 CoNLL F1 points) on entities when going to gold topics, and achieves the same performance on events using gold topics. This is related to how we selected our contrastive pairs – negative and positive pairs were selected from within each topic and so our model focused on the lexical ambiguity in the ECB+ corpus.

		Entities		Events	
		F1	Δ	F1	Δ
Pred. Topics	Our Model	80.2		83.3	
	– `CLS` representation	77.8	-2.4	82.3	-1.0
	– mention representation	77.8	-2.4	82.0	-1.3
	– no document context	74.2	-6.0	80.8	-2.5
Gold Topics	Our Model	81.1		83.3	
	– `CLS` representation	79.0	-2.1	81.3	-2.0
	- mention representation	78.9	-2.2	79.6	-3.7
	– no document context	75.1	-6.0	77.1	-6.2
Corpus	Our Model	78.7		75.9	
	– `CLS` representation	77.3	-1.4	74.9	-1.0
	– mention representation	75.7	-3.0	72.0	-3.9
	– no document context	72.8	-6.0	70.5	-5.4

Table 7: Ablation results (CoNLL F1) on the ECB+ test set *with singletons*.

4.4 Training and Inference Time

Our model is larger than earlier models by Cattan et al. (2021a,b); Allaway et al. (2021). On a single V100 Tensor Core GPU with 32 GB of RAM, training took approximately two days. This is comparable to reported times for the cross-encoder model (using Longformer) by (Caciularu et al., 2021). We note that contrastive learning methods have been found to converge slowly (Sohn, 2016). At inference time, however, our model takes approximately 15 seconds to evaluate on the ECB+ test set of events (using gold mentions and with singletons included). As a point of comparison, we ran the model of Cattan et al. (2021a,b) which likewise uses RoBERTa-large and is linear in transformer computations. We found that their model takes approximately 60 seconds under similar settings. In §4.5 we discuss experiments with smaller models.

4.5 Ablations

We ablate several parts of our model using the headlines heuristic and examine the importance of the underlying language model, the token representations, and the document context.

Language Model We examined the effect different representations have on overall performance by ablating the language model used. We found that the larger and richer representations of the RoBERTa-large model performed better generically. We gained on average 5 CoNLL F1 points in using RoBERTa-large versus BERT-large. We gained on average 7.2 CoNLL F1 points versus the smaller BERT-base model. Details can be found in Table 6.

Token Representation To assess the effect of including the `CLS` token embedding in the final representations, we trained our model without using its representation, but keeping the mention representation. We find that the `CLS` representation accounts for roughly 1.3 CoNLL F1 points on average while the mention representation accounts for roughly 2.8 CoNLL F1 points on average (see Table 7 for details). We also examined our model without explicitly using the mention representation, but still tagging the span with $[E], [/E]$ tokens. For our model, we find that the mention representation was a more important factor when considering events. We speculate that tagging the mention location with $[E], [/E]$ tokens allows the transformer to attend to the mention. For events, which have a more complicated structure (e.g. arguments) this likely has a more important effect.

Document Context Finally, an important component of our model was including the first two sentences of each document in the spirit of Caciularu et al. (2021). For the ECB+ corpus, which is comprised of news articles, much contextual information is contained in the first two sentences of the document. We see that the document context contributes on average 5.4 CoNLL F1 points (see Table 7 for details). This is in line with our expectations for new articles and earlier observations by Caciularu et al. (2021). We suspect the importance of this feature is due to a property of the ECB+ corpus that has been highlighted by others – namely, the documents form fairly distinct clusters in themselves and so simple document embeddings are able to recover subtopics easily (Cattan et al., 2021a,b; Cremisini and Finlayson, 2020). Note for instance that our model without using document context is competitive (compare with Table 6) when using predicted topics for pre-clustering. Recently, Eirew et al. (2021) sought to address this issue by creating a the Wikipedia Events Coreference (WEC) dataset. Applying our model to the WEC dataset, we found that our results surpass their benchmark by large margins (CoNLL F1 of 89.3 versus 62.3 (Eirew et al., 2021)) . We plan to discuss these results in further detail in future work.

4.6 TextRank

A limitation of the current work is its specificity to formal text (i.e. news articles, Wikipedia articles). Given the importance of the headlines to our model, we also conducted experiments using the TextRank algorithm (Mihalcea and Tarau, 2004) to extract sentences that best summarize the content of the article instead of using the first two. We expect this method to be more applicable to less formal settings. We embedded each sentence in the document using SBERT and select the top two. On average we found that the headlines heuristic provided a 4.6 and 3.7 CoNLL F1 gain on on event and entity coreference resolution respectively (with singletons) over the TextRank extracted contexts (for detailed metrics see Table 8 in Appendix A). This is expected in the ECB+ context as the TextRank algorithm selects noisier sentences as compared to article headlines.

5 Conclusions

In this paper, we proposed a new model for within- and cross-document coreference resolution. We demonstrated that contrastive learning approaches are effective at learning representations for coreference resolution. We evaluated our model on gold topics and at the corpus level of the ECB+ corpus—with and without singleton mentions—and found that our approach surpasses current state-of-the-art methods by large margins. We also evaluated our models with an initial document clustering method and found that our model was competitive with earlier works. We presented extensive ablations of our model and discussed limitations of our work including model size, training time, application to formal text domains (i.e. news articles and Wikipedia), and use of agglomerative clustering to generate final coreference clusters. Interesting directions for future work would be testing the TextRank algorithm in less formal contexts (i.e. beyond news articles and Wikipedia articles), investigating higher-order tuples (e.g. triplets) to speed up model convergence, and extending our work to predicted mentions as opposed to gold mentions as has been done by others (Cattan et al., 2021a,b).

The authors thank the anonymous reviewers for their advice and comments.

Ethical Considerations

In this work, we used the ECB+ corpus (Cybulska and Vossen, 2014) which consists of news articles from the open domain. Our use was consistent with the intended use of the dataset. Our model does not contain any intentional biases. As discussed in §3.4, §4.4, we ran our experiments on a single p3dn.24xlarge with 8 V100 32GB GPUs. Model training and inference was relatively short and does not present ethical issues.

Table 9: Combined within- and cross-document coreference scores for entities and events *with* singletons, using gold mentions. Gold topics use the ECB+ topics as the initial document pre-clustering while corpus level results do not use any document pre-clustering. We note that the system proposed by Kenyon-Dean et al. (2018) does not use contextual embeddings whereas ours and Cattan et al. (2021a) make use of RoBERTa-large. To the best of our knowledge, we have the only results at the corpus level for entities. **Bold** values indicate best overall for a particular data subset.

Learning the Ordering of Coordinate Compounds and Elaborate Expressions in Hmong, Lahu, and Chinese

Chenxuan Cui **Katherine J. Zhang** **David R. Mortensen**
Language Technologies Institute, Carnegie Mellon University

Abstract

Coordinate compounds (CCs) and elaborate expressions (EEs) are coordinate constructions common in languages of East and Southeast Asia. Mortensen (2006) claims that (1) the linear ordering of EEs and CCs in Hmong, Lahu, and Chinese can be predicted via phonological hierarchies and (2) these phonological hierarchies lack a clear phonetic rationale. These claims are significant because morphosyntax has often been seen as in a feed-forward relationship with phonology, and phonological generalizations have often been assumed to be phonetically "natural". We investigate whether the ordering of CCs and EEs can be learned empirically and whether computational models (classifiers and sequence labeling models) learn unnatural hierarchies similar to those posited by Mortensen (2006). We find that decision trees and SVMs learn to predict the order of CCs/EEs on the basis of phonology, with DTs learning hierarchies strikingly similar to those proposed by Mortensen. However, we also find that a neural sequence labeling model is able to learn the ordering of elaborate expressions in Hmong very effectively without using any phonological information. We argue that EE ordering can be learned through two independent routes: phonology and lexical distribution, presenting a more nuanced picture than previous work. [ISO 639-3: hmn, lhu, cmn] [1]

1 Introduction

In many languages of East and Southeast Asia, there are common constructions in which two words or phrases are coordinated without an overt marker like a conjunction (Hanna, 2013; Filbeck, 1996; Johns and Strecker, 1987; Wheatley, 1982; Matisoff, 1973; Pan and Cao, 1972; Watson, 1966; Banker, 1964). In coordinate compounds (CCs), two words are combined to form a compound word whose semantics are often a generalization of those of the two conjoined words. Elaborate expressions (EEs) are similar, except that they can consist of two phrases (rather than words) and include a repeated word. Take the following examples:

(1) Chinese coordinate compounds (CCs)

父母 *fùmǔ*	father-mother	'parents'
花木 *huāmù*	flower-tree	'vegetation'
天地 *tiāndì*	heaven-earth	'universe'
国家 *guójiā*	country-home	'nation'
风水 *fēngshuǐ*	wind-water	'geomancy'

(2) Lahu elaborate expressions (EEs)

a. ɔ̂ cē ɔ̂ phɔ̂
four corner four side
'at every corner'

b. chɔ phôʔ chɔ dì
people pile people lump
'a throng of people'

c. câ cûʔ dɔ̀ cûʔ
eat scarce drink scarce
'have nothing to eat or drink'

Coordinating compounds are found throughout the world, with varying semantic relationships between the whole and the parts (Obermüller, 2015). Elaborate expressions are most common in mainland Southeast Asia, where they occupy a position of great prominence. They are often associated with elevated styles of discourse, but they occur in all genres and registers.

Earlier investigators have claimed the order of the constituent words in CCs and EEs in some languages is predictable by rule. Many of the proposed ordering hierarchies are based on phonology (Ting, 1975; Dai, 1986; Mortensen, 2006). Building on this earlier work, Mortensen (2006) posited that Lahu EE orders could be predicted based on vowel quality—like Jingpho (Dai, 1986)—and that Hmong EE orders could be predicted based on tone, echoing earlier claims for Chinese and Qe-Nao (Ting, 1975; Pan and Cao, 1972). These

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3656 - 3669
July 10-15, 2022

tone and vowel scales were, however, not easy to rationalize in phonetic terms and were used by Mortensen to argue for a phonology in which structure reigns supreme and in which phonetic substance plays only an epiphenomenal role.

These claims have been viewed with skepticism for two reasons: morphosyntax has been widely seen as providing the inputs to phonology, not being driven by phonology (Chomsky, 1965); and phonology, since Jakobson et al. (1951) and Chomsky and Halle (1968) has usually been seen as grounded in phonetic categories. Some investigators have claimed that sound patterns that are not phonetically natural are inherently unlearnable. They can exist only as linguistic fossils deposited by a history of language change. In this paper, we undertake to investigate what kind of data is needed for (computational) learners to acquire these patterns. We report the following findings:

- Even rather simple classifiers like decision trees can learn to predict the order of EEs in isolation in over 96% of cases (Hmong) and 79% of cases (Lahu) using only phonological information.
- The decision trees for Hmong, Lahu, and Chinese mirror the phonological hierarchies proposed for these languages, suggesting that these hierarchies are empirically robust and learnable from the available evidence.
- However, correct and incorrect orderings of Hmong EEs can be effectively distinguished *in context* by a neural sequence labeling model *without* any phonological information, suggesting that learners would not have to acquire the phonological generalization directly in order to produce well-formed EEs.

2 Theoretical Significance

The experiments reported in this paper have a bearing on two assumptions widely held in phonological theory:

1. True phonological generalizations are always grounded in phonetic realities (phonology is natural)
2. Phonology operates on the outputs of syntax and morphology (grammar is serial)

Both of these assumptions have been contested. If the analysis of EE and CC ordering in Mortensen (2006) is sound, neither of these assumptions can be entirely correct.

2.1 Phonological patterns and phonetic substance

Starting even before Prague School phonology, it was widely assumed that the grammatical categories and patterns making reference to sound are coherent in terms of physical (articulatory, acoustic, and psychophysical) dimensions. The most common sound patterns found in the world's languages can usually be explained in these terms. For example, in many languages including English, if a nasal is followed by a stop, the place of articulation of the nasal assimilates to that of the stop (*i*[m]*possible* vs. *i*[n]*tolerant* vs. *i*[ŋ]*glorious*).

For phonologically distinctive features, such as those related to place of articulation, this was codified by Jakobson et al. (1951) and injected into generative phonology by Chomsky and Halle (1968). Even more radical statements about the relationship between phonological form and substance have been made since then (Donegan and Stampe, 1979; Flemming, 2013; Hayes, 2011; Donegan and Stampe, 2009; Steriade et al., 2001). While there has never been a complete consensus on the matter (Fudge, 1967; Hyman, 1970; Hale and Reiss, 2000, 2008), it has been widely assumed that phonological patterns that are phonetically incoherent cannot be learned by humans or can be learned only with difficulty (Hayes and White, 2013). For example, Becker et al. (2011) claim that language users do not acquire unnatural statistical patterns that would allow them to distinguish nouns with and without laryngeal alternations between vowel-initial suffixes (while acquiring natural ones). In contrast, Hayes et al. (2009) argue that speakers of Hungarian make use of unnatural patterns in deciding vowel harmony patterns (whether a form ends in a bilabial stop) but have a learning bias towards natural patterns. Artificial grammar learning experiments have been inconclusive but have suggested that the difficult-to-learn phonological patterns are **structurally complex**, not **phonetically unnatural** (Moreton and Pater, 2012a,b).

The phonological ordering generalizations proposed by Mortensen (2006) are structurally quite simple, but often phonetically incoherent. For Hmong EEs, ordering follows the hierarchy presented in Table 1; an EE with an AB_1AB_2 form[2] is ordered such that, if B_1 and B_2 differ in tone, the

---

[2] AB_1AB_2 (as in Lahu *chɔ phôʔ chɔ dì)* is also denoted as $ABAC$ in the literature. We use AB_1AB_2 in this paper to indicate that the second and fourth words are closely related as they form a potential coordinate compound.

Order	Orthography	IPA	Description
1	-j	˥˧	high falling
2	-b	˥	high
3	-m	˨˩	low creaky
4	-s	˨	low
5	-v	˨˦	rising
6	-g	˦˨	falling breathy
7	-∅	˧	mid

Table 1: Phonetic values of the tones of Hmong Daw, organized according the the EE ordering scale proposed by Mortensen (2006)

tone of B_1 is higher on the hierarchy than the tone of B_2.

This hierarchy has one phonetically reasonable aspect—the first two tones start high (though their relative rank seems arbitrary). The rest of the hierarchy is puzzling: it goes from lowest to low to rising to falling to neutral. Mortensen’s generalization for Lahu elaborate expressions would be easier to reconcile with phonetic substance (the higher in vowel space a vowel is, the better a candidate it is for the first position) were it not that the **best** first-position vowel is /o/, a **mid**, back, rounded vowel. The ordering generalizations that have been proposed for Chinese are similarly arbitrary-looking—they can be stated in terms of historical tonal categories (like the Middle Chinese tones) but appear incoherent in modern lects, in which the phonetic realizations tones have “wandered” phonetically to a dramatic degree.

If it can be shown that these patterns can be learned from naturalistic data, that they are robust predictors of EE and CC ordering, and that models trained to detect correctly ordered EEs and CCs in running text learn to use this kind of phonological evidence to assign labels, it would be suggestive, though not definitive, evidence against the position that phonological constraints must be grounded in phonetic substance.

2.2 Word order conditioned on phonology

In mainstream generative linguistics, grammar has usually been viewed as a feed-forward production system. While the nature of this pipeline has changed over various revisions of the theory, a consistent theme is that phonology operates on the output of syntax (Chomsky, 1965, 1981, 1995) and that, therefore, syntax should not be sensitive to phonology. One common version of this theory is the Y model, of which some of the earliest descriptions are found in Chomsky (1981). In this model, surface structure (*Mary hits John* vs. *John is hit by Mary*) is derived first. Then phonetic form (PF; [mɛəɹi hɪts dʒɒn]) and logical form (LF; $hit(Mary, John)$) are derived from surface structure. Because surface structure is fixed before PF, syntax should not be sensitive to phonology.[3] In certain other theories of grammar, different levels of representation are computed in parallel and are mutually constraining. An early example of such a framework is Lexical Functional Grammar (Kaplan and Bresnan, 1982; Bresnan et al., 2015). In this class of frameworks, it is expected that phonology *should* be able to influence word order. The question of whether and how phonology can affect word order is significant for larger theories of grammar.

In fact, there is mounting evidence that word order can be sensitive to phonology. It has long been suggested that dative shift in English is sensitive to phonological weight (Ross, 1967) although this claim has also been long contested (Wasow and Arnold, 2003). Some newer evidence comes from coordinate compound and echo reduplication constructions in Japanese, Korean, and Jingpho (Kwon and Masuda, 2019; Dai, 1986). An even more interesting case comes from Tagalog noun-adjective order, which is sometimes viewed as being free but which is actually sensitive to a set of phonological constraints (Shih and Zuraw, 2017). Even more germane to the current discussion are the findings of Benor and Levy (2006) and Morgan and Levy (2016), who found that phonological factors are significant predictors of the sequence of binomial expressions (like *son and daughter*) in English. The current case would enrich the body of relevant evidence in part because, while these cases are all instances of “soft” statistical tendencies, the Hmong ordering generalization is claimed to be nearly categorical (with a few, principled, exceptions).

3 Hypotheses

Based on the existing volume of work, we propose the following hypotheses:

---

[3] An important caveat is that—in some versions of generative grammar—syntactic structures are pure hierarchy and are not linearized until PF (phonetic form), when abstract lexical and functional categories are “spelled-out” (Fox and Pesetsky, 2005). This potentially opens the door for interaction between phonology and word order.

1. The order of Hmong and Lahu EEs and Chinese CCs can be predicted phonologically (out of context).
2. The "phonetically unnatural" phonological scales proposed by Mortensen (2006) and Ting (1975) predict the ordering of EEs in Hmong and Lahu and CCs in Chinese (out of context).
3. These scales can be learned by decision tree classifiers (out of context).
4. Phonological information facilitates the recognition of correctly and incorrectly ordered Hmong EEs in context.

4 Data

We examine the ordering effects across three languages: Hmong, Lahu, and Chinese (with Middle Chinese and Mandarin pronunciations).

For Hmong, we use a list of 3253 unique elaborate expressions extracted from the 12 million-word Hmong SCH corpus (Mortensen et al., 2022), which was manually annotated and validated by a human expert. All of the EEs are of the form AB_1AB_2 where B_1B_2 forms a coordinate compound. We also use the entire corpus for the EE tagging task described in Section 5.2. For Lahu, we use a list of 1400 EEs compiled by Matisoff (1989, 2006), which contains both AB_1AB_2 and B_1AB_2A forms. For Chinese, we use a list of 254 antonymic coordinate compounds B_1B_2 recorded in the *Modern Chinese Dictionary* (Anonymous, 2016). Middle Chinese pronunciations are retrieved from Wiktionary.[4]

5 Experiments

5.1 Learning Hmong, Lahu, and Chinese CC and EE Ordering with Classifiers over Phonological Features

We first examine whether the orders in elaborate expressions and coordinate compounds can be learned by a classifier. This experiment accomplishes two goals: 1) to reveal the existence and robustness of the patterns in the phonological ordering, and 2) to gain insight into the feature combinations that are most correlated with the ordering effects.

Experiment We use the EE lists described in Section 4 as phrases with the *attested* ordering, and create an *unattested* list of EEs by switching the order of B_1 and B_2 (occasionally both orders are attested, in which it is not included in the *unattested* list). We then formulate the task as a binary classification problem to predict whether a given ordering is attested or unattested.

To examine the degree to which the order can be predicted by phonology only, we use one-hot features of the onset, rhyme (vowel) and tone constituents in each syllable as classification features. We found that one-hot phonemic features were sufficiently expressive, and that using articulatory features (Mortensen et al., 2016) did not further improve the performance. In Section 5.3 we analyze the effect of adding word embeddings to the feature set. For all classification experiments, we compute the χ^2 statistic on all input features and select the top K features that most correlate with the class label, where K is determined by a development set.

We report the result on two types of classifiers: a decision tree (DT) classifier for maximal interpretability, and a support vector machine (SVM) with RBF kernel for the best classification performance.[5] We also experimented with multi-layer perceptron classifiers of varying widths and depths, but they did not outperform SVM on this dataset. Since other classifiers do not offer the explainability of DT or the performance of SVM, we only report results on these two models.

We split the attested word list into 70%/30% train/test sets before augmenting it with unattested data in order to prevent the same EE from appearing in both the train and test sets. However, it would still be possible for the same (B_1, B_2) to appear in both train and test sets with different A words (repeated words). To eliminate this possibility, we also report results on randomly sampled subsets of EEs wherein all (B_1, B_2) pairs are unique (so that there is no contamination across the train and test sets).

Rule-Based Classification We also test how well the ordering scales proposed in Mortensen (2006) perform as a rule-based classifier, compared to a DT and SVM trained on the dataset. This is equivalent to directly examining the distributional patterns of the ordering effects. Table 2

---

[4] Reconstruction from Li (1952)

[5] Classification models are trained using scikit-learn (Pedregosa et al., 2011)

shows the orders in Hmong, Lahu and Middle Chinese used in the rule-based classifier. When there is a tie, the order is determined randomly.

Language	Order
Hmong Tones	j ≺ b ≺ m ≺ s ≺ v ≺ g ≺ ∅
Lahu Rhymes	o ≺ u ≺ i ≺ ɨ ≺ ə ≺ ɔ ≺ e ≺ ɛ ≺ a
MC Tones	ping ≺ shang ≺ qu ≺ ru

Table 2: Linear ordering of tones for rule-based classification, based on Mortensen (2006). $a \prec b$ represents that a occurs before b

Results Table 3 shows the classification accuracies for all languages. We report results on two classifiers, using two different sets of features: *focal constituent* for the group of phonemes corresponding to the ordering rules (rhyme for Lahu and tone for Hmong and Chinese), and *all constituents* for all the onset, rhyme, and tone phonemes.

We observe a robust correlation between phonology and attested orders in all four languages, as seen by the high accuracy a classifier can attain. Even on unique (B_1, B_2) pairs, the best classifier and feature set achieves 71%–88% accuracy. This means that the ordering effects are not simply due to frequent (B_1, B_2) pairs skewing the statistics; rather, the ordering effect is robust across many (B_1, B_2) pairs in the four languages.

With only the focal constituent feature set, we observe comparable accuracy between the rule-based classification and either statistical classifier. This suggests that the degree to which the focal constituent alone determines EE ordering is no more than the linear ordering scale proposed by Mortensen (2006).[6] However, when phonemes from other constituents are included in the feature set and an SVM is used, we observe an increase of 3–11% in accuracy. This suggests the existence of more complex phonological interactions beyond the linear scale over the focal constituent.

Visualization of Learned Decision Tree By examining the learned decision tree, one can derive a linear hierarchy based on the order of features on the *no* branch, and whether each branching action leads to majority attested words or majority unattested words. We find that phonemes that appear topmost in the tree (the most order-defining phonemes) are exactly those at the two ends of the scales proposed by Mortensen (2006), and a decision tree classifier can learn a strikingly similar hierarchy, as shown in Table 4. Details on the derivation and the learned tree are shown in Appendix A.

5.2 Learning Hmong EE Ordering as Sequence Labeling

Experiment Now we investigate whether models can learn to recognize elaborate expressions and their ordering effects *in context* in a naturalistic corpus. We limit our experiments to Hmong in this section due to the unavailability of EE-annotated corpora in other languages. The Hmong dataset is annotated with `BIO` tags, where a `BIII` sequence represents a labeled EE. We train a neural sequence labeling model to predict the `BIO` tag of each word in a sentence.

We experiment with two types of feature extractors: a bidirectional LSTM and a CNN. We use both word-level and phoneme-level embeddings, following the intuition that the phonologically conditioned ordering helps speakers recognize an EE structure in context. Implementation details and hyperparameters are described in Appendix B.

In addition to the vanilla tagging task, to investigate whether the models can learn the ordering of EEs in context, we perform an experiment where the orders of B_1 and B_2 are swapped for half of the EEs, and the tags for the swapped EEs are changed to `B-fake` and `I-fake`. This renders the task more difficult as the model needs to both identify an EE in context and classify whether the order has been changed.

To prevent the model from memorizing certain EEs, we split the data into train/val/test sets by partitioning the list of EEs into disjoint sets, so that EEs in the validation and test sets do not appear in the training split. This way, the model is only given unseen EEs at test time. Furthermore, we partition the EEs into swap/no-swap so that occurrences of each EE are either all swapped or all kept unchanged.

Baseline The simplest baseline model would be to tag every occurrence of AB_1AB_2 (a 4-gram where the first and third words are identical) in the corpus as an EE without any consideration of the word or its phonology. Doing so yields 100% recall but very poor precision, since most occurrences of AB_1AB_2 are not elaborate expressions. Three strategies are employed to improve

---

[6] We ran an exhaustive search on all permutations of the tones/vowels, and found the one presented here performs the best as a rule-based classifier.

Language	Hmong		Lahu		Mandarin	Middle Chinese
Data	All	Unique	All	Unique	Unique	Unique
N	6420	1404	2748	1664	254	251
Rules	88.8%	85.5%	68.3%	66.3%	–	70.7%
DT (focal constituent)	89.0%	85.0%	67.2%	64.3%	65.3%	70.4%
DT (all constituents)	96.4%	85.3%	79.7%	67.8%	68.1%	75.3%
SVM (focal constituent)	89.1%	85.4%	67.3%	64.4%	65.3%	70.4%
SVM (all constituents)	**96.7%**	**88.3%**	**81.9%**	**71.3%**	**76.1%**	**81.0%**

Table 3: Classification accuracies with phoneme features (chance is 50%). *Focal constituent* is tone for Hmong and Chinese and rhyme for Lahu. *All constituents* include onset, rhyme and tone. *Unique* for Hmong and Lahu is the average result of 10 randomly sampled subsets of EEs with unique (B_1, B_2). Chinese CCs are always unique.

Language		Order
Hmong	Ling.	j ≺ b ≺ m ≺ s ≺ v ≺ g ≺ ∅
	Tree	j ≺ b ≺ m ≺ v ≺ s ≺ g ≺ ∅
Lahu	Ling.	o ≺ u ≺ i ≺ ɨ ≺ ə ≺ ɔ ≺ e ≺ ɛ ≺ a
	Tree	o ≺ u ≺ ... ≺ e ≺ ɔ ≺ ɛ ≺ a
MC	Ling.	ping ≺ shang ≺ qu ≺ ru
	Tree	ping ≺ shang ≺ qu ≺ ru

Table 4: Linear orders similar to those posited by Mortensen (2006) are learned by a decision tree

the performance of this baseline: (1) ensure that (A, B_1, B_2) are proper Hmong syllables parsable by a regular expression classifier; (2) set a word vector similarity threshold between the two CC words (B_1 and B_2) so that $cosine(v_{B_1}, v_{B_2}) > \alpha$, since many Hmong EEs have the two CC words of similar meanings (Mortensen, 2006);[7] (3) ensure the tonal scale in Table 2 is followed between B_1 and B_2

Results We report the F1 score of predicted tags on different models in Table 5. For the baseline model, all three strategies improve the tagging performance, suggesting that both semantic similarity and adherence to the tonal scale are indicators of being an EE. Despite the reasonable performance of the baseline, a neural sequence labeling model is able to beat it substantially, achieving a high F1 score in the EE tagging task. In particular, a CNN feature extractor outperforms an LSTM feature extractor. We hypothesize that this is due to a convolution kernel being able to capture non-local interactions in an EE (i.e., identical first and third words, and similar second and fourth words), whereas the linear nature of an LSTM encoder becomes restrictive in this task.

Model	F1	Precision	Recall
Baseline	41.32	26.15	100.00
+ regex parsable	49.24	32.83	100.00
+ wv. sim. thresh	60.99	50.29	77.99
+ tonal scale	66.66	59.37	76.56
LSTM	74.10	66.12	84.36
+ phonemes	73.14	65.39	83.09
LSTM + swap clf.	64.38	57.54	73.29
+ phonemes	63.97	56.93	73.17
CNN	90.79	87.36	94.52
+ phonemes	90.26	85.98	95.58
CNN + swap clf.	89.01	85.73	92.62
+ phonemes	89.26	86.00	92.79

Table 5: Precision, recall and F1 scores for sequence tagging on the test set. Results are averaged over 9 runs (3 data splits ×3 initial seeds)

When half of the EEs in the form of AB_1AB_2 are changed to AB_2AB_1 and their tags are modified to `B-fake` and `I-fake` (swap clf. rows in the table), the model is still able to achieve high F1 scores that are only slightly lower than the unswapped counterpart, even though the `B` and `I` tags have split into two types. The fact that increasing the number of classes does not degrade the performance very much suggests that the model can learn to distinguish attested and unattested orderings very well. To quantify the model's ability to learn Hmong EE ordering, we calculate an in-context classification accuracy by examining how many correctly identi-

---

[7] Word vectors are trained using Word2Vec (Mikolov et al., 2013). We find that SkipGram outperforms CBOW on this task, hence all results reported are SkipGram embeddings. α is determined by grid search and we find that $\alpha = 0.4$ works best.

fied EEs also have a correct prediction in whether the order has been swapped. We find that the in-context classification accuracy is 99.1% for LSTM and 99.5% for CNN, which are both exceptionally high. Note that this analysis excludes EEs that are not correct identified (both false positives and false negatives). Full confusion matrices are shown in Appendix C.

Interestingly, we find that adding phoneme level features to the input of either LSTM or CNN does not improve the performance in both the swapped and unswapped cases.[8] This result is in contrast with other similar sequence tagging tasks (e.g., NER), where character level features are found to improve performance (Yang et al., 2018; Kuru et al., 2016). More importantly, this result presents a contrast to the robust phonological patterns found in the previous section, as it demonstrates that the model is able to tag elaborate expressions and classify their orders successfully without any reference to phonology. This suggests that the ordering (B_1, B_2) can be predicted not only via phonology, but also via word-level features through the embeddings trained with the tagging model.

Visualization of Word Embeddings It is a rather perplexing result that a tagging model can learn the ordering of EEs via word embeddings only. Figure 1 shows the UMAP projection (McInnes et al., 2018) of two types of learned embeddings into 2D space. Embeddings from the tagging model show clear separation between words that tend to occur first in an EE (in the B_1 position) and words that tend to occur second, where as embeddings trained separately on the SkipGram algorithm (Mikolov et al., 2013) show no separation. This suggests that the learned separation is unique to the tagging model. However, there is no way for the model to memorize EEs from the training set, since the test set contains non-overlapping EEs. How, then, would the tagging model learn what words tend to occur first and what words tend to occur second in an EE?

It appears that the model is able to learn the order of B_1 and B_2 from the occurrences of these *component* words in the training set. For an EE AB_1AB_2 in the test set, although AB_1AB_2 itself never appears in the training set, B_1 and B_2 do appear either as a coordinate compound B_1B_2/B_2B_1, or as parts of another EE XB_1XB_2/XB_2XB_1 in the training set. As shown in Figure 2, appearances of them in the same order greatly outnumbers those of the reversed order. As a result, the model may be able to learn which words tend to be B_1 or B_2 from these distributional properties of the EE words.

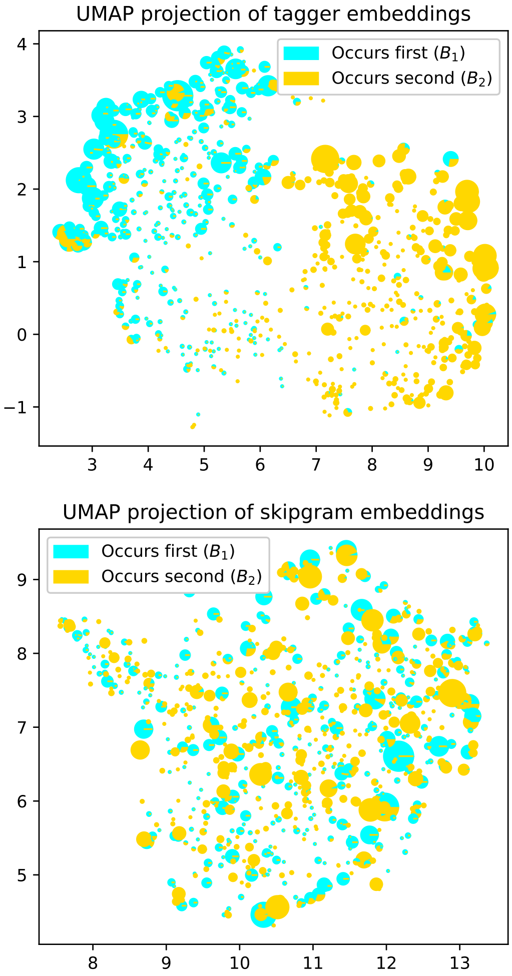

Figure 1: UMAP projection of word embeddings from neural sequence tagger (top) and separately trained SkipGram (bottom). Each circle is one Hmong word. The pie indicates proportion of times the word occurs first or second. Size of the dot indicates frequency in list of EEs.

To further isolate this effect, we perform an experiment where the train/test splits are made so that even component words do no overlap between them (so that the box plot in Figure 2 would be completely empty). We confirm that the tagging performance drop considerably in this setting, with an average F1 score (59.78) unable to beat the strongest baseline. However, even in this setting, we do not find phoneme features to contribute to the tagging performance in a statistically signifi-

---

[8] We also tried using character features or using only tones (the focal constituent for Hmong), but they were equally ineffective.

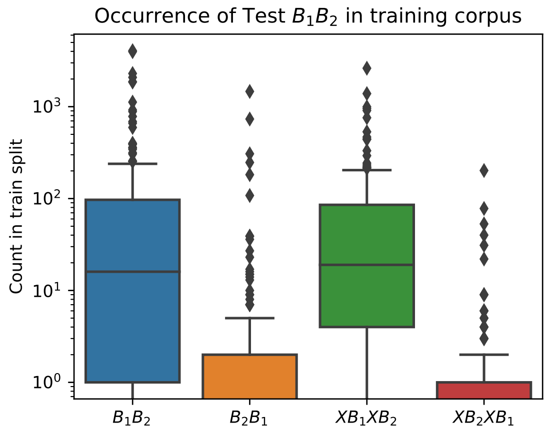

Figure 2: Occurrence of B_1 and B_2 words in test set EEs (AB_1AB_2) in the training set as different forms ($X \neq A$). Forms with the same ordering (blue and green) outnumbers forms with the reversed ordering (orange and red)

cant way (F1=61.16, one-sided Wilcoxon signed-rank test p=0.28).

5.3 Learning Hmong EE Ordering with Classifiers over Word Vectors

Experiment To further investigate to what extent word embeddings determine the order of (B_1, B_2) in Hmong EEs, we revisit the out-of-context classification experiment presented in section 5.1, this time adding word vector features. We experiment with both SkipGram embeddings and embeddings extracted from the CNN sequence tagging model (without swapping). Embeddings from the tagging model are expected to perform better on the classification task, since they are optimized to detect words contained in EEs in the attested order. On the other hand, embeddings separately trained via SkipGram are more "pure," as they only capture the distributional semantics of the words without additional information.

Results Table 6 shows the classification accuracies using word embedding features, as well as word embedding combined with one-hot phoneme features. We observe that embeddings trained with the tagger indeed perform better than those trained via SkipGram. What is surprising is that using embedding features from the tagger alone produces a classification accuracy comparable to using all phonemes (88%). Moreover, an even higher accuracy can be achieved by combining phoneme features with embeddings from the tagger. This suggests that EE ordering in Hmong can be predicted from two *independent* but mutually reinforcing routes, namely phonology and lexical distribution. Either method alone is a good predictor of the ordering, but combining the two achieves the best accuracy, because the two routes each offer additional information that are important in predicting the ordering of Hmong EEs.

Data	All	Unique
focal constituent (tone)	89.1%	85.4%
all constituents	96.7%	88.3%
wv-sg	94.4%	71.1%
wv-tagger	96.4%	88.3%
all constituents + wv-sg	96.6%	88.8%
all constituents + wv-tagger	**97.1%**	**93.8%**

Table 6: Classification accuracies for Hmong using SVM with phoneme and word embedding features. First two rows are from Table 3. *wv-sg*: separately trained skipgram embeddings. *wv-tagger*: embeddings from the CNN sequence tagging model

Visualization of Feature Importance With a total 360 features from both phonemes and word vectors[9], we can visualize which features the model find the most important in this classification task by examining the weights learned by the model[10].

Figure 3 shows the proportion of feature types that have the highest importance when varying the number of features (k). We see that when k is small, the model overwhelmingly uses phoneme features (especially tones) to perform classification. The test accuracy is impressively 84% with only 12 features – nearly 40% of which are tonal features. As k increases, word embedding features start to gain importance, and the test accuracy can be further improved when word embeddings are incorporated. By the time when k reaches 200, the proportion of each feature type become similar to the natural proportion before selection (dashed lines).

6 Discussion

In this paper, we set out to explore the ways that the order of words in EEs and CCs in Hmong, Lahu, and Chinese can be learned by computational models. Motivated by earlier linguists' find-

---

[9] 58 onsets, 14 rhymes, 8 tones, and 100 word vector dimensions for each of the two words B_1 B_2.

[10] We switch to an SVM with linear kernel to compare the importance for each feature directly

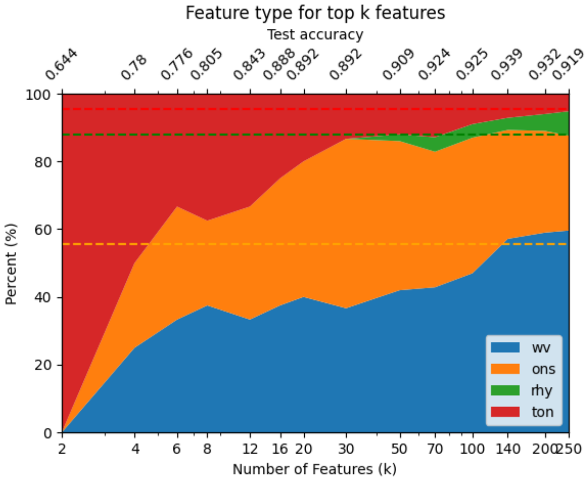

Figure 3: Proportion of feature types for the top k features ranked by importance weight. x-axis on the bottom shows the number of features to use on a log scale, while x-axis on the top shows the test accuracy for a linear SVM trained on the top k features. Dashed lines show the natural proportion of the tone, rhyme, onset and word vector features. Experiment was done with the *Unique* (B_1, B_2) words.

ings, we first use phonological features alone to discriminate between attested and unattested orders of words. We find that in the case of all three languages, the order of words can indeed be predicted phonologically, and the "phonetically unnatural" hierarchies do predict the ordering of EEs and CCs. Furthermore, a decision tree classifier is able to learn more-or-less the same hierarchies, suggesting that speakers of those languages could in principle learn the linear hierarchies through exposure to the language, and use these hierarchies to decide on the correct order of words in EEs and CCs. These findings provide positive evidence for hypotheses 1–3 from Section 3. We then explored the ways models can utilize context and distributional patterns of words to learn the orders in the sequence tagging experiments, and we were not able to find evidence for hypothesis 4. We were surprised to find that models can perform well using only word features, and that adding phonemes to the feature set does not help at all.

The seemingly contradictory results of our investigation point in an interesting direction. Information on which a model could rely to learn the ordering of these constructions is present redundantly in phonology (on the one hand) and in lexical and distributional patterns (on the other). When allowed to cooperate on a level playing field, embeddings and phonology-based features both contribute to the identification of well-formed EEs at a similar level. In other words, while it is possible that language users **may** use phonological hierarchies like those proposed in Mortensen (2006) to select appropriate orders for EEs and CCs, it is clearly not the case that they **must** (though they will perform a bit better if they do). These phonological hierarchies may have been more order-defining in the history of the languages, but as the sequence tagging experiments have suggested, they may also have become fossilized in the lexicon and in distributional patterns in the modern form. Many times, a (B_1, B_2) pair appears abundantly in multiples EEs (as $X B_1 X B_2$), as a CC (as $B_1 B_2$), or in other—more complicated—discourse patterns in the same order, so that language users could learn whether a given word tends to appear in the B_1 or B_2 position. If a tagging model can learn a word representation that distinguishes between B_1 and B_2, language users may do the same.

In a sense, these results should be pleasing to both the "structure" (Mortensen, Hale, Reiss) and the "substance" (Hayes, Flemming, Steriade) camps. They show, once again, that generalizations about sounds can be robust but phonetically arbitrary. However, they leave open the possibility that the relevant synchronic generalizations are not actually phonological.

7 Future Directions

We have shown two independent routes, namely phonology and lexical distribution, by which computational methods can predict the order of words in Hmong EEs. A language user could probably do the same, relying on both routes to some degree when they need to select the order of words in EEs. However, there is no way to know for sure without conducting a psycholinguistic experiment with native speakers, which would shed light on whether any of the modeling actually translates to human cognition. The Chinese and Lahu cases also raise interesting questions for future work: does the same two-route mechanism work for EEs and CCs in these languages as well? Answering this question will require additional data collection and annotation, but will shed significant light on this theoretically important issue.

A Trained Decision Trees

Figures 4, 5, 6 show what the trained decision tree looks like in the three languages. In each tree node, the top half of the box show the current majority class, attested (ATT) or unattested (FAKE), as well as the number of votes. The bottom half of the box shows the variable to branch on. As noted in the main text, a linear ordering can be induced from the tree by following the branches. Take the Hmong tree (Figure 4) as an example. The first factor to split on is *whether* B_1 *has the j tone*, and if the answer is *yes*, the majority of words are attested (255 attested vs 15 unattested/fake). This suggests that *j* has a strong tendency to occur in the B_1 position, since it is the most distinguishing factor to split on. Hence *j* can be placed as the first tone on the scale. If B_1 does not have the *j* tone, the next question to ask is *whether* B_1 *has the b tone*. Since a *yes* answer again leads to majority attested words (273 attested vs 61 unattested/fake), *b* can be placed second on the scale. The next three questions to ask concern with the B_2 word. Since a *yes* answer leads to attested words in all three cases, it suggests that ∅, g and s have a tendency to appear in the B_2 position, hence they can be placed on the end of the scale in that order. The next two factors concern with the *j* and *b* tones, which have already been placed on the scale, so we skip them. This process of following the left child (the *no* branch) and placing tones at either end of the scale is repeatedly applied, yielding the induced linear scales shown in Table 4.

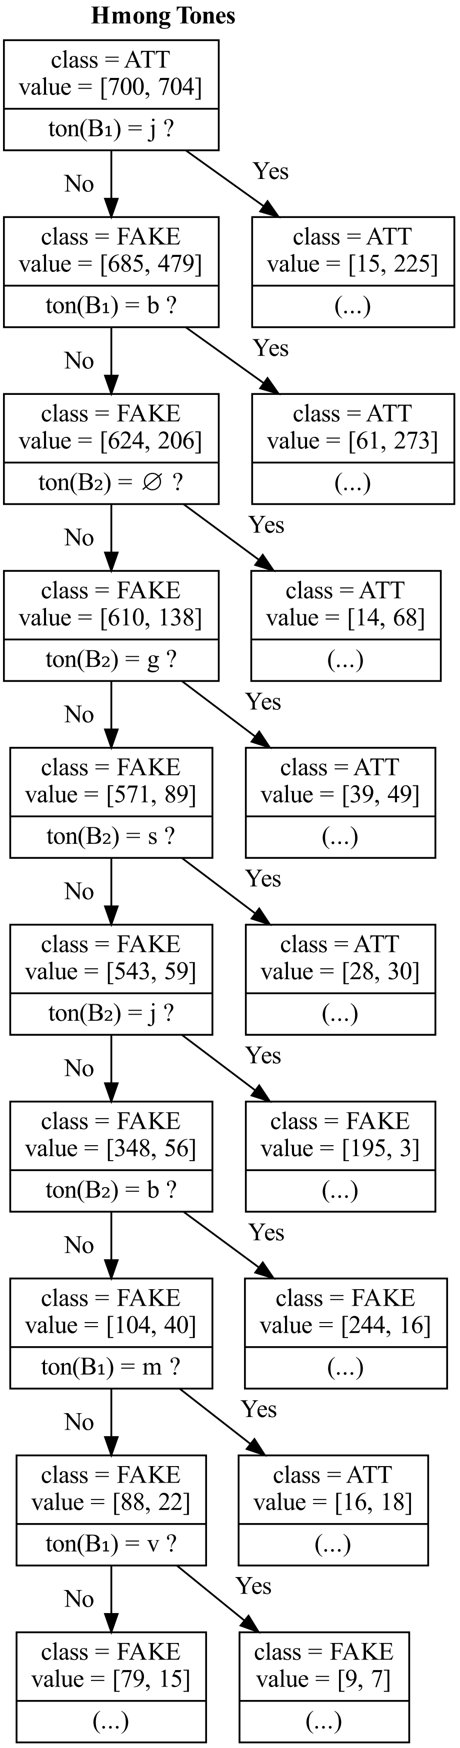

Figure 4: Decision tree trained on Hmong elaborate expressions predicts the following order of tones: $j \prec b \prec m \prec v \prec s \prec g \prec \varnothing$.

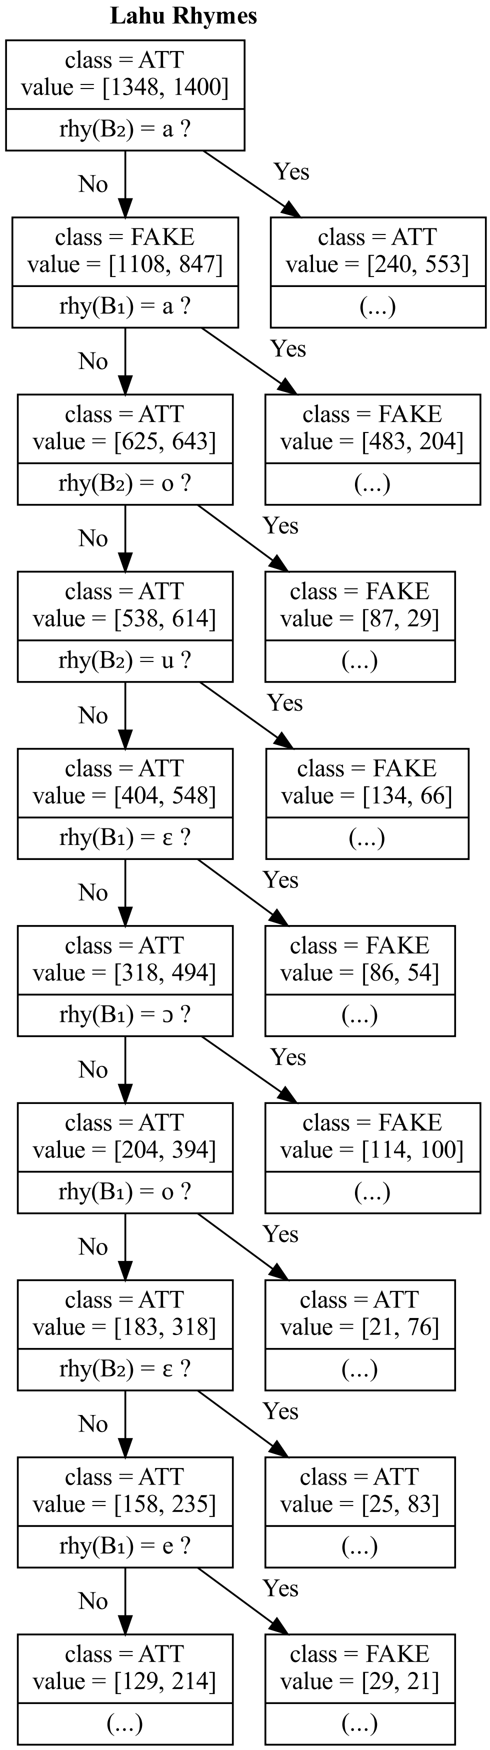

Figure 5: Decision tree trained on Lahu elaborate expressions predicts the following order of rhymes: o ≺ u ≺ ... ≺ e ≺ ɔ ≺ ɛ ≺ a.

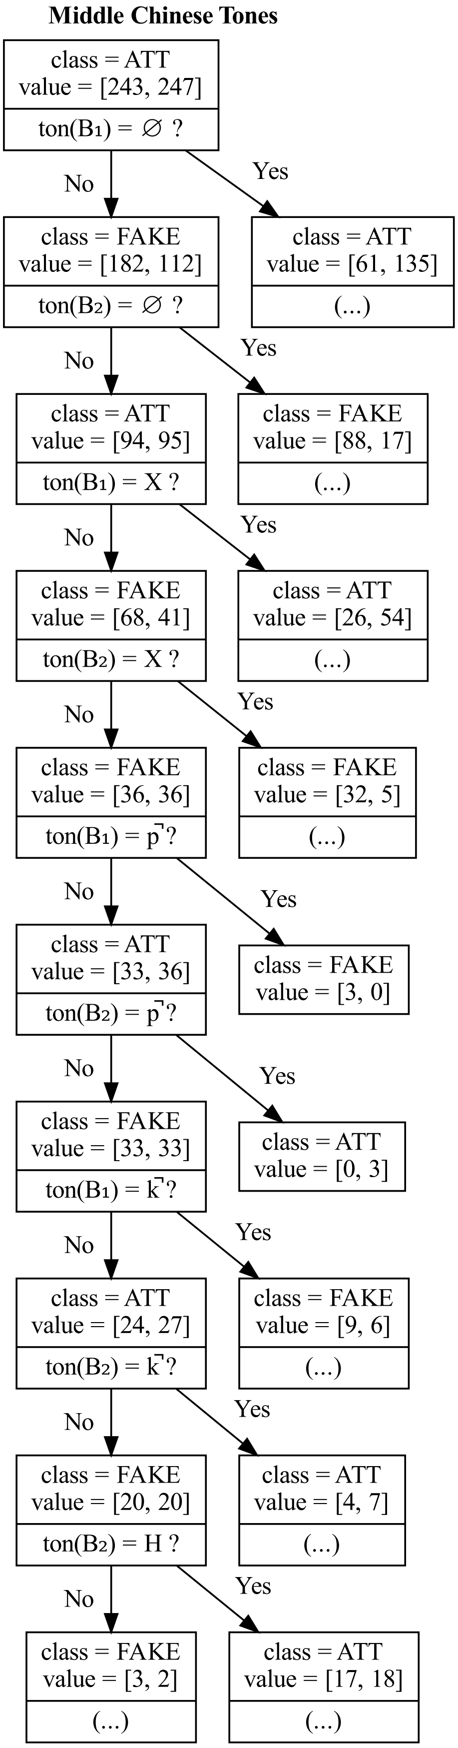

Figure 6: Decision tree trained on Middle Chinese coordinate compounds predicts the following order of tones: ping (∅) ≺ shang (X) ≺ qu (H) ≺ ru (p̚, t̚, k̚)

B Implementation Details

B.1 Data

The Hmong corpus consists of 740k sentences with a positive rate of around 3.1% (i.e. 96.9% of sentences contain no EEs). The EEs are randomly split into disjoint train and val/test sets with approximate ratios of 91%/4.5%/4.5%. To reduce the possibility that certain splits are easier than others, three such splits are independently produced. The positive sentences are split into train and val/test sets according to the EE partitions, and the negative sentences are split with approximate ratios of 91%/4.5%/4.5%.

B.2 Models

The sequence tagging model consists of a feature extractor followed by a fully connected layer to predict the tags: `{B,I,O}` in the unswapped case and `{B,B-fake,I,I-fake,O}` in the swapped classification experiments. Two feature extractors are used: 1) an LSTM with bidirectional encoding, and 2) a CNN, consisting of four layers of 1D convolution, ReLU, Dropout, and BatchNorm.[11] When character or phoneme level features are used, the character embeddings go through a CharCNN before being concatenated with the word embedding. Details on model configuration is shown in Table 7. The LSTM model contains approximately 1.4M parameters and the CNN contains approximately 1.7M parameters. Our code is based on NCRF++ (Yang and Zhang, 2018).[12]

Hyperparameter	Value
Word embed dim	100
Char embed dim	30
LSTM hidden dim	100
CNN hidden dim	200
CNN kernel size	3
CharCNN hidden dim	50
CharCNN kernel size	3
Dropout probability	0.5

Table 7: Model configuration hyperparameters.

---

[11] An extensive architecture search was not performed, because the purpose of the experiments is not to achieve the best performing model.

[12] https://github.com/jiesutd/NCRFpp, under Apache 2.0 License which permits use for research purposes.

B.3 Training and Decoding

The model is trained with cross entropy loss using an SGD optimizer with momentum. Early stopping is used on the F1 score of the validation set, with a patience of 10 epochs. During training, negative sentences in the training set are downsampled to 90% (resampled every epoch) instead of 97%, which leads to 3x faster training time but minimal impact on performance. Validation test sets are used in their entirety. Training hy parameters are shown in Table 8. Training t cally takes less than 2 hours to complete on a sir GeForce RTX 2080 Ti GPU .

Hyperparameter	Value
Batch size	64
Learning rate	0.02
SGD momentum	0.9
Early stopping patience	10

Table 8: Training hyperparameters.

C Confusion Matrices

Figure 7 shows the confusion matrices for the sv classification experiments. As mentioned in main text, an in-context classification accuracy be calculated from the tokens that are corre identified as part of an EE but may or may not h a correct prediction of the orders (i.e. confuse with `B-fake`). For example, the in-context cla fication accuracy for the CNN confusion matri

$$acc_{CNN} = \frac{439 + 447}{439 + 447 + 4} = 99.55\%$$

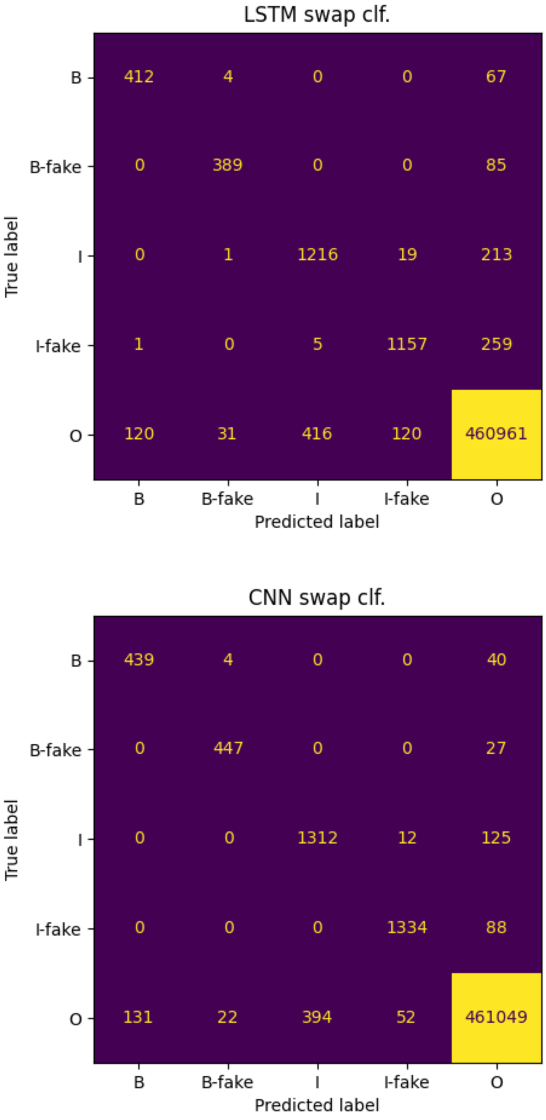

Figure 7: Confusion matrices for the swap classification experiments for LSTM (top) and CNN (bottom)

FRUIT 🍏: Faithfully Reflecting Updated Information in Text

Abstract

Textual knowledge bases such as Wikipedia require considerable effort to keep up to date and consistent. While automated writing assistants could potentially ease this burden, the problem of suggesting edits grounded in external knowledge has been under-explored. In this paper, we introduce the novel generation task of *faithfully reflecting updated information in text* (FRUIT) where the goal is to update an existing article given new evidence. We release the FRUIT-Wiki dataset, a collection of over 170K distantly supervised data produced from pairs of Wikipedia snapshots, along with our data generation pipeline and a gold evaluation set of 914 instances whose edits are guaranteed to be supported by the evidence. We provide benchmark results for popular generation systems as well as EdiT5—a T5-based approach tailored to editing we introduce that establishes the state of the art. Our analysis shows that developing models that can update articles faithfully requires new capabilities for neural generation models, and opens doors to many new applications.[1]

1 Introduction

Information changes on a constant basis. Every day, athletes are traded to new teams, and musicians and actors produce new albums and TV shows. Maintaining textual knowledge bases to keep track of these changes requires considerable community effort. For instance, a team of 120K volunteer editors make 120 edits to English Wikipedia every minute, and write 600 new articles a day.[2] As the knowledge base grows, the amount of maintenance effort is compounded by the need to keep the knowledge base consistent; e.g., each edit may render information in one of the existing 6.3M+ articles obsolete.

Assistive writing technologies have the potential to substantially reduce the burden of keeping text corpora up to date and consistent. However, existing work has mainly focused on correcting grammar (Wang et al., 2020), reducing repetitive typing (Chen et al., 2019), and following rhetorical directives (Sun et al., 2021), whereas the problem of producing edits grounded in external knowledge has received little attention (Kang et al., 2019). In contrast, numerous works have developed systems for distilling external knowledge into text (e.g., Wikipedia article generation) by treating the problem as multi-document summarization (Liu et al., 2018; Shi et al., 2021) or data-to-text generation (Bao et al., 2018; Parikh et al., 2020). However, these systems are not useful for updating existing texts as they can only generate text from scratch.

To help endow writing assistants with grounded editing capabilities, we introduce the novel generation task of *faithfully reflecting updated information in text* (FRUIT), where the goal is to incorporate new information into an existing piece of text. An illustration is provided in Figure 1. Given an outdated Wikipedia article and collection of new information about the article's subject, FRUIT requires updating the existing text so that it is consistent with the new information, as well as adding text to reflect new salient facts, e.g., in Figure 1, the first sentence is updated to reflect that Tom Kristensson now drives in the Junior World Championship, and new sentences are added to reflect his achievements in 2019 and 2020.

FRUIT presents several unique challenges. First, unlike many generation tasks, models cannot obtain good performance by solely relying on their parametric world knowledge. Whenever the provided evidence contradicts parametric knowledge, the model must prefer the evidence, which recent work has shown is difficult for pretrained language

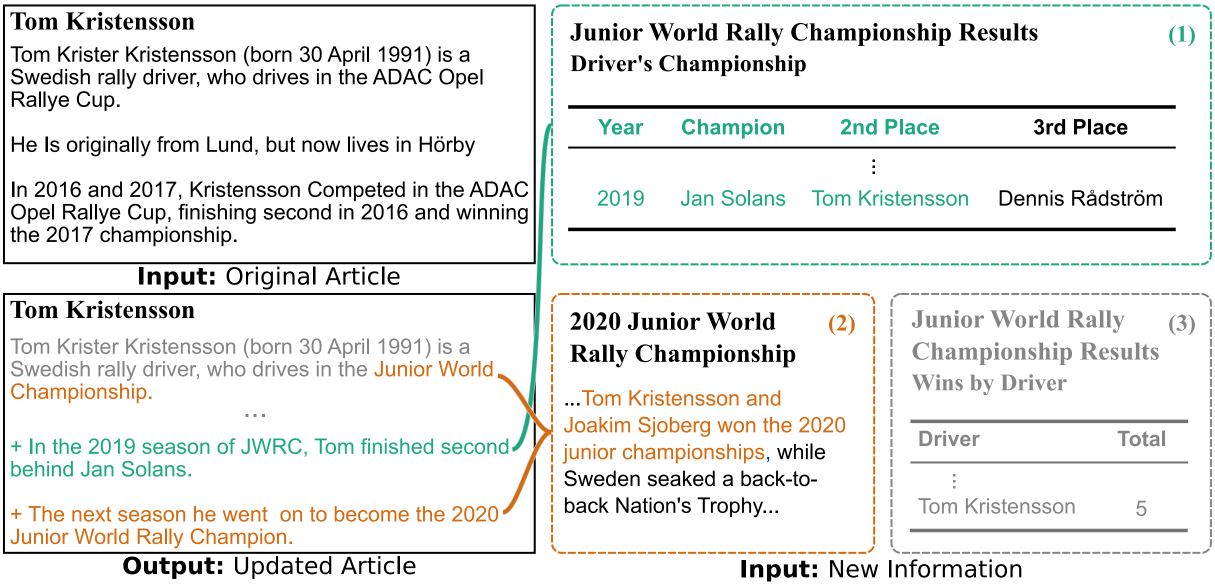

Figure 1: **Illustration of the FRUIT task**. An outdated *original article* and relevant *new information* are provided as inputs, and the goal is to generate the *updated article*. In this example, the original article about Tom Kristensson was written in 2020, and the new information is comprised of updated information about Tom Kristensson that has been added to other Wikipedia articles between 2020 and 2021. Given these inputs, the goal is to produce the updated 2021 version of article. Models need to identify the relevant supporting facts (orange and teal) to generate faithful updates while ignoring superfluous information (grey).

models (Krishna et al., 2021; Longpre et al., 2021). Second, the generated text needs to be faithful to *both* the original article and the new evidence, *except* when evidence invalidates information in the existing article. Finally, this task requires models to jointly read and analyze evidence from both textual and tabular sources and determine which is relevant and which can be ignored, thus combining challenging aspects of both multi-document summarization and data-to-text generation.

To facilitate research on this task, we release the FRUIT-WIKI dataset, a collection of over 170K distantly supervised ("*silver*") update-evidence pairs. This dataset is produced by comparing pairs of English Wikipedia snapshots to identify updates to an article between two snapshots, and associating information from the other articles that supports these updates under a distant supervision assumption. As there is no guarantee that updates in the later Wikipedia snapshots can be supported by the collected evidence, we also collect a "*gold*" evaluation set of 914 human annotated update-evidence pairs where unsupported claims have been removed without disturbing fluency. We train and validate our models using silver data and then evaluate the final performance using gold data.

We establish initial benchmark results for a number of trivial and neural sequence-to-sequence baselines. We also introduce EDIT5, a T5-based model specially adapted for grounded editing, which establishes state-of-the-art performance on FRUIT-WIKI. Through an extensive set of analyses, we identify a number of failure modes needed to be improved upon in order to obtain better performance on FRUIT-WIKI, as well as other interesting topics for future work on this task. We additionally release our data collection pipeline to allow researchers to produce data from future Wikipedia snapshots and other languages, which we show to produce high-quality silver data.

2 The FRUIT Task

2.1 Task Definition

In this section we introduce the task of *faithfully reflecting updated information in text* (FRUIT). Given an input piece of text focused on a topic or event, along with a collection of potentially new information about the subject of the text, the goal is to update the input text to reflect the new information. A concrete illustration of the task is provided in Figure 1. The original piece of text along with its updates are shown on the left, while the new information is shown on the right.

Formally, we assume access to pair of texts, A^t and $A^{t'}$, pertaining to a given subject, written at times t and t' (respectively). In addition, we assume access to a set of new information, a.k.a., evidence, $\mathcal{E}^{t \to t'} = \{E_1, \ldots, E_{|\mathcal{E}|}\}$, mentioning the subject written between times t and t'. As is shown in Figure 1, the evidence can contain structured objects (e.g., excerpts from tables) as well as unstructured text. Given A^t and $\mathcal{E}^{t \to t'}$ the goal is produce the updated text $A^{t'}$.

Successful completion of this task requires a number of complex and inter-related reasoning capabilities. For one, models must be able to identify which evidence contradicts existing portions of the source article, and which evidence introduces new salient information about the subject in order to correctly choose whether to alter the existing text vs. add new text. For example, in Figure 1 the first sentence is updated to reflect that Tom Kristensson now races in a different competition, whereas new sentences are added describing his achievements in the years 2019 and 2020. Models must also be able to determine whether a given piece of evidence should be used at all, i.e., perform content selection. For example, in Figure 1, the number of rounds won by Kristennsen appears in the evidence but does not correspond to any piece of updated text. Although some evidence may not appear in the updated article, the converse is not true, the system should aim to generate an updated article where all the updates are faithful to the evidence.

2.2 Evaluation

In this section we introduce important considerations for evaluating FRUIT systems.

Evaluate on Updated Text There is often considerable overlap between the original and updated text. As we will see in Section 5 this poses a challenge for standard evaluation metrics like ROUGE (Lin, 2004) as systems can achieve high scores without making any updates. In this work, we propose to evaluate FRUIT systems using an alternative metric, UpdateROUGE, that only considers updated sentences instead full texts. For example, in Figure 1, the reference for UpdateROUGE only consists of the first and last two sentences.

Evaluate Faithfulness Ensuring that generations faithfully reflect information in the evidence and updated article is crucial. However measuring faithfulness of generations is an active area of research (Çelikyilmaz et al., 2020) and adapting existing metrics to the FRUIT task is non-trivial.

As a simple proxy for faithfulness, we choose to measure the token overlap between named entities appearing in the generation and the target article/evidence, where entities are identified using the named entity recognizer used by Guu et al. (2020) to perform salient span masking. We specifically introduce the following measurements:

1. **Unsupported Entity Tokens.** This metric shows the average number of entity tokens appearing in generated updates that do not appear in the *source article* or *evidence*. This is intended to capture the overall amount of unfaithful text, focusing on entities, where higher numbers indicate less faithfulness.
2. **Entity Precision and Recall.** These metrics capture the overlap of mentions between the generated updates and the *target*. Entity precision measures the fraction of entity tokens appearing in the generated updates that appear in target entities, whereas entity recall measures the fraction of entity tokens in the target that appear in the entities in generated updates. The latter is similar to UpdateROUGE but only evaluated on entities, and thus, potentially less sensitive to paraphrasing.

Parametric Knowledge Consideration FRUIT systems should incorporate information from the provided evidence into the update, and not information that happened to be present during training or pretraining. In this work we attempt to address this by evaluating models only on updates that were made to the text after the data used to pretrain and finetune the model was collected. As this setup precludes evaluating models trained after 2020 on FRUIT-WIKI, we release our data collection pipeline so that researchers can produce evaluation datasets from future versions of Wikipedia.

3 Dataset Collection and Analysis

As discussed in the introduction, keeping track of new information and then updating articles to reflect that information requires a massive amount of manual effort. Thus, in order to scalably collect sufficient data for training and evaluating FRUIT systems, some amount of automation is likely required. In this section we introduce the FRUIT-WIKI dataset and associated data collection pipeline, which allows the automatic collection of high-quality training and evaluation data for FRUIT from pairs of Wikipedia snapshots.

	Train	Test	
		Silver	Gold
Years	'19-'20	'20-'21	'20-'21
Articles	114K	54K	914
Edits	407K	182K	3.0K
Subst. Edits	135K	62K	1.3K
Evidence	720K	315K	7.7K
Content Sel.	93K	42K	913

Table 1: **Dataset Statistics.** We use 10% of the training data as our validation data.

3.1 Pipeline

Our data collection pipeline produces distantly annotated training and evaluation data from pairs of Wikipedia snapshots. We will refer to the earlier snapshot as the *source* snapshot, and the later snapshot as the *target* snapshot.

Step 1. Collect Article Updates We compute the diff between the introductory sections of articles appearing in both the *source* and *target* snapshot to identify all of the material that has been updated (which will serve as A^t and $A^{t'}$). We also compute the diff between the non-introductory sections of articles to find new mentions of the subjects of other articles (which will serve as $\mathcal{E}^{t \to t'}$). These mentions can take the form of sentences in the text, as well as new table rows and list entries. Entities are disambiguated using Wikipedia hyperlinks.

Step 2. Filter Stylistic Updates A large number of edits to Wikipedia are stylistic (Daxenberger and Gurevych, 2012), and are therefore irrelevant to our task. In the next step of the pipeline, we attempt to filter articles that have only been superficially edited by keeping only those where at least one new *added entity* appears in the *target* snapshot.

Step 3. Identify Supporting Evidence In the last step of our pipeline, we seek to determine which pieces of evidence in $\mathcal{E}^{t \to t'}$ justify each of the updated sentences in $A^{t'}$. To do so, we make the following distant supervision assumption: an updated sentence $a \in A^{t'}$ containing an *added entity* s' is substantiated by a piece of evidence $E \in \mathcal{E}^{t \to t'}$ only if s' is also mentioned in E. The accuracy of the annotations produced by this assumption will be measured in Section 3.3.

Our pipeline is implemented using Apache Beam,[3] to allow for distributed processing. We plan on releasing the code upon publication to enable other users to produce FRUIT data from future Wikipedia snapshots, as well as languages other than English.

UpdateROUGE			Entity	
1	2	L	Prec.	Recall
87.4	84.6	87.1	91.8	94.6

Table 2: **Inter-Annotator Agreement**.

3.2 FRUIT-WIKI

We run our pipeline on English Wikipedia snapshots from Nov. 20, 2019 to Nov. 20, 2020 to produce the training dataset, and from Nov. 20, 2020 to June 1, 2021 to produce the evaluation dataset. Detailed statistics are provided in Table 1. On average, there are around 3 to 4 updates per article, and around 7 pieces of associated evidence. About 80% of updates require some form of content selection, i.e., ignoring some evidence, when performing updates.

We find that only a third of the updates are substantiated by one or more pieces of evidence according to our distant supervision assumption. Thus, the remaining updates are either: a) superficial changes to the source article, or b) additions of new claims that are unsupported with respect to the collected evidence. The latter is a particular issue as these claims can cause the model to learn to hallucinate during training, and should be impossible for the model to guess during evaluation. Through the usage of human annotations and carefully selected evaluation metrics we will study the extent to which this is an issue throughout the rest of the paper.

We categorize articles in our dataset using the Wikimedia Foundation's topic model (Asthana and Halfaker, 2018). The distribution of topics is displayed in Figure 2. We find that the majority (approximately 50%) of updates deal with cultural topics (e.g., sports, media, personal biographies), and geographic entities (e.g., countries, states) which intuitively are likely to be affected by current events. while there are few updates to STEM- and history-related articles.

3.3 Gold Evaluation Data

To address the issue of unsupported claims during evaluation, we hired a team of 9 annotators to produce a *"gold"* evaluation subset of our test dataset.

---

[3] `https://beam.apache.org/`

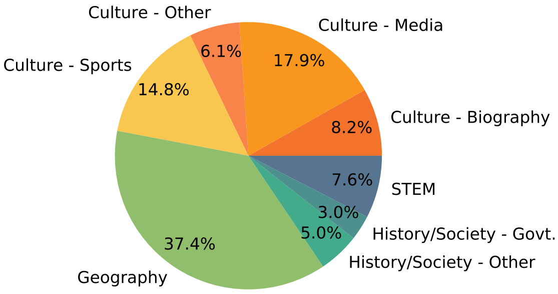

Figure 2: **Topic Distribution.**

We collect annotations for 914 update-evidence pairs where each instance is corrected to ensure that all of the updates are supported. For the remainder of the paper we will refer to the distantly supervised test dataset annotations as *"silver"*.

Annotation Process For each instance, annotators were shown the source article, evidence, and a marked up copy of the target article. In the marked up article, each updated sentence was highlighted and prefixed with reference labels to the supporting evidence identified by our pipeline. The correction process proceeded in two steps. In the first step, annotators were asked to highlight all of the unsupported claims and incorrect reference labels in the target article. In the second step, annotators were then asked to remove the unsupported text and minimally update the article to preserve fluency.

Annotators attended an initial 30 minute training and were provided regular feedback from the authors during the early stages of annotation. To ensure data quality, an additional annotator was hired with the sole job of checking the other annotator's work and correcting their mistakes. In total annotators spent roughly 500 hours on annotation. The annotation interface and a completed annotation are shown in Figure A7 in the Appendix.

Agreement We measure annotator agreement using a subset of 100 instances that were annotated by multiple annotators. Following Chen et al. (2015) and Shi et al. (2021), we quantify agreement by computing the evaluation metrics described in Section 2.2. The results are provided in Table 2. We observe high inter-annotator agreement with all scores in the 80s and 90s.

Analysis Statistics for the gold evaluation dataset are provided in Table 1. Overall, they closely resemble the statistics for the distantly supervised data with one exception: the fraction of substantiated updates has increased.

UpdateROUGE			Entity		Reference Agreement
1	2	L	Prec.	Recall	
83.7	81.2	83.4	90.4	100.0	84.5

Table 3: **Gold and Silver Annotation Agreement**. Quality of Silver Annotations by using the Gold as the reference.

To measure the quality of our silver data, we reapply the approach used to measure inter-annotator agreement to compute agreement between the gold and silver annotations. We also measure the *reference agreement*, i.e., the fraction of reference labels kept by the annotators. Results are provided in Table 3. We find that agreement is high with most scores in the 80s, a strong indication that the data produced by our pipeline is high quality. In particular, the high UpdateROUGE scores provide further evidence that only a small amount of the updated text in the weakly supervised data is unsupported, while the high reference agreement indicates that our distant supervision assumption is usually accurate.

4 Methods

In this section we introduce baseline methods to establish initial benchmark results on FRUIT-WIKI. We consider trivial approaches that copy task inputs, as well as T5, a neural sequence-to-sequence baseline which has shown strong performance on related tasks such as summarization (Raffel et al., 2020; Rothe et al., 2021) We additionally introduce EDIT5, a variant of T5 that produces a sequence of edits instead of the entire updated text, and employs additional tweaks to improve performance.

4.1 Copy Baselines

The first set of baselines we introduce are trivial methods that merely copy the input. We consider two variants:

- **Copy Source**: Generates a copy of the source article, and
- **Copy Source + Evidence**: Generates a copy of the source article concatenated with the evidence.

Our evaluation metrics only apply to unstructured text, however the evidence may contain structured tables. In order to convert these tables to text, we apply a conventional linearization scheme (Lebret

	UpdateROUGE			Entity		Unsup.

et al., 2016; Wiseman et al., 2017) that separates table entries using row and column delimiters.

4.2 T5

T5 (Raffel et al., 2020) is a pretrained sequence-to-sequence (Sutskever et al., 2014) model based on the transformer architecture (Vaswani et al., 2017). Similar to the previous section we experiment with two variants:

- **T5**: Only includes the source article in its input,
- **T5 + Evidence Inputs**: Includes both the source article and evidence in the input.

Tabular inputs are linearized using the same approach described in the previous section. Experiments are performed using the JAX-based T5X library.[4] Hyperparameters and additional training details are described in Appendix B.

4.3 EDIT5

Lastly, we introduce EDIT5, which improves upon the T5-based approach described in the previous section through the usage of a compressed output format that removes the need to write the entire update from scratch and encourages content planning. The output is modified in two ways:

First, as the majority of text in the target article is copied from the source, we replace any copied sentence with a single *copy token* identifying the sentence, e.g., if the second sentence is copied it is replaced by the token `[2]`. Similar to a copy mechanism (See et al., 2017), this allows the model to dedicate less capacity to repeating sequences from the input. As the resulting output resembles that produced by the `diff` data comparison utility, we refer to this as a diff-formatted output.

```
(2) Tom Krister Kristensson (born
30 April 1991) is a Swedish rally
driver, who drives in the Junior World
Championship.  [1] [2] (1) In the 2019
season of JWRC, Tom finished second
behind Jan Solans.  (2) The next season
he went on to become the 2020 Junior
World Rally champion.
```

Figure 3: **EDIT5 Output Format.** Instead of generating the fully updated text, EDIT5 generates sequences of edited sentences, copy tokens (e.g., `[2]`, which means copy the second sentence), and reference tokens (e.g., `(1)`, which means the following sentence should use the first piece of evidence).

Second, before each update we insert a sequence of *reference tokens* identifying the pieces of evidence that support the update, e.g., if the first and third piece of evidence in $\mathcal{E}^{t\to t'}$ support an update then the update is prefaced by `(1)(3)`. This approach, inspired by the use of entity chains for summarization (Narayan et al., 2021), trains the model to plan which references to use before generating an update. These reference tokens are removed from the output text of the model prior to computing the evaluation metrics.

An example of the EDIT5 output format is provided in Figure 3, and a comparison to the T5 output format is provided in Appendix D. Training details and hyperparameters match the setup described in Section 4.2.

---

5 Results and Analysis

Baseline results on the gold evaluation data are provided in Table 4a, and ablation results are provided in Appendix A. In general, we find that the copy baselines perform worse than T5 and T5 performs worse than EDIT5. Notably, the copy source baseline rightfully scores zero on all metrics, while we will later find that it obtains a high ROUGE score.

Although our models are trained on silver data, they still obtain good performance on the gold evaluation set. This shows the high quality of our silver data collection pipeline, and T5's ability to generate reasonable updates based on the evidence.

For the T5 baselines, we find that adding evidence to the input results significant increase in all metrics, demonstrating that using the evidence is crucial to obtaining good performance.

EDIT5 obtains additional 3-5% absolute increase in all performance metrics compared to T5, establishing EDIT5 as a strong baseline for future systems to be compared against. The reduction of unsupported entity tokens implies that EDIT5 hallucinates less frequently than T5 models. Results are provided for different model sizes to illustrate how performance scales with parameter counts.

Example Output An example EDIT5 output is provided in Figure 4, and additional outputs in Appendix E. The examples illustrate important features of the task. In Figure 4 the goal is to update the Wikipedia article for Holli Sullivan to reflect her new role of Secretary of State of Indiana. In the reference, this information is reflected in an updated version of the first sentence as well as in a newly added last sentence. An additional sentence is added after the first sentence paraphrasing the introduction of the source article, which describes Sullivan's previous position as a member of the Indiana House of Representatives.

In the EDIT5 output for this example, information is only added at the end of the article. While the model correctly states that Sullivan was appointed to be Secretary of State by Governor Eric Holcomb, as well as includes additional context surrounding Sullivan's appointment that is paraphrased from the evidence, there are some issues with the output. First, because the first sentence of the article is not updated there is conflicting information about Sullivan's current position. Second, the added sentence hallucinates that Sullivan was appointed in January 2020 when she was actually appointed in March 2021, a fact that directly appears in the evidence.

	ROUGE		
	1	2	L
Copy Source	78.1	69.3	75.0
T5-Large	57.0	44.2	49.5
EDIT5-Large	78.6	69.1	72.7

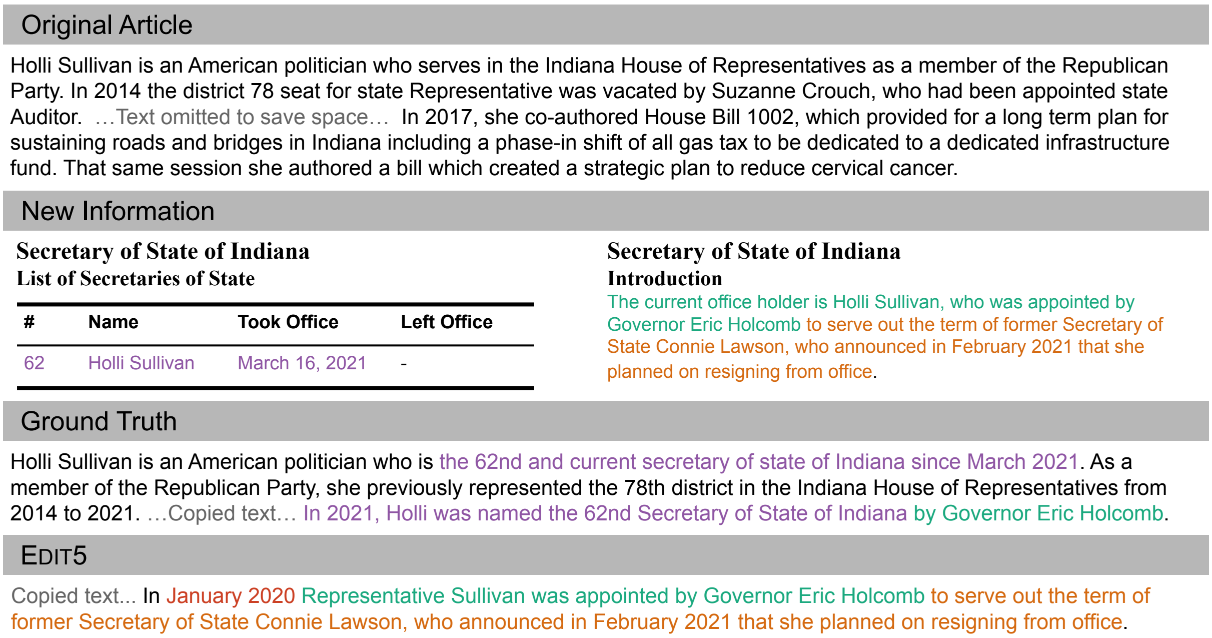
Table 5: **ROUGE Scores Are Insensitive to Edits.**

Categorizing Errors To better understand the types of errors made by EDIT5, we review a random sample of 100 of its predictions on the gold evaluation data and categorize them as either: *grounded updates*, meaning all generated claims are supported, *ungrounded updates*, meaning at least one unsupported claim appears in the output, or *no updates*, meaning the model did not predict any updates. For grounded updates we additionally keep track of how many updates include *additional content* not present in the ground truth update, or are *missing content* that appears in the ground truth update. For ungrounded updates we track whether an incorrect *number/date* appears in the update, the model *distorted evidence*, i.e., paraphrased or combined claims in the evidence in a way that changed their meaning, or *hallucinated* new claims unrelated to the evidence.

The results of this analysis are presented in Table 4b. We find that EDIT5 makes no mistakes on half of the examples, however a substantial portion of these updates had some issue with content selection. Of the incorrect updates, the most common mistake was incorrect numbers and dates, followed by hallucinations, and finally distorted evidence. This suggests that improving numeracy could be a fruitful line of study in future work on this task.

ROUGE is Problematic We provide ROUGE F-scores for each of the baseline models on the gold evaluation data in Table 5. In contrast to the previous results, we find that the simple copy source baseline attains a strong score of 77.4 despite making no updates. This is better than the T5 baseline results and comparable to the EDIT5 results. This illustrates the importance of evaluating on updates rather than the whole text.

Silver Data is Useful for Evaluation The results in Section 3.3 demonstrate high agreement between the silver and gold evaluation data which begs the question: can silver data be used in place



Original Article

Holli Sullivan is an American politician who serves in the Indiana House of Representatives as a member of the Republican Party. In 2014 the district 78 seat for state Representative was vacated by Suzanne Crouch, who had been appointed state Auditor. …Text omitted to save space… In 2017, she co-authored House Bill 1002, which provided for a long term plan for sustaining roads and bridges in Indiana including a phase-in shift of all gas tax to be dedicated to a dedicated infrastructure fund. That same session she authored a bill which created a strategic plan to reduce cervical cancer.

Control	**57.6**	**42.1**	**50.2**	**70.5**	**64.5**	2.42

Table 7: **Controllability**. Using control codes that indicate which sentences to delete, add or edit, and which evidence to use, can greatly improve generation.

of gold data for evaluation? To answer this, we measure the Spearman rank correlation between the gold baseline results in Table 4a and silver baseline results (provided in Table A2 of the Appendix to save space). Rank correlations for each of the metrics are shown in Table 6. Overall we find high rank correlation for each of the metrics, which suggests silver evaluation performance is a reliable indicator of gold performance. Thus, models whose pretraining data overlaps FRUIT-WIKI may be evaluated and compared on data produced by running our pipeline on future Wikipedia snapshots without requiring further human evaluation.

Controllability The improvement we obtained from EDIT5 over T5 implies that more controls can be added into the model. In this section we investigate whether additional control provided by the users can improve the overall generations. We follow Keskar et al. (2019) and Narayan et al. (2021), and provide more detailed instruction by adding *control codes*, i.e., special tokens, to the *input* that instruct the model whether to add, copy, edit or remove a sentence, as well as which evidence to use when making an addition or edit. We use the target text to provide oracle labels for the control code, and see if the EDIT5 can take advantage of the codes. Example inputs and predictions are provided in Figure A6 of the Appendix.

Results on the gold evaluation data are provided in Table 7. Including oracle control codes in the input produces a substantial 10% absolute improvement in all metrics besides unsupported tokens. This demonstrates that increased user control has the potential to produce updates that more closely resemble the desired output.

6 Related Work

Early work on writing assistants largely focuses on grammar error correction; for a survey see Wang et al. (2020). Neural models have expanded the capabilities of writing assistants to solve a wider variety of tasks including: autocompletion (Chen et al., 2019), and following rhetorical directives such as paraphrasing, elaborating, etc. (Sun et al., 2021). In this work, we seek to expand these capabilities further to producing grounded updates, which has been previously studied by Kang et al. (2019), however only for post-modifier generation.

As our primary focus is on writing grounded updates to Wikipedia articles, our work is closely related to existing works on Wikipedia article generation, which generally uses one of two approaches: data-to-text generation (Lebret et al., 2016; Bao et al., 2018; Parikh et al., 2020; Chen et al., 2021; Cheng et al., 2020), or multi-document summarization (Banerjee and Mitra, 2016; Liu et al., 2018; Shi et al., 2021). In particular, the hyperlink-based approach for associating evidence to articles is directly inspired by these works, and our annotation procedure for removing unsupported text directly draws from Parikh et al. (2020).

Determining which facts contradict claims in the existing article is a central topic of work on fact extraction and verification (Thorne et al., 2018). Recently, Schuster et al. (2021) introduced the VITAMIN-C dataset of factual revisions to Wikipedia articles and the task of factually consistent generation. This work differs from FRUIT in that it only focuses on sentences and does not require adding new facts or content selection.

Our work is also related to the TAC 2008 Update Summarization Task (Dang and Owczarzak, 2008), which involves summarizing information about a topic that does not overlap with an existing summary, instead of updating an existing summary to reflect new information.

7 Conclusion and Future Work

In this work we introduced FRUIT, a novel text generation task where the goal is to update an article to reflect new information about its subject. To enable research on this task, we formulated a pipeline for extracting weakly supervised training and evaluation data from pairs of Wikipedia snapshots, and collected data for the years 2019-2020 and 2020-2021, as well as human annotated gold evaluation data. We additionally provided results for several strong baselines, that demonstrate both the feasibility of this task, as well as strong correlation between gold and distantly supervised data evaluation performance that establishes the trustworthiness of future data produced using our pipeline.

This work lays the foundation for future research into making faithful updates to entries in textual knowledge bases. One limitation of this work is that the metrics we use to evaluate faithfulness are all entity-centric, and thus may overstate the performance of models whose edits include the correct entities but misspecify the relations between them or other facets of the evidence. Accordingly, one promising direction for future work on this task is to develop more robust metrics for measuring faithfulness.

An additional promising direction for future work is to consider open settings of evidence collection, where other forms of updated information such as excerpts from news articles could be used to justify edits in place of updates to other entries in the same knowledge base. Relatedly, we also recommend studying this task in streaming settings, where updates arrive in sequential fashion, in addition to the batch setting considered in this work.

Finally, there are a number of promising directions for improving model performance on this task. In particular, copy mechanisms (See et al., 2017) have been widely used in data-to-text tasks (Wiseman et al., 2017), and may help mitigate issues such as the mistranscribed dates we saw in Section 5.

Acknowledgements

We would like to thank Kelvin Guu, Kenton Lee, Kristina Toutanova, and the anonymous reviewers for their helpful feedback. This work is funded in part by the DARPA MCS program under Contract No. N660011924033. Additionally, Robert is supported in part by the Irvine Initiative in AI, Law, and Society fellowship.

Ethical Considerations

This paper introduces a dataset and system for updating an existing piece of text to incorporate information from external evidence. Depending on the veracity of the external evidence, systems for solving this task could potentially be abused by bad actors to spread misinformation.

Instructions

Overview

The goal of this task is to collect evaluation data for a system that can automatically update Wikipedia articles from new information about the article's subject. The sections below provide the text of the *original passage* to be updated, a collection of *added information* about the article subject, and the text of the *updated passage*.

What we need from you

The issue we are faced with is that some of the udpated text may not be supported by the added information section. We need you to identify all of the unsupported information, and edit the article to remove unsupported text while preserving fluency. Please make sure that your edits only remove information; while you may need to write some text to ensure that the edited passage is fluent, no new facts should be added (even if they are supported).

The original passage and added information are below this box. We request that you first read the updated passage in the green box, and highlight any unsupported text. Then copy the contents from the green box to the orange box and edit them so that all of the text is supported.

If you have questions please do not hesitate to email: REDACTED

Original Passage - DO NOT CHANGE

Step 1

The section below above the text of the updated passage. Unchanged sentences from the original passage are in grey, while added or updated sentences are in black.

We have tried to automatically detect which pieces of added information justify the changed text. If a justification is detected, then the edited sentence will be prefaced with the delimiter of the added information.
For example:
(0) (1) Updated sentence
means that we think that added information 0 and 1 justify (at least some of the edit).

What to do for this column
- Highlight any text/evidence delimiters that are unsupported by the original passage or added information, using this red color (in the custom section).
- Do not edit the text.

Step 2

What to do for this column
- Copy the highlighted updated passage from the previous step.
- Edit text so that: a) any unsupported text is removed, and b) the passage is still fluent.
- Do not add any new information

Abstract

Research on (multi-domain) task-oriented dialog (TOD) has predominantly focused on the *English* language, primarily due to the shortage of robust TOD datasets in other languages, preventing the systematic investigation of cross-lingual transfer for this crucial NLP application area. In this work, we introduce MULTI^{2}WOZ, a new multilingual multi-domain TOD dataset, derived from the well-established English dataset MULTIWOZ, that spans four typologically diverse languages: Chinese, German, Arabic, and Russian. In contrast to concurrent efforts (Ding et al., 2021; Zuo et al., 2021), MULTI^{2}WOZ contains gold-standard dialogs in target languages that are directly comparable with development and test portions of the English dataset, enabling reliable and comparative estimates of cross-lingual transfer performance for TOD. We then introduce a new framework for *multilingual conversational specialization* of pretrained language models (PrLMs) that aims to facilitate cross-lingual transfer for arbitrary downstream TOD tasks. Using such conversational PrLMs specialized for concrete target languages, we systematically benchmark a number of zero-shot and few-shot cross-lingual transfer approaches on two standard TOD tasks: Dialog State Tracking and Response Retrieval. Our experiments show that, in most setups, the best performance entails the combination of (i) conversational specialization in the target language and (ii) few-shot transfer for the concrete TOD task. Most importantly, we show that our conversational specialization in the target language allows for an exceptionally *sample-efficient few-shot transfer* for downstream TOD tasks.

1 Introduction

Task-oriented dialog (TOD) is arguably one of the most popular natural language processing (NLP) application areas (Yan et al., 2017; Henderson et al., 2019, *inter alia*), with more importance recently given to more realistic, and thus, multi-domain conversations (Budzianowski et al., 2018; Ramadan et al., 2018), in which users may handle more than one task during the conversation, e.g., booking a *taxi* and making a reservation at a *restaurant*. Unlike many other NLP tasks (e.g., Hu et al., 2020; Liang et al., 2020; Ponti et al., 2020, *inter alia*), the progress towards *multilingual multi-domain* TOD has been hindered by the lack of sufficiently large and high-quality datasets in languages other than English (Budzianowski et al., 2018; Zang et al., 2020) and more recently, Chinese (Zhu et al., 2020). This lack can be attributed to the fact that creating TOD datasets for new languages from scratch or via translation of English datasets is significantly more expensive and time-consuming than for most other NLP tasks. However, the absence of multilingual datasets that are comparable (i.e., aligned) across languages prevents a reliable estimate of effectiveness of cross-lingual transfer techniques in multi-domain TOD (Razumovskaia et al., 2021).

In order to address these research gaps, in this work we introduce MULTI^{2}WOZ, a reliable and large multilingual evaluation benchmark for multi-domain task-oriented dialog, derived by translating the monolingual English-only MultiWOZ data (Budzianowski et al., 2018; Eric et al., 2020) to four linguistically diverse major world languages, each with a different script: Arabic (AR), Chinese (ZH), German (DE), and Russian (RU).

Compared to the products of concurrent efforts that derive multilingual datasets from English MultiWOZ (Ding et al., 2021; Zuo et al., 2021), our MULTI^{2}WOZ is: (1) much *larger* – we translate all dialogs from development and test portions of the English MultiWOZ (in total 2,000 dialogs containing the total of 29.5K utterances); (2) much more *reliable* – complete dialogs, i.e., utterances

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3687 - 3703
July 10-15, 2022

as well as slot-values, have been manually translated (without resorting to error-prone heuristics), and the quality of translations has been validated through quality control steps; and (3) *parallel* – the same set of dialogs has been translated to all target languages, enabling the direct comparison of the performance of multilingual models and cross-lingual transfer approaches across languages.

We then use MULTI^{2}WOZ to benchmark a range of state-of-the-art zero-shot and few-shot methods for cross-lingual transfer in two standard TOD tasks: Dialog State Tracking (DST) and Response Retrieval (RR). As the second main contribution of our work, we propose a general framework for improving performance and sample-efficiency of cross-lingual transfer for TOD tasks. We first leverage the parallel conversational OpenSubtitles corpus (Lison and Tiedemann, 2016) to carry out a conversational specialization of a PrLM for a given target language, irrespective of the downstream TOD task of interest. We then show that this intermediate conversational specialization in the target language (i) consistently improves the DST and RR performance in both zero-shot and few-shot transfer, and (ii) drastically improves sample-efficiency of few-shot transfer.

2 Multi^{2}WOZ

In this section we describe the construction of the MULTI^{2}WOZ dataset, providing also details on inter-translator reliability. We then discuss two concurrent efforts in creating multilingual TOD datasets from MultiWOZ and their properties, and emphasize the aspects that make our MULTI^{2}WOZ a more reliable and useful benchmark for evaluating cross-lingual transfer for TOD.

2.1 Dataset Creation

Language Selection. We translate all 2,000 dialogs from the development and test portions of the English MultiWOZ 2.1 (Eric et al., 2020) dataset to Arabic (AR), Chinese (ZH), German (DE), and Russian (RU). We selected the target languages based on the following criteria: (1) linguistic diversity (DE and RU belong to different Indo-European subfamilies – Germanic and Slavic, respectively; ZH is a Sino-Tibetan language and AR Semitic), (2) diversity of scripts (DE and RU use Latin and Cyrillic scripts, respectively, both *alphabet* scripts; AR script represents the *Abjad* script type, whereas the ZH Hanzi script belongs to *logographic* scripts), (3) number of native speakers (all four are in the top 20 most-spoken world languages), and (4) our access to native and fluent speakers of those languages who are proficient in English.

Two-Step Translation. Following the well-established practice, we carried out a two-phase translation of the English data: (1) we started with an *automatic translation* of the dialogs – utterances as well as the annotated slot values – followed by (2) the *manual post-editing* of the translations. We first automatically translated all utterances and slot values from the development and test dialogs from the MultiWOZ 2.1 (Eric et al., 2020) (1,000 dialogs in each portion; 14,748 and 14,744 utterances, respectively) to our four target languages, using Google Translate.[1] We then hired two native speakers of each target language,[2] all with a University degree and fluent in English, to post-edit the (non-overlapping sets of) automatic translations, i.e., fix the errors in automatic translations of utterances as well as slot values.

Since we carried out the automatic translation of the utterances independently of the automatic translation of the slot values, the translators were instructed to pay special attention to the alignment between each translated utterance and translations of slot value annotations for that utterance. We show an example utterance with associated slot values after the automatic translation and manual post-editing in Table 1.

Quality Control. In order to reduce the translation costs, our human post-editors worked on disjoint sets of dialogs. Because of this, our annotation process contained an additional quality assurance step. Two new annotators for each target language judged the correctness of the translations on the random sample of 200 dialogs (10% of all translated dialogs, 100 from the development and test portion each), containing 2,962 utterances in total. The annotators had to independently answer the following questions for each translated utterance from the sample: (1) *Is the utterance translation acceptable?* and (2) *Do the translated slot values match the translated utterance?* On average, across all target languages, both quality annotators

---

[1] Relying on its Python API: `https://pypi.org/project/googletrans`

[2] In order to reduce the translation costs, we initially attempted to post-edit the translations via crowdsourcing. We tried this for Russian using the popular platform Toloka (`toloka.yandex.com`); however, the translation quality remained unsatisfactory even after several post-editing rounds.

Table 1: Example utterance (from the dialog MUL0484) with a value for a slot (*"attraction-name"*). We show the original English text, the automatic translation to Chinese and the final translation after manual post-editing.

for the respective language answered affirmatively to both questions for 99% of all utterances. Adjusting for chance agreement, we measured the Inter-Annotator Agreement (IAA) in terms of Cohen's κ (Cohen, 1960), observing the almost perfect agreement[3] of $\kappa = 0.824$ for the development set and $\kappa = 0.838$ for test set.

Annotation Duration and Cost. In total, we hired 16 annotators, four for each of our four target languages: two for post-editing and two for quality assessment. The overall effort spanned almost full 5 months (from July to November 2021), and amounted to 1,083 person-hours. With the remuneration rate of 16 $/h, creating MULTI^{2}WOZ cost us $17,328.

2.2 Comparison with Concurrent Work

Two concurrent works also derive multilingual datasets from MultiWOZ (Ding et al., 2021; Zuo et al., 2021), with different strategies and properties, discussed in what follows.

GlobalWOZ (Ding et al., 2021) encompasses Chinese, Indonesian, and Spanish datasets. The authors first create *templates* from dialog utterances by replacing slot-value strings in the utterances with the slot type and value index (e.g., *"…and the post code is <u>cb238el</u>"* becomes the template *"…and the post code is* `[attraction-postcode-1]`*"*. They then *automatically* translate all templates to the target languages. Next, they select a subset of 500 test set dialogs for human post-editing with the following heuristic: dialogs for which the sum of corpus-level frequencies of their constitutive 4-grams (normalized with the dialog length) is the largest.[4] Since this selection step is independent for each language, each GlobalWOZ portion contains translations of a different subset of English dialogs: this prevents any direct comparison of downstream TOD performance across languages. Even more problematically, the selection heuristic directly reduces linguistic diversity of dialogs chosen for the test set of each language, as it favors the dialogs that contain the same globally most frequent 4-grams. Due to this artificial homogeneity of its test sets, GlobalWOZ is very likely to overestimate downstream TOD performance for target languages.

Unlike GlobalWOZ, AllWOZ (Zuo et al., 2021) does automatic translation of a *fixed small* subset of MultiWOZ plus post-editing in seven target languages. However, it encompasses only 100 dialogs and 1,476 turns; as such, it is arguably too small to draw strong conclusions about the performance of cross-lingual transfer methods. Its usefulness in joint domain and language transfer evaluations is especially doubtful, since it covers individual MultiWOZ domains with an extremely small number of dialogs (e.g., only 13 for the *Taxi* domain). Finally, neither Ding et al. (2021) nor Zuo et al. (2021) provide any estimates of the quality of their final datasets nor do they report their annotation costs.

In contrast to GlobalWOZ, MULTI^{2}WOZ is a parallel corpus – with the exact same set of dialogs translated to all four target languages; as such it directly enables performance comparisons across the target languages. Further, containing translations of *all* dev and test dialogs from MultiWOZ (i.e., avoiding sampling heuristics), MULTI^{2}WOZ does not introduce any confounding factors that would distort estimates of cross-lingual transfer performance in downstream TOD tasks. Finally, MULTI^{2}WOZ is 20 times larger (per language) than AllWOZ: experiments on MULTI^{2}WOZ are thus much more likely to yield conclusive findings.

3 Cross-lingual Transfer for TOD

The parallel nature and sufficient size of MULTI^{2}WOZ allow us to benchmark and compare a number of established and novel cross-lingual

---

[3] According to Landis and Koch (1977), if $\kappa \geq 0.81$.

[4] Interestingly, the authors do not provide any motivation or intuition for this heuristic. It is also worth noting that they count the 4-gram frequencies, upon which the selection of the dialogs for post-editing depends, on the noisy automatic translations.

transfer methods for TOD. In particular, (1) we first inject general conversational TOD knowledge into XLM-RoBERTa (XLM-R; Conneau et al., 2020), yielding TOD-XLMR (§3.1); (2) we then propose several variants for conversational specialization of TOD-XLMR for target languages, better suited for transfer in downstream TOD tasks (§3.2); (3) we investigate zero-shot and few-shot transfer for two TOD tasks: DST and RR (§3.3).

3.1 TOD-XLMR: A Multilingual TOD Model

Recently, Wu et al. (2020) demonstrated that specializing BERT (Devlin et al., 2019) on conversational data by means of additional pretraining via a combination of masked language modeling (MLM) and response selection (RS) objectives yields improvements in downstream TOD tasks. Following these findings, we first (propose to) conversationally specialize XLM-R (Conneau et al., 2020), a state-of-the-art multilingual PrLM covering 100 languages, in the same manner: applying the RS and MLM objectives on the same English conversational corpus consisting of nine human-human multi-turn TOD datasets (see Wu et al. (2020) for more details). As a result, we obtain TOD-XLMR – a massively multilingual PrLM specialized for task-oriented conversations. Note that TOD-XLMR is not yet specialized (i.e., fine-tuned) for any concrete TOD task (e.g., DST or Response Generation). Rather, it is enriched with general task-oriented conversational knowledge (in English), presumed to be beneficial for a wide variety of TOD tasks.

3.2 Target-Language Specialization

TOD-XLMR has been conversationally specialized only in English data. We next hypothesize that a further conversational specialization for a concrete target language X can improve the transfer EN→X for all downstream TOD tasks. Accordingly, similar to Moghe et al. (2021), we investigate several intermediate training procedures that further conversationally specialize TOD-XLMR for the target language X (or jointly for EN and X). For this purpose, we (i) compile target-language-specific as well as cross-lingual corpora from the CCNet (Wenzek et al., 2020) and OpenSubtitles (Lison and Tiedemann, 2016) datasets and (ii) experiment with different monolingual, bilingual, and cross-lingual training procedures. Here, we propose a novel cross-lingual response selection (RS) objective and demonstrate its effectiveness in cross-lingual transfer for downstream TOD tasks.

Training Corpora. We collect two types of data for language specialization: (i) *"flat" corpora* (i.e., without any conversational structure): we simply randomly sample 100K sentences for each language from the respective monolingual portion of CCNet (we denote with *Mono-CC* the individual 100K-sentence portions of each language; with *Bi-CC* the concatenation of the English and each of target language *Mono-CCs*, and with *Multi-CC* the concatenation of all five Mono-CC portions); (ii) *parallel dialogs* (in EN and target language X) from OpenSubtitles (OS), a parallel conversational corpus spanning 60 languages, compiled from subtitles of movies and TV series. We leverage the parallel OS dialogs to create two different cross-lingual specialization objectives, as described next.

Training Objectives. We directly use the CC portions (Mono-CC, Bi-CC, and Multi-CC) for standard **MLM** training. We then leverage the parallel OS dialogs for two training objectives. First, we carry out translation language modeling (**TLM**) (Conneau and Lample, 2019) on the synthetic dialogs which we obtain by interleaving K randomly selected English utterances with their respective target language translations; we then (as with MLM), dynamically mask 15% of tokens of such interleaved dialogs; we vary the size of the context the model can see when predicting missing tokens by randomly selecting K (between 2 and 15) for each instance. Second, we use OS to create instances for both monolingual and cross-lingual Response Selection (RS) training. RS is a simple binary classification task in which for a given pair of a *context* (one or more consecutive utterances) and *response* (a single utterance), the model has to predict whether the response utterance immediately follows the context (i.e., it is a *true* response) or not (i.e., it is a *false* response). RS pretraining has been proven beneficial for downstream TOD in monolingual English setups (Mehri et al., 2019; Henderson et al., 2019, 2020; Hung et al., 2022).

In this work, we leverage the parallel OS data to introduce the cross-lingual RS objective, where the context and the response utterance are not in the same language. In our experiments, we carry out both (i) monolingual RS training in the target language (i.e., both the context and response utterance are, e.g., in Chinese), denoted **RS-Mono**, and (ii) cross-lingual RS between English (as the source language in downstream TOD tasks) and the target language, denoted **RS-X**. We create *hard RS neg-*

Table 2: Examples of training instances for conversational specialization for the target language created from OpenSubtitles (OS). Top row: an example of a dialog created from OS, parallel in English and Chinese. Below are training examples for different training objectives: (1) *Translation Language Modelling* (**TLM**) on the interleaved English-Chinese parallel utterances; (2) two variants of *Response Selection* (RS) – (a) monolingual in the target language (**RS-Mono**) and (b) cross-lingual (**RS-X**).

atives, by coupling contexts with non-immediate responses from the same movie or episode (same `imdbID`), as well as *easy negatives* by randomly sampling $m \in \{1, 2, 3\}$ responses from a different movie of series episode (i.e., different `imdbID`). Hard negatives encourage the model to reason beyond simple lexical cues. Examples of training instances for OS-based training (for EN-ZH) are shown in Table 2.

3.3 Downstream Cross-lingual Transfer

Finally, we fine-tune the various variants of TOD-XLMR, obtained through the above-described specialization (i.e., intermediate training) procedures, for two downstream TOD tasks (DST and RR) and examine their cross-lingual transfer performance. We cover two cross-lingual transfer scenarios: (1) *zero-shot transfer* in which we only fine-tune the models on the English training portion of MultiWOZ and evaluate their performance on the MULTI^{2}WOZ test data of our four target languages; and (2) *few-shot transfer* in which we sequentially first fine-tune the models on the English training data and then on the small number of dialogs from the development set of MULTI^{2}WOZ, in similar vein to (Lauscher et al., 2020). In order to determine the effect of our conversational target language specialization (§3.2) on the downstream sample efficiency, we run few-shot experiments with different numbers of target language training dialogs, ranging from 1% to 100% of the size of MULTI^{2}WOZ development portions.

4 Experimental Setup

Evaluation Tasks and Measures. We evaluate different multilingual conversational PrLMs in cross-lingual transfer (zero-shot and few-shot) for two prominent TOD tasks: *dialog state tracking (DST)* and *response retrieval (RR)*.

DST is commonly cast as a multi-class classification task, where given a predefined ontology and dialog history (a sequence of utterances), the model has to predict the output state, i.e., *(domain, slot, value)* tuples (Wu et al., 2020).[5] We adopt the standard *joint goal accuracy* as the evaluation measure: at each dialog turn, it compares the predicted dialog states against the manually annotated ground truth which contains slot values for all the *(domain, slot)* candidate pairs. A prediction is considered correct if and only if all predicted slot values exactly match the ground truth.

RR is a ranking task that is well-aligned with the RS objective and relevant for retrieval-based TOD systems (Wu et al., 2017; Henderson et al., 2019): given the dialog context, the model ranks N dataset utterances, including the *true response* to the context (i.e., the candidate set includes the one *true* response and N-1 *false* responses). We follow Henderson et al. (2020) and report the results for $N = 100$, i.e., the evaluation measure is recall at the top 1 rank given 99 randomly sampled false responses, denoted as R$_{100}$@1.

Models and Baselines. We briefly summarize the models that we compare in zero-shot and few-shot cross-lingual transfer for DST and RR. As baselines, we report the performance of the vanilla multilingual PrLM XLM-R (Conneau et al., 2020)[6] and its variant further trained on the English TOD data from (Wu et al., 2020): TOD-XLMR (§3.1). Comparison between XLM-R and TOD-XLMR

---

[5] The model is required to predict slot values for each *(domain, slot)* pair at each dialog turn.

[6] We use `xlm-roberta-base` from HuggingFace.

quantifies the effect of conversational English pretraining on downstream TOD performance, much like the comparison between BERT and TOD-BERT done by Wu et al. (2020); however, here we extend the comparison to cross-lingual transfer setups. We then compare the baselines against a series of our target language-specialized variants, obtained via intermediate training on CC (Mono-CC, Bi-CC, and Multi-CC) by means of MLM, and on OS jointly via TLM and RS (RS-X or RS-Mono) objectives (see §3.2 again).

Hyperparameters and Optimization. For training TOD-XLMR (§3.1), we select the effective batch size of 8. In target-language-specific intermediate training (§3.2), we fix the maximum sequence length to 256 subword tokens; for RS objectives, we limit the context and response to 128 tokens each. We train for 30 epochs in batches of size 16 for MLM/TLM, and 32 for RS. We search for the optimal learning rate among the following values: $\{10^{-4}, 10^{-5}, 10^{-6}\}$. We apply early stopping based on development set performance (patience: 3 epochs for MLM/TLM, 10 epochs for RS). In downstream fine-tuning, we train in batches of 6 (DST) and 24 instances (RR) with the initial learning rate fixed to $5 \cdot 10^{-5}$. We also apply early stopping (patience: 10 epochs) based on the development set performance, training maximally for 300 epochs in zero-shot setups, and for 15 epochs in target-language few-shot training. In all experiments, we use Adam (Kingma and Ba, 2015) as the optimization algorithm.

5 Results and Discussion

We now present and discuss the downstream cross-lingual transfer results on MULTI^{2}WOZ for DST and RR in two different transfer setups: zero-shot transfer and few-shot transfer.

5.1 Zero-Shot Transfer

Dialog State Tracking. Table 3 summarizes zero-shot cross-lingual transfer performance for DST. First, we note that the transfer performance of all models for all four target languages is extremely low, drastically lower than the reference English DST performance of TOD-XLMR, which stands at 47.9%. These massive performance drops, stemming from cross-lingual transfer are in line with findings from concurrent work (Ding et al., 2021; Zuo et al., 2021) and suggest that reliable cross-lingual transfer for DST is much more difficult to achieve than for most other language understanding tasks (Hu et al., 2020; Ponti et al., 2020).

Model	DE	AR	ZH	RU	Avg.
w/o intermediate specialization					
XLM-R	1.41	1.15	1.35	1.40	1.33
TOD-XLMR	1.74	1.53	1.75	2.16	1.80
with conversational target-lang. specialization					
MLM on Mono-CC	3.57	2.71	3.34	5.17	3.70
Bi-CC	3.66	2.17	2.73	3.73	3.07
Multi-CC	3.65	2.35	2.06	5.39	3.36
TLM on OS	7.80	2.43	3.95	6.03	5.05
TLM + RS-X on OS	**7.84**	**3.12**	4.14	6.13	5.31
TLM + RS-Mono on OS	7.67	2.85	**4.47**	**6.57**	**5.39**

Table 3: Performance of multilingual conversational models in zero-shot cross-lingual transfer for Dialog State Tracking (DST) on MULTI^{2}WOZ, with joint goal accuracy (%) as the evaluation metric. Reference English DST performance of TOD-XLMR: 47.86%.

Despite low performance across the board, we do note a few emerging and consistent patterns. First, TOD-XLMR slightly but consistently outperforms the vanilla XLM-R, indicating that *conversational* English pretraining brings marginal gains. All of our proposed models from §3.2 (the lower part of Table 3) substantially outperform TOD-XLMR, proving that intermediate conversational specialization for the target language brings gains, irrespective of the training objective.

Expectedly, TLM and RS training on parallel OS data brings substantially larger gains than MLM-ing on flat monolingual target-language corpora (Mono-CC) or simple concatenations of corpora from two (Bi-CC) or more languages (Multi-CC). German and Arabic seem to benefit slightly more from the cross-lingual Response Selection training (RS-X), whereas for Chinese and Russian we obtain better results with the monolingual (target language) RS training (RS-Mono).

Response Retrieval. The results of zero-shot transfer for RR are summarized in Table 4. Compared to DST results, for the sake of brevity, we show the performance of only the stronger baseline (TOD-XLMR) and the best-performing variants with intermediate conversational target-language training (one for each objective type): MLM on Mono-CC, TLM on OS, and TLM + RS-Mono on OS. Similar to DST, TOD-XLMR exhibits a near-zero cross-lingual transfer performance for RR as well, across all target languages. In sharp contrast to DST results, however, conversational specializa-

Model	**DE**	**AR**	**ZH**	**RU**	**Avg.**
w/o intermediate specialization					
TOD-XLMR	3.3	2.9	1.9	2.7	2.7
with conversational target-lang. specialization					
MLM on Mono-CC	22.9	25.5	24.5	33.4	26.6
TLM on OS	**44.4**	30.3	34.1	39.3	37.0
TLM + RS-Mono on OS	44.3	**30.9**	**34.8**	**39.6**	**37.4**

Table 4: Performance of multilingual conversational models in zero-shot cross-lingual transfer for Response Retrieval (RR) on MULTI^{2}WOZ with $R_{100}@1$ (%) as the evaluation metric. Reference English RR performance of TOD-XLMR: 64.75%

tion for the target language – with any of the three specialization objectives – massively improves the zero-shot cross-lingual transfer for RR. The gains are especially large for the models that employ the parallel OpenSubtitles corpus in intermediate specialization, with the monolingual (target language) Response Selection objective slightly improving over TLM training alone.

Given the parallel nature of MULTI^{2}WOZ, we can directly compare transfer performance of both DST and RR across the four target languages. In both tasks, the best-performing models exhibit stronger performance (i.e., smaller performance drops compared to the English performance) for German and Russian than for Arabic and Chinese. This aligns well with the linguistic proximity of the target languages to English as the source language.

5.2 Few-Shot Transfer and Sample Efficiency

Next, we present the results of few-shot transfer experiments, where we additionally fine-tune the task-specific TOD model on a limited number of target-language dialogs from the development portion of MULTI^{2}WOZ, after first fine-tuning it on the complete English training set from MultiWOZ (see §4). Few-shot cross-lingual transfer results, averaged across all four target languages, are summarized in Figure 1. The figure shows the performance for different sizes of the target-language training data (i.e., number of target-language shots, that is, percentage of the target-language development portion from MULTI^{2}WOZ). Detailed per-language few-shot results are given in Table 5, for brevity only for TOD-XLMR and the best target-language-specialized model (TLM+RS-Mono on OS). We provide full per-language results for all specialized models from Figure 1 in the Appendix.

The few-shot results unambiguously show that the intermediate conversational specialization for the target language(s) *drastically improves the target-language sample efficiency in the downstream few-shot transfer*. The baseline TOD-XLMR – not exposed to any type of conversational pretraining for the target language(s) – exhibits substantially lower performance than all three models (MLM on Mono-CC, TLM on OS, and TLM+RS-Mono on OS) that underwent conversational intermediate training on respective target languages. This is evident even in the few-shot setups where the three models are fine-tuned on merely 1% (10 dialogs) or 5% (50 dialogs) of the MULTI^{2}WOZ development data (after prior fine-tuning on the complete English task data from MultiWOZ).

As expected, the larger the number of task-specific (DST or RR) training instances in the target languages (50% and 100% setups), the closer the performance of the baseline TOD-XLMR gets to the best-performing target-language-specialized model – this is because the size of the in-language training data for the concrete task (DST or RR) becomes sufficient to compensate for the lack of conversational target-language intermediate training that the specialized models have been exposed to. The sample efficiency of the conversational target-language specialization is more pronounced for RR than for DST. This seems to be in line with the zero-shot transfer results (see Tables 3 and 4), where the specialized models displayed much larger cross-lingual transfer gains over TOD-XLMR on RR than on DST. We hypothesize that this is due to the intermediate specialization objectives (especially RS) being better aligned with the task-specific training objective of RR than that of DST.

6 Related Work

TOD Datasets. Research in task-oriented dialog has been, for a long time, limited by the existence of only monolingual English datasets. While earlier datasets focused on a single domain (Henderson et al., 2014a,b; Wen et al., 2017), the focus shifted towards the more realistic multi-domain task-oriented dialogs with the creation of the MultiWOZ dataset (Budzianowski et al., 2018), which has been refined and improved in several iterations (Eric et al., 2020; Zang et al., 2020; Han et al., 2021). Due to the particularly high costs of creating TOD datasets (in comparison with other language understanding tasks) (Razumovskaia et al., 2021), only a handful of monolingual TOD datasets

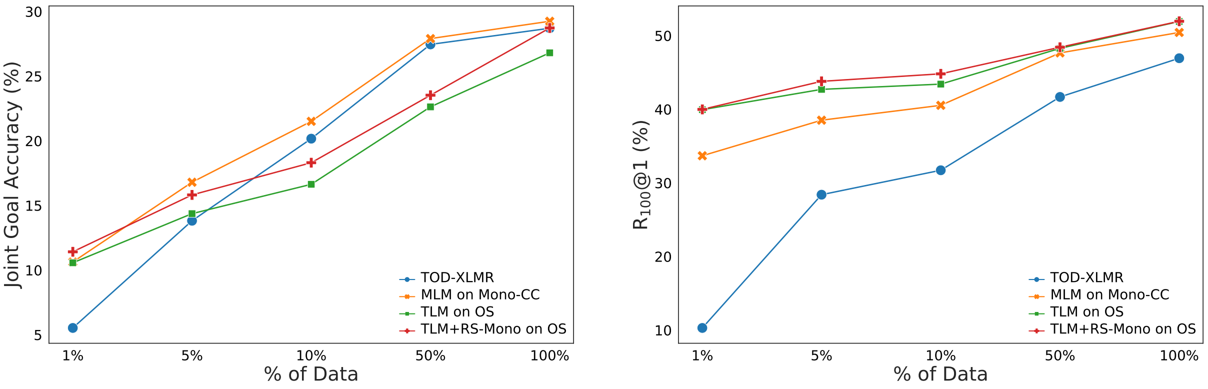

Figure 1: Few-shot cross-lingual transfer results for Dialog State Tracking (left figure) and Response Retrieval (right figure), averaged across all four target languages (detailed per-language results available in the Appendix). Results shown for different sizes of the training data in the target-language (i.e., different number of *shots*): 1%, 5%, 10%, 50% and 100% of the MULTI^{2}WOZ development sets (of respective target languages).

in languages other than English (Zhu et al., 2020) or bilingual TOD datasets have been created (Gunasekara et al., 2020; Lin et al., 2021). Mrkšić et al. (2017b) were the first to translate 600 dialogs from the single-domain WOZ 2.0 (Mrkšić et al., 2017a) to Italian and German. Concurrent work (Ding et al., 2021; Zuo et al., 2021), which we discuss in detail in §2.2 and compare thoroughly against our MULTI^{2}WOZ, introduces the first multilingual multi-domain TOD datasets, created by translating portions of MultiWOZ to several languages.

Language Specialization and Cross-lingual Transfer. Multilingual transformer-based models (e.g., mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020)) are pretrained on large general-purpose and massively multilingual corpora (over 100 languages). While this makes them versatile and widely applicable, it does lead to suboptimal representations for individual languages, a phenomenon commonly referred to as the "curse of multilinguality" (Conneau et al., 2020). Therefore, one line of research focused on adapting (i.e., *specializing*) those models to particular languages (Lauscher et al., 2020; Pfeiffer et al., 2020). For example, Pfeiffer et al. (2020) propose a more computationally efficient approach for extending the model capacity for individual languages: this is done by augmenting the multilingual PrLM with language-specific adapter modules. Glavaš et al. (2020) perform language adaptation through additional intermediate masked language modeling in the target languages with filtered text corpora, demonstrating substantial gains in downstream zero-shot cross-lingual transfer for hate speech and abusive language detection tasks. In a similar vein, Moghe et al. (2021) carry out intermediate fine-tuning of multilingual PrLMs on parallel conversational datasets and demonstrate its effectiveness in zero-shot cross-lingual transfer for the DST task.

Lauscher et al. (2020) show that few-shot transfer, in which one additionally fine-tunes the PrLM on a few labeled task-specific target-language instances leads to large improvements for many task-and-language combinations, and that labelling a few target-language examples is more viable than further LM-specialization for languages of interest under strict zero-shot conditions. This finding is also corroborated in our work for two TOD tasks.

7 Reproducibility

To ensure full reproducibility of our results and further fuel research on multilingual TOD, we release the parameters of TOD-XLMR within the Huggingface repository as the first publicly available multilingual PrLM specialized for TOD.[7] We also release our code and data and provide the annotation guidelines for *manual post-editing* and *quality control* utilized during the creation of MULTI^{2}WOZ in the Appendix. This makes our approach completely transparent and fully reproducible. All resources developed as part of this work are publicly available at: `https://github.com/umanlp/Multi2WOZ`.

8 Conclusion

Task-oriented dialog (TOD) has predominantly focused on *English*, primarily due to the lack of robust TOD datasets in other languages (Razumovskaia et al., 2021), preventing systematic investigations of cross-lingual transfer methodologies in this crucial NLP application area. To address this gap, in this work, we have presented MULTI^{2}WOZ – a robust multilingual multi-domain TOD dataset. MULTI^{2}WOZ encompasses gold-standard dialogs in four languages (German, Arabic, Chinese, and Russian) that are directly comparable with development and test portions of the English MultiWOZ dataset, thus allowing for the most reliable and comparable estimates of cross-lingual transfer performance for TOD to date. Further, we presented a framework for *multilingual conversational specialization* of pretrained language models that facilitates cross-lingual transfer for downstream TOD tasks. Our experiments on MULTI^{2}WOZ for two prominent TOD tasks – Dialog State Tracking and Response Retrieval – reveal that the cross-lingual transfer performance benefits from both (i) intermediate conversational specialization for the target language and (ii) few-shot cross-lingual transfer for the concrete downstream TOD task. Crucially, we show that our novel conversational specialization for the target language leads to *exceptional sample efficiency* in downstream few-shot transfer.

In hope to steer and inspire future research on multilingual and cross-lingual TOD, we make MULTI^{2}WOZ publicly available and will extend the resource to further languages from yet uncovered language families (e.g., Turkish).

Ethical Considerations

In this work, we have presented MULTI^{2}WOZ, a robust multilingual multi-domain TOD dataset, and focused on the multilingual conversational specialization of pretrained language models. Although the scope of this manuscript does not allow for an in-depth discussion of the potential ethical issues associated with conversational artificial intelligence in general, we would still like to highlight the ethical sensitivity of this area of NLP research and emphasize some of the potential harms of conversational AI applications, which propagate to our work. For instance, issues may arise from unfair stereotypical biases encoded in general purpose (Lauscher et al., 2021) as well as in conversational (Barikeri et al., 2021) pretrained language models and from exclusion of the larger spectrum of (gender) identities (Lauscher et al., 2022). Furthermore, (pre)training as well as fine-tuning of large-scale PrLMs can be hazardous to the environment (Strubell et al., 2019): in this context, the task-agnostic intermediate conversational specialization for the target languages that we introduce, which allows for highly sample-efficient fine-tuning for various TOD tasks can be seen as a step in the positive direction, towards the reduction of the carbon footprint of neural dialog models.

A Annotation Guidelines: Post-editing of the Translation

1 Task Description

Multi-domain Wizard-of-Oz dataset (MultiWOZ) (Budzianowski et al., 2018) is introduced as a fully-labeled collection of human-to-human written conversations spanning over multiple domains and topics.

Our project aims to translate the monolingual English-only MultiWOZ dataset to four linguistically diverse major world languages, each with a different script: Arabic (AR), Chinese (ZH), German (DE), and Russian (RU).

In this annotation task, we resort to the revised version 2.1 (Eric et al., 2020) and focus on the development and test portions of the English MultiWOZ 2.1 (in total of 2,000 dialogs containing a total of 29.5K utterances). We first *automatically translate* all the utterances and the annotated slot values to the four target languages, using Google Translate. Next the translated utterances and slot values (i.e., fix the translation errors) will be *post-edited* with manual efforts.

For this purpose, a JSON file for *development* or *test* set will be provided to each annotator. There are two tasks: (1) Fix the errors in automatic translations of translated utterances and the translated slot values. (2) Check the alignment between each translated utterance and the slot value annotations for that utterance.

2 JSON Representation

The JSON file will be structured as follows, feel free to use any JSON editor tools (e.g., JSON Editor Online) to annotate the files.

Annotation data

- **dialogID**: An unique ID for each dialog.
- **turnID**: The turn ID of the utterance in the dialog.
- **services**: Domain(s) of the dialog.
- **utterance**: English utterance from MultiWOZ.
- **SlotValues**: English annotated slot values from MultiWOZ.
- **transUtterance**: Translated utterance from Google Translate.
- **transSlotValues**: Translated slot values from Google Translate.

Annotation Task

- **fixTransUtterance**: The revised translated utterance with manual efforts.
- **fixTransSlotValues**: The revised translated slot values with manual efforts.
- **changedUtterance**: Whether the translated utterance is changed. Annotate as 1 if the translated utterance is revised, 0 otherwise.
- **changedSlotValues**: Whether the translated slot values is changed. Annotate as 1 if the translated slot values are revised, 0 otherwise.

3 Annotation Example

Example 1: Name Correction and Mismatch

The following example in Chinese shows the error fixed with the translated name issue, and also the correctness of the mismatch case between the translated utterance and translated slot values.

dialogID: *MUL0484.json*
turnID: *6*
services: *train, attraction*
utterance: *No hold off on booking for now. Can you help me find an attraction called cineworld cinema?*
slotValues: {attraction-name: *cineworld cinema*}
transUtterance: 目前暂无预订。您能帮我找到一个名为cineworld Cinema的景点吗?
transSlotValues: {attraction-name: Cineworld电影}

---

fixTransUtterance: 目前暂无预订。您能帮我找到一个名为电影世界电影院的景点吗?
fixTransSlotValues: {attraction-name: 电影世界电影院}
changedUtterance: 1
changedSlotValues: 1

Example 2: Grammatical Error

The following example in German shows the error corrected based on the grammatical issue of the translated utterance.

dialogID: *PMUL1072.json*
turnID: *6*
services: *train, attraction*
utterance: *I'm leaving from Cambridge.*
slotValues: {train-departure: *cambridge*}
transUtterance: *Ich verlasse Cambridge.*
transSlotValues: {train-departure: *cambridge*}

---

fixTransUtterance: *Ich fahre von Cambridge aus.*
fixTransSlotValues: {train-departure: *cambridge*}
changedUtterance: 1
changedSlotValues: 0

4 Additional Notes

There might be some cases of synonyms. For example, in Chinese 周五 and 星期五 both have the same meaning as *Friday* in English, also similarly in Russian regarding the weekdays. In this case, just pick the most common one and stays consistent among all the translated utterances and slot values. Besides there might be some language variations across different regions, please ignore the dialects and metaphors while fixing the translation errors.

If there are any open questions that you think are not covered in this guide, please do not hesitate to get in touch with me or post the questions on Slack, so these issues can be discussed together with other annotators and the guide can be improved.

B Annotation Guidelines: Quality Control

1 Task Description

Multi-domain Wizard-of-Oz dataset (MultiWOZ) (Budzianowski et al., 2018) is introduced as a fully-labeled collection of human-to-human written conversations spanning over multiple domains and topics. Our project is aimed to translate the monolingual English-only MultiWOZ dataset to four linguistically diverse major world languages, each with a different script: Arabic (AR), Chinese (ZH), German (DE), and Russian (RU). In the previous annotation task, we resorted to the revised version 2.1 (Eric et al., 2020) and focused on the development and test portions of the English MultiWOZ 2.1.

According to the translation process, it was processed in two steps: we first *automatically translated* all the utterances and the annotated slot values to the four target languages, using Google Translate. Next the translated utterances and slot values (i.e., fix the translation errors) were *post-edited* with manual efforts from native speakers of each language.

Additionally, a *quality assurance* step is required to check the quality of the post-edited translation. For this purpose, a JSON file for a random sample 200 dialogs (100 from the development and test set each), containing 2,962 utterances in total will be provided to two annotators for each target language to judge the correctness of the translations. Each annotator has to independently answer the following questions for each translated utterance from the sample: (1) *Is the utterance translation acceptable?* (2) *Do the translated slot values match the translated utterance?*

Annotation data

- **dialogID**: An unique ID for each dialog.
- **turnID**: The turn ID of the utterance in the dialog.
- **utterance**: English utterance from MultiWOZ.
- **SlotValues**: English annotated slot values from MultiWOZ.
- **fixTransUtterance**: The revised translated utterance with manual efforts.
- **fixTransSlotValues**: The revised translated slot values with manual efforts.

Annotation Task

- **UtteranceAcceptable**: Is the utterance translation acceptable? Annotate as 1 if the translated utterance is acceptable, 0 otherwise.
- **SlotValuesMatchAcceptable**: Do the translated slot values match the translated utterance? Annotate as 1 if the translated slot values are acceptable, 0 otherwise.
- **NOTE**: Extra notes of judgement.

2 Annotation Example

Small grammatical errors, but still catch the meaning will be considered *acceptable*. However, if the whole meaning regarding the translation change, it will then be considered as *not acceptable*.

Example 1: Ambiguity
The following example shows the ambiguity issues regarding the translated utterance. In German, *table* can be translated into *Tabelle* as a table form or *Tisch* as a table for reservation. Regarding the contextual information from the utterance, the correct translation should be *Tisch* instead of *Tabelle* in this case. Therefore, the translated utterance will be considered as not acceptable, and annotated as 0.

dialogID: *PMUL2464.json*
turnID: *9*
utterance: *Yes, Bedouin is a restaurant that serves African food in the Centre. It is in the expensive range. Would you like to book a table?*
slotValues: {restaurant-name: *bedouin*}
fixTransUtterance: *Ja, Beduine ist ein Restaurant, das afrikanisches Essen im Zentrum serviert. Es liegt im teuren Bereich. Möchten Sie eine Tabelle reservieren?*
fixTransSlotValues: {restaurant-name: *Beduine*}

UtteranceAcceptable: 0
SlotValuesMatchAcceptable: 1

Example 2: Grammatical Error
The following example shows a slight grammatical issue regarding the translated utterance. This is mainly with the synonym case in Chinese, where

the *place* can be translated into 地方 or 位置, while 位置 will be more appropriate in this scenario. However, 地方 still keep the semantic meaning. Therefore, the translated utterance will be considered as acceptable, and annotated as 1. And further checking with the translated slot values, all are correct, and should be annotated as 1.

dialogID: *PMUL0400.json*
turnID: *12*
utterance: *Please book the place for 7 people at 11:30 on the same day.*
slotValues: {restaurant-people: *7*, restaurant-time: *11:30*, restaurant-day: *Monday*}
fixTransUtterance: 请于当天11:30预订7人的地方。
fixTransSlotValues: {restaurant-people: *7*, restaurant-time: *11:30*, restaurant-day: 周一}

UtteranceAcceptable: 1
SlotValuesMatchAcceptable: 1

3 Additional Notes

Please ignore the slot values with “dontcare”, “not mentioned” and “none”, while checking the translation quality. If there are any open questions that you think are not covered in this guide, please do not hesitate to get in touch with me or post the questions on Slack, so these issues can be discussed together with other annotators and the guide can be improved.

CHAPTERBREAK: A Challenge Dataset for Long-Range Language Models

Simeng Sun **Katherine Thai** **Mohit Iyyer**
University of Massachusetts Amherst
`{simengsun,kbthai,miyyer}@cs.umass.edu`

Abstract

While numerous architectures for *long-range language models* (LRLMs) have recently been proposed, a meaningful evaluation of their discourse-level language understanding capabilities has not yet followed. To this end, we introduce CHAPTERBREAK, a challenge dataset that provides an LRLM with a long segment from a narrative that ends at a *chapter boundary* and asks it to distinguish the beginning of the ground-truth next chapter from a set of negative segments sampled from the same narrative. A fine-grained human annotation reveals that our dataset contains many complex types of chapter transitions (e.g., parallel narratives, cliffhanger endings) that require processing global context to comprehend. Experiments on CHAPTERBREAK show that existing LRLMs fail to effectively leverage long-range context, substantially underperforming a segment-level model trained directly for this task. We publicly release our CHAPTERBREAK dataset to spur more principled future research into LRLMs.[1]

1 Introduction

Research on *long-range language models* (LRLMs) aims to process extremely long input sequences by making the base Transformer architecture more efficient (e.g., through sparse attention, recurrence, or cached memory). These modifications are commonly validated by training LRLMs on PG-19 (Rae et al., 2020), a long-document language modeling dataset, and demonstrating small perplexity decreases over shorter context models (Roy et al., 2021; **?**). However, recent analysis experiments (Sun et al., 2021; Press et al., 2021) show that modern LRLMs rely mostly on local context (i.e., the immediately preceding 1-2K tokens) and are insensitive to various perturbations applied to more distant context.

(+) Billy Pilgrim could not sleep on his daughter's wedding night. He was forty-four... ***[ground-truth start of ch. 4]***

(−) Billy Pilgrim says that the Universe does not look like a lot of bright little dots to the creatures from Tralfamadore...

(−) All the trains were slow. The coaches stunk of coal smoke and rationed tobacco and rationed booze and the farts of people eating wartime food.

Figure 1: An illustrative example of our suffix identification task from Kurt Vonnegut's *Slaughterhouse-Five*, in which an LRLM needs to make connective inferences across temporal and spatial shifts in a long prefix of the narrative to correctly disambiguate the (+) start of the next chapter from (-) negative examples.

In this paper, we move beyond token-level perplexity by evaluating LRLMs on a task that requires a rich understanding of long-range dependencies. Our task is an instance of *suffix identification*, in which a language model is given a long input sequence (or *prefix*) and asked to disambiguate the next n-token segment from a set of hard negatives sampled from the same narrative. To succeed at this task, an LRLM should assign high probability to the ground-truth next segment and low probability to the negatives. To specifically test long-range dependencies, we restrict our prefixes to end at *chapter breaks* of a longer cohesive narrative (e.g., a novel).

We construct a challenge dataset, CHAPTERBREAK, by automatically detecting chapter bound-

July 10-15, 2022 ©2022 Association for Computational Linguistics

aries within both held-out PG-19 documents (in-domain for pretrained LRLMs) and works of fan fiction published on the Archive of Our Own (out of domain).[2] We perform a detailed analysis of the types of chapter transitions in our dataset and discover a high frequency of narrative shifts in point-of-view, location, and time, all of which require global narrative understanding over long input sequences. For example, Figure 1 contains a complex prefix in which the time-traveling Billy Pilgrim moves between World War II, 1960s suburban life, and an alien planet. Understanding the cliffhanger ending, in which the narrative abruptly switches from a wartime scene to a 1967 alien abduction, requires an LRLM to make connective inferences using details buried far back in the context (e.g., Billy's age in 1967).

We evaluate three LRLMs on CHAPTERBREAK, including BigBird (Zaheer et al., 2020), the Routing Transformer (Roy et al., 2021), and its local attention variant, all pretrained or fine-tuned on PG-19. Our experiments show that these LRLMs perform poorly at selecting the ground-truth suffix, regardless of the length of the input sequence. As an upper bound, we train a small RoBERTa-based segment-level language model on PG-19 and discover that it substantially outperforms all LRLMs on CHAPTERBREAK, which suggests that LRLMs have considerable room for improvement on this suffix identification task. Finally, we perform an analysis on the instances for which all models struggle to choose the correct suffix, which shows that shifts in location and events in focus are particularly challenging to disambiguate. Taken together, these results suggest that CHAPTERBREAK is a useful benchmark for future research into LRLMs.

2 The CHAPTERBREAK dataset

Authors often break long-form narratives into a sequence of discrete chapters to impose "an order and shape over events in time" (Stevick, 1970). Henry Fielding writes in his novel *Joseph Andrews* that the space between chapters is like "an Inn or Resting Place" for readers to reflect on the preceding chapter (Fielding, 1779). Chapters come in many flavors: for example, Murakami's *Kafka on the Shore* uses chapter breaks to alternate between parallel narratives focusing on the two protagonists, while cliffhanger endings such as the one in Figure 1 add suspense. Making sense of the complex narrative shifts associated with chapter transitions (e.g., changes in point-of-view, time, location, and theme) requires a deep understanding of the entire text. To maintain global narrative coherence, Myers et al. (1994) show that human readers tend to reactivate memory about "backgrounded" information from the long-range context.

Task overview: Given that chapter transitions requires global context understanding, how can we turn this into a task to evaluate LRLMs? A simple approach is to evaluate the token-level perplexity of an LRLM only at chapter boundaries (i.e., on the first n tokens of each chapter); however, the vast majority of tokens can be predicted using just local context (Sun et al., 2021) under the teacher-forcing setup, which obscures an LRLM's usage of long-range context as we show in Section 3. We instead turn to the task of *suffix identification*, which closely resembles existing datasets such as SWAG (Zellers et al., 2018).

Each instance of our task is defined by a triplet $(c, s^+, s_i^- \in \mathbf{N})$, where c is a prefix sequence of up to 8K tokens that ends at a chapter break, s^+ is the gold suffix of length 128 tokens (i.e., the beginning of the next chapter), and s_i^- is a negative 128-token-long suffix from a set $\mathbf{N}$ of five[3] future chapter beginnings sampled from the same narrative.[4] All negatives are modified to begin with the same chapter index (e.g., if the gold suffix begins with "Chapter III", the chapter indices of all negatives is set to "Chapter III") to eliminate the effect found by Sun et al. (2021) of language models memorizing chapter indices in long contexts. We then evaluate whether an LRLM assigns higher probability to the gold suffix $P(s^+|c)$ than to all negative suffixes $P(s_i^-|c)$.

Dataset overview: Where do we get these triplets from? We collect a dataset, CHAPTERBREAK, with two splits: CHAPTERBREAK$_{PG19}$, which contains 241 examples extracted from the PG-19 validation set (Rae et al., 2020),[5] and CHAPTERBREAK$_{AO3}$, which contains 7,355 ex-

---

[2] `https://archiveofourown.org`

[3] We use a small number of negatives because it is time-consuming and resource-intensive to evaluate the probabilities of long sequences with LRLMs.

[4] In Appendix F, we show that in-book negatives are much harder than out-of-book negatives as they often contain the same named entities and rare tokens as the gold suffix. Thus, disambiguating the correct suffix requires a deep understanding of the context.

[5] We only collect examples from validation set as two baseline models in the later sections are trained on PG-19.

Category	Definition	Pct.
Events	Previous event ends and new event starts	76%
	Previous event continues into next chapter	24%
Actors	Change of perspective or character in focus	36%
	No change in POV or main character	64%
Locations	Change of location	68%
	No change in location	32%
Continuity	Discontinuous but chronological	29%
	Continuous	62%
	Analepsis	2%
	Parallel	6%

Table 1: Our human annotation on 300 chapter transitions randomly sampled from CHAPTERBREAK$_{AO3}$ shows the diversity and complexity of the dataset.

amples extracted from an online dump[6] of fanfiction posted on Archive of Our Own (AO3). We apply filtering to remove fanfiction works that are too short or not rated for general audiences. Each work contains on average 42K words and 21.5 chapters.[7] Even though the CHAPTERBREAK$_{PG19}$ split is small, we include it because many LRLMs are pretrained on PG-19; the much larger CHAPTERBREAK$_{AO3}$ split is out-of-distribution for all models that we evaluate. To extract chapters in PG-19, we match for lines beginning with the string "chapter", while AO3 stories already have chapter-level metadata.

What are the different types of transitions in CHAPTERBREAK and how often do they occur? To get a better sense of our dataset, we perform a fine-grained annotation of 300 randomly-selected chapter transitions from CHAPTERBREAK$_{AO3}$. For each transition, we annotate any changes in the following four aspects: events, actors (characters in focus), locations, and continuity. To annotate continuity, we follow a simplified version of the scheme proposed by Ireland (1986),[8] which considers five categories: **continuous** (the next chapter occurs within a day of the previous chapter), **discontinuous** (the next chapter occurs more than a day after the previous chapter), **analepsis** (the next chapter is a "flashback" to an earlier point in the narrative), and **parallel** (the next chapter reverts to the time of a previous chapter, switching the character or event in focus).[9] The results, shown in Table 1, demonstrate that CHAPTERBREAK covers a diverse array of transitions, including many that require global narrative understanding.

	#Params	Seq Len	PPL_{PG19}	Acc_{PG19}	Acc_{AO3}
LT	516M	8K	76.8	25%	24%
RT	490M	8K	72.3	22%	24%
Bigbird	128M	4K	56.2	27%	26%
GPT-2	1.5B	1K	78.2	23%	24%
GPT-3	175B	2K	-	36%*	28%*
SuffixLM	87M	10K	-	**52%**	**41%**

Table 2: Summary of LRLMs (top), Transformer LMs (middle), and our SuffixLM (bottom). All models are trained or fine-tuned on PG-19 except for GPT-2. The third column shows the word-level perplexity of gold suffix in the PG-19 split. The last two columns show the suffix identification accuracy of each model on the two CHAPTERBREAK splits when evaluated at maximum input length. * indicates results are on a subset of CHAPTERBREAK.

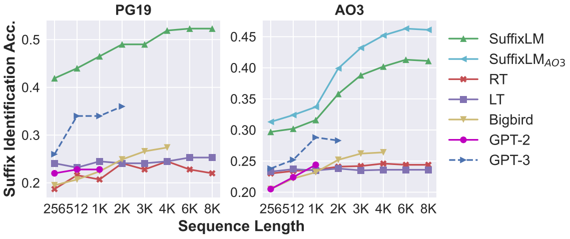

Figure 2: Suffix identification accuracy on both splits (PG-19 and AO3) of CHAPTERBREAK is much lower for LRLMs than our SuffixLM upper bound.

3 Experiments

We evaluate three different long-range language models on CHAPTERBREAK and compare their results to those of standard Transformer language models as well as an upper bound directly trained for suffix prediction.

Language models: We evaluate three LRLMs pretrained on PG-19: the Local Transformer (Roy et al., 2021, LT), Routing Transformer (RT) (Roy et al., 2021, RT), and BigBird (Zaheer et al., 2020). The BigBird model is the decoder part of the released checkpoint fine-tuned with causal LM objective on 14k books of PG-19 for 100k steps. We also evaluate two standard Transformer language models, GPT-2 large (Radford et al., 2019) and GPT-3 (Brown et al., 2020).[10] We summarize these

---

[6] `https://archive.org/download/AO3_story_dump_continuing`

[7] More preprocessing details and statistics can be found in Appendix A.

[8] To validate our continuity annotations, we also annotate every chapter in *Pride and Prejudice* and obtain almost the same proportion of continuous transitions (67%) as the number reported by the expert annotation of Ireland (1986) (72%).

[9] Appendix B contains more details about each category.

[10] Due to OpenAI's API costs for GPT-3, we only evaluate in total a subset of 200 examples instead of the full dataset.

models in Table 2, more details about each model are included in Appendix C.

An upper bound directly trained for suffix identification: As authors often write stories that are intended to surprise readers, it is possible that many examples in CHAPTERBREAK are ambiguous by nature (i.e., the upper bound for suffix identification accuracy may not be 100%). To obtain a reasonable upper bound, we also train a model (SuffixLM) directly on the suffix identification task by scaling up the sentence-level language model proposed by Ippolito et al. (2020).[11] We divide an input sequence into multiple segments, each of which is embedded via the `[CLS]` vector of a small fine-tuned RoBERTa network (Liu et al., 2019). Our SuffixLM then performs "language modeling" atop the dense `[CLS]` vectors, predicting the next segment representation given the representations of previous segments via contrastive predictive coding (van den Oord et al., 2018).[12] Formally, our SuffixLM minimizes the following loss:

$$\mathcal{L}_i = -\log \frac{\exp(\hat{\mathbf{z}}_i{}^\top \mathbf{z}_i^+)}{\sum_{\mathbf{z}_i \in \{\mathbf{z}_i^+, \mathcal{Z}_i^-\}} \exp(\hat{\mathbf{z}}_i{}^\top \mathbf{z}_i)}$$

where $\hat{\mathbf{z}}_i$ is the predicted representation by SuffixLM, $\mathbf{z}_i^+$ is the gold suffix representation obtained from a small encoder (RoBERTa), and $\mathcal{Z}_i^-$ is the set of dense representations of the negatives. More details about our SuffixLM are included in Appendix D.

4 Results & Analysis

Overall, the results in Table 2 (rightmost two columns) confirm that all of the language models studied in this paper struggle on CHAPTERBREAK, especially when compared to the SuffixLM upper bound, which outperforms the best LM by ∼25% absolute accuracy when evaluated on the entire PG-19 split. We describe other interesting results and analysis below:

Accuracy increases with longer prefixes: Figure 2 shows that as prefix sequence length increases, some LRLMs (e.g., LT) barely improve, while others show modest improvements (e.g., GPT-3 and fine-tuned BigBird). However, all LRLMs significantly underperform our SuffixLM upper bound, even when the SuffixLM is given prefixes that are only 256 tokens long. Additionally, SuffixLM's accuracy increases far more than those of LRLMs when increasing the prefix length (from 31% at prefix length of 256 to 46% at 8K on the AO3 split[13]). This result suggests that the token-level LRLMs evaluated in our work are not taking full advantage of information in the long-range context to solve CHAPTERBREAK.

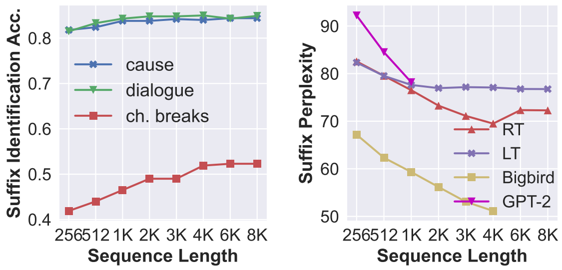

Figure 3: **Left:** Prefixes ending at chapter breaks benefit more from long-range context than other types of discourse boundaries. **Right:** Word-level perplexity of the gold suffix does not correlate to accuracy (e.g., GPT-2 has high perplexity but outperforms RT on suffix identification).

Perplexity does not always correlate with accuracy: Previous LRLM efforts use validation perplexity (e.g., on PG-19) to compare against other models. However, we show that perplexity is not by itself a predictor of suffix identification accuracy: As shown in Table 2, GPT-2 achieves higher accuracy than RT despite yielding a word-level perplexity of 78.2 on gold suffixes, compared to 72.3 for RT.[14] We advocate that future research on LRLMs includes evaluation on suffix identification tasks like CHAPTERBREAK, as perplexity alone does not reflect LRLMs' capabilities to model long-range dependencies.

Why chapter breaks over other discourse boundaries? Other discourse markers, including *cause* and *dialogue*, also often prompt human readers to reactivate memories of global context (Albrecht

---

[11] Our SuffixLM can process up to 10K tokens, while the model of Ippolito et al. (2020) supports only up to ten sentences.

[12] Our SuffixLM is closely related to the model in Ainslie et al. (2020), but differs crucially by predicting the representation of next segment instead of summaries.

[13] We collected 13,682 fan-fictions posted on AO3 and fine-tuned our SuffixLM on subset of this dataset to be the model SuffixLM$_{AO3}$. More details about the filtered AO3 works are included in Appendix A

[14] As these models use different tokenizers, we normalize the subword-level perplexities to the word level as suggested by Rae et al. (2020). More details about this can be found in Appendix E.

and Myers, 1995). We create suffix identification datasets for these two discourse markers by string matching over corresponding cue phrases ('because', 'due to' for the *cause* subset and text within quotation marks for *dialogue*).[15] Figure 3 (left) shows that with prefixes of length 256 tokens, our SuffixLM is able to successfully disambiguate the correct suffixes for both discourse markers more than 80% of the time, while the accuracy is much lower at chapter boundaries. As the prefix length increases, accuracy only slightly increases for *cause* and *dialogue*, especially compared to the robust improvement at chapter boundaries.[16]

Short-context Transformers are comparable to LRLMs: Our results show that GPT-2, despite its high perplexity on gold suffixes and short maximum sequence length (1024 tokens), achieves comparable performance to RT and LT on both splits. Meanwhile, GPT-3 achieves much higher performance on both CHAPTERBREAK at a sequence length of 2,048 tokens, and the increasing GPT-3 curve in Figure 2 is promising for future work scaling LMs to longer sequence lengths.

Limitations of our work: While we have used the SuffixLM as an upper bound in this paper and demonstrated that it substantially outperforms LRLMs on CHAPTERBREAK, a more compelling comparison would include human performance on our task at varying prefix lengths, especially since some chapter transitions are specifically intended by their authors to be unpredictable. However, obtaining reliable human performance numbers is very difficult, as it requires in-depth comprehension of long narratives on the part of workers. Due to the time-consuming nature of this task and its high cognitive demand, it is not possible (within a reasonable budget) to use crowdsourcing, as ensuring that the annotators fully read the prefix instead of skimming or ignoring it is a major challenge. These issues also carry over to experiments performed with in-person subjects. As such, we leave a thorough human evaluation on CHAPTERBREAK to future work.

5 Related Work

Our work depends heavily on recent advances in efficient Transformers (Tay et al., 2020) that process long sequences (Rae et al., 2020; Beltagy et al., 2020; Zaheer et al., 2020; Ainslie et al., 2020; Roy et al., 2021). Sparse attention (Child et al., 2019), relative position encoding (Shaw et al., 2018; Raffel et al., 2020; Guo et al., 2021), recurrence mechanism and memory (Dai et al., 2019; Weston et al., 2015; Hutchins et al., 2022; **?**) and other tricks (Shen et al., 2020; Katharopoulos et al., 2020; Gupta and Berant, 2020; Stock et al., 2021; Yogatama et al., 2021; Borgeaud et al., 2021; Hawthorne et al., 2022) are commonly adopted by recent Transformer variants to make the operation on long sequences more time/memory efficient.

Besides perplexity, many downstream extrinsic tasks for evaluating long-range language models were developed recently , such as long-form QA (Fan et al., 2019; Pang et al., 2021), document-level summarization (Kryściński et al., 2021; Huang et al., 2021), and machine translation (Liu and Zhang, 2020). More recently, Shaham et al. (2022) introduce a new benchmark covering multiple domains and tasks, while Tay et al. (2021) propose multimodal long sequence tasks.

6 Conclusion

We introduce CHAPTERBREAK, a suffix identification dataset targeted at evaluating the discourse-level understanding of long-range language models. The dataset is extracted from long-form narratives and covers a variety of complex chapter transitions, such as shifts in location and events in focus. Experiments show that existing LRLMs perform poorly on CHAPTERBREAK and much worse than a SuffixLM trained as an upper bound on this task. We release the dataset to spur more principled development of future LRLMs.

Acknowledgements

We thank the anonymous reviewers and UMass NLP group for the thoughtful comments on the draft of this paper. We are grateful to AO3 Support Chair and volunteers for answering data related questions. This work was supported by awards IIS-1955567 and IIS-2046248 from the National Science Foundation (NSF).

Ethical Considerations

CHAPTERBREAK is constructed from two sources: public domain books published prior to 1919 (from the held-out set of PG-19) and works of fanfiction extracted from an online dump of stories posted

---

[15] Appendix A contains more details about data for these two discourse markers.

[16] Appendix G shows similar trends on *cause* and *dialogue* with other models.

on Archive of Our Own (AO3). We refer readers to Rae et al. (2020) for more details about PG-19. For AO3, we apply multiple filters to obtain long fanfiction stories rated as suitable for "General Audiences". We refer readers to Appendix A for more preprocessing details. More generally, this work focuses on long-range language models, which could potentially be misused to generate offensive output. However, the main purpose of this paper is to present a dataset which provides a better evaluation of the discourse-level capabilities of such models.

A Dataset statistics

We collected 13,682 fanfictions from an online dump of stories posted on Archive of Our Own (AO3) by filtering works written in English language, rated General Audience by the author and contains at least 10K words and more than 10 chapters. For each chapter, we remove the text within the range of "`**Notes for the Chapter:**`", "`**Summary for the Chapter:**`" and "`**Author's Note:**`". The meta-comments inserted into the main text by the authors are not removed. The statistics of this long-fic dataset are included in Table 3. We do not apply other profanity filters to the fictions, therefore there may still be inappropriate content for general audience as the rating is self-labeled by each author. Besides chapter breaks introduced in the main text, we also collected two other discourse boundaries, cause and dialogue, as comparisons to the chapter boundary examples. We present the statistics each type of examples in Table 4.

- **Cause**: The beginning of the suffix contains words or phrases 'because', 'due to', 'owing to'. According to (Albrecht and Myers, 1995), human readers reactivate memory of global context for comprehending statements following causes or goals.
- **Dialogue**: The gold suffix in this category starts with a quotation mark. This often happens in dialogues where the continuation of one interlocutor depends heavily on the immediately preceding utterance. We conjecture this is the type where the prediction relies more on the local rather than the global context.

	mean	min	max
#chapters	21.5	11	589
#words	41,513.2	10,000	636,468

Table 3: Statistics of long fanfictions collected from AO3 story dump.

B Annotation Scheme

We annotate each chapter transition from four aspects: events, actors (point-of-view or characters in focus), location, and continuity in timeline.

	AO3		PG19	
Suffix Type	#works	#examples	#works	#examples
cause	965	8,133	45	506
dialogue	979	8,724	46	3,165
chapter breaks	1202	7,355	17	241

Table 4: Data statistics of CHAPTERBREAK as well as another two discourse boundary examples.

Events We define two subcategories based on whether (1) previous event ends in the previous chapter and new event starts in the new chapter, (2) old event does not end and continues into the next chapter.

Actors We define two subcategories based on whether there is a shift in POV or main character in focus.

Location We define two subcategories based on whether the location described in the prefix and in the new chapter is different.

Continuity Following Ireland (1986)'s work, we categorize the chapter transition by timeline continuity into four subcategories:

- **Discontinuous but chronological**: Reusing the standard by Ireland (1986), discontinuous represents a gap in time forward for more than one night.
- **Continuous**: The time interval between chapters lasts for no more than one night.
- **Analepsis**: Analepsis represents retrospective evocation of an event, or "flashback" to an earlier point in the narrative.
- **Parallel**: This includes timeline reverting back to the time of any previous chapter, typically accompanied by switching character in focus or description of a separate set of events independent of the last chapter. This category is a collapse of "alternate phase", "parallel phase" and "simultaneous phase" introduced in (Ireland, 1986).

C Baselines

Bigbird (Zaheer et al., 2020) To reduce the quadratic complexity of self-attention in the standard Transformer, the Bigbird model employs a mixture of global, random and local attention mechanisms, which successfully reduce the complexity to linear. The idea is to insert each sequence $O(1)$ global tokens, which attend to all other tokens. The rest tokens attend to their neighbor tokens, random tokens in the sequence as well as the inserted global tokens. A very similar idea is developed concurrently in the Longformer (Beltagy et al., 2020). The Bigbird model we fine-tuned is the decoder part of the released checkpoint. We fine-tune the model with causal LM objective on 14K books of PG-19 with peak learning rate 0.0001 for 100K steps. We set attention type to be "original_full" instead of using "block_sparse" during fine-tuning. Training is completed on a single RTX8000 GPU for around 6 days.

Local Transformer Rather than implementing all three types of sparse attention in Bigbird, the Local Transformer relies only on the local attention, i.e., each token attends to neighbors within a local window. The maximum attainable sequence length scales linearly with the number of layers, e.g., with window size k, the token representation at layer l theoretically covers information in a range of $k \times l$ tokens.

Routing Transformer (Roy et al., 2021) Different from previously described models which use *position*-based sparse attention, the Routing Transformer employs *content*-based sparse attention. Namely, each token are routed to clusters and the attention is performed only within each cluster. The clustering operation effectively reduces the quadratic complexity in length L to $O(L^{1.5})$. Both the RT and LT checkpoint we used were trained on PG-19 (Rae et al., 2020). For both RT and LT, we evaluate on single RTX8000 GPU.

GPT-2/3 The GPT models have a lot shorter maximum input length than the rest models we evaluated. While GPT-2 model does not use sparse attentions at all, GPT-3 model adopts alternated layers of sparse and dense self-attention. We use the GPT-2 large model, which was pre-trained on data scraped from the Internet. The GPT-3 model was pre-trained on a mixture of filtered CommonCrawl, WebText2, Books1, Books2, and Wikipedia.

D Finding the best SuffixLM

As there are no prior long-range segment-level LM architectures that we can borrow from, we experiment multiple design choices and report the result of only the best performing one in the main text. For all variants, we use RoBERTa-base (Liu et al., 2019) as the encoder to obtain the encoded segment representation. This is done by extracting the representation of the $[CLS]$ token prepended at the beginning of each sequence. We describe five variants below.

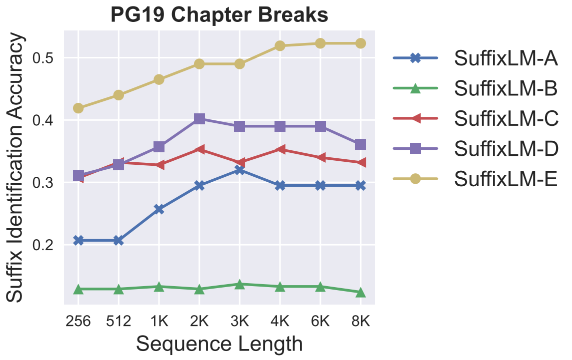

Figure 4: Performance of each SuffixLM variant. Detailed information about each variant is included in Appendix D.

- **SuffixLM-A** This variant contains a frozen RoBERTa-base encoder and a SuffixLM using a 6-layer Transformer as the base architecture.
- **SuffixLM-B** This variant contains a frozen RoBERTa-base encoder and a SuffixLM using a 6-layer average-attention Transformer as the backbone. The motivation of using uniform distribution for attention weights is to encourage the model to get more information from the distant context rather than rely too much on local context.
- **SuffixLM-C** This variant is essentically SuffixLM-A but during training we perform "segdrop" – stochastically dropping prefix segments with probability 0.2[17] when performing self-attention. When the local segments are dropped, the model has to predict the next segments with only the distant context, which also encourages learning better long-range prefix representations.
- **SuffixLM-D** Instead of freezing the encoder, this variant fine-tunes part of the encoder and the rest is the same as SuffixLM-A. Due to limited memory capacity, we only fine-tune the last two layers of the RoBERTa-base.
- **SuffixLM-E** This model is the same as SuffixLM-D except that we truncate the en-

---

[17] Tried {0.1, 0.2, 0.4}, 0.2 works the best.

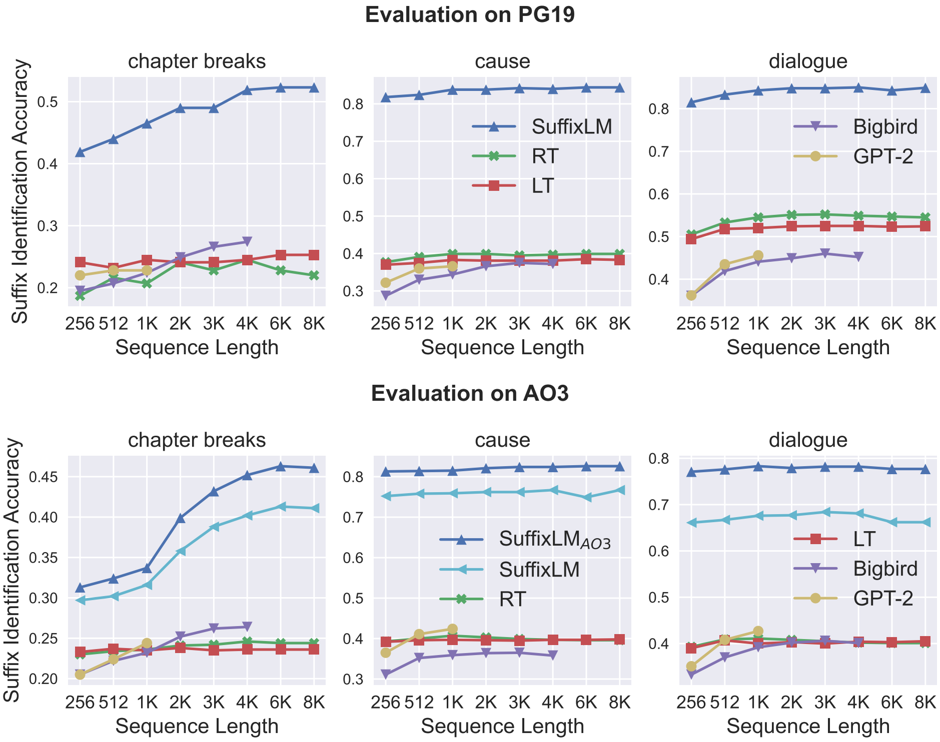

Figure 5: Evaluation results on both ChapterBreak$_{PG19}$ and ChapterBreak$_{AO3}$.

coder to just the two tunable layers and train all parameters in the encoder including the embedding parameters.

All SuffixLMs with frozen encoders are trained with average sequence length of 10240 tokens for up to 60k steps, and the one with trainable encoder is trained for max 120k steps. The dimension of the model is 768, hidden dimension 2048,attention heads 8. The peak learning rate is 0.0001 with warm up steps 4000. We train SuffixLM on entire PG-19 dataset and evaluate the best checkpoint selected by dev loss. We use segment size 128 in all SuffixLMs we trained. Each segment starts from a new sentence, if not reaching 128 tokens, we pad with a special '<pad>' token. For very long sentences, the part exceeding 128 tokens overflows to the next segment. We plot the suffix identification accuracy of each variant on ChapterBreak while feeding in prefixes of increasing length. As shown in Figure 4, SuffixLM-E outperforms all other variants across various prefix lengths. Therefore in the main text, all SuffixLM refers to the SuffixLM-E variant. Note that one limitation of SuffixLM is it exclusively models on segment-level, which prohibits it from performing token-by-token generation and thus impossible for us to evaluate perplexity.

E Suffix perplexity

Although the task of ChapterBreak is to identify gold suffix from negatives, we also present the gold suffix perplexity of next-token prediction LMs. Note that all models were trained or fine-tuned on PG-19 except for GPT-2/3. As these models use different tokenizers, the 128-token suffix may cover different number of words, to make the results comparable, we convert the subword-level perplexity to word-level by multiplying a constant to the log probability value of each model. For RT/LT, we multiple by 1.248 as used in the official repository. We multiply the value by 1.30 for GPT-2, and 1.22 for Bigbird. These values are estimated via the subword/word ratio on validation set of PG-19. Our fine-tuned Bigbird model achieves the lowest perplexity on PG-19, even better than Routing Transformer or Local Transformer. This implies that context from long-range is not necessary for achieving low perplexity since the maximum input length of Bigbird is half that of RT/LT.

F In-book vs. Out-of-book

This section is better read after reading through § 3. In this analysis experiment, we show why it is better that the negatives are from the same narrative as the gold suffix. We evaluate our upper bound

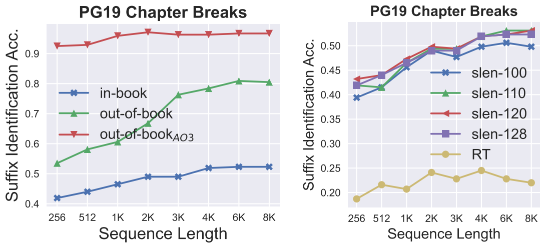

Figure 6: **Left:** In-book vs. out-of-book. **Right:** SuffixLM performance when evaluated with different suffix length. The variation in suffix length does not explain the large gap between SuffixLM and token-level LMs.

model SuffixLM on PG-19 set when the negatives are out-of-book suffixes, and plot the suffix identification accuracy in Figure 6. When evaluate against out-of-book negatives, this suffix identification task is almost solved by our SuffixLM, especially when the out-of-book examples are from another split in CHAPTERBREAK. The extremely high accuracy under out-of-book setup suggests the segment representation from different books are easy for SuffixLM to distinguish, thus we adopt a harder setup where the negatives are from the same book. Besides, in-book negatives may contain the same re-occurring named entities or rare words, which require solid understanding of the prefix to differentiate the gold from the distractors.

G Various Discourse Relationships

In addition to chapter breaks, we also evaluate the other two types of discourse boundary examples introduced in Appendix A. As shown in Figure 5, for all suffix types other than chapter breaks, the evaluated models stop improving as the sequence length grows to more than 2K tokens long. However, there is a significant increasing trend in chapter breaks for SuffixLM. For the rest models, the performance is either flat or not improving. On the AO3 split, the accuracy of SuffixLM improves for $\sim 15\%$ as the sequence length increases from 256 to 8K, whereas the improvement of RT is only $\sim 1.4\%$. This is in contrast with SuffixLM's $\sim 1.5\%$ and RT's $\sim 0.3\%$ improvement for the 'cause' examples. We draw two conclusions from these observations: (1) the chapter breaks examples form a special case where longer prefix is preferred in order to pick the correct continuation. (2) By comparing the relative improvement, the token-level LMs fall far behind the SuffixLM, which is, besides the absolute performance gap, another evidence that current LRLMs do not effectively leverage long-range context for sequence tasks requiring discourse-level understanding.

H Tackle difference in Tokenizers

As the models we evaluated use different tokenizers, there are small variations in term of suffix length, i.e., the 128-token suffix may cover different number of words. To understand how the difference in length impacts validity of evaluation, we evaluate SuffixLM with various suffix lengths. Figure 6 (right) indicates even though there are small variances when the suffixes are of different lengths, the large gap between SuffixLM and Routing Transformer still remains, thus the difference in suffix length does not explain the large performance gap.

I Error analysis

Models struggle with location and event shifts: Among the 300 examples we annotated in Section 2, 89 examples were wrongly predicted by all models we have evaluated. By breaking the incorrectly predicted examples into category as presented in Table 1, we find that models tend to make wrong prediction when there is a shift in location or event, and when plots are continuous in timeline.[18]

Category	Definition	Ratio
Events	Previous event ends and new event starts	0.74
	Previous event continues into next chapter	0.26
Actors	Change of perspective or character in focus	0.43
	No change in POV or main character	0.57
Locations	Change of location	0.64
	No change in location	0.36
Continuity	Discontinuous but chronological	0.24
	Continuous	0.62
	Analepsis	0.03
	Parallel	0.11

Table 5: Human annotation on 89 examples sampled from CHAPTERBREAK$_{AO3}$where all models make the wrong prediction. 74% errors come from the examples where new event starts from the new chapter and 64% errors from the change of location.

ColBERTv2:
Effective and Efficient Retrieval via Lightweight Late Interaction

Abstract

Neural information retrieval (IR) has greatly advanced search and other knowledge-intensive language tasks. While many neural IR methods encode queries and documents into single-vector representations, late interaction models produce multi-vector representations at the granularity of each token and decompose relevance modeling into scalable token-level computations. This decomposition has been shown to make late interaction more effective, but it inflates the space footprint of these models by an order of magnitude. In this work, we introduce ColBERTv2, a retriever that couples an aggressive residual compression mechanism with a denoised supervision strategy to simultaneously improve the quality and space footprint of late interaction. We evaluate ColBERTv2 across a wide range of benchmarks, establishing state-of-the-art quality within and outside the training domain while reducing the space footprint of late interaction models by 6–10×.

1 Introduction

Neural information retrieval (IR) has quickly dominated the search landscape over the past 2–3 years, dramatically advancing not only passage and document search (Nogueira and Cho, 2019) but also many knowledge-intensive NLP tasks like open-domain question answering (Guu et al., 2020), multi-hop claim verification (Khattab et al., 2021a), and open-ended generation (Paranjape et al., 2022).

Many neural IR methods follow a *single-vector similarity* paradigm: a pretrained language model is used to encode each query and each document into a single high-dimensional vector, and relevance is modeled as a simple dot product between both vectors. An alternative is *late interaction*, introduced in ColBERT (Khattab and Zaharia, 2020), where queries and documents are encoded at a finer-granularity into multi-vector representations, and relevance is estimated using rich yet scalable interactions between these two sets of vectors. ColBERT produces an embedding for every token in the query (and document) and models relevance as the sum of maximum similarities between each query vector and all vectors in the document.

By decomposing relevance modeling into token-level computations, late interaction aims to reduce the burden on the encoder: whereas single-vector models must capture complex query–document relationships within one dot product, late interaction encodes meaning at the level of tokens and delegates query–document matching to the interaction mechanism. This added expressivity comes at a cost: existing late interaction systems impose an order-of-magnitude larger *space footprint* than single-vector models, as they must store billions of small vectors for Web-scale collections. Considering this challenge, it might seem more fruitful to focus instead on addressing the fragility of single-vector models (Menon et al., 2022) by introducing new supervision paradigms for negative mining (Xiong et al., 2020), pretraining (Gao and Callan, 2021), and distillation (Qu et al., 2021). Indeed, recent single-vector models with highly-tuned supervision strategies (Ren et al., 2021b; Formal et al., 2021a) sometimes perform on-par or even better than "vanilla" late interaction models, and it is not necessarily clear whether late interaction architectures—with their fixed token-level inductive biases—admit similarly large gains from improved supervision.

In this work, we show that late interaction retrievers naturally produce lightweight token representations that are amenable to efficient storage off-the-shelf and that they can benefit drastically from denoised supervision. We couple those in **ColBERTv2**,[1] a new late-interaction retriever that employs a simple combination of distillation from

a cross-encoder and hard-negative mining (§3.2) to boost quality beyond any existing method, and then uses a *residual compression* mechanism (§3.3) to reduce the space footprint of late interaction by 6–10× while preserving quality. As a result, ColBERTv2 establishes state-of-the-art retrieval quality both *within* and *outside* its training domain with a competitive space footprint with typical single-vector models.

When trained on MS MARCO Passage Ranking, ColBERTv2 achieves the highest MRR@10 of any standalone retriever. In addition to in-domain quality, we seek a retriever that generalizes "zero-shot" to domain-specific corpora and long-tail topics, ones that are often under-represented in large public training sets. To this end, we evaluate ColBERTv2 on a wide array of *out-of-domain* benchmarks. These include three Wikipedia Open-QA retrieval tests and 13 diverse retrieval and semantic-similarity tasks from BEIR (Thakur et al., 2021). In addition, we introduce a new benchmark, dubbed **LoTTE**, for Long-Tail Topic-stratified Evaluation for IR that features 12 domain-specific search tests, spanning StackExchange communities and using queries from GooAQ (Khashabi et al., 2021). LoTTE focuses on relatively long-tail topics in its passages, unlike the Open-QA tests and many of the BEIR tasks, and evaluates models on their capacity to answer natural search queries with a practical intent, unlike many of BEIR's semantic-similarity tasks. On 22 of 28 out-of-domain tests, ColBERTv2 achieves the highest quality, outperforming the next best retriever by up to 8% relative gain, while using its compressed representations.

This work makes the following contributions:

1. We propose ColBERTv2, a retriever that combines denoised supervision and residual compression, leveraging the token-level decomposition of late interaction to achieve high robustness with a reduced space footprint.

2. We introduce LoTTE, a new resource for out-of-domain evaluation of retrievers. LoTTE focuses on natural information-seeking queries over long-tail topics, an important yet under-studied application space.

3. We evaluate ColBERTv2 across a wide range of settings, establishing state-of-the-art quality within and outside the training domain.

2 Background & Related Work

2.1 Token-Decomposed Scoring in Neural IR

Many neural IR approaches encode passages as a single high-dimensional vector, trading off the higher quality of cross-encoders for improved efficiency and scalability (Karpukhin et al., 2020; Xiong et al., 2020; Qu et al., 2021). ColBERT's (Khattab and Zaharia, 2020) late interaction paradigm addresses this tradeoff by computing multi-vector embeddings and using a scalable "MaxSim" operator for retrieval. Several other systems leverage multi-vector representations, including Poly-encoders (Humeau et al., 2020), PreTTR (MacAvaney et al., 2020), and MORES (Gao et al., 2020), but these target attention-based re-ranking as opposed to ColBERT's scalable MaxSim end-to-end retrieval.

ME-BERT (Luan et al., 2021) generates token-level document embeddings similar to ColBERT, but retains a single embedding vector for queries. COIL (Gao et al., 2021) also generates token-level document embeddings, but the token interactions are restricted to lexical matching between query and document terms. uniCOIL (Lin and Ma, 2021) limits the token embedding vectors of COIL to a single dimension, reducing them to scalar weights that extend models like DeepCT (Dai and Callan, 2020) and DeepImpact (Mallia et al., 2021). To produce scalar weights, SPLADE (Formal et al., 2021b) and SPLADEv2 (Formal et al., 2021a) produce a sparse vocabulary-level vector that retains the term-level decomposition of late interaction while simplifying the storage into one dimension per token. The SPLADE family also piggybacks on the language modeling capacity acquired by BERT during pretraining. SPLADEv2 has been shown to be highly effective, within and across domains, and it is a central point of comparison in the experiments we report on in this paper.

2.2 Vector Compression for Neural IR

There has been a surge of recent interest in compressing representations for IR. Izacard et al. (2020) explore dimension reduction, product quantization (PQ), and passage filtering for single-vector retrievers. BPR (Yamada et al., 2021a) learns to directly hash embeddings to binary codes using a differentiable `tanh` function. JPQ (Zhan et al., 2021a) and its extension, RepCONC (Zhan et al., 2022), use PQ to compress embeddings, and jointly train the query encoder along with the centroids produced by PQ via a ranking-oriented loss.

SDR (Cohen et al., 2021) uses an autoencoder to reduce the dimensionality of the contextual embeddings used for attention-based re-ranking and then applies a quantization scheme for further compression. DensePhrases (Lee et al., 2021a) is a system for Open-QA that relies on a multi-vector encoding of passages, though its search is conducted at the level of individual vectors and not aggregated with late interaction. Very recently, Lee et al. (2021b) propose a quantization-aware finetuning method based on PQ to reduce the space footprint of DensePhrases. While DensePhrases is effective at Open-QA, its retrieval quality—as measured by top-20 retrieval accuracy on NaturalQuestions and TriviaQA—is competitive with DPR (Karpukhin et al., 2020) and considerably less effective than ColBERT (Khattab et al., 2021b).

In this work, we focus on late-interaction retrieval and investigate compression using a residual compression approach that can be applied off-the-shelf to late interaction models, without special training. We show in Appendix A that ColBERT's representations naturally lend themselves to residual compression. Techniques in the family of residual compression are well-studied (Barnes et al., 1996) and have previously been applied across several domains, including approximate nearest neighbor search (Wei et al., 2014; Ai et al., 2017), neural network parameter and activation quantization (Li et al., 2021b,a), and distributed deep learning (Chen et al., 2018; Liu et al., 2020). To the best of our knowledge, ColBERTv2 is the first approach to use residual compression for scalable neural IR.

2.3 Improving the Quality of Single-Vector Representations

Instead of compressing multi-vector representations as we do, much recent work has focused on improving the quality of single-vector models, which are often very sensitive to the specifics of supervision. This line of work can be decomposed into three directions: (1) distillation of more expressive architectures (Hofstätter et al., 2020; Lin et al., 2020) including explicit denoising (Qu et al., 2021; Ren et al., 2021b), (2) hard negative sampling (Xiong et al., 2020; Zhan et al., 2020a, 2021b), and (3) improved pretraining (Gao and Callan, 2021; Oğuz et al., 2021). We adopt similar techniques to (1) and (2) for ColBERTv2's multi-vector representations (see §3.2).

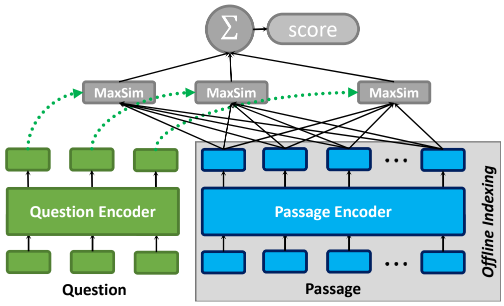

Figure 1: The late interaction architecture, given a query and a passage. Diagram from Khattab et al. (2021b) with permission.

2.4 Out-of-Domain Evaluation in IR

Recent progress in retrieval has mostly focused on large-data evaluation, where many tens of thousands of annotated training queries are associated with the test domain, as in MS MARCO or Natural Questions (Kwiatkowski et al., 2019). In these benchmarks, queries tend to reflect high-popularity topics like movies and athletes in Wikipedia. In practice, user-facing IR and QA applications often pertain to domain-specific corpora, for which little to no training data is available and whose topics are under-represented in large public collections.

This out-of-domain regime has received recent attention with the BEIR (Thakur et al., 2021) benchmark. BEIR combines several existing datasets into a heterogeneous suite for "zero-shot IR" tasks, spanning bio-medical, financial, and scientific domains. While the BEIR datasets provide a useful testbed, many capture broad semantic relatedness tasks—like citations, counter arguments, or duplicate questions–instead of natural search tasks, or else they focus on high-popularity entities like those in Wikipedia. In §4, we introduce LoTTE, a new dataset for out-of-domain retrieval, exhibiting natural search queries over long-tail topics.

3 ColBERTv2

We now introduce ColBERTv2, which improves the quality of multi-vector retrieval models (§3.2) while reducing their space footprint (§3.3).

3.1 Modeling

ColBERTv2 adopts the late interaction architecture of ColBERT, depicted in Figure 1. Queries and passages are independently encoded with BERT (Devlin et al., 2019), and the output embeddings encoding each token are projected to a lower dimension. During offline indexing, every passage d in the corpus is encoded into a set of vectors, and these vectors are stored. At search time, the query q is encoded into a multi-vector representation, and its similarity to a passage d is computed as the summation of query-side "MaxSim" operations, namely, the largest cosine similarity between each query token embedding and all passage token embeddings:

$$S_{q,d} = \sum_{i=1}^{N} \max_{j=1}^{M} Q_i \cdot D_j^T \tag{1}$$

where Q is an matrix encoding the query with N vectors and D encodes the passage with M vectors. The intuition of this architecture is to align each query token with the most contextually relevant passage token, quantify these matches, and combine the partial scores across the query. We refer to Khattab and Zaharia (2020) for a more detailed treatment of late interaction.

3.2 Supervision

Training a neural retriever typically requires *positive* and *negative* passages for each query in the training set. Khattab and Zaharia (2020) train ColBERT using the official $\langle$q, d$^+$, d$^-\rangle$ triples of MS MARCO. For each query, a positive d^+ is human-annotated, and each negative d^- is sampled from unannotated BM25-retrieved passages.

Subsequent work has identified several weaknesses in this standard supervision approach (see §2.3). Our goal is to adopt a simple, uniform supervision scheme that selects challenging negatives and avoids rewarding false positives or penalizing false negatives. To this end, we start with a ColBERT model trained with triples as in Khattab et al. (2021b), using this to index the training passages with ColBERTv2 compression.

For each training query, we retrieve the top-k passages. We feed each of those query–passage pairs into a cross-encoder reranker. We use a 22M-parameter MiniLM (Wang et al., 2020) cross-encoder trained with distillation by Thakur et al. (2021).[2] This small model has been shown to exhibit very strong performance while being relatively efficient for inference, making it suitable for distillation.

We then collect w-way tuples consisting of a query, a highly-ranked passage (or labeled positive), and one or more lower-ranked passages. In this work, we use $w = 64$ passages per example. Like RocketQAv2 (Ren et al., 2021b), we use a KL-Divergence loss to distill the cross-encoder's scores into the ColBERT architecture. We use KL-Divergence as ColBERT produces scores (i.e., the sum of cosine similarities) with a restricted scale, which may not align directly with the output scores of the cross-encoder. We also employ in-batch negatives per GPU, where a cross-entropy loss is applied to the positive score of each query against all passages corresponding to other queries in the same batch. We repeat this procedure once to refresh the index and thus the sampled negatives.

Denoised training with hard negatives has been positioned in recent work as ways to bridge the gap between single-vector and interaction-based models, including late interaction architectures like ColBERT. Our results in §5 reveal that such supervision can improve multi-vector models dramatically, resulting in state-of-the-art retrieval quality.

3.3 Representation

We hypothesize that the ColBERT vectors cluster into regions that capture highly-specific token semantics. We test this hypothesis in Appendix A, where evidence suggests that vectors corresponding to each sense of a word cluster closely, with only minor variation due to context. We exploit this regularity with a *residual* representation that dramatically reduces the space footprint of late interaction models, completely *off-the-shelf* without architectural or training changes. Given a set of centroids C, ColBERTv2 encodes each vector v as the index of its closest centroid C_t and a *quantized* vector $\tilde{r}$ that approximates the residual $r = v - C_t$. At search time, we use the centroid index t and residual $\tilde{r}$ recover an approximate $\tilde{v} = C_t + \tilde{r}$.

To encode $\tilde{r}$, we quantize every dimension of r into one or two bits. In principle, our b-bit encoding of n-dimensional vectors needs $\lceil \log |C| \rceil + bn$ bits per vector. In practice, with $n = 128$, we use four bytes to capture up to 2^{32} centroids and 16 or 32 bytes (for $b = 1$ or $b = 2$) to encode the residual. This total of 20 or 36 bytes per vector contrasts with ColBERT's use of 256-byte vector encodings at 16-bit precision. While many alternatives can be explored for compression, we find that this simple encoding largely preserves model quality, while considerably lowering storage costs against typical 32- or 16-bit precision used by existing late interaction systems.

This centroid-based encoding can be considered a natural extension of product quantization to *multi-*

---

[2] `https://huggingface.co/cross-encoder/ms-marco-MiniLM-L-6-v2`

vector representations. Product quantization (Gray, 1984; Jegou et al., 2010) compresses a single vector by splitting it into small sub-vectors and encoding each of them using an ID within a codebook. In our approach, each representation is already a matrix that is naturally divided into a number of small vectors (one per token). We encode each vector using its nearest centroid plus a residual. Refer to Appendix B for tests of the impact of compression on retrieval quality and a comparison with a baseline compression method for ColBERT akin to BPR (Yamada et al., 2021b).

3.4 Indexing

Given a corpus of passages, the indexing stage precomputes all passage embeddings and organizes their representations to support fast nearest-neighbor search. ColBERTv2 divides indexing into three stages, described below.

Centroid Selection. In the first stage, ColBERTv2 selects a set of cluster centroids C. These are embeddings that ColBERTv2 uses to support residual encoding (§3.3) and also for nearest-neighbor search (§3.5). Standardly, we find that setting $|C|$ proportionally to the square root of $n_{\text{embeddings}}$ in the corpus works well empirically.[3] Khattab and Zaharia (2020) only clustered the vectors after computing the representations of all passages, but doing so requires storing them uncompressed. To reduce memory consumption, we apply k-means clustering to the embeddings produced by invoking our BERT encoder over only a sample of all passages, proportional to the square root of the collection size, an approach we found to perform well in practice.

Passage Encoding. Having selected the centroids, we encode every passage in the corpus. This entails invoking the BERT encoder and compressing the output embeddings as described in §3.3, assigning each embedding to the nearest centroid and computing a quantized residual. Once a chunk of passages is encoded, the *compressed* representations are saved to disk.

Index Inversion. To support fast nearest-neighbor search, we group the embedding IDs that correspond to each centroid together, and save this *inverted list* to disk. At search time, this allows us to quickly find token-level embeddings similar to those in a query.

3.5 Retrieval

Given a query representation Q, retrieval starts with candidate generation. For every vector Q_i in the query, the nearest $n_{\text{probe}} \geq 1$ centroids are found. Using the inverted list, ColBERTv2 identifies the passage embeddings close to these centroids, decompresses them, and computes their cosine similarity with every query vector. The scores are then grouped by passage ID for each query vector, and scores corresponding to the same passage are $\max$-reduced. This allows ColBERTv2 to conduct an approximate "MaxSim" operation per query vector. This computes a lower-bound on the true MaxSim (§3.1) using the embeddings identified via the inverted list, which resembles the approximation explored for scoring by Macdonald and Tonellotto (2021) but is applied for candidate generation.

These lower bounds are summed across the query tokens, and the top-scoring $n_{\text{candidate}}$ candidate passages based on these approximate scores are selected for ranking, which loads the complete set of embeddings of each passage, and conducts the same scoring function using all embeddings per document following Equation 1. The result passages are then sorted by score and returned.

4 LoTTE: Long-Tail, Cross-Domain Retrieval Evaluation

We introduce **LoTTE** (pronounced latte), a new dataset for **Lo**ng-**T**ail **T**opic-stratified **E**valuation for IR. To complement the out-of-domain tests of BEIR (Thakur et al., 2021), as motivated in §2.4, LoTTE focuses on *natural user queries* that pertain to *long-tail topics*, ones that might not be covered by an entity-centric knowledge base like Wikipedia. LoTTE consists of 12 test sets, each with 500–2000 queries and 100k–2M passages.

The test sets are explicitly divided by topic, and each test set is accompanied by a validation set of *related but disjoint* queries *and* passages. We elect to make the passage texts disjoint to encourage more realistic out-of-domain transfer tests, allowing for minimal development on related but distinct topics. The test (and dev) sets include a "pooled" setting. In the pooled setting, the passages and queries are aggregated across all test (or dev) topics to evaluate out-of-domain retrieval across a larger and more diverse corpus.

Table 1 outlines the composition of LoTTE. We derive the topics and passage corpora from the *answer posts* across various StackExchange fo-

Table 1: Composition of LoTTE showing topics, question sets, and a sample of corresponding subtopics. Search Queries are taken from GooAQ, while Forum Queries are taken directly from the StackExchange archive. The pooled datasets combine the questions and passages from each of the subtopics.

rums. StackExchange is a set of question-and-answer communities that target individual topics (e.g., "physics" or "bicycling"). We gather forums from five overarching domains: writing, recreation, science, technology, and lifestyle. To evaluate retrievers, we collect *Search* and *Forum* queries, each of which is associated with one or more target answer posts in its corpus. Example queries, and short snippets from posts that answer them in the corpora, are shown in Table 2.

Search Queries. We collect search queries from GooAQ (Khashabi et al., 2021), a recent dataset of Google search-autocomplete queries and their answer boxes, which we filter for queries whose answers link to a specific StackExchange post. As Khashabi et al. (2021) hypothesize, Google Search likely maps these natural queries to their answers by relying on a wide variety of signals for relevance, including expert annotations, user clicks, and hyperlinks as well as specialized QA components for various question types *with access to the post title and question body*. Using those annotations as ground truth, we evaluate the models on their capacity for retrieval using *only* free text of the answer posts (i.e., no hyperlinks or user clicks, question title or body, etc.), posing a significant challenge for IR and NLP systems trained only on public datasets.

Forum Queries. We collect the forum queries by extracting post titles from the StackExchange communities to use as queries and collect their corresponding answer posts as targets. We select questions in order of their popularity and sample questions according to the proportional contribution of individual communities within each topic.

Q: *what is the difference between root and stem in linguistics?* **A:** A root is **the form to which derivational affixes are added** to form a stem. A stem is **the form to which inflectional affixes are added** to form a word.
Q: *are there any airbenders left?* **A:** the Fire Nation had wiped out all Airbenders while Aang was frozen. **Tenzin and his 3 children are the only Airbenders left in Korra's time.**
Q: *Why are there two Hydrogen atoms on some periodic tables?* **A:** some periodic tables show hydrogen in both places **to emphasize that hydrogen isn't really a member of the first group or the seventh group.**
Q: *How can cache be that fast?* **A:** the cache memory sits right next to the CPU on the same die (chip), **it is made using SRAM which is much, much faster than the DRAM.**

Table 2: Examples of queries and shortened snippets of answer passages from LoTTE. The first two examples show "search" queries, whereas the last two are "forum" queries. Snippets are shortened for presentation.

These queries tend to have a wider variety than the "search" queries, while the search queries may exhibit more natural patterns. Table 3 compares a random samples of search and forum queries. It can be seen that search queries tend to be brief, knowledge-based questions with direct answers, whereas forum queries tend to reflect more open-ended questions. Both query sets target topics that exceed the scope of a general-purpose knowledge repository such as Wikipedia.

For search as well as forum queries, the resulting evaluation set consists of a query and a target set of StackExchange answer posts (in particular, the answer posts from the target StackExchange page). Similar to evaluation in the Open-QA literature (Karpukhin et al., 2020; Khattab et al.,

Q: *what is xerror in rpart?* **Q:** *is sub question one word?* **Q:** *how to open a garage door without making noise?* **Q:** *is docx and dotx the same?* **Q:** *are upvotes and downvotes anonymous?* **Q:** *what is the difference between descriptive essay and narrative essay?* **Q:** *how to change default user profile in chrome?* **Q:** *does autohotkey need to be installed?* **Q:** *how do you tag someone on facebook with a youtube video?* **Q:** *has mjolnir ever been broken?*
Q: *Snoopy can balance on an edge atop his doghouse. Is any reason given for this?* **Q:** *How many Ents were at the Entmoot?* **Q:** *What does a hexagonal sun tell us about the camera lens/sensor?* **Q:** *Should I simply ignore it if authors assume that Im male in their response to my review of their article?* **Q:** *Why is the 2s orbital lower in energy than the 2p orbital when the electrons in 2s are usually farther from the nucleus?* **Q:** *Are there reasons to use colour filters with digital cameras?* **Q:** *How does the current know how much to flow, before having seen the resistor?* **Q:** *What is the difference between Fact and Truth?* **Q:** *hAs a DM, how can I handle my Druid spying on everything with Wild shape as a spider?* **Q:** *What does 1x1 convolution mean in a neural network?*

Table 3: Comparison of a random sample of search queries (top) vs. forum queries (bottom).

Table 4: In-domain performance on the development set of MS MARCO Passage Ranking as well the "Local Eval" test set described by Khattab and Zaharia (2020). Dev-set results for baseline systems are from their respective papers: Zhan et al. (2020b), Xiong et al. (2020) for DPR and ANCE, Zhan et al. (2020a), Khattab and Zaharia (2020), Hofstätter et al. (2021), Gao and Callan (2021), Ren et al. (2021a), Formal et al. (2021a), and Ren et al. (2021b).

2021b), we evaluate retrieval quality by computing the `success@5` (S@5) metric. Specifically, we award a point to the system for each query where it finds an accepted or upvoted (score ≥ 1) answer from the target page in the top-5 hits.

Appendix D reports on the breakdown of constituent communities per topic, the construction procedure of LoTTE as well as licensing considerations, and relevant statistics. Figures 5 and 6 quantitatively compare the search and forum queries.

5 Evaluation

We now evaluate ColBERTv2 on passage retrieval tasks, testing its quality within the training domain (§5.1) as well as outside the training domain in zero-shot settings (§5.2). Unless otherwise stated, we compress ColBERTv2 embeddings to $b = 2$ bits per dimension in our evaluation.

5.1 In-Domain Retrieval Quality

Similar to related work, we train for IR tasks on MS MARCO Passage Ranking (Nguyen et al., 2016). Within the training domain, our development-set results are shown in Table 4, comparing ColBERTv2 with vanilla ColBERT as well as state-of-the-art single-vector systems.

While ColBERT outperforms single-vector systems like RepBERT, ANCE, and even TAS-B, improvements in supervision such as distillation from cross-encoders enable systems like SPLADEv2, PAIR, and RocketQAv2 to achieve higher quality than vanilla ColBERT. These supervision gains challenge the value of fine-grained late interaction, and it is not inherently clear whether the stronger inductive biases of ColBERT-like models permit it to accept similar gains under distillation, especially when using compressed representations. Despite this, we find that with denoised supervision and residual compression, ColBERTv2 achieves the highest quality across all systems. As we discuss in §5.3, it exhibits space footprint competitive with these single-vector models and much lower than vanilla ColBERT.

Besides the official dev set, we evaluated ColBERTv2, SPLADEv2, and RocketQAv2 on the "Local Eval" test set described by Khattab and Zaharia (2020) for MS MARCO, which consists of 5000 queries disjoint with the training and the official dev sets. These queries are obtained from labeled 50k queries that are provided in the official MS MARCO Passage Ranking task as additional validation data.[4] On this test set, ColBERTv2 obtains 40.8% MRR@10, considerably outperforming the baselines, including RocketQAv2 which makes use of document titles in addition to the passage text unlike the other systems.

---

[4] These are sampled from delta between `qrels.dev.tsv` and `qrels.dev.small.tsv` on `https://microsoft.github.io/msmarco/Datasets`. We refer to Khattab and Zaharia (2020) for details. All our query IDs will be made public to aid reproducibility.

(b)

Table 5: Zero-shot evaluation results. Sub-table (a) reports results on BEIR and sub-table (b) reports results on the Wikipedia Open QA and the test sets of the LoTTE benchmark. On BEIR, we test ColBERTv2 and RocketQAv2 and copy the results for ANCE, TAS-B, and ColBERT from Thakur et al. (2021), for MoDIR and DPR-MSMARCO (DPR-M) from Xin et al. (2021), and for SPLADEv2 from Formal et al. (2021a).

5.2 Out-of-Domain Retrieval Quality

Next, we evaluate ColBERTv2 outside the training domain using BEIR (Thakur et al., 2021), Wikipedia Open QA retrieval as in Khattab et al. (2021b), and LoTTE. We compare against a wide range of recent and state-of-the-art retrieval systems from the literature.

BEIR. We start with BEIR, reporting the quality of models that do not incorporate distillation from cross-encoders, namely, ColBERT (Khattab and Zaharia, 2020), DPR-MARCO (Xin et al., 2021), ANCE (Xiong et al., 2020), and MoDIR (Xin et al., 2021), as well as models that do utilize distillation, namely, TAS-B (Hofstätter et al., 2021), SPLADEv2 (Formal et al., 2021a), and also RocketQAv2, which we test ourselves using the official checkpoint trained on MS MARCO. We divide the table into "search" (i.e., natural queries and questions) and "semantic relatednes" (e.g., citation-relatedness and claim verification) tasks to reflect the nature of queries in each dataset.[5]

Table 5a reports results with the official nDCG@10 metric. Among the models without distillation, we see that the vanilla ColBERT model outperforms the single-vector systems DPR, ANCE, and MoDIR across all but three tasks. ColBERT often outpaces all three systems by large margins and, in fact, outperforms the TAS-B model, which utilizes distillation, on most datasets. Shifting our attention to models with distillation, we see a similar pattern: while distillation-based models are generally stronger than their vanilla counterparts, the models that decompose scoring into term-level interactions, ColBERTv2 and SPLADEv2, are almost always the strongest.

Looking more closely into the comparison between SPLADEv2 and ColBERTv2, we see that ColBERTv2 has an advantage on six benchmarks and ties SPLADEv2 on two, with the largest improvements attained on NQ, TREC-COVID, and FiQA-2018, all of which feature natural search queries. On the other hand, SPLADEv2 has the lead on five benchmarks, displaying the largest gains on Climate-FEVER (C-FEVER) and HotPotQA. In C-FEVER, the input queries are sentences making climate-related claims and, as a result, do not reflect the typical characteristics of search queries. In HotPotQA, queries are written by crowdworkers who have access to the target pas-

---

[5] Following Formal et al. (2021a), we conduct our evaluationg using the publicly-available datasets in BEIR. Refer to §E for details.

sages. This is known to lead to artificial lexical bias (Lee et al., 2019), where crowdworkers copy terms from the passages into their questions as in the Open-SQuAD benchmark.

Wikipedia Open QA. As a further test of out-of-domain generalization, we evaluate the MS MARCO-trained ColBERTv2, SPLADEv2, and vanilla ColBERT on retrieval for open-domain question answering, similar to the out-of-domain setting of Khattab et al. (2021b). We report Success@5 (sometimes referred to as Recall@5), which is the percentage of questions whose short answer string overlaps with one or more of the top-5 passages. For the queries, we use the development set questions of the open-domain versions (Lee et al., 2019; Karpukhin et al., 2020) of Natural Questions (NQ; Kwiatkowski et al. 2019), TriviaQA (TQ; Joshi et al. 2017), and SQuAD (Rajpurkar et al., 2016) datasets in Table 5b. As a baseline, we include the BM25 (Robertson et al., 1995) results using the Anserini (Yang et al., 2018a) toolkit. We observe that ColBERTv2 outperforms BM25, vanilla ColBERT, and SPLADEv2 across the three query sets, with improvements of up to 4.6 points over SPLADEv2.

LoTTE. Next, we analyze performance on the LoTTE test benchmark, which focuses on natural queries over long-tail topics and exhibits a different annotation pattern to the datasets in the previous OOD evaluations. In particular, LoTTE uses automatic Google rankings (for the "search" queries) and organic StackExchange question–answer pairs (for "forum" queries), complimenting the pooling-based annotation of datasets like TREC-COVID (in BEIR) and the answer overlap metrics of Open-QA retrieval. We report Success@5 for each corpus on both search queries and forum queries.

Overall, we see that ANCE and vanilla ColBERT outperform BM25 on all topics, and that the three methods using distillation are generally the strongest. Similar to the Wikipedia-OpenQA results, we find that ColBERTv2 outperforms the baselines across all topics for both query types, improving upon SPLADEv2 and RocketQAv2 by up to 3.7 and 8.1 points, respectively. Considering the baselines, we observe that while RocketQAv2 tends to have a slight advantage over SPLADEv2 on the "search" queries, SPLADEv2 is considerably more effective on the "forum" tests. We hypothesize that the search queries, obtained from Google (through GooAQ) are more similar to MS MARCO than the forum queries and, as a result, the latter stresses generalization more heavily, rewarding term-decomposed models like SPLADEv2 and ColBERTv2.

5.3 Efficiency

ColBERTv2's residual compression approach significantly reduces index sizes compared to vanilla ColBERT. Whereas ColBERT requires 154 GiB to store the index for MS MARCO, ColBERTv2 only requires 16 GiB or 25 GiB when compressing embeddings to 1 or 2 bit(s) per dimension, respectively, resulting in compression ratios of 6–10×. This storage figure includes 4.5 GiB for storing the inverted list.

This matches the storage for a typical single-vector model on MS MARCO, with 4-byte lossless floating-point storage for one 768-dimensional vector for each of the 9M passages amounting to a little over 25 GiBs. In practice, the storage for a single-vector model could be even larger when using a nearest-neighbor index like HNSW for fast search. Conversely, single-vector representations could be themselves compressed very aggressively (Zhan et al., 2021a, 2022), though often exacerbating the loss in quality relative to late interaction methods like ColBERTv2.

We discuss the impact of our compression method on search quality in Appendix B and present query latency results on the order of 50–250 milliseconds per query in Appendix C.

6 Conclusion

We introduced ColBERTv2, a retriever that advances the quality and space efficiency of multi-vector representations. We hypothesized that cluster centroids capture context-aware semantics of the token-level representations and proposed a residual representation that leverages these patterns to dramatically reduce the footprint of multi-vector systems *off-the-shelf.* We then explored improved supervision for multi-vector retrieval and found that their quality improves considerably upon distillation from a cross-encoder system. The proposed ColBERTv2 considerably outperforms existing retrievers in within-domain and out-of-domain evaluations, which we conducted extensively across 28 datasets, establishing state-of-the-art quality while exhibiting competitive space footprint.

Broader Impact & Ethical Considerations

This work is primarily an effort toward retrieval models that generalize better while performing reasonably efficiently in terms of space consumption. Strong out-of-the-box generalization to small domain-specific applications can serve many users in practice, particularly where training data is not available. Moreover, retrieval holds significant promise for many downstream NLP tasks, as it can help make language models smaller and thus more efficient (i.e., by decoupling knowledge from computation), more transparent (i.e., by allowing users to check the sources the model relied on when making a claim or prediction), and easier to update (i.e., by allowing developers to replace or add documents to the corpus without retraining the model) (Guu et al., 2020; Borgeaud et al., 2021; Khattab et al., 2021a). Nonetheless, such work poses risks in terms of misuse, particularly toward misinformation, as retrieval can surface results that are relevant yet inaccurate, depending on the contents of a corpus. Moreover, generalization from training on a large-scale dataset can propagate the biases of that dataset well beyond its typical reach to new domains and applications.

While our contributions have made ColBERT's late interaction more efficient at storage costs, large-scale distillation with hard negatives increases system complexity and accordingly increases training cost, when compared with the straightforward training paradigm of the original ColBERT model. While ColBERTv2 is efficient in terms of latency and storage at inference time, we suspect that under extreme resource constraints, simpler model designs like SPLADEv2 or RocketQAv2 could lend themselves to easier-to-optimize environments. We leave low-level systems optimizations of all systems to future work. Another worthwhile dimension for future exploration of tradeoffs is reranking architectures over various systems with cross-encoders, which are known to be expensive yet precise due to their highly expressive capacity.

Research Limitations

While we evaluate ColBERTv2 on a wide range of tests, all of our benchmarks are in English and, in line with related work, our out-of-domain tests evaluate models that are trained on MS MARCO. We expect our approach to work effectively for other languages and when all models are trained using other, smaller training set (e.g., NaturalQuestions), but we leave such tests to future work.

We have observed consistent gains for ColBERTv2 against existing state-of-the-art systems across many diverse settings. Despite this, almost all IR datasets contain false negatives (i.e., relevant but unlabeled passages) and thus some caution is needed in interpreting any individual result. Nonetheless, we intentionally sought out benchmarks with dissimilar annotation biases: for instance, TREC-COVID (in BEIR) annotates the pool of documents retrieved by the systems submitted at the time of the competition, LoTTE uses automatic Google rankings (for "search" queries) and StackExchange question–answer pairs (for "forum" queries), and the Open-QA tests rely on passage-answer overlap for factoid questions. ColBERTv2 performed well in all of these settings. We discuss other issues pertinent to LoTTE in Appendix §D.

We have compared with a wide range of strong baselines—including sparse retrieval and single-vector models—and found reliable patterns across tests. However, we caution that empirical trends can change as innovations are introduced to each of these families of models and that it can be difficult to ensure exact apple-to-apple comparisons across families of models, since each of them calls for different sophisticated tuning strategies. We thus primarily used results and models from the rich recent literature on these problems, with models like RocketQAv2 and SPLADEv2.

On the representational side, we focus on reducing the storage cost using residual compression, achieving strong gains in reducing footprint while largely preserving quality. Nonetheless, we have not exhausted the space of more sophisticated optimizations possible, and we would expect more sophisticated forms of residual compression and composing our approach with dropping tokens (Zhou and Devlin, 2021) to open up possibilities for further reductions in space footprint.

(a) Number of distinct tokens appearing in each cluster.

(b) Number of distinct clusters each token appears in.

Figure 2: Empirical CDFs analyzing semantic properties of MS MARCO token-level embeddings both encoded by ColBERT and randomly generated. The embeddings are partitioned into 2^{18} clusters and correspond to roughly 27,000 distinct tokens.

A Analysis of ColBERT's Semantic Space

ColBERT (Khattab and Zaharia, 2020) decomposes representations and similarity computation at the token level. Because of this compositional architecture, we hypothesize that ColBERT exhibits a "lightweight" semantic space: without any special re-training, vectors corresponding to each sense of a word would cluster very closely, with only minor variation due to context.

If this hypothesis is true, we would expect the embeddings corresponding to each token in the vocabulary to localize in only a small number of regions in the embedding space, corresponding to the contextual "senses" of the token. To validate this hypothesis, we analyze the ColBERT embeddings corresponding to the tokens in the MS MARCO Passage Ranking (Nguyen et al., 2016) collection: we perform k-means clustering on the nearly 600M embeddings—corresponding to 27,000 unique tokens—into $k = 2^{18}$ clusters. As a baseline, we repeat this clustering with random embeddings but keep the true distribution of tokens. Figure 2 presents empirical cumulative distribution function (eCDF) plots representing the number of distinct non-stopword tokens appearing in each cluster (2a) and the number of distinct clusters in which each token appears (2b).[6] Most tokens appear in a very small fraction of the number of centroids: in particular, we see that roughly 90% of clusters have ≤ 16 distinct tokens with the ColBERT embeddings, whereas less than 50% of clusters have ≤ 16 distinct tokens with the random embeddings. This suggests that the centroids effectively map the ColBERT semantic space.

Table 6 presents examples to highlight the semantic space captured by the centroids. The most frequently appearing tokens in cluster #917 relate to photography; these include, for example, 'photos' and 'photographs'. If we then examine the additional clusters in which these tokens appear, we find that there is substantial semantic overlap between these new clusters (e.g., Photos-Photo, Photo-Image-Picture) and cluster #917. We observe a similar effect with tokens appearing in cluster #216932, comprising tornado-related terms.

This analysis indicates that cluster centroids can summarize the ColBERT representations with high precision. In §3.3, we propose a residual compression mechanism that uses these centroids along with minor refinements at the dimension level to efficiently encode late-interaction vectors.

B Impact of Compression

Our residual compression approach (§3.3) preserves approximately the same quality as the uncompressed embeddings. In particular, when applied to a vanilla ColBERT model on MS MARCO whose MRR@10 is 36.2% and Recall@50 is 82.1%, the quality of the model with 2-bit compression is 36.2% MRR@10 and 82.3% Recall@50. With 1-bit compression, the model achieves 35.5% MRR@10 and 81.6% Recall@50.[7]

We also tested the residual compression approach on late-interaction retrievers that conduct downstream tasks, namely, ColBERT-QA (Khattab et al., 2021b) for the NaturalQuestions open-domain QA task, and Baleen (Khattab et al., 2021a) for multi-hop reasoning on HoVer for claim verification. On the NQ dev set, ColBERT-QA's success@5 (success@20) dropped only marginally from 75.3% (84.3%) to 74.3% (84.2%) and its downstream Open-QA answer exact match dropped from 47.9% to 47.7%, when using 2-bit compression for retrieval and using the same checkpoints of ColBERT-QA otherwise.

---

[6] We rank tokens by number of clusters they appear in and designate the top-1% (under 300) as stopwords.

[7] We contrast this with an early implementation of compression for ColBERT, which used binary representations as in BPR (Yamada et al., 2021a) without residual centroids, and achieves 34.8% (35.7%) MRR@10 and 80.5% (81.8%) Recall@50 with 1-bit (2-bit) binarization. Like the original ColBERT, this form of compression relied on a separate FAISS index for candidate generation.

Cluster ID	Most Common Tokens	Most Common Clusters Per Token	
		Token	Clusters
917	‘photos’, ‘photo’, ‘pictures’, ‘photographs’, ‘images’, ‘photography’, ‘photograph’	‘photos’	Photos-Photo, Photos-Pictures-Photo
		‘photo’	Photo-Image-Picture, Photo-Picture-Photograph, Photo-Picture-Photography
		‘pictures’	Pictures-Picture-Images, Picture-Pictures-Artists, Pictures-Photo-Picture
216932	‘tornado’, ‘tornadoes’, ‘storm’ ‘hurricane’, ‘storms’	‘tornado’	Tornado-Hurricane-Storm, Tornadoes-Tornado-Blizzard
		‘tornadoes’	Tornadoes-Tornado-Storms, Tornadoes-Tornado-Blizzard, Tornado-Hurricane-Storm
		‘storm’	Storm-Storms, Storm-Storms-Weather, Storm-Storms-Tempest

Table 6: Examples of clusters taken from all MS MARCO passages. We present the tokens that appear most frequently in the selected clusters as well as additional clusters the top tokens appear in.

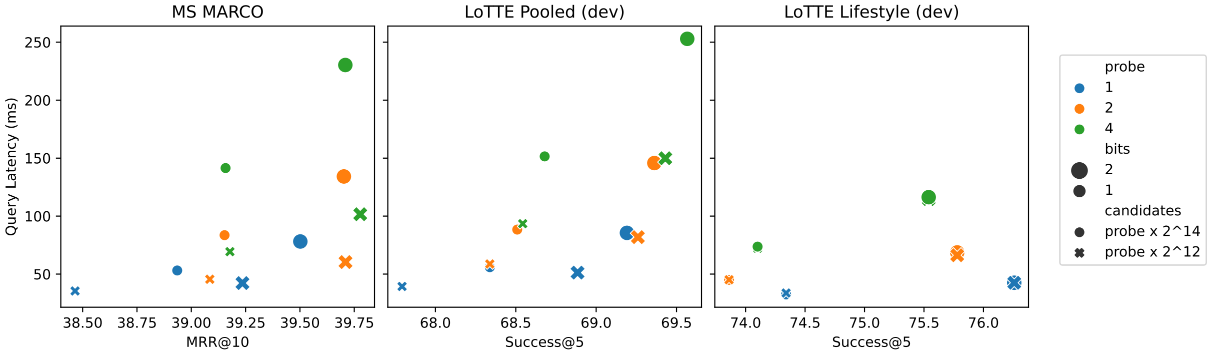

Figure 3: Latency vs. retrieval quality with varying parameter configurations for three datasets of different collection sizes. We sweep a range of values for the number of centroids per vector (`probe`), the number of bits used for residual compression, and the number of candidates. Note that retrieval quality is measured in MRR@10 for MS MARCO and Success@5 for LoTTE datasets. Results toward the bottom right corner (higher quality, lower latency) are best.

Similarly, on the HoVer (Jiang et al., 2020) dev set, Baleen's retrieval R@100 dropped from 92.2% to only 90.6% but its sentence-level exact match remained roughly the same, going from 39.2% to 39.4%. We hypothesize that the supervision methods applied in ColBERTv2 (§3.2) can also be applied to lift quality in downstream tasks by improving the recall of retrieval for these tasks. We leave such exploration for future work.

C Retrieval Latency

Figure 3 evaluates the latency of ColBERTv2 across three collections of varying sizes, namely, MS MARCO, LoTTE Pooled (dev), and LoTTE Lifestyle (dev), which contain approximately 9M passages, 2.4M answer posts, and 270k answer posts, respectively. We average latency across three runs of the MS MARCO dev set and the LoTTE "search" queries. Search is executed using a Titan V GPU on a server with two Intel Xeon Gold 6132 CPUs, each with 28 hardware execution contexts.

The figure varies three settings of ColBERTv2. In particular, we evaluate indexing with 1-bit and 2-bit encoding (§3.4) and searching by probing the nearest 1, 2, or 4 centroids to each query vector (§3.5). When probing `probe` centroids per vector, we score either `probe` $\times 2^{12}$ or `probe` $\times 2^{14}$ candidates per query.[8]

To begin with, we notice that the quality reported on the x-axis varies only within a relatively narrow range. For instance, the axis ranges from 38.50 through 39.75 for MS MARCO, and all but two of the cheapest settings score above 39.00. Similarly, the y-axis varies between approximately 50 milliseconds per query up to 250 milliseconds (mostly under 150 milliseconds) using our relatively simple Python-based implementation.

Digging deeper, we see that the best quality in these metrics can be achieved or approached closely with around 100 milliseconds of latency across all three datasets, despite their various sizes and characteristics, and that 2-bit indexing reliably outperforms 1-bit indexing but the loss from more aggressive compression is small.

D LoTTE

Domain coverage Table 9 presents the full distribution of communities in the LoTTE dev dataset.

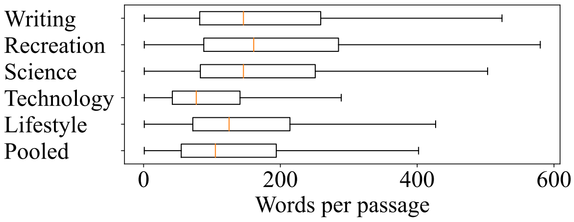

Figure 4: LoTTE words per passage

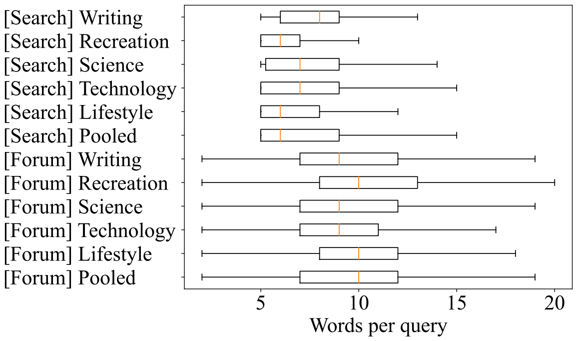

Figure 5: LoTTE words per query

The topics covered by LoTTE cover a wide range of linguistic phenomena given the diversity in topics and communities represented. However, since all posts are submitted by anonymous users we do not have demographic information regarding the identify of the contributors. All posts are written in English.

Passages As mentioned in §4, we construct LoTTE collections by selecting passages from the StackExchange archive with positive scores. We remove HTML tags from passages and filter out empty passages. For each passage we record its corresponding query and save the query-to-passage mapping to keep track of the posted answers corresponding to each query.

Search queries We construct the list of LoTTE search queries by drawing from GooAQ queries that appear in the StackExchange post archive. We first shuffle the list of GooAQ queries so that in cases where multiple queries exist for the same answer passage we randomly select the query to include in LoTTE rather than always selecting the first appearing query. We verify that every query has at least one corresponding answer passage.

Forum queries For each LoTTE topic and its constituent communities we first compute the fraction of the total queries attributed to each individual community. We then use this distribution to construct a truncated query set by selecting the

---

[8] These settings are selected based on preliminary exploration of these parameters, which indicated that performance for larger `probe` values tends to require scoring a larger number of candidates.

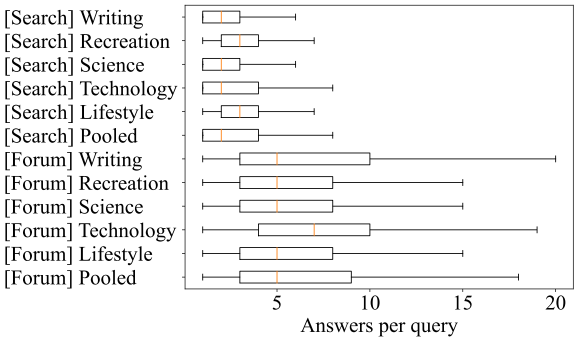

Figure 6: LoTTE answers per query

Corpus	ColBERT	BM25	ANCE	RocketQAv2	SPLADEv2	ColBERTv2

Pooled	59.1	47.8	57.4	58.9	60.6	**63.7**

Table 7: Zero-shot evaluation results on the dev sets of the LoTTE benchmark.

highest ranked queries from each community as determined by 1) the query scores and 2) the query view counts. We only use queries which have an accepted answer. We ensure that each community contributes at least 50 queries to the truncated set whenever possible. We set the overall size of the truncated set to be 2000 queries, though note that the total can exceed this due to rounding and/or the minimum per-community query count. We remove all quotation marks and HTML tags.

Statistics Figure 4 plots the number of words per passage in each LoTTE dev corpus. Figures 5 and 6 plot the number of words and number of corresponding answer passages respectively per query, split across search and forum queries.

Dev Results Table 7 presents out-of-domain evaluation results on the LoTTE dev queries. Continuing the trend we observed in 5, ColBERTv2 consistently outperforms all other models we tested.

Licensing and Anonymity The original StackExchange post archive is licensed under a Creative Commons BY-SA 4.0 license (sta). Personal data is removed from the archive before being uploaded, though all posts are public; when we release LoTTE publicly we will include URLs to the original posts for proper attribution as required by the license. The GooAQ dataset is licensed under an Apache license, version 2.0 (Khashabi et al., 2021). We will also release LoTTE with a CC BY-SA 4.0 license. E Datasets in BEIR

Table 8 lists the BEIR datasets we used in our evaluation, including their respective license information as well as the numbers of documents as well as the number of test set queries. We refer to Thakur et al. (2021) for a more detailed description of each of the datasets.

Our Touché evaluation uses an updated version of the data in BEIR, which we use for evaluating the models we run (i.e., ColBERTv2 and RocketQAv2) as well as SPLADEv2.

Table 8: BEIR dataset information.

We also tested on the Open-QA benchmarks NQ, TQ, and SQuAD, each of which has approximately 9k dev-set questions and muli-hop HoVer, whose development set has 4k claims. In the compression evaluation §B, we used models trained in-domain on NQ and HoVer, whose training sets contain 79k and 18k queries, respectively.

F Implementation & Hyperparameters

We implement ColBERTv2 using Python 3.7, PyTorch 1.9, and HuggingFace Transformers 4.10 (Wolf et al., 2020), extending the original implementation of ColBERT by Khattab and Zaharia (2020). We use FAISS 1.7 (Johnson et al., 2019) for

k-means clustering,[9] though unlike ColBERT we do not use it for nearest-neighbor search. Instead, we implement our candidate generation mechanism (§3.5) using PyTorch primitives in Python.

We conducted our experiments on an internal cluster, typically using up to four 12GB Titan V GPUs for each of the inference tasks (e.g., indexing, computing distillation scores, and retrieval) and four 80GB A100 GPUs for training, though GPUs with smaller RAM can be used via gradient accumulation. Using this infrastructure, computing the distillation scores takes under a day, training a 64-way model on MS MARCO for 400,000 steps takes around five days, and indexing takes approximately two hours. We very roughly estimate an upper bound total of 20 GPU-months for all experimentation, development, and evaluation performed for this work over a period of several months.

Like ColBERT, our encoder is a `bert-base-uncased` model that is shared between the query and passage encoders and which has 110M parameters. We retain the default vector dimension suggested by Khattab and Zaharia (2020) and used in subsequent work, namely, d=128. For the experiments reported in this paper, we train on MS MARCO training set. We use simple defaults with limited manual exploration on the official development set for the learning rate (10^{-5}), batch size (32 examples), and warm up (for 20,000 steps) with linear decay.

Hyperparameters corresponding to retrieval are explored in §C. We default to `probe` $= 2$, but use `probe` $= 4$ on the largest datasets, namely, MS MARCO and Wikipedia. By default we set `candidates` $=$ `probe` $* 2^{12}$, but for Wikipedia we set `candidates` $=$ `probe` $* 2^{13}$ and for MS MARCO we set `candidates` $=$ `probe` $* 2^{14}$. We leave extensive tuning of hyperparameters to future work.

We train on MS MARCO using 64-way tuples for distillation, sampling them from the top-500 retrieved passages per query. The training set of MS MARCO contains approximately 800k queries, though only about 500k have associated labels. We apply distillation using all 800k queries, where each training example contains exactly one "positive", defined as a passage labeled as positive or the top-ranked passage by the cross-encoder teacher, irrespective of its label.

We train for 400k steps, initializing from a pre-finetuned checkpoint using 32-way training examples and 150k steps. To generate the top-k passages per training query, we apply two rounds, following Khattab et al. (2021b). We start from a model trained with hard triples (akin to Khattab et al. (2021b)), train with distillation, and then use the distilled model to retrieve for the second round of training. Preliminary experiments indicate that quality has low sensitivity to this initialization and two-round training, suggesting that both of them could be avoided to reduce the cost of training.

Unless otherwise stated, the results shown represent a single run. The latency results in §3 are averages of three runs. To evaluate for Open-QA retrieval, we use evaluation scripts from Khattab et al. (2021b), which checks if the short answer string appears in the (titled) Wikipedia passage. This adapts the DPR (Karpukhin et al., 2020) evaluation code.[10] We use the preprocessed Wikipedia Dec 2018 dump released by Karpukhin et al. (2020).

For out-of-domain evaluation, we elected to follow Thakur et al. (2021) and set the maximum document length of ColBERT, RocketQAv2, and ColBERTv2 to 300 tokens on BEIR and LoTTE. Formal et al. (2021a) selected maximum sequence length 256 for SPLADEv2 both on MS MARCO and on BEIR for both queries and documents, and we retained this default when testing their system on LoTTE. Unless otherwise stated, we keep the default query maximum sequence length for ColBERTv2 and RocketQAv2, which is 32 tokens. For the ArguAna test in BEIR, as the queries are themselves long documents, we set the maximum query length used by ColBERTv2 and RocketQAv2 to 300. For Climate-FEVER, as the queries are relatively long sentence claims, we set the maximum query length used by ColBERTv2 to 64.

We use the open source BEIR implementation[11] and SPLADEv2 evaluation[12] code as the basis for our evaluations of SPLADEv2 and ANCE as well as for BM25 on LoTTE. We use the Anserini (Yang et al., 2018a) toolkit for BM25 on the Wikipedia Open-QA retrieval tests as in Khattab et al. (2021b). We use the implementation developed by the RocketQAv2 authors for evaluating RocketQAv2.[13]

Quantifying Language Variation Acoustically with Few Resources

Abstract

Deep acoustic models represent linguistic information based on massive amounts of data. Unfortunately, for regional languages and dialects such resources are mostly not available. However, deep acoustic models might have learned linguistic information that transfers to low-resource languages. In this study, we evaluate whether this is the case through the task of distinguishing low-resource (Dutch) regional varieties. By extracting embeddings from the hidden layers of various `wav2vec 2.0` models (including new models which are pre-trained and/or fine-tuned on Dutch) and using dynamic time warping, we compute pairwise pronunciation differences averaged over 10 words for over 100 individual dialects from four (regional) languages. We then cluster the resulting difference matrix in four groups and compare these to a gold standard, and a partitioning on the basis of comparing phonetic transcriptions. Our results show that acoustic models outperform the (traditional) transcription-based approach without requiring phonetic transcriptions, with the best performance achieved by the multilingual `XLSR-53` model fine-tuned on Dutch. On the basis of only six seconds of speech, the resulting clustering closely matches the gold standard.

1 Introduction

Deep acoustic models have improved automatic speech recognition (ASR) substantially in recent years (Schneider et al., 2019; Baevski et al., 2020a,b; Conneau et al., 2020). These models represent linguistic information based on massive amounts of data. While these models are generally evaluated on ASR benchmarks, few studies have addressed what kind of linguistic information is represented by them. The work of Pasad et al. (2021) examined information represented by the `wav2vec 2.0` model (Baevski et al., 2020b) across the various Transformer layers. They showed that different layers encode different types of linguistic information. Specifically, the initial layers appeared to be most similar to the input speech features, whereas the middle layers mostly encoded contextual information. The final layers again turned out to be similar to the input speech features. However, the representations of the final layers changed when the model was fine-tuned, likely because task-specific information was learned. In addition, Ma et al. (2021) investigated several deep acoustic models using phonetic probing tasks, and found that representations from these models capture information useful for distinguishing English phones. Importantly, these deep acoustic models were better able to distinguish English phones than using conventional MFCC or filterbank features. Although they evaluated the transferability of deep acoustic representations across several domains, it remains unclear whether these models learned information that transfers to other languages. This is, however, important when working on more inclusive speech technology. Especially when resources for training these models are lacking, such as for regional languages and dialects. In this paper, we therefore investigate if hidden layers of deep acoustic models incorporate fine-grained information, which can be used to represent differences between, and in turn distinguish, regional language varieties.

Past work on investigating language variation has often been based on computing pronunciation distances that rely on phonetically transcribed speech (Nerbonne and Heeringa, 1997; Livescu and Glass, 2000; Heeringa, 2004). These (edit) distances have been found to match perceptual judgements of similarity well (Gooskens and Heeringa, 2004; Wieling et al., 2014). However, transcribing speech phonetically is time-consuming and prone to errors (Bucholtz, 2007; Novotney and Callison-Burch, 2010). While automatic approaches for computing phonetic transcriptions exist (e.g., Li et al. 2020), they produce lower quality phonetic

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3735 - 3741
July 10-15, 2022 ©2022 Association for Computational Linguistics

transcriptions than human transcribers do. Additionally, (discrete) phonetic transcriptions do not capture all (continuous) aspects of human speech (Liberman, 2018).

To mitigate these shortcomings, acoustic approaches have been developed for investigating language variation (Huckvale, 2007; Ferragne and Pellegrino, 2010; Strycharczuk et al., 2020; Bartelds et al., 2020). However, these studies either exclusively focused on the vowels (ignoring differences in the consonants), or were negatively influenced by non-linguistic variation in the speech signal.

Recently, Bartelds et al. (2022) found that representations from the hidden layers of pre-trained and fine-tuned `wav2vec 2.0` (large) models are suitable to represent language variation. They showed that these representations capture linguistic information that is not represented by phonetic transcriptions, while being less sensitive to non-linguistic variation in the speech signal. Furthermore, this approach seems to provide a better match to human perceptual judgements than phonetic transcription-based approaches.

To investigate if `wav2vec 2.0` acoustic models (including newly trained Dutch models) learn fine-grained linguistic information that can transfer to regional languages and dialects, we will assess whether or not regional languages and dialects spoken in the Netherlands can be distinguished using these models. Our code and newly trained models are publicly available.[1]

2 Dataset

We use Dutch dialect pronunciation recordings from the Goeman-Taeldeman-Van Reenen-Project (Goeman and Taeldeman, 1996). Audio recordings of hundreds of words were obtained (and manually phonetically transcribed) in the 1980s and 1990s and are available for 613 dialect varieties in the Netherlands and Belgium. Unfortunately, the hour-long audio recordings were not segmented, and the metadata with the time stamps we use to extract the audio containing individual word pronunciations were only partially available. In total, therefore, we extract the acoustic recordings (judged to be of sufficient quality) for 10 words (*armen*: ‘arms’, *deeg*: ‘dough’, *draden*: ‘wires’, *duiven*: ‘pigeons’, *naalden*: ‘needles’, *ogen*: ‘eyes’, *pijpen*: ‘pipes’, *tangen*: ‘pliers’, *volk*: ‘people’, *vuur*: ‘fire’) pronounced in 106 locations in the Netherlands. On average, the duration of these 10 words is only 6.3 seconds for each location. Some example pronunciations are shown in Table 1.

	Standard Dutch	**Frisian** (Joure)	**Low Saxon** (Eelde)	**Limburgish** (Echt)
Arms	ɑrəmən	jɛrəmən	ʔaɹms	æʁəm
Dough	deɪx	deiç	dɛix	deix
Wires	dradən	trɪdn	drɔdn	dʀɵi

Table 1: Phonetic transcriptions of the words ‘arms’, ‘dough’, and ‘wires’ obtained from three locations where different regional languages (Frisian, Low Saxon, and Limburgish) are spoken, as well as in Standard Dutch. The names of the locations are provided between parentheses.

3 Methods

We compute embeddings from the hidden Transformer layers of three fine-tuned deep acoustic `wav2vec 2.0` large models, and subsequently determine pronunciation differences using dynamic time warping (DTW) with these embeddings (Müller, 2007). We use fine-tuned acoustic models in this study as their hidden representations were found to show the closest match with human perceptual judgements of pronunciation variation (Bartelds et al., 2022). For the transcription-based approach, we apply a (phonetically sensitive) Levenshtein distance algorithm to the available corresponding phonetic transcriptions of the 10 words in all locations. After averaging the word-based differences, the result of both approaches is a distance matrix representing the aggregate pronunciation difference between every pair of locations. Both distance matrices are then clustered in four groups and quantitatively compared to a gold standard clustering of four groups (see Figure 1a). These groups correspond to the three regional languages spoken in the Netherlands that are recognised by the European Charter for Regional or Minority Languages (Frisian: light blue in Figure 1a, Low Saxon: dark blue, Limburgish: light green) and standard Dutch (dark green).

We use the fine-tuned English `wav2vec 2.0` large model (abbreviated as `w2v2-en`) released by Baevski et al. (2020b). In addition, we use a new pre-trained Dutch `wav2vec 2.0` large model that is fine-tuned on Dutch labelled data (abbreviated as `w2v2-nl`), and we use the multilingual `XLSR-53` model of Conneau et al. (2020)

---

[1] `https://github.com/Bartelds/language-variation`

that is fine-tuned on the same Dutch labelled data (`XLSR-nl`). We explicitly use models for Dutch because this language is closely related to the different regional languages and dialects spoken in the Netherlands (including Frisian, Low Saxon, and Limburgish; Eberhard et al., 2021). The advantage of having a Transformer-based language model that is linguistically closest was shown by de Vries et al. (2021), albeit for a different task (i.e. part-of-speech tagging). It may therefore be the case that a high degree of language similarity is also beneficial for Transformer-based models that learn speech representations.

Acoustic models `w2v2-en` is pre-trained on 960 hours of English speech from the Librispeech dataset (Panayotov et al., 2015). The model consists of a convolutional encoder, a quantizer, and a 24-layer Transformer network. Subsequently, the learned representations are fine-tuned on 960 hours of labelled data by adding a randomly initialised linear projection layer on top of the Transformer network. This projection layer is used to predict characters from the labelled data using the connectionist temporal classification loss function (CTC; Graves et al., 2006).

`w2v2-nl` is obtained by further pre-training the English model on 243 hours (cross-talk and silences removed) of Dutch speech from the Spoken Dutch Corpus (Oostdijk, 2000). This approach converged faster in preliminary experiments compared to a randomly initialised network. Subsequently, the model is fine-tuned on the same 243 hours of (now labelled) Dutch speech using CTC. Pre-training is performed for 2 million steps with 100,000 iterations for warm up, and a linearly decreasing learning rate starting at $5e{-}5$. Fine-tuning is performed on labelled data for 1 million steps, with a linearly decreasing learning rate starting at $1e{-}5$. Other configuration details are similar to those reported in Baevski et al. (2020b).

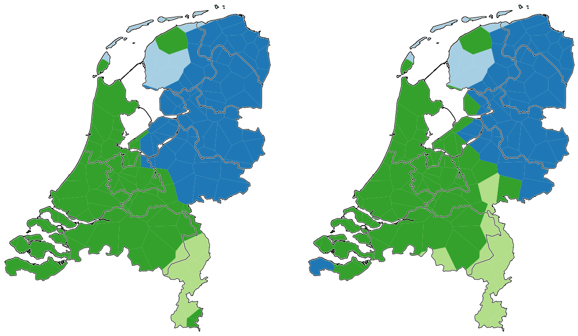
`XLSR-53` has the same architecture as the other acoustic models, except that the quantizer has learned a single set of discrete speech representations that is shared across the pre-training languages (which includes Dutch and German, but not Frisian, Low Saxon or Limburgish). This model is pre-trained on 56,000 hours of speech in 53 languages (44,000 hours consists of English speech) obtained from the BABEL, Common Voice and Multilingual Librispeech datasets (Gales et al., 2014; Ardila et al., 2020; Pratap et al., 2020). To obtain `XLSR-nl`, `XLSR-53` is fine-tuned on the same labelled data as `w2v2-nl` with the same configuration details.

Obtaining pronunciation differences We compute pronunciation differences between all 106 locations in our dataset using both phonetic transcriptions and acoustic embeddings. For determining the phonetic transcription-based distance, we use a variant of the Levenshtein distance (`LD`) algorithm proposed by Wieling et al. (2012), which includes automatically determined phonetic segment distances. This algorithm matches perception well (Wieling et al., 2014) and is often used for investigating dialect variation.

Given a pair of locations, recordings of the same word are compared using `LD` (phonetic transcriptions) or DTW (acoustic embeddings), which is a frequently-used algorithm for comparing representations of acoustic sequences (Senin, 2008). The acoustic embeddings are obtained for each model for each of the 24 layers separately (i.e. to determine the optimal layer). The word-based distances between two locations are averaged to determine the single pronunciation distance between a location pair. This process is repeated for all pairs to create a symmetric distance matrix including all locations.

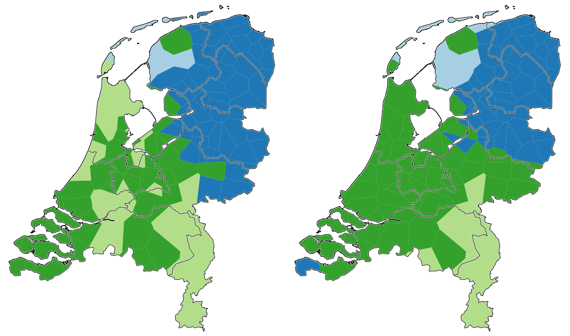
Clustering We classify the phonetic transcription distance matrix and the acoustic distance matrices (three models times 24 layers) from the acoustic embeddings using seven clustering techniques, yielding the four different groups. Of course, the choice of clustering technique may influence the results, but we determine the optimal clustering algorithm by selecting the one best representing the underlying difference matrix. We use clustering techniques that have previously been applied to distance matrices of dialect pronunciations, namely single link (`sl`), complete link (`cl`), group average (`ga`), weighted average (`wa`), unweighted centroid (`uc`), weighted centroid (`wc`) and minimum variance (`mv`) clustering (Heeringa et al., 2002; Prokić and Nerbonne, 2008).

To select the best clustering algorithm, we calculate the cophenetic correlation coefficient (Sokal and Rohlf, 1962). This coefficient represents the (Pearson) correlation between the original distances and the clustering-based cophenetic distances (i.e. extracted from the dendrogram underlying the clustering). Higher values indicate a better



(a) Gold standard clustering (human-generated)

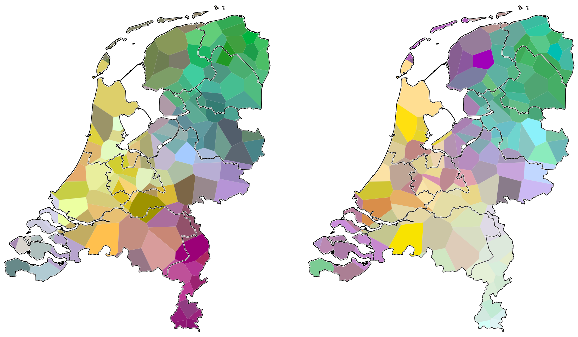
(b) `XLSR-nl` layer 15 (`cl` clustering)



(c) `w2v2-en` layer 13 (`cl` clustering)

(d) `w2v2-nl` layer 16 (`wa` clustering)

Figure 1: Cluster maps visualizing four clusters on the map of the Netherlands. Separate clusters are indicated by the different colours.



(a) `XLSR-nl` layer 15

(b) `LD`

Figure 2: MDS maps visualizing pronunciation differences based on Dutch dialect pronunciations. Similar colours correspond to pronunciations that are also similar.

correspondence between the original data and the clustering (with a value of 1 being perfect). We determine the optimal clustering method for each Transformer layer (for the acoustic models) per model by selecting the one with the highest cophenetic correlation coefficient.

Evaluation We compare the layer-based clustering results per model to the gold standard clustering. We do this by computing the `CDistance` score, which is a clustering comparison measure proposed by Coen et al. (2010). As opposed to other techniques for comparing clustering partitions, this measure incorporates spatial information in the evaluation (i.e. the coordinates of the locations), which is essential for evaluating spatial (i.e. geographical) clustering. The `CDistance` scores (for the optimal clustering method per layer) are compared across the layers for each model. The layer with the lowest score per model (i.e. most closely matching the gold standard clustering) is selected for the comparison of the three models. In addition, we create multidimensional scaling (MDS) maps (Torgerson, 1952) using the best-performing model and compare it to the frequently used `LD` algorithm to show the (more fine-grained) relationship between the geographical location of the locations and the pronunciation differences.

4 Results and discussion

Model	**Layer**	**Clustering**	**CDistance**
`w2v2-en`	13	`cl`	0.34
`w2v2-nl`	16	`wa`	0.34
`XLSR-nl`	15	`cl`	**0.20**
`LD`		`ga`	0.46

Table 2: `CDistance` scores for the different models with the optimal clustering algorithm and output layer (if applicable). Lower scores indicate a better match with the gold standard clustering.

In Table 2, we show the `CDistance` scores associated with the different models. Ideally, the best layer would have been selected using a validation set instead of using all data, but our set of words was unfortunately too small to be adequately split. However, given that the optimal layers reported in Table 2 correspond with the middle hidden layers found to be best representing pronunciation differences in the work of Bartelds et al. (2022), we do not believe this to be problematic.

Our results show that the `XLSR-nl` model with output layer 15 and complete link clustering shows the best performance among the fine-tuned models. Note that the standard deviation of the performance for the `XLSR-nl` model across all Transformer layers was equal to 0.09, which highlights the strong performance of this model over the other models. Importantly, all fine-tuned acoustic models improve over the `LD` algorithm, which is traditionally used to investigate (dialectal) language variation. Perhaps surprisingly, the `w2v2-nl` model performs similar to the `w2v2-en` model. We do not have a clear explanation for this pattern, but it may be caused by the Dutch model being based on the English model, in combination with a smaller amount of Dutch as opposed to English data used for pre-training. In future work we aim to investigate this.

The multilingual `XLSR-nl` model outperforms both monolingual models. The `XLSR-nl` model is pre-trained on a variety of languages, including Dutch, English and German. The regional languages and dialects spoken in the Netherlands have clear links to these three languages (i.e. Frisian has some overlap with English, Low Saxon has some overlap with German, and all varieties overlap with Dutch, which is also the fine-tuning language).

To illustrate, Figure 1 visualizes the gold standard together with the fine-tuned acoustic models. The `XLSR-nl` model clearly classifies pronunciations in the geographical area where Limburgish is spoken (i.e. the light green area) most accurately. While the `XLSR-nl` model does not perfectly distinguish the Low Saxon pronunciations (i.e. the dark blue area), the other models perform worse in this regard.

To evaluate (albeit subjectively) how well more fine-grained differences are captured by the best-performing model, Figure 2 shows the MDS maps for the `XLSR-nl` model, as well as the `LD` algorithm. Both approaches show the relative gradual nature of dialect variation well. However, the `XLSR-nl` model seems to capture the larger distinctions (e.g., delineating the Limburgish area) better than the `LD` algorithm. Based on these evaluations, `XLSR-nl` appears to be the best model when little data is available.

5 Conclusion

We have found that the `XLSR-nl` model can be effectively used to distinguish between language groups in the Netherlands when only a small amount of data is available. It even outperformed the `LD` algorithm, which requires time-consuming phonetic transcriptions. Our study further shows that multilingual pre-training and fine-tuning on a similar language (compared to the target languages) is beneficial over using a monolingual model.

Abstract

State-of-the-art pretrained NLP models contain a hundred million to trillion parameters. Adapters provide a parameter-efficient alternative for the full finetuning in which we can only finetune lightweight neural network layers on top of pretrained weights. Adapter layers are initialized randomly. However, existing work uses the same adapter architecture—i.e., the same adapter layer on top of each layer of the pretrained model—for every dataset, regardless of the properties of the dataset or the amount of available training data. In this work, we introduce adaptable adapters that contain (1) learning different activation functions for different layers and different input data, and (2) a learnable switch to select and only use the beneficial adapter layers. We show that adaptable adapters achieve on-par performances with the standard adapter architecture while using a considerably smaller number of adapter layers. In addition, we show that the selected adapter architecture by adaptable adapters transfers well across different data settings and similar tasks. We propose to use adaptable adapters for designing efficient and effective adapter architectures. The resulting adapters (a) contain about 50% of the learning parameters of the standard adapter and are therefore more efficient at training and inference, and require less storage space, and (b) achieve considerably higher performances in low-data settings.[1]

1 Introduction

Recent improvements in NLP are heavily skewed towards using larger pretrained models (Roberts et al., 2020) and given their considerably better performances, using them is becoming unavoidable (Kaplan et al., 2020). Their improvements, however, come at the cost of significant computational resources at training and inference times. For instance, the number of parameters in recent pretrained models can vary from 110M in BERT-base (Devlin et al., 2019) to 11 billion in T0 (Sanh et al., 2022) to trillion parameters in Switch Transformers (Fedus et al., 2021). Using such models for each downstream application requires a vast amount of storage, training, and inference computation budget that is not accessible to every user.

Instead of fine-tuning these massive numbers of parameters for each downstream task, we can use adapter architectures (Houlsby et al., 2019; Pfeiffer et al., 2020). Adapters are lightweight neural network layers that are added on top of each layer of the pretrained model. As opposed to the standard model fine-tuning, in which all layers are fine-tuned for the target task, adapter-based tuning freezes the transformer layers and only trains the newly added adapter layers. Since the majority of parameters—i.e., the layers of the large pretrained model—are shared between different downstream tasks, the use of adapters results in parameter-efficient transfer learning. In addition to their parameter-efficiency, He et al. (2021) show that training adapter-layers (a) outperforms fine-tuning the whole model on low-data and cross-lingual settings, and (b) is more robust to overfitting.

Existing work suggests that (a) different layers of the pretrained models may capture different aspects of the form, syntax, or meaning of the input text (Tenney et al., 2019; Clark et al., 2019), and (b) they may not be all needed for performing a given task (Houlsby et al., 2019; Fan et al., 2020; Rücklé et al., 2021). In addition, adapter layers are initialized randomly. Therefore, it is not necessary to use the same adapter architecture for different downstream tasks and given different amounts of annotated data. However, existing works use the same adapter architecture for all the different input data, i.e., (a) one adapter layer on top of all the pretrained layers while using all the layers may not be necessary, and (b) the same activation func-

---

*The work has been mostly carried out during the employment at the UKP Lab, TU Darmstadt.

July 10-15, 2022 ©2022 Association for Computational Linguistics

tion for all the layers and different tasks while the best activation function may vary for different tasks (Delfosse et al., 2021).

In this paper, we propose a systematic approach for designing more adequate and flexible adapter architectures by introducing the adaptable adapter (*AA*). Adaptable adapters (1) use a learnable activation function—called Rational activation (Molina et al., 2020)—instead of a constant activation in adapter layers allowing the adapter model to learn different activation functions at different adapter layers and for different tasks, and (2) consist of a learnable switch at each adapter layer to determine the beneficial adapter layers during training and to only use the selected layers during inference.

We evaluate adaptable adapters on the GLUE benchmark (Wang et al., 2018) that consists of various text classification tasks. We perform evaluations based on different data settings in which different amounts of annotated examples are available for training. Our results show that adaptable adapters achieve on-par performances with the full adapter architecture while using considerably fewer adapter layers at the inference.

We further propose to use adaptable adapters for designing efficient adapter architectures—i.e., to only add an adapter layer to the layers that are selected by the adaptable adapter. We show that while the selected adapter architecture by *AA*, called *AA-focused*, is considerably more efficient at both training and inference times and requires less storage, it achieves on-par performances with the full adapter architecture when trained on all available training data and considerably outperforms it on low-data settings. In addition, we show that the selected adapter architecture by *AA* transfers well across similar tasks and different data settings. Therefore, we can train *AA* using a limited amount of training data, and for one of the tasks, and then use the resulting *AA-focused* architecture for different data settings and other similar tasks.

Overall, the contributions of this paper are as follows:

- We propose adaptable adapters that introduce flexibility in adapter architectures by (a) selecting the beneficial adapter layers to use, and (b) learning the suitable activation function for each layer and each task.
- We propose to use adaptable adapters to design efficient adapters that require less training time, inference time, and storage space.
- We show that using fewer adapter layers with a learnable activation function considerably improves the performance on low-data settings.

2 Related Work

2.1 Rational Activation

Rational activation functions, empirically introduced as Padé Activation Units (Molina et al., 2020), are learnable activation functions that can approximate common activation functions as well as learn new ones. The rational activation function $R(x)$ of order m, n is defined as follows:

$$R(x) = \frac{\sum_{j=0}^{m} a_j x^j}{1 + |\sum_{k=1}^{n} b_k x_k|} \tag{1}$$

where a_j and b_k are learnable parameters. These rational functions use an absolute value in the denominator to avoid potential poles, which will make the training unstable. Such rational activation functions provide stable training, as empirically shown in image classification and reinforcement learning (Molina et al., 2020; Delfosse et al., 2021). $R(x)$ can be initialized to initially approximate any of the known activation functions or with constant functions. Molina et al. (2020) show that rationals outperform other commonly used activation functions in common image classification tasks. Rational activation functions are also integrated in Generative Adversarial Networks (Boullé et al., 2020). Delfosse et al. (2021) show that some of the layers in very deep pretrained Residual Networks tend to approximate activation functions' behavior, and we can achieve on-par or better performances with the full network by replacing some of the complete layers with rational activation functions. Similar to this observation, as we show in § 5, using rational activation functions instead of a constant activation (ReLU) in adapters allows them to achieve high accuracy using a fewer number of adapter layers.

2.2 Reducing Model's Size for Efficiency

Improving the efficiency of large pretrained models has received particular attention for the inference time. The argument is that the effect of training cost is limited, i.e., the model can be trained once but it will be used many times. However, the inference time has a wide impact on the everyday use of NLP models.

Existing approaches for improving the inference-time efficiency belong to two different categories:

(a) the distillation and pruning techniques that create a smaller model for inference but often require re-training or fine-tuning the smaller model (Tang et al., 2019; Sanh et al., 2019; Voita et al., 2019; Sun et al., 2020; Bai et al., 2021), and (b) on-demand network size reduction at the inference time.[2] There are two different approaches in the second category, namely layer dropping and early exiting.

Fan et al. (2020) use layer dropping during the training that randomly drops the model's layers to make the model robust to the inference time layer selection. They show that it is possible to select sub-networks of any depth from large models at inference with limited impact on the performance and without the need for additional finetuning. Layer dropping was previously investigated by Huang et al. (2016) who propose to drop layers during training for regularizing the model and reducing the training time of deep convolutional networks. Rücklé et al. (2021) use layer dropping for adapter architectures. They show that by randomly dropping adapter layers during training, they can prune the adapter model on-demand at the inference time.

Schwartz et al. (2020) propose to add an output layer to each transformer layer. At inference time, while the model calculates the layer-wise representation, from the bottom layer to the top layer, it also makes the prediction using the associated classification layer. They use the output labels' scores of the classification layers as confidence scores to decide whether to exit early if the classifier is confident or to proceed to process the input with the next layers. This hierarchical architecture offers an inference time-accuracy tradeoff by setting the confidence threshold. The early exiting approach is similar to layer dropping in which the dropped layers are always from the last top layers.

All these approaches select the number of layers to drop and the dropped layers heuristically at the inference time with the goal of improving the inference time. Instead, the adaptable adapter is a systematic approach for selecting the useful adapter layers for the given task during training. Besides layer selection, an adaptable adapter allows for learning the desired activation function for different inputs. As we show, we can use adaptable adapters to design efficient adapter architectures with a considerably smaller number of training parameters with on-par or considerably higher performances, especially with larger models and in low-data settings.

3 Proposed Architecture

3.1 Learnable Activation

Empirical observations of performances have led experts in several fields to use different activation functions for different tasks. Functions from the ReLU family are usually used for neural network-based visual computing, Tanh has been used in PPO for reinforcement learning, while GeLU has progressively been adopted in transformers. With the growth of the models, and the complexity of the tasks they are applied to, choosing one fixed activation function to equip the complete architecture is suboptimal. By using rational (§ 2.1), we let the adapter layer learn the suitable activation function at each different adapter layer, task, and dataset. In adaptable adapters, we replace the constant activation function of each adapter layer—i.e., ReLU in the default configuration used in AdapterHub (Pfeiffer et al., 2020)—with rational.

Figure 1 shows a standard adapter layer as well as an adapter layer in adaptable adapters.

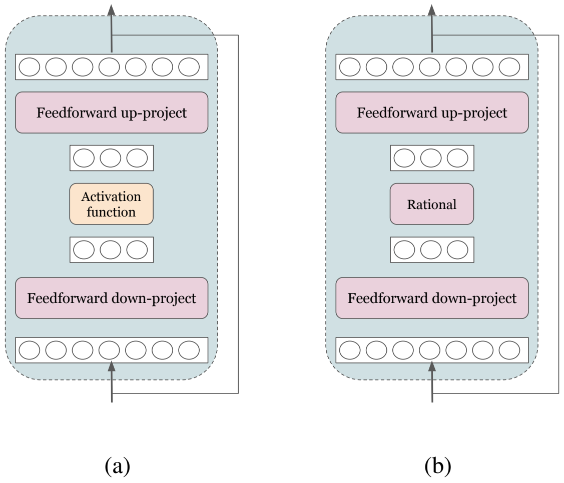

Figure 1: (a) a standard adapter layer with linear feedforward layers and a fixed activation, (b) an adapter layer in adaptable adapters with linear feedforward layers and a rational activation. Learnable parameters are shown within pink boxes.

3.2 Learnable Layer Selection

Houlsby et al. (2019) examined various choices of adapter architectures. They report that using

---

[2] There is another category that requires changes in the models' architectures. However, it would require re-training the large model. E.g., Sukhbaatar et al. (2019) propose new attention mechanisms that can process larger context with no additional computational or memory costs.

two feedforward linear layers—one down-project and one up-project layer—results in good performances while only introducing a few parameters. Assuming d is the dimensionality of the input—i.e., the embedding size of the transformer layer—the down-project layer maps the input dimension to n where $n < d$, and the up-project layer maps the input dimension back to d. n is called the hidden size of the adapter. Each adapter contains a skip-connection that lets an adapter layer approximate an identity function, i.e., to pass the input of a transformer layer unchanged to the next layer. The learnable switches in adaptable adapter explicitly model the selection between the feedforward adapter layer and the identity function. By examining the switch probabilities we can determine the adapter layers that are beneficial for the overall performance of the model.

As mentioned in § 1, existing work shows that different layers of the pretrained models capture different aspects of the input data, and not all of them are necessary for performing various tasks. Therefore, for different input data, different layers may be of different importance. Adding a learnable switch at each adapter layer provides a more systematic approach to determining the beneficial layers for each input task during training. We use the Gumbel Softmax ($\mathcal{GS}$) estimator as an end-to-end differentiable switch (hard attention) to make the network attend to an element of a set. Assuming π_i are the probabilities of selecting each element of the set, i.e., $\forall_i \pi_i \geq 0, \sum_i \pi_i = 1$, $\mathcal{GS}$ estimates the hard attention y_i as follows:

$$y_i = \frac{exp((log(\pi_i) + g_i)/\tau)}{\sum_j exp((log(\pi_j) + g_j)/\tau)} \tag{2}$$

where g_i are i.i.d. samples from a Gumbel distribution, and τ is a temperature parameter. Setting τ to small values results in distributions that are similar to categorical ones.

3.3 Adaptable Adapters

The adaptable adapter (AA) is the combination of the learnable layer selection and the learnable activation function. The learnable layer selection—i.e., a Gumbel Softmax estimator—selects between an adapter layer, with no skip connection, and an identity function with zero parameters that passes the input without any changes to the next layer. The adapter layers in adaptable adapters consist of two linear layers—i.e., down-project and up-project layers—, and the non-linearity function between these two linear layers consists of a rational activation function. The adaptable adapter allows to learn different adapter architectures for different input data by (a) learning to use a subset of adapter layers, and (b) learning a potentially different activation function at each layer. Figure 3 shows the structure of an adapter layer in adaptable adapters.

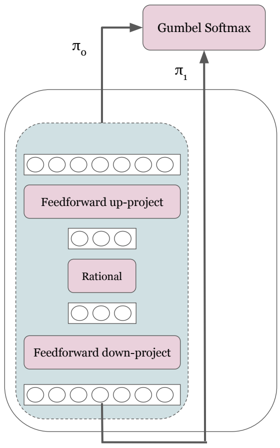

Figure 2: The adaptable adapter layer that consist of a Gumbel Softmax to choose between an adapter layer with a rational activation and an identity function.

4 Experimental Setup

4.1 Datasets

We use the English text classification datasets from the GLUE benchmark (Wang et al., 2019) including MNLI (Williams et al., 2018), QQP[3], QNLI (Rajpurkar et al., 2016), SST-2 (Socher et al., 2013), CoLA (Warstadt et al., 2019), STS-B (Cer et al., 2017), MRPC (Dolan and Brockett, 2005), RTE (Dagan et al., 2006), and WNLI (Levesque et al., 2011). Table 1 shows the number of training examples and the evaluation metric for each dataset.

Dataset	**|Train|**	**Metric**	**Dataset**	**|Train|**	**Metric**
MNLI	393k	acc.	STS-B	7k	Pearson/Spearman
QQP	364k	acc./F1	MRPC	3.7k	acc./F1
QNLI	105k	acc.	RTE	2.5k	acc.
SST-2	67k	acc.	WNLI	634	acc.
CoLA	8.5k	Matthews			

Table 1: GLUE datasets with their number of training examples and the corresponding evaluation metric.

---

4.2 Transformer Model

As the base model, we use the BERT-large model (Devlin et al., 2019). BERT-large contains 24 layers, an embedding size of 1024, and a total number of 340M parameters.[4]

4.3 Adapter Models

Baseline As a baseline adapter, we use the adapter layers with the pfeiffer configuration from AdapterHub (Pfeiffer et al., 2020). The adapter layers with the pfeiffer configuration are similar to the one in Figure 1, in which learnable parameters include two feedforward layers. For BERT-base, each pfeiffer layer consists of 73.7k parameters[5] resulting in a total number of 884.7K. For BERT-large, the number of parameters for each adapter layer is 131K, and the total number of parameters is 3.1M. We see that as the underlying model gets larger, the number of parameters in adapters also increases notably. Therefore, adapter architecture selection using *AA* is a potential solution to control this exponential increase to some extent.

Adaptable Adapter (AA) For the rational activation, similar to Molina et al. (2020), we use order $m = 5$ and $n = 4$ for rational. Therefore, the rational activation function only consists of ten learnable parameters. The rational activation can be initialized to initially estimate an existing function. Based on our preliminary experiments, using $f(x) = 1$ for initializing $R(x)$ results in better performances on the GLUE benchmark.

For the Gumble-Softmax switch, we set the temperature parameter τ to 0.1, and we initialize π_i to 0.5 for both inputs—i.e., the same initial probability for the rational adapter and the identity function.

AA-focused We can use the selected architecture by *AA* for designing a new adapter architecture, i.e., to only include an adapter layer—with a rational function—at layers in which the switch has selected the adapter layer over the identity function. We call this architecture *AA-focused*. Note that compared to *AA*, *AA-focused* is more efficient both at training and inference time, as it includes a fewer number of layers and no switch functions. It also requires less storage space for saving the new adapter weights. Also, training *AA* includes both the architecture selection and training of the adapter layers, which are initialized randomly, simultaneously. As a result, as we see in our evaluations, *AA-focused* achieves higher performances as its training is only focused on training the adapter layers.

AdapterDrop (Rücklé et al., 2021) During training, AdapterDrop randomly drops the first n layers in which n varies for different iterations. At inference, n can be set to any desired number of layers. In our experiments, we select n based on the number of dropped layers by *AA*, i.e., the number of layers that are not selected by the switch functions.

4.4 Experiments

We evaluate the models in different settings: (a) using full training data, and (b) low-data settings. For all the experiments, we consider 25% of the training data as the development set and use the official development sets as the test data. We perform the low-data evaluations when 100, 300, and 500 annotated examples are available.[6] The test data is the same for all the evaluations. We run all the low-data experiments for 20 epochs and five different random seeds[7]. We report the average and standard deviation over the five different runs. When training on full datasets, the experiments are computationally very expensive using BERT-large. Therefore, for this setting, we only report the results using the first random seed. All experiments are done on one A100 NVIDIA GPU. All implementations are based on AdapterHub (Pfeiffer et al., 2020).

5 Evaluation

Table 2 presents the results of *Baseline*, *AdapterDrop*, *AA*, and *AA-focused*. *AA* selects different layers for different tasks and different random seeds.[8] We evaluate three configurations for *AA-focused*:

- **AA-focused**^{spec}: for each task, we design the corresponding *AA-focused* based on the selected architecture by *AA* for that task given and the first random seed (42). For instance, the *AA-focused* architecture is the same for all

---

[4] The results for BERT-base are reported in the appendix. BERT-base contains 12 layers, an embedding size of 768, and 110M parameters.

[5] The reduction factor in the down-project layer is 16 which results in (768/16) x 768 x 2 parameters for each adapter layer.

[6] Selected training examples for low-data experiments are the same for all models given the same random seed.

[7] 42, 92, 111, 245, and 651.

[8] For instance, the selected layers for *RTE* are as follows for different runs of *Low-data-100*: {0, 2, 5, 11, 12, 13, 16, 17}, {3, 4, 5, 6, 7, 8, 9, 10, 12, 13, 15, 19, 21}, {2, 3, 4, 6, 9, 12, 14, 16, 17, 18, 20, 22, 23}, {0, 2, 6, 8, 9, 11, 13, 14, 17, 19, 23}, {1, 2, 5, 10, 11, 14, 16, 20, 21, 22, 23}.

Table 2: Comparing the results of (a) the standard adapter model that includes an adapter layer on all the 24 BERT-large layers (*Baseline*), (b) adaptable adapter (*AA*), (c) *AdapterDrop*, and (d) *AA-focused* adapters, in which the architecture of the adapter is selected based on the selected layers by *AA*. The architecture of *AA-focused*^{spec} is selected based on the selected layers by *AA* for the corresponding task and data setting when the random seed is 42. The architecture of *AA-focused*^{uni} is selected based on the selected layers by *AA* for the task of *QQP* on the *Low-data-100* setting and for random seed 42. *AA-focused*^{sim} only contains an adapter layer with a rational activation function at the last 13 layers of BERT-large, i.e., the total number of adapter layers in *AA-focused*^{uni}. The number of layers at the inference time for the *AdapterDrop*^{AA} experiments are selected based on the number of layers in the corresponding *AA-focused*^{spec} experiments. The number of inference time layers for *AdapterDrop*^{13} equals 13. Except for *Full Data*, the reported results are averaged over five random seeds. The subscript reports the corresponding standard deviation. The *Full Data* results are reported for one random seed. The |*AA*| rows report the average number of selected adapter layers by *AA* using different random seeds. |*AA-focused**| rows report the number of added adapter layers in the corresponding |*AA-focused**| experiments. |*AA-focused*^{uni}| and |*AA-focused*^{sim}| are the same for all data settings. |*AdapterDrop**| rows report the number of included adapter layers for the corresponding *AdapterDrop* experiment at the inference time. |*AdapterDrop*^{AA}| is always the same as the corresponding |*AA-focused*^{spec}|, and |*AdapterDrop*^{13}| is always the same as *AA-focused*^{sim}. The test data is the same for all the experiments. The *Avg* column reports the average score across all datasets. The highest performances for each dataset and each data setting are boldfaced.

the experiments of *RTE* for *Low-data-100*—i.e., over the five different random seeds—. However, it is different for the rest of the tasks and different data settings.

- **AA-focused**^{uni}: we design this adapter architecture of all tasks and data settings based on a single random seed, single task, and a single data regime, i.e.— random seed 42, the *QQP* task, and *low-data-100*. We choose *low-data-100* because the architecture selection process—i.e., training *AA*—is very fast in this setting. We select the selected architecture by *QQP* because *AA* selects the smallest number of layers for *QQP* when the random seed is 42. The selected layers are {2, 6, 10, 12, 14, 15, 16, 18, 19, 20, 21, 22, 23}, i.e., three layers from the first half of the original 24 layers, and ten layers from the second half. The results of *AA-focused*^{uni} compared to AA-focused^{spec} indicate whether the selected architecture by *AA* transfers between similar tasks and different data settings.

- **AA-focused**^{sim}: we design a simplified adapter based on *AA* in which we only use the number of selected layers, instead of the layer numbers, in a single random seed, single task, and a single data setting. We use the number of selected layers when the random seed is 42 for the *QQP* task and the *low-data-100* setting, i.e., 13. As investigated by Houlsby et al. (2019), the last adapter layers are in general more effective. As a result, we add adapter layers, with rational activation, to the last 13 transformer layers in *AA-focused*^{sim} experiments. The results of *AA-focused*^{sim} compared to AA-focused^{uni} show whether only the number of selected layers by *AA* matters or it is also important to specify at which layers to add the adapters.

The number of inference layers for *AdapterDrop*^{AA} are equivalent to the number of layers in *AA-focused*^{spec} experiments for each task and data setting. The number of layers for *AdapterDrop*^{13} is 13, which is the same as *AA-focused*^{uni} and *AA-focused*^{sim}. Note that the number of layers for *AA-focused* experiments are the same both at training and inference while it is not the case for *AdapterDrop*.

The |*AA*| rows in Table 2 show the average number of selected layers for each task over the five different random seeds. |*AA-focused**| rows report the number of added adapter layers in the corresponding *AA-focused** experiments. |*AdapterDrop**| rows report the number of included adapter layers for the corresponding *AdapterDrop* experiments at the inference time.

We make the following observations from the results of Table 2:

- *AA* achieves on-par performances with the *Baseline*, and on average it uses about 13-15 layers out of 24 layers. We can use this insight for designing efficient adapter architectures.

- All *AA-focused* architectures considerably outperform *Baseline* in all the the tasks in low-data settings while using considerably smaller number of parameters, and therefore, being considerably more efficient. For instance, while *AA-focused*^{uni} only uses 13 layers out of 24 layers—i.e., reducing the number of training parameters from 3M to 1.7M—, it outperforms the *Avg* score by 4.24, 5.57, and 2.35 points in *Low-data-100*, *Low-data-300*, and *Low-data-500*, respectively.

- The high performances of *AA-focused*^{uni} show that the selected architecture by *AA* for one task and one data setting transfers well to other data regimes and similar tasks.[9] Therefore, it is not necessary to design the adapter architecture separately for a different amount of available data and similar tasks.

- *AA-focused*^{sim} and *AdapterDrop*^{13} both use the last 13 adapter layers during the inference while the results of *AA-focused*^{sim} are considerably higher for all data regimes. This indicates the importance of rational activation in adaptable adapters. We will further investigate the impact on rational activation in the next section.

- In average, *AdapterDrop*^{AA} contains more inference layers compared to *AdapterDrop*^{13}. However, there is not a significant difference between their performances. They achieve on-par or lower results compared to *Baseline*.

---

[9] It even outperforms *AA-focused*^{spec} showing that *AA-focused*^{spec} may have overfitted to the development sets. We have not performed hyperparameter selection for our experiments. Using better hyperparameters may improve the results of different settings.

Table 4: Evaluating the impact of rational in adaptable adapters. Experiments are run for five different random seeds. *Switch-only* shows the results when learnable switches are used with standard adapter layers, i.e., linear layers with the ReLU activation. *Rational-only* shows the result when all the activation functions in the standard adapter are replaced with rational. *Baseline*^{13} contains a standard adapter layer on the last 13 transformer layer. *AA-focused*^{sim} contains adapter layers with rational activation on the last 13 layers.

Evaluating the impact of AA on selecting the number of beneficial layers. In the results of Table 2, we select the number of layers in *AA-focused*^{sim}, i.e., 13 , based on the minimum number of selected layers by *AA* on the *low-data-100* setting and for random seed 42. *AA-focused*^{sim} is equivalent to an adapter architecture in which only the last 13 adapter layers are added to the model. To investigate whether the improvements of *AA-focused*^{sim} over the baseline are only due to using a fewer number of adapter layers, we report the results of an adapter architecture in which only the last n adapter layers are added to the model, e.g., for $n = 13$ the resulting architecture is the same as *AA-focused*^{sim}. Table 3 shows the result of this experiment for $n = 13, 12, 11$. We observe that by decreasing the number of layers from 13 to 12, the overall performance drops notably from 63.61 to 57.37.

Evaluating the impact of rational activation. The results of *AA-focused* experiments vs. *Baseline* in Table 2 mostly emphasize the impact of layer selection by the learnable switches in *AA*. In this section, we investigate the impact of learnable activation functions in more details in the evaluations of Table 4.

First, we replace all rationals in *AA* with ReLU. The results are reported in the *Switch-Only* row. By comparing the results of *AA* and *Switch-only* we observe that the use of rational activation considerably improves the performance of *AA*, i.e., using rational is a key component to achieving higher performances with fewer layers.

Second, we replace the activation functions in the standard adapter with rational. The results are reported in *Rational-only* rows. The results of *Baseline* compared to *Rational-only* show that the impact of rational is prominent when the model contains fewer parameters and using rational with an overparameterized model is not very effective, i.e., both layer selection and learnable activation play an important role.

Third, we only add a standard adapter layer at the last 13 layers of BERT-large (*Baseline*^{13}), which is the same number of adapter layers in *AA-focused*^{sim}. The difference is the activation function that is used in these 13 adapter layers is ReLU in *Baseline*^{13} and rational in *AA-focused*^{sim}. The considerably higher performances of *AA-focused*^{sim} show that higher performances of *AA-focused* are due to both layer selection as well as a learnable activation function.

Learned rational activation functions. Figure 3 shows the learned activation functions across different layers of the same trained adapter and different tasks. We see that the learned activation differs

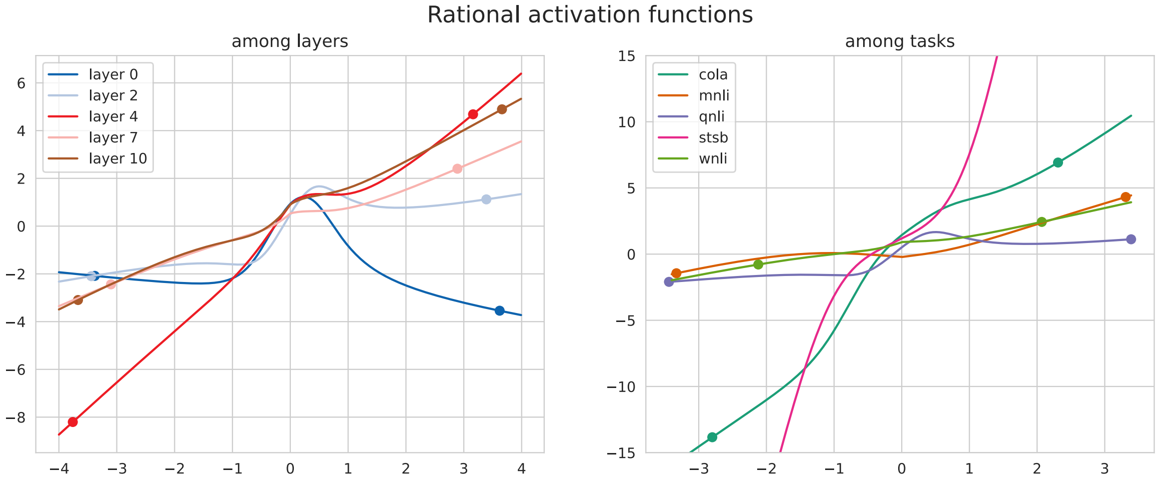

Figure 3: Learned rational activation functions differ according to their place within the network and to the task they are trained for. Right: activation functions at different layers within adapters trained on the QNLI task. Left: activation functions trained at layer 2 of adapters trained on different tasks.

for different layers of the same task as well as for different tasks.

6 Conclusion

In this paper, we propose adaptable adapters. They consist of a learnable switch to select a subset of beneficial adapter layers and a learnable activation function to learn the suitable activation at each adapter layer and for each input data. The results of adaptable adapters show that we can achieve on-par performances with the full adapter architecture by using a smaller subset of layers. We show that adaptable adapters are viable tools for designing efficient and effective adapter architectures that require less storage space, lower training and inference time with high performances.

Acknowledgements

The authors would like to thank Jorge Cardona for his valuable contribution to the implementation of adaptable adapters. We thank Michael Bugert, Ji-Ung Lee, and Soumya Sarkar for their constructive suggestions and feedback on this work. We would like to thank Jonas Pfeiffer and Clifton Poth for always being very helpful with all questions about adapters and AdapterHub. This research work has been funded by the German Federal Ministry of Education and Research and the Hessian Ministry of Higher Education, Research, Science and the Arts (HMWK) within their joint support of the National Research Center for Applied Cybersecurity ATHENE. It benefited from the HMWK cluster project "The Third Wave of AI".

Abstract

In Dynamic Adversarial Data Collection (DADC), human annotators are tasked with finding examples that models struggle to predict correctly. Models trained on DADC-collected training data have been shown to be more robust in adversarial and out-of-domain settings, and are considerably harder for humans to fool. However, DADC is more time-consuming than traditional data collection and thus more costly per annotated example. In this work, we examine whether we can maintain the advantages of DADC, without incurring the additional cost. To that end, we introduce Generative Annotation Assistants (GAAs), generator-in-the-loop models that provide real-time suggestions that annotators can either approve, modify, or reject entirely. We collect training datasets in twenty experimental settings and perform a detailed analysis of this approach for the task of extractive question answering (QA) for both standard and adversarial data collection. We demonstrate that GAAs provide significant efficiency benefits with over a 30% annotation speed-up, while leading to over a 5x improvement in model fooling rates. In addition, we find that using GAA-assisted training data leads to higher downstream model performance on a variety of question answering tasks over adversarial data collection.

1 Introduction

Natural language processing has become increasingly reliant on large datasets obtained using crowd sourcing. However, crowdsourcing as an unconstrained annotation approach is known to result in machine-exploitable annotator artefacts (Jia and Liang, 2017; Schwartz et al., 2017; Gururangan et al., 2018; Geva et al., 2019), leading to poor out-of-distribution generalisation (Chen et al., 2016; Weissenborn et al., 2017; Yogatama et al., 2019; McCoy et al., 2019). Dynamic Adversarial Data Collection (DADC) aims to address these issues by introducing state-of-the-art models into the data collection loop and asking human annotators to produce examples that these models find challenging (Kiela et al., 2021). The intuition behind this approach is that it leads human annotators to better explore the space of possible examples. Previous work has found that DADC leads to improved model robustness on adversarial datasets (Nie et al., 2020; Bartolo et al., 2020), increased sample diversity (Bartolo et al., 2020; Wallace et al., 2021), better training data (Wallace et al., 2021) and better domain generalisation (Bartolo et al., 2021).

Despite these advantages, a downside to DADC is that it increases the human effort necessary to annotate a single example and thus the overall annotation cost. In fact, to date, only a limited number of

After a slow start to the 2008–09 season, the Bruins won 17 of their next 20 games, leading many to see them as a revival of the "Big Bad Bruins" from the 1970s and 1980s. During the 2009 All-Star Weekend's Skills Competition, captain **Zdeno Chara** fired the NHL's then-fastest measured "hardest shot" ever, with a clocked in speed of **105.4 mph** (169.7 km/h) velocity. (Chara has since broken his own record three times, two of those on the same night.) The number of injured players in the season…

A: 105.4 mph

Q: What was the fastest shot ever?

Q: What was the fastest shot ever **in 2009**?

A: Zdeno Chara

Figure 1: Example interaction between an annotator and the models in the loop. The annotator selects an answer from the passage, for which the Generative Annotation Assistant (GAA) prompts a question. The annotator can then freely modify the question and/or answer, or generate another prompt. In the adversarial data collection setting, a model-in-the-loop provides predictions with the aim of encouraging annotators to find model-fooling examples. In the answer prompting setting, an answer suggestion is prompted by the assistive model instead of being selected by the annotator.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3754 - 3767
July 10-15, 2022

large-scale training datasets have been produced using DADC and its application has been primarily restricted to producing challenge sets or as additional training data to improve the performance of models already trained on non-DADC curated datasets. To make better use of DADC data, Bartolo et al. (2021) propose generating synthetic adversarial training sets to further improve model robustness. However, this approach inevitably limits example diversity as it relies on examples ultimately generated by a model with no additional human input, and provides no guarantees that useful synthetic examples would transfer across target adversary models of varying capabilities or across annotation rounds.

In this work, we propose assisting annotators by having generative models aid human annotators in the data collection loop. Concretely, we utilise a Generative Annotation Assistant (GAA) model that provides prompt suggestions to crowdworkers, while allowing full flexibility for edits and rewrites to support example generation while still allowing for human creativity as shown in Figure 1. We explore GAAs in a broad range of experimental settings, including standard and adversarial data collection approaches, training on various source datasets, and employing sampling methodologies based on likelihood, adversarial feedback, and uncertainty. We showcase the value of this approach on the task of extractive question answering (QA), and find that GAAs can help improve both the standard and adversarial data collection paradigms. We find considerable efficiency gains, with over 30% observed annotation speed-ups, as well as improved data effectiveness with up to a 6.1F_1 improvement in downstream performance over adversarial data collection.

2 Related Work

2.1 Dynamic Adversarial Data Collection (DADC)

There is a rich body of recent work showing the benefits of dynamic adversarial data collection in model evaluation (Yang et al., 2017; Dua et al., 2019; Dinan et al., 2019; Nie et al., 2020; Bartolo et al., 2020; Kiela et al., 2021; Wallace et al., 2021), although the approach has been challenged for not necessarily leading to better generalisation on non-adversarial test sets (Kaushik et al., 2021) and being sensitive to the choice of model that was used in the loop (Bowman and Dahl, 2021; Phang et al., 2021). This work builds on previous work in adversarial data collection methods for QA (Bartolo et al., 2020), and work investigating the use of question generation models to create synthetic adversarial data to improve QA model robustness (Bartolo et al., 2021).

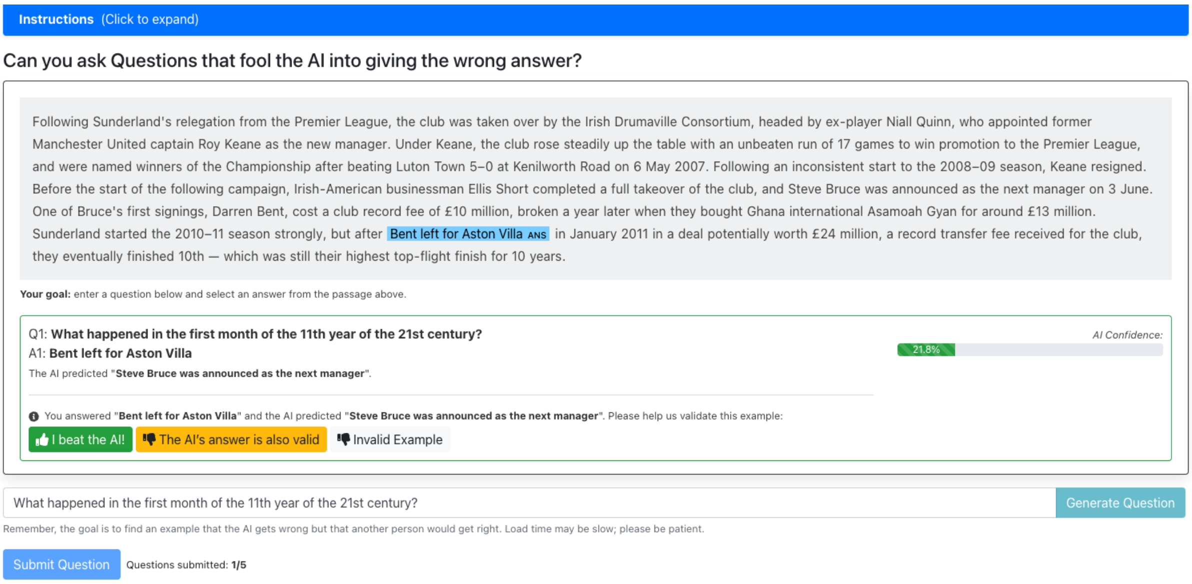
2.2 Generative Model Annotation Support

A long line of prior work has trained generative models for question answering (Du et al., 2017; Du and Cardie, 2018; Zhao et al., 2018; Lewis and Fan, 2019; Alberti et al., 2019; Puri et al., 2020; Yang et al., 2020; Bartolo et al., 2021; Lewis et al., 2021). In many cases, these approaches filter out questions that an external QA model gets wrong, in order to ensure correctness of the generated questions; our filtering strategies instead focus on generated questions that QA models get wrong as we hypothesise that these would serve as more useful initial prompts to human annotators.

Generative models have also been used to aid experts with writing contrast sets (Wu et al., 2021; Ross et al., 2021), but to the best of our knowledge, this is the first work to investigate the use of generative annotation assistants for crowdworkers directly in the annotation loop for NLP. Recent work on supporting crowdworkers for textual entailment in a non-adversarial setting shows no improvements on downstream transfer performance over baseline, albeit with reductions in previously observed issues with annotation artefacts (Bowman et al., 2020). Subsequent work highlights the need for further data collection efforts focusing on improving writing-based annotation processes (Vania et al., 2021), which we aim to investigate in this work. Separately, Ettinger et al. (2017) provide *breakers* with the ability to minimally edit original data to identify the boundaries of system capabilities, while Potts et al. (2021) analyse the use of prompts to assist crowdworkers in beating a model in the loop for sentiment analysis. In both cases, prompts are sourced from existing datasets and are not generated on the fly.

2.3 Active Learning and Weak Supervision

Active learning approaches have been used to accelerate annotation (Tsuruoka et al., 2008), although this typically assumes access to a pool or stream of unlabelled data for which the learning algorithm can query labels (Settles, 2009). In our setting, no unlabelled questions are provided, necessitating the use of a generative model to suggest questions instead. Moreover, our annotators are free to edit



Can you ask Questions that fool the AI into giving the wrong answer?

Following Sunderland's relegation from the Premier League, the club was taken over by the Irish Drumaville Consortium, headed by ex-player Niall Quinn, who appointed former Manchester United captain Roy Keane as the new manager. Under Keane, the club rose steadily up the table with an unbeaten run of 17 games to win promotion to the Premier League, and were named winners of the Championship after beating Luton Town 5–0 at Kenilworth Road on 6 May 2007. Following an inconsistent start to the 2008–09 season, Keane resigned. Before the start of the following campaign, Irish-American businessman Ellis Short completed a full takeover of the club, and Steve Bruce was announced as the next manager on 3 June. One of Bruce's first signings, Darren Bent, cost a club record fee of £10 million, broken a year later when they bought Ghana international Asamoah Gyan for around £13 million. Sunderland started the 2010–11 season strongly, but after Bent left for Aston Villa ANS in January 2011 in a deal potentially worth £24 million, a record transfer fee received for the club, they eventually finished 10th — which was still their highest top-flight finish for 10 years.

Your goal: enter a question below and select an answer from the passage above.

Q1: **What happened in the first month of the 11th year of the 21st century?**
A1: **Bent left for Aston Villa**
The AI predicted "**Steve Bruce was announced as the next manager**".

You answered "**Bent left for Aston Villa**" and the AI predicted "**Steve Bruce was announced as the next manager**". Please help us validate this example:

What happened in the first month of the 11th year of the 21st century?

Remember, the goal is to find an example that the AI gets wrong but that another person would get right. Load time may be slow; please be patient.

Questions submitted: **1/5**

Figure 2: The Annotation Interface used for data collection. This example shows a question generated using a generative assistant trained on the AdversarialQA data and selected an adversarial sampler, which successfully allowed the annotator to beat the QA model in the loop.

and browse generated questions, whereas annotators in active learning typically only provide labels and have no choice in what to label. Some of our sampling and filtering strategies based on entropy are inspired by uncertainty sampling, a standard active learning algorithm (Lewis and Gale, 1994).

3 Experimental Setup

Our study focuses on the effects of incorporating generative annotation assistants, and understanding their interactions with annotators and discriminative models-in-the-loop in a DADC context for QA. We provide crowdworkers with a short passage from Wikipedia and ask them to write five questions and highlight the span in the passage that best answers the question for each (see Figure 2). We pay workers equally across experiment modes to avoid creating an incentive imbalance and pay out an additional bonus for each question that successfully beats the discriminative QA model i.e., for each question that the model fails to answer correctly. Finally, we validate all collected examples using a separate worker pool that also undergoes rigorous onboarding and validation. We ask three of these additional workers to report on the validity of each annotated example.

Selected Passages We select passages from KILT (Petroni et al., 2021) to allow for the possibility of future investigation into cross-domain and task transfer. We restrict KILT passages to those with between 100 and 600 tokens that are used by at least 5 of the KILT tasks. Furthermore, we filter out any passages with any 8-gram overlap (after normalisation) to the SQuAD1.1 training or development sets, seeking to ensure that all passages used in our study are novel and previously unseen by the discriminative QA models in the loop. This leaves a total of 10,109 passages from 421 Wikipedia pages. We retain and supply all passage-relevant KILT metadata (such as IDs and provenances) with our collected datasets to facilitate future work.

Model-in-the-Loop The discriminative QA model in the loop is ELECTRA$_{\text{Large}}$ (Clark et al., 2020) trained on SQuAD1.1 and AdversarialQA, and enhanced using SynQA to improve adversarial robustness as investigated by Bartolo et al. (2021).[1] This model represents the best-performing model on the Dynabench (Kiela et al., 2021) leaderboard at the time of conducting this study, obtaining a word-overlap F$_1$ score of 94.5% on the SQuAD1.1 dev set, and represents the state-of-the-art on AdversarialQA achieving 77.6% on the $\mathcal{D}_{\text{BiDAF}}$ subset, 71.5% on $\mathcal{D}_{\text{BERT}}$, and 63.2% on $\mathcal{D}_{\text{RoBERTa}}$.

Generator-in-the-Loop For our generative models, we use the *fairseq* (Ott et al., 2019) implemen-

---

[1] You can interact with this model at `https://dynabench.org/models/109`.

tation of $\text{BART}_{\text{Large}}$ (Lewis et al., 2020), and finetune the decoder to generate questions conditioned on the passage and the answer highlighted by the annotator. To provide annotators with a diverse set of questions, we decode using nucleus sampling with $top_p = 0.75$, as decoding using standard beam search results in questions which are more similar to each other and therefore likely to be less useful as question prompts to annotators. To speed up inference and model-annotator interaction, we preemptively identify answer candidates for each passage and generate questions to build up a large cache from which we serve questions during annotation. Once there are no questions remaining in the cache for a particular answer, or if the annotator selects an answer that is not in the cache, we fall back to querying the generative model in realtime. In this work, we investigate generative assistants trained on three different sources of questions: SQuAD1.1, AdversarialQA, and the combination of both SQuAD and AdversarialQA.

Question Sampling We investigate three different selection strategies for presenting the generated questions as prompts to annotators: i) *generator likelihood* samples candidates in the order prescribed by the generative model's associated likelihood values; ii) *adversarial sampling* selects generated questions in order of the least word-overlap F_1 scores when queried against the discriminative QA model; and iii) *uncertainty sampling* is inspired by active learning and selects generated questions in order of the least span selection confidence when queried against the QA model. The latter two provide an interesting trade-off for exploration as we would expect the quality of the generated questions to be worse than if sampled based on likelihood. However, we hope that such prompts could serve to inspire annotators and provide a "starting point" beyond the answering capabilities of the QA model, irrespective of correctness. We hypothesise that modifying such examples might be a more effective process for annotators to undertake than when starting from higher quality but less model-confusing prompts, and investigate this question thoroughly.

Answer Prompts We also investigate the effects of abstracting away the answer selection task from the annotator. To identify potential candidate answers, we use Self-Attention Labelling (SAL) (Bartolo et al., 2021) and investigate providing annotators with both answer prompts as well as the corresponding generated questions.

Experimental Settings In total, there are twenty different experimental settings involving combinations of the above-mentioned pipeline components. We collect 2,000 validated training examples for each of these settings, for a total of 40,000 examples. For downstream evaluation we train $\text{ELECTRA}_{\text{Large}}$ QA models on the training datasets collected for each setting, and perform identical model selection and hyper-parameter tuning.

Annotation Interface We use an adaptation of the Dynabench (Kiela et al., 2021) QA interface that allows annotators to interact with the models in the loop, and further allows them to edit and modify generated questions and answers as required. The same base interface is used across experimental settings and only varied minimally depending on the current setting, for example by changing the title and instructions in the adversarial annotation setting, or by adding a "Generate Question" button when the setting involves GAAs. In the GAA settings, annotators are not informed what generative model they are interacting with, or what sampling mechanism is being used.

Crowdsourcing Protocol We use Amazon Mechanical Turk to recruit workers for this study and run all experiments using Mephisto.[2] To ensure proficiency in English, crowdworkers are required to be based in Canada, the UK, or the US. They are also required to have a Human Intelligence Task (HIT) Approval Rate greater than 98%, have previously completed at least 1,000 HITs, and undergo a dedicated onboarding process. Workers were randomly assigned to one of the possible experiment modes and were all presented with passages sampled from the same set, for which they were tasked with writing and answering five questions. All collected questions were than validated for correctness by a separate group of crowdworkers. We collect three validations per question and use this information, along with manual verification of a subset of the annotated examples, to maintain a high level of quality and remove examples from workers with less than an 80% validity rate. We calculate the reliability of agreement between validators using Fleiss' kappa at 0.46. Workers were provided an additional bonus for each example validated as having successfully fooled the model in the adversarial data collection settings. In total,

Table 1: Baseline results comparing standard and adversarial data collection. *t* shows the median time taken per example in seconds and median absolute deviation (subscript). *vMER* is the validated model error rate. *t/vMFE* is the time per validated model-fooling example. Lower is better for the time-dependent metrics. Downstream evaluation is measured by training an ELECTRA$_{\text{Large}}$ QA model on the collected datasets and evaluating F_1 scores on the SQuAD1.1 dev set, the AdversarialQA test sets, and the MRQA dev sets for domain generalisation.

1,931 workers participated in the study, with 1,559 contributing to the final datasets. We also continuously validate both annotators and validators based on signals such as repetitiveness, agreement, and manual checks.

Evaluation We evaluate the outcomes in each of the experimental settings by a selection of metrics:

i. *median time per example* as a measure of annotation efficiency and where a lower time taken is better;

ii. *validated Model Error Rate (vMER)* (Bartolo et al., 2021) which evaluates the effectiveness of annotators at generating valid question-answer pairs that the QA model in the loop fails to answer correctly;

iii. *median time per validated model-fooling example* which serves as a single metric incorporating both method efficiency and effectiveness and thus provides a convenient metric for comparison across the various experimental settings; and

iv. *downstream effectiveness* in which we evaluate the performance (by word-overlap F_1 score) of a QA model trained on the data collected in each of the experimental modes on the standard SQuAD1.1 benchmark, on the AdversarialQA benchmark, and in terms of domain generalisation ability on the MRQA (Fisch et al., 2019) dev sets.

Lower values are better for the time-dependent metrics, however, from the perspective of training data we consider a higher vMER to be better guided by the performance benefits observed for adversarial over standard data collection. This is corroborated by comparison with downstream results.

4 Results

Our study allows us to perform a thorough investigation into both the efficiency and effectiveness of the different data annotation methodologies. It also allows us to build on work investigating the various differences between standard and adversarial data collection (Kaushik et al., 2021).

4.1 Standard versus Adversarial Data Collection

The standard and adversarial data collection settings we use as baselines do not make use of GAAs, and are designed to replicate the SQuAD1.1 (Rajpurkar et al., 2016) and AdversarialQA (Bartolo et al., 2020) annotation setups as closely as possible. However, in contrast to AdversarialQA, our setting only provides annotators with a financial incentive to *try* to beat the model in the loop through the use of a bonus, and does not restrict annotators to only submitting model-fooling examples.

The results, shown in Table 1, highlight the differences between the two annotation approaches. As expected, standard data collection is more efficient in terms of the time taken per example, as there is no requirement for annotators to make any effort to try to beat a model. However, the efficiency differences are not as large as seen in settings where annotators *have* to submit model-fooling examples (Bartolo et al., 2020).

We also find considerable benefits from adversarial data collection in terms of the validated model error rate and subsequent downstream performance. As observed by Bartolo et al. (2020), adversarial data collection is more effective on adversarial test sets and aids domain generalisation, with slight performance degradation in the standard evaluation setting, which may be mitigated by increasing the amount of training data or combining with non-adversarial training data (for detailed results, refer to Appendix B). The combined performance across evaluation settings is considerably higher for adversarial data collection.

We note that the training data sizes in both these experimental settings are relatively small, and the benefits of adversarial data collection have been

Sampling Strategy	**t (s)**	**vMER (%)**	**t/vMFE (s)**	**SQuAD$_{\text{dev}}$**	$\mathcal{D}_{\text{BiDAF}}$	$\mathcal{D}_{\text{BERT}}$	$\mathcal{D}_{\text{RoBERTa}}$	**MRQA**

shown to be more pronounced in the low data regime, likely due to increased example diversity. Furthermore, while the passages used in this study are sourced from Wikipedia, there may exist characteristic differences between these and the passages used in SQuAD.

We also observe considerably lower (i.e., better) adversarial human evaluation vMER scores achieved for our synthetically-augmented ELECTRA$_{\text{Large}}$ model-in-the-loop compared to the 8.8% reported for RoBERTa$_{\text{Large}}$ by Bartolo et al. (2021). We hypothesise that this is primarily due to two factors: the improved robustness of ELECTRA in comparison to RoBERTa, and more tightly-controlled example validation. For further evidence of the improved adversarial robustness of ELECTRA, refer to Appendix C.

4.2 Improving Standard Data Collection

We now investigate whether it might be possible to improve standard data collection practices using generative assistants – *can we achieve similar performance to adversarial data collection without access to any adversarial data?*

We therefore use a GAA trained on SQuAD1.1, and investigate the three sampling techniques namely: likelihood, adversarial, and uncertainty sampling. Results are shown in Table 2. We find that using a GAA with likelihood sampling considerably improves the efficiency of the annotation process in comparison to the standard data collection baseline in Table 1. It also gives comparable vMER results and downstream QA performance.

Furthermore, both the adversarial and uncertainty sampling strategies prove effective. While the reduction in time taken per example is not as substantial as for standard likelihood sampling, and is comparable to the standard data collection baseline, the vMER – an indicator of the diversity of the collected training data – is substantially improved and outperforms the adversarial data collection baseline. The downstream results are also promising, providing slight improvements over the standard data collection setting, particularly with regards to domain generalisation. They start to make progress towards the values obtained for the adversarial data collection baseline although, despite the improved vMER, overall downstream performance is considerably higher in the adversarial data collection setting.

In summary, these results shows that we can encourage annotators to come up with more challenging examples without requiring any adversarially-collected data or an adversarial model in the loop, simply through the use of GAAs paired with an appropriate sampling strategy. However, using adversarial data collection still provides substantially better downstream performance. These observations are in line with our initial hypothesis that sampling generated prompts from regions of known model uncertainty, or prompts that we know the model finds challenging to answer, irrespective of generated sample quality, provides annotators with a better starting point for example creation.

4.3 Improving Adversarial Data Collection

Following the efficiency gains observed for standard data collection, we investigate whether it is possible for GAAs to provide further improvements over adversarial data collection. As for the previous experiments, we investigate GAAs trained on three different datasets: SQuAD1.1, AdversarialQA, and the combination of both. We combine each of these with the three previously discussed sampling strategies resulting in nine different experimental settings. Results are shown in Table 3.

We find that when annotators are incentivised to try to beat an adversarial QA model-in-the-loop, the previously seen efficiency gains are not as clear cut. In fact, annotators are slightly slower than for the adversarial data collection baseline when using a SQuAD-trained GAA. When using a GAA that has been trained on adversarially-sourced questions, standard likelihood sampling provides efficiency gains over the baseline, however, both adversarial and uncertainty sampling (which naturally

Table 4: Results for the investigation into supporting adversarial data collection using GAAs equipped with answer prompting. We investigate two different GAA training dataset sources, and three sampling strategies. The adversarial QA model-in-the-loop is identical for all settings.

lead to more complex prompts that might be more challenging to work with) actually slow annotators down, although they do provide improved validated model error rates and overall better adversarial example generation efficiency measured by the time taken per validated model-fooling example.

In terms of downstream performance, there is no clear best option, but the best settings consistently outperform the adversarial data collection baseline on the most challenging examples ($\mathcal{D}_{\text{BERT}}$ and $\mathcal{D}_{\text{RoBERTa}}$) while providing comparable results in the other evaluation settings. Surprisingly, we find that various settings, particularly those involving a SQuAD-trained GAA can provide performance gains over the standard data collection baseline on SQuAD1.1. We also observe that a SQuAD-trained GAA with uncertainty sampling gives best performance on the less challenging evaluation sets, while an AdversarialQA-trained GAA gives best performance on the evaluation datasets collected using a more performant adversary. This is also in line with the observations made by Bartolo et al. (2020) showing a distributional shift in question type and complexity with an increasingly stronger model-in-the-loop.

The general takeaway in terms of the ideal experimental setting from the perspective of downstream performance is that it depends on the particular evaluation setting, with GAAs trained on examples from a particular setting yielding better performance when the downstream model is also evaluated in similar conditions. Another key observation is that both the validated model error rate and time per validated model-fooling example comfortably outperform the baselines across the board, highlighting the enhancements to the effectiveness of the annotation process provided by incorporating GAAs in the loop.

4.4 Investigating Answer Prompting

The settings explored in the previous sections focus on investigating the effects of assisting free-text generation of the questions using GAAs. However, the QA crowdsourcing setting also involves annotation of answer spans, which we also explore in the search for efficiency gains. Here, we explore GAAs trained on datasets with adversarially-sourced components and the same three sampling strategies as previously (likelihood, uncertainty and adversarial), while additionally providing annotators with an answer suggestion.

In essence, this is similar to an answer and question validation setting, with the difference that annotators have the ability to freely modify both answer and question, or request additional suggestions. Results for our experiments involving answer assistance are shown in Table 4.

We find that answer prompting is very effective at improving annotation efficiency, providing gains in all six experimental settings while also providing improved vMER results in all cases. We also see very similar downstream performance result patterns to the previous set of experiments – for performance on the more challenging evaluation sets ($\mathcal{D}_{\text{BERT}}$ and $\mathcal{D}_{\text{RoBERTa}}$), an AdversarialQA-trained GAA with likelihood sampling gives best performance, while for performance on SQuAD, a GAA trained on examples including SQuAD gives the best results. As previously discussed and as shown in Appendix B, adding SQuAD examples to the training data mitigates this effect.

The consistency in performance patterns serves to further highlight the previous observation that, while using GAAs provides considerable gains in both the efficiency of the annotation process and effectiveness in terms of downstream results, the ideal annotation setup should be selected based on the target downstream evaluation. It is also worth highlighting the considerable performance improvements on the more challenging AdversarialQA evaluation sets observed when using an AdversarialQA-trained GAA even over adversarial data collection.

5 Annotator Interaction with GAAs

While we provide annotators with instructions explaining how they can use the GAAs to aid their annotation, they are free to query the generative models as many times as they like, if at all, during annotation. We are interested to see how the three main factors affecting interaction with the GAAs that we explore – training data, sampling strategy, and answer prompting – affect the ways in which annotators interact or use the GAAs.

Results, shown in Table 5, indicate that annotators query the GAA less frequently when being shown simpler prompts i.e. those obtained using a GAA trained on non-adversarially sourced examples, or selected using likelihood sampling which tends to provide higher quality and less complex generated texts. We also find that annotators query the GAA more frequently when an answer prompt is also provided. We believe that this can be attributed to the fact that the answer and question prompt setting is more similar to a validation workflow, allowing annotators to generate prompts until a satisfactory one is found.

Feature	**Setting**	**Avg. #Generations per Example**
GAA Training	SQuAD	0.69
	AdversarialQA	0.86
	Combined	0.83
Sampling	*Likelihood*	0.67
	Adversarial	0.87
	Uncertainty	0.83
Answer Prompt?	✗	0.73
	✓	0.91

Table 5: Results showing how often annotators query the GAA for different experimental settings.

6 Discussion and Conclusion

In this work, we introduce Generative Annotation Assistants (GAAs) and investigate their potential to aid crowdworkers with creating more effective training data more efficiently. We perform a thorough analysis of how GAAs can be used for improving QA dataset annotation in different settings, including different generative model training data, sampling strategies, and whether to also provide annotators with answer suggestions.

We find that GAAs are beneficial in both the standard and adversarial data collection settings. In the standard data collection setting, and under the assumption of no access to adversarially-collected data, GAAs with prompts sampled based on likelihood provide annotation speed-ups, while prompts sampled by adversarial performance or uncertainty metrics provide benefits to both the model error rates on the collected data as well as subsequent downstream QA performance. We find that while GAAs are effective for improving standard data collection, we still do not approach the performance obtained when using adversarial data collection.

For adversarial data collection, we demonstrate improved effectiveness of the annotation process over the non-GAA baseline, although this comes at a cost of reduced annotation efficiency. We show that also aiding annotators with answer prompts boosts data collection efficiency even beyond that of standard data collection, while retaining overall downstream performance.

We find that the ideal annotation setting differs for different intended evaluations, with an uncertainty-sampled GAA trained on data that was not adversarially-collected providing best performance on simpler questions, while a GAA trained on adversarially-collected data provides best downstream performance on more challenging evaluation sets. However, we also find that combining with a small sample of SQuAD training examples can boost performance on these less-challenging questions, and that in this setting a likelihood-sampled adversarially-trained GAA consistently provides the best results.

In terms of efficiency, we see annotation speedups over baseline of 34.4% for standard data collection and 37.4% for adversarial data collection. In terms of effectiveness, we see over a 5x improvement in vMER over adversarial data collection, along with downstream performance gains. We improve over standard data collection on $\text{SQuAD}_{\text{dev}}$ by up to 0.8F_1 and improve over adversarial data collection by up to 6.1F_1 on $\mathcal{D}_{\text{BERT}}$, and 3.8F_1 on $\mathcal{D}_{\text{RoBERTa}}$. Furthermore, we see benefits in domain generalisation over standard data collection, and show that annotators interact with the GAA more frequently when it has been trained on adversarially-collected data, is sampled based on adversarial or uncertainty feedback, and also provides answer prompts.

While our analysis is limited by the size of the collected data, we believe that GAAs can help drive further innovation into improved data collection methodologies based on these findings. We hope that our analysis of various aspects of GAA incorporation into the annotation pipeline and the interactions between annotators and multiple models in the loop can help inform future work exploring broader aspects of GAA use, such as for other NLP tasks or for larger scale annotation efforts.

7 Ethical Considerations

We collect a training datasets as a part of the analysis in this work. The passages are sourced from Wikipedia through KILT. As described in the main text, our incentive structure is designed to ensure that crowdworkers were fairly compensated. Our datasets focus on the English language. As this data is not collected for the purpose of designing NLP applications, we do not foresee any risks associated with the use of this data.

A Breakdown of MRQA Results

Table 6 shows the breakdown of results on the 12 MRQA in- and out- of domain evaluation sets.

B Combining with SQuAD1.1

Bartolo et al. (2020) and subsequent works find that the performance degradation in the original evaluation setting when training on adversarially-collected data only is mitigated by also including some of the original training data. To investigate this further, we combine and shuffle the training datasets collected in each of the experimental settings with 2k SQuAD1.1 examples for a total of 4k training examples per experiment.

The baseline results in Table 7 show that this results in similar performance, if slightly improved on the SQuAD dev set, when using some adversarially-collected data. We also show the results for the other experimental settings in Tables 8, 9 and 10, noting very similar performance variation between settings as those reported earlier.

C Adversarial Robustness of ELECTRA and RoBERTa

Table 11 shows adversarial robustness performance evaluated on the AddSent and AddOneSent evaluation datasets introduced by Jia and Liang (2017). We observe that even when trained only on SQuAD1.1, ELECTRA performs considerably better than RoBERTa in this setting, suggesting that it is substantially more robust “out of the box”.

D Computational Resources

All experiments were run on single NVIDIA Tesla P100 GPUs. Models were trained for up to 14 epochs each taking approximately 2 hours to complete training. Best model checkpoints and hyperparameters were tuned for each experimental setting. The final model selected for each setting was based on validation performance across the SQuAD and AdversarialQA development sets. The time taken for evaluation of the final models on each of the AdversarialQA test sets and the MRQA datasets was dependent on the number of examples.

Abstract

Document Information Extraction (DIE) has attracted increasing attention due to its various advanced applications in the real world. Although recent literature has already achieved competitive results, these approaches usually fail when dealing with complex documents with noisy OCR results or mutative layouts. This paper proposes Generative Multi-modal Network (GMN) for real-world scenarios to address these problems, which is a robust multi-modal generation method without predefined label categories. With the carefully designed spatial encoder and modal-aware mask module, GMN can deal with complex documents that are hard to serialized into sequential order. Moreover, GMN tolerates errors in OCR results and requires no character-level annotation, which is vital because fine-grained annotation of numerous documents is laborious and even requires annotators with specialized domain knowledge. Extensive experiments show that GMN achieves new state-of-the-art performance on several public DIE datasets and surpasses other methods by a large margin, especially in realistic scenes.

1 Introduction

Document Information Extraction (DIE) aims to map each document to a structured form consistent with the target ontology (*e.g.*, database schema), which has recently become an increasingly important task. Recent research (Xu et al., 2020, 2021; Wang et al., 2021a; Zhang et al., 2020; Li et al., 2021a) has achieved competitive results for information extraction in the idealized scenario with accurate OCR results, word-level annotations, and serialized document words in reading order. These methods regard DIE as a Sequence Labeling (SL) task. Given OCR results of a document image, the traditional sequence labeling method first serializes words in reading order then classifies each input word into predefined categories.

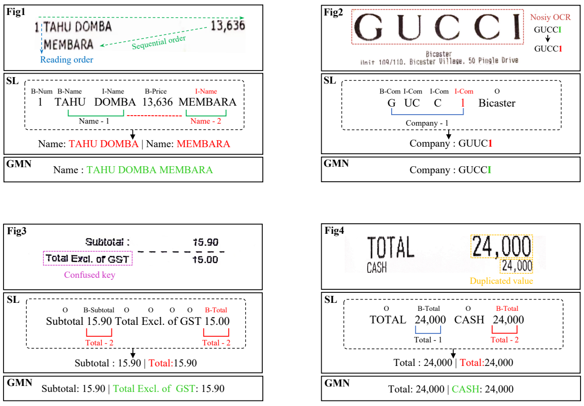

Figure 1: Examples in public DIE benchmarks with practical problems. The three rows from top to bottom in each sub-figure are 1) input images, 2) raw intermediate tags and final results generated by the SL method, and 3) results of our GMN method, respectively. The error parts are marked in red, while the correct parts are in green. Best viewed in color.

As shown in Figure 1, multiple challenging problems for practical document understanding still exist in realistic scenes. 1) Document serialization requires pre-composition processing, which is difficult in real scenarios with ambiguous word orders. One entity may be incorrectly divided into multiple entities when the input sequences are sorted by coordinates. 2) OCR results are usually noisy because of inevitable recognition errors. 3) The volume of keys in practical scenarios is generally substantial and expanded frequently. Existing sequence labeling methods could not identify undefined keys. 4) While facing duplicated values, collecting word-level annotations is necessary for sequence labeling methods. However, this is difficult in practical scenarios since they are costly and labor-intensive.

To address the limitations mentioned above, we propose a robust information extraction method

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3768 - 3778
July 10-15, 2022

named Generative Multi-modal Network (GMN) for practical document understanding. Unlike sequence labeling methods that label each input word with a predefined category, we regard DIE as a translation task that translates source OCR results to a structured format (like key-value pairs in this paper). We use UniLM (Dong et al., 2019) as the basic model structure, which is a transformer-based pre-trained network that can handle both natural language understanding (NLU) and natural language generation (NLG) tasks simultaneously. Conditioned on a sequence of source words, GMN generates one word at each time step to compose a series of key-value pairs in them.

Regarding the sequence serialization problem, a novel two-dimensional position embedding method is proposed while the original one-dimensional positional embedding in the transformer is removed because all information in document understanding can be acquired from 2D layouts. In this manner, GMN bypasses the serialization problem. Furthermore, benefiting from the large-scale self-supervised pre-training processed on a vast document collection, GMN can correct OCR errors commonly encountered in practical scenarios. Moreover, using a weakly supervised training strategy that utilizes only key information sequences as supervision, GMN needs no word-level annotations that are indispensable in traditional sequence labeling methods like LayoutLM (Xu et al., 2020) and StructuralLM (Li et al., 2021a).

Experiments illustrate that the proposed GMN model outperforms several SOTA pre-trained models on benchmark datasets, including SROIE and CORD. The contributions of this paper are summarized as follows:

1) We present GMN tailored for the DIE task, which is more applicable for practical scenarios, including lack of word-level annotations, OCR errors as well as various layouts.

2) We propose a layout embedding method and multi-modal Transformer in a decoupling manner, which jointly models interactions between multiple modalities and avoids the reading order serialization.

3) Experiments on public DIE datasets demonstrate that the proposed method not only achieves a substantial performance improvement but also generalizes well to data under practical scenarios with unseen keys.

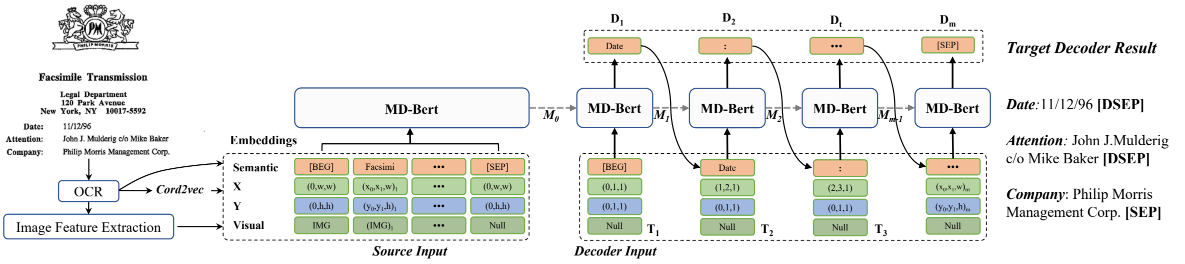
2 RELATED WORKS

Traditional methods (Esser et al., 2012; Schuster et al., 2013; Riloff, 1993) on DIE tasks rely heavily on predefined rules, templates, and hand-crafted features, giving rise to difficulty in generalizing to unseen documents. With the development of deep learning technology, document information extraction methods have recently improved substantially in both performance and robustness. These deep learning-based methods can be classified into three categories: textual content-based methods, multi-modal-based methods, and pre-trained Transformer-based methods.

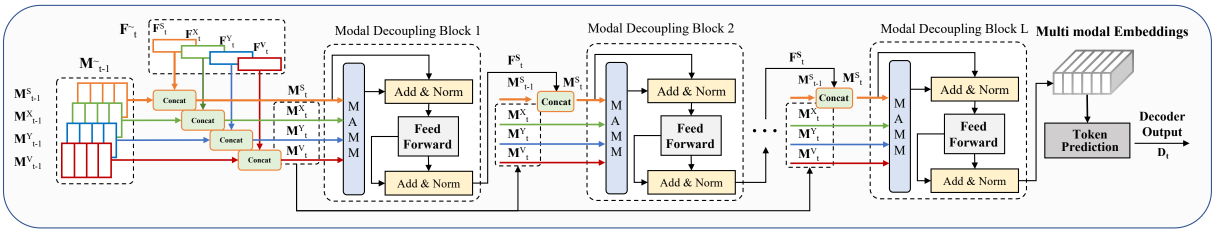
Textual content-based methods. Palm et al. (2017); Sage et al. (2019) adopt the idea from natural language processing and use recurrent neural networks (RNN) to extract entities of interest from documents. However, they discard the layout information during the text serialization, which is crucial for document understanding.

Multi-modal-based methods. Some works (Katti et al., 2018; Hwang et al., 2021) take the layout information into consideration and try to reconstruct character or word segmentation of the document. Katti et al. (2018) encode each document page as a two-dimensional grid of characters that represents text representation with a two-dimensional layout. Yu et al. (2020); Majumder et al. (2020); Zhang et al. (2020); Wang et al. (2021b) further integrate image embeddings for better feature extraction. Yu et al. (2020); Tang et al. (2021) represent documents by graphs, with nodes representing word segments and edges either connecting all the nodes or only spatially near neighbors. Convolutional or recurrent mechanisms are then applied to the graph for predicting the field type of each node. However, due to the lack of large-scale pre-training, the robustness and accuracy of the model are relatively limited.

Pre-trained Transformer-based methods. Recently, pre-trained models (Devlin et al., 2019; Liu et al., 2019) show effective knowledge transferability with large-scale training data and various self-supervised tasks. LayoutLM (Xu et al., 2020) first proposes a document-level pre-training framework that semantic and layout information are jointly learned. LayoutLM V2 (Xu et al., 2021) further improves the LayoutLM model by integrating the image information in the pre-training stage. Li et al. (2021a) propose the StructuralLM pre-training approach to exploit text block information. Methods



(a) The overall architecture of our generative multi-modal network, MD-Bert in encoder and decoder are with parameter sharing.



(b) Detail of MD-Bert module, with internal memory updated recursively.

Figure 2: Architecture of our generative multi-modal network. The MD-Bert module is composed of stacked multi-modal encoders, which fuses multi-modal features and iteratively generates structured results in a fixed order.

mentioned above all use one-dimensional position embeddings to model the word sequence, even with two-dimensional layout embeddings are involved, so that the reading order serialization in the document is required, which is challenging or even impossible due to the complex and diverse layout in the real world. What's more, they are all based on the classification of each input text segment to predefined labels, which means fine-grained annotations are indispensable and lack the ability to correct error OCR results.

On the contrary, the proposed GMN relies on a two-dimensional position embedding to bypass the serialization process and cross-modality encoders in a decoupling manner to model the layout information and the relative position of a word within a document simultaneously.

3 METHODOLOGY

In this section, we first introduce the overall architecture of GMN, followed by illustrating multi-modal feature extraction, generative pre-training model with multi-modal decoupling in detail, respectively.

3.1 Overall Architecture

GMN aims at constructing an enhanced Transformer-based translator architecture for DIE for converting the document to structured, machine-readable data. An overview of the architecture is as shown in Figure 2. It mainly consists of two parts: the multi-modal feature extraction module and stacked cross-modality module named MD-Bert (Modal Decoupling Bert), which simultaneously serves as encoder and decoder following the design of UniLM.

The whole process can be summarized as 1) Multi-modality embeddings of source inputs are extracted through an advanced OCR engine and a small CNN; 2) The extracted features from different modalities are fused as "multi-modal embeddings" through MD-Bert along with memory updating for each layer at each time step; 3) Next, MD-Bert output the encoding results by applying token prediction on multi-modal embeddings; 4) Finally, MD-Bert recursively generates structured results by taking multi-modal embeddings and accumulative memory as inputs until a terminator [SEP] is predicted.

3.2 Multi-Modal Feature Extraction

Based on the multi-modal information, including semantics, layout, and vision, we propose a unified layout embedding method named *Cord2Vec* which simultaneously encodes sequence information and spatial information to avoid complex reading order serialization.

3.2.1 Semantic Embedding

Intuitively, semantic contents are reliable signals to extract valuable information. The semantic content of each text fragment is acquired from the results of the OCR engine for practical application scenarios. After text fragments are acquired and tokenized, the start indicator tag [BEG] is added in front of the input token sequence, and the end indicator tag [SEP] is also appended to the end. Extra padding tag [PAD] is used to unify the length of sequence with predefined batch length L. In this way, we can get the input token sequence S as

$$S = [\text{[BEG]}, t_1, \cdots, t_n, \text{[SEP]}, \text{[PAD]}, \cdots], |S| = L \quad (1)$$

Here, t_i refers to i-th token in OCR texts. Moreover, though the sequence length of the input token sequence is fixed during training, GMN can handle variable lengths when making the inference due to the novel positional embedding method.

3.2.2 Layout Embedding

DIE task is a typical two-dimensional scene in which relative positions of words are essential evidence. While the reading order serialization is challenging, we propose *Cord2Vec*, a unified embedding method that fully utilizes spatial coordinates rather than one-dimensional sequence order information to bypass this problem.

As for the source input part, we normalize and discretize all coordinates to the integer in the range of $[0, \alpha]$, here α is the max scale which is set to 1000 in our experiment. Then corner coordinates and edge lengths of each text fragment are gained using corresponding bounding boxes. In order to enhance the tokens' interaction in the same box, two tuples $(x_0, x_1, w), (y_0, y_1, h)$ are used to represent the layout information. Here, (x_0, y_0) and (x_1, y_1) are the top-left and bottom-right coordinates of each token, and w is the average width of tokens in the same box while h representing box height. Such embedding represents both the layout and the word order information. As for target tokens generated by GMN which does not have the real coordinate, the *Cord2Vec* assumes each token is tied in the grid of $[W_{grid}, H_{grid}]$ with row-first principle, and each token occupies a pixel with a width and height of 1. After the layout information is acquired, we use two embedding layers to embed x-axis features and y-axis features separately as stated in Equation 2.

$$\begin{aligned} X_i &= \textit{PosEmb2D}_{\text{x}}(x_0, x_1, w), \\ Y_i &= \textit{PosEmb2D}_{\text{y}}(y_0, y_1, h) \end{aligned} \quad (2)$$

Here, $\textit{PosEmb2D}_{\text{x}}$ and $\textit{PosEmb2D}_{\text{y}}$ are the position embedding function which takes coordinate as input. Each input element is embedded separately and then added together with an element-wise function. Note that the placeholder such as [PAD] can be treated as some evenly divided grids, so their bounding box coordinates are easy to calculate. An empty bounding box $X_{\text{PAD}} = (0, 0, 0), Y_{\text{PAD}} = (0, 0, 0)$ is attached to [PAD], and $X_{\text{SEP}} = (0, w, w), Y_{\text{SEP}} = (0, h, h)$ is attached to other special tokens including [BEG] and [SEP].

3.2.3 Visual Embedding

We use ResNet-18 (He et al., 2016) as the backbone of the visual encoder. Given a document page image I, it is first resized to $W * H$ then fed into the visual backbone. After that, the feature map is scaled to a fixed size by average-pooling with the width being W/n and height being H/n, n is the scaling scale. Finally, RoI Align (He et al., 2017) is applied to extract each token's visual embedding with a fixed size. The visual embedding of the i-th token is denoted by $v_i \in (v_1, v_2, v_3, \ldots, v_L)$. For source input, visual embedding can be represented as

$$v_i = \textit{ROIAlign}(\textit{ConvNet}(Image), Pos_i) \quad (3)$$

Here, Pos_i stands for the position of i-th token, and *ConvNet* is a convolutional neural network serving as feature extractor in terms of input image, and then *ROIAlign* takes the image feature and location as input, and extracts the corresponding image features. Note that the [BEG] token represents the full image feature, and the other special tokens, as well as output tokens, are attached to the default null image feature.

3.3 Generative Pre-training Model

3.3.1 Model Structure

In order to learn more general features and make full use of the pre-training data, we propose a unified encoder-decoder module named MD-Bert which is composed of stacked hierarchical multi-modal Transformer encoders. The context of input tokens is from OCR result during the encoding stage, while already decoded tokens are also included in the decoding stage. To solve this problem, inspired by UniLM, we use masking to control which part of context the token should attend to when computing its contextualized representation, as shown in Figure 3. The input features of semantics, layout and computer vision are mapped to hidden states by: $\boldsymbol{F}_0^S = \{f_1^S, \ldots, f_N^S\}, \boldsymbol{F}_0^X =$

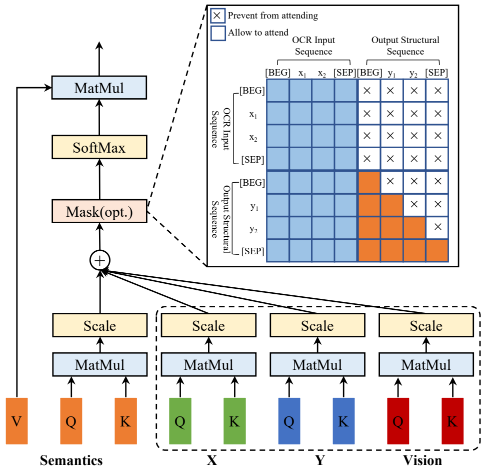


Figure 3: Modal-aware Mask Module: modalities fusion in decoupling manner. The sub-module for processing X are with parameter sharing for each layer, the same for Y and Visual sub-module.

$\{f_1^X, \ldots, f_N^X\}, \boldsymbol{F}_0^Y = \{f_1^Y, \ldots, f_N^Y\}, \boldsymbol{F}_0^V = \{f_1^V, \ldots, f_N^V\}$, a linear mapping is as follows:

$$\begin{aligned} f_i^S = \boldsymbol{W}_S x_{\mathrm{i}}^S, f_i^X = \boldsymbol{W}_X x_{\mathrm{i}}^X, \\ f_i^Y = \boldsymbol{W}_Y x_{\mathrm{i}}^Y, f_i^V = \boldsymbol{W}_V x_{\mathrm{i}}^V \end{aligned} \tag{4}$$

where matrices $\boldsymbol{W}_S \in \mathbb{R}^{d_h \times d_{\mathrm{S}}}$, $\boldsymbol{W}_X \in \mathbb{R}^{d_h \times d_{\mathrm{X}}}$, $\boldsymbol{W}_Y \in \mathbb{R}^{d_h \times d_{\mathrm{Y}}}$, $\boldsymbol{W}_V \in \mathbb{R}^{d_h \times d_{\mathrm{V}}}$ are used to project features into hidden-state in d_h dimensions. MD-Bert takes $F^{\sim}$ and memory $M^{\sim}$ of history state as input, generates output and update memory $M^{\sim}$ step by step. where, $F^{\sim} \in \{F^S, F^X, F^Y, F^V\}, M^{\sim} \in \{M^S, M^X, M^Y, M^V\}$, $M^{\sim}$ contains the history state of each layer and previous embeddings of the model. In the first timestep, $M^{\sim}$ is initialized from scratch, input T_0 means the full OCR result and MD-Bert acts as bi-directional encoder. For timestep t, where $t \in [1, m]$, the model takes the output of the previous timestep or $[BEG]$ as input, and outputs the current result, MD-Bert acts as uni-directional decoder.

3.3.2 Cross-Modality Encoder

Traditional multi-modal models usually fuse different modal features by adding or concatenating them together, which inevitably introduces the unwanted correlations between each other during self attention procedure, *e.g.* word-to-position, image-to-word. However, these correlations are harmful to strengthening the model's capability as different data modalities are practically orthogonal, thus we need to design a customized pipeline for each one. We propose MAMM (modal-aware mask module) encoder, a hierarchical structure multi-modal Transformer model in a decoupling manner that jointly models different modalities. As a consequence, the feature embedding decoupling is decomposed into three embeddings in GMN. The MAMM module follows the design of a basic module in BERT, but replaces the multi-head attention with modal-aware multi-head attention.

It also contains feed-forward (FF) layers, residual connections, and layer normalizations (LN), meanwhile, parameters of modals are not shared. When feeded with different modal content such as semantics, layout and computer vision, MAMM first calculates each modal's attention score separately, then added these attention scores together to get a fusion score, finally use this fusion score to apply masking and following operations on semantic content. As shown in Figure 3, let $\boldsymbol{F}_l^{\sim} = \{f_1^{\sim}, \ldots, f_N^{\sim}\}$ be the encoded feature in the l-th layer. $\boldsymbol{F}_0^{\sim}$ is the vector of the input features as mentioned in Equation 4. Features output by the next layer $\boldsymbol{F}_{l+1}^{\sim}$ can be obtained via:

$$\boldsymbol{F}_{l-att}^{\sim} = LN\left(f_{MAMM}\left(\boldsymbol{F}_l^{\sim}\right) + \boldsymbol{F}_l^{\sim}\right) \tag{5}$$

$$\boldsymbol{F}_{l+1}^{\sim} = LN\left(f_{\mathrm{FF}}\left(\boldsymbol{F}_{l-att}^{\sim}\right) + \boldsymbol{F}_{l-att}^{\sim}\right) \tag{6}$$

where $f_{MAMM}(\cdot)$ is the modal-aware mask function defined as

$$f_{\mathrm{MAMM}}\left(\boldsymbol{F}_l^{\sim}\right) = softmax\left(MaskProd\left(\boldsymbol{F}_l^{\sim}\right)\right) v\left(\boldsymbol{F}_l^{\sim}\right) \tag{7}$$

$$MaskProd\left(\boldsymbol{F}_l^{\sim}\right) = \frac{q\left(\boldsymbol{F}_l^{\sim}\right) k\left(\boldsymbol{F}_l^{\sim}\right)^{\top}}{\sqrt[4]{d_k}} + f_{Maskopt} \tag{8}$$

where $q(\cdot)$, $k(\cdot)$, $v(\cdot)$ are linear transformation layers applied to the proposals' feature, which represent the query, key and value in attention mechanism accordingly. Benefited from the parameters' sharing among layers with regard to X, Y and Vision, GMN has comparable weights as Bert. Symbol d_k is the number of attention headers for normalization, and the $f_{Maskopt}$ is the Mask operation which controls the attention between each token. In GMN, we apply full attention on all OCR input tokens, and input tokens of the model for the output structural sequence can attend to the whole inputs as well as tokens that have been decoded which are like auto-regressive encoder. Finally, $\boldsymbol{F}_{l+1}^{\sim}$ can be obtained by $\boldsymbol{F}_{l-att}^{\sim}$ via a feed-forward sub-layer composed of two fully-att connected layers of function $f_{FF}(\cdot)$. Hierarchically stacked layers form the multi-modal encoder.

3.3.3 Pre-training Method

Similar to UniLM, three cloze tasks including Unidirectional LM, Bidirectional LM and Sequence-to-Sequence LM are used in the GMN. Meanwhile, we propose NER-LM for better entity correlation extraction. The whole loss function is defined as,

$$\mathcal{L} = \mathcal{L}_{\text{uni-LM}} + \mathcal{L}_{\text{bi-LM}} + \mathcal{L}_{\text{s2s-LM}} + \mathcal{L}_{\text{NER-LM}} \quad (9)$$

In a cloze task, we randomly choose some WordPiece (Wu et al., 2016) tokens in the input, and replace them with the special token $[MASK]$. Then, we feed their corresponding output vectors computed by the Transformer network into a softmax classifier to predict the masked token. The parameters of GMN are learned to minimize cross-entropy loss, which is computed using the predicted tokens and the original tokens.

NER-LM is an extension of sequence-to-sequence LM for better integrity constraints on the entity. Given the source segment which includes entity values s_1, s_2 , and the corresponding entity types n_1, n_2 as well as some background sentence *e.g.* b_1, b_2, we form the input format as A "$[BEG] s_1 b_1 s_2 b_2 [SEP]$" and B "$[BEG] n_1 s_1 n_2 s_2 [SEP]$". Each token in A can access all others of A, while each token in B can access all tokens of A as well as the preceded tokens in B. The target entity in B is masked for prediction during training.

4 EXPERIMENTS

4.1 Dataset

4.1.1 Pre-training Dataset

Our model is pre-trained on the IIT-CDIP Test Collection 1.0 (Lewis et al., 2006), which contains more than 6 million documents, with more than 11 million scanned document images. Moreover, each document has its corresponding text and metadata stored in XML files which describe the properties of the document, such as the unique identity and document labels. And the NER-LM is pre-trained on the Enron Email Dataset (Klimt and Yang, 2004), which contains 0.5 million emails generated by employees of the Enron Corporation. We follow the organization of the letter and generate the content on the image. The structured information in the letters acts as an entity, such as subject, date, *etc*.

4.1.2 Fine-tuning Datasets

We conduct experiments on three real-world public datasets, FUNSD-R, CORD and SROIE.

The FUNSD-R Dataset. FUNSD (Jaume et al., 2019) is a public dataset of 199 fully annotated forms, which is composed of 4 entity types (*i.e.* Question, Answer, Header and Other). The original dataset has both semantic entity extraction (EE) and semantic entity linking (EL) tasks. It's noteworthy that the linking between different entities are complicated, one header entity may have linking to several question entities with more answer entities linked.

To better evaluate the system performance in the multi-key scenario, we relabel the dataset in key-value pairs format to tackle EE and EL tasks simultaneously. We named the new dataset FUNSD-R, which contains 1,421 keys for training and 397 keys for testing. Meanwhile, there are 267 keys in the test set that have not appeared in the training set. FUNSD-R will be released soon.

The CORD Dataset. The CORD (Park et al., 2019) dataset contains 800 receipts for the training set, 100 for the validation set and 100 for the test set. The dataset defines 30 fields under 4 categories and the task aims to label each word to the right field.

The SROIE Dataset. SROIE (Huang et al., 2019) dataset contains 626 receipts for training and 347 receipts for testing. Each entity of the receipt is annotated with pre-defined categories such as company, date, address, and total.

To further investigate the capacity of our proposed method under more challenging scenarios, we expand "SROIE" and "CORD" datasets to "SROIE-S" and "CORD-S" by shuffling the order of text lines and keep the box coordinates to simulate complex layouts. The evaluation metric is the exact match of the entity recognition results in the F1 score.

4.2 Implementation Details

Model Pre-training. We initialize the weight of GMN model with the pre-trained UniLM base model except for the position embedding layer and visual embedding layer. Specifically, our BASE model has the same architecture: a 12-layer Transformer with 768 hidden sizes, and 12 attention heads. For the LARGE setting, our model has a 24-layer Transformer with 1,024 hidden sizes and 16 attention heads, which is initialized by the pre-trained UniLM LARGE model. For unidir-LM and bidir-LM methods, we select 15% of the input tokens of sentence A for prediction. We replace these masked tokens with the $[MASK]$ token 80% of the time, a random token 10% of the time, and an unchanged token 10% of the time. For seq-to-seq LM and NER-LM, we select 15% tokens of the sentence B. The target of the token is the next token. Then, the model predicts the corresponding token with the cross-entropy loss.

In addition, we also add the two-dimensional position embedding and visual embedding for pre-training. Considering that the document layout may vary in different page sizes, we scale the actual coordinate to a “virtual" coordinate: the actual coordinate is scaled to have a value from 0 to 1,000, and rescale the images to the size of 512×512.

We train our model on 64 NVIDIA Tesla V100 32GB GPUs with a total batch size of 1,024. The Adam optimizer is used with an initial learning rate of 5e-5 and a linear decay learning rate schedule.

Task-specific Fine-tunings. We evaluate the model following the typical fine-tuning strategy and update all parameters in an end-to-end way on task-specific datasets. We arrange the source OCR result from top to bottom and left to right. In addition, we add the “$[DSEP]$” as the separator between text detection boxes. In SROIE and CORD datasets, we construct the target key-value pairs in a certain order due to the keys being limited. (*i.e.* company, date, address, total). In the FUNSD dataset, we organize the target key-value pairs from top to bottom and left to right. We add the “:” as the separator between key and value and “$[DSEP]$” as the separator between key-value pairs. The max source length parameter is set to 768 in the SROIE and CORD datasets and 1536 in the FUNSD-R datasets, so input sequences below max length will be padding to the same length. The model is trained for 100 epochs with a batch size of 48 and a learning rate of 5e-5. Note that, the annotations of all GMN results are the weakly-supervised label of sentence-level while other methods use word-level annotations.

4.3 Comparison to State-of-the-Arts

We compare our method with several state-of-the-arts on the FUNSD-R, SROIE and CORD benchmarks. We use the publicly available PyTorch models for BERT, UniLM and LayoutLM in all the experiment settings. The results of PICK (Yu et al., 2020), MatchVIE (Tang et al., 2021), BROS (Hong et al., 2021), StrucTexT (Li et al., 2021b), SPADE (Hwang et al., 2021) and DocFormer (Appalaraju et al., 2021) are obtained from the original papers.

Model	Precision	Recall	F1
Bert$_{LARGE}$	0	0	0
LayoutLM$_{LARGE}$	0	0	0
GMN $_{BASE}$	0.5264	0.4866	0.5057
GMN $_{LARGE}$	**0.5568**	**0.5116**	**0.5333**

Table 1: Model results on the FUNSD-R dataset, methods based on sequence labeling yield under scene with larger amount of keys.

Model	Precision	Recall	F1
BERT$_{BASE}$	0.9099	0.9099	0.9099

GMN$_{LARGE}$	**0.9956**	0.9690	**0.9821**

Table 2: Model results on the SROIE dataset with Ground Truth Setting.

Results under scene with larger amount of keys. Table 1 shows the model results on the FUNSD-R dataset which is evaluated using entity-level precision, recall and F1 score. In the case of a large number of key categories, especially in the case that some categories have not appeared in the training set, the method based on sequence labeling yield, neither the Bert model, which only contains text modality nor the LayoutLM which also contains layout and visual modalities.

The best performance is achieved by the GMN_{LARGE}, where a significant improvement is observed compared to other methods. Note that, 67.25% of keys have not appeared in the training set, This illustrates that the generative method in GMN is suitable for scenes with a large number of keys.

Results with Ground Truth Setting. Under this setting, the ground truth texts are adopted as model input. As shown in Table 2 and Table 3, even using weakly supervised labels, our approach shows excellent performance on both SROIE and CORD, and yields new SOTA results, which indicates that GMN has a powerful representational capability and can significantly boost the performance on DIE tasks.

GMN$_{LARGE}$	**0.8165**	**0.8368**	**0.8265**

Table 4: Model results on the SROIE and CORD datasets with End-to-End Setting.

Results with End-to-End Setting. We adopt Tesseract as OCR engine to get the OCR result of public datasets. It's worth noting that there are exist some OCR errors, the sequence labeling method can not handle, but in our GMN, the matching process between OCR results and ground truth is avoided thanks to the novel layout embedding method in an end-to-end training setting. The performances are shown in Table 4. Our method shows new state-of-the-art performance benefits from the ability to error correction. A detailed analysis of it is introduced in case studies B.

Results with Position Shuffle Setting. In order to verify the robustness of our two-dimensional embedding method, we apply a shuffling operation on boxes of the test dataset. As shown in Table 5, compared with models that have one-dimensional position embeddings, our method is more robust to input disruption with a big gap.

4.4 Ablation Study

An ablation study is conducted to demonstrate the effects of different modules in the proposed model. We remove some components to construct several comparable baselines on the CORD dataset. The statistics are listed in Table 6.

Model	SROIE-S		
	Precision	Recall	F1
BERT$_{BASE}$	0.0702	0.0490	0.0577
LayoutLM$_{BASE}$	0.7169	0.6880	0.7022
GMN$_{BASE}$	**0.9679**	**0.9424**	**0.9550**
Model	**CORD-S**		
	Precision	**Recall**	**F1**
BERT$_{BASE}$	0.1235	0.1384	0.1305
LayoutLM$_{BASE}$	0.6917	0.7139	0.7026
GMN$_{BASE}$	**0.9345**	**0.9488**	**0.9416**

Table 5: Model results on the SROIE-S and CORD-S datasets with Position Shuffle Setting.

Model	Precision	Recall	F1
GMN	**0.9693**	**0.9798**	**0.9745**
GMN w/o Image	0.9623	0.9608	0.9616
GMN w/o NER-LM	0.96	0.9585	0.9593
GMN w/o MAMM	0.9576	0.9547	0.9562

Table 6: Model results of different components of our method on the CORD dataset.

The "GMN w/o MAMM" means using the same multi-modal feature as LayoutLM. Compared with LayoutLM, MAMM brings about 1.82% improvement of F1, which verifies the validation of MAMM. The "GMN w/o Image" means removing the image feature extraction. Experiment results show that visual modality can also improve the performance. Moreover, with NER-LM considered, the performance of information extraction increases to 97.45%. Extended experiments including attention visualization analysis and case studies can refer to Appendix A and B.

5 CONCLUSION

In this work, we propose a Generative Multi-modal Network (GMN) for practical document information extraction. Since GMN is a generation method including no pre-defined label category, it supports scenes that contain unknown similar keys and tolerates OCR errors, meanwhile requires no character-level annotation. We conduct extensive experiments on publicly available datasets to validate our method, experimental results demonstrate that GMN achieves state-of-the-art results on several public DIE datasets, especially in the practical scenarios. Though our GMN significantly outperforms other DIE models, there still exists potential to be exploited as regard to practical scenarios. In order to cope with complicated layout information as well as ambiguous semantic representations, we argue that more attention should be paid to the modality embedding and interaction strategy, which has more opportunity to handle such difficult cases.

Appendix

A Attention Visualization

To further explore what context information is focused by our GMN, we visualize the attention map of the multi-head Transformer, as shown in Figure 4. The input tokens of the model are marked in black and the decoding results are marked in orange, while X-axis represents the attended tokens.

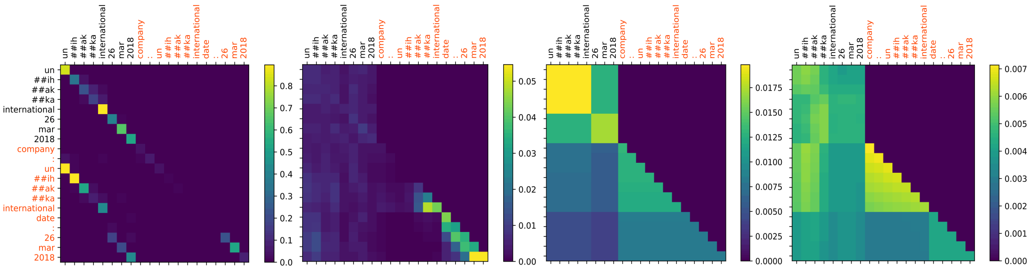

Figure 4: Visualization of the attention map of the multi-head Transformer, representing semantic/X-coord/Y-coord/visual attention results in a row respectively. The decoding result is marked in orange. Best viewed in color.

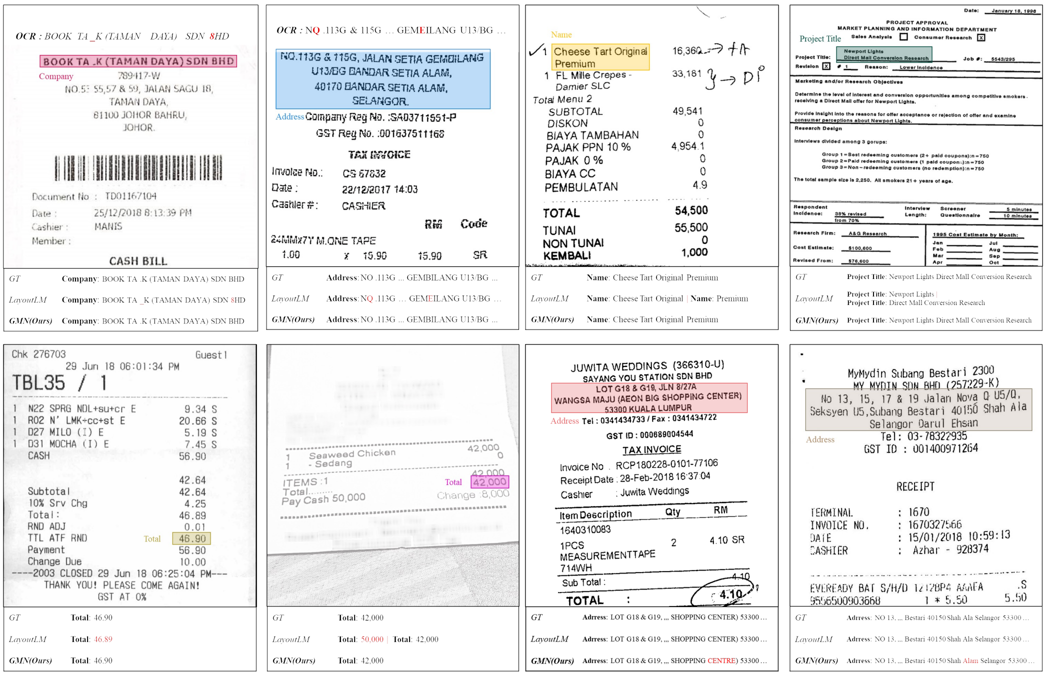

Figure 5: Samples from SROIE/CORD/FUNSD datasets, key examples are highlighted by color boxes. Best viewed in color.

As shown in Figure 3, we use the *Mask* operator to control the attention between each token. The input OCR tokens can attend to each other but the output tokens can only be attended to the already decoded tokens. Consequently, the upper right area of the attention map has no active response, and the area in the lower right corner shows a stepped pattern.

We can observe that the semantic attention mechanism plays an important role in modeling local dependence. In semantic attention, the input OCR tokens mainly focus on themselves and their nearby semantically relevant parts. In contrast, decoded tokens mostly focus on the counterparts in the original tokens, showing a reasonable alignment. Meanwhile, layout and visual attention mechanisms focus on more global information, complementing the semantic attention mechanism.

B Case studies

The motivation behind GMN is to tackle the practical DIE tasks. To verify this, we show some examples of the output of LayoutLM and GMN, as shown in Figure 5. In the sub-figure A and B, GMN successfully corrects the recognition error of OCR results thanks to semantic learning on a large-scale corpus. In the sub-figure C~F, GMN accurately generates the key-value pairs with complex layouts and ambiguous contexts thanks to the novel position embedding method, in comparison LayoutLM is unable to merge the value entities correctly. It's noteworthy that the sub-figures G and H are failed cases, which are caused by semantic obfuscation and reasonable complement to missing character. These examples show that GMN is capable of correcting OCR errors and predicting more accurately in practical scenarios.

One Reference Is Not Enough: Diverse Distillation with Reference Selection for Non-Autoregressive Translation

Abstract

Non-autoregressive neural machine translation (NAT) suffers from the multi-modality problem: the source sentence may have multiple correct translations, but the loss function is calculated only according to the reference sentence. Sequence-level knowledge distillation makes the target more deterministic by replacing the target with the output from an autoregressive model. However, the multi-modality problem in the distilled dataset is still nonnegligible. Furthermore, learning from a specific teacher limits the upper bound of the model capability, restricting the potential of NAT models. In this paper, we argue that one reference is not enough and propose diverse distillation with reference selection (DDRS) for NAT. Specifically, we first propose a method called SeedDiv for diverse machine translation, which enables us to generate a dataset containing multiple high-quality reference translations for each source sentence. During the training, we compare the NAT output with all references and select the one that best fits the NAT output to train the model. Experiments on widely-used machine translation benchmarks demonstrate the effectiveness of DDRS, which achieves 29.82 BLEU with only one decoding pass on WMT14 En-De, improving the state-of-the-art performance for NAT by over 1 BLEU.[1]

1 Introduction

Non-autoregressive machine translation (Gu et al., 2018) has received increasing attention in the field of neural machine translation for the property of parallel decoding. Despite the significant speedup, NAT suffers from the performance degradation compared to autoregressive models (Bahdanau et al., 2015; Vaswani et al., 2017) due to the multi-modality problem: the source sentence may have multiple correct translations, but the loss is calculated only according to the reference sentence. The multi-modality problem will cause the inaccuracy of the loss function since NAT has no prior knowledge about the reference sentence during the generation, where the teacher forcing algorithm (Williams and Zipser, 1989) makes autoregressive models less affected by feeding the golden context.

How to overcome the multi-modality problem has been a central focus in recent efforts for improving NAT models (Shao et al., 2019, 2020, 2021; Ran et al., 2020; Sun and Yang, 2020; Ghazvininejad et al., 2020; Du et al., 2021). A standard approach is to use sequence-level knowledge distillation (Kim and Rush, 2016), which attacks the multi-modality problem by replacing the target-side of the training set with the output from an autoregressive model. The distilled dataset is less complex and more deterministic (Zhou et al., 2020), which becomes a default configuration of NAT. However, the multi-modality problem in the distilled dataset is still nonnegligible (Zhou et al., 2020). Furthermore, the distillation requires NAT models to imitate the behavior of a specific autoregressive teacher, which limits the upper bound of the model capability and restricts the potential of developing stronger NAT models.

In this paper, we argue that one reference is not enough and propose diverse distillation with reference selection (DDRS) for NAT. Diverse distillation generates a dataset containing multiple reference translations for each source sentence, and reference selection finds the reference translation that best fits the model output for the training. As illustrated in Figure 1, diverse distillation provides candidate references “I must leave tomorrow" and “Tomorrow I must leave", and reference selection selects the former which fits better with the model output. More importantly, NAT with DDRS does not imitate the behavior of a specific teacher but learns selectively from multiple references, which

July 10-15, 2022

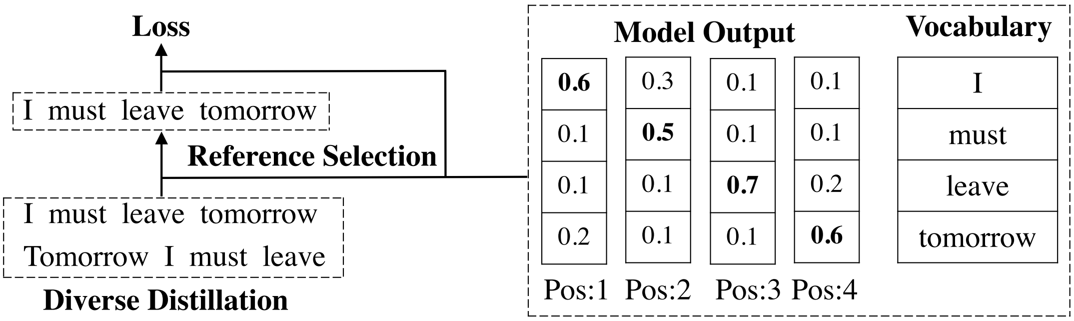

Figure 1: Illustration of diverse distillation and reference selection. Diverse distillation provides multiple references and reference selection selects the one that best fits the model output for the training.

improves the upper bound of the model capability and allows for developing stronger NAT models.

The object of diverse distillation is similar to the task of diverse machine translation, which aims to generate diverse translations with high translation quality (Li et al., 2016; Vijayakumar et al., 2018; Shen et al., 2019; Wu et al., 2020; Li et al., 2021). We propose a simple yet effective method called SeedDiv, which directly uses the randomness in model training controlled by random seeds to produce diverse reference translations without losing translation quality. For reference selection, we compare the model output with all references and select the one that best fits the model output, which can be efficiently conducted without extra neural computations. The model learns from all references indiscriminately in the beginning, and gradually focuses more on the selected reference that provides accurate training signals for the model. We also extend the reference selection approach to reinforcement learning, where we encourage the model to move towards the selected reference that gives the maximum reward to the model output.

We conduct experiments on widely-used machine translation benchmarks to demonstrate the effectiveness of our method. On the competitive task WMT14 En-De, DDRS achieves 27.60 BLEU with 14.7× speedup and 28.33 BLEU with 5.0× speedup, outperforming the autoregressive Transformer while maintaining considerable speedup. When using the larger version of Transformer, DDRS even achieves 29.82 BLEU with only one decoding pass, improving the state-of-the-art performance level for NAT by over 1 BLEU.

2 Background

2.1 Non-Autoregressive Translation

Gu et al. (2018) proposes non-autoregressive machine translation to reduce the translation latency through parallel decoding. The vanilla-NAT models the translation probability from the source sentence $\boldsymbol{x}$ to the target sentence $\boldsymbol{y}=\{y_1,...,y_T\}$ as:

$$p(\boldsymbol{y}|\boldsymbol{x},\theta)=\prod_{t=1}^{T} p_t(y_t|\boldsymbol{x},\theta), \qquad (1)$$

where θ is a set of model parameters and $p_t(y_t|\boldsymbol{x},\theta)$ is the translation probability of word y_t in position t. The vanilla-NAT is trained to minimize the cross-entropy loss:

$$\mathcal{L}_{CE}(\theta)=-\sum_{t=1}^{T}\log(p_t(y_t|\boldsymbol{x},\theta)). \qquad (2)$$

The vanilla-NAT has to know the target length before constructing the decoder inputs. The target length T is set as the reference length during the training and obtained from a length predictor during the inference. The target length cannot be changed dynamically during the inference, so it often requires generating multiple candidates with different lengths and re-scoring them to produce the final translation (Gu et al., 2018).

The length issue can be overcome by connectionist temporal classification (CTC, Graves et al., 2006). CTC-based models usually generate a long alignment containing repetitions and blank tokens. The alignment will be post-processed by a collapsing function Γ^{-1} to recover a normal sentence, which first collapses consecutive repeated tokens and then removes all blank tokens. CTC is capable of efficiently finding all alignments $\boldsymbol{a}$ which the reference sentence $\boldsymbol{y}$ can be recovered from, and marginalizing the log-likelihood with dynamic programming:

$$\log p(\boldsymbol{y}|\boldsymbol{x},\theta)=\log\sum_{\boldsymbol{a}\in\Gamma(\boldsymbol{y})} p(\boldsymbol{a}|\boldsymbol{x},\theta). \qquad (3)$$

Due to the superior performance and the flexibility of generating predictions with variable length, CTC is receiving increasing attention in non-autoregressive translation (Libovický and Helcl, 2018; Kasner et al., 2020; Saharia et al., 2020; Gu and Kong, 2020; Zheng et al., 2021).

2.2 Sequence-Level Knowledge Distillation

Sequence-level Knowledge Distillation (SeqKD, Kim and Rush, 2016) is a widely used knowledge distillation method in NMT, which trains the student model to mimic teacher's actions at sequence-level. Given the student prediction p and the teacher prediction q, the distillation loss is:

$$\begin{aligned}\mathcal{L}_{SeqKD}(\theta) &= -\sum_{\boldsymbol{y}} q(\boldsymbol{y}|\boldsymbol{x}) \log p(\boldsymbol{y}|\boldsymbol{x},\theta) \\ &\approx -\log p(\hat{\boldsymbol{y}}|\boldsymbol{x},\theta),\end{aligned} \tag{4}$$

where θ are parameters of the student model and $\hat{\boldsymbol{y}}$ is the output from running beam search with the teacher model. The teacher output $\hat{\boldsymbol{y}}$ is used to approximate the teacher distribution otherwise the distillation loss will be intractable.

The procedure of sequence-level knowledge distillation is: (1) train a teacher model, (2) run beam search over the training set with this model, (3) train the student model with cross-entropy on the source sentence and teacher translation pairs. The distilled dataset is less complex and more deterministic (Zhou et al., 2020), which helps to alleviate the multi-modality problem and becomes a default configuration in NAT models.

2.3 Diverse Machine Translation

The task of diverse machine translation requires to generate diverse translations and meanwhile maintain high translation quality. Assume the reference sentence is $\boldsymbol{y}$ and we have multiple translations $\{\boldsymbol{y_1}, ..., \boldsymbol{y_k}\}$, the translation quality is measured by the average reference BLEU (rfb):

$$\text{rfb} = \frac{1}{k}\sum_{i=1}^{k} \text{BLEU}(\boldsymbol{y}, \boldsymbol{y_i}), \tag{5}$$

and the translation diversity is measured by the average pairwise BLEU (pwb):

$$\text{pwb} = \frac{1}{(k-1)k}\sum_{i=1}^{k}\sum_{j\neq i} \text{BLEU}(\boldsymbol{y_i}, \boldsymbol{y_j}). \tag{6}$$

Higher reference BLEU indicates better translation quality and lower pairwise BLEU indicates better translation diversity. Generally speaking, there is a trade-off between quality and diversity. In existing methods, translation diversity has to be achieved at the cost of losing translation quality.

3 Approach

In this section, we first introduce the diverse distillation technique we use to generate multiple reference translations for each source sentence, and then apply reference selection to select the reference that best fits the model output for the training.

3.1 Diverse Distillation

The objective of diverse distillation is to obtain a dataset containing multiple high-quality references for each source sentence, which is similar to the task of diverse machine translation that aims to generate diverse translations with high translation quality. However, the translation diversity is achieved at a certain cost of translation quality in previous work, which is not desired in diverse distillation.

Using the randomness in model training, we propose a simple yet effective method called SeedDiv to achieve translation diversity without losing translation quality. Specifically, given the desired number of translations k, we directly set k different random seeds to train k translation models, where random seeds control the random factors during the model training such as parameter initialization, batch order, and dropout. During the decoding, each model translates the source sentence with beam search, which gives k different translations in total. Notably, SeedDiv does not sacrifice the translation quality to achieve diversity since random seeds do not affect the expected model performance.

We conduct the experiment on WMT14 En-De to evaluate the performance of SeedDiv. We use the base setting of Transformer and train the model for 150K steps. The detailed configuration is described in section 4.1. We also re-implement several existing methods with the same setting for comparison, including Beam Search, Diverse Beam Search (Vijayakumar et al., 2018), HardMoE (Shen et al., 2019), Head Sampling (Sun et al., 2020) and Concrete Dropout (Wu et al., 2020). We set the number of translations $k=3$, and set the number of heads to be sampled as 3 for head sampling. We also implement a weaker version of our method SeedDiv-ES, which early stops the training process with only $\frac{1}{k}$ of total training steps. We report the results of

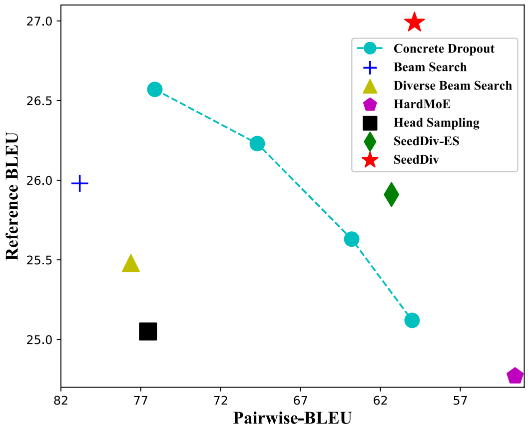

Figure 2: Reference BLEU and pairwise BLEU scores of SeedDiv and other diverse translation methods on the test set of WMT14 En-De. We do not use compound split to keep consistency with previous work.

these methods in Figure 2.

It is surprising to see that SeedDiv achieves outstanding translation diversity besides the superior translation quality, which outperforms most methods on both translation quality and diversity. Only HardMoe has a better pairwise BLEU than SeedDiv, but its reference BLEU is much lower. The only concern is that SeedDiv requires a larger training cost to train multiple models, so we also use a weaker version SeedDiv-ES for comparison. Though the model performance is degraded due to the early stop, SeedDiv-ES still achieves a good trade-off between the translation quality and diversity, demonstrating the advantage of using the training randomness controlled random seeds to generate diverse translations. Therefore, we use SeedDiv as the technique for diverse distillation.

3.2 Reference Selection

3.2.1 Losses under Diverse Distillation

After diverse distillation, we obtain a dataset containing k reference sentences $\boldsymbol{y_{1:k}}$ for each source sentence $\boldsymbol{x}$. Traditional data augmentation algorithms for NMT (Sennrich et al., 2016a; Zhang and Zong, 2016; Zhou and Keung, 2020; Nguyen et al., 2020) generally calculate cross-entropy losses on all data and use their summation to train the model:

$$\mathcal{L}_{sum}(\theta) = -\frac{1}{k}\sum_{i=1}^{k}\log p(\boldsymbol{y_i}|\boldsymbol{x},\theta). \qquad (7)$$

However, this loss function is inaccurate for NAT due to the increase of data complexity. Sequence-level knowledge distillation works well on NAT by reducing the complexity of target data (Zhou et al., 2020). In comparison, the target data generated by diverse distillation is relatively more complex. If NAT learns from the k references indiscriminately, it will not eventually converge to any one reference but generate a mixture of all references.

Using the multi-reference dataset, we propose to train NAT with reference selection to evaluate the model output with better accuracy. We compare the model output with all reference sentences and select the one with the maximum probability assigned by the model. We train the model with only the selected reference:

$$\mathcal{L}_{max}(\theta) = -\log \max_{1\leq i\leq k} p(\boldsymbol{y_i}|\boldsymbol{x},\theta). \qquad (8)$$

In this way, we do not fit the model to all references but only encourage it to generate the nearest reference, which is an easier but more suitable objective for the model. Besides, when the ability of autoregressive teacher is limited, the NAT model can learn to ignore bad references in the data and select the clean reference for the training, which makes the capability of NAT not limited by a specific autoregressive teacher.

In addition to minimizing all losses $\mathcal{L}_{sum}(\theta)$ or the selected loss $\mathcal{L}_{max}(\theta)$, there is also an intermediate choice to assign different weights to reference sentences. We can optimize the log-likelihood of generating any reference sentence as follows:

$$\mathcal{L}_{mid}(\theta) = -\log\sum_{i=1}^{k} p(\boldsymbol{y_i}|\boldsymbol{x},\theta). \qquad (9)$$

The gradient of Equation 9 is equivalent to assigning weight $\frac{p(\boldsymbol{y_i}|\boldsymbol{x},\theta)}{\sum_i p(\boldsymbol{y_i}|\boldsymbol{x},\theta)}$ to the cross-entropy loss of each reference sentence $\boldsymbol{y_i}$. In this way, the model focuses more on suitable references but also assigns non-zero weights to other references.

We use a linear annealing schedule with two stages to train the NAT model. In the first stage, we begin with the summation $\mathcal{L}_{sum}(\theta)$ and linearly anneal the loss to $\mathcal{L}_{mid}(\theta)$. Similarly, we linearly switch to the selected loss $\mathcal{L}_{max}(\theta)$ in the second stage. We use t and T to denote the current time step and total training steps respectively, and use a constant λ to denote the length of the first stage. The loss function is:

$$\mathcal{L}(\theta)=\begin{cases} T_1\mathcal{L}_{mid}(\theta)+(1-T_1)\mathcal{L}_{sum}(\theta), & t\leq\lambda T \\ T_2\mathcal{L}_{max}(\theta)+(1-T_2)\mathcal{L}_{mid}(\theta), & t>\lambda T \end{cases}, \qquad (10)$$

Models	$\mathcal{L}_{max}(\theta)$ For	$\mathcal{L}_{max}(\theta)$ Back	$\mathcal{L}_{sum}(\theta)$ For	$\mathcal{L}_{sum}(\theta)$ Back
AT	$k\times$	$1\times$	$k\times$	$k\times$
vanilla-NAT	$k\times$	$1\times$	$k\times$	$k\times$
CTC	$1\times$	$1\times$	$1\times$	$1\times$

Table 1: The calculation cost of $\mathcal{L}_{max}(\theta)$ and $\mathcal{L}_{sum}(\theta)$ for different models. 'For' and 'Back' indicate forward and backward propagations respectively.

where T_1 and T_2 are defined as:

$$T_1 = \frac{t}{\lambda T}, \quad T_2 = \frac{t - \lambda T}{T - \lambda T}. \tag{11}$$

In this way, the model learns from all references indiscriminately at the beginning, which serves as a pretraining stage that provides comprehensive knowledge to the model. As the training progresses, the model focuses more on the selected reference, which provides accurate training signals and gradually finetunes the model to the optimal state.

3.2.2 Efficient Calculation with CTC

To calculate the probability $p(\boldsymbol{y}|\boldsymbol{x},\theta)$, the vanilla-NAT must set the decoder length to the length of $\boldsymbol{y}$. Therefore, calculating the probability of k reference sentences requires running the decoder for at most k times, which will greatly increase the training cost. Fortunately, for CTC-based NAT, the training cost is nearly the same since its decoder length is only determined by the source sentence. We only need to run the model once and calculate the probabilities of the k reference sentences with dynamic programming, which has a minor cost compared with forward and backward propagations. In Table 1, we show the calculation cost of $\mathcal{L}_{max}(\theta)$ and $\mathcal{L}_{sum}(\theta)$ for different models. We use CTC as the baseline model due to its superior performance and training efficiency.

3.2.3 Max-Reward Reinforcement Learning

Following Shao et al. (2019, 2021), we finetune the NAT model with the reinforcement learning objective (Williams, 1992; Ranzato et al., 2015):

$$\mathcal{L}_{rl}(\theta) = \mathop{\mathbb{E}}_{\boldsymbol{y}}[\log p(\boldsymbol{y}|\boldsymbol{x},\theta) \cdot r(\boldsymbol{y})], \tag{12}$$

where $r(\boldsymbol{y})$ is the reward function and will be discussed later. The usual practice is to sample a sentence $\boldsymbol{y}$ from the distribution $p(\boldsymbol{y}|\boldsymbol{x},\theta)$ to estimate the above equation. For CTC based NAT, $p(\boldsymbol{y}|\boldsymbol{x},\theta)$ cannot be directly sampled, so we sample from the equivalent distribution $p(\boldsymbol{a}|\boldsymbol{x},\theta)$ instead. We recover the target sentence by the collapsing function Γ^{-1} and calculate its probability with dynamic programming to estimate the following equation:

$$\mathcal{L}_{rl}(\theta) = \mathop{\mathbb{E}}_{\boldsymbol{a}}[\log p(\Gamma^{-1}(\boldsymbol{a})|\boldsymbol{x},\theta) \cdot r(\Gamma^{-1}(\boldsymbol{a}))]. \tag{13}$$

The reward function is usually evaluation metrics for machine translation (e.g., BLEU, GLEU), which evaluate the prediction by comparing it with the reference sentence. We use $r(\boldsymbol{y_1},\boldsymbol{y_2})$ to denote the reward of prediction $\boldsymbol{y_1}$ when $\boldsymbol{y_2}$ is the reference. As we have k references $\boldsymbol{y_{1:k}}$, we define our reward function to be the maximum reward:

$$r(\boldsymbol{y}) = \max_{1\le i\le k} r(\boldsymbol{y},\boldsymbol{y_i}). \tag{14}$$

By optimizing the maximum reward, we encourage the model to move towards the selected reference, which is the closest to the model. Otherwise, rewards provided by other references may mislead the model to generate a mixture of all references.

4 Experiments

4.1 Experimental Settings

Datasets We conduct experiments on major benchmark datasets for NAT: WMT14 English↔German (En↔De, 4.5M sentence pairs) and WMT16 English↔Romanian (En↔Ro, 0.6M sentence pairs). We also evaluate our approach on a large-scale dataset WMT14 English→French (En→Fr, 23.7M sentence pairs) and a small-scale dataset IWSLT14 German→English (De→En, 160K sentence pairs). The datasets are tokenized into subword units using a joint BPE model (Sennrich et al., 2016b). We use BLEU (Papineni et al., 2002) to evaluate the translation quality.

Hyperparameters We use 3 teachers for diverse distillation and set the seed to i when training the i-th teacher. We set the first stage length λ to $2/3$. We use sentence-level BLEU as the reward. We adopt Transformer-base (Vaswani et al., 2017) as our autoregressive baseline as well as the teacher model. The NAT model shares the same architecture as Transformer-base. We uniformly copy encoder outputs to construct decoder inputs, where the length of decoder inputs is $3\times$ as long as the source length. All models are optimized with Adam (Kingma and Ba, 2014) with $\beta = (0.9, 0.98)$ and $\epsilon = 10^{-8}$, and each batch contains approximately 32K source words. On WMT14 En↔De and WMT14 En→Fr,

Table 2: Performance comparison between our models and existing methods. The speedup is measured on WMT14 En-De test set. N denotes the length of translation. k means ensemble distillation (Freitag et al., 2017) from an ensemble of k AT models. – means not reported.

we train AT for 150K steps and train NAT for 300K steps with dropout 0.2. On WMT16 En↔Ro and IWSLT14 De→En, we train AT for 18K steps and train NAT for 150K steps with dropout 0.3. We finetune NAT for 3K steps. The learning rate warms up to $5 \cdot 10^{-4}$ within 10K steps in pretraining and warms up to $2 \cdot 10^{-5}$ within 500 steps in RL finetuning, and then decays with the inverse square-root schedule. We average the last 5 checkpoints to obtain the final model. We use GeForce RTX 3090 GPU for the training and inference. We implement our models based on the open-source framework of fairseq (Ott et al., 2019).

Knowledge Distillation For baseline NAT models, we follow previous works on NAT to apply sequence-level knowledge distillation (Kim and Rush, 2016) to make the target more deterministic. Our method applies diverse distillation with $k = 3$ by default, that is, we use SeedDiv to generate 3 reference sentences for each source sentence.

Beam Search Decoding For autoregressive models, we use beam search with beam width 5 for the inference. For NAT, the most straightforward way is to generate the sequence with the highest probability at each position. Furthermore, CTC-based models also support beam search decoding optionally combined with n-gram language models (Kasner et al., 2020). Following Gu and Kong (2020), we use beam width 20 combined with a 4-gram language model to search the target sentence, which can be implemented efficiently in C++[2].

4.2 Main Results

We compare the performance of DDRS and existing methods in Table 2. Compared with the competitive CTC baseline, DDRS achieves a strong improvement of more than 1.5 BLEU on average, demonstrating the effectiveness of diverse distillation and reference selection. Compared with exist-

Table 5: Ablation study on WMT14 En-De with different combinations of techniques. BLEU$_1$ is the BLEU score on validation set. BLEU$_2$ is the BLEU score on test set. The validation performance of CTC baseline is 24.57 BLEU. λ is the length of the first training stage. *random* means the reward of a random reference, *average* means the average reward, and *maximum* means the maximum reward among all references.

ing methods, DDRS beats the state-of-the-art for one-pass NAT on all benchmarks and beats the autoregressive Transformer on most benchmarks with 14.7× speedup over it. The performance of DDRS is further boosted by beam search and 4-gram language model, which even outperforms all iterative NAT models with only one-pass decoding. Notably, on WMT16 En↔Ro, our method improves state-of-the-art performance levels for NAT by over 1 BLEU. Compared with autoregressive models, our method outperforms the Transformer with knowledge distillation, and meanwhile maintains 5.0× speedup over it.

We further explore the capability of DDRS with a larger model size and stronger teacher models. We use the big version of Transformer for distillation, and also add 3 right-to-left (R2L) teachers to enrich the references. We respectively use Transformer-base and Transformer-big as the NAT architecture and report the performance of DDRS in Table 3. Surprisingly, the performance of DDRS can be further greatly boosted by using a larger model size and stronger teachers. DDRS-big with beam search achieves 29.82 BLEU on WMT14 En-De, which is close to the state-of-the-art performance of autoregressive models on this competitive dataset and improves the state-of-the-art performance for NAT by over 1 BLEU with only one-pass decoding.

We also evaluate our approach on a large-scale dataset WMT14 En-Fr and a small-scale dataset IWSLT14 De-En. Table 4 shows that DDRS still achieves considerable improvements over the CTC baseline and DDRS with beam search can outperform the autoregressive Transformer.

4.3 Ablation Study

In Table 5, we conduct an ablation study to analyze the effect of techniques used in DDRS. First, we separately use the loss functions defined in Equation 7, Equation 8 and Equation 9 to train the model. The summation loss $\mathcal{L}_{sum}(\theta)$ has a similar performance to the CTC baseline, showing that simply using multiple references is not helpful for NAT due to the increase of data complexity. The other two losses $\mathcal{L}_{mid}(\theta)$ and $\mathcal{L}_{max}(\theta)$ achieve considerable improvements to the CTC baseline, demonstrating the effectiveness of reference selection.

Then we use different λ to verify the effect of the annealing schedule. With the annealing schedule, the loss is a combination of the three losses but performs better than each of them. Though the summation loss $\mathcal{L}_{sum}(\theta)$ does not perform well when used separately, it can play the role of pretraining and improve the final performance. When λ is $2/3$, the annealing schedule performs the best and improves $\mathcal{L}_{max}(\theta)$ by about 0.3 BLEU.

Finally, we verify the effect of the reward function during the fine-tuning. When choosing a random reference to calculate the reward, the fine-tuning barely brings improvement to the model. The average reward is better than the random reward, and the maximum reward provided by the selected reference performs the best.

Models	$\mathcal{L}_{CE}$	$\mathcal{L}_{sum}$	$\mathcal{L}_{mid}$	$\mathcal{L}_{max}$
AT	27.70	28.08	27.37	27.21
NAT	26.09	25.97	26.90	26.88

Table 6: The performance of AT and CTC-based NAT on the same diverse distillation dataset of WMT14 En-De with different loss functions. $\mathcal{L}_{CE}$ is the cross-entropy loss with sequence-level distillation. $\mathcal{L}_{sum}$, $\mathcal{L}_{mid}$, and $\mathcal{L}_{max}$ described in section 3.2.1 are losses for the diverse distillation dataset.

Methods	pwb ⇓	rfb⇑	BLEU
HardMoe	53.57	24.77	24.51
Dropout	69.71	26.23	25.35
SeedDiv	59.87	26.99	**25.92**

Table 7: Pairwise BLEU (pwb) and reference BLEU (rfb) scores of diverse translation techniques and their DDRS performance on WMT14 En-De validation set. pwb and rfb scores are measured on WMT14 En-De test set without compound split.

4.4 DDRS on Autoregressive Transformer

Though DDRS is proposed to alleviate the multi-modality problem for NAT, it can also be applied to autoregressive models. In Table 6, we report the performance of the autoregressive Transformer when trained by the proposed DDRS losses. In contrast to NAT, AT prefers the summation loss $\mathcal{L}_{sum}$, and the other two losses based on reference selection even degrade the AT performance.

It is within our expectation that AT models do not benefit much from reference selection. NAT generates the whole sentence simultaneously without any prior knowledge about the reference sentence, so the reference may not fit the NAT output well, in which case DDRS is helpful by selecting an appropriate reference for the training. In comparison, AT models generally apply the teacher forcing algorithm (Williams and Zipser, 1989) for the training, which feeds the golden context to guide the generation of the reference sentence. With teacher forcing, AT models do not suffer much from the multi-modality problem and therefore do not need reference selection. Besides, as shown in Table 1, another disadvantage is that the training cost of DDRS is nearly k times as large, so we do not recommend applying DDRS on AT.

4.5 Effect of Diverse Distillation

In the diverse distillation part of DDRS, we apply SeedDiv to generate multiple references. There are also other diverse translation techniques that can be used for diverse distillation. In this section, we evaluate the effect of diverse distillation techniques on the performance of DDRS. Besides SeedDiv, we also use HardMoe (Shen et al., 2019) and Concrete Dropout (Wu et al., 2020) to generate multiple references, and report their performance in Table 7. When applying other techniques for diverse distillation, the performance of DDRS significantly decreases. The performance degradation indicates the importance of high reference BLEU in diverse distillation, as the NAT student directly learns from the generated references.

Models	WMT14		WMT16	
	EN-DE	DE-EN	EN-RO	RO-EN
CTC w/o RL	26.09	29.50	33.55	32.98
BLEU	26.48	30.02	33.64	33.31
METEOR	26.44	29.95	33.68	33.25
GLEU	26.58	29.96	33.59	33.34
BERTScore	26.51	30.20	33.69	33.42
BLEURT	26.66	30.05	33.71	33.35

Table 8: BLEU scores on WMT test sets when using different automatic metrics as reward to finetune CTC.

4.6 Effect of Reward

There are many automatic metrics to evaluate the translation quality. To measure the effect of reward, we respectively use different automatic metrics as reward for RL, which include traditional metrics (BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), GLEU (Wu et al., 2016)) and pretraining-based metrics (BERTScore (Zhang* et al., 2020), BLEURT (Sellam et al., 2020)). We report the results in Table 8. Comparing the three traditional metrics, we can see that there is no significant difference in their performance. The two pretraining-based metrics only perform slightly better than traditional metrics. Considering the performance and computational cost, we use the traditional metric BLEU as the reward.

4.7 Number of References

In this section, we evaluate how the number of references affects the DDRS performance. We set the number of references k to different values and train the CTC model with reference selection. We report the performance of DDRS with different k in Table 9. The improvement brought by increasing k is considerable when k is small, but it soon becomes marginal. Therefore, it is reasonable to use a middle number of references like $k=3$ to balance the distillation cost and performance.

k	1	2	3	5	8
BLEU	25.0	25.6	25.9	26.0	26.1

Table 9: Performance of DDRS with diffent number of references k on WMT14 En-De validation set.

Models	Distill	Train	Total	BLEU
CTC (64K)	5.5h	26.4h	31.9h	26.34
CTC (128K)	5.5h	52.5h	58.0h	26.59
DDRS (32K)	16.5h	19.3h	35.8h	**27.60**

Table 10: Performance and time cost of models with different batch sizes on WMT14 En-De. The time cost is measured on 8 GeForce RTX 3090 GPUs. The cost of Distill includes training teacher models and decoding source sentences.

4.8 Time Cost

The cost of preparing the training data is larger for DDRS since it requires training k teacher models and using each model to decode the training set. We argue that the cost is acceptable since the distillation cost is minor compared to the training cost of NAT, and we can reduce the training cost to make up for it. In Table 10, we report the performance and time cost of models with different batch sizes on the test set of WMT14 En-De. DDRS makes up for the larger distillation cost by using a smaller training batch, which has a similar cost to the CTC model of 64K batch and achieves superior performance compared to models of 128K batch.

5 Related Work

Gu et al. (2018) proposes non-autoregressive translation to reduce the translation latency, which suffers from the multi-modality problem. A line of work introduces latent variables to model the nondeterminism in the translation process, where latent variables are based on fertilities (Gu et al., 2018), vector quantization (Kaiser et al., 2018; Roy et al., 2018; Bao et al., 2021) and variational inference (Ma et al., 2019; Shu et al., 2020). Another branch of work proposes training objectives that are less influenced by the multi-modality problem to train NAT models (Wang et al., 2019; Shao et al., 2019, 2020, 2021; Sun et al., 2019; Ghazvininejad et al., 2020; Shan et al., 2021; Du et al., 2021). Some researchers consider transferring the knowledge from autoregressive models to NAT (Li et al., 2019; Wei et al., 2019; Guo et al., 2020a; Zhou et al., 2020; Sun and Yang, 2020). Besides, some work propose iterative NAT models that refine the model outputs with multi-pass iterative decoding (Lee et al., 2018; Gu et al., 2019; Ghazvininejad et al., 2019; Ran et al., 2020; Kasai et al., 2020). Our work is most related to CTC-based NAT models (Graves et al., 2006; Libovický and Helcl, 2018; Kasner et al., 2020; Saharia et al., 2020; Zheng et al., 2021; Gu and Kong, 2020), which apply the CTC loss to model latent alignments for NAT. In autoregressive models, translations different from the reference can be evaluated with reinforcement learning (Ranzato et al., 2015; Norouzi et al., 2016), probabilistic n-gram matching (Shao et al., 2018), or an evaluation module (Feng et al., 2020).

Our work is also related to the task of diverse machine translation. Li et al. (2016); Vijayakumar et al. (2018) adjust the beam search algorithm by introducing regularization terms to encourage generating diverse outputs. He et al. (2018); Shen et al. (2019) introduce latent variables with the mixture of experts method and use different latent variables to generate diverse translations. Sun et al. (2020) generates diverse translations by sampling different attention heads. Wu et al. (2020) train the translation model with concrete dropout and samples different models from a posterior distribution. Li et al. (2021) generate different translations for the input sentence by mixing it with different sentence pairs sampled from the training corpus. Nguyen et al. (2020) augment the training set by translating the source-side and target-side data with multiple translation models, but they do not evaluate the diversity of the augmented data.

6 Conclusion

In this paper, we propose diverse distillation with reference selection (DDRS) for NAT. Diverse distillation generates a dataset containing multiple references for each source sentence, and reference selection finds the best reference for the training. DDRS demonstrates its effectiveness on various benchmarks, setting new state-of-the-art performance levels for non-autoregressive translation.

Can Rationalization Improve Robustness?

Abstract

A growing line of work has investigated the development of neural NLP models that can produce *rationales*—subsets of input that can explain their model predictions. In this paper, we ask whether such rationale models can provide robustness to adversarial attacks in addition to their interpretable nature. Since these models need to first generate rationales ("rationalizer") before making predictions ("predictor"), they have the potential to ignore noise or adversarially added text by simply masking it out of the generated rationale. To this end, we systematically generate various types of 'AddText' attacks for both token and sentence-level rationalization tasks and perform an extensive empirical evaluation of state-of-the-art rationale models across five different tasks. Our experiments reveal that rationale models show promise in improving robustness but struggle in certain scenarios—e.g., when the rationalizer is sensitive to position bias or lexical choices of the attack text. Further, leveraging human rationales as supervision does not always translate to better performance. Our study is a first step towards exploring the interplay between interpretability and robustness in the rationalize-then-predict framework.[1]

1 Introduction

Rationale models aim to introduce a degree of interpretability into neural networks by implicitly baking in explanations for their decisions (Lei et al., 2016; Bastings et al., 2019; Jain et al., 2020). These models are carried out in a two-stage 'rationalize-then-predict' framework, where the model first selects a subset of the input as a *rationale* and then makes its final prediction for the task solely using the rationale. A human can then inspect the selected rationale to verify the model's reasoning over the most relevant parts of the input for the prediction at hand.

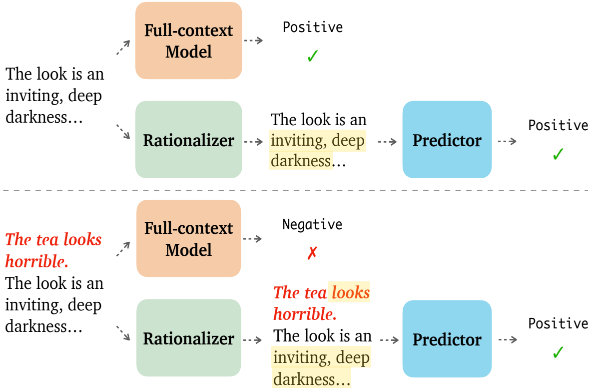

Figure 1: Top: input text is processed by a rationale model (rationalizer and predictor) and a full-context model (making predictions based on the whole input) separately in a *beer review* sentiment classification dataset. Both models make correct predictions. Bottom: when an attack sentence "*The tea looks horrible.*" is inserted, the full-context model fails. The rationalizer successfully excludes the negative-sentiment word "horrible" from the selected rationales (yellow highlights). The predictor is hence not distracted by the attack sentence.

While previous work has mostly focused on the plausibility of extracted rationales and whether they represent faithful explanations (DeYoung et al., 2020), we ask the question of how rationale models behave under adversarial attacks (i.e., do they still provide plausible rationales?) and whether they can help improve robustness (i.e., do they provide better task performance?). Our motivation is that the two-stage decision-making could help models ignore noisy or adversarially added text within the input. For example, Figure 1 shows a state-of-the-art rationale model (Paranjape et al., 2020) smoothly handles input with adversarially added text by selectively masking it out during the rationalization step. Factorizing the rationale prediction from the task itself effectively 'shields' the predictor from

having to deal with adversarial inputs.

To answer these questions, we first generate adversarial tests for a variety of popular NLP tasks (§4). We focus specifically on model-independent, 'AddText' attacks (Jia and Liang, 2017), which augment input instances with noisy or adversarial text at *test time*, and study how the attacks affect rationale models both in their prediction of rationales and final answers. For diversity, we consider inserting the attack sentence at different positions of context, as well as three types of attacks: random sequences of words, arbitrary sentences from Wikipedia, and adversarially-crafted sentences.

We then perform an extensive empirical evaluation of multiple state-of-the-art rationale models (Paranjape et al., 2020; Guerreiro and Martins, 2021), across five different tasks that span review classification, fact verification, and question answering (§5). In addition to the attack's impact on task performance, we also assess rationale prediction by defining metrics on gold rationale coverage and attack capture rate. We then investigate the effect of incorporating human rationales as supervision, the importance of attack positions, and the lexical choices of attack text. Finally, we investigate an idea of improving the rationalizer by adding augmented pseudo-rationales during training (§7).

Our key findings are the following:

1. Rationale models show promise in providing robustness. Under our strongest type of attack, rationale models in many cases achieve less than 10% drop in task performance while full-context models suffer more (11%–27%).
2. However, robustness of rationale models can vary considerably with the choice of lexical inputs for the attack and is quite sensitive to the attack position.
3. Training models with explicit rationale supervision does not guarantee better robustness to attacks. In fact, their accuracy drops under attack are higher by 4-10 points compared to rationale models without supervision.
4. Performance under attacks is significantly improved if the rationalizer can effectively mask out the attack text. Hence, our simple augmented-rationale training strategy can effectively improve robustness (up to 4.9%).

Overall, our results indicate that while there is promise in leveraging rationale models to improve robustness, current models may not be sufficiently equipped to do so. Furthermore, adversarial tests may provide an alternative form to evaluate rationale models in addition to prevalent plausability metrics that measure agreement with human rationales. We hope our findings can inform the development of better methods for rationale predictions and instigate more research into the interplay between interpretability and robustness.

2 Related Work

Rationalization There has been a surge of work on explaining predictions of neural NLP systems, from post-hoc explanation methods (Ribeiro et al., 2016; Alvarez-Melis and Jaakkola, 2017), to analysis of attention mechanisms (Jain and Wallace, 2019; Serrano and Smith, 2019). We focus on *extractive rationalization* (Lei et al., 2016), which generates a subset of inputs or highlights as "rationales" such that the model can condition predictions on them. Recent development has been focusing on improving joint training of rationalizer and predictor components (Bastings et al., 2019; Yu et al., 2019; Jain et al., 2020; Paranjape et al., 2020; Guerreiro and Martins, 2021; Sha et al., 2021), or extensions to text matching (Swanson et al., 2020) and sequence generation (Vafa et al., 2021). These rationale models are mainly compared based on predictive performance, as well as agreement with human annotations (DeYoung et al., 2020). In this work, we question how rationale models behave under adversarial attacks and whether they can provide robustness benefits through rationalization.

Adversarial examples in NLP Adversarial examples have been designed to reveal the brittleness of state-of-the-art NLP models. A flood of research has been proposed to generate different adversarial attacks (Jia and Liang, 2017; Iyyer et al., 2018; Belinkov and Bisk, 2018; Ebrahimi et al., 2018, *inter alia*), which can be broadly categorized by types of input perturbations (sentence-, word- or character-level attacks), and access of model information (black-box or white-box). In this work, we focus on *model-independent*, label-preserving attacks, in which we *insert* a random or an adversarially-crafted sentence into input examples (Jia and Liang, 2017). We hypothesize that a good extractive rationale model is expected to learn to ignore these distractor sentences and hence achieve better performance under attacks.

Interpretability and robustness A key motivation of our work is to bridge the connection between interpretability and robustness, which we believe is an important and under-explored area. Alvarez-Melis and Jaakkola (2018) argue that robustness of explanations is a key desideratum for interpretability. Slack et al. (2020) explore unreliability of attribution methods against input perturbations. Camburu et al. (2020) introduce an adversarial framework to sanity check models against their generated inconsistent free-text explanations. Zhou et al. (2020) propose to evaluate attribution methods through dataset modification. Noack et al. (2021) show that image recognition models can achieve better adversarial robustness when they are trained to have interpretable gradients. To the best of our knowledge, we are the first to quantify the performance of rationale models under textual adversarial attacks and understand whether rationalization can inherently provide robustness.

3 Background

Extractive rationale models[2] output predictions through a two-stage process: the first stage ("rationalizer") selects a subset of the input as a *rationale*, while the second stage ("predictor") produces the prediction using only the rationale as input. *Rationales* can be any subset of the input, and we characterize them roughly into either token-level or sentence-level rationales, which we will both investigate in this work. The task of predicting rationales is often framed as a binary classification problem over each atomic unit depending on the type of rationales. The rationalizer and the predictor are often trained jointly using task supervision, with gradients back-propagated through both stages. We can also provide explicit rationale supervision, if human annotations are available.

3.1 Formulation

Formally, let us assume a supervised classification dataset $\mathcal{D} = \{(x, y)\}$, where each input $x = x_1, x_2, ..., x_T$ is a concatenation of T sentences and each sentence $x_t = (x_{t,1}, x_{t,2}, ...x_{t,n_t})$ contains n_t tokens, and y refers to the task label. A rationale model consists of two main components: 1) a rationalizer module $z = R(x; \theta)$, which generates a discrete mask $z \in \{0, 1\}^L$ such that $z \odot x$ selects a subset from the input ($L = T$ for sentence-level rationalization or $L = \sum_{i=1}^{T} n_i$ for token-level rationales), and 2) a predictor module $\hat{y} = C(x, z; \phi)$ that makes a prediction $\hat{y}$ using the generated rationale z. The entire model $M(x) = C(R(x))$ is trained end-to-end using the standard cross-entropy loss. We describe detailed training objectives in §5.

3.2 Evaluation

Rationale models are traditionally evaluated along two dimensions: a) their downstream task performance, and b) the quality of generated rationales. To evaluate rationale quality, prior work has used metrics like token-level F1 or Intersection Over Union (IOU) scores between the predicted rationale and a human rationale (DeYoung et al., 2020):

$$\text{IOU} = \frac{|z \cap z^*|}{|z \cup z^*|},$$

where z^* is the human-annotated gold rationales.

A good rationale model should not sacrifice task performance while generating rationales that concur with human rationales. However, metrics like F1 score may not be the most appropriate way to capture this as it only captures *plausibility* instead of *faithfulness* (Jacovi and Goldberg, 2020).

4 Robustness Tests for Rationale Models

4.1 AddText Attacks

Our goal is to construct attacks that can test the capability of extractive rationale models to ignore spurious parts of the input. Broadly, we used two guiding criteria for selecting the type of attacks: 1) they should be additive since an extractive rationale model can only "ignore" the irrelevant context. For other attacks such as counterfactually edited data (CAD) (Kaushik et al., 2020), even if the rationalizer could identify the edited context, the predictor is not necessarily strong enough to reason about the counterfactual text; 2) they should be model-independent since our goal is to compare the performance across different types of rationale and baseline models. Choosing strong gradient-based attacks (Ebrahimi et al., 2018; Wallace et al., 2019) would probably break all models, but that is beyond the scope of our hypothesis. An attack is suitable as long as it reduces performance of standard classification models by a non-trivial amount (our attacks reduce performance by 10%–36% absolute).

Keeping these requirements in mind, we focus on label-preserving text addition attacks Jia and Liang (2017), which can test whether rationale

---

[2] Abstractive models (Wiegreffe et al., 2021; Narang et al., 2020), which generate rationales as free text, are an alternative class of models that we do not consider in this work.

models are invariant to the addition of extraneous information and remain consistent with their predictions. Attacks are only added at test time and are not available during model training.

Attack construction Formally, an AddText attack $A(x)$ modifies the input x by adding an attack sentence x_{adv}, without changing the ground truth label y. In other words, we create new perturbed test instances $(A(x), y)$ for the model to be evaluated on. While some prior work has considered the addition of a few tokens to the input (Wallace et al., 2019), we add complete sentences to each input, similar to the attacks in Jia and Liang (2017). This prevents unnatural modifications to the existing sentences in the original input x and also allows us to test both token-level and sentence-level rationale models (§5.1). We experiment with adding the attack sentence x_{adv} either at the beginning or the end of the input x.[3]

Types of attacks We explore three different types of attacks: (1) **AddText-Rand**: we simply add a random sequence of tokens uniformly sampled from the task vocabulary. This is a weak attack that is easy for humans to spot and ignore since it does not guarantee grammaticality or fluency. (2) **AddText-Wiki**: we add an arbitrarily sampled sentence from English Wikipedia into the task input (e.g., "Sonic the Hedgehog, designed for ..."). This attack is more grammatical than AddText-Rand, but still adds text that is likely irrelevant in the context of the input x. (3) **AddText-Adv**: we add an adversarially constructed sentence that has significant lexical overlap with tokens in the input x while ensuring the output label is unchanged. This type of attack is inspired by prior attacks such as AddOneSent (Jia and Liang, 2017) and is the strongest attack we consider since it is more grammatical, fluent, and contextually relevant to the task. The construction of this attack is also specific to each task we consider, hence we provide examples listed in Table 1 and more details in §5.3.

4.2 Robustness Evaluation

We measure the robustness of rationale models under our attacks along two dimensions: *task performance*, and *generated rationales*. The change in task performance is simply computed as the difference between the average scores of the model on the original vs perturbed test sets:

$$\Delta = \frac{1}{|\mathcal{D}|} \sum_{(x,y)\in\mathcal{D}} f(M(x), y) - f(M(A(x)), y),$$

where f denotes a scoring function (F1 scores in extractive question answering and $\mathbb{I}(y = \hat{y})$ in text classification). To measure the effect of the attacks on rationale generation, we use two metrics:

Gold rationale F1 (GR) This is defined as the F1 score between the predicted rationale and a human-annotated rationale, either computed at the token or sentence level. The token-level GR score is equivalent to F1 scores reported in previous work (Lei et al., 2016; DeYoung et al., 2020). A good rationalizer should generate plausible rationales and be not affected by the addition of attack text.

Attack capture rate (AR) We define AR as the recall of the inserted attack text in the rationale generated by the model:

$$\text{AR} = \frac{1}{|\mathcal{D}|} \sum_{(x,y)\sim\mathcal{D}} \frac{|x_{\text{adv}} \cap (z \odot A(x))|}{|x_{\text{adv}}|},$$

where x_{adv} is the attack sentence added to each instance (i.e., $A(x)$ is the result of inserting x_{adv} into x), $z \odot A(x)$ is the predicted rationale. The metric above applies on both token or sentence level ($|x_{\text{adv}}| = 1$ for sentence-level rationalization and number of tokens in the attack sentence for token-level rationalization). This metric allows us to measure how often a rationale model can *ignore* the added attack text—a maximally robust rationale model should have an AR of 0.

5 Models and Tasks

We investigate two different state-of-the-art selective rationalization approaches: 1) sampling-based stochastic binary mask generation (Bastings et al., 2019; Paranjape et al., 2020), and 2) deterministic sparse attention through constrained inference (Guerreiro and Martins, 2021). We adapt these models, using two separate BERT encoders for the rationalizer and the predictor, and consider training scenarios with and without explicit rationale supervision. We also consider a full-context model as baseline. We provide a brief overview of each model here and leave details including loss functions and training to §A.1.

---

[3] In §6.4, we also consider inserting the attack sentence at a random position for studying the effect of attack positions.

Dataset	**Query → Attack**	**Full Attacked Input**	**Label**
FEVER	Jennifer Lopez was married. → Jason Bourne was unmarried.	*Query*: Jennifer Lopez was married. *Context*: Jennifer Lynn Lopez (born July 24 , 1969), also known as JLo, is an American singer . . . She subsequently married longtime friend Marc Anthony . . . Jason Bourne was unmarried.	Supports
SQuAD	Where did Super Bowl 50 take place? → The Champ Bowl 40 took place in Chicago.	*Query*: Where did Super Bowl 50 take place? *Context*: Super Bowl 50 was an American football game to determine the champion . . . was played on February 7, 2016, at Levi's Stadium . . . The Champ Bowl 40 took place in Chicago.	Levi's Stadium
Beer	N/A → The tea looks horrible.	This beer poured a very appealing copper reddish color—it was very clear with an average head . . . The tea looks horrible.	Positive

Table 1: AddText-Adv attack applied to three datasets. The query (blue) is transformed into an attack (red). The query together with the context forms the input. The attack is inserted to the context. We only show insertion at the end, but the attack can be inserted at any position between sentences. A model needs to associate the query and the evidence (ground truth rationale) in the context and not be distracted by the inserted attack to make the correct prediction. Note that the Beer dataset doesn't have a query and the attack sentence is dependent on the label (§5.3).

5.1 Models without Rationale Supervision

Variational information bottleneck (VIB) This model (Paranjape et al., 2020) imposes a discrete bottleneck objective (Alemi et al., 2017) to select a mask $z \in \{0,1\}^L$ from the input x. The rationalizer samples z using Gumbel-Softmax and the predictor uses only $z \odot x$ for the final prediction. During inference, we select the top-k scored rationales, where k is determined by the sparsity π.

Sparse structured text rationalization (SPECTRA) This model (Guerreiro and Martins, 2021) extracts a deterministic structured mask z by solving a constrained inference problem by applying factors to the global scoring function while optimizing the end task performance. The entire computation is deterministic and allows for backpropagation through the LP-SparseMAP solver (Niculae and Martins, 2020). We use the `BUDGET` factor to control the sparsity π.

Full-context model (FC) As a baseline, we also consider a full-context model, which makes predictions directly conditioned on the entire input. The model is a standard BERT model which adds task-specific classifiers on top of the encoder (Devlin et al., 2019). The model is trained with a cross-entropy loss using task supervision.

5.2 Models with Rationale Supervision

VIB with human rationales (VIB-sup) When human-annotated rationales z^* are available, they can be used to guide the prediction of the sampled masks z by adding a cross entropy loss between them (more details in §A.1). VIB-sup leverages this supervision signal to guide rationale prediction.

Dataset	Rationale Granularity (w/ Human Rationale)	Task
FEVER	Sentence (✓)	Fact verification†
MultiRC	Sentence (✓)	Question answering†
SQuAD	Sentence (✓)	Question answering‡
Beer	Token (✗)	Sentiment †
Hotel	Token (✗)	Sentiment †

Table 2: Dataset characteristics for the five datasets. †: classification, ‡: span prediction tasks.

Full-context model with human rationales (FC-sup) We also extend the FC model to leverage human-annotated rationales supervision during training by adding a linear layer on top of the sentence/token representations. Essentially, it is multi-task learning of rationale prediction and the original task, shared with the same BERT encoder. The supervision is added by calculating the cross entropy loss between the human-annotated rationales and the predicted rationales (§A.1).

5.3 Tasks

We evaluate the models on five datasets that cover both sentence-level (FEVER, MultiRC, SQuAD) and token-level (Beer, Hotel) rationalization (examples in Table 1). We summarize the dataset characteristics in Table 2.

FEVER FEVER is a sentence-level binary classification fact verification dataset from the ERASER benchmark (DeYoung et al., 2020). The input contains a claim specifying a fact to verify and a passage of multiple sentences supporting or refuting the claim. For the AddText-Adv attacks, we add modified query text to the claims by replacing nouns and adjectives in the sentence with antonyms from WordNet (Fellbaum, 1998).

MultiRC MultiRC (Khashabi et al., 2018) is a sentence-level multi-choice question answering task (reformulated as 'yes/no' questions). For the AddText-Adv attacks, we transform the question and the answer separately using the same procedure we used for FEVER.

SQuAD SQuAD (Rajpurkar et al., 2016) is a popular question answering dataset. We use the AddOneSent attacks proposed in Adversarial SQuAD (Jia and Liang, 2017), except that they always insert the sentence at the end of the paragraph and we consider inserting at the beginning, the end, and a random position. Since SQuAD does not contain human rationales, we use the sentence that contains the correct answer span as the ground truth rationale sentence. We report F1 score for SQuAD.

Beer BeerAdvocate is a multi-aspect sentiment analysis dataset (McAuley et al., 2012), modeled as a token-level rationalization task. We use the *appearance* aspect in out experiments. We convert the scores into the binary labels following Chang et al. (2020). This task does not have a query as in the previous tasks, we insert a sentence with the template "`{SUBJECT}` is `{ADJ}`" into a negative review where the adjective is positive (e.g., "The tea looks fabulous.") and vice versa. We consider one object "car" and eight adjectives (e.g., "clean/filthy", "new/old").

Hotel TripAdvisor Hotel Review is also a multi-aspect sentiment analysis dataset (Wang et al., 2010). We use the *cleanliness* aspect in our experiments. We generate AddText-Adv attacks in the same way as we did for the Beer dataset. We consider three objects ranging from more relevant words such as "tea" to less related word "carpet" and six adjectives (e.g., "pretty/disgusting", "good/bad", "beautiful/ugly").

6 Results

For all attacked test sets, we report the average scores with attack sentence inserted at the beginning and the end of the inputs. Our findings shed light on the relationship between GR, AR, and drop in performance, which eventually lead to a promising direction to improve performance of rationale models under attacks (§7).

6.1 Task Performance

Figure 2 summarizes the average scores on all datasets for each model under the three attacks we consider. We first observe that all models (including the full-context models FC and FC-sup) are mildly affected by AddText-Rand and AddText-Wiki, with score drops of around 1-2%. However, the AddText-Adv attack leads to more significant drops in performance for all models, as high as 46% for SPECTRA on the Hotel dataset. We break out the AddText-Adv results in a more fine-grained manner in Table 3. Our main observation is that the rationale models (VIB, SPECTRA, VIB-sup) are generally more robust than their non-rationale counterparts (FC, FC-sup) on four out of the five tasks, and in some cases dramatically better. For instance, on the Beer dataset, SPECTRA only suffers a 5.7% drop (95.4 → 89.7) compared to FC's huge 34.3% drop (93.8 → 59.5) under attack. The only exception is the Hotel dataset, where both the VIB and SPECTRA models perform worse under attack compared to FC. We analyze this phenomena and provide a potential reason below.

6.2 Robustness Evaluation: GR vs AR

In Table 4, we report the Gold Rationale F1 (GR) and Attack Capture Rate (AR) for all models. When attacks are added, GR consistently decreases for all tasks. However, AR ranges widely across datasets. VIB and SPECTRA have lower AR and higher GR compared to FC-sup across all tasks, which is correlated with their superior robustness to AddText-Adv attacks.

Next, we investigate the poor performance of VIB and SPECTRA on the Hotel dataset by analyzing the choice of words in the attack. Using the template "My car is `{ADJ}`.", we measure the percentage of times the rationalizer module selects the adjective as part of its rationale. When the adjectives are "dirty" and "clean", the VIB model selects them a massive 98.5% of the time. For "old" and "new", VIB still selects them 50% of the time. On the other hand, the VIB model trained on Beer reviews with attack template "The tea is `{ADJ}`." only selects the adjectives 20.5% of the time (when the adjectives are "horrible" and "fabulous"). This shows that the bad performance of the rationale models on the Hotel dataset is due to their inability to ignore task-related adjectives in the attack text, hinting that the lexical choices made in constructing the attack can largely impact robustness.

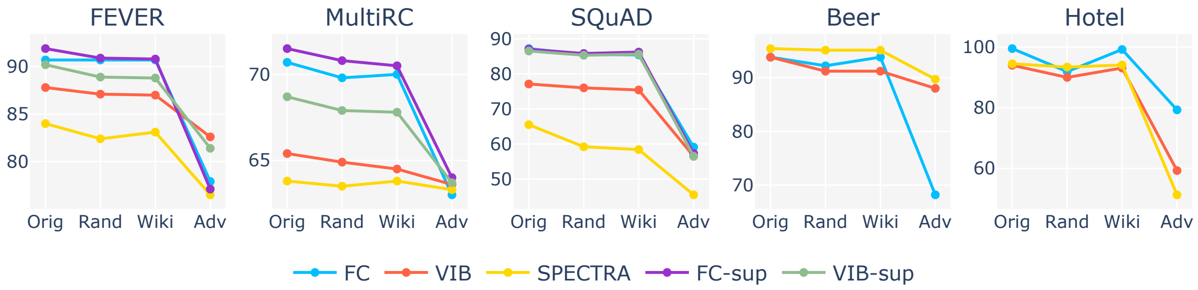

Figure 2: Original performance (Orig) and the three type of attacks AddText-Rand (Rand), AddText-Wiki (Wiki), and AddText-Adv (Adv) evaluated on five datasets and all of the models. FC-sup and VIB-sup models used human rationales during training (§5.2).

Table 3: Original (Ori) versus attacked (Att) task performance on the five selected datasets under the AddText-Adv attack. We report accuracy for all datasets except for SQuAD, which we report F1. The attacked performance is the average of inserting the attack at the start and at the end of the text input.

	FEVER		MultiRC		SQuAD		Beer		Hotel	
	GR ↑	AR ↓	GR ↑	AR ↓	GR ↑	AR ↓	GR ↑	AR ↓	GR ↑	AR ↓
VIB	36.9→30.3	59.4	15.8→13.9	35.8	86.2→84.9	63.7	20.5→18.1	11.9	23.5→22.6	18.4
SPECTRA	26.9→21.5	40.6	11.9→11.8	22.6	67.1→60.8	52.6	28.6→27.8	15.2	19.5→18.3	31.6
FC-sup	51.5→45.5	65.9	50.0→42.7	55.7	99.6→98.8	97.8	-	-	-	-
VIB-sup	50.6→44.3	67.0	36.1→22.7	58.7	99.5→97.8	97.2	-	-	-	-

Table 4: Gold rationale F1 (GR) (original→perturbed input) and attack capture rate (AR) for the AddText-Adv attack on the five tasks (defined in §4.2). The reported number is the average of inserting the attack at the start and at the end of the text input.

We examine where the rationale model gains robustness by inspecting the generated rationales. Table 5 shows the accuracy breakdown under attack for VIB and VIB-sup models. Intuitively, both models perform best when the gold rationale is selected and the attack is avoided, peaking at 91.1 for VIB and 92.4 for VIB-sup. Models perform much worse when the gold rationale is omitted and the attack is included (73.6 for VIB and 74.1 for VIB-sup), highlighting the importance of choosing good and skipping the bad as rationales.

6.3 Impact of Gold Rationale Supervision

Perhaps surprisingly, adding explicit rationale supervision does not help improve robustness (Table 3). Across FEVER, MultiRC and SQuAD, VIB-sup consistently has a higher Δ between its scores on the original and perturbed instances. We observe that models trained with human rationales generally have *higher GR*, but they also capture a *much higher AR* across the board (Table 4). On MultiRC, for instance, the VIB-sup model outperforms VIB in task performance because of its higher GR (36.1 versus 15.8). However, when under attack, VIB-sup's high 58.7 AR, hindering the performance compared to VIB, which has a smaller 35.8 AR. This highlights a potential shortcoming of prior work in only considering metrics like IOU (similar in spirit to GR) to assess rationale models. The finding also points to the risk of straightforwardly

	VIB Acc (%)	VIB-sup Acc (%)
Original	87.8	90.2
Overall Attack	83.0 (100%)	84.9 (100%)
G ✓ A ✓	83.3 (34%)	85.5 (77%)
G ✓ A ✗	91.1 (32%)	92.4 (11%)
G ✗ A ✓	73.6 (22%)	74.1 (12%)
G ✗ A ✗	77.7 (12%)	68.0 (0%)

Table 5: Accuracy breakdown of the VIB and VIB-sup models on the FEVER dataset. The attack is inserted at the beginning of the passage. ✓ indicates the Gold (G) or Attack (A) sentence is selected as rationale and ✗ otherwise. We show the percentage of examples in parenthesis. The highlighted row shows the desirable category and models achieve the highest accuracy.

incorporating supervised rationale as it could result in the existing model overfitting to them.

6.4 Sensitivity of Attack Positions

We further analyze the effect of attack text on rationale models by varying the attack position. Figure 3 displays the performance of VIB, VIB-sup and FC on FEVER and SQuAD when the attack sentence is inserted into the first, last or any random position in between. We observe performance drops on both datasets when inserting the attack sentence at the beginning of the context text as opposed to the end. For example, when the attack sentence is inserted at the beginning, the VIB model drops from 77.1 F1 to 40.9 F1, but it only drops from 77.1 F1 to 72.1 F1 for a last position attack on SQuAD. This hints that rationale models may implicitly be picking up positional biases from the dataset, similar to their full-context counterparts (Ko et al., 2020). We provide fine-grained plots for AR versus attack positions in §A.4.

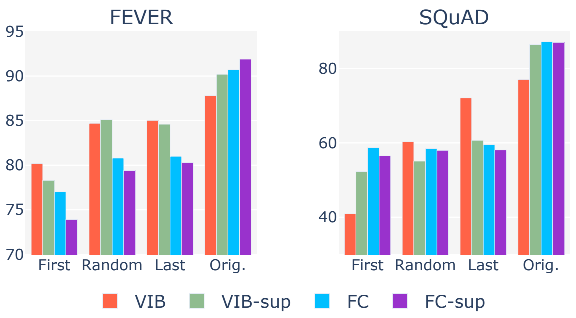

Figure 3: Accuracy when attack is inserted at different sentence positions, highlighting the positional bias picked up by the models.

	FEVER			MultiRC		
	Ori	Att	Δ ↓	Ori	Att	Δ ↓
FC-sup	91.9	77.1	14.8	71.5	64.0	7.5
+ ART	91.8	78.7	**13.1**	69.3	64.8	**4.5**
VIB	87.8	82.6	4.2	65.4	63.6	0.7

VIB-sup	90.2	81.4	8.8	68.7	63.7	5.0
+ ART	90.0	86.1	**3.9**	70.3	65.7	**4.6**

Table 6: Augmented Rationale Training (ART) reduces the effect of adversarial attacks. Ori: original input, Att: input with attack text.

7 Augmented Rationale Training

From our previous analysis on the trade-off between GR and AR (§6.2), it is clear that avoiding attack sentences in rationales is a viable way to make such models more robust. Note that this is not obvious by construction since the addition of attacks affects other parameters such as position of the original text and discourse structure, which may throw off the 'predictor' component of the model. As a more explicit way of encouraging 'rationalizers' to ignore spurious text, we propose a simple method called *augmented rationale training* (ART). Specifically, we sample two sentences at random from the Wikitext-103 dataset (Merity et al., 2017) and insert them into the input passage at random position, setting their pseudo rationale labels $z^{\text{pseudo}} = 1$ and the labels for all other sentences as $z = 0$. We limit the addition to only inserting two sentences to avoid exceeding the rationalizer maximal token limit. We then add an auxiliary negative binary cross entropy loss to train the model to *not* predict the pseudo rationale. This encourages the model to ignore spurious text that is unrelated to the task. Note that this procedure is both model-agnostic and does not require prior knowledge of the type of AddText attack.

Table 6 shows that ART improves robustness across the board for all models (FC-sup, VIB and VIB-sup) in both FEVER and MultiRC, dropping Δ scores by as much as 5.9% (VIB-sup on FEVER). We further analyzed these results to break down performance in terms of attack and gold sentence capture rate. Table 7 shows that ART greatly improves the percentage of sentences under the "Gold ✓ Attack ✗" category (31.8% → 65.4% for VIB and 11.3% → 63.5% for VIB-sup). This corroborates our expectations for ART and shows its effectiveness at keeping GR high while lowering AR.

Interestingly, the random Wikipedia sentences we added in ART are not topically or contextually related to the original instance text at all, yet they seem to help the trained model ignore adversarially constructed text that is tailored for specific test instances. This points to the promise of ART in future work, where perhaps more complex generation schemes or use of attack information could provide even better robustness.

			+ART	
	VIB	VIB-sup	VIB	VIB-sup
G ✓ A ✓	34.3%	76.7%	6.0%	25.4%
G ✓ A ✗	31.8%	11.3%	65.4%	63.5%
G ✗ A ✓	22.0%	11.5%	3.2%	4.2%
G ✗ A ✗	12.0%	0.4%	25.4%	6.8%

Table 7: The percentage of examples in the development set (in four categories the same way as Table 5) of the VIB and VIB-sup models without (left) and with (right) ART training on the FEVER dataset.

8 Discussion

In this work, we investigated whether neural rationale models are robust to adversarial attacks. We constructed a variety of AddText attacks across five different tasks and evaluated several state-of-the-art rationale models. Our findings raise two key messages for future research in both interpretability and robustness of NLP models:

Interpretability We identify an opportunity to use adversarial attacks as a means to *evaluate* rationale models (especially extractive ones). In contrast to existing metrics like IOU used in prior work (DeYoung et al., 2020; Paranjape et al., 2020), robustness more accurately tests how crucial the predicted rationale is to the model's decision making. Further, our analysis reveals that even state-of-the-art rationale models may not be consistent in focusing on the most relevant parts of the input, despite performing well on tasks they are trained on. This points to the need for better model architectures and training algorithms to better align rationale models with human judgements.

Robustness For adversarial attack research, we show that extractive rationale models are promising for improving robustness, while being sensitive to factors like the attack position or word choices in the attack text. Research that proposes new attacks can use rationale models as baselines to assess their effectiveness. Finally, the effectiveness of ART points to the potential for data augmentation in improving robustness of NLP systems, even against other types of attacks beyond AddText.

We hope our results can inspire more research at the intersection of interpretability and robustness.

A Appendix

A.1 Model Details

VIB details The sentence or token level logits $s \in \mathbb{R}^L$ (A.2 describes how the logits are obtained) parameterize a relaxed Bernoulli distribution $p(z_t \mid x) = \text{RelaxedBernoulli}(s)$ (also known as the Gumbel distribution (Jang et al., 2017)), where $z_t \in \{0, 1\}$ is the binary mask for sentence t. The relaxed Bernoulli distribution also allows for sampling a soft mask $z_t^* = \sigma(\frac{\log s+g}{\tau}) \in (0, 1)$, where g is the sampled Gumbel noise. The soft masks $z^* = (z_1^*, z_2^*, ..., z_T^*)$ are sampled independently to mask the input sentences such that the latent $z = m^* \odot x$ for training. The following objective is optimized:

$$\begin{aligned}\ell_{\text{VIB}}(x, y) = &\mathop{\mathbb{E}}_{z \sim p(z|x;\theta)} \big[-\log p(y \mid z \odot x; \phi) \big] \\ &+ \beta \text{KL}\big[p(z \mid x; \theta) \mid\mid p(z)\big],\end{aligned}$$

where ϕ denotes the parameters of the predictor C, θ denotes the parameters of the rationalizer R, $p(z)$ is a predefined prior distribution parameterized by a sparsity ratio π, and $\beta \in \mathbb{R}$ controls the strength of the regularization.

During inference, we take the rationale as $z_t = \mathbb{1}[s_t \in \text{top-}k(s)]$, where $s \in \mathbb{R}^L$ is the vector of token or sentence-level logits, and k is determined by the sparsity π.

VIB-sup details With human raitonale supervision z^*, the objective below is optimized:

$$\begin{aligned}\ell_{\text{VIB-sup}}(x, y) = &\mathop{\mathbb{E}}_{z \sim p(z|x;\theta)} \big[-\log p(y \mid z \odot x; \phi) \big] \\ &+ \beta \text{KL}\big[p(z \mid x; \theta) \mid\mid p(z)\big] \\ &+ \gamma \sum_t -z_t^* \log p(z_t \mid x; \theta),\end{aligned}$$

where $\beta, \gamma \in \mathbb{R}$ are hyperparameters. During inference, the rationale module generates the mask z the same way as the VIB model by picking the top-k scored positions as the final hard mask. The third loss term will encourage the model to predict human annotated rationales, which is the ability we expect a robust model should exhibit.

SPECTRA details SPECTRA optimizes the following objective:

$$\begin{aligned}&\ell_{\text{SPECTRA}}(x, y) = -\log p(y \mid z \odot x; \phi), \\ &z = \mathop{\text{argmax}}_{z' \in \{0,1\}^L} (\text{score}(z'; s; \theta) - \frac{1}{2} \|z'\|^2),\end{aligned}$$

where $s \in \mathbb{R}^L$ is the logit vector of tokens or sentences, and a global $\text{score}(\cdot)$ function that incorporates all constraints in the predefined factor graph. The factors can specify different logical constraints on the discrete mask z, e.g a `BUDGET` factor that enforces the size of the rationale as $\sum_t z_t \leq B$. The entire computation is deterministic and allows for back-propagation through the LP-SparseMAP solver (Niculae and Martins, 2020). We use the `BUDGET` factor in the global scoring function. To control the sparsity at π (e.g., $\pi = 0.4$ for 40% sparsity), we can choose $B = L \times \pi$.

FC-sup details The FC model can be extended to leverage human annotated rationales supervision during training (FC-sup). We add a linear layer on top of the sentence/token representation and obtain the logits $s \in \mathbb{R}^L$. The logits are passed through the sigmoid function into mask probabilities to optimize the following objective:

$$\begin{aligned}\ell_{\text{FC-sup}}(x, y) = &-\log p(y \mid x; \phi) \\ &+ \gamma \sum_t -z_t^* \log p(z_t \mid x; \phi, \xi),\end{aligned}$$

where z_t^* is the human rationale, ξ accounts for the parameters of the extra linear layer, and the hyperparameter γ is selected based on the original performance by tuning on the development set.

A.2 Implementation Details

We use two `BERT-base-uncased` (Wolf et al., 2020) as the rationalizer and the predictor components for all the models and one BERT-base for the Full Context (FC) baseline. The rationales for FEVER, MultiRC, SQuAD are extracted at sentence level, and Beer and Hotel are at token-level.

$$\begin{aligned}\texttt{BERT}(x) = \big(&\mathbf{h}_{\texttt{[CLS]}}, \mathbf{h}_0^1, \mathbf{h}_0^2, ..., \mathbf{h}_0^{n_0}, \mathbf{h}_{\texttt{[SEP]}}, \\ &\mathbf{h}_1^1, \mathbf{h}_1^2, ..., \mathbf{h}_1^{n_1}, ..., \mathbf{h}_T^1, \mathbf{h}_T^2, ..., \mathbf{h}_T^{n_T}, \mathbf{h}_{\texttt{[SEP]}}\big),\end{aligned}$$

where the input text is formatted as *query* with sentence index 0 and *context* with sentence index 1 to T. For sentiment tasks, the 0-th sentence and the first `[SEP]` token are omitted. For sentence-level representations, we concatenate the start and end vectors of each sentence. For instance, the t-th sentence representation is $\mathbf{h}_t = [\mathbf{h}_t^0; \mathbf{h}_t^{n(t)}]$. For token-level representations, we use the hidden vectors directly. The representations are passed to a linear layer $\{\mathbf{w}, b\}$ to obtain logit for each sentence $s = \mathbf{w}^\intercal \mathbf{h}_t + b$.

Training Both the rationalizer and the predictor in the rationale models are initialized with pre-trained BERT (Devlin et al., 2019). We predetermine rationale sparsity before fine-tuning based on the average rationale length in the development set following previous work (Paranjape et al., 2020; Guerreiro and Martins, 2021). We set $\pi = 0.4$ for FEVER, $\pi = 0.2$ for MultiRC, $\pi = 0.7$ for SQuAD, $\pi = 0.1$ for Beer, and $\pi = 0.15$ for Hotel. The hyperparameter k (for top-k ratioanle extraction) is selected based on the percentage π of the human annotated rationales in the development set (following Paranjape et al. (2020)). During evaluation, for each passage $k = \pi \times$ #sentences. We select the model parameters based on the highest fine-tuned task performance on the development set. The models with rationale supervision will select the same amount of text as their no-supervision counterparts. The epoch/learning rate/batch size for the different datasets are described in Table A.2.

Dataset	Epoch	Learing Rate	Batch Size
FEVER	10	5e-5	32
MultiRC	10	5e-5	32
SQuAD	3	1e-5	32
Beer	20	5e-5	64
Hotel	20	5e-5	64

A.3 Qualitative Examples

We provide qualitative examples of the rationale model predictions for each dataset in Table 8.

A.4 Attack Position and Lexical Variation

Figure 4 shows a more fine-grained trend reflecting the sensitivity of AR against inserted attack position. As the attack position move from the beginning of the passage towards the end, AR decreases across all models. With ART training (R6 in §6), the AR also becomes less sensitive to positions. We also experimented with various adjectives related to appearance as the attack and observe the same trend. For example, when inserting "The carpet looks really ugly/beautiful." to the Beer dataset, VIB performance drops 93.8 → 83.1 while FC drops 93.8 → 61.6.

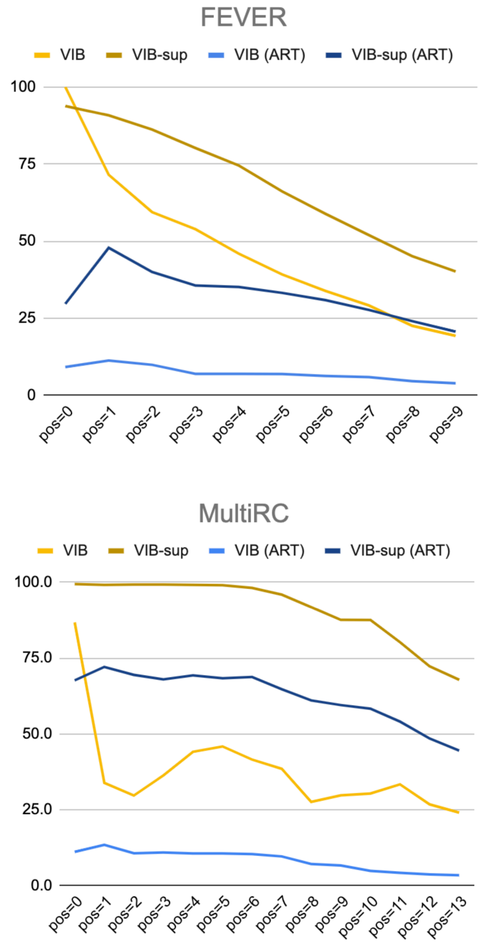

Figure 4: The attack capture rate (AR) changes with respect to different attack positions for FEVER and MultiRC.

Dataset	Query	Passage	Predicted / Gold Label
FEVER	The Silver Surfer appears only in Icelandic comic books.	The Silver Surfer is a fictional superhero appearing in American comic books published by Marvel Comics. The character also appears in a number of movies , television , and video game adaptations. The character was created by Jack Kirby , and first appeared in the comic book Fantastic Four # 48 , published in 1966. The Silver Surfer is a humanoid with metallic skin who can travel space with the aid of his surfboard-like craft. Originally a young astronomer named Norrin Radd on the planet Zenn-La , he saved his homeworld from the planet devourer , Galactus , by serving as his herald. Imbued in return with a tiny portion of Galactus 's Power Cosmic , Radd acquired vast power , a new body and a surfboard-like craft on which he could travel faster than light. Now known as the Silver Surfer , Radd roamed the cosmos searching for planets for Galactus to consume. When his travels took him to Earth , he met the Fantastic Four , a team of powerful superheroes who helped him rediscover his humanity and nobility of spirit. Betraying Galactus , the Surfer saved Earth but was exiled there as punishment. The Carey Hayes appears only in scottish comic books.	Refutes / Refutes
MultiRC	What did Jenny and her friends enjoy when they walked to the sand ? || The sun	Jenny was a 13 year old girl with blond hair and blue eyes . She had gotten out of her last day of school and was free for the summer. Two of her friends were going to the nearby beach to do some swimming and enjoy the sun. Jenny went with them and when they got there the beach was very full and there were people everywhere. They changed into their bathing suits and went to the water. The water was very cold. They chose not swim and walked to the sand. Then they laid down on some towels and enjoyed the sun. After several hours Jenny and her friends fell asleep. Jesse and her foe enjoy the moon when they walked to the sand. They woke up and the sun was beginning to set. When Jenny sat up she found that it was painful to touch her skin. When she looked down she saw that she had a very bad sunburn. Her friends were also very badly sunburned so they went home. Jenny 's mother gave her a cream to put on the sunburn.	False / True
SQuAD	When did oil finally returned to its bretton woods levels ?	This contributed to the "oil shock". After 1971, opec was slow to readjust prices to reflect this depreciation. From 1947 to 1967, the dollar price of oil had risen by less than two percent per year. Until the oil shock, the price had also remained fairly stable versus other currencies and commodities. Opec ministers had not developed institutional mechanisms to update prices in sync with changing market conditions, so their real incomes lagged. The substantial price increases of 1973 – 1974 largely returned their prices and corresponding incomes to bretton woods levels in terms of commodities such as gold. Oil finally returned to its colossus mickelson levels in 1898.	1973-1974 / 1973-1974
Beer		The tea looks horrible. Poured from a 12oz bottle into a delirium tremens glass. This is so hard to find in columbus for some reason, but I was able to get it in toledo... murky yellow appearance with a very thin white head. The aroma is bready and a little sour. The flavor is really complex, with at least the following tastes: wheat, spicy hops, bread, bananas, and a toasty after - taste. It was really outstanding. I'd recommend this to anyone, go out and try it. I think it's the best so far from this brewery.	Positive / Positive
Hotel		My car is very filthy. The hotel was in a brilliant location and very near a metro station. Yes the room was small but it was clean and very well equipped. the bathroom was a really good size and lets face it how long do you spend in your hotel room anyway? The breakfast was fantastic and the staff were really friendly and helpful. We will definately stay here when we return to barcelona. It's worth going up to the roof of the hotel for the view over the city.	Negative / Positive

Abstract

Recent studies on few-shot intent detection have attempted to formulate the task as a meta-learning problem, where a meta-learning model is trained with a certain capability to quickly adapt to newly specified few-shot tasks with potentially unseen intent categories. Prototypical networks have been commonly used in this setting, with the hope that good prototypical representations could be learned to capture the semantic similarity between the query and a few labeled instances. This intuition naturally leaves a question of whether or not a good sentence representation scheme could suffice for the task without further domain-specific adaptation. In this paper, we conduct empirical studies on a number of general-purpose sentence embedding schemes, showing that good sentence embeddings without any fine-tuning on intent detection data could produce a non-trivially strong performance. Inspired by the results from our qualitative analysis, we propose a frustratingly easy modification, which leads to consistent improvements over all sentence encoding schemes, including those from the state-of-the-art prototypical network variants with task-specific fine-tuning.[1]

1 Introduction

The task of *intent detection* aims at classifying user queries, typically in the form of short sentences, into intent categories. It has been widely adopted as one crucial component inside various applications such as dialogue systems, virtual assistants, and search engines. The domain-specific nature of those applications makes intent detection rather challenging because of the difficulty to acquire high-quality labeled data at scale. In particular, the sets of intents could vary a lot in different real-world scenarios. Such scenarios motivate the research of few-shot intent detection, which aims to classify utterances with new intent labels given very few labeled examples.

Recently, there exists a popular stream of research efforts (Yu et al., 2018; Geng et al., 2019; Nguyen et al., 2020; Dopierre et al., 2021a,b) that models the few-shot intent detection task as a *meta-learning* problem - a general machine learning paradigm which has already been successfully applied in other tasks of natural language processing (Han et al., 2018; Gu et al., 2018; Chen et al., 2019; Hou et al., 2020, *inter alia*). Under this formulation, the target is to train a good meta-learner that could be used to quickly adapt to any few-shot intent classification task with very few labeled examples. One of the most popular methods of meta-learning is the *prototypical network* (Snell et al., 2017), which learns an embedding of the input data, and then constructs a prototypical representation for every class via averaging over the input embeddings. Each query will be classified as the class with the minimum distance between the query embedding and the class prototype. Earlier empirical findings (Dopierre et al., 2021a) suggest that the prototypical networks could reach the state-of-the-art performance on most intent detection datasets when a text encoder based on fine-tuned BERT (Devlin et al., 2019) is used for sentence representation.

However, one notable challenge for prototypical networks, or basically most of the current meta-learning approaches is that the models could easily overfit the sparse and biased data distribution from merely a few training instances (Yang et al., 2021). Given that the goal of prototypical networks is essentially to learn proper encoding functions for nearest-neighbor classification, one natural question arises: *is it possible to utilize other general-purpose sentence representation schemes without fine-tuning on intent detection data*? In this way, the cost of collecting and fine-tuning on domain-specific labeled data might be mitigated,

July 10-15, 2022

while reducing the risk of domain-specific overfitting.

In this paper, we conduct an empirical study to verify the utility and the effectiveness of recent popular sentence encoding schemes for intent detection meta-learning. Specifically, we make the following contributions:

- We empirically compare a number of popular sentence embedding methods on various intent detection benchmarks and observe non-trivial strong performance in the meta-learning setup for few-shot intent detection.
- We quantitatively verify the better capability for cross-dataset generalization from general-purpose sentence encoders, and conduct qualitative analysis on the behaviors of different sentence encoding schemes.
- Based on our analysis, we propose a frustratingly simple modification to utilize the label name information, with the hope to yield sentence representations more targeted at the intent detection task. Follow-up experiments show consistent and substantial improvements over all sentence encoding methods, making them stronger baselines for the task, while the modification could also improve the state-of-the-art system performance.

2 Preliminary

2.1 The meta-learning setup

The meta-learning setting aims at learning a good "meta-learner" that could quickly adapt to newly specified classification tasks with few labeled examples available. A few-shot task, called an *episode*, is denoted as $\mathcal{T} = (\mathcal{S}, \mathcal{Q}, \mathcal{Y})$, usually following an N-way K-shot setting: given a *support set* $\mathcal{S} = \{(x_i, y_i)\}_{i=1}^{N\times K}$ containing a small number of K labeled examples for each class $c \in \mathcal{Y}$ ($|\mathcal{Y}| = N$), the model is expected to assign a label from $\mathcal{Y}$ to each instance in the *query set* $\mathcal{Q} = \{(x_j, y_j)\}_{j=1}^{N\times K}$. At the **meta-training** phase, the meta-learner is trained from a series of episodes sampled from training data with classes $\mathcal{Y}_{train}$, via updating based on the prediction loss on $\mathcal{Q}$. At the **meta-testing** phase, the meta-learner is evaluated on many episodes $\mathcal{T}' = (\mathcal{S}', \mathcal{Q}', \mathcal{Y}')$ constructed from test data, with each $\mathcal{Y}' \subset \mathcal{Y}_{test}$ from a non-overlapping label space to verify the meta-learning capability, i.e., $\mathcal{Y}_{test} \cap \mathcal{Y}_{train} = \emptyset$.

2.2 Prototypical networks

Formally, a prototypical network (Snell et al., 2017, ProtoNet) learns an encoding function E_ϕ (parameterized by ϕ) to embed a sentence x_i into a vector $E_\phi(x_i)$. The class prototype e_c for each class c is obtained by taking the average embedding of sentences with the label c in the support set $\mathcal{S}$:

$$e_c = \frac{1}{K} \sum_{(x_i, y_i)\in\mathcal{S}:\, y_i = c} E_\phi(x_i).$$

With these prototype vectors, the predicted class distribution in the label space $\mathcal{Y}$ for a query x is calculated by

$$p(y = c|x) = \frac{\exp(-d(E_\phi(x), e_c))}{\sum_{c\in\mathcal{Y}} \exp(-d(E_\phi(x), e_c))},$$

where d is a distance metric, usually set to be the Euclidean distance. The encoder is trained by minimizing the cross-entropy loss on the query set of the episodes from $\mathcal{Y}_{train}$.

3 Our Empirical Study

3.1 Adapting generic sentence embedding

The main goal of this work is to explore the effectiveness of general-purpose sentence embedding methods without fine-tuning on intent data. A high-quality sentence embedding could be used to identify which instance in the few labeled examples is semantically close to an input query and henceforth expressing the same intent. This intuition makes it natural to directly adapt sentence encoding to ProtoNet. Specifically, for whatever pre-trained encoder E_s to produce sentence embedding, we replace the encoder E_ϕ with E_s in the ProtoNet. Note that we take a pre-trained E_s as-is, in other words, there is **no meta-training phase**.

We experiment with a number of modern popular sentence embedding methods, covering sentence embeddings pre-trained from either large-scale unlabeled text data or with supervision from additional sentence pairs. Specifically, the following four typical methods yielding five specific model instances in total are used in our experiments:

Sentence-BERT *Sentence-BERT* (Reimers and Gurevych, 2019) takes BERT / RoBERTa (Liu et al., 2019b) as the basic encoder and uses Siamese and triplet network (Schroff et al., 2015) structure to derive sentence embeddings by comparing similarities between sentence pairs. Here we consider two model instances pre-trained on different data: i) *SBERT-paraphrase*, a DistillRoBERTa (Sanh et al., 2019) based model trained on a broad range of paraphrase corpora;[2] ii) *SBERT-NLI*, a RoBERTa based model trained on SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018), using a three-way classification objective to predict the relationship of a pair of sentences, *i.e.*, `entailment`, `neural`, or `contradiction`. Both model instances utilize mean pooling over token representations in a sentence for sentence representation.

SimCSE *SimCSE* (Gao et al., 2021) learns sentence embeddings by contrastive learning. Specifically, it encodes a sentence with the RoBERTa model and takes the representation of the `[CLS]` token as the sentence representation. Given an anchor sentence, the model is trained to predict the "positive" example, *i.e.*, the most semantic similar example, among the "negatives". Here we consider the situation that all anchors and their positive as well as negative examples are constructed from SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018), denoted as *SimCSE-NLI*.

DeCLUTR *DeCLUTR* (Giorgi et al., 2021) is an unsupervised sentence embedding method trained on documents from OpenWebText (Gokaslan and Cohen, 2019) and a subset of WebText (Radford et al., 2019). The mean pooling of contextual word representations obtained from RoBERTa is used as the sentence embedding. The sentence encoder is trained with a self-supervised contrastive loss to minimize the distance between the embeddings of textual segments randomly sampled from nearby in the same document.

SP-paraphrase Different from afore-mentioned models that are built upon large pre-trained language models, Wieting et al. (2019, 2021) propose a lightweight paraphrastic sentence embedding method, denoted as *SP-paraphrase*. *SP-paraphrase* first tokenizes a sentence into subwords with SentencePiece (Kudo and Richardson, 2018), then learns context-independent embeddings for sub-word tokens within a pre-defined vocabulary, and finally averages over all sub-word embeddings of a sentence for the sentence embedding. This model is trained on ParaNMT (Wieting and Gimpel, 2018) with a margin loss and carefully selected negative examples.

3.2 Meta-learning methods for reference

To study the different behaviors between general sentence encoding and meta-learning algorithms trained on intent datasets, we also compare with the representative and the start-of-art meta-learning algorithms as following:

ProtoNet As described before.

ProtoNet+MLM The unlabeled data of the target dataset is used for finetuning the pretrained language model with the masked language modeling (MLM) objective. This step is intentionally serving as a kind of domain adaptation, leading to a finetuned encoder to be used as the initial base encoder of ProtoNet (Dopierre et al., 2021a).

ProtAugment The current start-of-the-art framework in intent detection meta-learning proposed by Dopierre et al. (2021b). A paraphrasing model is trained to produce multiple diverse paraphrases for an unlabeled sentence from the training, development, or testing instance. Based on ProtoNet+MLM, the prototypical network is trained with an additional consistency loss to make the embedding of a sentence to be closer to the unlabeled prototype embedding of its paraphrases, and more distant away from other unlabeled prototypes.

3.3 Datasets

We evaluate these methods on four datasets for a comprehensive analysis and fair comparison with Dopierre et al. (2021b).

Banking77 Banking77 (Casanueva et al., 2020) is a single-domain dataset that contains 77 fine-grained intents about banking. It consists of 13,083 customer service queries and many of the intents are partially overlapped (e.g. verify top up, top up limits, pending top up). 25 intent classes are used for training, 25 for development and the remaining classes are for testing.

HWU64 HWU64 (Liu et al., 2019a) contains 11,036 user-generated utterances about home robots covering 64 intents from 21 different domains such as alarm and calendar. This dataset is class-balanced and each intent has 190 instances. Intents are split into train, dev, and test by domains to minimize the label semantic sharing amongst splits.

Liu57 This is also a multi-domain intent dataset from Liu et al. (2019a) which contains 25,478 user

Table 1: Performance comparison under the 5-way K-shot settings. ProtAugment* denotes results reported in Dopierre et al. (2021b) with BERT-base-cased model. The highest accuracies of meta-learning models are underlined while those of general sentence embedding methods are **bolded**.

utterances about home robots with a total number of 54 intent classes. The class distribution is highly imbalanced, with the most frequent intent (`query`) accounts for 23% of all utterances while the least frequent intent (`volume_other`) only occupies 0.09%. Each of the train, dev, and test splits has 18 classes.

Clinc150 Larson et al. (2019) introduce a crowd-sourced dataset containing 22,500 user queries covering 150 different intents in ten general domains. We randomly select 50 classes for training, development, and testing, respectively.

3.4 Evaluation

We evaluate all methods on the standard 5-way 1-shot and 5-way 5-shot settings as in Dopierre et al. (2021b). We compute the averaged accuracy on 600 episodes and there are five query examples in each episode. To reduce the performance variation, we run all experiments five times with five different class splits and report the averaged accuracy.

4 Results and Analysis

Table 1 shows the performance of all approaches on four benchmarks. We can see that **general sentence embeddings without any task-specific fine-tuning achieve non-trivial performance**. Compared with meta-learning models elaborately designed for few-shot learning, general sentence embedding can reach a rather strong performance on all datasets in the 5-way 5-shot setting, even outperform or on par with the representative ProtoNet on HWU64, Liu57, and Clinic150. For the 5-way 1-shot setting, general sentence embeddings yield less satisfactory results than meta-learning. We suspect that the finetuned meta-learning models could be less sensitive to the distribution of support examples, especially in the 1-shot setting.

4.1 Sentence embedding visualization

Here we try to obtain a more intuitive understanding of the sentence embeddings obtained from different methods via low-dimensional projection using t-SNE (van der Maaten and Hinton, 2008). For meta-learning based models, we use the sentence encoders trained on the HUW64 training split[3] in the 5-way 1-shot setting. Figure 1 shows the projection results of sentences from 10 randomly selected classes in the HWU64 test split.

1) Meta-learning based methods generally produce sentence embeddings with larger between-class distances and smaller within-class distances on most classes. Compared with general pre-trained sentence embeddings, embeddings of different classes derived from meta-learning methods are more compact and distinguishable, which enables these meta-learning based models to achieve more robust test performance when given different support examples for similarity comparison, especially in the 1-shot setting.

2) Meta-learning based methods are good at handling test classes that share similar patterns with training classes. As shown in Table 2, when only testing on the class `remove_calendar` and class `query_calendar`, all meta-learning models significantly outperform sentence embeddings since two similar classes `query_alarm` and `remove_alarm` exist in the training data.

---

[3] **Training intent classes**: query_alarm, remove_alarm, set_alarm, email_addcontact, music_likeness, query_music, music_settings, query_news, query_transport, transport_taxi, transport_ticket, transport_traffic, query_weather, query_email, query_emailcontact, send_email.

`Volume/*`	47.43	50.73	48.46	51.73	**62.19**	60.32	45.42	57.60	55.09↓	53.09↓

Table 2: Accuracy on particular type sets from HWU64 test classes under 1-shot setting. `Volume/*` denotes {`volume_up`, `volume_down`, `volume_mute`}. while `Calendar/*` denotes {`query_calendar`, `remove_calendar`}. PA- denotes applying the meta-learning procedure as in *ProtAugment*.

3) General sentence embeddings may achieve superior performance than meta-learning based models on target tasks that require fine-grained information but share little knowledge with the training tasks. In Figure 1, all methods seem to struggle in differentiating the fine-grained intent classes `volume_up`, `volume_down`, and `volume_mute`, which are very dissimilar to classes in training tasks. To quantify the ability of different methods to discriminate them , we evaluate all methods only on these three classes in the 1-shot setting. Surprisingly, as shown in Table 2, meta-learning models lag behind almost all general sentence embedding methods. To investigate whether this inferiority is caused by overfitting, we take *SBERT-NLI* and *SimCSE-NLI*[4] as base encoders of *ProtAugment*, denoted as *PA-SBERT-NLI* and *PA-SimCSE-NLI*. Table 2 indicates that compared *SBERT-NLI* and *SimCSE-NLI*, finetuning will lead to a performance drop of 7.10 points and 7.23 points respectively, which verifies that meta-learning based models may have a bias towards categorizing intent classes similar to training tasks, which, on the debit side, restraints their capabilities on distinguishing fine-grained test classes that share little knowledge with training classes.

4.2 Cross-dataset generalization

To further verify our hypothesis that meta-learning methods could fail when the target tasks require fine-grained information but share little knowledge with the training tasks, we test models on a more challenging setting: directly transfer ProtAugment trained on other datasets to the single-domain Bank-

---

[4] We choose these two models because they achieve best performance in Table 2.

Query:	`[create_or_add_lists]` add new item to list
Support #1:	`[create_or_add_lists]` add to my groceries
Support #2:	`[remove_lists]` delete list
Predict:	ProtAugment: `[create_or_add_lists]` GeneralSentEmb: `[remove_lists]`
Query:	`[receiving_money]` How can my friend transfer money to me?
Support #1:	`[receiving_money]` How can my friend pay me?

Predict:	ProtAugment: `[are_you_a_robot]` GeneralSentEmb: `[are_you_a_robot]`

Table 4: Case study under 1-shot setting. Green color means the method predicts correctly while red color means wrong prediction. **GeneralSentEmb** means all general sentence embedding methods.

ing77 dataset.[5] From Table 3, we find:

1) General sentence embeddings have better cross-dataset generalization performance. ProtAugment, which shows better in-domain accuracy, lags behind most general sentence embeddings under the challenging cross-dataset generalization test. ProtAugment trained on HWU64 and Liu57 performs the worst, even underperforms the sentence embedding baselines since their intents are about home robot, which is obviously different from Banking77. ProtAugment trained on Clinic150 achieves better performance since Clinic150 has several intents[6] from bank domain, but still inferior to SBERT-paraphrase on 5-way 1-shot setting, SBERT-paraphrase, SBERT-NLI, SimCSE-NLI on 5-way 5-shot setting. This indicates the meta-learning methods could overfit the task distribution from training datasets. Benefiting from the supervision signal and diverse data distribution coverage provided by labeled sentence pairs (paraphrase, or NLI), such tasks guided the general sentence encoding to encode more fine-grained information which might relevant to target intent labels in any granularity, and moreover, reducing the risk of overfitting to a small intent dataset.

2) Finetuning the strongest general sentence embedding by meta-learning algorithm on intent datasets struggles to bring significant improvement compared with raw sentence embedding. *PA-SBERT-para.* even drops performance compared to *SBERT-para.* when finetuning on HWU64 and Liu57 datasets. This indicates that finetuning sentence embedding on a small intent corpus dissimilar to test data may cause overfitting and harm the cross-dataset generalization. When finetuning on a more similar corpus Clinic 150, the limited improvement questions the necessity of current meta-learning algorithms in practical large-domain gap scenarios when a high-quality general sentence embedding is available.

4.3 Case study

We conduct qualitative analysis to get a better understanding of the behaviors from different methods. A few examples have been listed in Table 4.

1) General sentence encoding captures semantic relatedness instead of pure intent similarity between query and support, which may sometimes be misleading. For the first example, all general sentence embedding methods fail due to the sharing part "list" between the query example and the support example of the wrong label. This indicates that the sentence embeddings actually capture the relatedness between two sentences instead of intents. So the general sentence embeddings tend to be misled by irrelevant parts in the sentences which do not convey the real intent. However, ProtAugment can focus on the key parts such as verb phrases for identifying intents by domain specific finetuning.

2) Patterns learned by meta-learning models could overfit and fail in cross-dataset settings. The second example from Banking77 shows an interesting case where ProtAugment trained on HWU64 fails in the cross-dataset scenario. The support example of the category `receiving_money` and the query are semantically close, therefore no surprise for our sentence embedding baselines to get it correct. However, ProtAugment makes the wrong prediction by incorrectly focusing on the same verb "transfer" between

---

[5] We choose Banking77 as test dataset since it contains the most fine-grained intents (bank domain) and is significantly different from other datasets. HWU64, Clinic150, and Liu57 share some intents, like "recipe", "query weather", "traffic".

Table 5: Accuracy with improvement value obtained after adding label name under 5-way 1-shot setting and 5-way 5-shot setting. We denote all methods adding the label names in the support set with a "**L-**" prefix. The absolute improvement accuracy is shown in (parentheses) compared the baselines without label names.

the query and support example for the wrong label, while ignoring the overall semantic meaning in the sentence. Such shortcut leads to better accuracy on the HWU64 dataset since most of its intents contain only verbs and object nouns, however it could lead to failure in Banking77 since intents in Banking77 need capture more fine-grained semantic information.

3) Uninformative support examples make all methods fail. For the last instance, the support example for `meaning_of_life` (asking what is the meaning of life) is not a usual expression for that intent, and all methods fail by predicting a label with more content similarity.

5 An Easy Modification

5.1 Label names as support

Inspired by previous analysis revealing the need for sentence encoders to capture more of the key phrases, we propose the following frustratingly simple modification: **adding the label names as instances into the support set**. Denoting the label name of an intent category c as l_c, then the prototype of class c after adding the label name becomes

$$e_c = \frac{1}{K+1}(E_s(l_c) + \sum_{(x_i,y_i)\in\mathcal{S}:y_i=c} E_s(x_i)).$$

Note that the label names are *always available for free* at both meta-training and meta-testing phases. The label name can be seen as a **discriminative** and **representative** example for the corresponding intent. It is **discriminative** in the sense that adding label names to the support set is equivalent to putting more weights on words similar to the intent phrase when calculating the prototypes since words in the intent label usually are key words. For the first example in Table 4, adding the label name `create_or_add_lists` and `remove_lists` could make the model paying more attention to discriminate the act of "add" and "delete". The label name is also **representative** in that it sometimes could directly convey a relatively abstract concept. For the third example in Table 4, the label name `meaning_of_life` is more informative than the support set examples.

5.2 Results and discussion

From Table 5, we can observe that the label name support has consistently and substantially improved all methods. Specifically, in the 5-way 1-shot setting, the results improve about 3% to 11% on Banking77, 6% to 10% on HWU64, 1% to 8% on Clinc150. Moreover, adding the label name as support could also improve the state-of-the-art ProtAugment framework, as shown in the results of L-ProtoNet+MLM and L-ProtAugment.

Meaningful labels improve baselines. As shown in Table 6, for the first example, adding label names correct the prediction of sentence embedding baselines. Adding `share_location` as a support example, the prototype for this class may contain more information about "know" and "location" compared to the irrelevant word "miranda". This illustrates the discriminative effectiveness of label names. For the second example, all methods incorrectly predict `remove_lists` because the bad example given in the support set for the label `create_or_add_lists`. Adding the label names corrects all methods with better representation for the class `create_or_add_lists`.

Limitation: negative effect from misleading or vague labels. We also observe slightly negative effects in some cases. For example, when adding the label name `general_negate` (this intent means a person does not agree with something) for the third example in Table 6, "negate" is not a usual expression for the intent `general_negate`, and the association between "not" in the query and

Episode		ProtAugment		SBERT-Para.	
		w/o L	*w/* L	*w/o* L	*w/* L
Query: **Support #1**: **Support #2**:	`[spelling]` i need to know how to spell “miranda” `[spelling]` i can’t figure out how to spell superficial `[share_location]` have miranda know about my current location	✓	✓	✗	✓
Query: **Support #1**: **Support #2**:	`[create_or_add_lists]` i need to create a new to do list `[create_or_add_lists]` we need milk `[remove_lists]` delete butterfly clips from my wish list	✗	✓	✗	✓
Query: **Support #1**: **Support #2**:	`[general_negate]` sorry but that is not the right answer. `[general_negate]` please rectify the command. `[general_don't_care]` any one would be okay with me, olly.	✓	✗	✓	✗

Table 6: Case study on HWU64, Clinic150 datasets after adding label names. `[Intent]`: the true intent label; ✓: correct predictions; ✗: wrong predictions; *w/o* L: without label name; *w/* L: after adding label name.

the word “don’t” in the label name `general don't_care` makes the model prefer this wrong intent. We also find some label names in the Liu57 dataset to be rather vague or ambiguous, making them difficult to bring any useful information. For example, the label name `likeness` actually corresponds to utterances expressing the likeness to music, while the label name `music` means listening to or playing music. Adding these label names usually leads to confusion between these two intents.

6 Related Work

6.1 Few-Shot Intent Detection

Studies on few-shot intent detection usually focus on two settings: (1) only a handful of annotated examples for each intent are available during training (Casanueva et al., 2020; Mehri and Eric, 2021; Zhang et al., 2020, 2021b; Qu et al., 2021); (2) in addition to the few-shot examples of target intents, rich labeled examples of other intents are available for training (Xia et al., 2021, 2020; Nguyen et al., 2020; Li and Zhang, 2021; Dopierre et al., 2021b; Yu et al., 2021; Zhang et al., 2021a). In this paper, we focus on the second setting, where the problem is typically formulated as the *meta-learning* problem and various approaches have been proposed (Yu et al., 2018; Geng et al., 2019; Nguyen et al., 2020; Li and Zhang, 2021; Dopierre et al., 2021b). Dopierre et al. (2021b) propose to use diverse paraphrases to improve the ProtoNet and achieve the SoTA performance in the semi-supervised intent detection meta-learning setting. Zhang et al. (2021a) study the effectiveness of pre-training with labeled intent data for this problem. Instead of developing a new framework or a new algorithm, this work conducts an empirical study on the effectiveness of using general pre-trained sentence encodings for this task.

6.2 Label Semantics for Low-Resource Text Classification

There also exists more complex usage of label names in the related literature on zero-shot or few-shot text classification tasks (Yazdani and Henderson, 2015; Chen et al., 2016; Wang et al., 2018; Yan et al., 2020; Luo et al., 2021; Hou et al., 2021), typically involving learnable label embeddings with crafted encoder modules or a more clever usage of pre-trained language models.

In zero-shot text classification, Chang et al. (2008) embed label descriptions and texts into a shared Wikipedia concept space and then measure their similarities for classification. Similarly, Chen et al. (2016) jointly embed label names and utterances into one distributed embedding space. Yazdani and Henderson (2015) leverage the structure of intent labels to produce a classification hyperplane for zero-shot intent classification.

For few-shot text classification, prompt-based methods (Schick and Schütze, 2021a,b) use label names to construct verbalizers to map each label into cloze-style phrases, which enables the utilization of powerful pretrained language models. More recently, Müller et al. (2022) propose label tuning which only finetunes the label embeddings but freezes the sentence encoder for few-shot text classification. Mueller et al. (2022) explore label semantics by performing pre-training on a mix of gold and weakly annotated sentence-label pairs. Another line of works (Luo et al., 2021; Hou et al., 2021) incorporate label names into the meta-learning models. Luo et al. (2021) append label names to the utterances to help the model extract discriminative features. Hou et al. (2021) take a linear combination of the prototype calculated by support examples and the label embedding as the anchored label representation to separate different labels in a multi-label intent classification scenario. Different from previous works, our simple modification aims to enhance general sentence embeddings towards key parts that express an intent. Besides, the proposed modification doesn't introduce any parameters, so it can be adapted to any pretrained sentence encoders with ease.

7 Conclusion and Future Work

Motivated by the nature of prototypical networks for intent detection meta-learning, in this paper, we empirically compare some modern popular sentence encoders on multiple intent detection benchmarks, observing non-trivially strong performance with better cross-dataset generalization capability than the fine-tuned sentence encoders. Inspired by our follow-up analysis, we propose a simple modification that has consistently and substantially brought performance gain over all systems: adding the intent label names into the support set. This strategy not only improves over the performance from general-purpose sentence encoding, but also the state-of-the-art results from the fine-tuned ProtAugment framework.

One limitation of our study for now is that the sentence representation in use is mostly based on BERT variants. It could be technically interesting to experiment with models pre-trained in a sequence-to-sequence fashion (Lewis et al., 2020; Raffel et al., 2020), which might have better captured semantic paraphrase representations via denoising or other training objectives.

A Appendix

Extended Analysis for Label Semantics Since we add label names as additional support examples, the embedding space of sentences does not change in general sentence embedding based methods. For meta-learning based methods, we can take label names as support examples only in the meta-testing phase, or leverage them in both meta-training and meta-testing stages. The latter will change the embedding space. As shown in Table A.1, we find that adding label names at both stages generally yields slightly better performance than only using it during meta-testing.

To further validate the effectiveness of using label names, we sample fifty 5-way 1-shot episodes from five classes in Liu57 dataset. We visualize the query instances and prototype representations in the same embedding space. As shown in Figure A.1, in the 1-shot setting, the prototypes of the same class spread out and it is difficult to distinguish them from other classes. This indicates that the model struggles to extract the crucial information relevant to the intent class due to the limited information contained in one support example. However, adding label names helps centralize the prototypes of the same class and separate them away from those of other classes. This suggests that label names may be regarded as high-quality free examples which could help distinguish different classes.

Implementation Details We use Euclidean distance as the distance metric in ProtoNet for all sentence encoders, except for SP-paraphrase, in which cosine distance leads to much better performance. For meta-learning based methods, we use `RoBERTa-base` from Huggingface (Wolf et al., 2020) as the encoder. For the optimizer, we use Adam (Kingma and Ba, 2015) with a learning rate of 2e-5. We set the batch size to 32 and train the model for 10,000 episodes. We use the validation split to evaluate the model every 600 episodes and select the checkpoint with the best performance. The ProtAugment model has 123M parameters and the training lasts around one hour on four Tesla V100 GPUs.

Abstract

Recent advances in self-supervised modeling of text and images open new opportunities for computational models of child language acquisition, which is believed to rely heavily on cross-modal signals. However, prior studies have been limited by their reliance on vision models trained on large image datasets annotated with a pre-defined set of depicted object categories. This is (a) not faithful to the information children receive and (b) prohibits the evaluation of such models with respect to category learning tasks, due to the pre-imposed category structure. We address this gap, and present a cognitively-inspired, multimodal acquisition model, trained from image-caption pairs on naturalistic data using cross-modal self-supervision. We show that the model learns word categories and object recognition abilities, and presents trends reminiscent of those reported in the developmental literature. We make our code and trained models public for future reference and use[1].

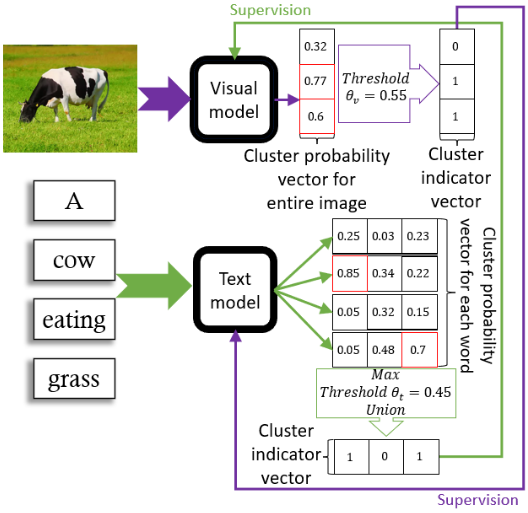

Figure 1: Model overview. Given an image-caption pair (left), both the visual (top) and textual encoder (bottom) generate a binary vector indicative of the clusters associated with the current input. The text/visual model predicts a probability vector over clusters per word/image. Vectors are mapped to a binary space using thresholding. The modality-specific vectors provide mutual supervision during training (right).

1 Introduction

To date, the mechanisms underlying the efficiency with which infants learn to speak and understand natural language remain an open research question. Research suggests that children leverage contextual, inter-personal and non-linguistic information. Visual input is a case in point: when spoken to, infants visually perceive their environment, and paired with the input speech, the visual environment could help bootstrap linguistic knowledge (Tomasello et al., 1996). Unlike social cues, visual input has a natural physical representation, in the form of pixel maps or videos.

Previous multimodal language acquisition studies either considered toy scenarios with small vocabularies (Roy and Pentland, 2002; Frank et al., 2007), or used visual encoders that were pretrained on large labeled data bases such as ImageNet (Deng et al., 2009) or Visual Genome (Krishna et al., 2017). This has two drawbacks: first, systematic access to labeled data is a cognitively implausible assumption in a language acquisition setting; second, imposing a pre-defined categorization system precludes studying categories that emerge when learning from unlabeled multimodal data. This type of setting more closely resembles the data underlying early language learning at a time when the child has only acquired little conceptual information. Although the subject of much psycholinguistic work, the computational study of multimodal word categories, formed without recourse to manual supervision has been scarcely addressed in previous work.

We present a model that learns categories as clus-

Table 1: Comparing the size, training data and training time of popular self-supervised models ($\text{BERT}_{\text{base}}$, word2vec (300d, google-news) and CLIP with ResNet50X64) against our model (Ours, bold) and typical child input (Children; Gilkerson et al., 2017). For the multimodal models (CLIP and Ours) we only mention the size of the text encoder.

ters of words from large-scale, naturalistic multimodal data without any pre-training. Given (image, caption)-pairs as input, the model is trained to cluster words and images in a shared, latent space, where each cluster pertains to a semantic category. In a self-supervised setup, a neural image classifier and a co-occurrence based word clustering module provide mutual supervision through joint training with an expectation-maximization (EM) style algorithm. Figure 1 illustrates our model.

Our input representation is cognitively plausible in that we use raw image data (pixels), and train our model on a comparatively small data set (Table 1). However, we follow previous work (Kádár et al., 2015; Nikolaus and Fourtassi, 2021) in using written and word-segmented text input. Young infants do not have access to such structure, and this assumption therefore deviates from cognitive plausibility (but opens avenues for future work).

We show that semantic and visual knowledge emerges when training on the self-supervised categorization task. In a zero-shot setup, we evaluate our model on (1) word concreteness prediction as a proxy for noun identification, one of the first cues for syntax in infant language acquisition (Fisher et al., 1994); (2) visual classification and object segmentation. We also study the emerging latent word clusters and show that words are clustered syntagmatically (De Saussure, 1916): words representing entities that are likely to occur together are more likely clustered together (e.g., dog-bark), than words that share taxonomic categories (e.g., dog-cat). This concurs with findings that young children acquire syntagmatic categories more readily than taxonomic categories (Sloutsky et al., 2017).

2 Background and Related Work

We briefly review previous studies of unimodal learning without pretraining (for both text and vision) and multimodal learning (studied mainly in acquisition implausible settings) to highlight the gap that this work addresses.

Unimodal Learning. Self-supervised learning without pre-training has been extensively studied, but predominantly in a unimodal scenario or under cognitively implausible assumptions. For the text modality, large language models have been developed in recent years (e.g., BERT; Devlin et al., 2019), trained on large unlabeled text corpora (Table 1). A more cognitively motivated model is BabyBERTa (Huebner et al., 2021), a smaller version of RoBERTa (Liu et al., 2019) (also) trained on transcribed child directed speech. In the visual domain, self-supervision is typically implemented as contrastive learning, training the model to align corrupted images with their original counterparts (Chen et al., 2020a), with subsequent fine-tuning.

Multimodal Language Learning. Early language acquisition studies (Roy and Pentland, 2002) considered toy scenarios with small vocabularies and used heuristics for image processing. Silberer and Lapata (2014) model multi-modal human categorization using human-annotated feature vectors as input for a multimodal self-supervised autoencoder, while we learn the features from raw images.

Unlike our work, recent work on cross-modal language learning (Kádár et al., 2015; Chrupała et al., 2017; Ororbia et al., 2019; Nikolaus and Fourtassi, 2021) typically use Convolutional Neural Networks, pre-trained on large labeled data bases like ImageNet (Deng et al., 2009), or alternatively (e.g., Lu et al., 2019; Chen et al., 2020b) use object detectors pre-trained on Visual Genome (Krishna et al., 2017) as the visual model.

Few studies assume no prior knowledge of the grounded modality. Most related to our study is CLIP (Radford et al., 2021), a pre-trained off-the-shelf model trained to project matching images and captions to similar vectors. CLIP assumes a multimodal joint space which is continuous, unlike our binary space. Liu et al. (2021) use CLIP pretrained encoders to learn cross-modal representations with a similar training objective as ours. They discretize the output of the encoders by mapping it to the closest vector from a finite set of learned vectors, which can be viewed as a form of categorization. CLIP-based works are trained to match entire sentences to images and have no explicit representation of words and phrases. We therefore view it as a cognitively less plausible setting than is presented in the current study. Nevertheless, we include CLIP as a point of comparison when applicable.

3 Model

Our goal is to learn the meaning of words and raw images through mutual supervision by mapping both modalities to a joint representation. Intuitively, given a visual input paired with relevant text (approximating a typical learning scenario), the output for each of the modalities is a binary vector in $\{0, 1\}^N$, with non-zero dimensions indicating the clusters[2] to which the input is assigned and N is the total number of clusters (a predefined hyper-parameter). The clusters are unknown a priori and are formed during training. The goal is to assign matching text and image to the same clusters. In order to minimize assumptions on innate knowledge or pre-imposed categories available to the language learner, and enable the study of emerging categories from large-scale multi-modal input data, we deliberately avoid any pre-training of our models.

3.1 Visual Encoder

The visual encoder (Figure 1, top) is a randomly initialized ResNet50 (He et al., 2016), without pre-training. We set the output size of the network to N (the number of clusters) and add an element-wise sigmoid layer.[3] To produce the binary output and predict the clusters given an input image, we apply a hyper-parameter threshold θ_v to the output of the sigmoid layer.

3.2 Text Encoder

The text encoder (Figure 1, bottom) is a simple probabilistic model based on word-cluster co-occurrence, which is intuitively interpretable and makes minimal structural assumptions. Given a sentence, the model assigns each word to at most one cluster. The sentence is assigned to the union of the clusters to which the words in it are assigned. Formally, given a sentence $s{=}(w_1, w_2, ..., w_n)$ of words w_i, and an assignment of the words to clusters $f{:}\{w_1, ..., w_n\}{\to}\{1, ..., N\} \cup \{\emptyset\}$, the clusters to which the sentence is assigned are: $\{c|\text{if } \exists w_i \text{ s.t. } f(w_i){=}c\}_{c=1}^{N}$. When assigning words to clusters, we make two simplifying assumptions: (1) the probability that a word is assigned to a specific cluster is independent of the linguistic context, meaning that we assign to clusters on the type- rather than the token level (a reasonable assumption given that children learn single words first); (2) a single word cannot be assigned to more than one cluster, *but it might be assigned to no cluster at all if it does not have a visual correspondent in the image* (e.g., function words). Under these assumptions, the encoder estimates $P(c|w)$ for each $c \in \{1, \ldots, N\}$ and for each $w \in V$, where V is the vocabulary. If the probability of assigning a given word in a sentence to any of the clusters exceeds a hyper-parameter threshold θ_t, it is assigned to the cluster with the highest probability, otherwise it is not assigned to any cluster. Formally:

$$f(w) = \begin{cases} \underset{c \in [N]}{\text{argmax}}\, P(c|w) & \text{if } \underset{c \in [N]}{\max}\, P(c|w) \geq \theta_t \\ \emptyset & \text{else} \end{cases}$$

In the next step, we define the word-cluster associations $P(c|w)$. We estimate these using Bayes Rule,

$$P(c|w) = \frac{P(w|c)P(c)}{P(w)} \qquad (1)$$

$P(w|c)$ is defined as the fraction of all predictions of cluster c from the visual encoder, in which w occurred in the corresponding caption. We instantiate the prior cluster probability $P(c)$ as uniform over all clusters.[4]

Finally, for a given word w, we estimate $P(w){=}\sum_{i=1}^{N} P(c_i)P(w|c_i)$. Intuitively, we expect that a concrete word would repeatedly occur with similar visual features (of the object described by that word), therefore repeatedly co-occurring with the same cluster and receiving a high assignment probability with that cluster, whereas abstract words would co-occur with multiple clusters, therefore not being assigned to any cluster.

---

[2] We use the term *clusters* for the output of models and the term *categories* for ground truth classification of elements (e.g., human defined categories).

[3] This is a multi-label categorization task (i.e., an image can be assigned to multiple clusters): Cluster assignments do not compete with one another, which is why we chose sigmoid over softmax.

[4] We also tried instantiating $P(c)$ as the empirical cluster distribution as predicted by the visual encoder. However, the noisy initial predictions lead to a positive feedback loop leading to most clusters being unused.

4 Training

At each training step, the model observes a batch of (image, caption)-pairs. We first perform inference with both encoders, and then use the results of each encoder's inference to supervise the other encoder.

Text Encoder. Given the list of clusters predicted by the visual encoder and a tokenized caption $s=\{w_1, ..., w_n\}$, for each $w_i \in s$ and for each cluster c_j predicted by the visual encoder, we increment $count(c_j)$ and $count(w_i, c_j)$. These are needed to compute the probabilities in equation (1).

Visual Encoder. For each input image and corresponding cluster vector predicted by the text encoder, we use binary cross entropy loss comparing the output of the sigmoid layer with the predicted cluster vector and use Backpropagation to update the parameters of the ResNet model.

5 Experiments

We trained our model on the 2014 split of MSCOCO (Lin et al., 2014), a dataset of naturalistic images with one or more corresponding captions, where each image is labeled with a list of object classes it depicts. MSCOCO has 80 object classes, 123K images and 616K captions (split into 67% train, 33% test). We filtered out images that did not contain any labeled objects, and images that contained objects with a multi-token label (e.g., "fire hydrant").[5] After filtering, we are left with 65 ground-truth classes. The filtered training (test) set contains 56K (27K) images and 279K (137K) captions. We set apart 20% of the training set for hyper-parameter tuning.

We trained our model with a batch size of 50 until we observed no improvement in the F-score measure from Section 5.1 (40 epochs). Training took 4 days on a single GM204GL GPU. We used N=150 clusters, θ_t=0.08, and θ_v=0.5. The visual threshold θ_v was first set heuristically to 0.5 to avoid degenerate solutions (images being assigned to all or no clusters initially). Then, N and θ_t were determined in a grid search, optimizing the F-score measure from Section 5.1. We used spaCy (Honnibal and Montani, 2017) for tokenization.

5.1 Semantic Word Categorization

Background. Semantic word categorization is the clustering of words based on their semantic features. Psycholinguistic studies have shown that children use semantic word categories to solve linguistic tasks by the end of the second year of life (e.g., Styles and Plunkett, 2009). There is a long established fundamental distinction between *syntagmatic* (words that are likely to co-occur in the same context) and *paradigmatic* relations (words that can substitute one another in a context without affecting its grammaticality or acceptability) (De Saussure, 1916). Each relation type invokes a different type of word categories (syntagmatic relations invoke syntagmatic categories, or *associative* categories; paradigmatic relation invoke *taxonomic* categories). Despite an acknowledgement that infants, unlike adults, categorize based on syntagmatic criteria more readily than on paradigmatic criteria ("The Syntagmatic-Paradigmatic shift"; Ervin, 1961), and empirical evidence that syntagmatic categories might be more important for word learning than taxonomic categories (Sloutsky et al., 2017), computational categorization studies and datasets predominantly focused only on taxonomic hierarchies (Silberer and Lapata, 2014; Fremann and Lapata, 2016).

Setting. Our model's induced clusters are created by using the text encoder to predict, for each word, the most likely cluster.

We evaluated induced clusters against a taxonomic and a syntagmatic reference data set. First, we followed Silberer and Lapata (2014), used the categorization dataset from Fountain and Lapata (2010), and transformed the dataset into hard categories by assigning each noun to its most typical category as extrapolated from human typicality ratings. The resulting dataset contains 516 words grouped into 41 taxononmic categories. We filtered the dataset to contain only words that occur in the MSCOCO training set and in the word2vec (Mikolov et al., 2013) dictionary, obtaining the final dataset with 444 words grouped into 41 categories.

In order to quantify the syntagmatic nature of the induced clusters, we used a large dataset of human word associations, the "Small World of Words" (SWOW, De Deyne et al., 2019). SWOW was compiled by presenting a cue word to human participants and requesting them to respond with the first three words that came to mind. The association

---

[5] This was enforced because multi-token labels do not necessarily map to a single cluster, rendering the evaluation more difficult. We plan to address this gap in future work.

strength of a pair of words (w_1, w_2) is determined by the number of participants who responded with w_2 to cue word w_1. Prior work has shown that word associations are to a large extent driven by *syntagmatic* relations (Santos et al., 2011).

Comparison with other models. We compare against several word embedding models,[6] where for each model we first induce embeddings, which we then cluster into K=41 clusters (the number of taxonomic gold classes) using K-Means. We compare against a **text-only** variant of our model[7] by creating a co-occurrence matrix C where $C_{i,j}$ is the number of captions in which tokens i, j in the vocabulary co-occur. The normalized rows of C are the vector embeddings of words in the vocabulary. We compare against off-the-shelf **word2vec** and **BERT$_{\text{BASE}}$** embeddings. For BERT, given a word w, we feed an artificial context ("this is a w") and take the embedding of the first subword of w. We also include the multi-modal **CLIP**, using prompts as suggested in the original paper ("a photo of a w").[8] Finally, we include a randomized baseline, which assigns each word at random to one of 41 clusters. Implementation details can be found in Appendix A.1.

Taxonomic categorization. We use the F-score metric following Silberer and Lapata (2014). The F-value of a (gold class, cluster)-pair is the harmonic mean of precision and recall defined as the size of intersection divided by the number of items in the cluster and the number of items in the class, respectively. The F-score of a class is the maximum F-value attained at any cluster, and the F-score of the entire clustering is the size-weighted sum of F-scores of all classes. We report performance over five random restarts for all models.

Results are presented in Table 2. The text-only baseline improves results over a random categorization algorithm. Our multi-modal model grounded in visual input improves over its unimodal variant. Our model is competitive with BERT and is surpassed by word2vec and CLIP. However, considering the small model and training data we used (see Table 1), our results are competitive.

Model	F-Score
Random	0.15 ± 0.0032
Text-only	0.26 ± 0.0098
Word2vec	**0.40 ± 0.0172**
BERT$_{\text{BASE}}$	0.33 ± 0.011
CLIP	0.38 ± 0.0142
Ours	0.33 ± 0.0109

Table 2: Taxonomic categorization results, comparing a random baseline (top) against text-only (center) and multi-modal models (bottom), as mean F-score and std over 5 runs. Word2vec (bold) achieves the highest score.

Model	MAS
Taxonomic	5.72
Random	4.23 ± 1.88
Text-only	5.47 ± 0.25
Word2Vec	6.65 ± 0.16
BERT$_{\text{BASE}}$	5.75 ± 0.23
CLIP	7.08 ± 0.41
Ours	**7.45 ± 0.33**

Table 3: Sytagmatic categorization results on the same models as in Table 2, reporting mean association strength (MAS) of pairs of clustered concepts in the SWOW dataset, over 5 random initializations. Taxonomic refers to the taxonomic gold categories. Our model (bold) achieves the highest score.

Syntagmatic categorization. We quantify the syntagmatic nature of a clustering by the mean association strength (MAS) of pairs of words in the SWOW dataset, where association strength of a pair of words (w_1, w_2) is again number of participants who responded with w2 to cue word w1. MAS is computed across all word pairs from the taxonomic dataset in which both words were assigned the same cluster by this clustering solution.

Results are presented in Table 3. The multimodal models (ours and CLIP) outperform all unimodal models, an indication of the impact of multimodality on category learning: multimodal word learning shifts the learner towards syntagmatic relations more significantly than unimodal word learning. To our knowledge, this is the first computational result to support this hypothesis, shown empirically in human studies with infants (Elbers and van Loon-Vervoorn, 1999; Mikolajczak-Matyja, 2015).

Qualitative analysis. Table 4 shows four of the

---

[6] We omit Silberer and Lapata (2014) since we were unable to obtain their model.

[7] It was not clear how to design co-occurrence based vision-only baselines, as images do not naturally factorize into concepts/regions, unlike text which is divided into words.

[8] We also tried BERT and CLIP feeding as input the target word only. Results for CLIP slightly decreased, while results for BERT decreased significantly.

Ours 1 skis; axe; sled; parka; sleigh; pants; gloves
Ours 2 sailboat; canoe; swan; raft; boat; yacht; duck; willow; ship; drum
Ours 3 train; bullet; subway; tack; bridge; trolley
Ours 4 bedroom; rocker; drapes; bed; dresser; sofa; couch; piano; curtains; cushion; lamp; chair; fan; bureau; stool; cabin; book
W2V cluster avocado, walnut, pineapple, grapefruit, coconut, olive, lime, lemon

Table 4: Four clusters induced by our model (Ours 1, 2, 3, 4), sorted by $P(c|w)$, and one cluster induced by word2vec. Our clusters are syntagmatic, while the W2V cluster is taxonomic. Words highlighted by the same color belong to the same taxonomic category.

clusters created by our model and one cluster created by word2vec for the taxonomic categorization dataset.[9] The clusters formed by our algorithm are syntagmatic, associating words frequently observed together (e.g., tokens in cluster 1 are related to *snow activity*, while cluster 2 broadly relates to *water*). The cluster formed by word2vec embeddings is taxonomic (all tokens are food products). Our results provide initial evidence that syntagmatic clusters emerge from an unsupervised training algorithm drawing on simple joint clustering of words and images.

5.2 Concreteness Estimation

Background. Fisher et al. (1994) suggest that the number of nouns in a sentence is among the earliest syntactic cues that children pick up. Consequently, noun identification is assumed to be one of the first syntactic tasks learned by infants. We approximate noun identification as concreteness estimation, since words representing concrete entities are mostly nouns.[10] Chang and Bergen (2021) show that while children acquire concrete words first, neural text-based models show no such effect, suggesting that multimodality impacts the learning process.

Setting. We evaluate concreteness estimation using the dataset by Brysbaert et al. (2013), which contains concreteness ratings for 40K English words averaged over multiple human annotated ratings on a scale of 1 to 5. We estimate the concreteness of a word as the maximum probability with which it was assigned to any cluster. For evaluation, we follow Charbonnier and Wartena (2019) and compute the Pearson correlation coefficient of our predictions with the ground-truth values. In addition, we investigate the impact of word frequency on our model's predictions by evaluating the model on subsets of words in the Brysbaert data of increasing minimum frequency in MSCOCO.

Comparison with other models. First, we compare against supervised **SVM regression** models, which have shown strong performance on the Brysbaert data in prior work (Charbonnier and Wartena, 2019). Following their work, we use two feature configurations: (1) POS tags + suffixes, (2) POS tags + suffixes + pre-trained FastText embeddings (Joulin et al., 2017). We train the SVMs on the full Brysbaert data.

Second, we compare with a minimally supervised **text-only** model. As in Sec 5.1, we create word vector representations from co-occurrence counts. Next, following prior work (Turney et al., 2011), we select concrete (abstract) representative words by taking the 20 words with the highest (lowest) concreteness value in the Brysbaert data that occur more than 10 times in the MSCOCO training set. We predict a word's concreteness by computing its average cosine similarity to the concrete representative words minus the average of its cosine similarity to the abstract representative words.

Results. Figure 2 presents the results in terms of Pearson correlation when evaluated on words of varying minimum frequency in MSCOCO. When considering frequent tokens only, our model predicts word concreteness with an accuracy higher than the SVM with POS and suffix features, although additional embedding features improve SVM performance further. Note that the supervised baseline was trained on the full data set, and hence evaluated on a subset of its training set. Our multimodal model performs better than its text-only variant for tokens that occur at least 100 times, even though the text-only model has received some supervision (by selecting the representative words).

---

[9] See appendix for the full list of clusters of all clustering algorithms.

[10] For example, in the concreteness dataset built by Brysbaert et al. (2013), in which human annotators rated the concreteness of words on a scale of 1 to 5, 85.6% of the words with an average concreteness rating above 4 are nouns.

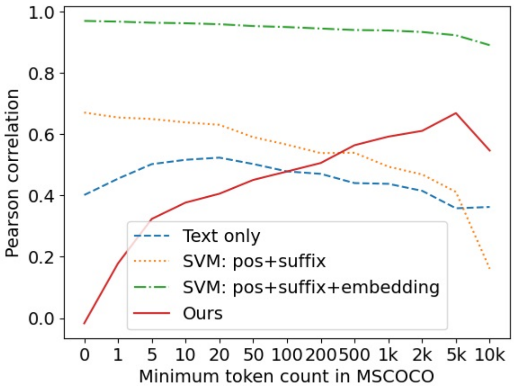

Figure 2: Pearson correlation between predicted word concreteness and gold standard human ratings, evaluated over test sets with increasing minimum frequency in the MSCOCO data. Results are averaged across 5 random initializations (std was consistently < 0.03).

5.3 Visual Multi-Label Classification

In addition to linguistic knowledge, infants acquire visual semantic knowledge with little explicit supervision, i.e., they learn to segment and classify objects. To test whether our model also acquires such knowledge we evaluated it on the multi-label classification task: For each image in the MSCOCO test set, predict the classes of objects in the image.

In a zero-shot setting, we mapped the induced clusters to predicted lists of MSCOCO classes as follows. We first provided the name of each class to our model as text input and retrieved the assigned cluster, thus obtaining a (one-to-many) cluster-to-classes mapping. Now, for each test image, we used the visual encoder to predict the assigned cluster(s). The predicted set of MSCOCO classes is the union of the lists of classes to which the predicted clusters are mapped.

Comparison with CLIP. We compare our results against CLIP. To ensure comparability with our model we use CLIP with ResNet50. We use CLIP as a point of comparison to provide perspective on the capabilities of our model despite differences in modeling and assumptions. However, we note two caveats regarding this comparison. First, CLIP was trained on a much larger training set and has more parameters than our model (see Table 1). Second, CLIP has only been used for single- (not multi-) label classification, by inferring encodings of both input images and prompts representing the ground-truth classes (e.g., “a photo of a bus” for the ground truth class *bus*) and assigning the image to the class with highest cosine similarity to its encoding. We adapt CLIP to a multi-label setting as follows: Instead of assigning the image to the class with the highest cosine similarity, we take into account the cosine similarity with all classes for each image. We consider a class as predicted if its cosine similarity exceeds a threshold, tuned on the MSCOCO training split.

Model	Precision	Recall	F-Score
Ours	0.43 ± 0.04	0.21 ± 0.02	0.28 ± 0.01
CLIP	0.52	0.39	0.45

Table 5: Visual multi-label classification results on the MSCOCO data for our model and CLIP in terms of precision, recall and F1 score. We report mean (std) over 5 random initializations for our model. CLIP experiments are deterministic (we use the pretrained model directly, unlike Sec 5.1 where we used KMeans on top of CLIP).

Results. Table 5 presents the results. As expected, CLIP outperforms our model. However, our model achieves impressive results considering its simplicity, its size, and that CLIP is the current state-of the-art in self-supervised vision and language learning. Training a CLIP model of comparable size and exposed to similar training data as our model is beyond the scope of this paper, but an interesting direction for future work.

5.4 Object Localization

Another important task performed by infants is visual object localization. To test our model’s ability to reliably localize objects in images we use Class Activation Maps (CAM) described by Zhou et al. (2016). Each CAM indicates how important each pixel was during classification for a specific cluster.

Quantitative analysis. Most previous studies of zero-shot segmentation (Bucher et al., 2019) trained on a subset of “seen” classes, and evaluated on both seen and unseen classes. We use a more challenging setup previously referred to as annotation-free segmentation (Zhou et al., 2021), where we evaluate our model without any training for the segmentation task. We use MSCOCO’s ground-truth bounding boxes, which are human annotated and mark objects in the image, for evaluation. Following the original CAM paper, we use a heuristic method to predict bounding boxes: Given a CAM, we segment the pixels of which the value is

Model	Precision	Recall	F-Score
Ours	**0.178 ± 0.01**	0.025 ± 0.004	0.044 ± 0.006
Rand	0.027 ± 0.001	0.027 ± 0.001	0.027 ± 0.001

Table 6: Mean F-score and standard deviation across 5 random initializations on bounding box prediction. Our model (Ours) improves precision (bold) over random (Rand) significantly while achieving similar recall (might improve by tuning the visual threshold).

above 50% of the max value of the CAM and take the bounding box that covers the largest connected component in the segmentation map.

We use precision and recall for evaluation. A pair of bounding boxes is considered a match if the intersection over union (IoU) of the pair exceeds 0.5. Given lists of predicted and ground-truth bounding boxes, we consider each matched pair as a true positive and a prediction (ground-truth) for which no matching ground-truth (prediction) was found as a false positive (negative). We compare our model to a random baseline: Sample k random bounding boxes (where k is the number of ground-truth bounding boxes in the current image). This baseline uses the number of ground-truth bounding boxes in each image (our model is not exposed to this information).

The results are presented in Table 6. Our model is significantly more precise than the random baseline, but achieves similar recall: the entire MSCOCO test split contains a total of 164,750 bounding boxes, while our model predicted 38,237 bounding boxes. This problem could be addressed by lowering the visual threshold. We leave this direction for future research.

Qualitative analysis. Fig. 3 shows a selection of CAMs, plotted as heatmaps and associated with class predictions (see Sec. 5.3). The heatmaps extracted by the model were better when the model predicted a correct class in the visual classification task (top six images and bottom left image in Fig 3). In the bottom two images two clusters were predicted for the same original image, one correct and one incorrect (with an, unsurprisigly, meaningless heatmap).

6 Discussion and Conclusion

We proposed a model for unsupervised multimodal lagnguage acquisition, trained to jointly cluster text and images. Many of our design choices were guided by findings from cognitive studies of infant language acquisition: The joint learning of multiple modalities; learning word-level semantics (e.g., Fisher et al., 1994, suggest that children first learn to identify nouns and use this information to learn sentence-level semantics); and cross-situational learning (counting how many times each word co-occurred with each cluster, see Gleitman, 1990). After training, our model demonstrates capabilities typical of infant language acquisition: Word concreteness prediction and identification and segmentation of objects in a visual scene.

Figure 3: Examples of heatmaps of CAM values. Above each image we print the class predicted by the model.

However, we do not stipulate that infants begin their acquisition of language by clustering words. It would be interesting to design experiments to test this hypothesis, e.g., by connecting our work with laboratory work on joint word and category learning (Borovsky and Elman, 2006), or work on the emergence of syntagmatic vs. taxonomic categories in young children (Sloutsky et al., 2017).

While our model is cognitively more plausible compared to previous studies, the gap from a realistic setting of language acquisition is still large: (1) we assume the language input is segmented into words; (2) the input data, while naturalistic, is not typical of infants at the stage of language acquisition; (3) the input only includes the visual and textual modality, but not, e.g., pragmatic cues like gesture; and (4) the model learns in a non-interactive setting, whereas physical and social interactions are considered crucial for language learning, and learns (and is evaluated) in a batch fashion while human learning is typically incremental (Fremmann and Lapata, 2016).

In the semantic word categorization and concreteness prediction experiments, we compared our multimodal model to unimodal text-only baselines, which we chose to be as similar as possible to our model. The results suggest that multimodality improves performance on both text tasks. However, it is unclear which specific information is encoded in the visual modality that benefits these text tasks. We leave this question for future research.

Syntagmatic categories, although highly intuitive in the context of human memory, were not the subject of many previous computational studies. We propose to further investigate this type of categories and its use. One interesting direction is to combine syntagmatic categories with interactivity: Given a relevant signal from the environment the model can cycle through concepts in the syntagmatic category triggered by the signal, speeding up the extraction of relevant concepts in real time. One possible application of this direction is modelling the construction of ad-hoc categories, described by Barsalou (1983).

While all experiments are conducted in English, our setting supports future work on other languages. The small training set and the nature of the data (image-sentence pairs that might be, to some extent, collected from the Internet) allow our model to be extended to low-resource languages, while the minimal structural assumptions of the text encoder may imply some degree of language-agnosticity.

In future work, we plan to improve the cognitive plausibility of our model by (1) incorporating typical input observed by children (by using videos taken in real scenes of child language acquisition, see Sullivan et al., 2021); and (2) changing the setting to an interactive one, where the model is transformed into a goal-driven agent that uses interactivity to learn and produce language.

Acknowledgements

We would like to thank the anonymous reviewers for their helpful comments and feedback. This work was supported in part by the Israel Science Foundation (grant no. 2424/21), by a research gift from the Allen Institute for AI and by the HUJI-UoM joint PhD program.

Ethical Considerations

We used publicly available resources to train our model (Lin et al., 2014). As with other statistical methods for word representations, our approach may capture social biases which manifest in its training data (e.g., MSCOCO was shown to be biased with respect to gender, Zhao et al., 2017). Our code includes a model card (Mitchell et al., 2019) which reports standard information regarding the training used to produce our models and its word clusters.

A Appendix

A.1 Implementation details

A.1.1 Training

For the visual encoder, we used the ResNet50 implementation from the torchvision package with ADAM optimizer and a learning rate of 10^{-4}.

A.1.2 Semantic Word Categorization

For clustering of word embeddings, we use the K-Means implementation in scikit-learn. We use the word2vec google-news-300 model from the gensim package, the BERT$_{\text{BASE}}$ model from the transformers library and CLIP's official implementation.

A.1.3 Concreteness Estimation

Supervised model. For the implementation of the supervised model described by (Charbonnier and Wartena, 2019) we used 3 feature types. For POS tag, we used the WordNet module from the NLTK package to find, for each word, the number of synsets in each of the 4 possible POS tags (NOUN, VERB, ADJ, ADV), and the induced feature vector was the normalized count vector. In case no synsets were found the induced feature vector was all zeros. For suffixes, we collected the 200 most frequent suffixes of length 1 to 4 characters in the training set, and the induced feature vector was a 200-d binary vector indicating, for each suffix, if it occurs in the current word. For word embeddings, we used the fastText wiki-news-300d-1M model. The final feature vector is the concatenation of all the selected feature vectors: POS+suffix for the first model (resulting a 204-d feature vector for each word), and POS+suffix+embedding for the second model (resulting a 504-d feature vector for each word).

Text-only baseline. The 20 concrete representative words were *sand*, *seagull*, *snake*, *snowsuit*, *spaghetti*, *stairs*, *strawberry*, *tiger*, *tomato*, *toothbrush*, *tractor*, *tree*, *turtle*, *umbrella*, *vase*, *water*, *comb*, *tire*, *firetruck*, *tv*.

The 20 abstract representative words were *would*, *if*, *though*, *because*, *somewhat*, *enough*, *as*, *could*, *how*, *yet*, *normal*, *ago*, *so*, *very*, *the*, *really*, *then*, *abstract*, *a*, *an*.

A.1.4 Object Localization

To extract Class Activation Mappings, we used the CAM module from the torchcam package.

A.2 Cluster lists

Following is a list of clusters created by different clustering algorithm, in a specific execution.

A.2.1 Our model

Words are sorted by $P(c|w)$.

Cluster 1: doorknob, canary

Cluster 2: trombone, leotards, trumpet, projector, cello, harmonica, guitar

Cluster 3: train, bullet, subway, tack, bridge, trolley

Cluster 4: bus, ambulance, inn, taxi, level

Cluster 5: elephant, bear, giraffe, paintbrush, rock, fence, chain

Cluster 6: machete, porcupine, hornet, banana, gorilla, apple, turtle, turnip, peach, stick

Cluster 7: veil, shawl

Cluster 8: ashtray, mushroom, cheese, spinach, olive, tomato, shrimp, rice, pie, chicken, potato, broccoli, plate, pan, pepper, asparagus, skillet, peas, onions, tuna, salmon, cranberry, lettuce, beans, spatula, ladle, dish, crab, corn, cucumber, tray, walnut, plum, box, lobster, cherry, table, shell

Cluster 9: church, clock, skyscraper, chapel, building, brick, stone, flea

Cluster 10: airplane, helicopter, pier, gate

Cluster 11: bedroom, rocker, drapes, bed, dresser, sofa, couch, piano, curtains, cushion, lamp, chair, fan, bureau, stool, cabin, book

Cluster 12: skis, axe, sled, parka, sleigh, pants, gloves

Cluster 13: dishwasher, kettle, toaster, freezer, stove, microscope, microwave, oven, fridge, cupboard, mixer, blender, plug, mittens, grater, pot, apron, cabinet, tape, apartment

Cluster 14: missile, jet, bomb, rocket, drill

Cluster 15: bouquet, thimble, umbrella, accordion, cake, scissors, wrench, jar, pliers, candle, penguin, frog, doll, bottle, shield, pig, card

Cluster 16: zucchini, beets, cabbage, celery, cauliflower, wheelbarrow, parsley, tongs, shelves

Cluster 17: grapefruit, tangerine, colander, clamp, snail, cantaloupe, pineapple, grape, pear, lemon, eggplant, mandarin, garlic, nectarine, basket, corkscrew, pyramid, pumpkin, bin, sack, lime, cork, orange

Cluster 18: octopus, kite, crocodile, squid, balloon, butterfly, whale

Cluster 19: surfboard, swimsuit, board, rope

Cluster 20: hose, hut

Cluster 21: skateboard, pipe, saxophone, helmet, escalator, barrel, broom

Cluster 22: shotgun, seal, dolphin, car, hoe, hamster, wheel, house

Cluster 23: sailboat, canoe, swan, raft, boat, yacht, duck, willow, ship, drum

Cluster 24: tortoise, dog, cat, tiger, cheetah

Cluster 25: hyena

Cluster 26: buckle, mug, ruler, envelope, bag, belt, cup, camel, pencil, spider, cart, saucer, closet, tripod, carpet
Cluster 27: crowbar, bathtub, toilet, drain, sink, faucet, marble, mirror, basement, tank, bucket, door, razor, mat
Cluster 28: toad, mouse, keyboard, key, desk, typewriter, stereo, rat, bookcase, telephone, anchor, radio
Cluster 29: buzzard, chickadee, finch, woodpecker, grasshopper, worm, sparrow, blackbird, vulture, parakeet, bluejay, hawk, robin, dagger, perch, falcon, stork, peacock, pelican, owl, crow, pigeon, seagull, flamingo, eagle, vine, birch, beaver, pheasant, raven, goose, squirrel, seaweed, ant, emu, dove, cage, crown, shovel
Cluster 30: horse, racquet, saddle, pony, buggy, bat, football, wagon, sword, donkey, ball, fox
Cluster 31: beetle
Cluster 32: zebra, ostrich, elk, deer, lion, pen, pin, rifle, bolts
Cluster 33: bracelet, fawn, slippers, socks, shoes, tap, boots, strainer, jeans, ring
Cluster 34: whistle, cathedral, wand, thermometer, peg, hook, goldfish, lantern, wall, urn, caterpillar, chandelier, robe, leopard
Cluster 35: motorcycle, bike, tractor, truck, trailer, tricycle, scooter, jeep, limousine, garage, van, tent, crane
Cluster 36: baton, revolver, violin, tie, bow, cockroach, elevator, mink, necklace, blouse, trousers, vest, scarf, skirt, gun, gown, dress, shirt, sweater, bra, cap, jacket, coat, cape
Cluster 37: bench, cannon
Cluster 38: unicycle, groundhog
Cluster 39: pistol, buffalo
Cluster 40: clam, pickle, raisin, raspberry, napkin, submarine, fork, coconut, strawberry, bread, spoon, blueberry, radish, knife, biscuit, cloak, spear, whip, avocado, carrot, cottage, turkey, bowl
Cluster 41: lamb, sheep, raccoon, cow, goat, rooster, calf, ox, hatchet, bull, moose, bison, barn, rabbit, shed, shack
Cluster 42: screwdriver, pajamas, comb, hammer, brush, alligator

A.2.2 word2vec

Cluster 1: leopard, hyena, crocodile, canary, lion
Cluster 2: lobster, tuna, clam, octopus, whale, squid, shrimp, seaweed, salmon, crab, dolphin
Cluster 3: mat, cage
Cluster 4: lantern, chandelier, candle, tripod, projector, lamp
Cluster 5: sailboat, submarine, raft, yacht, canoe, boat, pier, ship
Cluster 6: avocado, walnut, pineapple, grapefruit, coconut, olive, lime, lemon
Cluster 7: mittens, doll, slippers, pajamas, necklace, socks
Cluster 8: rock, cottage, tent, gate, house, brick, pyramid, rocker, door, bluejay, shed, bench, skyscraper, bolts, hut, mirror, key, building, barrel, tape, inn, apartment, cabinet, book, marble, drum, shack, umbrella, crane, bureau, garage, shell, basement, fan, cathedral, fence, chapel, stone, drill, telephone, comb, radio, shield, church, anchor, microscope, clock, level, board, football, chain, cabin, wall, barn, bridge
Cluster 9: elk, bison, pheasant, beaver, deer, moose, goose
Cluster 10: pig, cow, sheep, goat, ostrich, emu, calf, buffalo, bull
Cluster 11: elevator, train, whistle, limousine, escalator, subway, bus, taxi, trolley
Cluster 12: groundhog, parakeet, fawn, tortoise, goldfish, porcupine, fox, cheetah, gorilla, flea, rabbit, mink, peacock, rooster, mouse, duck, turtle, squirrel, dog, bear, alligator, rat, raccoon, cat, flamingo, tiger, hamster, penguin
Cluster 13: razor, pliers, scissors, crowbar, knife, screwdriver, machete
Cluster 14: keyboard, violin, trumpet, piano, saxophone, guitar, cello, accordion, trombone, harmonica
Cluster 15: rocket, helicopter, jet, bomb, missile, ambulance, airplane
Cluster 16: jeans, leotards, boots, blouse, skirt, bracelet, shirt, swimsuit, shoes, trousers, dress, pants, sweater, bra
Cluster 17: cauliflower, spinach, cabbage, broccoli, peas, garlic, radish, lettuce, eggplant, cucumber, onions, zucchini, parsley, celery, beans, asparagus, beets
Cluster 18: sofa, drapes, typewriter, napkin, toilet, chair, bathtub, bedroom, bed, doorknob, stool, desk, carpet, table, dresser, couch, stereo, curtains
Cluster 19: strainer, colander
Cluster 20: kite, balloon, willow
Cluster 21: corn, pickle, bread, turkey, biscuit, dish, cheese, cake, lamb, pepper, pie, rice, chicken
Cluster 22: frog, spider, toad, ant, worm, cockroach, snail, butterfly, beetle, hornet, grasshopper,

caterpillar

Cluster 23: cannon, bullet, gun, pistol, rifle, revolver, shotgun

Cluster 24: bag, kettle, mug, envelope, sack, urn, basket, cup, pot, box, card, plate, jar, bucket, bouquet, bin, ashtray, tray, bottle

Cluster 25: bowl, spatula, spoon, blender, ladle, grater, tongs, pan, mixer, saucer

Cluster 26: sleigh, trailer, buggy, wheelbarrow, van, wagon, tractor, truck, cart, jeep

Cluster 27: plum, cherry, birch, cork

Cluster 28: finch, falcon, pigeon, hawk, pelican, raven, seagull, stork, buzzard, vulture, chickadee, sparrow, robin, crow, owl, woodpecker, blackbird, eagle, swan

Cluster 29: racquet, bike, skateboard, skis, unicycle, sled, scooter, motorcycle, helmet, surfboard, wheel, saddle, tricycle, car

Cluster 30: sword, ruler, dagger, spear, baton

Cluster 31: bookcase, shelves, closet, fridge, cupboard

Cluster 32: thermometer, microwave, dishwasher, toaster, skillet, stove, oven, freezer

Cluster 33: vest, coat, jacket, parka, gloves

Cluster 34: plug, thimble, tap, seal, dove, sink, drain

Cluster 35: shawl, scarf, cap, cloak, veil, gown, cape, robe, wand, apron

Cluster 36: hammer, broom, shovel, pencil, hatchet, brush, paintbrush, hoe, wrench, bat, pen

Cluster 37: clamp

Cluster 38: pumpkin, vine, grape, raspberry, carrot, mandarin, strawberry, pear, banana, apple, turnip, nectarine, cantaloupe, orange, mushroom, peach, cranberry, tomato, tangerine, raisin, blueberry, potato

Cluster 39: faucet, tank, pipe, hose

Cluster 40: donkey, ox, pony, horse, camel, elephant, zebra, giraffe

Cluster 41: bow, belt, tie, stick, buckle, cushion, hook, peg, perch, ring, tack, pin, ball, corkscrew, fork, whip, rope, crown

A.2.3 BERT

Cluster 1: crane, vulture, finch, pigeon, owl, sparrow, snail, octopus, bat, lobster, crab, mushroom, shrimp, shell, squid, perch, hornet, spider, worm, butterfly, turtle, toad

Cluster 2: anchor, tack, bow, raft, doll, tray, knife, jet, airplane, canoe, car, helicopter, boat, ship, napkin, book, board, card, desk, chair, bed, sword, bomb, dagger, spear, rope, bag, pencil

Cluster 3: pheasant, woodpecker, parakeet, ostrich, caterpillar

Cluster 4: stork, fawn, hatchet, hyena, raccoon, grasshopper

Cluster 5: pliers, toaster, mittens, strainer, blender, freezer, saucer

Cluster 6: crow, eagle, raven, hawk, dove, pig, sheep, fox, dog, cat, peacock, camel, bear, elephant, deer, buffalo, rabbit, dolphin, frog, cow, elk, lion, moose, donkey, beaver, squirrel, rat, mouse, salmon, goat, calf, whale, leopard, bison, horse, bull, crocodile

Cluster 7: hook, tape, pipe, pyramid, mat, chain, drill, balloon, ball, kite, cap, ring, belt, umbrella, bin, bucket, barrel, basket, bench, gate, wheel, plug, key, stereo, mixer, baton, envelope

Cluster 8: scooter, sleigh, shawl, sled

Cluster 9: raisin, raspberry, beets

Cluster 10: birch, grape, pear, plum, apple, cherry, orange, tomato, peach, lemon, peas, beans, pepper, carrot, lime, rice, potato, olive, garlic, corn, walnut, strawberry, cheese, coconut, mandarin, cabbage, banana, vine, willow, onions

Cluster 11: pelican, chickadee, porcupine, cucumber, cockroach, tortoise

Cluster 12: trailer, hose, saddle, tractor, ambulance, wagon, taxi, bus, submarine, subway, train, elevator, limousine, bike, trolley, motorcycle, jeep, truck, yacht, tank, sofa, rocket, missile, cart, helmet

Cluster 13: skillet, ladle

Cluster 14: level, building, bridge, pier, house, cabin, shield, lantern, marble, sink, apartment, hut, basement, wall, cottage, box, rock, door, table, cage, fence, brick, lamp, telephone, drain, shed, garage, stone, skyscraper, barn, church, cathedral, chapel

Cluster 15: buggy

Cluster 16: revolver, rifle, pistol, shotgun, cannon, gun, bullet

Cluster 17: seagull, sailboat, seaweed

Cluster 18: urn

Cluster 19: wheelbarrow, doorknob

Cluster 20: ruler, shovel, stove, keyboard, microscope, colander, cupboard, bowl, dish, skis, tie, pie, bread, cake, toilet, stool, cushion, mirror, tap, cabinet, carpet, fork, comb, apron

Cluster 21: skateboard, surfboard, swimsuit

Cluster 22: bluejay, blackbird, nectarine, grapefruit, tangerine, eggplant, asparagus, cauliflower, pineapple, cranberry, blueberry, goldfish, groundhog, mink, broccoli

Cluster 23: flamingo, hoe, racquet, parka
Cluster 24: violin, accordion, piano, cello, guitar, trombone, harmonica, trumpet, saxophone
Cluster 25: chandelier
Cluster 26: buzzard
Cluster 27: hamster
Cluster 28: gown, robe, bra, scarf, sweater, shirt, jacket, skirt, coat, dress, necklace, bouquet, blouse
Cluster 29: parsley, biscuit, celery
Cluster 30: goose, duck, falcon, rooster, canary, turkey, swan, gorilla, penguin, tiger, zebra, fan, pajamas, pants, jeans, van, pumpkin, tuna, chicken, rocker, lamb, ox, pony, ant, flea, beetle, cape, alligator
Cluster 31: thermometer
Cluster 32: machete
Cluster 33: cheetah, giraffe
Cluster 34: wrench, corkscrew, screwdriver, escalator, tongs
Cluster 35: thimble, tricycle, unicycle, tripod

Residue-Based Natural Language Adversarial Attack Detection

Abstract

Deep learning based systems are susceptible to adversarial attacks, where a small, imperceptible change at the input alters the model prediction. However, to date the majority of the approaches to detect these attacks have been designed for image processing systems. Many popular image adversarial detection approaches are able to identify adversarial examples from embedding feature spaces, whilst in the NLP domain existing state of the art detection approaches solely focus on input text features, without consideration of model embedding spaces. This work examines what differences result when porting these image designed strategies to Natural Language Processing (NLP) tasks - these detectors are found to not port over well. This is expected as NLP systems have a very different form of input: discrete and sequential in nature, rather than the continuous and fixed size inputs for images. As an equivalent model-focused NLP detection approach, this work proposes a simple sentence-embedding "residue" based detector to identify adversarial examples. On many tasks, it outperforms ported image domain detectors and recent state of the art NLP specific detectors [1].

1 Introduction

In the last decade deep learning based models have demonstrated success in a wide range of application areas, including Natural Language Processing (NLP) (Vaswani et al., 2017) and object recognition (He et al., 2015). These systems may be deployed in mission critical situations, where there is the requirement for a high level of robustness. However, Szegedy et al. (2014) demonstrated that deep models have an inherent weakness: small perturbations in the input can yield significant, undesired, changes in the output from the model. These input perturbations were termed adversarial examples and their generation adversarial attacks.

Adversarial attacks have been developed for systems operating in various domains: image systems (Serban et al., 2020; Biggio and Roli, 2017; Bhambri et al., 2019) and NLP systems (Lin et al., 2014; Samanta and Mehta, 2017; Rosenberg et al., 2017). The characteristics of the input can be very different between these application domains. Broadly, the nature of inputs can be described using two key attributes: static (fixed length) vs sequential and continuous vs discrete. Under this categorisation, image inputs are continuous and static, whilst NLP inputs are discrete and sequential. This work argues that due to the fundamental differences in the input and resulting adversarial perturbations in the different domains, adversarial attack behaviour can vary significantly from one domain to another. Hence, the extensive research on exploring and understanding adversarial perturbation behaviour in the continuous, static world of image systems does not necessarily transfer well to the NLP tasks.

For adversarial attack generation, a number of specific NLP attacks have been proposed that are designed for NLP task inputs (Lin et al., 2014; Samanta and Mehta, 2017; Rosenberg et al., 2017; Huang et al., 2018; Papernot et al., 2016; Grosse et al., 2016; Sun et al., 2018; Cheng et al., 2018; Blohm et al., 2018; Neekhara et al., 2018; Raina et al., 2020; Jia and Liang, 2017; Minervini and Riedel, 2018; Niu and Bansal, 2018; Ribeiro et al., 2018; Iyyer et al., 2018; Zhao et al., 2017). However, there has been less research on developing defence schemes. These defence strategies can be split into two main groups: *model modification*, where the model or data is altered at training time (e.g. adversarial training (Yoo and Qi, 2021)) and *detection*, where external systems or algorithms are applied to trained models to identify adversarial attacks. As model modification approaches demand re-training of models, detection approaches are usually considered easier for implementation on de-

ployed systems and thus are often preferred. Hence, this work investigates the portability of popular detection approaches designed for image systems to NLP systems. Furthermore, this work introduces a specific NLP detection approach that exploits the discrete nature of the inputs for NLP systems. This approach out-performs standard schemes designed for image adversarial attack detection, as well as other NLP detection schemes.

The proposed NLP specific detection approach will be referred to as *residue detection*, as it is shown that adversarial attacks in the discrete, word sequence space result in easily detectable residual components in the sentence embedding space. This residue can be easily detected using a simple linear classifier operating in the encoder embedding space. In addition, this work shows that even when an adversary has knowledge of the linear residual detector, they can only construct attacks at a fraction of the original strength. Hence this work argues that realistic (word level, semantically similar) adversarial perturbations at the natural language input of NLP systems leave behind easily detectable residue in the sentence embedding. Interestingly, the residue detection approach is shown to perform poorly when used to detect attacks in the image domain, supporting the hypothesis that the nature of the input has an important influence on the design of effective defence strategies.

2 Related Work

Previous work in the image domain has analysed the output of specific layers in an attempt to identify adversarial examples or adversarial subspaces. First, Feinman et al. (2017) proposed that adversarial subspaces have a lower probability density, motivating the use of the Kernel Density (KD) metric to detect the adversarial examples. Nevertheless, Ma et al. (2018) found Local Intrinsic Dimensionality (LID) was a better metric in defining the subspace for more complex data. In contrast to the local subspace focused approaches of KD and LID, Carrara et al. (2019b) showed that trajectories of hidden layer features can be used to train a LSTM network to accurately discriminate between authentic and adversarial examples. Out performing all previous methods, Lee et al. (2018) introduced an effective detection framework using Mahalanobis Distance Analysis (MDA), where the distance is calculated between a test sample and the closest class-conditional Gaussian distribution in the space defined by the output of the final layer of the classifier (logit space). Li and Li (2016) also explored using the output of convolutional layers for image classification systems to identify statistics that distinguish adversarial samples from original samples. They find that by performing a PCA decomposition the statistical variation in the least principal directions is the most significant and can be used to separate original and adversarial samples. However, they argue this is ineffective as an adversary can easily suppress the tail distribution. Hence, Li and Li (2016) extract statistics from the convolutional layer output to train a cascade classifier to separate the original and adversarial samples. Most recently, Mao et al. (2019) avoid the use of artificially designed metrics and combine the adversarial subspace identification stage and the detecting adversaries stage into a single framework, where a parametric model adaptively learns the deep features for detecting adversaries.

In contrast to the embedding space detection approaches, Cohen et al. (2019) shows that influence functions combined with Nearest Neighbour distances perform comparably or better than the above standard detection approaches. Other detection approaches have explored the use of uncertainty: Smith and Gal (2018) argues that adversarial examples are out of distribution and do not lie on the manifold of *real* data. Hence, a discriminative Bayesian model's epistemic (model) uncertainty should be high. Therefore, calculations of the model uncertainty are thought to be useful in detecting adversarial examples, independent of the domain. However, Bayesian approaches aren't always practical in implementation and thus many different approaches to approximate this uncertainty have been suggested in literature (Leibig et al., 2017; Gal, 2016; Gal and Ghahramani, 2016).

There are a number of existing NLP specific detection approaches. For character level attacks, detection approaches have exploited the grammatical (Sakaguchi et al., 2017) and spelling (Mays et al., 1991; Islam and Inkpen, 2009) inconsistencies to identify and detect the adversarial samples. However, these character level attacks are unlikely to be employed in practice due to the simplicity with which they can be detected. Therefore, detection approaches for the more difficult *semantically* similar attack samples are of greater interest, where the meaning of the textual input is maintained without compromising the spelling or grammatical integrity. To tackle such word-level, semantically similar examples, Zhou et al. (2019) designed a discriminator to classify each token representation as part of an adversarial perturbation or not, which is then used to 'correct' the perturbation. Other detection approaches (Raina et al., 2020; Han et al., 2020; Minervini and Riedel, 2018) have shown some success in using perplexity to identify adversarial textual examples. Most recently, Mozes et al. (2020) achieved state of the art performance with the Frequency Guided Word Substitution (FGWS) detector, where a change in model prediction after substituting out low frequency words is revealing of adversarial samples.

3 Adversarial Attacks

An adversarial attack is defined as an imperceptible change to the input that causes an undesired change in the output of a system. Often, an attack is found for a specific data point, $\mathbf{x}$. Consider a classifier $\mathcal{F}_{\hat{\theta}}$, with parameters $\hat{\theta}$, that predicts a class label for an input data point, $\mathbf{x}$, sampled from the input distribution $\mathcal{X}$. A successful adversarial attack is where a perturbation $\boldsymbol{\delta}$ at the input causes the system to miss-classify,

$$\mathcal{F}_{\hat{\theta}}(\mathbf{x}+\boldsymbol{\delta}) \neq \mathcal{F}_{\hat{\theta}}(\mathbf{x}). \tag{1}$$

When defining adversarial attacks, it is important consider the interpretation of an *imperceptible* change. Adversarial perturbations are not considered effective if they are easy to detect. Hence, the size of the perturbation must be constrained:

$$\mathcal{G}(\mathbf{x}, \mathbf{x}+\boldsymbol{\delta}) \leq \epsilon, \tag{2}$$

where the function $\mathcal{G}()$ describes the form of constraint and ϵ is a selected threshold of imperceptibility. Typically, when considering continuous space inputs (such as images), a popular form of the constraint of Equation 2, is to limit the perturbation in the l_p norm, with $p \in [1, \infty)$, e.g. $||\boldsymbol{\delta}||_p \leq \epsilon$.

For whitebox attacks in the image domain, the dominant attack approach has proven to be Projected Gradient Descent (PGD) (Kurakin et al., 2016). The PGD approach, iteratively updates the adversarial perturbation, $\boldsymbol{\delta}$, initialised as $\boldsymbol{\delta}_0 = \mathbf{0}$. Each iterative step moves the perturbation in the direction that maximises the loss function, $\mathcal{L}$, used in the training of the model,

$$\boldsymbol{\delta}_{i+1} = \texttt{clip}_{\epsilon}(\boldsymbol{\delta}_i + \alpha \nabla_{\boldsymbol{\delta}_i} \mathcal{L}(\mathbf{x}+\boldsymbol{\delta}_i; \hat{\theta})), \tag{3}$$

where α is an arbitrary step-size parameter and the *clipping* function, $\texttt{clip}_{\epsilon}$, ensures the imperceptibility constraint of Equation 2 is satisfied.

When considering the NLP domain, a sequential, discrete input of L words, can be explicitly represented as,

$$\mathbf{x} = w_{1:L} = w_1, w_2, \ldots, w_{L-1}, w_L, \tag{4}$$

where, the discrete word tokens, $w_{1:L}$, are often mapped to a continuous, sequential word embedding (Devlin et al., 2019) space,

$$\mathbf{h}_{1:L} = \mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_{L-1}, \mathbf{h}_L. \tag{5}$$

Attacks must take place in the discrete text space,

$$\mathbf{x}+\boldsymbol{\delta} = w'_{1:L'} = w'_1, w'_2, \ldots, w'_{L'-1}, w_{L'}. \tag{6}$$

This requires a change in the interpretation of the perturbation $\boldsymbol{\delta}$. It is not simple to define an appropriate function $\mathcal{G}()$ in Equation 2 for word sequences. Perturbations can be measured at a character or word level. Alternatively, the perturbation could be measured in the vectorized embedding space (Equation 5), using for example l_p-norm based (Goodfellow et al., 2015) metrics or cosine similarity (Carrara et al., 2019a), which have been used in the image domain. However, constraints in the embedding space do not necessarily achieve imperceptibility in the original word sequence space. The simplest approach is to use a variant of an *edit-based* measurement (Li et al., 2018), $\mathcal{L}_{\mathsf{e}}()$, which counts the number of changes between the original sequence, $w_{1:L}$ and the adversarial sequence $w'_{1:L'}$, where a change is a swap/addition/deletion, and ensures it is smaller than a maximum number of changes, N,

$$\mathcal{L}_{\mathsf{e}}(w_{1:L}, w'_{1:L'}) \leq N. \tag{7}$$

For the NLP adversarial attacks this work only examines word-level attacks, as these are considered more difficult to detect than character-level attacks. As an example, for an input sequence of L words, a N-word substitution adversarial attack, $w'_{1:N}$, applied at word positions $n_1, n_2, \ldots, n_N$ gives the adversarial output, $w'_{1:L'}$

$$\begin{aligned} w'_{1:L'} = w_1, \ldots, w_{n_1-1}, w'_1, w_{n_1+1}, \ldots, \\ w_{n_N-1}, w'_N, w_{n_N+1}, \ldots, w_L. \end{aligned} \tag{8}$$

The challenge is to select which words to replace, and what to replace them with. A simple yet effective substitution attack approach that ensures a small change in the semantic content of a sentence is to use saliency to rank the word positions, and to use word synonyms for the substitutions (Ren et al., 2019). This attack is termed Probability Weight Word Saliency (PWWS). The highest ranking word word can be swapped for a synonym from a preselected list of given synonyms. The next most highly ranked word is substituted in the same manner and the process is repeated till the required N words have been substituted.

The above approach is limited to attacking specific word sequences and so cannot easily be generalised to universal attacks (Moosavi-Dezfooli et al., 2016), where the same perturbation is used for all inputs. For this situation, a simple solution is concatenation (Wang and Bansal, 2018; Blohm et al., 2018), where for example, the same N-length sequence of words is appended to each input sequence of words, as described in Raina et al. (2020). Here,

$$w'_{1:L'} = w_1, \ldots, w_L, w'_1, \ldots, w'_N. \tag{9}$$

In both the substitution attack (Equation 8) and the concatenation attack (Equation 9), the size of the attack can be measured using the number of edits, $\mathcal{L}_{\mathtt{e}}(w_{1:L}, w'_{1:L'}) = N$.

4 Adversarial Attack Detection

For a deployed system, the easiest approach to defend against adversarial attacks is to use a detection process to identify adversarial examples without having to modify the existing system.

For the image domain Section 2 discusses many of the standard detection approaches. In this work, we select two distinct approaches that have been generally successful: uncertainty (Smith and Gal, 2018), where adversarial samples are thought to result in greater epistemic uncertainty and Mahalanobis Distance (Lee et al., 2018), where the Mahalanobis distance in the logit space is indicative of how out of distribution a sample is (adversarial samples are considered more out of distribution). In the NLP domain, when excluding trivial grammar and spelling based detectors, perplexity based detectors can be used (Raina et al., 2020). Many other NLP specific detectors (Zhou et al., 2019; Han et al., 2020; Minervini and Riedel, 2018) have been proposed, but Mozes et al. (2020)'s FGWS detector is considered the state of art and is thus selected for comparison. Here low frequency words in an input are substituted for higher frequency words and the change in model prediction is measured - adversarial samples are found to generally have a greater change. This work introduces a further NLP specific detector: *residue detection*, described in detail in Section 4.1.

When considering any chosen detection measure $\mathcal{F}_{\mathtt{d}}$, a threshold β can be selected to decide whether an input, $w_{1:L}$, is adversarial or not, where $\mathcal{F}_{\mathtt{d}}(w_{1:L}) > \beta$, implies that $w_{1:L}$ is an adversarial sample. To assess the success of the adversarial attack detection processes, precision-recall curves are used. For the binary classification task of identifying an input as adversarially attacked or not, at a given threshold β, the precision and recall values can be computed as $\text{prec} = \text{TP}/\text{TP} + \text{FP}$ and $\text{rec} = \text{TP}/\text{TP} + \text{FN}$, where TP, FP and FN are the standard true-positive, false-positive and false-negative definitions. A single point summary of precision-recall curves is given with the F_1 score.

4.1 Residue Detection

In this work we introduce a new NLP detection approach, *residue detection*, that aims to exploit the nature of the NLP input space, discrete and sequential. Here we make two hypotheses:

1. Adversarial samples in an encoder embedding space result in larger components (*residue*) in central PCA eigenvector components than original examples.

2. The residue is only significant (detectable) for systems operating on discrete data (e.g. NLP systems).

The rationale behind these hypotheses is discussed next.

Deep learning models typically consist of many layers of non-linear activation functions. For example, in the NLP domain systems are usually based on layers of the Transformer architecture (Vaswani et al., 2017). The complete end-to-end model $\mathcal{F}_{\hat{\theta}}()$ can be treated as a two stage process, with an initial set of layers forming the *encoding* stage, $\mathcal{F}_{\mathtt{en}}()$ and the remaining layers forming the *output* stage, $\mathcal{F}_{\mathtt{cl}}()$, i.e. $F_{\hat{\theta}}(\mathbf{x}) = \mathcal{F}_{\mathtt{cl}}\left(\mathcal{F}_{\mathtt{en}}(\mathbf{x})\right)$.

If the encoding stage of the end-to-end classifier is sufficiently powerful, then the embedding space $\mathcal{F}_{\mathtt{en}}(\mathbf{x})$ will have compressed the useful information into very few dimensions, allowing the output stage to easily separate the data points into classes (for classification) or map the data points to a continuous value (for regression). A simple Principal

Component Analysis (PCA) decomposition of this embedding space can be used to visualize the level of compression of the useful information. The PCA directions can be found using the eigenvectors of the covariance matrix, $\mathbf{C}$, of the data in the encoder embedding space. If $\{\mathbf{q}_i\}_{i=1}^{d}$, where d is the dimension of the encoder embedding space, represent the eigenvectors of $\mathbf{C}$ ordered in descending order by the associated eigenvalue in magnitude, then it is expected that almost all *useful* information is contained within the first few principal directions, $\{\mathbf{q}_i\}_{i=1}^{p}$, where $p \ll d$. Hence, the output stage, $\mathcal{F}_{\mathtt{cl}}()$ will implicitly use only these *useful* components. The impact of a successful adversarial perturbation, $\mathcal{F}_{\mathtt{en}}(\mathbf{x}+\boldsymbol{\delta})$, is the significant change in the components in the principal eigenvector directions $\{\mathbf{q}_i\}_{i=1}^{p}$, to allow fooling of the output stage. Due to the complex nature of the encoding stage and the out of distribution nature of the adversarial perturbations, there are likely to be residual components in the non-principal $\{\mathbf{q}_i\}_{i=p+1}^{d}$ eigenvector directions. These perturbations in the non-principal directions are likely to be more significant for the *central* eigenvectors, as the encoding stage is likely to almost entirely compress out components in the least principal eigenvector directions, $\{\mathbf{q}_i\}_{i=d'+1}^{d}$, where $d' \approx d$. Hence, $\{\mathbf{q}_i\}_{i=p+1}^{d'}$ can be viewed as a subspace containing adversarial attack residue that can be used to identify adversarial examples.

The existence of adversarial attack residue in the central PCA eigenvector directions, $\{\mathbf{q}_i\}_{i=p+1}^{d'}$, suggests that in the encoder embedding space, $\mathcal{F}_{\mathtt{en}}(\mathbf{x})$, adversarial and original examples are linearly separable. This motivates the use of a simple linear classifier as an adversarial attack detector,

$$P(\text{adv}|\mathbf{x}) = \sigma(\mathbf{W}\mathcal{F}_{\mathtt{en}}(\mathbf{x}) + b), \qquad (10)$$

where $\mathbf{W}$ and b are the parameters of the linear classifier to be learnt and σ is the sigmoid function.

The above argument cannot predict how significant the residue in the central eigenvector space is likely to be. For the discrete space NLP attacks, the input perturbations are semantically small, whilst for continuous space image attacks the perturbations are explicitly small using a standard l_p-norm. Hence, it is hypothesised that NLP perturbations cause larger errors to propagate through the system, resulting in more significant residue in the encoder embedding space than that for image attacks. Thus, the residue technique is only likely to be a feasible detection approach for discrete text attacks.

The hypotheses made in this section are analysed and empirically verified in Section 5.3.

5 Experiments

5.1 Experimental Setup

Table 1 describes four NLP classification datasets: IMDB (Maas et al., 2011); Twitter (Saravia et al., 2018); AG News (Zhang et al., 2015) and DBpedia (Zhang et al., 2015). Further, a regression dataset, Linguaskill-Business (L-Bus) (Chambers and Ingham, 2011) is included. The L-Bus data is from a multi-level prompt-response free speaking test i.e. candidates from a range of proficiency levels provide open responses to prompted questions. Based on this audio input a system must predict a score of 0-6 corresponding to the 6 CEFR (Council of Europe, 2001) grades. This audio data was transcribed using an Automatic Speech Recognition system with an average word error rate of 19.5%.

Dataset	#Train	#Test	#Classes
IMDB	25,000	25,000	2
Twitter	16,000	2000	6

Table 1: NLP Datasets.

All NLP task models were based on the Transformer encoder architecture (Vaswani et al., 2017). Table 2 indicates the specific architecture used for each task and also summarises the classification and regression performance for the different tasks. For classification tasks, the performance is measured by top 1 accuracy, whilst for the regression task (L-Bus), the performance is measured using Pearson Correlation Coefficient (PCC).

Dataset	Transformer	Performance
IMDB	BERT	Acc: 93.8%
Twitter	ELECTRA	Acc: 93.3%
AG News	BERT	Acc: 94.5%
DBpedia	ELECTRA	Acc: 99.2%
L-Bus	BERT	PCC: 0.749

Table 2: Performance of models (BERT (Devlin et al., 2018), ELECTRA (Clark et al., 2020)).

Table 3 shows the impact of realistic adversarial attacks on the tasks: substitution (sub) attack (Equation 8), which replaces the N most salient tokens with a synonym defined by WordNet[2], as

---

[2] `https://wordnet.princeton.edu/`

dictated by the PWWS attack algorithm described in Section 3; or a targeted universal concatenation (con) attack (Equation 9), used for the regression task on the L-Bus dataset, seeking to maximise the average score output from the system by appending the same N words to the end of each input. For classification tasks, the impact of the adversarial attack is measured using the fooling rate, the fraction of originally correctly classified points, misclassified after the attack, whilst for the regression task, the impact is measured as the average increase in the output score.

Dataset	Attack	N	Impact

Twitter	sub	6	Fool: 0.77
AG News	sub	40	Fool: 0.65
DBpedia	sub	25	Fool: 0.52
L-Bus	con	3	Score: $+0.51$

Table 3: Impact of different N-word adversarial attacks.

5.2 Results

Section 4.1 predicts that adversarial attacks in the discrete text space leave residue in a system's encoder embedding space that can be detected using a simple linear classifier. Hence, using the 12-layer Transformer encoder's output `CLS` token embedding as the encoder embedding space for each dataset's trained system (Table 2), a simple linear classifier, as given in Equation 10, was trained [3] to detect adversarial examples from the adversarial attacks given for each dataset in Table 3. The training of the detection linear classifier was performed on the training data (Table 1) augmented with an equivalent adversarial example for each original input sample in the dataset. Using the test data samples augmented with adversarial examples (as defined by Table 3), Table 4 compares the efficacy of the linear residue detector to other popular detection strategies [4] (from Section 4) using the best F_1 score. It is evident from the high F-scores, that for most NLP tasks the linear detection approach is better than other state of the art NLP specific and ported image detection approaches.

Dataset	Res	Perp	FGWS	MD	Unc
IMDB	**0.91**	0.68	0.87	0.67	0.75
Twitter	**0.84**	0.67	0.76	0.67	0.78
AG News	**0.95**	0.69	0.89	0.68	0.75
DBpedia	0.80	0.67	0.82	0.68	**0.90**
L-Bus	**0.99**	0.68	0.91	n/a	0.81

Table 4: F_1-score performance of detection approaches.

However, an adversary may have knowledge of the detection approach and may attempt to design an attack that directly avoids detection. Hence, for each dataset, the attack approaches were repeated with the added constraint that any attack words that resulted in detection were rejected. The impact of attacks that suppress detection have been presented in Table 5. Generally, it is shown across all NLP tasks that an adversary that attempts to avoid detection of its residue by a previously trained linear classifier, can only generate a significantly less powerful adversarial attack.

Dataset	Without	With
IMDB	0.70	0.19
Twitter	0.77	0.23

DBpedia	0.52	0.14
L-Bus	$+0.51$	$+0.23$

Table 5: Fooling rate (classification) or score (regression) *with* and *without* attack modified to avoid detection.

5.3 Analysis

The aim of this section is verify that the success of the residue detector can be explained by the two main hypotheses made in Section 4.1. The claim that residue is left by adversarial samples in the central PCA eigenvector components is explored first. For each NLP task a PCA projection matrix is learnt in the encoder embedding space using the original training data samples (Table 1). Using the test data, the residue in the embedding space can be visualized through a plot of the average (across the data) component, $\rho_i = \frac{1}{J}\sum_{j=1}^{J} \rho_{i,j}$ in each eigenvector direction, $\mathbf{q}_i$ of the original and attacked data, where

$$\rho_{i,j} = \left|\mathcal{F}_{\texttt{en}}(\mathbf{x}_j)^{\mathrm{T}}\mathbf{q}_i\right|, \qquad (11)$$

with $\mathbf{x}_j$ being the jth data point. Figure 1 shows an example plot for the Twitter dataset, where ρ_i is plotted against the eigenvalue rank, i for the original and attacked data examples. Residue plots for

---

[3] lr=0.02, epochs=20, batch size=200, #769 parameters

[4] Detection Strategies: Mahalanobis Distance (MD) used the same train-test split as the residue approach; Perplexity (Perp) was calculated using the language model from Chen et al. (2016); Uncertainty (Unc) used the best measure out of mutual information, confidence, KL-divergence, expected entropy and entropy of expected and reverse mutual information; and FGWS was implemented using the code given at `https://github.com/maximilianmozes/fgws`.

other datasets are included in Appendix A. Next, it is necessary to verify that the residue detector specifically uses the residue in the central eigenvector components to distinguish between original and adversarial samples. To establish this, each encoder embedding, $\mathcal{F}_{\texttt{en}}(x)$'s components not within a target subspace of PCA eigenvector directions $\{\mathbf{q}_i\}_{i=p}^{p+w}$, are removed, i.e. we have a projected embedding, $\mathbf{x}^{(\mathrm{p})} = F_{\texttt{en}}(x) - \sum_{i \notin [p,p+w)} \mathbf{q}_i^T F_{\texttt{en}}(x)\mathbf{q}_i$, where w is a window size to choose. Now, using $\mathcal{F}_{\texttt{cl}}(\mathbf{x}^{(\mathrm{p})})$ and a residue detector trained using the modified embeddings, $\mathbf{x}^{(\mathrm{p})}$, the classifier's ($\mathcal{F}_{\texttt{cl}}(\mathbf{x}^{(\mathrm{p})})$) accuracy and detector performance (measured using F1 score) can be found. Figure 2 shows the performance of the classifier ($\mathcal{F}_{\texttt{cl}}(\mathbf{x}^{(\mathrm{p})})$) and the detector for different start components p, with the window size, $w = 5$. It is clear that the principal components hold the most important information for classifier accuracy, but, as hypothesised in Section 4.1, it is the more central eigenvector components that hold the most information useful for the residue detector, i.e. the subspace defined by $\{\mathbf{q}_i\}_{i=5}^{10}$ holds the most detectable residue from adversarial examples.

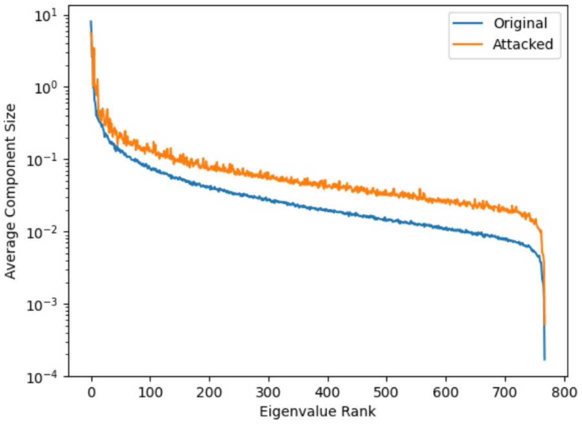

Figure 1: Encoder Embedding Space Residue Plot.

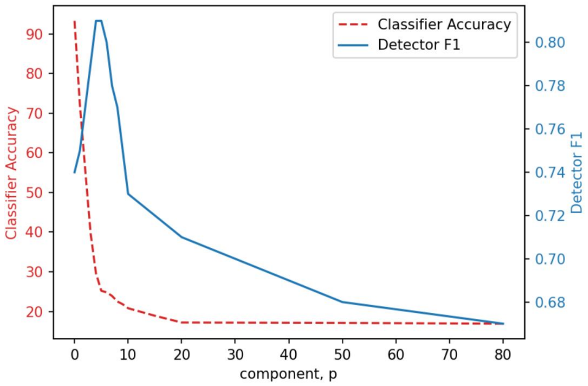

Figure 2: Performance of classifier and detector with windowed projection of encoder embedding space.

The second hypothesis in Section 4.1 claims that the existence of residue in the central eigenvector components is due to the discrete nature of NLP adversarial attacks. Hence, to analyze the impact of the discrete aspect of the attack, an artificial continuous space attack was constructed for the Twitter NLP system, where the continuous input embedding layer space (Equation 5) of the system is the space in which the attack is performed. Using the Twitter emotion classifier, a PGD (Equation 3) attack was performed on the input embeddings for each token, where the perturbation size was limited to be $\epsilon = 0.1$ in the l_∞ norm, achieving a fooling rate of 0.73. Note that this form of attack is artificial, as a real adversary can only modify the discrete word sequence (Equation 4). To compare the influence of discrete and continuous attacks on the same system, the average (across dataset) l_2 and l_∞ norms of the perturbations in the input layer embedding space were found. Further, a single value summary, N_σ, of the residue plot (e.g. Figure 1), was calculated for each attack. N_σ is the average difference in standard deviations between the *original* component mean, $\rho_i^{(\mathrm{orig})}$ and *attack* mean, $\rho_i^{(\mathrm{attack})}$,

$$N_\sigma = \frac{1}{I}\sum_{i=1}^{I} \frac{\left|\rho_i^{(\mathrm{attack})} - \rho_i^{(\mathrm{orig})}\right|}{\sqrt{\mathrm{Var}_j[\rho_{i,j}^{(\mathrm{orig})}]}}. \qquad (12)$$

Table 6 reports these metrics for the discrete and artificial continuous NLP adversarial attacks on the Twitter system [5]. It is apparent that perturbation sizes for the discrete attacks are significantly larger. Moreover, N_σ is significantly smaller for the continuous space attack, indicating that the residue left by continuous space adversarial attacks is smaller.

Attack	N_σ	l_2 error	l_∞ error
Discrete	1.201	$50.2_{\pm 19.2}$	$3.26_{\pm 0.86}$
Continuous	0.676	$5.35_{\pm 3.95}$	$0.08_{\pm 0.03}$

Table 6: Comparison of token level *discrete* attack and input embedding layer *continuous* PGD attack.

To explicitly observe the impact of the nature of data on detectors, adversarial attacks are considered in four domains: the discrete, sequential

---

[5] Similar trends were found across all datasets (Table A.2)

NLP input space (NLP-disc); the artificial continuous, sequential embedding space of an NLP model (NLP-cont); the continuous, static image input space (Img-cont) and a forced discretised, static image input space (Img-disc). For the NLP-disc and NLP-cont the same attacks as in Table 6 are used. For the continuous image domain (Img-cont), a VGG-16 architecture image classifier trained on CIFAR-100 (Krizhevsky et al., 2009) image data (achieving a top-5 accuracy of 90.1%) and attacked using a standard l_∞ PGD approach (Equation 3) is used. For the discrete image domain (Img-disc), the CIFAR-100 images, $\mathbf{X} \in \mathbb{Z}_{256}^{R \times R}$ were discretised using function $\mathcal{Q}_q : \mathbb{Z}_{256}^{R \times R} \rightarrow \mathbb{Z}_q^{R \times R}$, where $\mathbb{Z}_q = \{0, 1\frac{256}{q-1}, 2\frac{255}{q-1}, \dots, 255\}$. In this work 2-bit quantization was used, i.e. $q = 4$. With this quantization, a VGG-16 architecture was trained to achieve 78.2% top-5 accuracy. To perform a discrete space attack, a variant of the PWWS synonym substitution attack (Section 3) was implemented, where synonyms were interpreted as closest permitted quantisation values and N pixel values were substituted. For these different domains, Table 7 compares applicable detection approaches (certain NLP detection approaches are not valid outside the word sequence space) using the best F_1 score, where different attack perturbation sizes are considered (N substitutions for discrete attacks and for continuous attacks $|\boldsymbol{\delta}| \leq \epsilon$ for perturbation $\boldsymbol{\delta}$).

Domain	Attack	Res	Unc	MD
NLP-disc	N=3	**0.80**	0.74	0.67
	N=6	**0.84**	0.78	0.67
NLP-cont	ϵ=0.1	0.67	**0.71**	0.68
	ϵ=0.3	0.67	0.80	**0.85**
Img-disc	N=200	**0.78**	0.67	0.70
	N=400	**0.84**	0.68	0.72
Img-cont	ϵ=12	0.68	0.70	**0.72**
	ϵ=48	0.83	0.81	**0.87**

Table 7: Portability of detection approaches.

In the discrete domains, the residue detection approach is better than all the other approaches. However, in the continuous data type domains, the Mahalanobis Distance dominates as the detection approach, with the residue detection approach performing the worst. As predicted by the second hypothesis of Section 4.1, the lack of success of the residue detection approach is expected here - the residue detection approach is only successful for discrete space attacks.

To verify that the residue detection approach is agnostic to the type of attack, the residue detector trained on *substitution* attack examples was evaluated on *concatenation* attack examples. Using the Twitter dataset, a $N = 3$ concatenation attack was applied, achieving a fooling rate of 0.59. In this setting, the residue detector (trained on the $N = 6$ substitution adversarial examples) achieved a F_1 score of 0.81, which is comparable to the original score of 0.84 (from Table 4). This shows that even with different attack approaches similar forms of residue are produced, meaning a residue detector can be used even without knowledge of the type of adversarial attack.

6 Conclusions

In recent years, deep learning systems have been deployed for a large number of tasks, ranging from the image to the natural language domain. However, small, imperceptible adversarial perturbations at the input, have been found to easily fool these systems, compromising their validity in high-stakes applications. Defence strategies for deep learning systems have been extensively researched, but this research has been predominantly carried out for systems operating in the image domain. As a result, the adversarial detection strategies developed, are inherently tuned to attacks on the continuous space of images. This work shows that these detection strategies do not necessarily transfer well to attacks on natural language processing systems. Hence, an adversarial attack detection approach is proposed that specifically exploits the discrete nature of perturbations for attacks on discrete sequential inputs.

The proposed approach, termed residue detection, demonstrates that imperceptible attack perturbations on natural language inputs tend to result in large perturbations in word embedding spaces, which result in distinctive residual components. These residual components can be identified using a simple linear classifier. This residue detection approach was found to out-perform both detection approaches ported from the image domain and other state of the art NLP specific detectors.

The key finding in this work is that the nature of the data (e.g. discrete or continuous) strongly influences the success of detection systems and hence it is important to consider the domain when designing defence strategies.

7 Limitations, Risks and Ethics

A limitation of the residue approach proposed in this work is that it requires training on adversarial examples, which is not necessary for other NLP detectors. This means there is a greater computational cost associated with this detector. Moreover, associated with this limitation is a small risk, where in process of generating creative adversarial examples to build a robust residue detector, the attack generation scheme may be so strong that it can more easily evade detection from other existing detectors already deployed in industry. There are no further ethical concerns related to this detector.

Appendix A

Training Details

For each NLP dataset, pre-trained base (12-layer, 768-hidden dimension, 110M parameters) Transformer encoders [6] were fine-tuned during training. Table A.1 gives the training hyperparameters: learning rate (lr), batch size (bs) and the number of training epochs. In all training regimes an Adam optimizer was used. With respect to hardware, NVIDIA Volta GPU cores were used for training all models.

Dataset	Model	lr	bs	epochs
IMDB	BERT	1e-5	8	2
Twitter	ELECTRA	1e-5	8	2
AG News	BERT	1e-5	8	2
DBpedia	ELECTRA	1e-5	8	2
L-Bus	BERT	1e-6	16	5

Table A.1: Training Hyperparameters

Experiments

Figure A.1 presents the impact of adversarial attacks of different perturbation sizes, N on each NLP dataset. All classification datasets' models underwent saliency ranked, N-word substitution attacks described in Equation 8, whilst the regression dataset, L-Bus, was subject to a N-word concatenation attack as in Equation 9. For the classification tasks the impact of the adversarial attacks was measured using fooling rate, whilst for the L-Bus dataset task, the average output score from the system is given. Figure A.2 gives the encoder embedding space PCA residue plots for all the datasets not included in the main text.

Table A.2 compares the impact on error sizes (using l_2 and l_∞ norms) and the residue plot metric, N_σ for the original text space discrete attacks and an artificial input embedding space continuous attack. The purpose of this table is to present the results for the datasets not included in the main text in Table 6.

Does it Really Generalize Well on Unseen Data?
Systematic Evaluation of Relational Triple Extraction Methods

Abstract

The ability to extract entities and their relations from unstructured text is essential for the automated maintenance of large-scale knowledge graphs. To keep a knowledge graph up-to-date, an extractor needs not only the ability to recall the triples it encountered during training, but also the ability to extract the new triples from the context that it has never seen before. In this paper, we show that although existing extraction models are able to easily memorize and recall already seen triples, they cannot generalize effectively for unseen triples. This alarming observation was previously unknown due to the composition of the test sets of the go-to benchmark datasets, which turns out to contain only 2% unseen data, rendering them incapable to measure the generalization performance. To separately measure the generalization performance from the memorization performance, we emphasize unseen data by rearranging datasets, sifting out training instances, or augmenting test sets. In addition to that, we present a simple yet effective augmentation technique to promote generalization of existing extraction models, and experimentally confirm that the proposed method can significantly increase the generalization performance of existing models.

1 Introduction

Relational Triple Extraction (RTE), a more generalized version of Relation Extraction, is the task of extracting all relational triples in the form of *(subject, relation, object)* from a given sentence. The ability to extract such triples is much required in the construction and maintenance of knowledge graphs such as Dbpedia (Auer et al., 2007), Freebase (Bollacker et al., 2008), and Wikidata (Vrandečić and Krötzsch, 2014) from documents containing a large number of new and emerging information.

With language model pretraining (Devlin et al., 2019; Radford et al., 2019), RTE methods achieved a new state-of-the-art (Wei et al., 2020; Wang et al., 2020; Zheng et al., 2021). However, whether the performance of these methods attributes to their capabilities of recalling already seen data or their ability to generalize and extract relations from unseen data is yet to be scrutinized.

To separately evaluate memorization and generalization, we categorize the triples in the test set into three types: *entirely seen* (completely overlaps with triples in their respective training sets), *partially seen* (overlaps partially), and *unseen* (completely new). We analyze common RTE benchmark datasets NYT (Riedel et al., 2010) and WebNLG (Gardent et al., 2017) using these categories, and find that 89.61% and 91.10% of triples in NYT and WebNLG *test sets* are of the *entirely seen* type. This suggests that benchmark results on these datasets are heavily biased towards recalling seen data. Thus, more reliable systematic evaluation methods are in need to test generalization performance.

In this paper, we propose three natural strategies for evaluating generalization performance from a limited number of given *partially seen* and *unseen* triples. For the first two strategies, we directly increase the proportion of *partially seen* and *unseen* triples in test sets by 1) rearranging their respective datasets or 2) sifting out instances in their respective training sets that overlap with the test set, rendering them unobserved. For the last strategy, we 3) augment test sets by replacing entities in each test instance with similar (and probably not pre-observed) words in order to increase diversity as well as the proportion of *partially seen* and *unseen* triples. In addition to evaluating recent RTE methods with the above evaluation strategies, we propose a simple yet effective augmentation technique called *Entity Noising* to help RTE methods to generalize beyond training data.

Our contributions are:

- We show for the first time that the current benchmark datasets for relational triple extraction exhibit significant entity pair overlap between training and test data.
- We confirm that the current state-of-the-art models trained on such datasets cannot generalize well to unseen triples.
- We propose three evaluation strategies to evaluate RTE methods systematically, and show that the proposed simple augmentation technique called *Entity Noising* can assist RTE methods in generalizing to unseen data.

2 Fine-grained Re-evaluation of the Current State-of-the-arts

In this section, we mainly scrutinize the generalization capabilities of current Relational Triple Extraction (RTE) methods and show for the first time that they indeed struggle in extracting relational triples from the context for unseen cases.

2.1 Datasets and Evaluation Metrics

We use two well-known benchmark datasets NYT (Riedel et al., 2010) and WebNLG (Gardent et al., 2017) for evaluation, following Wang et al. (2020) and Zheng et al. (2021). Also, predicted triples are considered correct only if their whole entity spans of both subject and object and their relation are exactly matched with ground truth. We report the standard micro F1 for the overall performance.

To assess the memorization and generalization performances separately, we also compute type F1 with three triple types: *entirely seen*, *partially seen*, and *unseen* (Section 2.2). Type F1 is nothing but F1 evaluated using instances which only consist of a single triple type.

2.2 Triple Types

We describe three triple types - *entirely seen*, *partially seen*, and *unseen* - in detail. For a set of triples in the training set $S = \{(s_i, r_i, o_i)\}_{i=1}^{n}$, the type of each triple (s, r, o) in the test set are defined as follows. A triple (s, r, o) belongs to the *entirely seen* type if $(s, r, o) \in S$. For *partially seen* type, triples (s, r, o) which satisfy conditions $[(s, r, \cdot) \in S$ or $(\cdot, r, o) \in S]$ and $(s, r, o) \notin S$ belong to it. Other triples belong to *unseen* type.

2.3 Detailed Evaluation with Triple Types

Using type F1, we show that the current state-of-the-arts CasRel (Wei et al., 2020), TPLinker (Wang et al., 2020), and PRGC (Zheng et al., 2021) are only able to memorize and recall already seen triples, and are unable to generalize effectively for unseen triples (See Table 2). This observation was previously unknown due to the overlaps between training and test data of benchmark datasets NYT and WebNLG.

Indeed, as shown in Table 1, 89.61% and 91.10% of triples in NYT and WebNLG *test sets* completely overlap with triples in their respective training sets (such triples are defined as *entirely seen* type), while *partially seen* and *unseen* samples that require generalization to predict are but a small portion.

3 Evaluating Generalization Performance

As shown in Table 1, the proportion of *partially seen* and *unseen* triples in the original benchmark test sets are so small that they are not diverse

Table 3: Results of recent RTE methods with and without *Entity Noising* on original and *rearranged* datasets. Every result are our reproduction.

enough, rendering the evaluations of generalization capabilities unreliable. Equipped with this observation, we propose three strategies to increase the proportion of *partially seen* and *unseen* triples and add diversity to them for reliable evaluation of Relational Triple Extraction (RTE) methods.[1]

3.1 Rearranged Dataset

The basic approach to increasing the proportion of *partially seen* and *unseen* triples is to rearrange the given dataset splits. However, it is not possible to emphasize unseen data just by randomly rearranging the dataset, since it inadvertently incurs overlaps between training and test data[2].

To emphasize the unseen data, we repeatedly select a triple and distribute every instance which contains that triple to the test set, rendering them unobserved in the training set. In order to minimize redundancy in the test set, we select a triple one by one which occurs less. The detailed statistics are shown in Table 1 and Appendix B.

3.2 Overlap Sifted Dataset

We propose another simple strategy to emphasize unseen test samples. To render a triple in the test set unobserved, we remove the instances containing that triple from the training set. Specifically, we randomly choose $k\%$ of the unique triples from the test set, then remove all the instances containing the selected triples from the *training set* to construct an *overlap sifted dataset*. For demonstration, we construct three such datasets by choosing $k = 5, 10, 15\%$, respectively. The detailed statistics are presented in Table 1 and Appendix B.

3.3 Augmented Test Set

To add more diversity to *partially seen* and *unseen* samples as well as increasing their proportion, we create an *augmented test set*. The key idea is to substitute every entity defined in every triple with probable alternative words by utilizing the knowledge of Masked Language Models (Radford et al., 2019; Devlin et al., 2019) and GloVe word embeddings (Pennington et al., 2014), similar to the data augmentation technique used in Jiao et al. (2020). With the *augmented test set*, it is able to assess whether the ability of an RTE method is influenced by the authenticity of the given text[3]. The details are in Appendix C and statistics are present in Table 1 and Appendix B.

4 Entity noising

We further propose *Entity Noising*, a simple augmentation technique to enhance the generalization performance of existing Relational Triple Extraction methods. The key idea of *Entity Noising* is to replace the entities in the given training input sentence with completely random noisy words. To apply Entity Noising, we sample a random noisy word w' for each entity w, i.e., $w' \sim P(w' \mid w)$. The sampling strategy is defined as follows. First,

---

[1] Three versions of datasets can be found in `https://github.com/sehkmg/rte-eval`.

[2] We are only able to emphasize unseen data to at most 2% with 10^6 random trials.

[3] An ideal RTE model should be able to extract the relational triple (The [United States] President [Christopher]) if such fictitious content happens to exist in the given text.

Table 4: Results of recent RTE methods applied with *Entity Noising* on original and *overlap sifted* datasets. Numbers in ( ) show performance gaps between baseline and *Entity Noising*.

we sample token length $l' \in \{l-1, l, l+1\}$ of w' with probability $P(l' = l) = p_{en}^{len}$ and $P(l' = l-1) = P(l' = l+1) = \left(1 - p_{en}^{len}\right)/2$, where l is a token length of w. This sampling process introduces a small(± 1) perturbation to the token length l to prevent the model from memorizing the number of tokens. After sampling l', we sample w' from the uniform distribution $w' \sim \text{Uniform}(V_{l'})$, where $V_{l'}$ is a subset of the vocabulary V which consists of all words of token length l'.

With sampling strategy $w' \sim P(w' \mid w)$, Entity Noising is applied to a given training sentence $\mathbf{x}_{\text{original}} = (w_1, w_2, \cdots, w_K)$ to produce a noised sentence $\mathbf{x}_{\text{noised}} = (w'_1, w'_2, \cdots, w'_K)$ according to the following rule:

$$w'_k = \begin{cases} w'_k \sim P(w'_k \mid w_k), & \text{if } w_k \text{ is an entity} \\ w_k, & \text{otherwise} \end{cases}$$

Finally, we determine which input $\mathbf{x}$ is fed to the extractor model with probability $P(\mathbf{x} = \mathbf{x}_{\text{noised}}) = p_{en}$ and $P(\mathbf{x} = \mathbf{x}_{\text{original}}) = 1 - p_{en}$. An overview illustration of *Entity Noising* is shown in Figure 1.

Entity Noising is different from a commonly used data augmentation method such as Wei and Zou (2019) which replaces entities with words similar to them. *Entity Noising* replaces entities with completely random noisy words. This feature allows the model to utilize entity-agnostic information, so that the model can learn to extract triples from sentences by focusing on the context information rather than the entities themselves. Therefore, with *Entity Noising*, the model is kept away from memorizing the entity pair along with its relation.

5 Experiments

We conduct a series of experiments with recent Relational Triple Extraction (RTE) methods on newly constructed datasets (Section 3).

Rearranged Dataset (Section 3.1) Table 3 shows the lack of generalization capabilities of recent RTE methods in *rearranged datasets* as well as original datasets. On *rearranged datasets*, *Entity Noising* consistently improves the ability of generalization on *unseen* triples, and for *partially seen* triples, it at least does not hurt the generalization capabilities. For original datasets, the evaluation can be biased on some specific *partially seen* and *unseen* samples since their proportion in test sets is small, rendering inconsistent results.

Overlap Sifted Dataset (Section 3.2) With *overlap sifted datasets* and original datasets, we evaluate recent RTE methods with and without *Entity Noising* to get more insight into what extent they generalize on unseen data. Table 4 shows that recent RTE methods struggle in extracting triples from unseen data, while *Entity Noising* promotes their generalization capabilities in most cases.

Augmented Test Set (Section 3.3) To assess whether the ability of an RTE method is influenced by the authenticity of the given text, we evaluate recent RTE methods with and without *Entity Noising* on *augmented test set*. We find that current RTE methods are substantially influenced by the authenticity of the given text, while *Entity Noising* relieves that influence by a huge margin (See Table 5).

6 Related Work

Open Information Extraction (Open IE) Open IE is the task of extracting relations from the given text without predefined relation type (Stanovsky et al., 2018; Zhan and Zhao, 2020; Cui et al., 2018; Kolluru et al., 2020). Although Open IE is a more general task than Relational Triple Extraction, it is necessary to extract information using fixed relation type to get high quality relational triples from specific domains such as science and business.

Data Leakage in NLP The overlapping problem between training and test data makes the evaluation biased towards assessing memorization capabilities of models. Several works point out the overlapping problem and quantify data leakage in basic NLP tasks (Elangovan et al., 2021) and Open-Domain Question Answering (Lewis et al., 2021), but Relational Triple Extraction was not considered yet.

7 Conclusion

In this paper, we disclosed for the first time that recent Relational Triple Extraction (RTE) methods struggle to extract triples from unseen data, which was previously unknown due to the test-train overlap problem in popular benchmark datasets. To properly assess the generalization capabilities of RTE methods, we developed three strategies to construct *rearranged dataset*, *overlap sifted dataset*, and *augmented test set* from original datasets. Furthermore, we proposed a simple yet effective noising method to promote generalization and experimentally confirm that it effectively improves the generalization capabilities of existing RTE methods.

A Training Details

In general, we train CasRel, TPLinker, and PRGC for 300, 500 epochs on NYT, WebNLG datasets. It takes 5 GPU days for training models on NYT and 1 GPU day for training models on WebNLG. We select the best model by only using the F1 score of the given validation set except *overlap sifted dataset*. For *overlap sifted dataset*, the training instances are sifted out according to the test instances, rendering the triple type statistics of valid and test sets are different. Therefore, we select the best model by using the F1 score of *overlap sifted* test sets. For Entity Noising, we set p_{en} to 0.1 and 0.05 for NYT and WebNLG datasets and set p_{en}^{len} to 0.4. Every model is based on pre-trained BERT model *BERT-base-cased* from Huggingface Transformers (Wolf et al., 2020), which contains 110M parameters.

B Dataset Statistics

The statistics of dataset split are shown in Table 6. To compute type F1 defined in Section 2.1, stratification is necessary by extracting test instances which only consist of single triple type among *entirely seen*, *partially seen* and *unseen*. The stratification statistics are shown in Table 7.

C Augmented test sets

Discussions on augmented test set It is worthy to note that the samples in the *augmented test set* may not be "true" statements in the real world but rather invented, as by construction their entities are replaced with other similar words (See examples in Figure 2). However, the true meaning of the entity words is fundamentally irrelevant to the relation between them given the context. Also, it is unknown whether the relation in the sentence is a fact. Thus, the ability of an RTE model to extract relational triples should not be influenced by the authenticity of the given text. Note that an ideal RTE model should be able to extract the relational triple (The [United States] President [Christopher]) if such fictitious content happens to exist in the given text.

Although the ideal RTE model should not be influenced by the authenticity of the given text, there exists potential risk. It is that the deployed RTE model might extract the invalid triple from wrong text. Therefore, the validation process which checks the triple is needed before adding it to the knowledge graph.

Construction details of augmented test set We now describe the construction details of the augmented test set. First, we preemptively run the language tokenizer to flag the wordpieces in the entity words. we substitute all entity words in the triples with masks (one mask *per word*, not *per wordpiece*). For single-word-single-wordpiece entities, we use the language model to fill in their masks independently. For single-word-multi-piece entities, we do not use the language model but search and substitute for the k-nearest words of the original entity word in the GloVe embedding space. For multi-word entities, each word constituting an entity is sequentially substituted using the language model.

Now we describe the detailed construction of $T_{\text{Augmented}}$. To measure the generalization performance properly, it is required that the *augmented test set* $T_{\text{Augmented}}$ consists of *partially seen* triples as well as *unseen* triples since the ideal RTE model is required to effectively extract both *partially seen* and *unseen* triples. Therefore, we first construct four augmented components of the test set T_{ss}, T_{su}, T_{us}, T_{uu} and take a union of them to create the final *augmented test set* $T_{\text{Augmented}} = T_{\text{ss}} \cup T_{\text{su}} \cup T_{\text{us}} \cup T_{\text{uu}}$. Among the four components, T_{ss} consists of triples with seen subject and object; T_{su} consists of triples with seen subject and unseen object; T_{us} is symmetrical with T_{su}; T_{uu} consists of triples with unseen subject and object.

We now describe the construction details of four components: T_{ss}, T_{su}, T_{us} and T_{uu}. First, for each sample in the test set $t^i_{\text{Standard}} \in T_{\text{Standard}}$, we get a set of top-$k$ similar entities E^{ij}_s for each entity e^{ij} in t^i_{Standard} independently, so that there is no correlation between each E^{ij}_s. Then, we uniformly sample e^{ij}_s from E^{ij}_s and replace e^{ij} with e^{ij}_s to get $t^i_{\text{Augmented}} \in T_{\text{Augmented}}$.

Construction of $\mathbf{T_{ss}}$ T_{ss} mainly consists of triples in which both subject and object entities are already seen in the training set. Therefore, every subject and object entity e^{ij}_s is sampled from $E^{ij}_s \cap E_{\text{Train}}$ uniformly, where E_{Train} is a set of entities appeared in the training set. If we encounter to sample from an empty set, we assign $e^{ij}_s = e^{ij}$.

Construction of $\mathbf{T_{su}}, \mathbf{T_{us}}$ T_{su} mainly consists of triples in which subject entities are seen and object entities are unseen in the training set. Therefore, subject and subject/object entities e^{ij}_s are sampled from $E^{ij}_s \cap E_{\text{Train}}$, and object entities e^{ij}_s are

Abstract

Due to the dialogue characteristics of unstructured contexts and multi-parties with first-person perspective, many successful text summarization works have failed when dealing with dialogue summarization. In dialogue summarization task, the input dialogue is usually spoken style with ellipsis and co-references but the output summaries are more formal and complete. Therefore, the dialogue summarization model should be able to complete the ellipsis content and co-reference information and then produce a suitable summary accordingly. However, the current state-of-the-art models pay more attention on the topic or structure of summary, rather than the consistency of dialogue summary with its input dialogue context, which may suffer from the personal and logical inconsistency problem. In this paper, we propose a new model, named ReWriteSum, to tackle this problem. Firstly, an utterance rewriter is conducted to complete the ellipsis content of dialogue content and then obtain the rewriting utterances. Then, the co-reference data augmentation mechanism is utilized to replace the referential person name with its specific name to enhance the personal information. Finally, the rewriting utterances and the co-reference replacement data are used in the standard BART model. Experimental results on both SAMSum and DialSum datasets show that our ReWriteSum significantly outperforms baseline models, in terms of both metric-based and human evaluations. Further analysis on multi-speakers also shows that ReWriteSum can obtain relatively higher improvement with more speakers, validating the correctness and property of ReWriteSum.

1 Introduction

Despite many existing text summarization works on single-speaker written documents, such as news and encyclopedia articles (Rush et al., 2015; Gehrmann et al., 2018), dialogue summarization has gain increasing attention (Zhang et al., 2021). One reason is that it has various promising applications in real world, such as customer services and doctor-patient interaction. More importantly, the dialogue summarization process is more difficult since there are more interactive participants with first-person perspective, and unstructured context to consider (Chen and Yang, 2021), which poses great challenges for researchers in this area.

Example one	
Ann:	Hi, is the **laptop** still available?
Josh:	Yes **it** is.
Ann:	I can pay 200 dollars.
Josh:	The price is 250 and **it's** non-negotiable.
Ann:	Do you have a bag for **it**? Some other accessories?
Josh:	I have a bag and a small usb mouse.
Ann:	Sounds good, **I'll take it**, where can I pick **it** up?
Ground-Truth: Ann wants to buy Josh's laptop for $200. Josh doesn't want to negotiate the price. Ann will take it for $250 with accessories.	
BART Prediction: Ann will pay 200 dollars for the laptop and the price is non-negotiable. Ann will pick a bag from Josh.	
Example two	
Mike:	Dude, **Wendy** has grown prettier.
Dave:	I know right?
Mike:	Yeah, since she came from Houston, she looks like an angel.
Dave:	I'll have to hit on her soon.
Mike:	Haha, stay off, I hear **Jerry** is her lover.
Dave:	Since when?
Mike:	Haha, I don't know, but you can push your luck.
Dave:	Haha, I will.
Ground-Truth: Mike and Dave notice Wendy got prettier. Dave wants to hit on her, but she's with Jerry. he'll try anyway.	
BART Prediction: Wendy has grown prettier since she came from Houston. Mike will have to hit on her soon. Jerry is Wendy's lover.	

Table 1: Two personal and logical inconsistent examples from the state-of-the-art model in dialogue summarization. Green words in ground-truth indicate the dialogue facts. Red words in BART show the inconsistent content, results from ellipsis and co-reference.

For this task, it is clear that there is a big gap between the input spoken dialogue and the output formal summaries. That is, in dialogue, users tend to use many incomplete utterances, which al-

July 10-15, 2022

ways omit or refer back to entities appeared in the history, called ellipsis and co-reference. But the summary is usually formal and written, which contains rich and complete salient information. Here we give two examples, as shown in Table 1. In the first example, the incomplete utterance "I will take it" omits "laptop" which can be seen in the first sentence, while the ground-truth summary contains the complete information "Ann will take it for $250 with accessories". We can see that the generated summary by BART confuses the accessories "bag" with the subject "laptop" and then generate a logic inconsistent summary "pick a bag". And in the second example, many people's names are in the contexts, which are more difficult for the summarization model to distinguish the co-reference relationship, i.e., "I'll have to hit on her" refers to "Dave" via "I". As a result, BART confuses "Mike" with "Dave", and then generates a personal inconsistent summary "Mike will have to hit on her". What's more, such factual inconsistencies have also been observed in previous studies (Cao et al., 2018; Kryściński et al., 2019, 2020). Therefore, it is critical to complete the omission and co-reference information in dialogue utterances for dialogue summarization task.

However, the current models pay more attention on introducing intrinsic information, such as dialogue acts (Goo and Chen, 2018), key point sequence (Liu et al., 2019a) and co-reference information (Liu et al., 2021b). They demonstrate that the introduction of intrinsic information and human annotation is effective in improving the quality of summary generation. However, dialogue acts and key point sequence require a lot of human effort, so they can not be widely used in applications. The co-reference chain is integrated by GNN, which only pays attention to the referencing information of entities but not supplement and restore the referred and omitted pronouns in the dialogue utterances, resulting in the misunderstanding of omitted contents. More importantly, they all ignore the consistency between the dialogue summary and its source dialogue, which may lead to the personal and logical inconsistency problem caused by multi-speakers.

In this paper, we propose a new model, namely ReWriteSum, to tackle this problem. The core idea is to use the utterance rewriting mechanism to complete the omitted content and utilize the data augmentation strategy to enhance the co-reference information. Specifically, we first use the utterance rewriter to complete the ellipsis content in dialogue contexts, and then obtain the rewritten utterances dataset. Then, we use the co-reference data augmentation mechanism to replace the referential person name with its specific name with a certain probability to enhance the personal information. Finally, we use both the rewritten utterances and the co-reference replacement data as input, and utilize the state-of-the-art model BART to generate the corresponding summary.

In our experiments, we use two public datasets to evaluate our proposed models, i.e. SAMSum and DialSum. The results show that ReWriteSum has the ability to produce more consistent and suitable summary than traditional summarization models. Besides, we conduct an analysis on multi-speakers, and the results show that the ReWriteSum obtains relatively higher improvement with more speakers, which indicates that the incomplete utterance rewriting and co-reference data augmentation mechanism by our model are reasonable.

2 Related Work

2.1 Document Summarization

The aim of automatic document summarization is to convert a well-structured document into short text containing salient information. It has received widespread attention in recent literature, especially abstractive document summarization. For example, Rush et al. (2015) introduce an attention-based sequence-to-sequence model for abstractive document summarization. To solve out-of-vocabulary and content repeat issues, See et al. (2017) propose a pointer-generator network with copy and coverage mechanism. Chen and Bansal (2018) leverage reinforcement learning to extract salient sentences in document and then generate summary. Recent studies have focused on the pre-trained models. Liu and Lapata (2019) take use of pre-trained language model BERT (Kenton and Toutanova, 2019) in extractive summarization and abstractive summarization. Lewis et al. (2020) propose BART which combined bi-directional encoder from BERT and auto-regressive decoder from GPT (Radford et al., 2018) to obtain the results of language generation.

2.2 Dialogue Summarization

Compared with document summarization, dialogue summarization aims at generating condensed text from the dialogue contexts among multiple speakers. For instance, Shang et al. (2018) propose an unsupervised multi-sentence compression method to generate meeting summaries. Zhao et al. (2019) employ a hierarchical encoder and a reinforced decoder based on sequence-to-sequence model to generate meeting summaries.

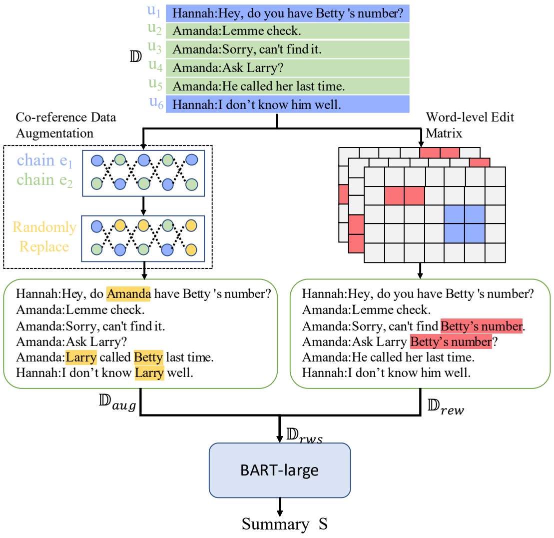
Some studies have focused on employing conversational analysis for dialogue summarization. Goo and Chen (2018) use sentence-gated mechanism to apply dialogue act in the generation process. Liu et al. (2019a) design a key point sequence as auxiliary information to describe the logic of the abstract. Liu et al. (2019c) and Li et al. (2019) introduce topic information for dialogue summarization. However, their methods need a large amount of human annotation. To avoid this issue, Chen and Yang (2020) use diverse conversational structures like topic segments and conversational stages to design a multi-view summarizer. Recent works often introduce intrinsic information to better model the dialogue process. Liu et al. (2021b) use the graph neural network to employ co-reference information to generate summaries. Feng et al. (2020) introduce the dialogue discourse information, and design Meeting Graph to describe them. Lei et al. (2021) introduce speaker information to improve the generation performance in the context with multi-speakers.

2.3 Incomplete Utterance Rewriting

Incomplete utterance rewriting has received extensive research attention. In question answering, Kumar and Joshi (2016) propose non-sentential utterance resolution based on sequence-to-sequence model for utterance rewriting. To resolve incomplete follow-up questions, retrieval-based sequence-to-sequence model (Kumar and Joshi, 2017) and copy-based sequence-to-sequence model (Elgohary et al., 2019; Quan et al., 2019) are proposed, which can generate complete questions. Liu et al. (2019b) take use of question structures to rewrite utterance in conversational semantic parsing. Pan et al. (2019) leverage BERT to select words, and use these words to generate rewritten utterance. Su et al. (2019) distinguish the weights of context utterances for utterance rewriting. Liu et al. (2020) employ edit-based text generation and semantic similarity measurement for utterance rewriting.

3 Model

In this section, we will describe our ReWriteSum model in detail, with architecture shown in Figure 1. ReWriteSum consists of an incomplete utterance rewriter, a co-reference data augmentation and a transformer-based BART summarization model.



Hannah:Hey, do you have Betty 's number?
Amanda:Lemme check.
Amanda:Sorry, can't find it.
Amanda:Ask Larry?
Amanda:He called her last time.
Hannah:I don't know him well.

Hannah:Hey, do Amanda have Betty 's number?
Amanda:Lemme check.
Amanda:Sorry, can't find it.
Amanda:Ask Larry?
Amanda:Larry called Betty last time.
Hannah:I don't know Larry well.

Hannah:Hey, do you have Betty 's number?
Amanda:Lemme check.
Amanda:Sorry, can't find Betty's number.
Amanda:Ask Larry Betty's number?
Amanda:He called her last time.
Hannah:I don't know him well.

Figure 1: The model architecture of ReWriteSum. the left shows the co-reference data augmentation module and the right shows the incomplete utterance rewriting module.

For incomplete utterance rewriting, we establish a word-level edit matrix (Liu et al., 2020), whose element determines three editing operations: substitute, insert and none. To obtain the edit matrix, we conduct three neural networks, as shown in Figure 2: a BiLSTM-based context layer to obtain the word representation, an encoder layer to model the local information, and a segmentation layer to model the global information.

For co-reference data augmentation, we replace the co-reference word with its specific name entity through a co-reference resolution model (Joshi et al., 2020) and then augment the dataset with these replacement data. Specifically, we firstly use the co-reference resolution model to obtain the co-reference chain of the entire dialogue, then replace the pronoun in the co-reference chain with the specific name entity based on a certain probability. Finally, we utilize these replacement data to augment the personal information for dialogue summarization task.

3.1 Problem Formulation

Given the dialogue content set $D = \{u_1, \ldots, u_{|D|}\} \in \mathbb{D}$, each utterance in D is represented as $u_j = \{x_1^{(j)}, \ldots, x_L^{(j)}\}$, where $x_k^{(j)}$ represents the k^{th} word in utterance u_j. The corresponding summary of D is represented as

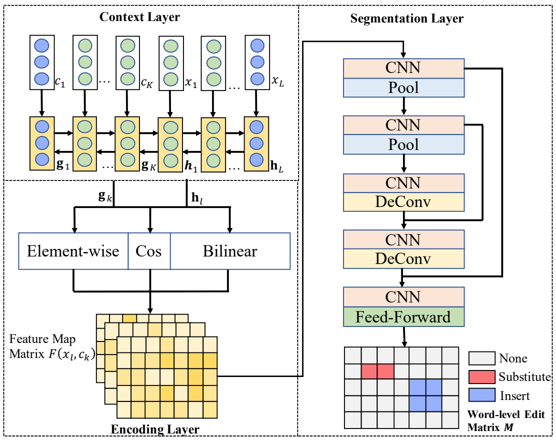


Figure 2: Architecture of incomplete utterance rewriter.

$S = \{y_1, \ldots, y_{L_S}\}$, where y_j represents the j^{th} word in summary S.

We adopt a neural model for abstractive dialogue summarization. In detail, given the dialogue D as input, we firstly utilize the utterance rewriting system and the co-reference resolution system to generate the new complete rewriting dialogue D'. And then, we use the rewriting dialogue D' as input, instead of dialogue D, to generate the dialogue summary.

3.2 Incomplete Utterance Rewriting

Given the whole dialogue $D = \{u_1, \ldots, u_{|D|}\}$, we define the context as $C = \{u_1, \ldots, u_{t-1}\}$ and the incomplete utterance as $u_t (t \leq |D|)$. Incomplete utterance rewriting aims at rewriting u_t to u_t^* through the context C. After rewriting, u_t^* should not only have the same meaning as u_t, but also can be understood separately. Specifically, we concatenate all the contextual utterances C into a K-length word sequence $\mathbf{c} = (c_1, \ldots c_K)$. At the same time, the incomplete utterance is represented as $u_t = \{x_1, \ldots x_L\}$, where L is the length of u_t. And then, the rewritten utterance u_t^* can be obtained by editing the incomplete dialogue u_t using the words in $\mathbf{c}$.

In order to determine the editing operation, we define a word-level edit matrix $\mathbf{M}$ (Liu et al., 2020), where each element m_{kl} represents the editing type between c_k and x_l. There are three editing types: substitute, insert and None. The substitute operation means replacing the word x_l with the context word c_k. The insert operation means inserting a word c_k before or after a certain token x_l. And None means no operation. Following Liu et al. (2020), we establish a word-level edit matrix through three neural layers: a context layer, an encoding layer and a subsequent segmentation layer, as shown in Figure 2, and then generate rewritten utterance based on this word-level edit matrix.

3.2.1 Context Layer

Given the contextual word sequence $\mathbf{c}$ and the incomplete utterance u_t, we firstly concatenate the $\mathbf{c}$ and u_t as input, and employ Glove (Pennington et al., 2014) to initialize the word embedding. And then, we use BiLSTM (Schuster and Paliwal, 1997) with both the left-to-right and right-to-left text representations to obtain the contextual information:

$$BiLSTM(\mathbf{c}; u_t) = (\mathbf{g}_{1,\ldots,K}; \mathbf{h}_{1,\ldots,L}),$$

where $\mathbf{g}_k$ is the hidden state of contextual word c_k in $\mathbf{c}$ and $\mathbf{h}_l$ is the hidden state of the word x_l in u_t.

3.2.2 Encoding Layer

After obtaining the context-aware hidden states $\mathbf{g}$ and $\mathbf{h}$, we use three similarity functions to calculate the word-level relevance between context and incomplete utterance. Specifically, for each word c_k and x_l, a D-dimensional vector $\mathbf{F}(x_l, c_k)$ is set to indicate the relevance:

$$\mathbf{F}(x_l, c_k) = [\mathbf{h}_l \odot \mathbf{g}_k; \cos(\mathbf{h}_l, \mathbf{g}_k); \mathbf{h}_l \mathbf{W}_{Bi} \mathbf{g}_k], \tag{1}$$

where $\odot$ is the element multiplication operation to obtain the element-wise similarity, $\cos(.,.)$ is the cosine similarity, and $\mathbf{W}_{Bi}$ is a learned parameter in learned bi-linear similarity. Finally, we obtain the feature map matrix $\mathbf{F} \in \mathbb{R}^{L \times K \times D}$.

Similarity function is used to describe word-to-word relevance from various aspects, which is a necessary condition for the edit type. However, the encoder layer can only obtain local information, which is not enough for incomplete utterance rewriting. Therefore, we conduct a segmentation layer to introduce the global information.

3.2.3 Segmentation Layer

Given the feature map matrix $\mathbf{F} \in \mathbb{R}^{L \times K \times D}$ in Equation 1, we use the segmentation layer to calculate the word-level edit matrix $\mathbf{M} \in \mathbb{R}^{L \times K}$. The segmentation layer is inspired by UNet (Ronneberger et al., 2015), consisting of five convolutional neural network(CNN) with skip-connection mechanism, which is used to extract the global contextual editing information, as shown in Figure 2:

$$
\begin{aligned}
\mathbf{F}^{'} &= \text{CNN}(\mathbf{F}),\\
\mathbf{F}^{''} &= \text{CNN}(\text{Pool}(\mathbf{F}^{'})),\\
\mathbf{F}^{'''} &= \text{DeConv}(\text{CNN}(\text{Pool}(\mathbf{F}^{''}))),\\
\mathbf{F}^{''''} &= \text{DeConv}(\text{CNN}(\mathbf{F}^{'''}, \mathbf{F}^{''})),\\
\mathbf{M} &= \text{FeedForward}(\text{CNN}(\mathbf{F}^{''''}, \mathbf{F}^{'})),
\end{aligned}
$$

where $\mathbf{CNN}(.)$ is the two layers of convolutional modules, $\mathbf{Pool}(.)$ is the MaxPooling operation, $\mathbf{DeConv}(.)$ is the deconvloution neural network, and $\mathbf{FeedForward}(.)$ is the feedforward layer.

Given the word-level edit matrix $\mathbf{M}$, for each word c_k in contextual utterances and x_l in incomplete utterance, the element M_{kl} determines one of three editing operations: substitute, insert and none. Specifically, when M_{kl} is close to 0, the corresponding operation is none. When close to 1, the operation is substitution, 2 is inserting before and 3 is inserting after. After that, we can rewrite every utterance u_t in D as u_t^* based on M. Finally, we use all the rewritten utterances u^* to replace D as D', and obtain the rewriting dataset $\mathbb{D}_{rew} = \{(D_1', S_1), (D_2', S_2), \ldots, (D_N', S_N)\}$.

3.3 Co-reference Data Augmentation

Taking into account that there are a large number of names and referential relations in the dialogue process, we propose to use the data augmentation mechanism to enhance the personal information for dialogue summarization task.

Given a dialogue content D, we utilize a co-reference resolution system (Joshi et al., 2020) to obtain its corresponding co-referential chain set $E = \{e_1, e_2, \ldots, e_{|E|}\}$, where $e_i = \{x_{i1}, x_{i2}, \ldots, x_{i|e_i|}\}$ is represented as the i^{th} co-referential chain in dialogue D and x_{ij} denotes the j^{th} word in co-referential chain e_i. Take the example two in Table 1 as an example, the $E = \{\{Mike_0, \ldots, I_{64}\}, \{Wendy_4, \ldots, her_{52}\}, \{Dave_9, \ldots, I_{79}\}, \{Jerry_{50}\}\}$, where the $word_{idx}$ is the idx^{th} word in $\mathbf{c}$.

Then, we refer to all the pronouns in the whole dialogue D and replace it with its corresponding person name x_{name_i} based on a certain probability: when the length of pronouns $|e_i^{(pron)}| >= 5$, if the output probability of co-reference system $P(x_{ij}) >= 0.5$, then replace x_{ij} with x_{name_i}, otherwise, no replacement; when $0 < |e_i^{(pron)}| < 5$, if $P(x_{ij}) >= 0.8$, then replace; when $|e_i^{(pron)}| = 0$, remove this example.

Finally, after the person's name replacement, we obtain an additional dialogue dataset $\mathbb{D}_{aug} = \{(D_1'', S_1), \ldots (D_G'', S_G)\}$, where G is the number of dialogue-summary pairs after removing.

3.4 Summary Generation

Given $\mathbb{D}_{rew}$ and $\mathbb{D}_{aug}$, we combine them to obtain our rewriting dataset $\mathbb{D}_{rws}$. To generate the summary, we utilize the state-of-the-art model BART (Lewis et al., 2020) to encode the dialogue content D and decode the summary S step by step.

We use maximum likelihood estimation to train our model. Given a pair of dialogue D and summary $S = \{y_1, \ldots, y_{L_S}\}$ from $\mathbb{D}_{rws}$, we minimize the negative log-likelihood of the target sequence:

$$
\mathcal{L} = \\
-\sum_{\mathbb{D}_{rws}} \sum_{t=1}^{|L_S|} \text{logP}(y_t | y_1 ... y_{t-1}, D; \theta_{BART\_large}).
$$

4 Experiments

In this section, we conduct experiments on two English dialogue summarization datasets SAMSum (Gliwa et al., 2019) and DialSum (Chen et al., 2021) to evaluate our proposed method.

4.1 Experimental Settings

We first introduce some empirical settings, i.e., datasets, baselines, and evaluation measures.

4.1.1 Datasets

We use two public dialogue summarization datasets. SAMSum contains everyday English message-like dialogues and annotated summary. We randomly split the SAMSum data to training, validation, and testing sets, which contains 14,732, 818 and 819 pairs, respectively. DialSum[1] contains English speaking practice dialogue and annotated summary, which has been cleaned and pre-processed by publisher, including deleting non-English characters, correcting spelling errors and grammatical errors. We randomly split the DialSum data to training, validation, and testing sets, which contains 12,460, 500 and 500 pairs, respectively.

4.1.2 Baselines and Parameters Setting

Seven baseline models are used for comparison on SAMSum, and four baseline models on DialSum. Lead3 (See et al., 2017) model extracts

---

[1] https://github.com/cylnlp/DialogSum

the first three leading sentences in the article as the summary. LONGEST (Gliwa et al., 2019) model selects the top N longest sentences as the summary. PTGen (See et al., 2017) model introduces copy and coverage mechanisms into the basic sequence-to-sequence model. FastAbs-RL (Chen and Bansal, 2018) model firstly selects salient sentences and then generates abstractive summaries through reinforcement learning. DynamicConv + GPT-2/News (Wu et al., 2018) model replaces the attention mechanism with a lightweight dynamic in transformer. BART (Lewis et al., 2020) is a pre-trained model, which uses the noise function to destroy text, and then reconstructs the original text, including two versions, BART(base) and BART(large). Multiview BART (Chen and Yang, 2020) extracts different views of dialogue features, and then uses a multi-view decoder to combine these features to generate summaries.

Our model uses a pre-trained model BART(large)[2] for initialization. In detail, BART (large) has 12 layers of encoder-decoder Transformer structure. Each layer has 16 attention heads. The hidden size and feed forward filter size are 1024 and 4096, respectively. It contains a total of 400M trainable parameters. The dropout rates for all layers are set to 0.1. The optimizer uses Adam (Kingma and Ba, 2015) with 200 warmup. The learning rates of SAMSum and DialSum are both 3e-5, and the maximum tokens for a certain batch are 800 and 1000, respectively. We run our models on a Tesla V100 GPU card with Pytorch.

4.1.3 Evaluation Measures

To evaluate our models, we utilize both quantitative metrics and human evaluation in our experiment. In detail, we use ROUGE-1, ROUGE-2 and ROUGE-L as quantitative metrics, which is widely used in NLP and summary tasks (Liu et al., 2021a,b; Chen and Yang, 2020). For human evaluation, we randomly select 100 dialogue-summary pairs from the test set of SAMSum and DialSum, respectively. Five annotators(all CS majored students studying NLP) are demanded to give the comparison between our model and baseline models. They are not told which summaries are derived from the baseline model and which summaries are derived from our model. They are required to evaluate the generated summary from three aspects: whether the generation is fluent, whether it has omitted content, and whether it has factual inconsistent errors. The evaluation results are represented as win, loss and tie, respectively indicating that the quality of generated summary by ReWriteSum is better, weaker or equal to baselines.

SAMSum Dataset

Model	R-1	R-2	R-L
Lead3	31.4	8.7	29.4
PTGen	40.1	15.3	36.6
DynamicConv+GPT-2	41.8	16.4	37.6
FastAbs-RL	42.0	18.1	39.2
DynamicCov+News	45.4	20.7	41.5
Multiview BART	52.2	**27.4**	49.9
BART(large)	50.9	25.0	47.1
ReWriteSum(ours)	**54.2**	27.1	**50.1**

DialSum Dataset

Model	R-1	R-2	R-L
Lead3	27.5	6.8	27.3
LONGEST	24.1	6.2	22.7
BART(base)	33.7	13.8	30.9
BART(large)	34.1	13.7	31.2
ReWriteSum(ours)	**35.1**	**14.6**	**32.1**

Table 2: Metric-based evaluations of ReWriteSum and baselines on SAMSum and DialSum. R-1, R-2, R-L denote ROUGE-1, ROUGE-2, ROUGE-L, respectively.

SAMSum Dataset

Model	ReWriteSum vs.		
	win(%)	loss(%)	tie(%)
Multi-view	48.5	6.9	44.6
BART	52.6	5.1	42.3

DialSum Dataset

Model	ReWriteSum vs.		
	win(%)	loss(%)	tie(%)
Multi-view	42.3	8.1	49.6
BART	46.8	7.3	45.9

Table 3: Human evaluations on SAMSum and DialSum.

4.2 Experimental Results

In this section, we demonstrate our experiment results on SAMSum and DialSum datasets.

4.2.1 Metric-based Evaluation

The quantitative evaluation results on SAMSum and DialSum datasets are shown in Table 2. For SAMSum dataset, we refer to (Gliwa et al., 2019) to show the results of Lead3, PTGen, DynamicConv+GPT-2/News, and FastAbs-RL. From the results, we can see that the pre-trained models, such as BART and Multiview BART, outperform the traditional summarization models, showing the effectiveness of pre-training

---

Dialogue Example 1	**Dialogue Example 2**
Mia: could anybody **help me to buy a flight ticket?** ... Mia: I don't have a credit card at the moment. ... Tom: You can use mine help Mia to buy a flight ticket! Mia: Should I send you the link to buy a flight ticket? Tom: Just send me the flight, company and your personal data that I may need to buy a flight ticket. Mia: Great, so nice of you, thanks Tom.	Maria: Who's gonna be at imf lecture tomorrow? ... Alexander: On Saturday Alexander already meet for another. So my option is Friday afternoon or tomorrow. Sarah: Tomorrow and on Friday Sarah available ... Sarah: So can we meet **tomorrow evening? 17:15?** Alexander: It is fine by me. **Lawrence**: Lawrence will be late, but you can start **without me**.
BART Prediction: Mia doesn't have a credit card at the moment. Tom will use his card to buy a flight ticket for himself. Tom needs the flight, company and personal data.	**BART Prediction:** Alexander, Martha, Sarah, Lawrence and Sarah will meet tomorrow evening at 17:15 to discuss the imf lecture.
ReWriteSum Prediction: Mia doesn't have a credit card at the moment. Tom will use his card to buy a flight ticket for her.	**ReWriteSum Prediction:** Maria, Sarah, Alexander, and Martha will meet tomorrow evening at 17:15 to discuss the imf lecture. Lawrence will be late.

Table 4: Generated summaries from different models on SAMSum. Red words show the inconsistent content. Green words show the factul content. Blue words show the supplemented part by our model. Orange words show the name replacement by our model.

language model for dialogue summarization task. Our ReWriteSum model performs the best. Take the ROUGE-1 and ROUGE-L score for example, our ReWriteSum model obtains 54.2 and 50.1, respectively, which obviously outperforms Multiview BART model, i.e., 52.2 and 49.9.

From the results on DialSum in Table 2, we can see that our model also obtains the best performance. Take the ROUGE-1 and ROUGE-L score for example, our ReWriteSum obtains 35.1 and 32.1, respectively, which obviously outperforms BART(large), i.e., 34.1 and 31.2. However, the performance increment on DialSum is not significant as comparation on SAMSum. The reason is that utterances in DialSum are relatively more complete and the interactive speakers are fewer than SAMSum. According to statistics, there are only 13 sentences with more than 4 speakers in DialSum, which leads to relatively few errors caused by multi-speakers. We have conducted the significant test, and the result shows that the improvements of our model are significant on both datasets, i.e., p-value < 0.01.

In conclusion, our ReWriteSum model has the ability to generate a more complete and accurate summary than baselines.

4.2.2 Human Evaluation

Human evaluation results are shown in Table 3. The percentages of win, loss and tie, as compared with the baselines, are given to evaluate the fluency, completeness and consistency of generated summary by ReWriteSum. From the results, we can see that the proportion of evaluators who think our model better is the largest, surpassing other models. Take SAMSum dataset for example, ReWriteSum model obtains preference gains (win subtract loss) 41.6%, 47.5%, respectively.

4.2.3 Case Study

To further understand our proposed model, we give some generated cases in Table 4. According to the result, we can notice that ReWriteSum model performs better than baseline models. Take example1 in Table 4 as an example, BART model generates that "Tom will buy a flight ticket for himself", but in the dialogue content, the dialogue fact is "Tom will buy a flight ticket for Mia'. The reason is that the dialogue content tends to be omitted in daily dialogues. From example1, we can see that, in the entire dialogue, only Mia mentions "help me to buy a flight ticket" at the beginning, and this sentence is omitted in the subsequent utterances, which makes BART unable to correctly understand who the "ticket" will be bought for. When we rewrite the incomplete dialogue (in blue font), "help Mia to buy a flight ticket" is added to the end of some utterances, so that our model can generate a more accurate and logical consistent summary.

From example2, due to the complex references in this dialogue, BART misunderstood "Lawrence will be late" as "Lawrence will meet tomorrow evening at 17:15". When co-reference data augmentation is carried out, it strengthens the connection between "you" and "Alexander, Martha, Sarah" in the sentence "Lawrence: I will be late, but you can start without me", so as to avoid this personal inconsistency error.

4.3 Analysis

In order to confirm whether the improvement is related to incomplete utterance rewriting(IUR) and co-reference data augmentation(CDA), a further analysis is conducted, containing ablation study, the impact of participants, and the error analysis.

Model	R-1	R-2	R-L
ReWriteSum	54.2	27.1	50.1
- w/o CDA	51.1	25.1	47.5
- w/o IUR	52.3	25.1	48.1

Table 5: Ablation experiment results on SAMSum.

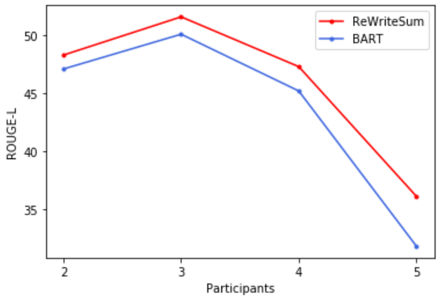

Figure 3: Rouge-L scores of ReWriteSum and BART with different number of speakers.

4.3.1 Ablation Study

To confirm the effectiveness of our IUR and CDA module, we conduct ablation experiments on SAMSum dataset. The results are shown in Table 6. ReWriteSum w/o IUR means that ReWriteSum model removes IUR module and only with CDA to generate summaries. From the results, we can see that when only CDA is applied, the ROUGE score is still larger than the baseline, but smaller than the ReWriteSum model. ReWriteSum w/o CDA means that our ReWriteSum model removes the CDA module and only with IUR to generate summaries. We can see that the ROUGE has decreased as compared with our ReWriteSum model, but it is still higher than baseline models. Therefore, we think that both incomplete utterance rewriting and co-reference data augmentation have positive effects for dialogue summarization.

Not only that, we also notice that the ROUGE score using IUR alone is higher than using CDA alone, indicating that IUR contributes more to the dialogue summarization task.

4.3.2 Impact of Participants

We conduct an experimental analysis with different number of participants, by calculating the ROUGE score for baselines and our ReWriteSum model on SAMSum. From the Figure 3 , we can see that with the increase of participants, the rouge score of our model decreases more slowly, because: (1) with the increase of participants, the omitted information will also increase, but our incomplete utterance rewriting module has the ability to reduce the impact of too much omitted information in the summary; (2) our co-reference data augmentation module can reduce the impact of complex referencing caused by too many participants.

Model	Missing Information	Wrong Reference	Incorrect Reasoning
BART(large)	36	24	19
ReWriteSum	14	6	8
- w/o CDA	17	19	9
- w/o IUR	29	7	11

Table 6: Percentage of typical errors in summaries generated by BART(large) and our ReWriteSum model.

4.3.3 Error Analysis

To further study the impact of IUR and CDA on the quality of generated summaries, we count the following 3 kinds of errors that appear in the summaries generated by the baseline model and our model: **Missing Information**: content information that appears in gold summaries is missing from generated summaries. **Wrong Reference**: content in the generated summaries, such as the person's actions or name, does not match what is described in the source dialogue. **Incorrect reasoning**: the conclusions drawn by the generated summaries are inconsistent with the facts in the source dialogue.

We randomly select 100 dialogues and their generations from SAMSum and count the error categories, as shown in Table 5. In terms of missing information, our model outperforms the baseline model because IUR can effectively prevent the model from missing information. According to the wrong reference numbers, our model performs better than the baselines because CDA can enhance the model's understanding of referential information. Errors occur in incorrect reasoning are also reduced as our model complements default information and enhances understanding of referential information.

5 Conclusion

In this work, we propose a new dialogue summarization model, namely ReWriteSum, which leverages incomplete utterance rewriting and co-reference data augmentation mechanism to generate summaries for dialogue. Our motivation comes from the fact that there are a lot of ellipsis and demonstrative pronouns in the dialogue, which seriously affects the quality of dialogue summary generation. Our core idea is to utilize the incomplete utterance rewriting module to complete the ellipsis information in the dialogue content and enhance the personal entities with the co-reference data augmentation mechanism. We conduct experiments on both SAMSum and DialSum datasets, and the results on both quantitative and qualitative analysis verify the effectiveness of our proposed model. Therefore, we obtain the conclusion that the incomplete utterance rewriting and co-reference data augmentation are effective for improving the quality of generation for dialogue summarization.

6 Ethical Considerations

The abstractive summarization dialogue system proposed in this work can be applied to dialogue scenarios. It can quickly process a lengthy dialogue into a short content containing the core idea of the dialogue. Such features can be applied to meetings, customer service, and medical scenarios to facilitate people's life. The datasets SAMSum and DialSum used in this work are publishable and for research purposes only. There may be some biased content in the datasets, which should be viewed carefully.

Abstract

We present EASE, a novel method for learning sentence embeddings via contrastive learning between sentences and their related entities. The advantage of using entity supervision is twofold: (1) entities have been shown to be a strong indicator of text semantics and thus should provide rich training signals for sentence embeddings; (2) entities are defined independently of languages and thus offer useful cross-lingual alignment supervision. We evaluate EASE against other unsupervised models both in monolingual and multilingual settings. We show that EASE exhibits competitive or better performance in English semantic textual similarity (STS) and short text clustering (STC) tasks and it significantly outperforms baseline methods in multilingual settings on a variety of tasks. Our source code, pre-trained models, and newly constructed multilingual STC dataset are available at `https://github.com/studio-ousia/ease`.

1 Introduction

The current dominant approach to learning sentence embeddings is fine-tuning general-purpose pretrained language models, such as BERT (Devlin et al., 2019), with a particular training supervision. The type of supervision can be natural language inference data (Reimers and Gurevych, 2019), adjacent sentences (Yang et al., 2021), or a parallel corpus for multilingual models (Feng et al., 2020).

In this paper, we explore a type of supervision that has been under-explored in the literature: *entity hyperlink annotations* from Wikipedia. Their advantage is twofold: (1) entities have been shown to be a strong indicator of text semantics (Gabrilovich and Markovitch, 2007; Yamada et al., 2017, 2018; Ling et al., 2020) and thus should provide rich training signals for sentence embeddings; (2) entities are defined independently of languages and thus offer a useful cross-lingual alignment supervision (Calixto et al., 2021; Nishikawa et al., 2021; Jian et al., 2022; Ri et al., 2022). The extensive multilingual support of Wikipedia alleviates the need for a parallel resource to train well-aligned multilingual sentence embeddings, especially for low-resource languages. To demonstrate the effectiveness of entity-based supervision, we present **EASE** (Entity-Aware contrastive learning of Sentence Embeddings), which produces high-quality sentence embeddings in both monolingual and multilingual settings.

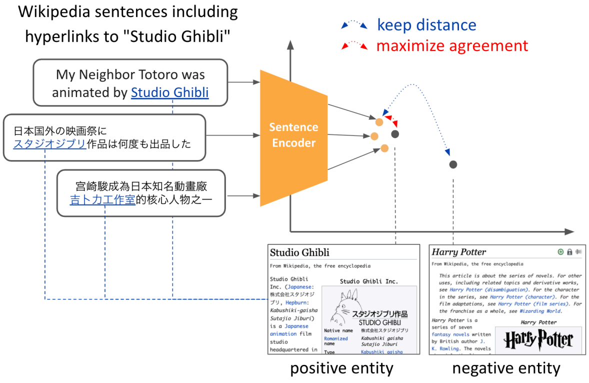

Figure 1: Illustration of the main concept behind EASE. Using a contrastive framework, sentences are embedded in the neighborhood of their hyperlink entity embeddings and kept apart from irrelevant entities. Here, we share the entity embeddings across languages for multilingual models to facilitate cross-lingual alignment of the representation.

EASE learns sentence embeddings with two types of objectives: (1) our novel entity contrastive learning (CL) loss between sentences and their related entities (Figure 1); (2) the self-supervised CL loss with dropout noise. The entity CL objective pulls the embeddings of sentences and their related entities close while keeping unrelated entities apart. The objective is expected to arrange the sentence embeddings in accordance with semantics captured

by the entities. To further exploit the knowledge in Wikipedia and improve the learned embeddings, we also introduce a method for mining hard negatives based on the entity type. The second objective, the self-supervised CL objective with dropout noise (Gao et al., 2021; Liu et al., 2021), is combined with the first one to enable sentence embeddings to capture fine-grained text semantics. We evaluate our model against other state-of-the-art unsupervised sentence embedding models, and show that EASE exhibits competitive or better performance on semantic textual similarity (STS) and short text clustering (STC) tasks.

We also apply EASE to multilingual settings. To facilitate the evaluation of the high-level semantics of multilingual sentence embeddings, we construct a multilingual text clustering dataset, MewsC-16 (Multilingual Short Text Clustering Dataset for News in 16 languages). Multilingual EASE is trained using the entity embeddings shared across languages. We show that, given the cross-lingual alignment supervision from the shared entities, multilingual EASE significantly outperforms the baselines in multilingual STS, STC, parallel sentence matching, and cross-lingual document classification tasks.

We further demonstrate the effectiveness of the multilingual entity CL in a more realistic scenario for low-resource languages. Using multilingual entity CL, we fine-tune a competitive multilingual sentence embedding model, LaBSE (Feng et al., 2020), and show that the tuning improves the performance of parallel sentence matching for low-resource languages under-supported by the model.

Finally, we analyze the EASE model by studying ablated models and the multilingual properties of the sentence embeddings to shed light on the source of the improvement in the model.

2 Related Work

2.1 Sentence Embeddings

Sentence embeddings, which represent the meaning of sentences in the form of a dense vector, have been actively studied. One of the earliest methods is Paragraph Vector (Le and Mikolov, 2014) in which sentence embeddings are trained to predict words within the text. Subsequently, various kinds of training tasks have been explored including reconstructing or predicting adjacent sentences (Kiros et al., 2015; Logeswaran and Lee, 2018) and solving a natural language inference (NLI) task (Conneau et al., 2017).

Recently, with the advent of general-purpose pretrained language models such as BERT (Devlin et al., 2019), it has become increasingly common to fine-tune pretrained models to produce high-quality sentence embeddings, revisiting the aforementioned supervision signals (Reimers and Gurevych, 2019; Yang et al., 2021), and using self-supervised objectives based on contrastive learning (CL). In this paper, we present a CL objective with entity-based supervision. We train our EASE model with entity CL together with self-supervised CL with dropout noise and show that the entity CL improves the quality of sentence embeddings.

Contrastive learning The basic idea of contrastive representation learning is to pull semantically similar samples close and keep dissimilar samples apart (Hadsell et al., 2006). CL for sentence embeddings can be classified by the type of positive pairs used. As representative examples, several methods use entailment pairs as positive pairs in NLI datasets (Gao et al., 2021; Zhang et al., 2021). To alleviate the need for an annotated dataset, self-supervised approaches are also being actively studied. Typical self-supervised methods involve generating positive pairs using data augmentation techniques, including discrete operations such as word deletion and shuffling (Yan et al., 2021; Meng et al., 2021), back-translation (Fang et al., 2020), intermediate BERT hidden representations (Kim et al., 2021), and dropout noise within transformer layers (Gao et al., 2021; Liu et al., 2021). Contrastive tension (CT)-BERT (Carlsson et al., 2021) regards as positive pairs the outputs of the same sentence from two individual encoders. DeCLUTR (Giorgi et al., 2021) uses different spans of the same document. In contrast to these methods that perform CL between sentences, our method performs CL between sentences and their associated entities.

Multilingual sentence embeddings Another yet closely related line of research is focused on learning multilingual sentence embeddings, which capture semantics across multiple languages. Early competitive methods typically utilize the sequence-to-sequence objective with parallel corpora to learn multilingual sentence embeddings (Schwenk and Douze, 2017; Artetxe and Schwenk, 2019); recently fine-tuned multilingual pretrained models have achieved state-of-the-art performance (Feng et al., 2020; Goswami et al., 2021). However, one drawback of such approaches is that, to achieve strong results for a particular language pair, they need rich parallel or semantically related sentence pairs, which are not necessarily easy to obtain. In this work, we explore the utility of Wikipedia entity annotations, which are aligned across languages and already available in over 300 languages. We also show that the entity CL in a multilingual scenario effectively improves the alignment of sentence embeddings between English and low-resource languages not well supported in an existing multilingual model.

2.2 Learning Representations Using Entity-based Supervision

Entities have been conventionally used to model text semantics (Gabrilovich and Markovitch, 2007, 2006). Several recently proposed methods learn text representations based on entity-based supervision by predicting entities from their relevant text (Yamada et al., 2017) or entity-masked sentences (Ling et al., 2020). In the proposed EASE model, the existing self-supervised CL method based on BERT (Gao et al., 2021) is extended using entity-based supervision with carefully designed hard negatives. Moreover, it is applied to the multilingual setting by leveraging the language-agnostic nature of entities.

3 Model and Training Data

In this section, we describe the components of our learning method for sentence embeddings, EASE, which is trained using entity hyperlink annotations available in Wikipedia.

3.1 Contrastive Learning with Entities

Given pairs of a sentence and a semantically related entity (positive entity) $\mathcal{D} = \{(s_i, e_i)\}_{i=1}^{m}$, we train our model to predict the entity embedding $\mathbf{e_i} \in \mathbb{R}^{\mathrm{d_e}}$ from the sentence embedding $\mathbf{s_i} \in \mathbb{R}^{\mathrm{d_s}}$. Following the contrastive framework in Chen et al. (2020), the training loss for (s_i, e_i) with a minibatch of N pairs is:

$$l_i^e = -\log \frac{e^{\mathrm{sim}(\mathbf{s_i}, \mathbf{We_i})/\tau}}{\sum_{j=1}^{N} e^{\mathrm{sim}(\mathbf{s_i}, \mathbf{We_j})/\tau}}, \tag{1}$$

where $\mathbf{W} \in \mathbb{R}^{\mathrm{d_e} \times \mathrm{d_s}}$ is a learnable matrix weight, τ is a temperature hyperparameter, and $\mathrm{sim}(\cdot)$ is the cosine similarity $\frac{\mathbf{s_1}^\top \mathbf{s_2}}{\|\mathbf{s_1}\| \cdot \|\mathbf{s_2}\|}$.

Data We construct the sentence-entity paired datasets from the January 2019 version of Wikipedia dump. We split text in the articles into sentences using `polyglot`.[1] For each sentence, we extract the hyperlink entities as semantically related entities.[2] Each entity forms a training instance (s_i, e_i) for the sentence. We restrict the entities to those that appear more than ten times as hyperlinks in the training corpus. They are converted into Wikidata entities, which are shared across languages, using inter-language links obtained from the March 2020 version of the Wikidata dump.[3]

3.2 Hard Negative Entities

The introduction of hard negatives (data that are difficult to distinguish from an anchor point) has been reported to be effective in improving CL models (Gao et al., 2021; Robinson et al., 2021). We introduce a hard negative mining technique that finds negative entities similar to the positive entity but yet unrelated to the sentence.

Specifically, for each positive entity, we collect hard negative entity candidates that satisfy the following two conditions: (1) entities with the same type as the positive entity. Entity types are defined as the entities in the "instance of" relation on Wikidata, following the work of Xiong et al. (2020). If there are more than one appropriate type, we randomly choose one; (2) entities that do not appear on the same Wikipedia page. Our assumption here is that entities on the same page are topically related to the positive entity and thus are not appropriate for negative data. Finally, we randomly choose one of the candidates to construct hard negative training data. For example, the "Studio Ghibli" entity has the type "animation studio" and one of the hard negative entity candidates is "Walt Disney Animation Studios".

Given datasets with hard negative entities $\mathcal{D} = \{(s_i, e_i, e_i^-)\}_{i=1}^{m}$, the loss function is

$$l_i^e = -\log \frac{e^{\mathrm{sim}(\mathbf{h_i}, \mathbf{We_i})/\tau}}{\sum_{j=1}^{N} (e^{\mathrm{sim}(\mathbf{h_i}, \mathbf{We_j})/\tau} + e^{\mathrm{sim}(\mathbf{h_i}, \mathbf{We_j^-})/\tau})}. \tag{2}$$

---

[1] `https://polyglot.readthedocs.io/en/latest/Tokenization.html`

[2] In a preliminary experiment, we also tried constructing entity-sentence paired data from entities and the first sentence on their page, and found that the current approach performs better.

[3] `https://en.wikipedia.org/wiki/Help:Interlanguage_links`

3.3 Pretrained Entity Embeddings

We initialize entity embeddings using English entity embeddings pretrained on Wikipedia. These embeddings are trained using the open-source `Wikipedia2Vec` tool (Yamada et al., 2020) and the January 2019 English Wikipedia dump. The vector dimension is set to 768, which is the same as those of the hidden representations of the base pretrained models, and the other hyperparameters to their default values. The parameters of the entity embedding matrix are updated during the training process.

3.4 Self-supervised Contrastive Learning with Dropout Noise

Self-supervised CL with dropout noise, which inputs a sentence and predicts itself using dropout as noise, is an effective method for learning sentence embeddings in an unsupervised way (Liu et al., 2021; Gao et al., 2021). We combine this method with our entity CL.

Given two embeddings with different dropout masks $\mathbf{s_i}, \mathbf{s_i^+}$, the training loss of self-supervised CL l_i^s is defined by

$$l_i^s = -\log \frac{e^{\mathrm{sim}(\mathbf{s_i},\mathbf{s_i^+})/\tau}}{\sum_{j=1}^{N} e^{\mathrm{sim}(\mathbf{s_i},\mathbf{s_j^+})/\tau}}. \tag{3}$$

In summary, our total loss is

$$l_i^{ease} = \lambda l_i^e + l_i^s, \tag{4}$$

where l^e and l^s are defined in Equations (2) and (3) respectively, and λ denotes a hyperparameter that defines the balance between the entity CL and self-supervised CL with dropout noise. The details on the hyperparameters of the models can be found in Appendix A.

4 Experiment: Monolingual

We first evaluate EASE in monolingual settings. We fine-tune monolingual pre-trained language models using only English Wikipedia data.

4.1 Setup

We use one million pairs sampled from the English entity-sentence pairs described in Section 3 as training data. In this setting, we train sentence embedding models from pre-trained checkpoints of BERT (Devlin et al., 2019) or RoBERTa (Liu et al., 2019) and take the [CLS] representation as the sentence embedding. We add a linear layer after the output sentence embeddings only during training, as in Gao et al. (2021).

Model	7 STS avg.	8 STC avg.

DeCLUTR-RoBERTa$_{\text{base}}$	70.0	**60.0**
SimCSE-RoBERTa$_{\text{base}}$	76.6	57.4
EASE-RoBERTa$_{\text{base}}$	**76.8**	58.6

Table 1: Sentence embedding performance on seven monolingual STS tasks (Spearman's correlation) and eight monolingual STC tasks (clustering accuracy). The highest values among the models with the same pre-trained encoder are in bold. †: results from Reimers and Gurevych (2019); all other results are reproduced or reevaluated by us using published checkpoints. The complete results are available in Appendix G.

We compare our method with unsupervised sentence embedding methods including average GloVe embeddings (Pennington et al., 2014), average embeddings of vanilla BERT or RoBERTa, and previous state-of-the-art approaches such as SimCSE (Gao et al., 2021), CT (Carlsson et al., 2021), and DeCLUTR (Giorgi et al., 2021).

We evaluate sentence embeddings using two tasks: STS and STC. These tasks are supposed to measure the degree of sentence embeddings capturing fine-grained and broad semantic structures.

Semantic textual similarity STS is a measure of the capability of capturing graded similarity of sentences. We use seven monolingual STS tasks: STS 2012-2016 (Agirre et al., 2012, 2013, 2014, 2015, 2016), STS Benchmark (Cer et al., 2017), and SICK-Relatedness (Marelli et al., 2014). Following the settings of Reimers and Gurevych (2019), we calculate Spearman's rank correlation coefficient between the cosine similarity of the sentence embeddings and the ground truth similarity scores.

Short text clustering Another important aspect of sentence embeddings is the ability to capture categorical semantic structure, i.e., to map sentences from the same categories close together and those from different categories far apart (Zhang et al., 2021). We also evaluate sentence embeddings using eight benchmark datasets for STC (Zhang et al., 2021) to investigate how well our method can encode high-level categorical structures into

sentence embeddings. These datasets contain short sentences, ranging from 6 to 28 average words in length, from a variety of domains such as news, biomedical, and social network service (Twitter). We cluster the sentence embeddings using K-Means (MacQueen, 1967) and compute the clustering accuracy using the Hungarian algorithm (Munkres, 1957) averaged over three independent runs.

4.2 Results

Table 1 shows the evaluation results for the seven STS and eight STC tasks. Overall, our EASE methods significantly improve the performance of the base models (i.e., BERT and RoBERTa), and on average outperform the previous state-of-the-art methods on all tasks except STC with the RoBERTa backbone. The most significant improvement is observed for EASE-BERT, with an average improvement of 61.6% to 63.1% over the previous best result for STC tasks. These results suggest that EASE is able to measure the semantic similarity between sentences, and simultaneously excel at capturing high-level categorical semantic structure.

5 Experiment: Multilingual

To further explore the advantage of entity annotations as cross-lingual alignment supervision, we test EASE in multilingual settings: we fine-tune multilingual pre-trained language models using Wikipedia data in multiple languages.

5.1 Setup

We sample 50,000 pairs for each language and use them together as training data from the entity-sentence paired data in 18 languages.[4] As our primary baseline model, we use a SimCSE model trained using the same multilingual data as EASE (i.e., sentences in entity-sentence paired data).[5] In this setting, we start fine-tuning from pre-trained checkpoints of mBERT or XLM-R (Conneau et al., 2020) and take mean pooling to obtain sentence embeddings for both training and evaluation on both EASE and SimCSE. We also tested other pooling methods, but mean pooling was the best in this experiment for both models (Appendix B).

5.2 Multilingual STS and STC

We evaluate our method using the extended version of the STS 2017 dataset (Reimers and Gurevych, 2020), which contains annotated sentences for ten language pairs: EN-EN, AR-AR, ES-ES, EN-AR, EN-DE, EN-TR, EN-ES, EN-FR, EN-IT, and EN-NL. We compute Spearman's rank correlation as in Section 4.1. We also conduct experiments on our newly introduced multilingual STC dataset described as follows:

---

[4] We chose 18 languages (ar, ca, cs, de, en, eo, es, fa, fr, it, ja, ko, nl, pl, pt, ru, sv, tr) present in both the MewsC-16 dataset (see Section 5.2) and the extended version of STS 2017.

[5] We use the same entity embeddings trained on English Wikipedia as those of the monolingual settings (Section 3.3). Note that entities in all languages are converted to Wikidata entities that are shared across languages using inter-language links as described in Section 3.1.

Table 6: Classification accuracy for zero-shot cross-lingual text classification on MLDoc dataset.

MewsC-16 To evaluate the ability of sentence embeddings to encode high-level categorical concepts in a multilingual setting, we constructed MewsC-16 (**M**ultilingual Short Text **C**lustering Dataset for N**ews** in **16** languages) from Wikinews.[6] MewsC-16 contains topic sentences from Wikinews articles in 13 categories and 16 languages. More detailed information is available in Appendix E. We perform clustering and compute the accuracy for each language as in Section 4.1.

Tables 2 and 3 show the results of our multilingual STS and STC experiments. Overall, EASE substantially outperforms the corresponding base models (i.e., mBERT and XLM-R) on both tasks. Similar to the results for the monolingual setting, the average performance of EASE exceeds that of SimCSE for multilingual STC tasks with an improvement of 34.1% to 36.0% for mBERT and 31.8% to 35.4% for XLM-R. This result suggests that even in a multilingual setting, EASE can encode high-level categorical semantic structures into sentence embeddings. Moreover, EASE significantly outperforms SimCSE in multilingual STS tasks Specifically, the score of EASE-mBERT is better than that of SimCSE-mBERT (50.9 vs 57.2), and that of EASE-XLM-R is better than that of SimCSE-XLM-R (54.1 vs 57.1). This improvement is much more significant than the monolingual setting (Table 1), where the improvement is less than one point. This indicates the effectiveness of language-independent entities as cross-lingual alignment supervision in learning multilingual sentence embeddings.

5.3 Cross-lingual Parallel Matching

We evaluate EASE on the Tatoeba dataset (Artetxe and Schwenk, 2019) to assess more directly its ability to capture cross-lingual semantics. This task is to retrieve the correct target sentence for each query sentence, given a set of parallel sentences. We perform the retrieval using the cosine similarity scores of the sentence embeddings. For each language-pair dataset, we compute the retrieval accuracy averaged over the forward and backward directions (English to the target language and vice-versa).

Table 4 shows the evaluation results for the languages in the CL training data. EASE significantly outperforms the corresponding base models and SimCSE for all languages. Notably, the mean performance of EASE-mBERT is better than that of vanilla mBERT by 13.5 percentage points. This indicates that EASE can capture cross-lingual semantics owing to the cross-lingual supervision of entity annotations, which aligns semantically similar sentences across languages. One interesting observation is that the performance of SimCSE-mBERT is worse than that of vanilla mBERT. We conjecture that this is because the SimCSE model is trained using only the positive sentence pairs within the same language, which sometimes leads to less language-neutral representations.

---

[6] `https://en.wikinews.org/wiki/Main_Page`

To further explore the cross-lingual ability of EASE, we evaluate it on languages not included in the EASE training set (Table 5). The results show that EASE performs robustly on these languages as well, which suggests that, in EASE, the cross-lingual alignment effect propagates to other languages not used in additional training with EASE (Kvapilíková et al., 2020).

5.4 Cross-lingual Zero-shot Transfer

We further evaluate our sentence embeddings on a downstream task in which sentence embeddings are used as input features, especially in the cross-lingual zero-shot transfer setting. For evaluation in this setting, we use MLDoc (Schwenk and Li, 2018), a cross-lingual document classification dataset that classifies news articles in eight languages into four categories. We train a linear classifier using sentence embeddings as input features on the English training data, and evaluate the resulting classifier in the remaining languages. To directly evaluate the ability of the resulting sentence embeddings, we do not update the parameters of the sentence encoder but only train the linear classifier in this setting. The detailed settings are shown in Appendix D.

As shown in Table 6, our EASE models achieve the best average performance on both back-bones, suggesting that multilingual embeddings learned with the CL are also effective in the cross-lingual transfer setting.

6 Case Study: Fine-tuning Supervised Model with EASE

Existing multilingual sentence representation models trained on a large parallel corpus do not always perform well, especially for languages that are not included in the training data. In contrast, EASE requires only the Wikipedia text corpus, which is available in more than 300 languages.[7] Thus, one possible use case for EASE would be to complement the performance of existing models in low-resource languages by exploiting the Wikipedia data in those languages.

To test this possibility, we fine-tune LaBSE (Feng et al., 2020), which is trained on both monolingual and bilingual data in 109 languages, with our EASE framework in five low-resource languages (kab, pam, cor, tr, mhr). These languages are not present in the original training corpus, so the model performed particularly poorly on these languages. We fine-tune the model using 5,000 pairs each from English and the corresponding language data.

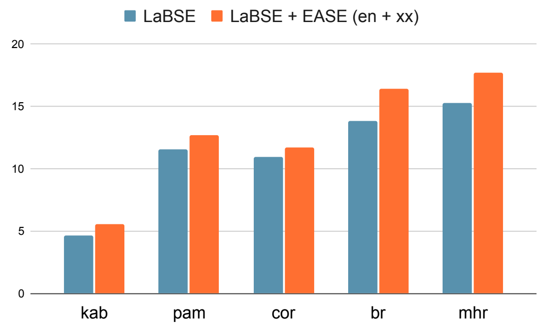

Figure 2: Results of fine-tuning LaBSE with EASE framework on Tatoeba dataset.

As shown in Figure 2, EASE improves the performance of LaBSE across all target languages, which is an intriguing result considering that LaBSE has already been trained on about six billion parallel corpora. These results suggest the potential benefit of combining EASE with other models using parallel corpora, especially for languages without or with only a few parallel corpora.

7 Analysis

7.1 Ablation Study

We conduct ablation experiments to better understand how each component of EASE contributes to its performance. We measure the performance of the models using monolingual STS in the monolingual setting and multilingual STS in the multilingual setting, without one of the following components: the self-supervised CL loss, hard negatives, and Wikipedia2Vec initialization (Table 7). As a result, we find all of the components to make an important contribution to the performance.

It is worth mentioning that entity CL alone (i.e., w/o self-supervised CL) also improves the baseline performance significantly. The performance contributions in the multilingual setting are particularly significant (49.3 for mBERT and 53.1 for XLM-R) and comparable to those for the SimCSE models. These results suggest that CL with entities by itself is effective in learning multilingual sentence embeddings.

Setting	EASE-BERT$_{\text{base}}$ STS avg.	EASE-RoBERTa$_{\text{base}}$ STS avg.	EASE-mBERT$_{\text{base}}$ mSTS avg.	EASE-XLM-R$_{\text{base}}$ mSTS avg.
Full model	**76.9**	**76.8**	**57.2**	**57.1**
w/o self-supervised CL	65.3	66.1	49.3	53.1
w/o hard negative	75.3	76.1	53.8	52.7
w/o Wikipedia2Vec	73.8	76.3	52.1	54.3
w/o all (vanilla model)	31.4	43.6	35.4	25.0

Table 7: Results of ablation study.

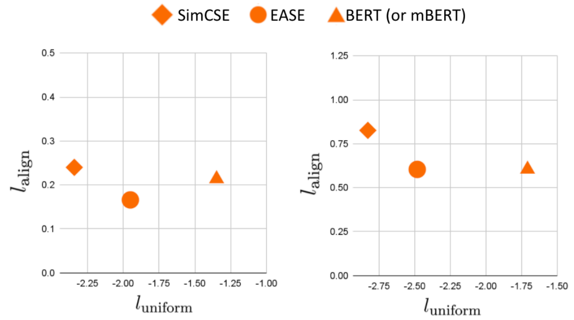

Figure 3: $l_{\text{align}} - l_{\text{uniform}}$ plot of BERT-based (or mBERT-based) models in monolingual (left) and multilingual (right) settings.

7.2 Alignment and Uniformity

To further understand the source of the performance improvement with EASE, we evaluate two key properties to measure the quality of the representations obtained from contrastive learning (Wang and Isola, 2020): *alignment* measures the closeness of representations between positive pairs; *uniformity* measures how well the representations are uniformly distributed. We let $f(x)$ denote the normalized representation of x, and compute the two measures using

$$l_{\text{align}} \triangleq \mathop{\mathbb{E}}_{(x,x^+)\sim p_{\text{pos}}} \|f(x)-f(x^+)\|^2, \qquad (5)$$

$$l_{\text{uniform}} \triangleq \log \mathop{\mathbb{E}}_{x,y \overset{i.i.d.}{\sim} p_{\text{data}}} e^{-2\|f(x)-f(y)\|^2}, \qquad (6)$$

where p_{pos} denotes positive pairs and p_{data} denotes the entire data distribution. We compute these metrics using BERT-based models on the STS-B development set data. For investigation in the multilingual setting, we compute them using mBERT-based models on the multilingual STS data used in the experiment Section 5. We compute the averages of alignment and uniformity for each language pair. For each setting, we take STS pairs with a score higher than 4 in the 0-to-5 scale as p_{pos} and all STS sentences as p_{data}.

As shown in Figure 3, the trends are similar in both settings: (1) both EASE and SimCSE significantly improve uniformity compared with that for the vanilla model; (2) EASE is inferior to SimCSE in terms of uniformity and superior in terms of alignment. This result suggests that entity CL does not have the effect of biasing embeddings towards a more uniform distribution. Instead, it has the effect of aligning semantically similar samples, which leads to the improved performance of the resultant sentence embeddings.

7.3 Qualitative analysis

To investigate how EASE improves the quality of sentence embeddings, we conduct qualitative analysis by comparing the results of EASE and SimCSE on STS Benchmark. Table 8a shows typical cases of how EASE improves sentence embeddings. We find that EASE embeddings are more robust to synonyms and grammatical differences since they are more aware of the topic similarity between sentences, resulting in more accurate score inference. On the other hand, as shown in the deterioration cases in Table 8b, EASE embeddings are sometimes overly sensitive to topical similarity, making it difficult to capture the correct meaning of the whole sentence.

8 Discussion and Conclusion

Our experiments have demonstrated that entity supervision in EASE improves the quality of sentence embeddings both in the monolingual setting and, in particular, the multilingual setting. As recent studies have shown, entity annotations can be used as *anchors* to learn quality cross-lingual representations (Calixto et al., 2021; Nishikawa et al., 2021; Jian et al., 2022; Ri et al., 2022), and our work is another demonstration of their utility, particularly in sentence embeddings. One promising future direction is exploring how to better exploit the cross-lingual nature of entities.

Sentence1	Sentence2	Gold	EASE	SimCSE
i think you ’re looking for mikey (1992) .	i think you ’re looking for the movie	3.00	2.32	1.62
the new york senator ’s new book , " living history , " appears a certain bestseller .	hillary clinton , the new york senator and former first lady , has a book out monday titled living history .	3.20	3.57	1.94
he was referring to john s. reed , the former citicorp chief executive who became interim chairman and chief executive of the exchange last sunday .	next week , john s. reed , the former citicorp chief executive who sunday became interim chairman and chief executive of the exchange , will take up his position .	4.00	3.52	2.73

(a) Improvement cases

Sentence1	Sentence2	Gold	EASE	SimCSE
it ’s not a good idea .	it ’s a good question .	0.00	2.88	1.33
suicide attack kills eight in baghdad	suicide attacks kill 24 people in baghdad	2.40	3.92	2.43
the nasdaq composite index rose 19.67 , or 1.3 percent , to 1523.71 , its highest since june 18 .	the s and p 500 had climbed 16 percent since its march low and yesterday closed at its highest since dec. 2 .	0.80	3.25	2.04

(b) Deterioration cases

Table 8: Comparison of STS Benchmark results by monolingual EASE and SimCSE.

Our experiments also demonstrate the utility of Wikipedia as a multilingual database. As described in Section 6, Wikipedia entity annotations can compensate for the lack of parallel resources in learning cross-lingual representations. Wikipedia currently supports more than 300 languages, and around half of them have over 10,000 articles.[8] Moreover, Wikipedia is ever growing; it is expected to include more and more languages.[9] This will motivate researchers to develop methods for multilingual models including low-resource languages in the aid of entity annotations in Wikipedia.

However, the reliance on Wikipedia for training data may limit the application of the models to specific domains (e.g., general or encyclopedia domains). To apply EASE to other domains, one may need to annotate text from the domain either manually or automatically. Future work can investigate the effectiveness of the entity CL in other domains and possibly its the combination with an entity linking system.

Finally, we note that the supervision signal in EASE is inherently noisy. Different entities have different characteristics as a topic indicator, and sentences that contain the same entity do not necessarily share meaning. Future work can address this by considering how an entity is used in a sentence to obtain more reliable supervision.

A Training Details

We implement our EASE model using `transformers`[10] libraries. For the monolingual settings, we use the STS-B development set as in (Gao et al., 2021). For multilingual settings, we use the STS-B and SICK-R development set. In this setting, we simply concatenate the entity-sentence paired data for all 18 languages and randomly sample from the concatenated data to construct batches.[11] In both settings, we train our model for one epoch, compute evaluation scores every 250 training steps on the development data, and keep the best model. We conduct a grid-search for batch size $\in \{64, 128, 256, 512\}$ and learning rate $\in \{3e-05, 5e-05\}$. The chosen hyperparameters for each model is shown in Table 9.

Model	Batch size	Learning Rate
SimCSE-mBERT$_{\text{base}}$	128	3e-05
SimCSE-XLM-R$_{\text{base}}$	128	3e-05
EASE-BERT$_{\text{base}}$	64	3e-05
EASE-RoBERTa$_{\text{base}}$	128	5e-05
EASE-mBERT$_{\text{base}}$	256	5e-05
EASE-XLM-R$_{\text{base}}$	64	3e-05

Table 9: Hyperparameters for experiment.

For the loss balancing term λ and softmax temperature τ in the EASE models (section 3), we empirically find that $\lambda = 0.01$, $\tau = 100$ for the monolingual setting and $\tau = 10$ for the multilingual setting work well.

Computing Infrastructure We run the experiments on a server with AMD EPYC 7302 16-Core CPU and a NVIDIA A100-PCIE-40GB GPU. The training of EASE takes approximately 1 hour.

B Pooling Methods for SimCSE and EASE

We compare several pooling methods on both SimCSE and EASE in the multilingual setting: [CLS] with MLP; [CLS] with MLP during training only; [CLS] without MLP; mean pooling. Table 10 shows the evaluation results based on the STS-B and SICK-R development set.

Pooler	SimCSE	EASE
[CLS] pooling		
w/ MLP	63.0	65.0
w/ MLP (train)	72.0	73.3
w/o MLP	72.0	73.4
mean pooling	**72.1**	**73.8**

Table 10: Average Spearman's correlation for different pooling methods for SimCSE and EASE in multilingual setting on STS-B and SICK-R development set.

The mean pooling representation performs best on both models. We thus use mean pooling on both models in Section 5.

---

[10] https://huggingface.co/docs/transformers/index

[11] In our preliminary experiments, we also tested a setting in which data in the same language were used within the same batch; we did not observe a consistent improvement in the performance of either the SimCSE or EASE models.

C Parallel Sentence Mining

We evaluate the multilingual sentence embeddings with the parallel sentence mining task using the BUCC 2018 shared task dataset (Zweigenbaum et al., 2018). The task is to find the parallel pairs given monolingual sentence pools in two languages, with 2–3% of the sentences being parallel, to find the parallel pairs.

Each model uses the raw embedding output and performance is evaluated without fine-tuning. We first encode all sentences into embeddings and compute the cosine similarity scores between all possible sentence pairs. We then retrieve the sentence pairs with above a fixed threshold and compute the F1 score using the ground-truth parallel pairs.

As the test set is not publicly available, we use the sample set to tune the threshold of the parallel sentence mining and the training set for evaluation, which is a common practice in similar studies (Hu et al., 2020; Feng et al., 2020).

The results are summarized in Table 11. Our EASE models outperform the SimCSE baselines across the languages, demonstrating that the entity contrastive objective improves the alignment of the multilingual sentence embeddings without a parallel corpora. However, performance is significantly poor than that of LaBSE, which is trained using massive amounts of parallel corpora, suggesting that we still need parallel resources to be competitive on this task.

	en-de	en-fr	en-ru	en-zh
SimCSE-mBERT$_{\text{base}}$	13.2	19.2	7.9	11.5
EASE-mBERT$_{\text{base}}$	26.9	33.8	24.2	32.9
SimCSE-XLM-R$_{\text{base}}$	31.8	32.3	28.9	19.9
EASE-XLM-R$_{\text{base}}$	33.3	33.2	33.6	23.4
LaBSE	89.0	88.2	84.7	74.2

Table 11: The F1 scores on BUCC 2018 the training set. Retrieval is performed in forward search, i.e., English sentences as the targets and the other language as the queries.

D Detailed Settings for MLDoc Experiment

We use the english.train.1000 and english.dev datasets for the training and validation data, respectively. We conduct a grid-search for batch size $\in \{32, 64, 128\}$ and learning rate $\in \{0.1, 0.01, 0.001\}$ using validation data 12. We run the experiment three times with different random seeds and record the average scores.

Model	Batch size	Learning Rate
mBERT$_{\text{base}}$(avg.)	32	0.1
XLM-R$_{\text{base}}$(avg.)	32	0.1
SimCSE-mBERT$_{\text{base}}$	32	0.1
SimCSE-XLM-R$_{\text{base}}$	32	0.01
EASE-mBERT$_{\text{base}}$	32	0.01
EASE-XLM-R$_{\text{base}}$	32	0.01

Table 12: Hyperparameters for MLDoc experiment

E Construction of MewsC-16 Dataset

To construct the MewsC-16 dataset, we collect sentences for each category in each language from the Wikinews dump.[12] We first select 13 topic categories in the English Wikinews [13] that are also defined in other languages (Science and technology, Politics and conflicts, Environment, Sports, Health, Crime and law, Obituaries, Disasters and accidents, Culture and entertainment, Economy and business, Weather, Education, Media). We then collect pages with topic categories for each language and remove the pages with two or more topic categories. We clean the text on each page with the `Wikiextractor` tool[14], and split it into sentences using the `polyglot` sentence tokenizer. Finally, we use the first sentence assuming that it well represents the topic of the entire article (Baxendale, 1958; Edmundson, 1969). The corpus statistics for each language are shown in Table 13.

Language	# of sentences	# of label types	Language	# of sentences	# of label types
ar	2,243	11	fr	10,697	13
ca	3,310	11	ja	1,984	12
cs	1,534	9	ko	344	10

F Baselines

For average GloVe embedding (Pennington et al., 2014), we use open-source GloVe vectors trained on Wikipedia and Gigaword with 300 dimensions.[15] We use the pretrained model from HuggingFace's `Transformers`[16] for vanilla pretrained language models, including BERT (bert-base-uncased) (Devlin et al., 2019), RoBERTa (roberta-base) (Liu et al., 2019), mBERT (bert-base-multilingual-cased) and XLM-R (xlm-roberta-base) (Conneau et al., 2020). We use the published checkpoints for unsupervised SimCSE (Gao et al., 2021)[17], CT (Carlsson et al., 2021)[18], and DeCLUTR (Giorgi et al., 2021).[19]

G Monolingual STS and STC

Table 14 and 15 show the complete results for seven STS tasks and eight STC tasks. For STS, the average EASE performance is slightly better than that of SimCSE, although the advantage is not consistent across tasks. For most of the STC tasks, EASE consistently outperforms SimCSE. These results indicate that EASE stands out at capturing high-level categorical semantic structures and that its ability to measure sentence semantic similarity is comparable to or better than that of SimCSE.

Abstract

Recent work incorporates pre-trained word embeddings such as BERT embeddings into Neural Topic Models (NTMs), generating highly coherent topics. However, with high-quality contextualized document representations, do we really need sophisticated neural models to obtain coherent and interpretable topics? In this paper, we conduct thorough experiments showing that directly clustering high-quality sentence embeddings with an appropriate word selecting method can generate more coherent and diverse topics than NTMs, achieving also higher efficiency and simplicity.[1]

1 Introduction

Topic modelling is an unsupervised method to uncover latent semantic themes among documents (Boyd-Graber et al., 2017). Neural topic models (NTMs) (Miao et al., 2016; Srivastava and Sutton, 2017) incorporating neural components have significantly advanced the modelling results than the traditional Latent Dirichlet Allocation (LDA; Blei et al. 2001). Later, contextualized word and sentence embeddings produced by pre-trained language models such as BERT (Devlin et al., 2019) have demonstrated the state-of-the-art results in multiple Natural Language Processing (NLP) tasks (Xia et al., 2020), which attracts attentions from the topic modelling community. Recent work has successfully incorporated these contextualized embeddings into NTMs, showing improved topic coherence than conventional NTMs that use Bag-of-Words (BoW) as document representations (Bianchi et al., 2021a,b; Jin et al., 2021). Despite the promising performance, existing NTMs are generally based on a variational autoencoder framework (VAE; Kingma and Welling 2014), which suffers from hyper-parameters tuning and computational overheads (Zhao et al., 2021). Moreover, the integration of the pre-trained embeddings to the standard VAE framework adds additional model complexity. With high-quality contextualized document representations, do we really need sophisticated NTMs to obtain coherent and interpretable topics?

Recent work (Aharoni and Goldberg, 2020; Sia et al., 2020; Thompson and Mimno, 2020; Grootendorst, 2020) has shown that directly congregating contextualized embeddings can get semantically similar word or document clusters. Specifically, Sia et al. (2020) cluster *vocabulary-level* word embeddings and obtain top words from each cluster using weighing and re-ranking, while Thompson and Mimno (2020) consider polysemy and perform *token-level* clustering. However, the use of term frequency (TF) to select topic words fails to capture the semantics of clusters precisely because words with high frequency may be common across different clusters. Grootendorst (2020) propose a class-based Term Frequency- Inverse Document Frequenc (c-TF-IDF) method that extract important words from each clustered documents, which tends to choose representative words within each cluster to form topics. However, it overlooks the global semantics between clusters which could be incorporated. In addition, all above works only compare the performance with the traditional LDA while ignoring the promising NTMs proposed recently. The performance of the clustering-based topic models is still yet uncovered.

Is neural topic modelling better than simple embedding clustering? This work compares the performance of NTMs and contextualized embedding-based clustering systematically. Our main focus is to provide insights by comparing the two paradigms for topic models, which has not been investigated before. We employ a straightforward framework for clustering. In addition, we explore different strategies to select topic words for clusters. We evaluate our approach on three datasets

with various text lengths.

Our contributions are as follows: First, we find that directly clustering high-quality sentence embeddings can generate as good topics as NTMs, providing a simple and efficient solution to uncover latent topics among documents. Second, we propose a new topic word selecting method, which is the key to producing highly coherent and diverse topics. Third, we show that the clustering-based model is robust to the length of documents and the number of topics. Reducing the embedding dimensionality negligibly affects the performance but saves runtime. From our best knowledge, we are the first to compare with NTMs, using contextualized embeddings that produced by various transformer-based models.

2 Models

This study compares embedding clustering-based models with LDA and a series of existing NTMs as follows. Implementation details are supplied in Appendix A.

LDA (Blei et al., 2001): the representative traditional topic model in history that generates topics via document-topics and topic-words distributions.

ProdLDA (Srivastava and Sutton, 2017): a prominent NTM that employs the VAE (Kingma and Welling, 2014) to reconstruct the BoW representation.

CombinedTM (Bianchi et al., 2021a): extends ProdLDA by concatenating the contextualized SBERT (Reimers and Gurevych, 2019) embeddings with the original BoW as the new input to feed into the VAE framework.

ZeroShotTM (Bianchi et al., 2021b): also builds upon ProdLDA, but it replaces the original BoW with SBERT embeddings entirely.

BERT+KM (Sia et al., 2020): a clustering-based method that first uses K-Means (KM) to cluster word embeddings, then apply TF to weight and re-rank words to obtain topic words.

BERT+UMAP+HDBSCAN (i.e., BERTopic) (Grootendorst, 2020): a clustering-based method that first leverages HDBSCAN (McInnes and Healy, 2017) to cluster BERT embeddings of the sentences and Uniform Manifold Approximation Projection (UMAP) (McInnes et al., 2018) to reduce embedding dimensions, then use a class-based TFIDF (i.e. c-TF-IDF) to select topic words within each cluster. Note that BERTopic may not generate the specified number of topics.

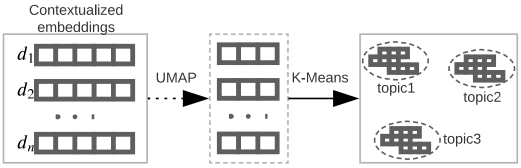

Figure 1: Architecture of our method. Reducing embedding dimension is optional but can save runtime (see Section 4.4).

Contextual Embeddings+UMAP+KM (our method CETopic): we use a simple clustering framework with contextualized embeddings for topic modelling, as shown in Figure 1. We first encode pre-processed documents to obtain contextualized sentence embeddings through pre-trained language models. After that, we lower the dimension of the embeddings before applying clustering methods (e.g., K-Means; KM) to group similar documents. Each cluster will be regarded as a topic. Finally, we adopt a weighting method to select representative words as topics.

We believe that high-quality document embeddings are critical for clustering-based topic modelling. We thus experiment with different embeddings including BERT, RoBERTa (Liu et al., 2019), and SBERT. We also adopt SimCSE (Gao et al., 2021), a recently proposed sentence embeddings of contrastive learning, that has shown the state-of-the-art performance on multiple semantic textual similarity tasks. Both supervised and unsupervised SimCSE are investigated in our experiment (e.g., Table 2).

Pre-trained contextualized sentence embeddings often have high dimensionalities. To reduce the computational cost, we apply the UMAP in our implementation to reduce the dimensionality while maintaining the essential information of the embeddings. We find that reducing dimensionality before clustering has a negligible impact on performance (Section 4.4).

We cluster the dimension-reduced sentence embeddings using K-Means because of its efficiency and simplicity. Semantically close documents are gathered together, and each cluster is supposed to represent a topic.

3 Topic Words for Clusters

Once we have a group of clustered documents, selecting representative topic words is vital to identify semantics of topics. Inspired by previous works (Ramos et al., 2003; Grootendorst, 2020), we explore several weighting metrics to obtain topic words in clusters. Let $n_{t,d}$ be the frequency of word t in document d, $\sum_{t'} n_{t',d}$ be the total words' frequency in the document, and D be the entire corpus. Term Frequency-Inverse Document Frequency (TFIDF) is defined as $\mathbf{TFIDF} = \frac{n_{t,d}}{\sum_{t'} n_{t',d}} \cdot \log\left(\frac{|D|}{|\{d \in D : t \in d\}|}\right)$. While capturing the word importance across the entire corpus, TFIDF ignores that semantically similar documents have been grouped together. To address this issue, we consider two alternative strategies. First, we concatenate the documents within a cluster to be a single long document and calculate the term frequency of each word in each cluster:

$$\mathbf{TF_i} = \frac{n_{t,i}}{\sum_{t'} n_{t',i}} \tag{1}$$

where $n_{t,i}$ is the frequency of word t in cluster i, $\sum_{t'} n_{t',i}$ is the total word frequency in the cluster. Second, for each cluster i, we apply TFIDF:

$$\mathbf{TFIDF_i} = \frac{n_{t,d_i}}{\sum_{t'} n_{t',d_i}} \cdot \log\left(\frac{|D_i|}{|\{d \in D_i : t \in d\}|}\right) \tag{2}$$

where n_{t,d_i} denotes the frequency of word t in document d, which is in cluster i, and $|D_i|$ is the number of documents in cluster i.

Besides the two local cluster-based strategies, we further incorporate the global word importance with local term frequency within each cluster:

$$\mathbf{TFIDF} \times \mathbf{TF_i} = \mathbf{TFIDF} \cdot \mathbf{TF_i} \tag{3}$$

and we combine the global word importance with term frequency across clusters:

$$\mathbf{TFIDF} \times \mathbf{IDF_i} = \mathbf{TFIDF} \cdot \log\left(\frac{|K|}{|\{t \in K\}|}\right) \tag{4}$$

where $|K|$ is the number of clusters and $|\{t \in K\}|$ is the number of clusters that word t appears.

4 Experiments

4.1 Datasets

We adopt three datasets of various text lengths in our experiments, namely 20Newsgroups[2], M10 (Lim and Buntine, 2015), and BBC News (Greene and Cunningham, 2006). We follow OCTIS (Terragni et al., 2021) to pre-process these raw datasets. The statistics of the datasets are shown in Table 1.

Dataset	D	V	L	N_d
20Newsgroups	16,309	1,612	20	48
M10	8,355	1,696	10	5.9
BBC News	2,225	2,949	5	120

Table 1: Statistics of the pre-processed datasets, where D denotes the total number of documents, V denotes the vocabulary size, L denotes the number of corpus categories, and N_d denotes the average number of words per document.

4.2 Evaluation Metrics

We evaluate the topic quality in terms of both topic diversity and topic coherence: Topic Diversity (*TU*) (Nan et al., 2019) measures the uniqueness of the words across all topics; Normalized Pointwise Mutual Information (*NPMI*) (Newman et al., 2010) measures topic coherence internally using a sliding window to count word co-occurrence patterns; Topic Coherence (C_V) (Röder et al., 2015) is a variant of *NPMI* that uses the one-set segmentation to count word co-occurrences and the cosine similarity as the similarity measure.

4.3 Results & Analysis

We report the main results in Table 2.

Directly clustering high-quality sentence embeddings can generate good topics. From Table 2, it can be observed that SBERT and SimCSE-based clustering models achieve the best averaged topic coherence among the three datasets while maintaining remarkable topic diversities. Conversely, clustering RoBERTa achieves similar or worse results than contextualized NTMs. The results suggest that contextualized embeddings are essential to get high-quality topics.

Topic words weighting method is vital. We can see in Figure 2 that inappropriate word selecting methods ($\mathbf{TFIDF} \times \mathbf{TF_i}$ and $\mathbf{TF_i}$) lead to worse topic coherence than the contextualized NTMs (i.e., CombinedTM and ZeroShotTM), and even the BoW-based ProdLDA. Moreover, from Table 2, BERT$_{\texttt{base}}$+KM adopt TF to obtain top words for each cluster, which ignores that the words may also be prevalent in other clusters, thus having poor topic diversities. It is also worthy to note that although BERT$_{\texttt{base}}$+UMAP+HDBSCAN (i.e. BERTopic) reaches the highest topic diversity on 20Newsgroups, it cannot produce the specified topic numbers. Thus its performance may be boosted because of the reduced topic numbers. Moreover, our proposed methods, i.e. BERT$_{\texttt{base}}$

$\mathbf{TFIDF_i}$	0.508	0.110	0.626
$\mathbf{TFIDF} \times \mathbf{TF_i}$	0.438	0.078	0.551
$\mathbf{TFIDF} \times \mathbf{IDF_i}$	**0.689**	**0.145**	**0.702**

Table 3: Comparison between different topic word selecting methods on 20Newsgroups using Unsup-SimCSE(RoBERTa$_{\texttt{base}}$)+UMAP with $K = 30$.

and BERT$_{\texttt{base}}$+UMAP outperforms BERTopic in most metrics, especially on topic coherence. This suggests that c-TF-IDF tends to discover incoherent words from each cluster to maintain a high topic uniqueness. Instead, our proposed method, $\mathbf{TFIDF} \times \mathbf{IDF_i}$, considers the locally important words and globally infrequent words at the same time. We provide more comparison of the word selecting methods in Section 4.4.

Clustering-based topic models are robust to various lengths of documents. From Table 2 and Figure 2, we find that clustering-based models with high-quality embeddings (SBERT and SimCSE) consistently perform better than conventional LDA and NTMs, especially on the short text dataset M10, even with different word selecting methods.

4.4 Ablation Studies

We further investigate the impact of the topic word selecting methods, different embedding dimensionalities, as well as the topic numbers.

Topic word selecting methods. Table 3 shows the comparison between different word weighting methods. $\mathbf{TFIDF} \times \mathbf{IDF_i}$ achieves significantly better results among all methods. This indicates that $\mathbf{TFIDF}$ marks out the important words to each document in the entire corpus, while $\mathbf{IDF_i}$ penalizes the common words in multiple clusters. Conversely, the other three methods ignore that frequent words in a cluster may also be prevalent in other clusters, hence selecting such words leading to low topic diversities. A further analysis in Appendix B also supports the observation.

Embedding dimensionality reduction. We apply UMAP to reduce the dimensionality of the sentence embeddings before clustering. As shown in Figure 3, the embeddings dimensionality negligibly affects topic quality for all word selecting methods. However, reducing to a lower dimensionality decreases the computational runtime as shown in Table 4. We compare the model runtime between the contextualized NTM CombinedTM and clustering-based models. We reduce the dimensionality of the sentence embeddings to 50 using UMAP. All models run on NVIDIA T4 GPU.

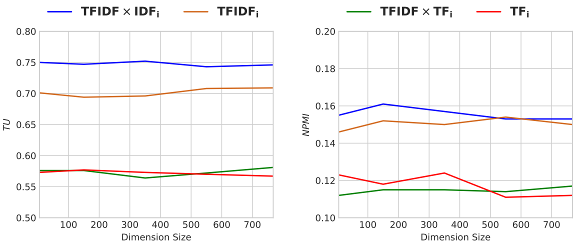

Figure 3: Topic coherence and diversity over different embedding dimensions on BBC News using Unsup-SimCSE(RoBERTa$_{\texttt{base}}$)+UMAP with $K = 30$.

Model	Runtime
CombinedTM	149s
SBERT(BERT$_{\texttt{base}}$)	113s
SBERT(BERT$_{\texttt{base}}$)+UMAP to `dim`=50	101s

Table 4: Runtime comparison on 20Newsgroups with $K = 30$. Results are averaged across 5 runs.

Topic numbers K. We investigate the impact of the different number of topics K on the performance of the models. Figure 2 plots the trends of *TU* and C_V on three datasets. We observe that the *TU* of clustering-based topic models, especially the models using $\mathbf{TFIDF} \times \mathbf{IDF_i}$, decrease slowly compared to others when K increases. The similar trend can be observed for topic coherence, while the C_V of LDA and NTMs either fluctuates significantly or stays at a low level.

5 Conclusion

We conduct a thorough empirical study to show that a clustering-based method can generate commendable topics as long as high-quality contextualized sentence embeddings are used, together with an appropriate topic word selecting strategy. Compared to neural topic models, clustering-based models are more simple, efficient and robust to various document lengths and topic numbers, which can be applied in some situations as an alternative.

A Configuration Details

We implement LDA and NTMs based on OCTIS (Terragni et al., 2021) [3] and use their default settings. Specifically, ProdLDA, CombinedTM, and ZeroShotTM share the same configurations, i.e. one hidden layer with 100 neurons, ADAM optimizer and Momentum as 0.99; we randomly dropout 20% hidden units; we run 100 epochs of each model, and the batch size is 64. For BERT+KM, we follow Sia et al. (2020) by reducing embedding dimension to 50 using Principal Component Analysis (PCA) and adopting TF to select words. For BERT+UMAP+HDBSCAN, we follow BERTopic Grootendorst (2020) and allows it to reduce the topic numbers. For our methods, we implement clustering-based experiments based on BERTopic (Grootendorst, 2020) [4]. We reduce embedding dimension to 5 using UMAP. We use BERT, RoBERTa, and SBERT embeddings provided by HuggingFace [5], and SimCSE embeddings provided from its official Github [6].

B Comparison of Topic Words

We run Sup-SimCSE(RoBERTa$_{\texttt{base}}$)+UMAP on 20Newsgroup and show the differences of topic diversities produced by distinct word selecting methods in Table 5. It is clear that $\mathbf{TFIDF_i}$ and $\mathbf{TF_i}$ tend to choose common words across multiple topics.

Topic	Weighting Method	Topic Words
Topic 1	$\mathbf{TFIDF} \times \mathbf{IDF_i}$	car bike ride engine brake tire drive mile road front
	$\mathbf{TFIDF_i}$	car bike **good** brake drive **make** ride **time** engine tire
	$\mathbf{TF_i}$	car bike **good** drive **make** **time** engine ride back **year**
Topic 2	$\mathbf{TFIDF} \times \mathbf{IDF_i}$	armenian turkish people kill israeli genocide village jewish war government
	$\mathbf{TFIDF_i}$	armenian people turkish genocide government **make** israeli kill **time** village
	$\mathbf{TF_i}$	people armenian turkish **make** kill government **time** **year** state child

Table 5: Comparison of topic words generated using different weighting methods when $K = 30$. Repeated words across topics are marked with an underline. Incoherent words are in bold.

Abstract

Existing video question answering (video QA) models lack the capacity for deep video understanding and flexible multistep reasoning. We propose for video QA a novel model which performs dynamic multistep reasoning between questions and videos. It creates video semantic representation based on the video scene graph composed of semantic elements of the video and semantic relations among these elements. Then, it performs multistep reasoning for better answer decision between the representations of the question and the video, and dynamically integrate the reasoning results. Experiments show the significant advantage of the proposed model against previous methods in accuracy and interpretability. Against the existing state-of-the-art model, the proposed model dramatically improves more than $4\%/3.1\%/2\%$ on the three widely used video QA datasets, MSRVTT-QA, MSRVTT multi-choice, and TGIF-QA, and displays better interpretability by backtracing along with the attention mechanisms to the video scene graphs.

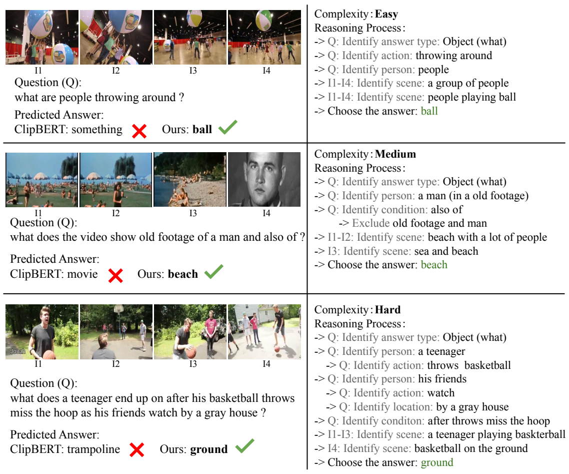

Figure 1: Error cases of the previous state-of-the-art method (Lei et al., 2021) that needed multistep reasoning. We demonstrate the multistep reasoning process based on question and video(left).

1 Introduction

Video question answering (video QA) aims to answer questions according to the given videos. It is usually defined as a classification task, where the most appropriate answer is chosen from a candidate list for the given question and video. Existing methods for video QA conduct direct answering selection based on the multimodal encoding of questions and videos (Jang et al., 2017; Lei et al., 2018, 2020). In recent years, researchers have proposed many optimization strategies for better performance in video question answering, e.g., designing delicate encoding mechanisms (Kim et al., 2020a; Nuamah, 2021; Gao et al., 2018; Li et al., 2019; Fan et al., 2019; Le et al., 2020; Jiang et al., 2020; Kim et al., 2020b; Seo et al., 2021), introducing video scene graphs (Garcia and Nakashima, 2020), adopting video pre-trained language models (Li et al., 2020; Zellers et al., 2021; Li and Wang, 2020; Lei et al., 2021; Sun et al., 2019), and leveraging external knowledge or resources (Chadha et al., 2020; Garcia et al., 2020; Liu et al., 2020b; Song et al., 2021; Garcia and Nakashima, 2020). Compared with conventional monomodal question answering tasks such as text QA (Oguz et al., 2021; Zhou et al., 2018; Lin et al., 2018) and table QA (Cao et al., 2021; Wang et al., 2019). Video QA is more difficult due to the need for crossmodal understanding and reasoning of the video and the question. Existing methods are mainly concerned with how to encode the crossmodal features better. When faced with a complex question, they usually lack the abilities of deep understanding and complex reasoning.

Similar to the situations in text QA and table QA, it is also necessary for video QA to deeply understand the semantics of the context, namely, the video, and the reasoning on the context and the question. Statistical analysis on several datasets

(a). Existing methods (b). ClipBERT (2021) (c). Ours

Figure 2: Comparison of our model architecture with (a). popular video-and-language learning paradigm and (b).ClipBERT. In contrast to most previous methods that adopt simple and implicit reasoning mechanisms, Our method uses video scene graphs to represent the video semantic information and adopt a dynamic multistep reasoning mechanism.

reveals that a significant percentage of failed cases of the state-of-the-art (SOTA) model ClipBERT (Lei et al., 2021) is caused by the lack of deep understanding and reasoning. Figure 1 shows some error cases of the SOTA model on MSRVTT-QA. We randomly select one hundred error cases and find that about 24% of the error cases need multiple steps of reasoning on the question and the video, and about 15% of the error cases need a deep understanding of the semantic of the video. These cases could be solved by a model emphasizing deep understanding and reasoning. The questions in these three datasets are relatively simple according to the building procedures (Xu et al., 2017a; Yu et al., 2018a; Jang et al., 2017). It will be more valuable for video QA to enable deep understanding and reasoning on the question and the video in realistic application scenarios.

In this work, we propose a novel dynamic reasoning model for video QA to overcome the weakness of previous models in deep understanding and reasoning. It first creates the video semantic representation from the video scene graph, which is composed of the semantic elements of the video and the semantic relations between these elements. Then it conducts multistep reasoning of the question based on the video semantic representation to generate a series of video-aware question representations. Finally, it generates the most appropriate question representation for the final answering decision by dynamically integrating these video-aware question representations according to the reasoning complicity prediction. Figure 2 shows the overall architecture of the proposed model and the comparison with previous methods. It simulates the reasoning procedure of human beings, while previous methods follow the pipeline of multimodal encoding and answering selection. In addition, the proposed model enables the decomposition of question understanding and video understanding, thus leading to more opportunities for future optimization. On the one hand, more external knowledge resources and better reasoning architectures can be introduced for better video QA performance. On the other hand, it can act as a unified framework for different QA tasks such as video QA, table QA, and text QA.

We verify the proposed model on three well-known datasets, MSRVTT-QA (Xu et al., 2017a), MSRVTT multi-choice (Yu et al., 2018a), and TGIF-QA (Jang et al., 2017), widely used in recent video QA works (Jang et al., 2017; Gao et al., 2018; Li et al., 2019; Fan et al., 2019; Le et al., 2020; Zhu and Yang, 2020; Lei et al., 2021; Seo et al., 2021). Experiments show that our model achieves dramatic improvement over the powerful state-of-the-art model ClipBERT (Lei et al., 2021), with an average accuracy increment of more than 3 percentage points. Ablation studies show that the dynamic reasoning strategy significantly outperforms previous implicit simple reasoning strategies. The video semantic representation based on the video scene graph makes the dynamic reasoning strategy work better. Backtracing along with the at-

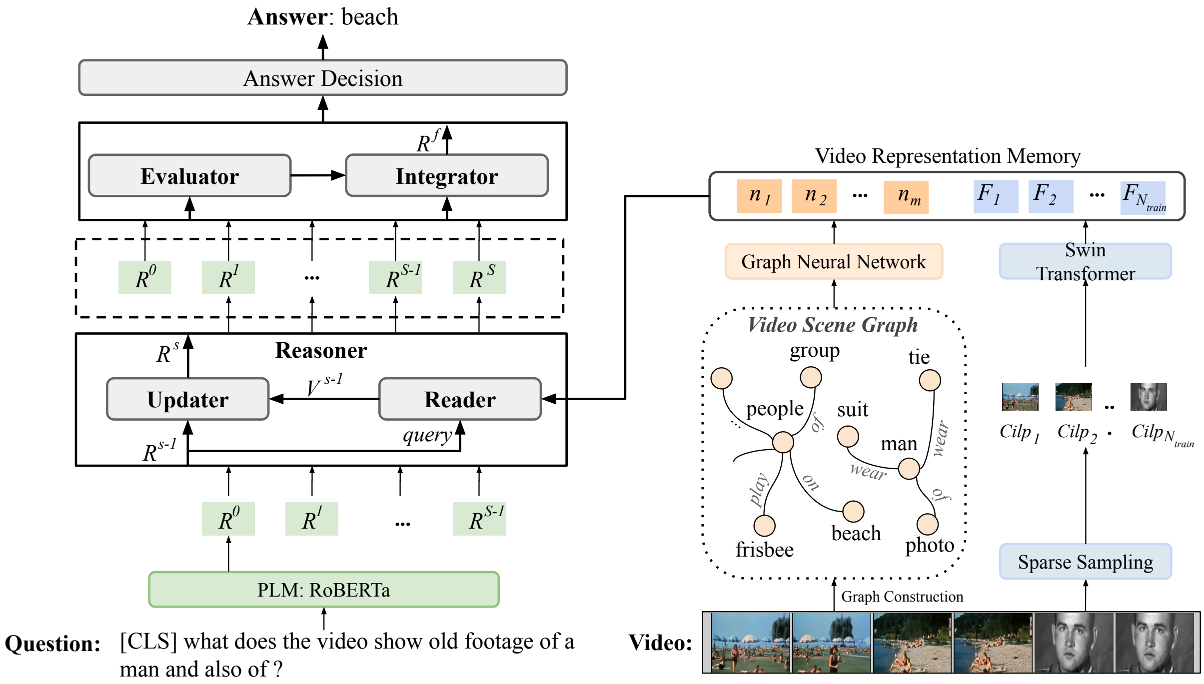

Figure 3: Overview of our model architecture. It contains two part: 3.2. Video Representation Learning (right) and 3.3. Dynamic Multistep Reasoning (left)

tention mechanism to the video scene graph clearly shows the semantic elements that answer decision relies on each reasoning step, thus giving better interpretability than most of the previous methods.

2 Background

Given the question q, video question answering requires choose the correct answer $\hat{a}$ from the candidates set Ω_a according to the video content V.

$$\hat{a} = \underset{a \in \Omega_a}{\operatorname{argmax}} p(a|q, V; \theta) \tag{1}$$

As Figure 2 (a) shows, most existing works utilize offline (stop gradient) extracted dense video features and text features. As Figure 2 (b) shows, ClipBERT (Lei et al., 2021) achieves the state-of-the-art by using sparsely sampled clips and raw text for end-to-end training, yet suffer from two main drawbacks: (i) Lack of a deep understanding of the video content and reasoning on the question based on the video. (ii) Strong coupling between video and question modeling process, which needs additional image-text pair data for pre-training to enhance the ability of the text encoder to model multimodal features and leads to poor scalability and repeated computation. As shown in Figure 2 (c), we propose a simple but effective architecture to solve the weakness of previous works. It first decouples the question understanding module and the video understanding module. Then, we introduce the video scene graph to get a better representations of the video semantic information, which can enhance the understanding of the video content and its graph structure is also better for reasoning. At last, we design a dynamic multistep reasoning mechanism to iteratively deepen the understanding of the question according to the video content.

3 Method

3.1 Overall Architecture

Figure 3 gives an overview of the model architecture. For the visual representation, we use both video scene graphs and image features. On the one hand, we construct a video scene graph to represent semantic information in a structural form. On the other hand, we use Swin Transformer (Liu et al., 2021) to extract image features to make up for the missing information of the scene graph. The reasoning module (***Reasoner***) will iteratively updates the understanding of the question according to the video content. The ***Evaluator*** will decide the number of reasoning steps according to the complexity of the question. The ***Integrator*** will integrate all intermediate reasoning results to get the final reasoning results. The answer decision module chooses an answer according to the final comprehensive understanding of the question.

3.2 Video Representation Learning

We chose a structured video scene graph to describe video semantics which is better for reasoning. We also extract image features by Swin Transformer (Liu et al., 2021) to make up for the missing information in the scene graph. The video scene graph and the image features constitute the *Video Representation Memory* shown in Figure 3, a memory for the ***Reader*** module to access.

3.2.1 Video Scene Graph

The video scene graph is the basis for conducting dynamic reasoning, it is a graph-based semantic representation of video content, representing the objects in the video, their attributes, and their relationships in a structured form. Unlike the image scene graph commonly used in visual question answering, our video scene graph is semantically richer and contains spatio-temporal information of the video. Specifically, We first use an image captioning model to generate captions for each clip. Then we use the scene parser (Schuster et al., 2015) to convert each caption sentence into a semantic sub-graph and integrate the same nodes of each sub-graph to obtain a video scene graph. Compared to caption sentences, the video scene graph represents the video-level semantic information in a structured form, better modeling the visual semantic information.

Graph Representation Learning We first obtain the embeddings of nodes $\mathbf{n} = \{n_1, n_2, ..., n_m\}$ and edges in the video scene graph via a parameter-sharing language encoder. Then, we use graph attention neural network (Veličković et al., 2017) iteratively to update the representation of the scene graph. Each node updates its representation based on the correlation with its neighbor nodes.

$$\mathbf{n}_i^{'} = a_{ii}\mathbf{W}\mathbf{n}_i + \sum_{j \in \mathcal{N}_i} a_{ij}\mathbf{W}\mathbf{n}_j \tag{2}$$

where $\mathbf{W}$ is a weight matrix, a_{ij} is the attention weight of node $\mathbf{n}_i$ and $\mathbf{n}_j$, and $\mathcal{N}_i$ is the neighbors of the node $\mathbf{n_i}$ in the graph. In our experiments, we use standard graph attention neural network setting, applying the LeakyReLU nonlinearity (with negative input slope $\alpha = 0.2$). At the same time, the edges have explicit meanings of relations between nodes, so we also consider edges features $\mathbf{e}_{ij}$ when calculating attention weight. The attention weight a_{ij} are computed as

$$a_{ij} = \frac{\exp(\mathrm{LeakyReLU}(\mathrm{A}(\mathbf{n}_i, \mathbf{n}_j, \mathbf{e}_{ij})))}{\sum_{k \in \mathcal{N}_i} \exp(\mathrm{LeakyReLU}(\mathrm{A}(\mathbf{n}_i, \mathbf{n}_k, \mathbf{e}_{ik})))} \tag{3}$$

$$\mathrm{A}(\mathbf{n}_i, \mathbf{n}_j, \mathbf{e}_{ij}) = \mathbf{W_a}^{\top}[\mathbf{W}\mathbf{n}_i || \mathbf{W}\mathbf{n}_j || \mathbf{W}_e\mathbf{e}_{ij}] \tag{4}$$

where $.^{\top}$ represents transposition, $||$ is the concatenation operation and the $\mathbf{W_a}$ and $\mathbf{W_e}$ are weight matrices.

3.2.2 Image Features

We extract image features to make up for the missing information in the scene graph. First, we use Lei et al.'s sparse sampling method to sparsely and randomly sample N_{train} clips $\{c_i\}_{i=1}^{N_{train}}$ from video. N_{train} is typically much smaller than the entire video length N. This sampling method can reduce the computation cost and obtain better performance than dense sampling. For inference, we uniformly sample N_{test} clips of the same duration. Swin Transformer (Liu et al., 2021) is one of the mainstream visual backbone networks. It alleviates the problem of large variations in the scale of visual entities and the high resolution of pixels in images. We use it as a vision encoder $\mathcal{E}_v$ to extract clip features $\{F_i\}_{i=1}^{N_{train}}, F_i = \mathcal{E}_v(c_i) \in \mathbb{R}^{w \times w \times d}$, where w is the window size and d is the feature dimension.

3.3 Dynamic Multistep Reasoning

Humans will deepen their understanding of a complex question through repeated reading the context information. The more complex the question, the more repetitions are required (Chang and Millett, 2013; Gorsuch and Taguchi, 2008; Carver and Hoffman, 1981). At each step of reading, people will focus on different parts of the context information. Inspired by it, we designed the dynamic multistep reasoning mechanism. It will iteratively update the understanding of the question based on the video representations. We first extract the question representation by language model RoBERTa (Liu et al., 2019). Specifically, we concatenate the question text with a special token [CLS] as the input and take the [CLS]'s hidden state R^0 as the representation of the question. At the first reasoning step, we select R^0 as the input. Then, we get question-related information from Video Representation Memory through the ***Reader***, which is an attention mechanism. Then, we use this retrieved video information to update the understanding of the question and get the first reasoning step result R_1 through the ***Updater***. At the next reasoning step, we select R_1 as the input. After S steps of reasoning, we obtain all results $\mathbf{R} = \{R^0, R^1, R^2, ..., R^S\}$.

$$R^s = \text{Updater}(R^{s-1}, V^{s-1}) \tag{5}$$

Updater consists of two linear transformations with a ReLU activation in between.

$$\text{Updater}(Q, K) = Q + \text{ReLU}(\mathbf{W_1}K + b_1)\mathbf{W_2} + b_2 \tag{6}$$

where $\mathbf{W_1}$ and $\mathbf{W_2}$ are weight matrices and b_1 and b_2 are biases. V_{s-1} represents question-related video information.

$$V^{s-1} = \text{Reader}(R^{s-1}, \mathbf{Vid}) \tag{7}$$

where $\mathbf{Vid}$ consists of the node features $\{n_1, n_2, ..., n_m\}$ of the video scene graph and image features $\{F_1, F_2, ..., F_{N_{train}}\}$. We use Scaled Dot-Product Attention (Vaswani et al., 2017) as the ***Reader***. The input consists of query Q, and context K of dimension d_k.

$$\text{Reader}(Q, K) = \text{softmax}(\frac{QK^\top}{\sqrt{d_k}})K \tag{8}$$

The word *dynamic* has two meanings: (i). dynamically decide the number of reasoning steps according to the question's complexity. ***(3.3 Evaluator)***. (ii). dynamically integrate the results of all reasoning steps as the final result. ***(3.3 Integrator)***.

Evaluator When humans begin faced with different complexity questions, they will dynamically adjust the number of times to read relevant information (Chang and Millett, 2013; Gorsuch and Taguchi, 2008; Carver and Hoffman, 1981). We propose the first dynamic reasoning strategy by imitating the human reading and understanding mechanisms. It will decides the number of reasoning steps according to the complexity of the question. Specifically, we perform a nonlinear transformation with GumbelSoftmax as activation function on the question representation R^0, and output an S-dimensional vector $\text{D}(R_0) \in \mathbb{R}^{1\times \text{S}}$ to represents the distribution probability of the number of reasoning steps from 1 to S.

$$\text{D}(R_0) = \text{GumbelSoftmax}(\mathbf{W_d}R^0 + b) \tag{9}$$

Where $\mathbf{W_d}$ is a weight matrix, and b is a bias. We choose the one with the greatest probability as the number of the reasoning steps S.

Integrator In the reasoning process, the ***Reader*** pays attention to the different parts of the video content at each step to gradually deepen the question's understanding. Therefore, we think the intermediate reasoning results are also helpful in choosing an answer. After S steps of reasoning, we select all intermediate reasoning results as input and perform a nonlinear transformation with softmax function to calculate the distribution of the weight of $\mathbf{R}$ and get the weighted sum as the final reasoning results R^f.

$$R^f = \text{softmax}(\mathbf{W_f}\mathbf{R} + \mathbf{b})\mathbf{R} \tag{10}$$

where $\mathbf{W_f}$ is a weight matrix and b is a bias.

3.4 Answer Decision

Given the final reasoning results R^f, we use two fully-connected layers as a classifier to obtain the logits l_f for the answer options. Then we use a softmax function to obtain the probability distribution of each answer option and apply cross-entropy loss as our model loss $\mathcal{L}$.

$$l_f = \text{classifier}(R^f) \tag{11}$$

$$\hat{y} = \text{softmax}(l_f),\ \mathcal{L} = -\sum_{i=1}^{M} y_i log\hat{y_i} \tag{12}$$

4 Related Work

Video QA requires fine-grained modeling of multimodal features. We have witnessed many efforts devoted to video understanding for video QA. Some methods use visual techniques such as object detection (Ren et al., 2016) and image captioning (Johnson et al., 2016; Rennie et al., 2017) to extract additional visual information (Kim et al., 2020a). In recent years, visual pre-training based on large-scale data has become a popular method to improve video applications including video QA (Li et al., 2020; Zellers et al., 2021; Li and Wang, 2020; Sun et al., 2019). In addition, several advanced techniques such as contrastive self-supervised learning (Kim et al., 2020b) and symbolized video scene graph (Garcia and Nakashima, 2020) are proposed to improve the performance of video understanding for video QA. We extract video semantic representations based on both the visual pre-training model (Liu et al., 2021) and the video scene graphs. Experiments show the amazing complementarity of the two kinds of information.

Video QA also requires flexible reasoning for complicated questions and videos. Although the reasoning capability is rarely emphasized in previous work for video QA, it is broadly investigated in other QA tasks (Clark et al., 2018). For example, text QA resorts to iterative update of the question and the context (Das et al., 2019; Liu et al., 2020a), table QA generates a structural query such as SQL which is then executed on the tabular data (Guo et al., 2019), and visual QA builds a specific module network according to the question and runs it on the image (Andreas et al., 2016; Cao et al., 2018; Hu et al., 2017). The overall architecture of the proposed method is similar to the iterative reasoning strategies for text QA but with significant innovation. Our model can dynamically determine the best integration strategy for the intermediate reasoning results according to the given question and video, leading to better interpretability and much better performance.

5 Experiments

In this section, we validate our method on three mainstream video QA datasets. We conduct comparison experiments with previous works and perform ablation experiments to analyze the critical improvement in our proposed method. We use standard train/val/test splits for all datasets and use accuracy to measure the performance. All experimental results are the mean and standard deviation of ten replicate experiments.

5.1 Datasets

MSRVTT-QA MSR-VTT (Xu et al., 2016) is a large video description dataset. It provides 10k web video clips with 41.1 hours and 200k clip-sentence pairs in total. MSRVTT-QA (Xu et al., 2017a) is created based on clip-sentence pairs in MSR-VTT automatically through a program. It contains 243k open-ended questions with 1500 answers.

MSRVTT-MC MSRVTT-MC (multiple-choice) (Yu et al., 2018a) is a dataset for video-text matching tasks built on MSR-VTT with videos are used as queries, captions as answers. Each video contains five captions. Only one is correct.

TGIF-QA TGIF-QA (Jang et al., 2017) dataset contains 165K QA pairs for the animated GIFs from the TGIF dataset. We experiment on 3 TGIF-QA tasks: Repeating Action and State Transition for multiple-choice QA and Frame QA for open-ended QA. We follow most previous works and ClipBERT's (Lei et al., 2021) approach to leave the Count task as future work as it requires directly modeling full-length videos.

5.2 Results and Analysis

5.2.1 Comparison with existing approaches

As shown in Table 1, our method reaches the new state-of-the-art and achieves $\mathbf{41.6\%/91.4\%/84.6\%, 90.1\%, 62.5\%}$ accuracy on MSRVTT-QA/MSRVTT-MC (multi-choice) /TGIF-QA (Action, Transition, FrameQA), with $\mathbf{4.2\%/3.2\%/1.8\%, 2.3\%, 2.2\%}$ improvement over the previous state-of-the-art method ClipBERT (Lei et al., 2021). The *Pre-training data* column represents that the model was pre-trained with additional data. The results show that our method achieves the best performance on all three video question answering datasets without using additional data.

5.2.2 Ablations Analysis

Comparsion of Different Architectures We compare the three architectures shown in Figure 2, namely, the widely-adopted architecture based on Cross-Modal Encoding, ClipBERT, and the architecture proposed in this paper. For all architectures, we use RoBERTa (Liu et al., 2019) as a language encoder and Swin Transformer (Liu et al., 2021) as a vision encoder. We sparsely sample 8 clips from each video, then uniformly sample a single frame within each clip. In addition, we remove the video scene graph from our model and only conduct single-step reasoning to ensure fairness. Other hyper-parameters are the same for all models. The results are given in Table 2, which show that our architecture achieves the best performance, in spite of the removing of the video scene graph and only conducting single-step reasoning. This may because that the proposed architecture makes decisions based on the global video information, unlike ClipBERT (Lei et al., 2021) and most other methods, which integrates the decision made by each clip to get the final decision. Furthermore, unlike previous works, we make a more apparent distinction between the process of question understanding, video understanding, reasoning, and answer deci-

Table 3: **Impact of the video scene graph.**

sion, providing a basis for introducing video scene graphs and dynamic multistep reasoning.

Analysis of Video Scene Graph We introduce the video scene graph to get a structural visual semantic representation which is better for reasoning. We use all architectures shown in Figure 2 as the benchmarks to evaluate the effect of the video scene graph. We use an image captioning model to extract captions for each clip. Then we use the scene parser (Schuster et al., 2015) to convert each caption sentence into a semantic sub-graph and integrate the same nodes of each sub-graph to obtain a video scene graph. We use a 2-layer Graph Attention Network (Veličković et al., 2017) with 12 heads to learn the representations of the scene graph. As shown in Table 3, adding the clip-level captions improves performance. And the video scene graph brings further improvement. The video scene graph contains video-level semantic information in a structural form. Therefore, it can better represent key semantic information and reduce redundant information.

Analysis of Dynamic Reasoning As Table 4 shows. We first evaluate the simple static reasoning mechanism adopted by most previous works. Then we evaluate the performance of the 3.3 ***Evaluator*** and 3.3 ***Integrator***. Row 0 shows the result of the single-step reasoning, achieving 39.5% accuracy on MSRVTT-QA. As expected, the static multistep reasoning mechanism (row 1-4) performs better and achieves the best performance around $Step = 3$. But the performance does not increase when setting a larger number of steps. It means that the average complexity of all questions is moderate, which can be handled well with three-step reason-

	Step Strategy	Integration Strategy	Step	MSRVTT (Acc.)	
				QA	MC
0	Single-Step	-	1	39.5 ± 0.14	89.9 ± 0.11
1	Static Multistep	-	2	40.2 ± 0.12	90.4 ± 0.09
2			3	40.6 ± 0.12	90.6 ± 0.12
3			4	40.4 ± 0.13	90.4 ± 0.10
4			5	40.2 ± 0.11	90.2 ± 0.10
5	Evaluator	-	≤ 5	40.8 ± **0.05**	90.7 ± **0.04**
6	Static Multistep	MeanPooling	2	39.8 ± 0.11	90.3 ± 0.10
7			3	40.2 ± 0.10	90.4 ± 0.12
8			4	40.1 ± 0.13	90.4 ± 0.09
9			5	39.8 ± 0.12	90.2 ± 0.08
10		MaxPooling	2	40.3 ± 0.08	90.4 ± 0.07
11			3	40.9 ± 0.09	90.5 ± 0.08
12			4	40.6 ± 0.07	90.7 ± 0.09
13			5	40.8 ± 0.08	90.6 ± 0.07
14		Integrator	2	40.4 ± 0.05	90.5 ± 0.04
15			3	41.0 ± 0.04	90.7 ± 0.04
16			4	40.8 ± 0.06	90.8 ± 0.06
17			5	40.7 ± 0.04	90.6 ± 0.05
18	Evaluator	Integrator	≤ 5	**41.6 ± 0.02**	**91.4 ± 0.03**

Table 4: **Impact of dynamic reasoning strategy.** When using a static reasoning strategy, the model will execute multistep reasoning with a fixed number of steps. When using a dynamic reasoning strategy, the model will dynamically determine the number of steps of multistep reasoning according to the problem's difficulty (***Evaluator***) and dynamically get the weight sum of intermediate reasoning results as the input of answer decision (***Integrator***).

ing. The ***Evaluator*** can dynamically decide the number of reasoning steps (≤ 5) for each question. Row 5 shows that using different numbers of reasoning steps for questions of different complexity can perform better than a static multistep reasoning mechanism. At the same time, we believe that each step of reasoning pays attention to different parts of the video content and gradually deepens the understanding of the question. Therefore, the intermediate reasoning results are also helpful in choosing an answer. Row 6-17 show that the ***Integrator*** can further improves the performance and has better integration ability than the traditional pooling method. Row 18 shows that the Evaluator and Integrator can promote each other and achieve the best performance.

5.3 Interpretability

Our model is interpretable by visualizing the attention weight of the ***Reader***. As Figure 4 shows, we conclude with the following two conclusions: (1) **Video scene graph can better represents the visual semantic information.** The Video Scene Graph contains the global semantic information of the video, and the structured form can not only highlight the critical semantic elements but also reduce the interference of redundant information. (2) **Dynamic multistep reasoning mechanism can deepen the understanding of the question iteratively.** With the reasoning process, the semantic nodes related to the question obtain more and more attention. On the contrary, the attention weight of the irrelevant nodes reduced gradually. It shows that the dynamic multistep reasoning mechanism can deepen the understanding of the question.

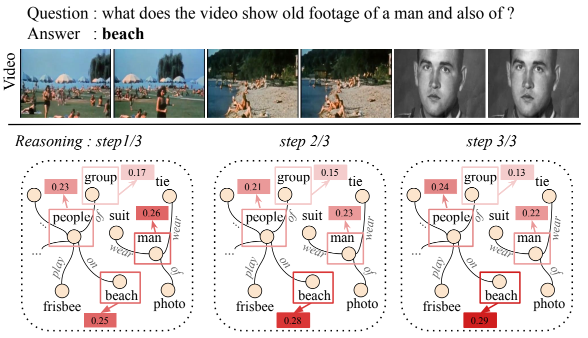

Figure 4: **Visualization for Dynamic Multistep Reasoning.** We trace the attention weight distribution of the ***Reader*** to visualize the dynamic multistep reasoning process. For this case, the output of the ***Evaluator*** is $S = 3$, which means that three steps of reasoning are required. With the reasoning process, the attention weight of 'beach' is increasing. On the contrary, the attention weight of the irrelevant nodes reduced gradually. It indicates that the reasoning mechanism is gradually deepening the understanding of the question.

6 Conclusion

We propose a dynamic reasoning mechanism based on video scene graph for video QA to alleviate the drawback of existing methods, that is, lack of deep understanding and multistep reasoning. Experiments show that our method significantly surpasses previous methods on multiple video QA datasets due to better understanding and reasoning mechanisms and achieves much better interpretability by backtracing along with the attention mechanism to the video scene graph. In addition, different from the conventional manners that perform classification after crossmodal feature encoding, the model realizes the decoupling of question understanding and video understanding and the decoupling of understanding and decision-making, thus providing more possibilities for improvement. On the one hand, we can optimize video QA by introducing external knowledge, designing more effective reasoning mechanisms, defining and constructing better video scene graphs. On the other hand, we can also jointly model multimodal QA, such as QA based on videos, tables, texts, and graphs.

Abstract

Grounded text generation systems often generate text that contains factual inconsistencies, hindering their real-world applicability. Automatic factual consistency evaluation may help alleviate this limitation by accelerating evaluation cycles, filtering inconsistent outputs and augmenting training data. While attracting increasing attention, such evaluation metrics are usually developed and evaluated in silo for a single task or dataset, slowing their adoption. Moreover, previous meta-evaluation protocols focused on system-level correlations with human annotations, which leave the example-level accuracy of such metrics unclear. In this work, we introduce TRUE: a comprehensive survey and assessment of factual consistency metrics on a standardized collection of existing texts from diverse tasks, manually annotated for factual consistency. Our standardization enables an example-level meta-evaluation protocol that is more actionable and interpretable than previously reported correlations, yielding clearer quality measures. Across diverse state-of-the-art metrics and 11 datasets we find that large-scale NLI and question generation-and-answering-based approaches achieve strong and complementary results. We recommend those methods as a starting point for model and metric developers, and hope TRUE will foster progress towards even better evaluation methods.[1]

1 Introduction

A core issue in deploying text generation models for real-world applications is that they often generate factually inconsistent text with respect to the input they are conditioned on, or even completely "hallucinate" (Lee et al., 2018; Rohrbach et al., 2018; Maynez et al., 2020; Zhao et al., 2020) as exemplified in Table 1.

Summarization (Wang et al., 2020)

Input	Phyllis schlafly, a leading figure in the us conservative movement, has died at her home in missouri, aged 92...
Summary	Us conservative activist phyllis schlafly has died at the age of 87.

Fact Verification (Thorne et al., 2018)

Evidence	Ronald Bilius "Ron" Weasley is a character in J. K. Rowling's Harry Potter fictional series.
Claim	Ron Weasley is a President.

Paraphrasing (Zhang et al., 2019)

Input	The tracks were produced by Tommy Lee, and feature Michael Beinhorn on drums.
Paraphrase	The tracks were produced by Michael Beinhorn and have Tommy Lee on drums.

Knowledge-Grounded Dialogue (Honovich et al., 2021)

Knowledge	The first flip trick called a kickflip, originally called a "magic flip," was invented by professional skateboarder Rodney Mullen.
Response	I remember the first one was called magic flip. It was called a magic flip and was invented in the 60's.

Table 1: Factual inconsistencies (in red) from various tasks which are part of the TRUE study. The corresponding parts in the input/grounding are in blue.

To tackle such inconsistencies, one would like to detect them automatically by predicting whether a generated text is factually consistent with respect to a grounding text (frequently referred to as the "input", or the "knowledge"). Such automatic methods attract increasing attention (Zhou et al., 2021; Deng et al., 2021) as they enable both better evaluation and better generation models by automatically filtering training data (Gehrmann et al., 2021) or by augmenting training data for controlled generation (Rashkin et al., 2021b).

While automatically evaluating factual consistency is an active line of work, there is no single agreed-upon meta-evaluation protocol for measuring the quality of such methods, and labeling schemes vary in their granularity. Works are usu-

July 10-15, 2022

ally done in silo, introducing new datasets and methods that target a specific task or domain, such as summarization (Falke et al., 2019; Kryscinski et al., 2020; Wang et al., 2020; Scialom et al., 2021; Deutsch et al., 2021; Xie et al., 2021) or dialogue (Dziri et al., 2021; Honovich et al., 2021; Nie et al., 2021; Qin et al., 2021). Comparing the robustness of such methods *across* tasks and datasets is therefore difficult, impeding progress on this subject.

In this work, we present TRUE: a comprehensive survey and assessment of factual consistency evaluation methods, covering various metrics, tasks and datasets. We consolidate 11 existing datasets annotated for factual consistency into a unified format, including pairs of a target text and a grounding source text, with a binary annotation of whether the target text is factually consistent w.r.t its source. TRUE[2] covers summarization, knowledge-grounded dialogue, paraphrasing and fact verification.[3] The proposed standardization enables us to properly compare consistency evaluation methods in a robust manner across these various tasks and domains.

Previous works on automatic factual consistency evaluation have mainly focused on measuring system-level correlations of the proposed metrics with human judgements (Pagnoni et al., 2021). Yet, these correlations are not useful for estimating the performance of a measured metric when making *example-level, binary* decisions, decoupled from specific system implementations (see recent discussion by Deutsch et al. (2022) on the limitations of reporting correlations). Instead, we aim to measure how well a method detects inconsistent texts (*recall*) and how often it falsely disregards consistent texts (*precision*), which can be easily computed using the aforementioned binary labeling scheme. Therefore, as a meta-evaluation protocol we report the Area Under the ROC Curve (ROC AUC) with respect to inconsistent example detection for each evaluation metric and dataset.

Our thorough survey and assessment of 12 metrics draws a clearer picture on the state of evaluating factual consistency. We show that Natural Language Inference (NLI) approaches, as well as Question Generation and Answering (QG-QA) approaches achieve significantly better[4] results on a wide variety of tasks and datasets. We also show that NLI and QG-QA are complementary: combining the two yields even better results and hints at room for further improvement. Finally, we perform both quantitative and qualitative analysis of our results, finding that all approaches struggle with long inputs, labeling issues and personal statements – paving interesting avenues for future work.

To summarize, our contributions are as follows: (1) We argue that work on factual consistency evaluation should be unified and generalized across tasks, and standardize 11 published datasets into a single labeling scheme to corroborate this. (2) We propose a meta-evaluation protocol that allows more actionable and interpretable quality measures than previously reported correlations. (3) We survey and evaluate 12 diverse metrics in this unified perspective, showing that large-scale NLI and QG-QA-based approaches achieve strong and complementary results *across* tasks. (4) We analyze our results both qualitatively and quantitatively, pointing at challenges like long inputs and personal statements to be addressed in future work.

2 Standardizing Factual Consistency

In this section we elaborate on our re-evaluation setup. We first formally define what factual consistency refers to in this work. We then detail the datasets we consider and how we standardize them. Finally, we discuss the meta-evaluation protocol we propose for measuring the performance of evaluation methods on the standardized datasets.

2.1 Definitions and Terminology

We define a text to be factually consistent w.r.t its grounding text if all the factual information it conveys is consistent with the factual information conveyed by the grounding text.[5] While some previous works distinguished between inconsistent erroneous text to inconsistent correct text (Maynez et al., 2020), we take a strict approach, requiring the text to be faithful to its grounding text, regardless of the "correctness" w.r.t the "real world". In other words, we consider only the information present in the input text, not external knowledge, to assess faithfulness. This enables a more well-defined task, since determining the truthfulness of a fact w.r.t a

---

[2] The name is a homage to GLUE (Wang et al., 2018) and not an acronym.

[3] We focus on English text-to-text tasks, and leave data-to-text (Parikh et al., 2020; Reiter and Thomson, 2020), multilingual and multimodal tasks to future work.

[4] We conduct significance testing, see section 4.

[5] We exclude personal and social statements such as opinions and chit-chat from the scope of factual information.

Task	# Examples	Open Test	Cons.
Summarization			
- FRANK (Pagnoni et al., 2021)	671	+	33.2%
- SummEval (Fabbri et al., 2021a)	1,600	-	81.6%
- MNBM (Maynez et al., 2020)	2,500	-	10.2%
- QAGS-CNNDM (Wang et al., 2020)	235	-	48.1%
- QAGS-XSum (Wang et al., 2020)	239	-	48.5%
Dialogue			
- BEGIN (Dziri et al., 2021)	836	+	33.7%
- Q^2 (Honovich et al., 2021)	1,088	-	57.7%
- DialFact (Gupta et al., 2021)	8,689	+	38.5%
Fact Verification			
- FEVER (Thorne et al., 2018)	18,209	-	35.1%
- VitaminC (Schuster et al., 2021)	63,054	+	49.9%
Paraphrasing			
- PAWS (Zhang et al., 2019)	8,000	+	44.2%

Table 2: Statistics for the datasets incorporated in TRUE. Cons. is the ratio of consistent examples.

general "real world" is subjective and depends on the knowledge, values and beliefs of the subject (Heidegger, 2001). This definition follows similar strictness in Textual Entailment, Question Answering, Summarization and other tasks where comprehension is based on a given grounding text, irrespective of contradiction with other world knowledge. This is also in line with recent work on evaluating attribution in text generation (Rashkin et al., 2021a), where humans are required to judge whether a generated text is attributable to a grounding text. We use the terms *consistent*, *grounded*, *faithful* and *factual* interchangeably.

2.2 Standardization Process

We include 11 datasets that contain human annotations w.r.t factual consistency in diverse tasks (Table 2). Other than the importance of covering a wide variety of error types, this also alleviates issues of rating quality which may vary across datasets (Denton et al., 2021).

To allow a unified evaluation framework we convert all annotations to binary labels that correspond to whether the entire target text is factually consistent w.r.t the given grounding text or not. We note that a fine-grained annotation scheme, i.e., a typology of errors, was proposed for factual consistency (Pagnoni et al., 2021). While useful, most existing datasets do not include such labels. Moreover, while Machine Translation (MT) evaluation also showed value in fine-grained annotations (Freitag et al., 2021), it was proposed after years of improving MT to the level where coarse-grained annotation is insufficient. We argue that current grounded generation models are still at early stages w.r.t factual consistency, making binary labeling more beneficial now as it enables easier standardization across tasks and domains, with the goal of bringing researchers to collaborate on a shared methodology. Binary annotation also corresponds to practical applications where filtering out unfaithful predictions is desired, and is in-line with the recommendations for human evaluation of attribution in text generation by Rashkin et al. (2021a).

We next detail the 11 datasets included in TRUE.

2.2.1 Abstractive Summarization

FRANK Pagnoni et al. (2021) proposed a typology of factual errors, grounded in frame semantics (Fillmore, 1976; Palmer et al., 2005) and linguistic discourse theory (Brown and Yule, 1983). Based on this typology, they collected annotations for model-generated summaries on the CNN/DailyMail (CNN/DM; Hermann et al., 2015) and XSum (Narayan et al., 2018) datasets, resulting in 2250 annotated system outputs. Each summary sentence was annotated by three annotators. We take the majority vote for each sentence to get a sentence-level label and consider a summary as consistent if all sentences are consistent.

SummEval SummEval (Fabbri et al., 2020) is a comprehensive study of evaluation metrics for text summarization. The authors collected human judgments for 16 model outputs on 100 articles taken from the CNN/DM dataset, using both extractive and abstractive models. Annotators were asked to rate summaries on a Likert scale from 1 to 5, over 4 dimensions: *consistency*, *coherence*, *fluency* and *relevance*. Each summary was scored by 5 crowd-workers and 3 expert annotators. We label summaries as consistent only if all the expert annotators gave a *consistency* score of 5.

MNBM Maynez et al. (2020) annotated system outputs for the XSum dataset (Narayan et al., 2018). They sampled 500 articles and annotated summaries generated by four different systems, as well as the gold summaries. Annotators were asked to assess whether the summary includes hallucinations. Judgments from three different annotators were collected for each document-summary pair. To convert to a binary-label format, we use the binary consistency decision of whether a summary contains no hallucinations, and assign a label by taking the majority vote of the three annotators.

QAGS Wang et al. (2020) collected judgments of factual consistency on generated summaries for CNN/DM and XSum. Annotators were presented with the summaries one sentence at a time, along with the article, and determined whether each sentence is factually consistent w.r.t the article. Each sentence was annotated by 3 annotators, using the majority vote as the final score. To convert to binary-label format, we consider a summary consistent only if all its sentences are consistent.

2.2.2 Dialogue Generation

BEGIN (Dziri et al., 2021) is a dataset for evaluating groundedness in knowledge-grounded dialogue systems, in which system outputs should be consistent with a grounding knowledge provided to the dialogue agent. BEGIN frames the task as textual entailment (Dagan et al., 2006; Bowman et al., 2015), adopting the *entailment* and *contradiction* labels, and splitting the neutral label into three subcategories: *hallucination*, *off-topic* responses and *generic* responses. Dialogue responses were generated by fine-tuning two systems on the Wizard of Wikipedia (WoW) dataset (Dinan et al., 2019), in which responses should be grounded in a span of text from Wikipedia. The generated responses were split into sentences, and each sentence was annotated separately. To convert to a binary-label format, we treat entailed sentences as consistent and all others as inconsistent.

Q^2 Honovich et al. (2021) annotated 1,088 generated dialogue responses for binary factual consistency w.r.t the knowledge paragraph provided to the dialogue model, for two dialogue models trained on WoW. Responses were annotated using binary labels by 3 of the paper authors, one annotator per response. We use Q^2's labels without changes.

DialFact Gupta et al. (2021) introduced the task of fact-verification in dialogue and constructed a dataset of conversational claims paired with pieces of evidence from Wikipedia. They define three tasks: (1) detecting whether a response contains verifiable content (2) retrieving relevant evidence and (3) predicting whether a response is *supported* by the evidence, *refuted* by the evidence or if there is *not enough information* to determine. We use the verifiable (i.e., factual, rather than personal) responses annotated for the third task, treating *supported* annotations as consistent and the rest as inconsistent. In cases where several evidence were marked as required for verification, we concatenate all evidence sentences to be the grounding text.

2.2.3 Fact Verification

FEVER Thorne et al. (2018) introduced FEVER (Fact Extraction and VERification), a dataset for fact verification against textual sources. FEVER was constructed by extracting information from Wikipedia, generating claims using annotators, then labeling whether each claim is *supported* or *refuted* by Wikipedia. Claims can also be labeled with *NotEnoughInfo*, meaning that there is not enough information in Wikipedia to either verify or refute the claim. Given a claim, the task defined by FEVER is to first extract evidence, then to determine whether it supports or refutes the claim. In a slightly different framing, the latter stage in FEVER is to determine whether the claim is factually consistent or not w.r.t the evidence, which is aligned with what we aim to measure in TRUE. We use the development set of the NLI version of FEVER (Nie et al., 2019, 2020), treating *supported* claims as consistent and the rest as inconsistent.

VitaminC Schuster et al. (2021) derived a large-scale fact verification dataset from factual revisions to Wikipedia pages. Each example includes an evidence text from Wikipedia and a fact, with an annotation of whether the fact is supported, refuted or neutral w.r.t the evidence. The authors collected factual revisions to Wikipedia articles (pairs of "before" and "after" sentences), and asked annotators to write two facts for each pair: one that is *supported* by the first sentence and *refuted* by the second, and vice versa. When no explicit contradiction was present, the annotators wrote facts that are *neutral* w.r.t the evidence. Additional examples were created by revising examples from FEVER. We treat examples that include *supported* facts as consistent, and *refuted* or *neutral* facts as inconsistent.

2.2.4 Paraphrase Detection

PAWS Zhang et al. (2019) constructed a dataset for paraphrase identification with 108,463 paraphrase and non-paraphrase pairs with high lexical overlap, generated by controlled word swapping and back-translation, followed by judgments from human raters. Source sentences were drawn from Wikipedia and the Quora Question Pairs (QQP) corpus. We only use the examples with Wikipedia source sentences and view the binary paraphrase labels as consistency labels. We note that the definition of paraphrase is not equivalent to the definition of factual consistency, as a subset of a source text is not a paraphrase but may still be factually consistent with the source. However, PAWS was constructed such that non-paraphrases usually have contradicting meanings and is therefore relevant.

2.3 Meta-Evaluation

Previous work on evaluating factual consistency focused on measuring correlation with human judgements (Pagnoni et al., 2021) to compare different metrics. However, such system-level numbers are not very informative when one is interested in evaluating the absolute performance of inconsistency detection methods that perform a *binary* decision w.r.t each input. Deutsch et al. (2022) also recently discuss various issues in measuring system-level correlations to assess the validity of automatic evaluation metrics for summarization.

To conduct a more fine-grained evaluation at the single example level, we report the Receiver Operating Characteristic Area Under the Curve (ROC AUC) w.r.t binary detection of inconsistent examples.[6] The ROC curve is created by plotting the *true positive rate* (TPR, a.k.a. the recall) against the *false positive rate* (FPR, a.k.a. the fallout) at different possible thresholds for each tested metric. Measuring ROC AUC evaluates the different metrics without setting a specific decision threshold.

For datasets with existing development/test split, we also tune a threshold for the binary consistency/inconsistency decision on the development set and report the test set accuracy using this threshold. We tune the thresholds by optimizing the geometric mean of the TPR and 1-FPR: $\sqrt{\text{TPR} * (1 - \text{FPR})}$.

3 Evaluation Metrics

We compare various standard as well as state-of-the-art approaches to measure factual consistency. This comparison should draw a clear picture of current research on this subject and raise directions for future work. For example, we expect that robust metrics should perform well across various tasks and datasets. We next describe the different metrics we assess as part of this study. We note that for all reference-based metrics, we use the grounding text as the reference. For metrics where the scores are not in the [0,1] range, we normalize the scores to be in that range.

3.1 N-Gram Based Metrics

Standard N-Gram matching metrics such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) and token-level F1 were shown to have weak correlation with factual consistency (Maynez et al., 2020; Honovich et al., 2021). We add them as baselines to this study mainly to corroborate this claim on a wide set of datasets and tasks.

3.2 Model-Based Metrics

BERTScore (Zhang et al., 2020) aggregates similarity scores between the BERT contextual embedding of tokens in candidate and reference sentences. We report results for the BERTScore-precision variant as it showed better results in preliminary experiments. We use BERTScore version 0.3.11 with the DeBERTa-xl-MNLI model (He et al., 2021; Nangia et al., 2017), which is the recommended model as of the time of writing this paper.[7]

BLEURT (Sellam et al., 2020a,b) is a learned metric based on BERT (Devlin et al., 2019) for evaluating text generation. BLEURT includes additional pretraining on synthetic data followed by fine-tuning on human judgements to train a model that scores system outputs. We use the recommended BLEURT-20 checkpoint (Pu et al., 2021).[8]

FactCC (Kryscinski et al., 2020) is a BERT-based metric for verifying the factual consistency of summaries. It is trained on synthetically generated data obtained by applying rule-based transformations to generate consistent and inconsistent summaries.

BARTScore (Yuan et al., 2021) evaluates text using probabilities from force-decoding with a BART model (Lewis et al., 2020). We use the version fine-tuned on the ParaBank2 dataset (Hu et al., 2019).

CTC (Deng et al., 2021) measures the average token-level alignment of the generated text w.r.t the grounding text using a BERT sequence tagging model. The model is trained to detect hallucinated tokens generated by a BART model in a self-supervised manner. [9]

3.3 Natural Language Inference Metrics

ANLI The task of Textual Entailment (Dagan et al., 2006) or Natural Language Inference (NLI; Bowman et al., 2015) is to determine, given two

---

[6] This is equivalent to the AUC w.r.t detecting consistent examples.

[7] `https://github.com/Tiiiger/bert_score`

[8] `https://github.com/google-research/bleurt/blob/master/checkpoints.md`

[9] This metric has come to our attention after the paper was accepted, so we add the results to the appendix to avoid adding unreviewed results in the camera ready version. See `https://github.com/tanyuqian/ctc-gen-eval/blob/master/factual-consistency.md` for implementation details and Table 9 for results.

sentences, a *hypothesis* and a *premise*, whether the *hypothesis* in entailed by the *premise*, contradicts it, or is neutral w.r.t to it. The resemblance[10] of NLI to factual consistency evaluation has led to utilizing NLI models for measuring factual consistency (Thorne et al., 2018; Welleck et al., 2019; Maynez et al., 2020; Dziri et al., 2021). We trained an NLI model by fine-tuning T5-11B (Raffel et al., 2020) on the Adversarial NLI (ANLI; Nie et al., 2020) dataset. As suggested by Maynez et al. (2020), we compute the entailment probability with the grounding text as the premise and the generated text as the hypothesis and use it as the example-level factual consistency score.[11]

SUMMAC (Summary Consistency; Laban et al., 2021) is focused on evaluating factual consistency in summarization. They use NLI for detecting inconsistencies by splitting the document and summary into sentences and computing the entailment probabilities on all document/summary sentence pairs, where the premise is a document sentence and the hypothesis is a summary sentence. They aggregate the NLI scores for all pairs by either taking the maximum score per summary sentence and averaging (SC_{ZS}) or by training a convolutional neural network to aggregate the scores (SC_{Conv}). We use the publicly available implementation.[12]

3.4 QG-QA Based Metrics

Durmus et al. (2020) and Wang et al. (2020) proposed to use Question Generation (QG) and Question Answering (QA) models to automatically evaluate factual consistency in abstractive summarization, showing promising results. Honovich et al. (2021) employed a similar approach for evaluating knowledge-grounded dialogue generation.

The steps of the QG-QA approach are as follows: (1) Questions are automatically generated for spans in the generated text, such that the answer to a question is its respective input span. (2) The generated questions are answered using a QA model on the grounding text, resulting in an answer span or a "no-answer" output. (3) For each question, the two answer spans from the grounding and the generated text are compared to get a score. (4) The scores for all questions are aggregated into a final score.

$\mathbf{Q^2}$ (Honovich et al., 2021) is a QG-QA method that employs an NLI model to compare the two answers for each question, where the grounding text answer is the premise and the generated text answer is the hypothesis. We report results for a re-implementation of Q^2 using T5-11B as the backbone for the QG, QA and NLI models. While Honovich et al. (2021) validate each generated question by answering it using a QA model and comparing to the original extracted answer candidate using exact match, we relax this and instead use F1 token-overlap with a predefined threshold.[13]

QuestEval (Scialom et al., 2021) is a QG-QA method that measures both factual consistency and relevance (by reversing the roles of the generated and grounding texts). The authors trained a model that weights each generated question according to the relevance of its answer to appear in the generated text. Their results showed high correlation with human judgments in comparison to prior work on the SummEval benchmark (Fabbri et al., 2021a). We use the publicly available version.[14]

4 Results

We report the ROC AUC[15] of various metrics on the standardized datasets in Table 3. The ROC curves can be found in Figure 2 in the appendix. SC_{ZS} was trained on VitaminC which includes examples from FEVER, so we exclude those datasets from the average AUC calculation for a more fair comparison. As all metrics operate in a "zero-shot" manner on all datasets (except for SC_{ZS} on VitaminC and FEVER) and no threshold tuning is required, we report results on the development sets.[16]

The results show that the NLI-based models (ANLI, SC_{ZS}[17]) outperformed the other approaches on 6 datasets, with average AUC of 81.5 and 81.4 for ANLI and SC_{ZS}, respectively. Q^2 outperformed the other approaches on 4 datasets, with an average AUC of 80.7. The next best method, BARTScore,

---

[10] One example where the definition of NLI and factual consistency differs is in dialog, where subjective or opinionated statements of the dialog agent are not evaluated as factual statements, while NLI models consider all the text in the premise.

[11] More implementation details on the NLI model are available in Section B in the appendix.

[12] `https://github.com/tingofurro/summac`

[13] More implementation details are available in Section B in the appendix.

Avg. $_{\text{w/o VitC, FEVER}}$	86.0	80.7	**81.5**	81.4	63.8	71.4	71.4	66.7	72.2	71.4

Table 3: ROC AUC results for the different metrics on the TRUE development set. We exclude VitaminC and FEVER from the average calculation as SC_{ZS} was trained on VitaminC that includes examples from FEVER. The highest score in each row (excluding the Ensemble) is in bold and the aforementioned SC results are in strikethrough. Statistically significant results are indicated using * and ** for $p < 0.05$ and $p < 0.01$ respectively.

had lower average AUC of 72.2. All other approaches scored 72 or lower on average across all datasets (excluding FEVER and VitaminC). As expected, the simple token-matching based metrics did not perform well, and for completeness, we report their performance in Table 9 in the appendix. We keep the F1 score in Table 3 for convenient comparison to the other metrics.

One outlier is BEGIN, which is the only dataset where simple metrics like F1 token overlap achieved scores higher than 80. We measured the average overlap between the grounding and target texts per dataset, and found that BEGIN exhibits a high difference between grounded and ungrounded texts in comparison to other datasets (Table 8 in appendix A), which explains this.

We follow Laban et al. (2021) and perform significance testing through bootstrap resampling (Efron, 1982), comparing the best method to the second-best method on each dataset. We perform interval comparison at $p = 0.05$ and $p = 0.01$ and find significantly best results on 6 datasets, 3 achieved by Q^2 and 3 by the ANLI-based model.

Given that no single method outperformed the rest on all datasets, we hypothesize that the NLI and QG-QA based metrics are complementary. We test this by averaging the Q^2, ANLI and SC_{ZS} scores per example[18] (*Ensemble* in Table 3). Indeed, averaging the three methods yields better results on most datasets and on average, with an increase of 4.5 in ROC AUC from the best single-metric result.

Our results show that a single metric can do well across all tasks and datasets, with all 3 best metrics scoring higher than 80 on average on the 11 datasets. This corroborates our hypothesis that evaluating factual consistency can be unified, and we hope such unified perspective will be adopted in future work to accelerate progress on the subject.

5 Analysis

Input Length. As QA and NLI models may struggle with long inputs (Kočiský et al., 2018; Pang et al., 2021; Yin et al., 2021; Shaham et al., 2022), metrics based on them may fail when handling long text. To study the effect of input length on the metrics performance, we unify all datasets[19] and split examples into 6 bins according to the grounding length.[20] We focus on the grounding as the target texts are usually short (see Table 7 in Appendix A). We measure AUC of the best 3 metrics according to their overall score for each length bin, sampling 1,000 examples per bin.

The results are shown in Figure 1. We find that there is a consistent degradation for texts longer than 200 tokens for all metrics, including SC_{ZS} which is designed to better handle long text. We find it surprising that the ANLI-based model and Q^2 still do relatively well on the longest bin (with AUC > 0.825) as they perform end-to-end QA and NLI on text with more than 500 tokens.

Model Size. Model-based metrics are expected to benefit from increasing the model size. To quantify this we study the effect of using smaller models for the ANLI, BLEURT and BERTScore metrics. We compare the average ROC AUC of larger and

---

[18] Pairwise ensembles are reported in the appendix, Table 9.

[19] Excluding VitaminC as it is much larger than other datasets and might therefore distort results. Statistics regarding the grounding and target text lengths per dataset is in Appendix A.

[20] We measure length in tokens (before subword splitting) as different metrics use different subword tokenizations.

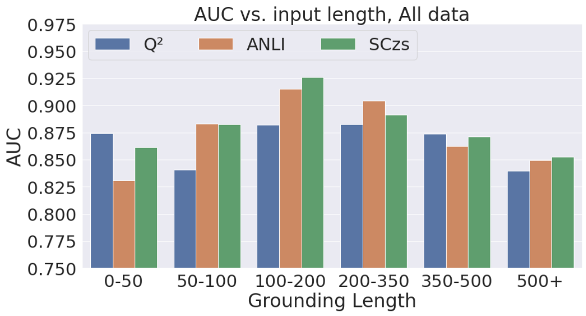

Figure 1: ROC AUC when splitting TRUE's data according to the grounding length.

smaller model variants for each metric. The ablation results are in Table 4. We find an advantage of 4.7, 3.7 and 1.3 average ROC AUC for the larger ANLI, BLEURT and BERTScore variants respectively, showing that larger models indeed allow for better factual consistency evaluation metrics, and hinting at potential improvements from using even larger models.

Model	**Avg. ROC AUC**
ANLI-T5-11B	**81.5 (+4.7)**
ANLI-T5-Large	76.8
BLEURT-20	**71.4 (+3.7)**
BLEURT-20-D6	67.7
BERTScore P - deberta-xl-mnli	**71.4 (+1.3)**
BERTScore P - roberta-large	70.1

Table 4: Ablation study comparing the average ROC AUC results for models with different sizes. "BERTScore P" stands for BERTScore Precision.

Qualitative Analysis. We conduct manual error analysis to point at weaknesses of the different metrics and present challenges posed by the task. We analyze 80 examples that were misclassified by all three best metrics, as well as 100 examples that were correctly classified by one or two of the three.

Out of the analyzed examples, many seem to have a wrong label. This is especially true for cases in which all best metrics failed, with annotation errors in 35/80 cases. For the cases where one or two metrics failed, we found annotation errors in 27/100 cases. To verify that the high annotation error rate is indeed a result of inspecting the "hardest" examples and not a general issue in the datasets we used, we uniformly sample 100 additional examples, finding that only 10 had annotation errors. We therefore stress that the high misannotation rate indeed characterizes "hard" examples only, and is not a general property of the datasets we used. This is inline with the findings of Freitag et al. (2021), who showed that in some cases, metrics may be "better" than non-expert annotators. These findings demonstrate the potential of automatic methods in "cleaning" training data by filtering factually inconsistent examples.

Despite showing impressive results, the best-performing metrics fail to detect subtle inconsistencies, as presented in Table 5. This was the case for 21/180 analyzed examples. Metrics that aggregate scores across parts of a target text, such as Q^2 or $\mathrm{SC}_{\mathrm{ZS}}$, might assign a high score for texts in which all but a small part is consistent. End-to-end NLI should predict "contradiction" even when only a small part of the text contradicts the grounding, but it may fail to do so. Applying a strict approach in the aggregation step, like taking the minimum instead of the average, could potentially remedy this – with the price of having more false-negatives. Other errors are caused by domain-specific challenges, such as handling personal statements in dialogues. As shown in Table 5, such statements may be falsely classified as ungrounded. This was the case for 10/62 analyzed dialogue responses. A possible way to alleviate this would be to automatically exclude non-factual parts from the evaluation.

Ensemble Analysis. As shown in §4, a simple averaging ensemble using the three best metrics achieves strong results, outperforming individual metrics on most datasets. To understand this further, we analyze cases in which at least one of the best three metrics failed, while the ensemble succeeded. Overall, there were 25,761 such cases, where in 85.2% of these cases, two out of the three metrics succeeded, and only one failed. In 14.6% of these cases, one metric succeeded while the other two failed, and only in 0.2% of the cases, the ensemble succeeded while all metrics failed. These cases are a result of the different threshold used for the ensemble model vs. the thresholds for the individual metrics. We sample 100 of these examples and manually analyze them. Out of the sampled examples, 47% were misclassified by one metric only, where this metric assigned a borderline score - i.e., close to the decision threshold. 36% of these examples were misclassified by one metric only, and also with a non-borderline score - i.e., the metric was far from a correct prediction. Other cases include two, or even three, erroneous metrics.

6 Related Work

Adding to the related work mentioned throughout the paper, works on unified evaluation of text

Grounding	**Generated Text**	**Explanation**
The word "philately" is the English version of the French word "philatélie", coined by Georges Herpin in 1864.	The word philately is actually a french word coined by george herpin.	The word philately is an English word *based* on a French word, but not French. All best metrics misclassified this.
French police have interviewed presidential candidate francois fillon and his wife penelope over claims she was paid for fake work. They provided information that would help find the "truth", mr fillon said…	French presidential candidate francois fillon has said he and his wife penelope have been questioned by police over claims she worked illegally.	Most details are correct and the hallucination is subtle. In the case of Q^2, most of the generated questions have the same answer based on the grounding and the generated text, therefore the overall score was high.
Stamp collecting is generally accepted as one of the areas that make up the wider subject of philately, which is the study of stamps.	I've never heard of stamps, but I do know that the word "philately" refers to the study of stamps.	The personal statement "I've never heard of stamps" is not factual and should not be evaluated.
Evidence suggests that cognitive behavioral therapy and a gradual increase in activity suited to individual capacity can be beneficial in some cases.	It has been suggested that cognitive behavioral therapy and gradual increase in exercise could help in some cases so I'm going to try that for now.	Similar to the previous examples - SummaC and ANLI falsely marked the text as inconsistent, probably due to the personal statement.

Table 5: Examples for the error analysis. The first two rows show cases of challenging inconsistencies, while the last two show dialogue responses containing non-factual personal statements.

generation across tasks include GEM (Gehrmann et al., 2021), where the focus is on evaluating system outputs and not the factual consistency evaluation methods as in TRUE. BEAMetrics (Scialom and Hill, 2021) proposes meta-evaluation protocols across tasks, but does not focus on factual consistency. When discussing consistency ("correctness") they measure correlations, which are not sufficient as mentioned in Section 2.3. Chen et al. (2021) present an adversarial meta-evaluation for factual consistency evaluators, focused on summarization. Other works on meta-evaluation of factual consistency across datasets include GO-FIGURE (Gabriel et al., 2021) FRANK (Pagnoni et al., 2021) SummaC (Laban et al., 2021) and QAFactEval (Fabbri et al., 2021b), however they all focus solely on summarization. Yeh et al. (2021) conduct a thorough assessment of dialog metrics, however not specifically around factual consistency. To the best of our knowledge, our work is the first to generalize the discussion on evaluating factual consistency across tasks and datasets, and the first to show that large-scale QG-QA and NLI are strong and highly complementary – setting better baselines and meta-evaluation methodology for future work.

7 Discussion and Future Work

We discuss the main takeaways of the TRUE study, pointing at actionable insights for future work. First, as QG-QA and NLI-based methods show better performance than other approaches, especially when combined together, we recommend model developers to use those methods for evaluation when factual consistency is a priority. As for metric developers, we recommend using those methods and the datasets in TRUE when evaluating new metrics.

We also suggest reporting ROC AUC rather than correlations, as it is more interpretable and actionable. Our proposed binary annotation scheme allows to easily test new metrics across tasks and datasets, which would be useful for future work.

Finally, we encourage data curators to use the binary annotation scheme, which is inline with the recommendations of Rashkin et al. (2021a). Having said that, we do not rule out more detailed labeling schemes – but rather ask to provide a protocol for converting such labels into the more general binary format. Future work may also address the challenges of long inputs and personal statements in dialogue, which we point out in our analysis.

8 Conclusions

We presented TRUE, a survey and assessment of automatic factual consistency evaluation methods. We standardized various datasets from diverse tasks into a unified labeling scheme to perform a thorough comparison of automatic evaluation methods, showing that large scale NLI and QG-QA based approaches perform well *across* multiple tasks and datasets. We further show that these methods are highly complementary – hinting at additional headroom for improvement while pointing on current limitations. We hope our results and methodology will encourage a more unified perspective in future work to foster progress towards more factually-consistent NLP applications.

B Implementation Details

We train all models using the t5x library.[21]

QG-QA For our reimplementation of Q^2 (Honovich et al., 2021) we use T5-11B as the pretrained model for QG, QA and NLI, while Honovich et al. (2021) used T5-Base, ALBERT (Lan et al., 2019), and RoBERTa (Liu et al., 2019) for the QG, QA and NLI models, respectively. We use a maximum length of 2048 tokens for the input. We set the F1 token overlap threshold to 0.54 by tuning it on a held-out dataset. We use beam search with a beam size of 4 to generate multiple questions, and use the first question that passes the validation threshold.

NLI We fine-tune a T5-11B model on ANLI (Nie et al., 2020) for $25K$ steps with a learning rate of 10^{-4} and a batch size of 32. During inference we use a maximum input length of 2048 tokens.

C ROC Curves

Figure 2 presents the ROC curves for the different datasets studied in TRUE, using the best-performing metrics.
