Table B.9: Qualitative examples of Fine-grained TST on the Yelp Dataset

is it Contradiction/Neutrality to Entailment or vice versa. Intuitively, this makes sense as the Entailment to Contradiction/Neutrality tasks can be achieved simply by randomly editing either the subject or predicate or both, in any one sentence, to trigger a contradiction/neutrality between the two. However, in the reverse task, the edited part must be carefully chosen to precisely match the context of the other sentence to trigger entailment.

To analyze this, direction-specific quantitative metrics for Discourse TST are conducted for the SNLI (B.10), DNLI (B.11) and SciTail (B.12) datasets. We notice a disparity in performances in fact, does exist, mainly highlighted by the differences in the TST% metric. This sensitivity to direction is present in all models across all datasets but is most significant in the SNLI dataset in which TST% goes as low as 20.6% for the Contradiction to Entailment task and as high as 83.7% for the opposite task. Future work can focus on trying to specifically improve the Contradiction to Entailment task, as doing so will be a measure of a model's ability to detect and carefully align the content of one sentence to match another.

C Details on Datasets

Here we provide some additional details of all the datasets used in this work.

Complexity of Styles in Datasets: As discussed in Section 5.2, we consider three tasks- sentiment, discourse and fine-grained text style transfer. As prepossessing, we remove non-essential special characters and lowercase all sentences. Except for the Yelp dataset, no pruning is done based on sentence length. The vocab size during training was limited at 25k unless mentioned otherwise.

Sentiment Style Datasets: We use the preprocessed version from (Shen et al., 2017) of the Yelp dataset. It contains 200k, 10k, 10k sentences in the train, dev and test split respectively. The sentiment labels (positive, negative) were considered as style.

Discourse Style Datasets: We used three NLI datasets - SNLI, DNLI, and Scitail. Each instance in the SNLI dataset (Bowman et al., 2015) consists of two sentences. These sentences either contradict, entail (agree) or are neutral towards each other. The resultant dataset contained 341k, 18k, 18k in the train, dev, test splits respectively. The DNLI dataset (Welleck et al., 2019) consists of contradiction, entailment and neutrality labelled instances instead in the form of a first-person dialogue like representation. The dataset contains 208k, 11k, 11k sentences in train, dev and test respectively. Scitail (Khot et al., 2018) is an entailment dataset created from multiple-choice science exams and the web, in a two-sentence format similar to SNLI and DNLI. The first sentence is formed from a question and answer pair from science exams and the second sentence is either a supporting (entailment) or non-supporting (neutrality) premise obtained from the internet. The dataset contained 24k, 1.3k, 1.3k sentences in the train, dev, test splits respectively. For SNLI and DNLI, all instances with the "neutrality" label were removed. Style transfer task performed from "contradict" to "entail" and vice versa. For SciTail (Khot et al., 2018), the transfer task was from "neutral" to "entail" and vice versa.

Fine-grained Style Datasets: We used StylePTB dataset (Lyu et al., 2021) for fine-grained style. It consists of 21 styles/labels with themes ranging from syntax, lexical, semantic and thematic transfers as well as compositional transfers which consist of transferring more than one of the aforementioned fine-grained styles. To check whether the EPAAE can capture fine-grained styles better by leveraging its better organized latent space, we make use of three styles i.e. Tenses, Voices (Active

D More details on related work

Bowman et al. (2016) extend Variational Auto-Encoders (Kingma and Welling, 2014) for text generation and address the posterior collapse problem wherein the decoder completely ignores the latent channel leading to poor generation. Adversarial auto-encoders (Makhzani et al., 2015) substitute the KL loss with an adversarial approach to enforce the latent Gaussian prior. On the other hand, AAEs are shown to naturally avoid the posterior collapse problem and promote strong coupling between the encoder and decoder. Wasserstein autoencoders (Tolstikhin et al., 2018) introduce a family of regularized autoencoders that learn a flexible prior by solving an optimal transport problem to match P(z) and Q(z) using an adversarial approach. Adversarially regularised autoencoders (ARAEs) follow the Wasserstein Autoencoder framework to learn a learnt prior unlike AAEs, which assume the prior to be a fixed standard Gaussian distribution.

E Computational Expense and Infrastructure used

The most parameter-heavy EPAAE model was from the SNLI dataset and we therefore report statistics for this model. The model has 13 million parameters and each epoch took approximately 60 seconds to train on an Nvidia V100-SMX2 GPU and an Intel(R) Xeon(R) E5-2698 CPU. For complete details, please refer to the log.txt files present in each model's directory present in `https://github.com/sharan21/EPAAE`.

Towards Robust and Semantically Organised Latent Representations for Unsupervised Text Style Transfer

Sharan Narasimhan **Suvodip Dey** **Maunendra Sankar Desarkar**

Indian Institute of Technology Hyderabad, India

sharan.n21@gmail.com suvodip15@gmail.com maunendra@cse.iith.ac.in

Abstract

Recent studies show that auto-encoder based approaches successfully perform language generation, smooth sentence interpolation, and style transfer over unseen attributes using unlabelled datasets in a zero-shot manner. The latent space geometry of such models is organised well enough to perform on datasets where the style is "coarse-grained" i.e. a small fraction of words alone in a sentence are enough to determine the overall style label. A recent study uses a discrete token-based perturbation approach to map "similar" sentences ("similar" defined by low Levenshtein distance/ high word overlap) close by in latent space. This definition of "similarity" does not look into the underlying nuances of the constituent words while mapping latent space neighbourhoods and therefore fails to recognise sentences with different style-based semantics while mapping latent neighbourhoods. We introduce EPAAEs (Embedding Perturbed Adversarial AutoEncoders) which completes this perturbation model, by adding a finely adjustable noise component on the continuous embeddings space. We empirically show that this (a) produces a better organised latent space that clusters stylistically similar sentences together, (b) performs best on a diverse set of text style transfer tasks than similar denoising-inspired baselines, and (c) is capable of fine-grained control of Style Transfer strength. We also extend the text style transfer tasks to NLI datasets and show that these more complex definitions of style are learned best by EPAAE. To the best of our knowledge, extending style transfer to NLI tasks has not been explored before. [*]

1 Introduction

The Text Style transfer (TST) task is a form of controlled language generation. The goal is to produce fluent style-altered sentences from a given base sentence, while also preserving its style-independent content. The definition of "style" depends on the class labels of the end task. Our work focuses on the unsupervised scenario i.e. performing the training on completely unlabelled corpora. By inducing the latent space organization through input perturbation, TST can be performed using a simple vector arithmetic method (discussed in Section 6).

Background. Several well-known architectures use auxiliary objectives that serve as regularizers to ensure that the latent space geometry is smoothly interpolatable and learns high-level semantic features (refer Appendix D). Inspired by successes in denoising approaches in vision (Creswell and Bharath, 2019; Vincent et al., 2008), we look at input perturbation based approaches for unsupervised style transfer. Unlike text, in vision, freedom exists to finely control the degree of Gaussian "blur" on the continuous input image space. We conjecture that this notion of "controlling blur" may be useful in the text domain as well, serving as our motivation for our chosen model for Input Perturbation. Shen et al. (2020) map "similar" (defined by low Levenshtein distance/ high word overlap) sentences together in the latent space by introducing a simple denoising objective over an underlying Adversarial Autoencoder (AAE) (Makhzani et al., 2015). This noise model includes simple token manipulation

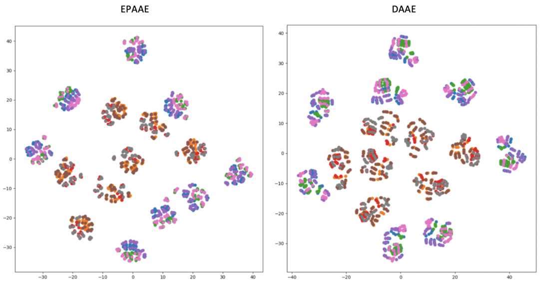

Figure 1: A TSNE plot of encoded latent vectors for all 1950 sentences in the Toy Dataset. EPAAE shows tighter and more organised clustering. Refer to B.1 and B.2 for larger plots with legend.

---

[*] Our code, data and outputs are available at https://github.com/sharan21/EPAAE

(token dropout and substitution) with some probability p, to reconstruct the original sentences from the perturbed inputs. We can reason intuitively that discrete word dropout allows sentences with high word overlap (or low Levenshtein distance) to have a higher chance of being perturbed into one another, thereby mapping them close in the latent space during the training time. However, this method allows for stylistically dissimilar sentences, albeit with high word overlap, to be mapped together in the latent space.

Idea. We argue that this negatively impacts the quality of final latent geometry and the results of the subsequent style transfer task. As an alternative, we explore Embedding Perturbation, where a noise vector is sampled, appropriately scaled and added to the embeddings of each input sentence, such that the resultant embeddings are constrained to live inside an E-dimensional hypersphere. The radius of this hypersphere is controllable using a tune-able hyper-parameter ζ. This hypersphere constraint is partially inspired by concepts in adversarial robustness and ensures that each resultant noised word embedding is not altered to the extent of causing the underlying semantics of the sentence to change. We argue that this allows sentences with stylistically similar constituent embeddings to be mapped together, also encouraging the formation of style-preserving latent neighbourhoods (more on this in Section 4). The resulting latent representation from "embedding-perturbed" autoencoders consequently are better semantically organized and stylistically robust, enabling us to perform TST using an inductive method i.e. simple vector arithmetic on latent vectors.

Contributions. We show that this extended model of input perturbation with both discrete and continuous components, allows for overall better quality text style transfer, particularly in its ability to preserve style-independent "content" information. To expand the traditional definitions of styles such as Polarity, Formality, which are based on simple "intra-sentence" attributes, we introduce the "Discourse Style Transfer Task" by salvaging NLI datasets in which the flow of logic between sentences are captured using "Entailment", "Contradiction", and "Neutral" labels. This enables interesting applications such as discourse manipulation in which a pair of sentences agreeing with each other can be made to contradict, and vice versa. We also test our model on fine-grained styles present in the Style-PTB dataset. We empirically show that our model performs the best on a diverse set of datasets with styles ranging from coarse-grained styles (like sentiment) to fine-grained styles (like tenses) and complex inter-sentence styles (like discourse or flow of logic).

2 Related work

Seminal work in TST. Autoencoder based approaches for TST on labelled non-parallel datasets are quite well explored (Shen et al., 2017; Fu et al., 2018). Some techniques involve implicit Style-Content disentanglement of the latent space using Back Translation (Prabhumoye et al., 2018) and adversarial learning (John et al., 2019). Li et al. (2018) achieve disentanglement using simple keyword replacement. Most studies look at simple non-parallel classification datasets, defining their style to be the class label. Studies also look at Syntax-Semantic disentanglement of the latent space (Chen et al., 2019; Bao et al., 2019). A λ_1 penalty is imposed on the log variance of the perturbations to prevent it from vanishing. The latent vacancy problem (Xu et al., 2020) of the $\beta-$VAE is mitigated by introducing auxiliary losses and provided for one of the earliest methods for unsupervised TST. Similar to our work, Rubenstein et al. (2018) introduces the Latent noised AAE (LAAE), Gaussian perturbation is instead added to latent encodings to promote organization. Unsupervised work includes using a language model as a discriminator for a richer feedback mechanism (Yang et al., 2018), allowing it to increase performance in word substitution decipherment, sentiment modification, and related language translation. More seminal work related to autoencoders in the context of Style Transfer is mentioned in Appendix D.

Contemporary work in TST. More recent work, treat the style transfer problem as paraphrase generation and fine-tune pre-trained language models (Krishna et al., 2020). Malmi et al. (2020) trains masked language models or MLMs on the source and target domains to identify input tokens to be removed and replace them with tokens from the target MLM in an unsupervised manner. Liu et al. (2020) uses gradient-based update rules in the continuous latent space z from style and content predictor networks, enabling the transfer of fine-grained styles without using an adversarial approach. Reid and Zhong (2021) performs TST on sentiment and politeness datasets using token editing methods (similar to Li et al. (2018)) using Levenshtein editing operations. Lee et al. (2021) also focuses on enhancing content preservation by introducing a method to remove style at the token level using reverse attention and fuse this content representation with style using a conditional layer normalization technique. Riley et al. (2021) adapts the T5 model (Raffel et al., 2020) for few shot text style transfer by extracting a style representation and performing conditioned decoding, using only a handful of examples at inference time.

3 Method

The underlying language model is a generative auto-encoder which models an input distribution $p(\mathbf{x})$ assumed to be from an underlying latent distribution $p(\mathbf{z})$. A deterministic encoder E representing the distribution $q(\mathbf{z}|\mathbf{x})$, in the form of an RNN, whose output is reparameterized by another distribution $z_i \sim \mathcal{N}(\mu_i(\mathbf{x}), \sigma_i(\mathbf{x}))$ to give the aggregated posterior distribution $q(\mathbf{z})$. Various auxiliary loss functions are used to enforce the learned prior $q(\mathbf{z})$ to match $p(\mathbf{z})$. The Generator G representing $p(\mathbf{x}|\mathbf{z})$, also in the form of an RNN, decodes back the sample from the learnt prior $q(\mathbf{z})$ into its corresponding input from $p(\mathbf{x})$. Gradient descent is applied on the reconstruction loss of the autoencoder given by:

$$\mathcal{L}_{\text{rec}}(\theta_E, \theta_G) = E_{p_{\text{data}}(x)}[-\log p_G(x|E(x))] \quad (1)$$

We use the AAE (Makhzani et al., 2015) as our choice for the underlying generative autoencoder over which the input perturbation techniques were applied. AAE uses a discriminator D to enforce $q(\mathbf{z})$ to match $p(\mathbf{z})$, a standard Gaussian, by learning to distinguish between samples from the two different distributions. This adversarial loss serves as a regularizer for the latent space, giving it the ability the organize itself better for smooth sentence interpolation.

$$\begin{aligned}\mathcal{L}_{\text{adv}}(\theta_E, \theta_D) = \ & \mathbb{E}_{p(z)}[-\log D(z)] + \\ & \mathbb{E}_{p_{\text{data}}(x)}[-\log(1 - D(E(x)))]\end{aligned} \quad (2)$$

The final min-max objective is a sum of the reconstruction loss (given below) and λ weighted adversarial loss:

$$\min_{E,G} \max_{D} \mathcal{L}_{\text{rec}}(\theta_E, \theta_G) - \lambda \mathcal{L}_{\text{adv}}(\theta_E, \theta_D) \quad (3)$$

We found empirically that AAEs performed well and were stable during training. On the other hand, β-VAEs required careful tuning of the β hyperparameter to prevent posterior collapse and did not perform as well.

3.1 Finely-controlled continuous noise on embedding space

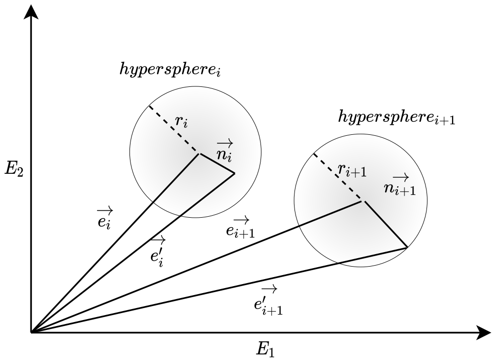

Figure 2: An abstract representation of the continuous embedding noise approach for two arbitrary embeddings e_i and e_{i+1} on an embedding space $E \in R^2$

To further organize the latent geometry of the underlying AAE to encode style-based semantic similarity among sentences, we propose a perturbation-based approach on the continuous embedding space. Word embeddings of dimensionality E, of each input token x_i are denoted as e_i. Consider an input sentence of length l containing tokens $x_0, \cdots, x_{l-1}$ having embeddings $e_0, \cdots, e_{l-1}$ respectively. Our objective is to blur every embedding vector e_i by adding some appropriately scaled noise vector n_i to produce a resultant noised embedding vector e'_i, such that e'_i does not lie too far away from e_i to not change the underlying semantics of the word completely. We do this by ensuring that each new e'_i lives inside an E-dimensional hypersphere. The center of the hypersphere is the original embedding e_i and its radius is defined as $|e_i| * s_i$, where $s_i \in \mathbb{R}^1$ is a random variable sampled from a distribution $P(s)$. $P(s)$ is probability distribution of the form $\mathcal{Y}(\mu = 0, \sigma)$ where $\mathcal{Y}$ is some arbitrarily chosen distribution and σ as function of hyperparameter $\zeta \in R$. This distribution $P(s)$ parameterized by $Y, \zeta)$ models the probability density cloud inside the embedding hypersphere, controlling its radius and interior densities. Figure 1 neatly summarizes the aforementioned embedding perturbation mechanism for a simple example with only two individual word embeddings. In practice, we use a vectorized representation of the above mechanism to blur the embeddings of a mini-batch of sentences of size L in constant O(1) time. The embedding perturbation method is summarized below in a vectorized form:

$$\begin{aligned} z &\sim \mathcal{N}(\mu, \sigma^2) \\ \hat{z} &= z/|z| \\ s &\sim Y(\mu = 0, \sigma^2 = (\zeta/3)^2) \\ n &= (s \odot |e|)^T \hat{z} \\ e' &= e + n \\ r &= \zeta * |e| \end{aligned} \tag{4}$$

where z, $\hat{z}$, s, n and e are vectorized representations of z_i, $\hat{z_i}$, s_i, n_i and e_i respectively for a mini-batch of sentences of size l. $\odot$ and $*$ denote element wise and scalar multiplication respectively. $|x|$ denotes the magnitude of a vector/batch of vectors x. r is the vectorized mini-batch representation of r_i, the expected radius of $hypersphere_i$. We choose the Gaussian distribution as our choice of the probability distribution $\mathcal{Y}$, as on testing it produced the best results[†]. To couple the radius r_i of $hypersphere_i$ to our hyperparameter ζ to enable fine-grained control using ζ, we constrain the probability density of Y to live inside the hypersphere within three standard deviations. To achieve this, we equate 3σ to ζ, and consequently set the variance σ^2 of $\mathcal{Y}$ to be $(\zeta/3)^2$.

3.2 Discrete word dropout probability

The "Denoising Autoencoder" or DAAE (Shen et al., 2020) considered discrete token-level perturbations such as token masking, substitution and deletion. We consider token deletion as discrete noise. Drop probability $p = 0.3$ is found to be the best in both their experiments and ours.

Token deletion is the only type of input perturbation that can alter the number of tokens in a sentence. Any continuous model for input noise cannot mathematically generalize the effects of this kind of discrete word dropout. Furthermore, during our experiments, we find that for some datasets, both discrete and continuous noise components are required to produce the overall best model. In such a case, we first perform token deletion and then subject the leftover token embeddings to perturbation. We refer to this generalized noise model as "Embeddings-Perturbed Adversarial Autoencoder" or "EPAAE" parameterized by ζ and p.

4 Semantic Similarity in Latent Space Neighbourhoods

We contrast and compare the resultant latent space neighbourhoods of DAAEs and EPAAEs.

4.1 Preliminary reasoning

Here, we first investigate the question - *Does token deletion during training group truly put semantically similar sentences together in latent space Z?*. Intuitively we can reason that the answer may be in the affirmative if the drop probability is small. For example, the sentences "The food was good" and "The food was superb" might get perturbed into a common version, i.e. "The food was" and therefore be mapped nearby in Z during training. As analysed and concluded in (Shen et al., 2020), latent neighbourhoods in the latent space of DAAEs successfully cluster sentences with high word overlap (low Levenshtein/Edit distance) together. However, the Levenshtein distance metric is not an accurate measure of the true semantic similarity between sentences. A pair of sentences with high word overlap might convey different ideas w.r.t the underlying style-based semantics of the dataset. For example, in the context of the Yelp dataset, the sentences "The food was good" and "The food was bad" are stylistically opposing (style being polarity in this case) and yet still get mapped close by in Z for DAAEs.

4.2 Testing the hypothesis with a Toy Dataset

We conduct specifically curated experiments on a synthetic dataset to verify our hypothesis that EPAAEs map stylistically similar sentences together.

Details of Toy dataset: Inspired by Yelp, each sentence in this dataset either represents a positive or negative sentiment. It also contains different sentiment independent components, such as the identity of the person and the subject of the review. Each sentence is of the format: "The <*identity_token*> said the <*subject_token*> is <*decision_token*>" where *identity*, *subject* and *decision* token classes are the only variable parameters in each sentence. The entire set of all permutations of these token classes forms the dataset. For example, the decision class is further subdivided into two subclasses, i.e. positive/ negative sentiment,

---

[†] We also tried the uniform distribution with varying values for ζ

Token Class	**Sub Classes**	**Token Options**
(0) Identity	(0) Male	boy, man, husband, boyfriend, waiter
	(1) Female	girl, woman, wife, girlfriend, waitress
(1) Subject	(0) Food	food, meal, dinner, breakfast, lunch, pasta, chicken
	(1) Others	service, staff, experience, atmosphere, location, place
(2) Decision	(0) Positive	good, great, excellent, decent, amazing, wonderful, reasonable
	(1) Negative	bad, worst, horrible, spicy, bland, expensive, disgusting, mediocre

Table 1: Structure of token classes and division of subclasses with token options used to create Toy Dataset

DAAE ($p = 0.3$)	**L2 Norm**	**EPAAE** ($\zeta = 3.0$)	**L2 Norm**
the man said the pasta is spicy	0	the man said the pasta is spicy	0
the man said the pasta is good	2.79	the man said the staff is spicy	2.62
the girl said the pasta is spicy	2.88	the man said the pasta is bad	2.69
the man said the pasta is wonderful	2.89	the man said the pasta is bland	2.77
the man said the service is spicy	3	the girl said the pasta is spicy	2.84
the man said the pasta is bad	3.02	the husband said the pasta is spicy	2.89

Table 2: Nearest Neighbour experiment performed on EPAAE and DAAE. Sentences in red indicate dissimilarity in semantics with respect to cluster center

Dataset	**Model**	**Mean L2 Norm for Label Flip**	**Mean Hops for Label Flip**
Toy Dataset	DAAE	**5.725**	14.979
	EPAAE	4.324	**19.587**
Yelp	DAAE	**9.386**	5.850
	EPAAE	8.211	**6.513**
SNLI	DAAE	9.794	3.185
	EPAAE	**10.373**	**3.528**
DNLI	DAAE	9.320	**6.027**
	EPAAE	**11.681**	4.882
SciTail	DAAE	10.224	5.750
	EPAAE	**10.676**	**6.253**
PP Removal	DAAE	8.195	6.722
	EPAAE	**8.774**	**7.409**
Tenses	DAAE	7.686	**8.802**
	EPAAE	**10.924**	5.426
Voices	DAAE	6.805	8.367
	EPAAE	**9.657**	**8.726**

Table 3: Quantitative metrics to capture model's ability to preserve style-based semantics inside Latent Neighbourhoods. Bold indicates model with higher value for that corresponding metric in that specific dataset, which is suggestive of ability to better preserve style-based semantics.

each subclass containing 7 and 8 choosable tokens, respectively. The resultant dataset consisted of 1950 sentences. The details of the subclasses and the representative tokens inside each subclass are shown in Table 1. We produce output labels for each sentence by using a 3-bit representation, one bit for each of three token classes, where the values of each bit represent the token label subclass within that class. For example, a label of 5 is encoded as 101 corresponding to a sentence with *Female*, *Food* and *Negative* labels. There are $2^3 = 8$ labels in total labelled 0-7.

Qual. Analysis of Latent space. We consider two models, DAAE with token deletion probability $p = 0.3$ and EPAAE with $\zeta = 2.5$. Both models are initially pre-trained over the unlabelled Yelp dataset. The synthetic dataset is used during inference time only. We encode all 1950 sentences into their respective latent space vectors and use TSNE plots to visualise the latent space of each model (Figure 1). We pick a random *query* sentence, e.g. "The man said the pasta is spicy", and encode it into Z. We then retrieve the top five nearest encoding to the query and observe their decoded outputs to check for the preservation of style-based semantics (Table 2) around the query. We find that the EPAAE maps the latent neighbourhood such that stylistically similar (positive/negative sentiment in this context) are grouped. This is not the case with the DAAE, evident from Table 2 in which neighbours 1 and 3 have a differing sentiment from the query. This offers an explanation as to why the DAAE is not able to produce tightly confined clusters.

Quant. Analysis of Latent space. To further validate our hypothesis that EPAAEs better preserve style-based semantics in latent neighbours, we generate useful quantitative metrics over a k-nearest neighbours experiment, done on the test split across all datasets. We document these metrics in Table 3. Column 3 conveys the mean distance to the closest neighbour with the opposite label. Column 4 conveys the mean number of hops to reach to the closest neighbour with opposite labels. In all but a few datasets, the DAAE reports a smaller "mean hops for label flip", supporting our hypothesis that stylistically dissimilar sentences are mapped closer together in the latent neighbour than our proposed model. We also see this trend mostly holds true for the "Mean L2 Norm for Label Flip" metric in Column 4 as well, providing further evidence to our hypothesis.

5 Setup, Datasets and Metrics

5.1 Experimental Setup

Baselines. This work focuses on simple denoising approaches for Unsupervised TST and subsequently constrains our choice of baselines to follow these criteria. We consider three other autoencoder based models for our experimentation, i.e. Denoising AAE (DAAE), Latent-Noised AAE (LAAE) and the β-VAE.

Hyperparameters and Setup. Details on hyperparameter selection can be found in A.2. Other common hyperparameters (detailed in A.1) related to encoder/decoder architectures remained identical across all models. Training is completely unsupervised, and labels are only used during inference time. Details on computation time, number of parameters and infrastructure used can be found in Appendix. E.

5.2 Datasets

In this section, we briefly describe the different kinds of datasets used for experimentation. Further details is provided in in Appendix C.

Complexity of Styles in Datasets: Current studies mainly focus on high-level styles to validate the approaches. To validate our hypothesis that the EPAAE can perform fine-grained style transfer due to semantics learnt from embeddings, we consider three tasks: sentiment, discourse and fine-grained text style transfer. As prepossessing, we remove non-essential special characters and lowercase all sentences. Except for the Yelp dataset, no pruning is done based on sentence length.

Sentiment Style Datasets: We use the preprocessed version from (Shen et al., 2017) of the Yelp dataset. The sentiment labels (positive, negative) were considered as style.

Discourse Style Datasets: To check for the model's ability to alter the discourse or *flow of logic* between two sentences we make use of NLI datasets such as SNLI, DNLI, and Scitail. Each instance in the SNLI dataset (Bowman et al., 2015) consists of two sentences that either contradict, entail (agree) or are neutral towards each other. Similarly, the DNLI dataset (Welleck et al., 2019) consists of contradiction, entailment and neutrality labelled instances. Scitail (Khot et al., 2018) is an entailment dataset created from multiple-choice science exams and the web, in a two-sentence format similar to SNLI and DNLI. The first sentence is formed from a question and answer pair from science exams and the second sentence is either a supporting (entailment) or non-supporting (neutrality) premise.

Fine-grained Style Datasets: The Style-PTB dataset (Lyu et al., 2021) consists of 21 styles/labels with themes ranging from syntax, lexical, semantic and thematic transfers as well as compositional transfers which consist of transferring more than one of the aforementioned fine-grained styles. To check whether the EPAAE can capture fine-grained styles better by leveraging its better organised latent space, we make use of three styles i.e. Tenses, Voices (Active or Passive) and Syntactic PP tag removal (PPR). In the Tenses dataset, each sentence is labelled with "Present", "Past", and "Future". The Voices dataset contains "Active" and "Passive" voices labels and the PPR dataset contains "PP removed" and "PP not removed" labels.

5.3 Automatic Evaluation metrics

Evaluation for text style transfer includes checking for a) Style Transfer accuracy, b) Content preservation metrics and c) Fluency of output sentences. Recent studies show that automatic Evaluation metrics are still an open problem and can be gamed (Xu et al., 2020).

Style Transfer Measure: A pre-trained classifier is used to check the presence of the target label in the output sentence. (Mir et al., 2019) introduces the notion of checking the style transfer intensity apart from just the presence of the target label. While we find this notion intriguing, we wish to first accomplish the style transfer task convincingly for the current set of tasks before assuming a more complex metric.

Content Preservation: In recent work, we observe that models typically struggle more in content preservation and the ability to preserve the contextual meaning of the base sentence. The BLEU score alone does not suffice to correlate strongly with actual qualitative results. To truly validate our hypothesis that EPAAE's are better able to preserve content better, we augment the bucket of standard content preservation metrics [‡]. Apart from the standard of using BLEU between sentences of source and target styles, we borrow evaluation techniques from fields similar to Text Style Transfer such as Machine Translation and Text Summarization, such as METEOR (Banerjee and Lavie, 2005),

---

[‡] To generate all our content preservation metrics, we use the nlg-eval package from: `https://github.com/Maluuba/nlg-eval`

ROUGE-L (Lin, 2004), CIDEr (Vedantam et al., 2015) which have been shown to correlate more strongly with human judgement. Following the study of (Sharma et al., 2017), in which they show BLEU does not necessarily correlate with human evaluations in dialogue response generation, we also adopt Embedding Average, Vector Extrema (Forgues et al., 2014) and Greedy matching score (Rus and Lintean, 2012).

Fluency of generations: Past work measures the perplexity using a pre-trained language model to gauge the fluency or grammatical correctness of the style transferred outputs. (Mir et al., 2019) argues such perplexity calculations for style transfer tasks may not necessarily correlate with a human judgement of fluency. Adversarial classifiers in the form of logistic regression networks are trained with the goal of distinguishing between human-produced and machine produced sentences. These classifiers are then used to score the naturalness of the output sentences. We follow this metric during our evaluation of fluency or naturalness [§]

6 Experiments

In this section, we look at the quantitative and quantitative results for the text style transfer task for four autoencoder models in seven datasets. We use the vector arithmetic method on latent space representations, inspired by (Mikolov et al., 2013) where it showed that word embeddings learnt can capture linguistic relationships using simple vector arithmetic. Analogous to the standard example where "King" - "Man" + "Woman" ≈ "Queen", we manipulate an arbitrary sentence encoding z_x of Style X to Style Y [¶]:

$$z_x = z_y + k\left(\frac{1}{N_y}\sum_{i=0}^{N_y} z_y^i - \frac{1}{N_x}\sum_{i=0}^{N_x} z_x^i\right) \quad (5)$$

where z_y^i, z_y^i denotes the latent vector of the i^{th} sentence in style y and x respectively and N_x and N_y represent the number of encoding present in the corpus for style x and y respectively. k is a scaling parameter used to control the style transfer strength. The resultant latent vector is passed through the decoder to produce the output sentence.

6.1 Quantitative Analysis

TST accuracy, content preservation and naturalness were computed on the converted sentences (shown in Table 4, 5, 6). Content preservation metrics can be found from Column 4 onwards. We consider two versions of the EPAAE i.e. only continuous embedding noise, continuous embedding noise + token deletion, and find that in some cases a mixture of both is required for optimal performance. We find that a slightly lowered value p for the EPAAE combined with its optimal ζ parameter outperforms other models as well.

6.1.1 Sentiment TST

Table 4 summarises the results of TST on the Yelp dataset. On visual inspection, there appears to be a general tradeoff between TST% and content preservation metrics. For example, the β-VAE achieves the best TST% but suffers from bad content preservation capability. In this case, we observe that EPAAE ($\zeta = 2.0, p = 0.1$) has the best content preservation capabilities across all metrics and achieves a reasonable tradeoff of TST%=77.1 as well.

6.1.2 Discourse TST

Table 5 summarises the results on four NLI datasets. Similar to the sentiment task, we see that EPAAEs have the best content preservation capabilities as well as the naturalness metric. It achieves this while achieving a comparable TST% as well. β-VAE shows best TST% but again suffers in content preservation. DAAE also display reasonable TST% vs Content preservation tradeoffs but overall cannot match the tradeoffs achieved by EPAAEs. Human evaluations on the SNLI dataset (Table 8) confirm this as well. The TST% achieved by any model in any task peaks at only 60.4% compared to 81.9% in sentiment task, a significant difference that hints at the fact that the Discourse TST task might be intrinsically more complex than sentiment style. Future work that aims to increase performance on the NLI task will be beneficial.

6.1.3 Style-PTB TST

Table 6 summarises the results on three datasets from the Style-PTB benchmark. (Lyu et al., 2021) produces a hierarchy of styles based on transfer difficulty measured by the average token-level ham-

---

[§] We use code and pretrained models from `https://github.com/passeul/style-transfer-model-evaluation` to measure naturalness.

[¶] Simply put, the difference of the means of all vectors in Style Y and X is computed and scaled by a factor k, then added to any arbitrary latent vector with style Y to convert it to style X.

Model	Naturalness	TST Acc.	BLEU-2	METEOR	ROUGE-L	CIDER	Embedding Average	Vector Extrema	Greedy Matching Score

Table 5: Quantitative results of TST experiments on NLI datasets

ming distance between the base and converted sentence. According to this hierarchy Tense inversion, PP removal/addition and Voice change are labelled in ascending order as easy, medium and hard respectively. Our results seem to partially validate this observation, in that the max TST% is obtained on the Tenses dataset (100%). Generally speaking, we also observe that TST has much better performance on fine-grained Style-PTB datasets than sentiment and discourse styles. Similar to before, the EPAAE shows best content preservation at competitive values of TST% as well.

It is also noteworthy to consider the direction of style transfer, particularly in the case of complex styles such as Discourse styles present in NLI datasets. Results and analysis on direction-specific metrics for Discourse TST are presented in Appendix B.2.2.

6.2 Qualitative Analysis

Samples of Output. For qualitative analysis, sample outputs by DAAE and EPAAE for the Yelp, SNLI and Tenses dataset are given in Table B.4. For a full list of qualitative examples on all datasets along with setup details, please refer to Appendix B.2.1.

Varying k for Fine-Grained TST. By varying the value of k in Equation 5, it is possible to finely control the strength of Text Style transfer. We show examples of this for the Yelp (Table B.9) and the SNLI (Table 7) dataset, for the baseline DAAE ($p = 0.3$) and the proposed model EPAAE. For the proposed EPAAE model, the best performing models (specifically in content preservation metrics) were chosen i.e. $zeta = 2.0$, $p = 0.1$ for the Yelp dataset and $zeta = 2.5$ for the SNLI dataset. The chosen qualitative examples highlight the EPAAEs slight superiority in performing fine-grained TST compared to the baseline.

Smooth Interpolation. Sentence interpolation experiments are reported in Appendix B.1, in which latent space points in an interpolation along a specific direction are decoded to gauge the smoothness of the space and its ability to generate coherent sentences

6.3 Human Evaluations

Each human annotator was given a set of base sentences and asked to vote for which model produced the most appropriate corresponding style inverted sentences. Please refer to Appendix A.3 for full details on the setup. Results are shown in Table 8. We observe that the proposed EPAAE model was overall more preferred across all three chosen datasets. This margin was most significant in the case of the SNLI dataset.

7 Conclusion

We introduce the "Embedding Perturbed AAE" or EPAAE and show that it best captures underlying style-based semantic features in the latent space in an unsupervised manner compared to its baselines. By inducing robust latent space organization through embedding perturbation in an unsupervised manner, we also demonstrate the possibility of fine-grained TST, where we can control the strength of the target style. Using a diverse set of datasets with varying formulations and complexities of style, we empirically that EPAAE performs overall best in the text style transfer task, particularly in its ability to preserve style-independent content across all datasets.

8 Future Work and Limitations

Regarding work in TST. We wish to augment existing state of the art methods with embedding perturbation to check if doing so aids performance. We see degrading TST performance in the Entailment to Contradiction Task across all models. Future work will focus on methods to improve this task.

Generally. It is also interesting to further analyse the effects of embedding perturbation to latent representations and resultant properties. A theoretical analysis would be beneficial to cement the use of embedding perturbation in a more general setting. There also remain more important questions that need answering for, e.g. "What if you apply continuous perturbation to hidden states instead of embeddings?", "What is the relation between this type of perturbation and techniques like dropout?". We wish to explore these important questions in the future.

Ethics Statement

Any TST model can be used for nefarious purposes, e.g. performing a "Non-toxic to toxic" modification of text in a real-world setting and causing social harm. Therefore, it is important we keep in mind a code of ethics (e.g. `https://www.acm.org/code-of-ethics`) for usage, research and development in this type of research. We have made all our code open-source and provided all details of experimentation and implementation to the best of our knowledge.

Acknowledgements

We would like to thank the reviewers whose feedback we believe substantially increased the quality of this work. We would like to thank the human annotators for their participation.

Appendix

A Additional details on Text Style Transfer Experiments

A.1 Model Architecture

All baseline models were trained with all underlying architectures apart from their individual objective losses. Bi-directional GRUs were used for the encoder and decoder with input embeddings of size 300, a hidden representation of size 256 and a latent space of size 128. For all models using AAEs as the underlying autoencoder, the discriminator was a single-layered perceptron with 512 units. The ADAM optimiser with β_1, β_2 as 0.5, 0.999 and a learning rate of 0.001. All models were trained for 30 epochs as any more training steps caused the reconstruction loss to dominate and decrease overall performance on the TST task. All input perturbations were disabled in inference time.

A.2 Hyperparameter Selection

For the hyperparameters p, λ_l, and β for the DAAE, LAAE and β-VAE, we fixed the values as 0.3, 0.05, 0.15 respectively. This decision was aligned with the results in Shen et al. (2020), which showed that these values produced the best reconstruction vs BLEU trade-off. We found this to be the case during subjective manual testing as well. λ_{adv} was set to 10 for all models having AAEs as the underlying architecture. For EPAAE, we found that $\zeta \in [2.0, 3.0]$ overall showed the best results across all datasets. Therefore a manual search around this range was conducted to determine the optimal ζ for each dataset.

A.3 Human Evaluations

TST outputs of two models, the baseline DAAE and the proposed EPAAE model, on the Yelp, SNLI and Tenses dataset were considered. The best performing EPAAE was chosen according to the results in Table 4, 5 and 6, particularly with respect to the content preservation metrics (Since TST% were similar across all models). Two hundred sentences (hundred from each base style) were randomly sampled from the test split of each dataset and style inverted (with scaling factor $k = 2$). Six hundred instances (each instance being a base and converted sentence pair) were equally split between three human evaluators. Each evaluator was given the task of labelling all two hundred instances from each dataset. The models were anonymous to evaluators and randomly named as "Model 1" and "Model 2". Each instance was to be labelled by an evaluator with four possible decision outcomes, i.e. "1 is best", "2 is best", "All are bad" and "All are good". For each instance, the majority of three votes from each of the three annotators were taken as the final decision for that corresponding instance. Instances without a majority were marked as "NA". The evaluation guidelines was formulated to consider which model a) successfully transferred the target style b) preserved the style-independent content and c) was overall fluent and grammatically coherent.

B Additional Experiments:

B.1 Sentence Interpolation in Latent Space - Qualitative Examples

We perform sentence interpolation using DAAE and EPAAE, starting from the same input sentence, incrementally moving along the same direction in the latent space in five fixed-size steps. We see that both the baseline and proposed model are able to produce fluent and coherent sentences, indicative of a smoothly populated latent space.

B.2 Text Style Transfer

B.2.1 Qualitative Examples

TST with scaling factor $k = 2$ was performed on DNLI, Scitail datasets as seen in B.5 and B.6 respectively. Similarly, it was also performed on Voices and PP Removal datasets from the Style-PTB benchmark as shown in B.7 and B.8 respectively. The proposed model for each dataset, was chosen to be the EPAAE with best performance in the content preservation metrics (shown in Table 4, 5 and 6). Samples were specifically selected in which at least one of the models was able to generate the ideal, style converted sentence with near-perfect content preservation and coherence. This was done by human evaluators, where both the models were anonymized.

B.2.2 Direction specific Discourse Transfer metrics

Particularly in the case of Discourse Style, it is natural to speculate that the difficulty of style transfer might be sensitive to the direction i.e.

two blond women are hugging one another the women are sleeping	**two blond women are hugging one another the women are sleeping**
two blond women are hugging one another the women are sleeping	two blond women are hugging one another the women are sleeping
three dogs affectionately playing the dogs are sleeping	three dogs affectionately playing the dogs are sleeping
two dogs are playing and wrestling with each other two cats are chasing each other through the house	two dogs are playing and wrestling with each other two cats are chasing each other through the house
two men in wheelchairs crash and they reach for the ball the men are sleeping	two men in wheelchairs crash and they reach for the ball the men are sleeping
three dogs in different shades of brown and white biting and licking each other the dogs are fighting	three dogs in different shades of brown and white biting and licking each other the dogs are fighting

Table B.9: Qualitative examples of Fine-grained TST on the Yelp Dataset

is it Contradiction/Neutrality to Entailment or vice versa. Intuitively, this makes sense as the Entailment to Contradiction/Neutrality tasks can be achieved simply by randomly editing either the subject or predicate or both, in any one sentence, to trigger a contradiction/neutrality between the two. However, in the reverse task, the edited part must be carefully chosen to precisely match the context of the other sentence to trigger entailment.

To analyze this, direction-specific quantitative metrics for Discourse TST are conducted for the SNLI (B.10), DNLI (B.11) and SciTail (B.12) datasets. We notice a disparity in performances in fact, does exist, mainly highlighted by the differences in the TST% metric. This sensitivity to direction is present in all models across all datasets but is most significant in the SNLI dataset in which TST% goes as low as 20.6% for the Contradiction to Entailment task and as high as 83.7% for the opposite task. Future work can focus on trying to specifically improve the Contradiction to Entailment task, as doing so will be a measure of a model's ability to detect and carefully align the content of one sentence to match another.

C Details on Datasets

Here we provide some additional details of all the datasets used in this work.

Complexity of Styles in Datasets: As discussed in Section 5.2, we consider three tasks- sentiment, discourse and fine-grained text style transfer. As prepossessing, we remove non-essential special characters and lowercase all sentences. Except for the Yelp dataset, no pruning is done based on sentence length. The vocab size during training was limited at 25k unless mentioned otherwise.

Sentiment Style Datasets: We use the preprocessed version from (Shen et al., 2017) of the Yelp dataset. It contains 200k, 10k, 10k sentences in the train, dev and test split respectively. The sentiment labels (positive, negative) were considered as style.

Discourse Style Datasets: We used three NLI datasets - SNLI, DNLI, and Scitail. Each instance in the SNLI dataset (Bowman et al., 2015) consists of two sentences. These sentences either contradict, entail (agree) or are neutral towards each other. The resultant dataset contained 341k, 18k, 18k in the train, dev, test splits respectively. The DNLI dataset (Welleck et al., 2019) consists of contradiction, entailment and neutrality labelled instances instead in the form of a first-person dialogue like representation. The dataset contains 208k, 11k, 11k sentences in train, dev and test respectively. Scitail (Khot et al., 2018) is an entailment dataset created from multiple-choice science exams and the web, in a two-sentence format similar to SNLI and DNLI. The first sentence is formed from a question and answer pair from science exams and the second sentence is either a supporting (entailment) or non-supporting (neutrality) premise obtained from the internet. The dataset contained 24k, 1.3k, 1.3k sentences in the train, dev, test splits respectively. For SNLI and DNLI, all instances with the "neutrality" label were removed. Style transfer task performed from "contradict" to "entail" and vice versa. For SciTail (Khot et al., 2018), the transfer task was from "neutral" to "entail" and vice versa.

Fine-grained Style Datasets: We used Style-PTB dataset (Lyu et al., 2021) for fine-grained style. It consists of 21 styles/labels with themes ranging from syntax, lexical, semantic and thematic transfers as well as compositional transfers which consist of transferring more than one of the aforementioned fine-grained styles. To check whether the EPAAE can capture fine-grained styles better by leveraging its better organized latent space, we make use of three styles i.e. Tenses, Voices (Active

The resultant sizes of the test, dev, test splits were 71k,8.8k,8.8k (tenses), 90k,11k,11k (PPR) and 44k,5.5k,5.5k (voices).

D More details on related work

Bowman et al. (2016) extend Variational Auto-Encoders (Kingma and Welling, 2014) for text generation and address the posterior collapse problem wherein the decoder completely ignores the latent channel leading to poor generation. Adversarial auto-encoders (Makhzani et al., 2015) substitute the KL loss with an adversarial approach to enforce the latent Gaussian prior. On the other hand, AAEs are shown to naturally avoid the posterior collapse problem and promote strong coupling between the encoder and decoder. Wasserstein autoencoders (Tolstikhin et al., 2018) introduce a family of regularized autoencoders that learn a flexible prior by solving an optimal transport problem to match P(z) and Q(z) using an adversarial approach. Adversarially regularised autoencoders (ARAEs) follow the Wasserstein Autoencoder framework to learn a learnt prior unlike AAEs, which assume the prior to be a fixed standard Gaussian distribution.

E Computational Expense and Infrastructure used

The most parameter-heavy EPAAE model was from the SNLI dataset and we therefore report statistics for this model. The model has 13 million parameters and each epoch took approximately 60 seconds to train on an Nvidia V100-SMX2 GPU and an Intel(R) Xeon(R) E5-2698 CPU. For complete details, please refer to the log.txt files present in each model's directory present in `https://github.com/sharan21/EPAAE`.

Automatic Correction of Human Translations

Abstract

We introduce translation error correction (TEC), the task of automatically correcting human-generated translations. Imperfections in machine translations (MT) have long motivated systems for improving translations post-hoc with automatic post-editing. In contrast, little attention has been devoted to the problem of automatically correcting human translations, despite the intuition that humans make distinct errors that machines would be well-suited to assist with, from typos to inconsistencies in translation conventions. To investigate this, we build and release the ACED corpus with three TEC datasets[1]. We show that human errors in TEC exhibit a more diverse range of errors and far fewer translation fluency errors than the MT errors in automatic post-editing datasets, suggesting the need for dedicated TEC models that are specialized to correct human errors. We show that pre-training instead on synthetic errors based on human errors improves TEC F-score by as much as 5.1 points. We conducted a human-in-the-loop user study with nine professional translation editors and found that the assistance of our TEC system led them to produce significantly higher quality revised translations.

1 Introduction

Despite recent progress in machine translation (MT), a tremendous amount of translated content in the world is still written by humans (DePalma, 2021). Humans are often assumed to produce trusted, high-quality translations. In reality, they do make errors, including spelling, grammar, and translation errors (Hansen, 2009). This paper introduces the task of **translation error correction** (TEC). Given a source sentence s and a human-generated translation t, the goal of TEC is to produce an improved translation t' by correcting all errors in t.

"Translation correction" has long been studied in the MT community through the task of automatic post-editing (APE), which aims to correct errors in machine-generated translations (Simard et al., 2007). TEC is structurally identical to APE. However, it requires modeling a different data distribution: errors made by humans, which differ from those made by MT systems (Freitag et al., 2021). We characterize the error distribution in TEC by building, analyzing, and releasing the ACED corpus, a collection of three TEC datasets from varying domains, with a total of 35,261 English–German translations produced and corrected by professional translators in the natural course of their work. While APE is dominated by the fluency errors that are characteristic of MT systems (74% of sentences), our TEC corpus exhibits a broader distribution of errors that human translators are prone to make.

Using this error analysis, we propose an approach for TEC that pre-trains on synthetic corruptions more similar to errors made by humans, outperforming models that were developed for the related tasks of MT, grammatical error correction, and APE on all ACED datasets.

The task of TEC is often currently performed by humans, e.g. translators hired to review and edit translations ("reviewers"). Can a TEC system help reviewers edit faster, or produce higher quality final translations than they would have without assistance? We ran a human-in-the-loop user study with nine professional translators using our best-performing TEC model. We found that the reviews produced when assisted with a TEC system were rated as higher quality than those produced without, and produced with less manual effort. Qualitatively, users commented that trust and consistency of the suggestions were critical. They speculated future automated assistance could be helpful for onboarding to new content, spotting technical errors, and improving their own awareness of errors to catch.

Table 1: Error taxonomy for the ACED corpus, with examples from the dataset.

Looking forward, a natural question arises of whether the research community should focus on learning to revise *model* outputs (APE) or *human* outputs (TEC). With recent improvements in MT, it has been increasingly difficult for APE models to improve model output that is already high quality (Chollampatt et al., 2020). On the other hand, we should expect that humans will continue to make errors. TEC models will continue to provide benefit as a way of assisting humans, whether for professional translation work or everyday language learners. TEC is synergistic with continuing advancements in MT: improved MT will lead to improved error correction for human-generated translations. While APE pits models against models, TEC is an opportunity to combine the best of humans and models *because* humans and models make different errors.

In sum, this paper revisits the notion of "translation correction" conceived narrowly as the MT-centered task of APE, with an empirical investigation of translation error correction (TEC), the task of learning to correct human translations. Our contributions are:

1. We release ACED, the first corpus for TEC containing three datasets of human translations and revisions generated naturally from a commercial translation workflow.
2. We analyze the kinds of errors humans make in ACED, finding that while APE is dominated by correcting translation *fluency*, TEC focuses on correcting a broader range of errors that appear in translation.
3. We propose a pre-training approach for TEC that outperforms approaches developed for similar tasks such as APE. Together, our results suggest the need for distinct approaches to correct human translation errors.
4. We perform a human-in-the-loop user study, finding that professional translators produce *higher quality* translations when assisted by a TEC model.

2 The ♠ ACED Corpus for TEC

Given a source language sentence s and a human-generated translation t, the goal of TEC is to produce a corrected target language sentence t'.

We introduce the ACED corpus, a set of three TEC datasets: ASICS, EMERSON, and DIGITALOCEAN (DO), each consisting of English–German sentence triples (s, t, t') from varying domains.

ACED is a *real-world benchmark*, containing naturalistic data from a task humans perform, rather than manually annotated data. All translations were created by professional translators working with Lilt, a localization services provider. All translators have at least 5 years of professional translation experience and experience working with the customer and domain. Each document was translated from scratch (i.e. not post-edited) by a human translator using an interactive neural MT system. Each translated document was then reviewed by a reviewer, who Lilt selects as one of the more senior translators. As a result, the examples in our corpus exhibit

Dataset	Domain	# sentences			% edited	# edits (mean)	Edit distance (mean)
		train	dev	test			
ASICS	Marketing	1395	525	616	29 %	1.6	7.5
EMERSON	Technical	4287	1255	1662	20 %	1.5	5.8
DIGITALOCEAN (DO)	Technical	11773	6104	7644	8 %	1.5	7.1

Table 2: Corpus statistics for each dataset in the ACED corpus, including edit statistics on % of sentences that edited, and for edited sentences, the average number of edits and average edit distance.

real errors that translators make, and the corrected translations are publication quality.

Secondly, ACED is *diverse*, with the three datasets from varying domains exhibiting different error distributions and difficulty for initial work on the TEC task. Information for each dataset is shown in Table 2. The ASICS dataset consists of marketing content with product names and descriptions for an activewear company. EMERSON consists of industrial product names for a manufacturing company. DO consists of software engineering tutorials. The various content types pose different challenges for translators and thus for TEC systems, which we discuss in Section 2.1 and Section 2.2.

Duplicate sentences with the same source s were removed. A portion of sentences were rewritten by the reviewer rather than being edited (a relative edit distance of more than 25% and a minimum of two edited words). We replace t in these sentences with t' in the corpus, so that training and evaluation focuses on local edits rather than re-translations. The train, dev, and test splits were constructed by splitting along document boundaries.

2.1 How do TEC and APE errors differ?

To understand how the human errors in the TEC task differ from model errors in APE, we compare the types of errors in ACED with 100 randomly sampled errors in the WMT 2021 APE shared task dev set [2], which we then annotate with error types. We define an error taxonomy that classifies each edit as one of three types: (1) **Monolingual edits** are identifiable from only the target-side text. We divide these further into subcategories that highlight different capabilities needed to correct edits: *typos* (including spelling, punctuation, spacing, orthographic issues), *grammar*, and *fluency* (awkward phrasing, word choice, or non-native-sounding disfluencies); (2) **Bilingual edits** concern mismatches between the source and target text, e.g. over- or under-translation, mis-translations; (3) **Preferential edits** correct text that is inconsistent with the preferences of the customer, as described in extralinguistic project requirements (e.g. terminology or stylistic preferences). Examples of each error type are shown in Table 1. Our error taxonomy closely mirrors those of previous analyses of human translation errors (Specia and Shah, 2014; Yuan and Sharoff, 2020; Gupta et al., 2021), and we confirm their findings that human translation errors differ from MT errors. However, while previous work focuses on error *detection* and quality estimation, TEC is concerned with error *correction*. Our error types are intended to isolate the capabilities that models need to learn to correct edits (e.g., target-side language models can learn to correct monolingual errors, but cannot do well on bilingual edits).

We annotate and release error labels for all test sentences in ASICS to enable its use as a diagnostic set for per-type evaluation of models. On the larger EMERSON and DO datasets, we randomly sample 50 errors to annotate for this analysis. Error types were annotated by a professional German translator. Each segment can have multiple error types. In Table 3, we report the percentage of sentences with at least one error of each type. 74% of sentences in APE exhibit a fluency error, in contrast to up to 22% of sentences in ACED, while other types like monolingual grammar, bilingual, and preferential errors are notably underrepresented in APE. We also note that all sentences in the APE shared task are edited, while a key feature of TEC is identifying when a sentence does *not* need to be edited. The error distributions suggest that different modeling techniques may shine in each: while APE challenges models to correct disfluent translations characteristic of MT systems, our task is designed to focus on identifying and correcting the typos, mismatches, and grammatical errors more commonly exhibited by humans. Guided by this observation, we describe an approach in Section 3 that pre-trains on synthetic edits that are more representative of this

	TEC			APE
	ASICS	EMERSON	DO	WMT '21
Monolingual				
typos	13	16	22	16
grammar	41	4	2	6
fluency	22	0	20	74
Bilingual	22	70	32	5
Preferential	7	24	40	6

Table 3: Percentages of erroneous sentences that contain at least one error of each type for ASICS, EMERSON, DO, and the dev set of the WMT 2021 APE shared task. As a task, APE exhibits many more fluency errors than TEC.

		ASICS	EMERSON	DO
Train	Total Edits	606	1436	1212
	Unique Edits	418	486	940
Dev	Total Edits	246	381	1004
	% in train	14	63	21
Test	Total Edits	287	364	766
	% in train	23	60	21

Table 4: Edit and edit overlap statistics for each ACED dataset: total number of edits, unique edits in each train split, and percentage of total edits in each dev and test split that appear in the train split.

error distribution.

2.2 How difficult is it to learn to edit?

To quantify how difficult it may be to learn the correct edits in ACED, we report statistics on *edit overlap*: what proportion of edits that we expect models to perform (e.g. adding a comma) appear exactly in the training set? We use the *errant* toolkit to identify discrete edits (Bryant et al., 2017). Each edit is represented as a tuple *(original span, replacement span)*, e.g. *("auf", "an")* to replace "auf" with "an." Edit statistics are reported in Table 4: in ASICS and DO, ~20% of the total number of edits in dev and test appear in the training set, while EMERSON has ~60% of dev and test edits appear in the training set.

While the edit overlap rate provides a relative sense of scale for precision and recall numbers, it does not provide an upper bound on recall. It is possible to learn edits that do not exactly appear in the training set. For example, capitalizing product names ("winterized" → "WINTERIZED") is a learnable pattern that would appear as many distinct edits. Additionally, some errors can be corrected without fine-tuning because they are generic typo, grammatical, fluency, or bilingual errors. Conversely, it is also possible that it is wrong to make an edit that appears in the training set, depending on the surrounding sentential context.

3 Approaches to TEC

We propose a TEC model and compare it to several models designed for related tasks to determine whether they are also effective for TEC. An overview of the differences between the models is shown in Figure 1. All models use the Transformer neural architecture (Vaswani et al., 2017) that generates the target sequence t' from left to right. All are pre-trained on 36M sentences from the WMT18 translation task[3] and fine-tuned on ACED, unless indicated otherwise. All pre-training and fine-tuning data is pre-processed by normalizing punctuation with the Moses toolkit (Koehn et al., 2007).

All models have 6 encoder and decoder layers, model dimension of 256, feed-forward dimension of 512, and 8 attention heads. We use a joint English–German vocabulary with 33k byte pair encoding subwords (Sennrich et al., 2016). During pre-training, we set the dropout to 0.1 and use the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 0.0002. During fine-tuning, we decrease the learning rate to 0.0001 and reset the Adam momentum parameters. We select the best fine-tuning checkpoint with edit-level $\mathrm{F}_{0.5}$ score on our dev set. We use greedy inference.

3.1 Dual-Source Encoder-Decoder Model

We first describe the dual-source encoder-decoder we use for the APE and TEC models. Formally, the original Transformer architecture (Vaswani et al., 2017) takes a sequence of J source tokens $\mathbf{s}_{1\ldots J}$ and predicts a sequence of I' target tokens $\mathbf{t'}_{1\ldots I'}$. We adapt the architecture to additionally encode the original translation t, a sequence of I tokens, $\mathbf{t}_{1\ldots I}$. We independently project $\mathbf{t}$ into the embedding space, add an offset vector $\mathbf{o}$, and then concatenate the embedding with the embedding of the source $\mathbf{s}$ to form the encoder input. To allow the dual-source model to copy tokens from the original translation t, we implement the copy-mechanism proposed by Zhao et al. (2019), which augments the model with an additional encoder-decoder attention layer. An expanded description of the model can be found in Appendix Section A.

---

[3] http://www.statmt.org/wmt18

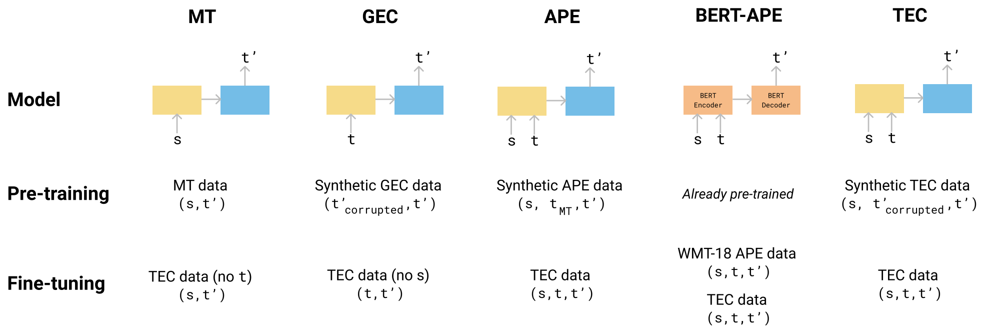

Figure 1: Overview of model architectures, pre-training data, and fine-tuning data for each approach to TEC. Transformer encoders and decoders are depicted as yellow and blue rectangles, respectively. The GEC and TEC models are pre-trained with synthetic corruptions of t' ($t'_{\text{corrupted}}$), as detailed in the description of the TEC and GEC models. APE uses MT-generated translations of s (t_{MT}) as synthetic data. BERT-APE is a state-of-the-art pre-trained APE model made available by Correia and Martins (2019).

3.2 Synthetic Data Generation

For the TEC and GEC model, we generate synthetic triples (s, t, t') for pre-training. We generate a synthetic t by corrupting the German side of the translation data into $t'_{\text{corrupted}}$. For each sentence, we sample the probability of corruption $p_c \sim \mathcal{N}(\mu = 0.01, \sigma = 0.04)$ clipped at 0. On each character and word in that sentence, with probability p_c, we randomly select one of the following perturbations to apply at that position: insertion, deletion, transposition, repetition.

3.3 TEC Models

The five approaches we compare are:

TEC (this work) We implement the dual-source encoder-decoder model that encodes two inputs (s, t) and outputs t', as described in Section 3.1, and then pre-train on synthetic data generated with the procedure in Section 3.2. We then fine-tune on ACED.

MT We train an English-German neural machine translation model (with the standard architecture described previously) and fine-tune it on (s, t') ACED pairs, ignoring the original translation t.

GEC We evaluate a encoder-decoder (monolingual) GEC model that takes an incorrect German sentence t as input and outputs a corrected t'. We use the same copy mechanism to attend to t as our TEC model. To pre-train, we perturb t' using the procedure described in Section 3.2, throwing away the source side to obtain $(t, t') = (t'_{\text{corrupted}}, t')$ pairs. We then fine-tune on the ACED corpus, ignoring s.

APE We implement a dual-source encoder-decoder model that is identical to our TEC model. Following common practice in APE (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018), we pre-train on synthetic "post-editing" triples (s, t, t') where $t = t_{\text{MT}}$ is generated by translating s with an MT system. We split the training dataset into two parts, train an MT model on each half, and use each model to translate the other half of the dataset not seen during training. We then fine-tune on ACED.

BERT-APE We also evaluate whether a state-of-the-art APE model can be directly applied to our task. We evaluate the BERT-based encoder-decoder of Correia and Martins (2019), on which the WMT 2019 shared task winner was based (Lopes et al., 2019). Following Correia and Martins (2019), we fine-tuned on 23K English–German SMT triplets from the WMT18 shared task[4]. We reproduce their results on the APE shared task test sets, and continue fine-tuning this model on ACED. Following their paper, the inputs are pre-processed by tokenizing and joining the two inputs with a separator to form (s [SEP] t, t') pairs.

4 Results & Discussion

The primary metric for TEC is MaxMatch scores (M^2) (Dahlmeier and Ng, 2012) computed with the *errant* toolkit (Bryant et al., 2017). M^2 is a standard metric for GEC that aligns t and t' to extract discrete "edits." We choose to follow the GEC evaluation practice of up-weighting precision by comparing $F_{0.5}$, since the original translation is

---

BERT-APE	6.8	10.8	7.3	32.0	57.8	35.1	2.3	3.8	2.5
TEC	**57.4**	9.4	**28.4**	**82.1**	57.2	**75.5**	**21.7**	2.0	**7.2**

Table 5: Main results on ACED. Our fine-tuned TEC model outperforms on $F_{0.5}$. The fine-tuned MT model scores highest on recall because it makes many edits, but at the cost of unacceptably low precision.

mostly correct: it is better to suggest few correct edits than potentially introduce new errors.

Table 5 shows that TEC achieves the best overall $F_{0.5}$ score on all datasets, from $+0.1$ (on DO) up to $+5.1$ (on ASICS) above the next-best model. Fine-tuning on actual human corrections provides substantial gains; results without fine-tuning can be found in Appendix Section B.

Both the MT model (which ignores t) and the GEC model (which ignores s) underperform TEC. The MT model's high edit recall can be attributed to the fact that it proposes many edits, greatly trading off precision. Without conditioning on t, direct MT translations of the source diverge from the reference. The GEC model obtains high precision but underperforms on recall. Conditioning on s not only makes it possible to propose bilingual edits, but also provides additional information to correct monolingual edits, as we show in Section 4.1.

Can APE models be directly adapted for TEC? Since our task is structurally identical to APE, a natural question is whether models that are trained on the APE objective can be directly adapted for TEC. The APE and TEC models differ only in pretraining, but the performance difference between them is substantial, indicating that the more GEC-like data synthesis procedure is a better fit for TEC than APE-style data synthesis via MT. Even more, the BERT-APE model, which is first fine-tuned to achieve state-of-the-art on APE before fine-tuning on ACED, achieves a particularly low $F_{0.5}$ score because it makes too many edits (low precision). Although future work may find insights in APE, our results emphasize that models that excel at correcting machine errors cannot be assumed to work well on human translations.

4.1 Fluency & Per-category Error Analysis

We perform a more in-depth comparison using alternative metrics on ASICS, which includes annotated error labels as a diagnostic tool. First, to understand how much models are editing, we look at *n-gram overlap* with the GLEU metric (Napoles et al., 2015), a variant of BLEU used in GEC evaluation to measure the fluency of holistic rewrites (Sakaguchi et al., 2016). Next, we compare *sentence-level accuracy*, which measures exact match with t'. We compute overall sentence-level accuracy, which includes unedited sentences (which some models may incorrectly edit). We also report accuracy per error type over (edited) sentences annotated with that error type. These metrics need to be interpreted carefully: a no-edit baseline achieves a GLEU score of 87.85 (since original translations are mostly close in edit distance to the final) and sentence-level accuracy of 70.62% (the % of unedited sentences), outperforming models like MT and BERT-APE that make too many incorrect edits.

Our TEC model achieves the best score overall on both alternative metrics over all sentences, but various models outperform on specific error types. The full results are shown in Table 6. Examples of system outputs for different error types can be found in Appendix Section C.

Notably, APE models lose the most accuracy relative to our model on monolingual typo edits. This may be because neural MT decoders much less frequently introduce target-side errors that would be similar to typos (compared to the frequency of fluency errors). Still, the observation that different models do well at different errors suggests that future work can improve on TEC by leveraging the strengths of different models, e.g. using MT models to propose alternative translations.

5 User Study: Assisting Professional Translators with TEC

Our automatic evaluation shows how our TEC model can outperform other baseline systems, but

		Sentence-level Accuracy (%)						
		Overall	Unedited	Mono. Typos	Mono. Grammar	Mono. Fluency	Bilingual	Preferential
Model	**GLEU**	/616	/435	/16	/78	/41	/41	/14
No-edit	87.85	70.62	(100)	-	-	-	-	-
MT	44.79	31.66	40.00	0.00	11.54	**2.44**	**24.39**	**14.29**
GEC	88.46	71.10	97.01	**31.25**	14.10	0.00	0.00	0.00
APE	88.39	71.43	**97.47**	12.50	16.67	**2.44**	0.00	0.00
BERT-APE	82.35	39.77	52.18	6.25	**19.23**	0.00	4.88	0.00
TEC (this work)	**88.81**	**71.92**	97.01	25.00	17.95	0.00	7.32	0.00

Table 6: Additional analysis of n-gram overlap (via GLEU) and exact-match sentence accuracy over all test sentences (Overall) and per error category for the ASICS dataset. Number of sentences with an error of each type are indicated in gray, with some sentences containing errors from multiple categories. For each error category, we report the percentage of those sentences with at least one error of that type that a system predicted exactly.

we are ultimately interested in whether any TEC system is indeed useful in practice. Presently, TEC is done manually by humans. To investigate whether TEC systems can already be useful to humans—improving the quality, speed, or ease of human review—we performed a human-in-the-loop user study with our TEC model.

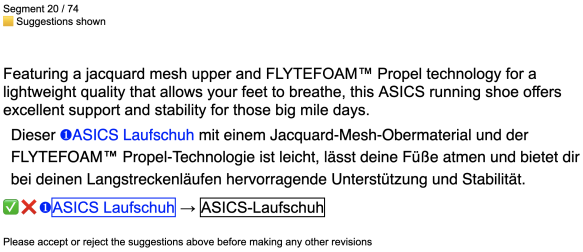
5.1 Methodology

We recruited 9 professional translators to serve as reviewers. None of them had prior experience with ASICS content. They were allowed to read and reference the sentences in the ASICS training set to familiarize themselves with the content and preferred terminology. Then, they were each assigned to review 74 sentences from the test set of ASICS. Of the 74 sentences, our TEC system predicted a suggested edit for 57 sentences, and for the remaining 17 sentences our TEC system did not predict any edits.

We opt for a within-subjects design to control for speed and experience differences between reviewers. For each reviewer, the 74 sentences were randomized such that half were in the "assisted condition" showing the TEC suggestion if available for the sentence, and the other half were in the "unassisted condition" where no TEC suggestion was shown. The reviewing interface is shown in Figure 2. If the sentence has suggestions available, the reviewer is asked to first accept or reject each of the suggestions. Then, they are asked to make edits to the text until they are satisfied with the translation. They then click a button to confirm their translation and move to the next sentence.

During the review process, we track:

1. Whether the TEC suggestion, if shown, was accepted or declined
2. Total time spent reviewing each sentence
3. Number of edit operations (insertions and deletions) the user made
4. Levenshtein edit distance from the original text to the final text



Segment 20 / 74

Please accept or reject the suggestions above before making any other revisions

Figure 2: The interface used to show suggestions to reviewers in our user study.

Finally, to evaluate whether TEC has an effect on quality, we asked a 10th translator to compare the quality of the reviewed sentences by ranking the 9 reviewed translations, with ties allowed. This translator was the translator who had reviewed the reference translations in the corpus, as the explicit goal is to ensure consistency with conventions in the training documents.

5.2 Results

In the user study, **79%** of TEC suggestions were accepted. For the purpose of analyzing effects of the TEC suggestions on time spent and translation quality, we will focus on only the 255 sentences (across 9 reviewers) where a TEC suggestion exists. Results are shown in Table 7. For all statistical significance tests, we use the Mann-Whitney (MW) U-test for testing statistical significance as all quantities are neither normally distributed nor log-normal.

Suggestions	Review Time (ms/char)	Inserts + Deletes	Levenshtein Distance
Hidden	361	0.0625	0.0347
Shown *(Overall)*	367	0	0.0185
Accepted	328	0	0.0176
Declined	841	0.0625	0.0426

Table 7: Length-normalized medians from our user study for review times, number of characters the user inserted and deleted, and final Levenshtein edit distances from the original to the final translations. Data is split based on whether the suggestion was hidden or shown, and "Suggestion Shown" is further broken down according to whether the user accepted or declined the suggestion.

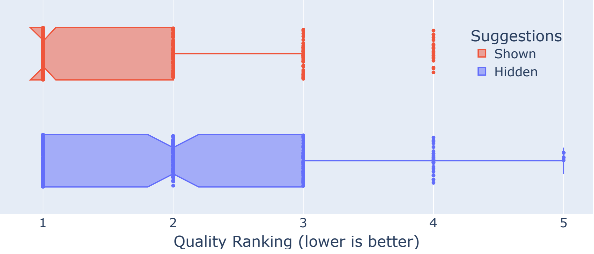

Figure 3: Box plot showing quality rankings of segments reviewed with suggestions hidden vs shown. Lower is better. Notches indicate median quality rankings. Bars indicate the upper fence (3^{rd} quartile + IQR$*1.5$).

5.2.1 Effects of Suggestions on Time Spent During the Review Process

We first analyze how TEC suggestions influence the time spent reviewing a sentence. We compare the time durations normalized by the length of the sentence that needed to be reviewed (the *length-normalized review time*), as longer sentences require more time to be read and reviewed.

There is no significant difference in length-normalized review time when the suggestion is hidden vs. shown (MW $U = 31654, p = 0.460$). When suggestions are shown, the length-normalized review time is significantly less on sentences where reviewers accepted the suggestion, compared to sentences where they declined (MW $U = 3555, p < 0.0005$).

A potential explanation for these results is that when reviewers are shown incorrect TEC suggestions, they are distracted and slowed down, providing some evidence that precision should indeed be emphasized in automatic evaluations of TEC.

5.2.2 Effects of Suggestions on Edits Made During the Review Process

We also analyze the effects of suggestions on the editing effort, as measured by the number of characters the reviewer had to insert and delete, as well as how different the final reviewed sentences were from the original.

When suggestions are shown vs. hidden, there is a significant reduction in the number of insertions+deletions (MW $U = 41348.5, p < 0.0001$). There is also a significant reduction when a shown suggestion is accepted vs. declined (MW $U = 4007.5, p < 0.005$). There is no significant difference in the Levenshtein distance from the original translation to the final translation, between when a suggestion is shown vs. hidden (MW $U = 33750.0, p = 0.611$), or between when a shown suggestion is accepted vs. declined (MW $U = 5485.0, p = 0.783$).

Thus, the TEC system suggestions help to significantly reduce the amount of manual typing that the user must perform.

5.2.3 Effects of suggestions on reviewed sentence quality

To assess the effects of TEC assistance on quality, we used the quality rankings produced by the independent reviewer. Quality rankings were not normally distributed, so we use the Mann-Whitney U-test for testing statistical significance. A box plot of the quality rankings is shown in Figure 3. The median quality ranking when the suggestion is shown is 1, vs. 2 when the suggestion is hidden. The quality ranking is significantly lower (meaning quality is higher) when the suggestion is shown, vs. hidden (MW $U = 28738.0, p < 0.01$).

This suggests that showing TEC suggestions may be helping reviewers correct errors they may not have otherwise noticed, or help nudge them towards desired corrections.

5.3 Qualitative Findings

We also conducted a post-study survey for reviewers to report qualitative feedback. To understand common themes in the responses, we present all themes that at least two reviewers mention in their commentary.

5.3.1 The Role of Reliability and Trust

Five reviewers commented that *reliability is critical*: it was difficult to trust the system when they noticed some suggestions were incorrect, or the system did not reliably make an edit when applicable (e.g. always hyphenating when appropriate):

> "Because I wasn't sure I can trust the suggestions (because I saw several incorrect ones) so it took me longer to think/check whether the suggestion is right. And I have to read the entire sentence again anyway to check for other errors the suggestion didn't catch...would only work if I knew 100% that the suggestions are always right"

These comments are in concordance with our quantitative findings. Perhaps unlike other assistive applications, it is not enough to only have high precision: if reviewers cannot trust that the system has caught most or all errors, they will not save time as they still have to read the entire sentence carefully. Conversely, a high-recall, low-precision system is not only distracting, but also leads reviewers to be suspicious of whether suggestions are correct in general. In general, future TEC systems must manage this balance of precision and recall for user trust.

5.3.2 Use Cases for TEC

Many reviewers highlighted scenarios where trustworthy TEC systems could be particularly useful.

Two reviewers said TEC is helpful for **corrections and typos**, similar to the use cases for GEC in the wild (Omelianchuk et al., 2021):

> "If the tool would manage to reliably show missing punctuation marks, or numbers, or that the translation contains different numbers than the source, that would be helpful and save time."; "recurring mistakes"

On the other hand, three reviewers mentioned that they hoped such a system would make more substantial corrections in order to save a non-negligible amount of time, although of course these edits may come at the expense of precision:

> "There were not many suggestions, and they only offered small improvements...Not clear whether I would save time or not."

Three reviewers commented that a TEC system could be a **memory aid or substitute for researching client-specific requirements**, which is often an intensive part of the production translation process. One reviewer pointed out it could be particularly useful as an *instructive* tool for translators who are new to a client:

> "if I am new to an account and don't yet know whether this client wants hyphens or not (always an issue with German). So usually I have to research... (or guess), but if the QA suggestions knew this client's preference and would tell me, that would save me time."

Finally, three reviewers commented that it could be useful as an **attention-directing tool** by making them aware of what errors they might look out for, especially in repetitive content where it may be easy to miss details:

> "makes you more sensitive for spotting similar errors"; "makes you aware of what kind of errors to look for in upcoming segments"; "maybe it helps with [repetitive sentences] that you would otherwise just quickly glance at."

6 Conclusion & Future Work

We introduced the task of translation error correction (TEC) and released the ACED corpus to study automatic correction of human translations, consisting of three TEC datasets across varying domains. In our analysis of TEC data, we showed how the errors that humans make differ from those made by MT systems, suggesting that this task warrants different approaches from those previously studied in the task of automatic post-editing. We confirm this empirically by proposing a synthetic data generation procedure that more closely matches the distribution of human translation errors and showing that our TEC model, pre-trained on this data, consistently outperforms models developed for APE, as well as those for MT and GEC. Finally, we showed how our TEC system is helpful to real humans, assisting professional reviewers and leading them to produce higher quality reviewed translations.

Future work may improve on our TEC system by investigating how to leverage the strengths of recent MT systems (e.g. for initializing systems or proposing edits) or developing more sophisticated synthetic data generation techniques (e.g. using the source sentence or linguistic knowledge). Beyond our benchmark, it would be interesting to apply TEC systems to other settings in which human translation errors appear, e.g., to correct translations written by language learners, denoise MT training sets, or clean up MT evaluation sets.

From the perspective of human-AI interaction, TEC presents a real-world use case and testbed to study how to assist experts with modern NLP systems, hinting at the opportunity to combine the best of humans and machines.

Acknowledgments

We thank Sai Gouravajhala, Yunsu Kim, Eric Wallace, and the other members of the Lilt research team and Berkeley NLP group for helpful discussion and feedback. We thank Morgan Raymond and Spence Green for their support in releasing the dataset. Finally, we are grateful to the professional translators who annotated the dataset and participated in the user study.

A Transformer Architecture Background and Model Description

A.1 Transformer Architecture

The neural models implemented in this work are based on the self-attentional Transformer architecture (Vaswani et al., 2017). Formally, given a sequence of source tokens (encoded as one-hot vectors) $\mathbf{s}_{1\ldots J} = (s_1, \ldots, s_J)$, $s_j \in \mathbf{V}$, the goal is to predict a sequence of target tokens $\mathbf{t}'_{1\ldots I'} = (t'_1, \ldots, t'_{I'})$, $t'_i \in \mathbf{V}$, that is a translation of the source sequence, where $\mathbf{V}$ is the vocabulary. The model has two main components, the *encoder* and the *decoder*. The encoder transforms the source sequence $\mathbf{s}_{1\ldots J}$ into a sequence of hidden states by first mapping each individual token into a continuous embedding space, adding a positional embedding and then processing it through a sequence of self-attention and feed-forward layers:

$$\mathbf{x}_{1\ldots J} = \mathbf{E}\mathbf{s}_{1\ldots J} + \mathbf{p}_{1\ldots J} \tag{1}$$
$$\mathbf{h}^{\text{enc}}_{1\ldots J} = \text{encoder}(\mathbf{x}_{1\ldots J}), \tag{2}$$

where $x_j \in \mathbf{V}, j \in (1, \ldots, J)$, $\mathbf{E}$ is the embedding matrix for vocabulary $\mathbf{E}$ and $\mathbf{p}_{1\ldots J}$ is the sequence of positional embeddings described in Sec. 3.5 of (Vaswani et al., 2017). At a given time step i, the decoder defines a probability distribution P_i over all vocabulary items in $\mathbf{V}$:

$$\mathbf{y}'_{1\ldots i-1} = \mathbf{E}\mathbf{t}'_{1\ldots i-1} + \mathbf{p}_{1\ldots i-1} \tag{3}$$
$$\mathbf{h}^{\text{dec}}_i = \text{decoder}(\mathbf{y}'_{1\ldots i-1}, \mathbf{h}^{\text{enc}}_{1\ldots J}) \tag{4}$$
$$P_i(t'_i) = \text{softmax}(\mathbf{h}^{\text{dec}}_i \mathbf{E}^\top) \tag{5}$$

where we assume a single shared vocabulary $\mathbf{V}$ and embedding matrix $\mathbf{E}$. At training time we optimize the cross-entropy loss

$$\mathcal{L}_{\text{CE}}(P) = -\sum_i \log(P_i(t'_i)). \tag{6}$$

A.2 Dual-Source Encoder-Decoder Model

Given an additional input sequence $\mathbf{t}_{1\ldots I} = (t_1, \ldots, t_I)$. the dual-source model used for the APE and TEC models is implemented by independently projecting $\mathbf{t}_{1\ldots I}$ into the embedding space, adding an offset vector $\mathbf{o}$ and concatenating the embedding sequences. Equations 2 and 4 are rewritten as

$$\mathbf{y}_{1\ldots I} = \mathbf{E}\mathbf{t}_{1\ldots I} + \mathbf{p}_{1\ldots I} + \mathbf{o} \tag{7}$$
$$\mathbf{h}^{\text{enc}}_{1\ldots (J+I)} = \text{encoder}([\mathbf{x}_{1\ldots J}; \mathbf{y}_{1\ldots I}]) \tag{8}$$
$$\mathbf{h}^{\text{dec}}_i = \text{decoder}(\mathbf{y}'_{1\ldots i-1}, \mathbf{h}^{\text{enc}}_{1\ldots (J+I)}), \tag{9}$$

where $\mathbf{o}$ is a single learned vector that is broadcast to all positions $i \in (1, \ldots, I)$ and $[\cdot;\cdot]$ denotes the concatenate operation.

A.3 Copy-Attention Mechanism

The new output probability distribution for the next target token $P_i(t'_i)$ is a weighted sum of the probability of generating and the probability of copying token t'_i:

$$\hat{P}_i(t'_i) = (1 - \alpha^{\text{copy}}_i) P_i(t'_i) + \alpha^{\text{copy}}_i P^{\text{copy}}_i(t'_i), \tag{10}$$

where the copy probabilities are calculated from the attention matrix of an additional encoder-decoder attention layer that is added on top of the final decoder layer, $\mathbf{A}_i$:

$$P^{\text{copy}}_i(t'_i) = \text{softmax}(\mathbf{A}_i) \tag{11}$$

The copy probability weight α^{copy}_i is determined with the attention context vector $\mathbf{c}_i$, computed as a weighted sum of the attention values (i.e. linearly transformed encoder states) where the weights are defined by $\mathbf{A}_i$:

$$\alpha^{\text{copy}}_i = \text{sigmoid}(\mathbf{W}^\top \mathbf{c}_i). \tag{12}$$

This copy-attention layer applies a source-side mask so that it only attends to the positions $(J + 1, \ldots, J + I)$ that correspond to the second input sequence $\mathbf{t}_{1\ldots I}$, and its implementation follows Zenkel et al. (2019). In particular, it uses a single attention head, no skip connection, and contains a separate output layer that predicts the target word based on its context vector with probability distribution $P^{\text{align}}_i(\cdot)$. At training time both output layers are optimized jointly by defining the overall loss $\mathcal{L}$ as the weighted sum of both cross-entropy losses:

$$\mathcal{L} = \mathcal{L}_{\text{CE}}(\hat{P}) + \lambda \mathcal{L}_{\text{CE}}(P^{\text{align}}) \tag{13}$$

λ is set to 0.05 in all experiments. We further apply source-word dropout (Junczys-Dowmunt et al., 2018), setting the full embedding vector for words in t to $1/p_{\text{src}}$ with probability $p_{\text{src}} = 0.05$.

Abstract

We study the robustness of machine reading comprehension (MRC) models to entity renaming—do models make more wrong predictions when the same questions are asked about an entity whose name has been changed? Such failures imply that models overly rely on entity information to answer questions, and thus may generalize poorly when facts about the world change or questions are asked about novel entities. To systematically audit this issue, we present a pipeline to automatically generate test examples at scale, by replacing entity names in the original test sample with names from a variety of sources, ranging from names in the same test set, to common names in life, to arbitrary strings. Across five datasets and three pretrained model architectures, MRC models consistently perform worse when entities are renamed, with particularly large accuracy drops on datasets constructed via distant supervision. We also find large differences between models: SpanBERT, which is pretrained with span-level masking, is more robust than RoBERTa, despite having similar accuracy on unperturbed test data. We further experiment with different masking strategies as the continual pretraining objective and find that entity-based masking can improve the robustness of MRC models.[1]

1 Introduction

The task of machine reading comprehension (MRC) measures machines' understanding and reasoning abilities. Recent research advances (Devlin et al., 2019; Yang et al., 2019; Khashabi et al., 2020) have driven MRC models to reach or even exceed human performance on several *MRC benchmark datasets*. However, their actual ability to solve the general *MRC task* is still questionable (Kaushik and Lipton, 2018; Sen and Saffari, 2020; Sugawara et al., 2020; Lai et al., 2021). While humans show robust generalization on reading comprehension, existing works have revealed that MRC models generalize poorly to out-of-domain data distributions (Fisch et al., 2019) and are brittle under test-time perturbations (Pruthi et al., 2019; Jia et al., 2019; Jia and Liang, 2017). All these issues could naturally happen to MRC systems deployed in the wild, hindering them to make reliable predictions on user inputs with great flexibility.

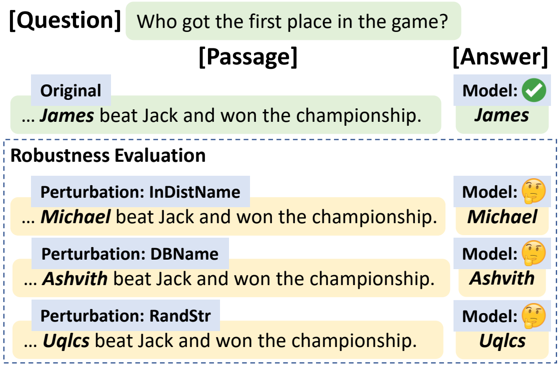

Figure 1: An illustrative example of the robustness to entity renaming and our proposed perturbations for robustness evaluation. "Michael" is from the answer of another test instance. "Ashvith" is a person name from an external database. "Uqlcs" is a random string with the same length as the original name.

In this work, we focus on an important but understudied type of test-time distribution shift caused by novel entity (e.g., person and company) names. Besides the evidence provided by the surrounding context, an MRC model also has the capacity to leverage the entity information to make predictions (Sugawara et al., 2018; Chen et al., 2016). The information associated with the entity name covers both world knowledge that can change over time and dataset shortcuts that are unlikely to generalize. While contributing to performance on certain benchmarks, the over-reliance on specific entity names leads to an overestimation of model's actual ability to read and comprehend the provided

passage (Peñas et al., 2011). It also hinders model generalization to novel entity names, which itself is challenging due to the large space of valid entity names induced by the flexibility of entity naming. For example, person names can be chosen from a large vocabulary depending on the country, while companies can be named in an even more creative way, not to mention new names that are being invented every day. As illustrated in Figure 1, keeping the reasoning context unchanged, a robust MRC model is supposed to correctly locate the same span of a named entity as the answer, even after it gets renamed.

To audit model robustness, we use entity renaming as test time perturbation to mimic the situation where a deployed MRC model encounters questions asking for novel entity names in the emerging data. We design a general pipeline to generate natural perturbations of MRC instances by swapping the answer entity name with another valid name throughout the passage. We design perturbation rules and collect resources for three types of entities with large name space: Person, Organization, and Geopolitical Entity.

With this proposed analysis framework, we conduct extensive experiments on five datasets and three pretrained language models. Data-wise, we find that distantly supervised MRC datasets lead to less robustness. Entity-wise, we find that geopolitical entities pose a greater challenge than people and organizations when renamed. Model-wise, we find that SpanBERT is more robust than BERT and RoBERTa, mainly due to its lower sensitivity to domain shift on names, which is likely a benefit of its span-focused pretraining objective. Inspired by this, we investigate several continual pretraining objectives and find that an entity-based masking strategy can further improve robustness.

2 Analysis Setup

2.1 Extractive MRC

The task of MRC tests a machine' understanding and reasoning abilities by asking it to answer the question based on the provided passage. We focus on extractive MRC, where the answer is a span in the passage. Formally, given a **question** Q and a **passage** P of n tokens $P = \{x_1 \ldots, x_n\}$, a model is expected to predict an **answer** span $a = \{x_i, \ldots, x_{i+k}\} (1 \leq i \leq i + k \leq n)$ in the passage P as a response to the question Q. We use exact match (**EM**) as the metric for MRC evaluation, which is the percentage of test instances that the model exactly predicts one of the gold answers.

Dataset	# Train	# Dev	# Test	DS?
SQuAD	77,929	8,659	10,507	✗
NQ	84,577	9,367	12,836	✗
HotpotQA	65,636	7,292	5,901	✗
SearchQA	105,646	11,738	16,980	✓
TriviaQA	42,569	4,696	7,785	✓

Table 1: Evaluation datasets. "DS?" indicates whether distant supervision is used for data collection.

In both real-world scenarios and MRC datasets, a large portion of questions ask about entities like people, organizations and locations. While unmentioned background knowledge about the entities might be helpful for solving the questions, overly relying on it makes the model hard to adapt to updated facts provided by the passage and generalize to novel entities. Especially, we contrast MRC with closed-book QA, which requires a model to directly answer questions without access to any document passage. Closed-book QA tests a model's ability to pack knowledge into its parameters and retrieve knowledge from parameters to answer the question. On the contrary, we expect an MRC model to reason based on the provided passage.

2.2 Evaluation Protocol

We study the robustness of MRC models via test-time perturbation. Given an original test set D_{test} and a perturbation function f_{perturb} (detailed in §3) as inputs, we construct N perturbed test sets with N *perturbation seeds*. We evaluate the model on the N perturbed test sets. By averaging the results, we get the **average-case EM score** as the final metric, which measures the average impact on the model performance caused by the names from a certain perturbation. We set $N = 5$ in experiments.

2.3 Datasets

We choose five datasets with different characteristics from the MRQA 2019 shared task (Fisch et al., 2019): **SQuAD** (Rajpurkar et al., 2016), **Natural Questions (NQ)** (Kwiatkowski et al., 2019), **HotpotQA** (Yang et al., 2018), **SearchQA** (Dunn et al., 2017), and **TriviaQA** (Joshi et al., 2017). Since the official test sets of the MRQA datasets are hidden, we use the development set as the in-house test set, and hold out 10% of the training data as the in-house development set. Their statistics are shown in Table 1.

As a major difference in data collection, SQuAD, NQ, and HotpotQA employ crowdworkers to annotate the answer span in the passage, while SearchQA and TriviaQA use distant supervision to match the passage with the question. Distant supervision provides no guarantee that the passage contains enough evidence to derive the answer. The context where the entity span shows up may not even be related to the question.

2.4 MRC Models

We experiment with three pretrained language models that have demonstrated strong performance on popular MRC benchmarks. **BERT** (Devlin et al., 2019) is trained on English Wikipedia plus BookCorpus with masked language modeling (MLM) and next sentence prediction (NSP) as self-supervised objectives. **RoBERTa** (Liu et al., 2019) improves over BERT mainly by dropping the NSP objective and increasing the pretraining time and the size of pretraining data. **SpanBERT** (Joshi et al., 2020) masks random contiguous spans to implement MLM and replaces NSP with a span-boundary objective (SBO).

The pretrained language models are finetuned on the MRC dataset to predict the start and end tokens of the answer span based on the concatenated question and passage (Devlin et al., 2019). By default, all pretrained language models in the main experiments are case-sensitive and in their `BASE` sizes. More details are shown in Appendix §A.

3 Entity Name Substitution

In this section, we introduce our method for perturbing an MRC test set with substitution entity names, i.e., the instantiation of f_{perturb}. Generating substitution names is at the core of our evaluation as different kinds of names measure a model's behavior in different situations with different robustness implications. We propose three categories of perturbations on three entity types and collect the corresponding name resources, aiming to audit a model's robustness from different perspectives.

3.1 Perturbation Pipeline

As illustrated in Figure 2, our perturbation pipeline consists of four steps, which are introduced below.

Step 1: Answer Entity Recognition. As we focus on the effect of answer entity renaming, we first identify entities in the answers by performing named entity recognition (NER) with spaCy (Honnibal et al., 2020) on the passage and extract the results on the answer spans. We identify three types of named entities: Person (**PER**), Organization (**ORG**), and Geopolitical Entity (**GPE**). All of them frequently appear as answers and have large space of valid names, making it important and challenging for models to robustly handle.

Entity Type		Applicable Types of Perturbable Spans
PER (4)		<First Name-Male> (e.g., Richard, Morton) <First Name-Female> (e.g., Lauren, Jennifer) <First Name-Neutral> (e.g., Shine, Frankie) <Last Name> (e.g., Marx, Winfrey)
ORG (5)		<NNP> (e.g., Celtic, Tiffany) <Rare> (e.g., Hufflepuff, Pokemon)
	GPE (3)	<GPE-Country> (e.g., Iceland, Algeria) <GPE-State> (e.g., New Brunswick, Ohio) <GPE-City> (e.g., Boston, Sonsonate)

Table 2: Applicable metadata for each entity type in the perturbation pipeline.

Dataset	# PER	# ORG	# GPE	# MIX
SQuAD	1,170	1,095	602	2,613
NQ	3,257	1,207	1,414	5,150
HotpotQA	1,351	824	788	2,614
SearchQA	5,707	2,450	2,248	8,688
TriviaQA	2,747	1,276	1,270	4,351

Table 3: Statistics of the perturbable subsets for different entity types and their union ("MIX").

Step 2: Perturbable Span Identification. To facilitate name substitution, we assign metadata to detected entity names by identifying *perturbable spans* within the entity name. For each type of entity names, we define the applicable *span types* in Table 2. The heuristics for identifying each type of perturbable spans are introduced in Appendix §B. Note that given one or more entity types of interest, in this step we filter the test data to only keep a subset of instances with non-empty metadata for the corresponding entity types, which are instances that are ready to be perturbed. Sizes of the perturbable subsets for different entity types and their union (**MIX**) are shown in Table 3.

Step 3: Candidate Name Sampling. For each perturbable span, we get its substitution name by querying an external dictionary with the span type. The substitution name is randomly sampled from a pool of names in the external dictionary with the same span type. We collect dictionaries with names of different characteristics serving for different analysis purpose, which are detailed in §3.2.

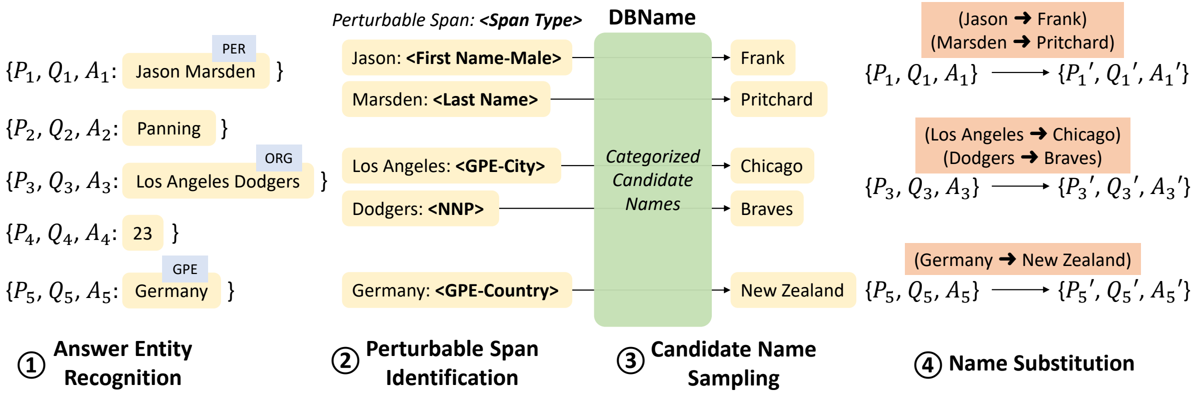

Figure 2: The perturbation pipeline for performing entity name substitution on MRC instances.

Step 4: Name Substitution. Once we have a candidate name for each perturbable span, we perform string mapping on the passage, question, and the gold answer, to finish the entity renaming in MRC instances. The name substitution changes *all* mentions of the answer entity in the passage while keeping the other reasoning context.

3.2 Candidate Name Collection

We consider three types of candidate names for perturbations in our main experiments to simulate the domain shift of entity names during test time.

In-Distribution Name (InDistName). The set of candidate names with their span types is the same as the perturbable spans with their types identified from the gold answers in the test set. This ensures that no new name is introduced to the test set.

Database Name (DBName). We collect names in the real world by referring to relevant databases. For PER, we collect first names[2] (with gender frequency) and last names[3] from the official statistics of person names in the U.S. (We experiment with names from other countries and languages in §4.5.) We regard a first name as a male/female name if its male/female frequency is two times larger than its frequency of the opposite gender. The remaining names are considered as neutral. Following the practice for identifying perturbable spans, we get the list of country/state/city names using *Countries States Cities Database* and the NNP list using PTB. Rare words constitute an open vocabulary so they will not be substituted under the DBName perturbation.

Accuracy	PER	ORG	GPE
Perturbable Span Identification	93.3%	86.7%	93.3%
Name Substitution	86.7%	96.7%	96.7%

Table 4: Validity of the two key steps in the perturbation pipeline on 30 randomly sampled TriviaQA instances for each entity type.

Random String (RandStr). The RandStr perturbation is different from the other two as it neglects the query span type when preparing the candidates. We generate a random alphabetical string of the same length and casing as the original perturbable span. Names from low-resource languages can look quite irregular to the pretrained language models. Random string as an extreme case provides an estimation of the performance in this scenario.

3.3 Perturbation Quality

The validity of the perturbed instances depends on the quality of the perturbation pipeline (§3.1). We manually check the accuracy of the perturbation steps on TriviaQA, which demonstrates the largest performance drop as we will show. Out of the four steps in the pipeline (Figure 2), we evaluate the accuracy of step 2 (“Perturbable Span Identification”) and step 4 (“Name Substituion”) while the accuracy of the other two steps can be inferred. The evaluation details are provided in Appendix §C. As shown in Table 4, our method gets acceptable accuracy on the three entity types, confirming the quality of the perturbed test sets.

4 Results and Analysis

The average-case EM scores on the original and perturbed test sets are presented in Figure 3. We report the mean and standard deviation over 3 *train-*

ing seeds. We analyze the results from several angles by aggregating across certain dimensions.

4.1 Which datasets lead to less robustness?

Training on MRC datasets created with distant supervision leads to less robustness. In Table 5, we show the results of BERT on the original and perturbed test sets, while results of RoBERTa and SpanBERT follow similar patterns. The perturbations on all 3 entity types are combined (shown as "MIX"). We find that models trained on SQuAD, NQ, and HotpotQA (with at most 6% performance drop under the DBName perturbation) are significantly more robust than models trained on SearchQA and TriviaQA (with about 20% performance drop under the DBName perturbation). While the first group of datasets are human-labeled, the later group of datasets are constructed using distant supervision. Such correlation indicates that training noise due to mismatched questions and passages harms model's robustness. We hypothesize the reason to be that, the passage in the human-annotated datasets usually provides enough evidence to derive the answer, so a model is able to learn the actual task of "reading comprehension" from the data. On the contrary, SearchQA and TriviaQA use web snippets as the source of passages. The labeling process of distant supervision assumes that "the presence of the answer string implies the document *does* answer the question" (Joshi et al., 2017), while the document may or may not contain all facts needed to support the answer. In this case, because the actual reading comprehension task is difficult to learn due to lack of evidence, the model could be prone to use entity-specific background knowledge (e.g. assuming that "Jack Higgins" is a British author regardless of the context) or learn dataset-specific shortcuts associated with certain names via memorization (e.g., choosing "Jack Higgins" whenever it's mentioned in the passage and the question asks for an author), which causes the robustness issue.

To better understand the failure cases, we catego-

rize the errors made by the model into two classes: wrong entity errors and wrong boundary errors, based on whether the predicted span has any word overlap with the gold answer. We report the percentage of wrong entity errors in Table 6. On all datasets, wrong entity errors make up a larger percentage of all errors when the test sets get perturbed. This suggests that the performance drop is mainly caused by the increasing errors in identifying the correct answer entity rather than accurately predicting the boundary of a correctly-identified answer entity.

4.2 Which entity types are more challenging?

GPE renaming poses the greatest robustness challenge. The renaming of PER and ORG are similarly less challenging. In Table 7, we present the performance drop caused by the DBName perturbation for each entity type. GPE renaming shows the largest performance drop. The comparison of PER and ORG differs across datasets, but their corresponding performance drops are generally similar. The reason is likely to be that the model is only exposed to a small number of distinct GPE names during finetuning compared to PER and ORG. In the training set of TriviaQA, there are 40k ORG names and 54k PER names, but only 12k GPE names. The lack of seen names makes it hard to learn the generalization ability.

MIX	BERT	RoBERTa	SpanBERT

InDistName	$59.0_{\pm 1.4}/61.3_{\pm 0.4}$	$67.8_{\pm 1.1}/70.8_{\pm 0.6}$	$\mathbf{68.3}_{\pm 0.8}/\mathbf{72.1}_{\pm 0.7}$
DBName	$50.4_{\pm 1.6}/52.6_{\pm 0.7}$	$60.5_{\pm 0.9}/62.6_{\pm 1.3}$	$\mathbf{63.1}_{\pm 0.8}/\mathbf{66.9}_{\pm 0.6}$
RandStr	$25.4_{\pm 1.4}/27.9_{\pm 2.4}$	$35.6_{\pm 0.2}/35.8_{\pm 3.1}$	$\mathbf{51.9}_{\pm 2.3}/\mathbf{53.6}_{\pm 4.9}$

Table 9: **Comparison of different model sizes.** EM scores of the `BASE`/`LARGE` variants of models on the original and perturbed test sets of the MIX entity type on TriviaQA.

4.3 Which models are more robust?

On distantly supervised datasets, SpanBERT is more robust than RoBERTa, which is more robust than BERT. In Table 8, we show the performance of the three models under perturbations of the MIX entity type on SearchQA and TriviaQA. While RoBERTa and SpanBERT show comparable performance on the original and InDistName test sets, SpanBERT's improvement over RoBERTa becomes larger with more difficult perturbations. Meanwhile, BERT shows even larger performance decreases than RoBERTa. The models' performance differences are mainly attributed to their different pretraining strategies. RoBERTa's improvement over BERT indicates that a better pretraining configuration (as measured by the performance on the in-domain original test set) is also beneficial to the performance on the perturbed test sets, suggesting better generalization ability to the out-of-domain data. This correlation is consistent with the findings in Miller et al. (2021). SpanBERT's particular advantage on the perturbed test sets indicates its span-focused pretraining objective (span-based MLM and span prediction based on boundary tokens) is especially helpful for the span-related robustness, which is desired for the MRC task.

Larger models are not more robust. In Table 9, we compare the performance of the `BASE` and `LARGE` variants of pretrained models on TriviaQA. The performance drops from the original test sets to the perturbed test sets are similar for these two variants in most cases, suggesting that simply increasing the model size can not resolve the robustness issue.

4.4 How can we disentangle reasons for performance drop?

Both loss of entity knowledge and domain shift on names happen during renaming. The information associated with the entity name that can

Unseen@MIX	Original/ InDistName	DBName	RandStr
SQuAD	33% / 24%	94% / 92%	100% / 100%
NQ	14% / 4%	95% / 89%	100% / 100%
HotpotQA	19% / 3%	96% / 89%	100% / 100%
SearchQA	7% / 0%	92% / 78%	100% / 100%
TriviaQA	21% / 2%	93% / 83%	100% / 100%

Table 10: The percentage of test answer entity tokens that are never seen in the training answer/passage entities.

Accuracy	Original	InDistName	DBName	RandStr
PER	75.6%	73.4%	58.0%	60.0%
ORG	60.1%	50.6%	49.2%	48.0%
GPE	84.4%	83.4%	43.2%	27.6%

Table 11: Accuracy of the trained NER model to recognize the original and perturbed answer entities on SQuAD.

be leveraged by the model includes both entity knowledge and name clues. **Entity knowledge** refers to the *world knowledge* associated with *the referred entity*, like "Michelle Obama is the wife of Barack Obama," while **name clues** refer to *statistical clues* associated with the name's *surface form*, like "Barack Obama is likely to be a male name", "Barack Obama as an in-distribution name is likely to be the answer for this dataset". While all perturbations break the entity knowledge about the original entity, InDistName doesn't introduce additional domain shift on names and largely preserve the name clues. Going from InDistName to other perturbations, the substitution names become more and more out of the dataset distribution. This performance drop can be attributed to the model's sensitivity to name-related domain shift.

We adopt two measurements to better understand the domain shift on names. As a token-level measurement, we calculate the percentage of test answer entity tokens that are never seen in entities in training answers and entities in training passages, as shown in Table 10. Different datasets have different percentages of unseen tokens in the original test sets, which are mainly affected by the size and diversity of training data. The number goes up with the DBName and RandStr perturbations. As an entity-level measurement, we train an NER model[4] on the training passages, with named entities annotated by spaCy as ground truth. We evaluate the trained model on perturbed test sets and calculate its accuracy of recognizing the perturbed answer entity. The results are shown in Table 11. As a sign of domain shift, the recognition of answer entities become more difficult when they get perturbed. GPE shows the most significant perturbation drop, which correlate with our observation on the MRC task (§4.2).

SpanBERT's superior robustness over RoBERTa is mainly from handling domain shift. From SearchQA and TriviaQA results in Table 8, we find that RoBERTa and SpanBERT rely similarly on the entity knowledge (~13% performance drop from Original to InDistName on SearchQA and ~11% on TriviaQA). SpanBERT's advantage over RoBERTa is mainly on its good robustness to domain shift on names, shown by the perfromance drop from IndistName to other perturbations. BERT relies slightly more on entity knowledge but much more sensitive to domain shift on names.

4.5 Bias Exhibited by Person Names

National Origins. As the DBName perturbation uses person names in the U.S., it cannot fully reflect the model's robustness behavior when encountering real-world names of different national origins. Therefore, we additional collect names from more countries (India, China) and languages (French, Arabic) to study the potential bias in MRC models. We use the romanized form of names. Table 12 shows the performance comparison of models when evaluated with the person names from different countries and languages on SearchQA and TriviaQA. Names form the U.S. and French-speaking countries generally achieve the highest EM scores. Names from China get the lowest performance for the most of time, with significant EM drop (8.4% on SearchQA and 9.8% on TriviaQA for BERT) from U.S. names. The performance gap between different countries and languages becomes smaller with more robust models.

Other Factors. We also consider other factors of a name that could be related to biased model performance. We limit our scope to the U.S. first names and sample 1500 names from the database. We consider two features for each name. *Gender polarity* is defined as $\texttt{max}(\frac{f_m}{f_f}, \frac{f_f}{f_m})$, where f_m, f_f are the male frequency and female frequency of a name provided by the database. It measures the gender ambiguity of the name. *Popularity* is defined as $f_m + f_f$. We calculate the EM score for a

name by evaluating on a test set where all answer first names get replaced with this name. For what we have tried, we didn't find evidence to support a correlation between each factor and the EM score. For example, with SpanBERT on TriviaQA, names with top 20% gender polarity gets 72.7% EM on average; while the bottom 10% names gets 72.8% EM. The numbers are 73.0% vs 72.7% for popularity. We leave exploring factors that correlate with the difficulty of a name as future work.

4.6 Improving Robustness with Continual Pretraining

SpanBERT's advantage over BERT suggests that some variants of MLM could be helpful for model robustness. To further improve the robustness of SpanBERT, we adopt a training paradigm with an inserted continual pretraining stage and compare MLM with different masking strategies as the objectives.

Training Paradigm. Existing works mainly seek to improve model robustness during finetuning with strategies like data augmentation (Ribeiro et al., 2019; Min et al., 2020), but they usually increase finetuning time and requires additional data. Some recent works (Gururangan et al., 2020; Ye et al., 2021) have explored improving a pretrained language model with "continual pretraining"—continuing to train a pretrained model for more steps with some objective. The generated checkpoint can be used for finetuning on any dataset in the *standard* way with no additional cost.

Experimental Setup. The masking policy in MLM plays an important role in instructing model learning, which can be potentially used to improve model robustness. Inspired by previous works, we experiment with four heuristic masking policies to implement the MLM objective: **MLM (vanilla)**, **MLM (whole word)**, **MLM (span)**, and **MLM (entity)**. They perform masking at token, whole-word, span, and entity level respectively. Starting from SpanBERT (`-BASE`), we run continual pretraining with the above objectives for 8,000 steps. More details are described in Appendix §D.

Results. The results for models finetuned from SpanBERT and different continually pretrained models are shown in Table 13. On SQuAD, all masking policies slightly downgrade the performance. With not much room for robustness improvement, running continual pretraining is probably at the cost of slightly sacrificing the performance due to the inconsistent objective and discontinuous learning rate that are applied when starting the continual pretraining. On SearchQA and TriviaQA, out of the four masking policies, the entity-based masking policy shows consistent improvement over SpanBERT. As analyzed in §4.4, name-related domain shift is a major challenge for the model to handle. By predicting the masked entity, the model is exposed to the diverse entities in the pertraining corpus in a more explicit way, and gain a better sense in recognizing entities. Note that the improvement is not statistically significant in some cases and we leave the exploration of more effective methods to improve model robustness as future work.

5 Related Work

Robustness of MRC Models. The robustness of MRC models are usually evaluated against test-time perturbations and out-of-domain data. Research on test-time perturbation proposes perturbation methods at different levels as attacks (Si et al., 2021), such as word replacement with neighbors in the vector space (Rychalska et al., 2018; Jia et al., 2019), question paraphrasing (Gan and Ng, 2019; Ribeiro et al., 2018), sentence distractor injection (Jia and Liang, 2017; Zhou et al., 2020). Another line of research (Fisch et al., 2019; Sen and Saffari, 2020) tests a model on data with out-of-domain passage or question distributions, usually from different datasets. Our work mainly falls into the category of test-time perturbation. We distinguish from previous work by focusing on the effect of entity renaming, with the motivation that entities can have flexible and diverse names in the real life.

Model Robustness to Entity Substitution. It is non-trivial for NLP models to be able to properly handle the large space of named entities. Previ-

ous works use entity substitution to audit or improve model robustness on different tasks like NER (Agarwal et al., 2020; Lin et al., 2021), Natural Language Inference (Mitra et al., 2020), Coreference Resolution (Subramanian and Roth, 2019), and Dialogue State Tracking (Cho et al., 2021). Shwartz et al. (2020) experiment with name swapping to show that a trained MRC model has bias on some U.S. given names due to the grounding effects that associate names with certain entities. Ribeiro et al. (2020) and Balasubramanian et al. (2020) investigate the robustness of models on several tasks with named entity replacement. However, these works didn't systematically test on MRC datasets with different characteristics to unveil the actual robustness challenge. Liu et al. (2021) study the novel entity generalization ability of open-domain QA models by categorizing the test questions based on whether the named entities have been seen during training. Longpre et al. (2021) analyze the memorization behavior of *generative* open-domain QA models using *knowledge conflicts*. They use entity substitution to create test passages that contain facts contradicting to what the model has learned during training time. In contrast, we analyze *extractive* MRC model's robustness when encountering new entities, by evaluating on modified test sets without intentionally introduced knowledge conflicts. The extractive task formulation also makes the model unable to output its memorized knowledge as generative models, leading to different analysis questions and methods.

6 Conclusion

In this paper, we systematically study the robustness of MRC models to entity name substitution. Specifically, we propose a substitution framework along with candidate names of different implications. We experiment with three pretrained language models on five MRC datasets. We find that models trained on distantly-supervised datasets are susceptible to entity name substitution, while models trained on human-annotated datasets are relatively robust, with GPE renaming harder than PER and ORG renaming. The lack of robustness can be further attributed to model's overreliance on entity knowledge and name clues. We also find that SpanBERT, which is pretrained using span-level objectives, shows better robustness than BERT and RoBERTa. Leveraging these insights, we study defense approaches based on continual pretraining and demonstrate that entity-based masking policies are beneficial to model's robustness. Future works include systematically studying the effect of background knowledge in MRC, and developing more effective methods to improve the robustness of MRC models.

A Details for MRC Model Training

We train all MRC models using mixed precision, with batch size of 16 sequences for 4 epochs. The maximum sequence length is set to 256 tokens. We use the AdamW optimizer (Loshchilov and Hutter, 2019) with an initial learning rate of 2e-5 that is linearly decayed to 0 during finetuning.

B Perturbable Span Identification

For PER, we only consider names with one or two words. A one-word name is considered as a first name, while a two-word name is considered as a full name, with the first word being the first name and the second word being the last name. We infer the gender of the detected name to be male, female, or neutral with `gender-guesser`[5].

For GPE, we detect its contained country names, state names, and city names by string matching with the *Countries States Cities Database*[6].

For ORG, besides mentions of GPE names, we include two additional types of perturbable words identified using Penn Treebank (PTB) (Marcus et al., 1993). Words that are annotated as NNP(S) for more than 90% of the time in PTB are considered as proper nouns (dented as <NNP>), which are usually specialized for naming an entity. Words outside PTB are considered as rare words (denoted as <Rare>), which are likely to be invented by people to name an entity. These two kinds of words are weakly related to the characteristics of the entity and thus can be flexible.

C Evaluation of Perturbation Quality

The accuracy of step 2 is evaluated based on whether the perturbable spans and their corresponding span types are all correct for an instance, which also implies the quality of step 1 ("Answer Entity Recognition") as different entity types have different applicable span types.

The accuracy of step 4 is evaluated based on whether the string mapping function successfully locates all mentions of the perturbable spans in the passage to perform string mapping.

The quality of step 3 can be inferred from the accuracy of step 2 for InDistName perturbation. For DBName, we assume the database is of acceptable quality in the sense that all names it provides belongs to the correct span type, which is guaranteed by the source of the data—PTB is annotated by human experts, U.S. names come from official statistics, and GPE names are actively maintained by its creator and the community for more than 3 years. RandStr is proposed to simulate the extreme case, and we therefore do not evaluate its quality.

D Details for Continual Pretraining

MLM (vanilla) refers to the masking strategy used by BERT (Devlin et al., 2019), where the masked tokens are randomly sampled. **MLM (whole word)** always masks all tokens corresponding to a word at once. **MLM (span)** uses the masking strategy proposed by Joshi et al. (2020), which masks random spans rather than individual whole words or tokens. **MLM (entity)** masks a random entity for 50% of the time, and uses MLM (span) for the other 50% of the time. The idea is inspired by salient span masking proposed in Guu et al. (2020). All strategies mask 15% of the training tokens in total.

To eliminate domain shift during continual pretraining as a possible explanation for any improvements, we keep the corpus for continual pretraining consistent with the pretraining corpus used by SpanBERT, which is the concatenation of BookCorpus and English Wikipedia. We train using mixed precision, with effective batch size of 2,048 sequences for 8,000 steps, with 256 tokens per sequence. We use the AdamW optimizer with a constant learning rate of 1e-4.

Abstract

Systems like Voice-command based conversational agents are characterized by a pre-defined set of skills or intents to perform user specified tasks. In the course of time, newer intents may emerge requiring retraining. However, the newer intents may not be explicitly announced and need to be inferred dynamically. Thus, there are two important tasks at hand (a). identifying emerging new intents, (b). annotating data of the new intents so that the underlying classifier can be retrained efficiently. The tasks become specially challenging when a large number of new intents emerge simultaneously and there is a limited budget of manual annotation. In this paper, we propose **MNID** (**M**ultiple **N**ovel **I**ntent **D**etection) which is a cluster based framework to detect multiple novel intents with budgeted human annotation cost. Empirical results on various benchmark datasets (of different sizes) demonstrate that MNID, by intelligently using the budget for annotation, outperforms the baseline methods in terms of accuracy and F1-score.

1 Introduction

The conversational agents such as Amazon Alexa, Apple Siri are characterised by the skill of understanding *intents* which help them to efficiently handle a user's query. For example, the query **'Will it be colder in Ohio'** requires getting the weather updates for the city 'Ohio' and would be associated to the intent *GetWeather*. The agents are trained with a pre-defined set of intents such as {*GetWeather*, *RateBook*, *BookRestaurant*} so as to perform the goal-oriented user tasks. But with the passage of time, a user may be interested in performing newer tasks adding hitherto unknown intents. For example, **'Play some music from 1954'** would be associated to the intent *PlayMusic* that may not be a part of the set of pre-defined intents.

Emergence of novel intent detection has been periodically checked by different models in the last decade. There are works on incremental learning in dynamic environment for evolving new classes (Zhou and Chen, 2002; Kuzborskij et al., 2013; Scheirer et al., 2012). There are also several approaches (Sun et al., 2016; Masud et al., 2010; Haque et al., 2016; Wang et al., 2020; Mu et al., 2017b,a) to detect new classes in the form of outlier detection but they do not distinguish among multiple new class labels so are not effective in novel multi-class detection. Xia et al. (2018); Siddique et al. (2021) detect user intents using zero-shot generalized intent detection framework. However, they assume that the unseen intent class LABELS are already known, while in our case neither the number of unseen intent classes, nor the corresponding class labels are known. The other line of works (Xia et al., 2021; Halder et al., 2020) supply the system with new intents, albeit with a limited amount of tagged data per class and then have an efficient algorithm to incrementally learn new classes. These models work on the assumption that some instances of these new classes would be provided for model building. However, in a realistic setting, the system may not have any knowledge of the number and types of new intents appearing, it may at most understand that some new out-of-domain samples are generated. So, the problem statement is to probe the incoming data wisely and **use minimum human intervention to identify all types of novel intents emerging and intelligently tag a limited set of data covering all discovered intents**, which can be be fed into a model for retraining.

More concretely the system is at first trained with an initial set of known intents; side-by-side an out-of-distribution (OOD) detector classifier is also trained to identify datapoints which do not fit the known intents. When substantial amount of

such points are detected, the task is to (a) identify whether the points are originating from introduction of a single novel intent or multiple and (b) choose (a limited number of) samples to annotate so that the classifier can be retrained efficiently.

In order to determine the number of novel intents present in the OOD data, we undertake a clustering based approach with the idea that each cluster would represent a novel intent. By increasing the cluster number progressively, we can make a highly accurate estimate of the number of novel intents. If sample points of an intent mainly correspond to a well formed cluster, the implication is that without much probing we can shortlist enough training samples (through silver tagging) for that class. On the other hand, if the sample points of an intent tend to intertwine with other intent points in the feature space, these can be considered as uncertain points and require human intervention for tagging (gold tagging). With this intuition in place, we design a mix of silver and gold tagging to produce high-quality training samples which can be used to retrain the classifier.

Our proposed framework of Multiple Novel Intent Detection (**MNID**) is compared with competitive baselines and evaluated across several standard public datasets in NLU domain where it performs substantially better. We use datasets with different number of intent classes. SNIPS (Coucke et al., 2018) and ATIS (Tur et al., 2010) are smaller datasets, consisting of less number intent classes - 7 and 21, respectively. HWU (Liu et al., 2019a), BANKING (Casanueva et al., 2020) and CLINC (Larson et al., 2019) consist of large number of intent classes - 64, 77 and 150, respectively.

The paper is organized as follows. We discuss the Problem Setting and solution overview in Section 2. Our algorithmic framework is described in Section 3. We present the datasets with experimental statistics and data pre-processing in Section 4. In Section 5, we discuss the experimental design and baselines. Detail evaluation results with different algorithmic variations are in Section 6. We conclude with a summary in Section 7[1].

Algorithm 1 Multiple Novel Intent Detection (**MNID**)

```

Algorithm 2 OOD Detection Algorithm **OODD**($|D|$, $|D_{init}|$)

```
Train OOD-SDA on $D_{init}$ and predict on $(D - D_{init})$ to get OOD samples, $\mathcal{OS}$
Return $\mathcal{OS}$
```

Algorithm 3 Novel Class Detection **NCD**($\mathcal{OS}$, $\mathcal{L}$)

```
Initial number of clusters, $K = 1$.
Number of new classes, $N_{new} = 0$.
while $N_{new} \geq \lfloor K/2 \rfloor$ do
    Perform $K$-Means Clustering on $\mathcal{OS}$
    Annotate $x$ ($\geq 2$) points from each cluster. That results in discovering of $n'$ new classes
    Add $x * K$ point labels to $\mathcal{L}$
    $N_{new} \leftarrow N_{new} + n'$
    $K \leftarrow 2 * K$
end while
$\mathcal{CL}$ = Store All $K$ Clusters
Return ($\mathcal{L}$, $N_{new}$, $\mathcal{CL}$)
```

2 Problem Setting and Solution Overview

Problem Setting: To formally describe the problem setting, let there be a dataset W containing overall N classes. However, the value of N is not known apriori. Let $T \in W$ be the test set and $W - T = D$ be the rest of the dataset, out of which $|D_{init}|$ ($<< |D|$) labelled data of N_{init} ($< N$)

    end if
end for
while $|\mathcal{L}| < B$ do
    Select datapoint with least CS
    if $\mathcal{B}_{\mathcal{CL}}$ exists then
        From $\mathcal{B}_{\mathcal{CL}}$ in Round-Robin way
    else
        From $\mathcal{G}_{\mathcal{CL}}$ in Round-Robin way
    end if
    $L_g \leftarrow$ Gold Annotation Strategy
    $\mathcal{L} \leftarrow \mathcal{L} + L_g$
end while
$\mathcal{L} \leftarrow \mathcal{L} \cup L_s \cup L_g$
Return ($\mathcal{L}$)
```

classes is initially provided, while the rest of the data is unlabelled. The task is to design an algorithm to (a). detect all the remaining $N - N_{init}$ classes and (b). spent a limited budget (B - $|D_{init}|$) to annotate high fidelitous new datapoints, so that the classifier can achieve high accuracy when retraining.

Solution Overview: The solution steps are as follows: (a) Identify the OOD (out of distribution) datapoints which do not belong to the initial N_{init} classes. This can be considered as a preprocessing step. (b) Use a part of the allotted budget to annotate a portion of these OOD datapoints. These points (for annotation) are selected by repeatedly running a clustering algorithm with increasing number of clusters as input, and choosing cluster centre points to identify the unknown classes. **Rationale:** The intuition/expectation is that each cluster hosts a separate intent, hence annotating the cluster centres would lead to discovery of maximum number of novel intents. (c) Further identify the classes which are well clustered in feature space and which are not. Use another portion of the budget to increase the annotations of not-so well formed clusters and then build up a classifier with all the classes. **Rationale:** If a cluster is well-formed, most likely it is hosting a single class, hence there is no need to annotate further points there, rather annotate more points in not-so-well-formed clusters. (d) Use the classifier to classify points from the clusters. Identify low-confidence points from the bad clusters and annotate them. High-confidence points from good clusters are silver annotated. **Rationale:** The low-confidence points in the bad clusters are the most uncertain points, hence annotating them helps in increasing classifier accuracy. Similarly high-confident points in the good clusters almost surely will belong to that particular cluster, hence silver annotation is pursued. (e). Retrain the classifier.

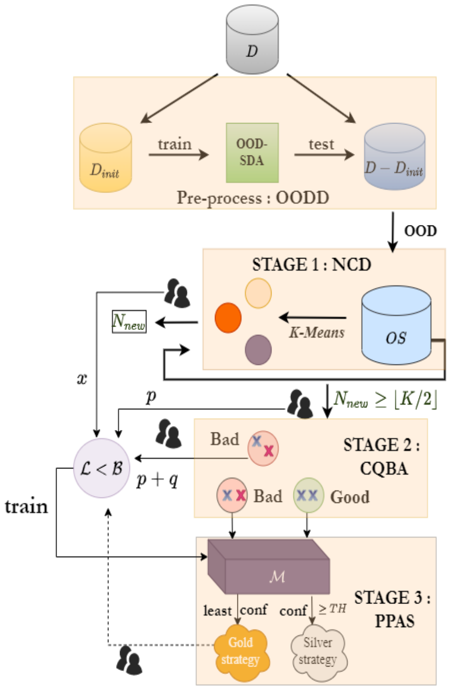

Figure 1: End-to-end architecture of MNID: Multiple Novel Intent Detection

The overall MNID framework with different algorithmic modules is shown in Fig. 1.

3 MNID: Solution Detail

The proposed framework for Multiple Novel Intent Detection (MNID) is explained through Algorithm 1. As highlighted in the overview, the algorithm consists of data pre-processing step, followed by three stages, each of them are discussed below. The total budget of (gold) annotation is B. Besides the system can undertake unlimited silver annotation. The advantage of silver strategy is that it is free as no human probing is required. However, it is also likely to bring in noise if used indiscriminately.

Pre-process: OOD Detection (OODD): For the dataset (D), this module (Algorithm 2) takes the initial labelled data (D_{init}) as input and predicts the Out-of-Domain (OOD) samples on the remaining data, ($D - D_{init}$). We call the set of OOD samples predicted as $\mathcal{OS}$. This is a part of the data pre-processing.

Stage 1. Novel Class detection (NCD): In this sub-module (Algorithm 3), we aim at finding all the new classes, N_{new}. On the OOD samples ($\mathcal{OS}$), obtained in the previous sub-module (Algorithm 2), we do clustering using K-Means. We start the algorithm with $K = 1$ and number of new classes, N_{new} = 0. We perform - (i) K-Means clustering. (ii) Annotate x points from each cluster, add those points to $\mathcal{L}$ and identify n' new classes. (iii) Increase new class count (N_{new}+ n'). (iv) Double the number of cluster count (we compare N_{new} with $K/2$). We execute the above steps until cluster count exceeds the new intent count. The algorithm returns current annotations ($\mathcal{L}$), newly discovered class count (N_{new}) and newly formed clusters ($\mathcal{CL}$). The budget spent in this step is B_1.

Stage 2. Cluster Quality Based Annotation (CQBA): In this step (Algorithm 4), we evaluate the quality of each of the clusters obtained by the previous algorithm. We annotate p points from each of these clusters and if all the p points belong to the same class, we term it as a *good cluster* or else a *bad cluster*. An example of a *bad cluster* in BANKING would be the one containing data points from multiple classes, which may have high similarity, such as: *declined_cash_withdrawal* and *pending_cash_withdrawal*. For the *bad clusters*, we annotate q more points. All these annotated points are then added to the labelled data, $\mathcal{L}$. The budget spent in this step is B_2. Hence the remaining budget B - (B_1 + B_2) is used in the next step.

Stage 3. Post Processing Annotation Strategy (PPAS): In this step (Algorithm 5), we add more data to the labelled set, $\mathcal{L}$, through gold annotation (*gold strategy*), as well as silver-annotated data (*silver strategy*). To select these data points, we first train a classifier ($\mathcal{M}$) with the labelled set, $\mathcal{L}$ as obtained in the last step (CBQA), and consider the clusters $\mathcal{CL}$. We predict on the remaining points of the clusters to get the confidence of the datapoints. We perform silver strategy based on confidence score (CS) and gold strategy in round-robin way to operate on each cluster one after another.

Gold Strategy: Least confident data-points are annotated from the bad clusters (if present) or else from the good clusters. Gold strategy is performed in a round-robin way to retrieve data points with the least score for each cluster until our budget exhausts.

Silver strategy: If the confidence score (CS) of a datapoint from a cluster is greater than a predefined threshold ($\mathcal{TH}$), we measure the average cosine similarity of points annotated within that cluster with this point. If similarity is above a predefined threshold (τ), we label this point with class label of that cluster. The predefined threshold (τ) is required to choose good samples selectively instead of choosing all the points. Silver strategy does not require human intervention therefore there is no extra addition to the annotation cost, but the multiple conditions are checked to prevent noise in the training set.

Final Step: We again train the neural model $\mathcal{M}$ on $\mathcal{L}$ and test on $\mathcal{T}$ to find out Accuracy and F1.

4 Dataset and Pre-Processing

We perform our experiments on a variety of datasets, which are widely used as benchmarks for Natural Language Understanding tasks. The datasets are SNIPS (Coucke et al., 2018), ATIS (Tur et al., 2010), HWU (Liu et al., 2019a), BANKING (Casanueva et al., 2020) and CLINC (Larson et al., 2019). SNIPS (7) and ATIS (21) are smaller datasets consisting of less number of intents (in bracket) where HWU (64), BANKING (77) and CLINC (150) are larger datasets with many intents. ATIS is the most imbalanced, skewed dataset. In BANKING data - several intents are highly similar among themselves. The detailed statistics of these datasets including our experimental framework are shown in Table 1. Since the datasets are already fully labelled, annotation essentially means utilizing the already available labels. Hence, we

Dataset (W)	**# Intent Class** ($\|N\|$)	**Dataset Size** ($\|W\|$)	**#Labelled** $\|D_{init}\|$	**#Unlab** ($\|D\|$ - $\|D_{init}\|$)			**#Test** ($\|T\|$)
				#IND	**#OOD**	**#Total**

BANKING	56.3	20.4	52.5	20.2	52.9	51.3	**73.7**	**64.1**
CLINC	54.8	18.7	53.4	20.5	54.1	59.9	**77.7**	**65.7**

Table 2: Accuracy (A) and F1-Score in (%) of various OODD algorithms to detect OOD points from different datasets. **Bold** denotes the best for each dataset.

In the pre-processing step, we filter the out-of-domain samples. We consider four algorithms for detecting out-of-domain samples. i) Softmax Prediction Probability (MSP) (Hendrycks and Gimpel, 2018) predicts out-of-domain samples based on a threshold on the softmax prediction scores. ii) Deep Open Classification (DOC) (Shu et al., 2017) method builds a multi-class classifier with one vs rest layer of sigmoids. iii) Large Margin Cosine Loss (LMCL) (Lin and Xu, 2019) trains a network with margin loss and predictions are then fed into an algorithm called Local Outlier Factor (LOF) for outlier detection. iv) Few-shot OOD (FS-OOD) (Tan et al., 2019) uses a ProtoTypical Network to detect OOD examples and classifying in-domain examples with few-shot examples from the in-domain class. We fine-tune BERT embeddings using all these out of domain sample detection algorithms. We use bert-base-uncased for these methods. We set the threshold for MSP as 0.5 as in Lin and Xu (2019), Xu et al. (2020). The results of all these algorithms are shown in Table 2. FS-OOD (Tan et al., 2019) provides us the best accuracy and F1 for detecting OOD samples ($\mathcal{OS}$). Only DOC performs better in case of SNIPS but overall FS-OOD outperforms other approaches so we use FS-OOD produced out-of-sample data.[2]

5 Experimental Setup

The efficacy of the algorithm needs to be tested on two aspects. (a). The number of unknown intents identified. (b). The accuracy achieved when the data is annotated by our algorithm, MNID. To test the accuracy, we use state-of-the-art several classification algorithms used for intent detection.

Different Neural Models: We explore different neural models to evaluate **MNID** as discussed next:

1. IFSTC (Xia et al., 2021): This finetunes a trained model on few shot data of new classes using an entailment and hybrid strategy. We use the hybrid strategy (best performing in their case).

2. PolyAI (Casanueva et al., 2020): It performs intent classification task based on dual sentence encoders - Universal Sentence Encoders (USE) (Cer et al., 2018) and ConveRT. Since authors have taken down the ConveRT model, we apply USE only. [3]

Along with the above two, we also consider other standard models, **3. BERT ('bert-base-uncased')** (Devlin et al., 2019) and **4. RoBERTa ('roberta-base-uncased')** (Liu et al., 2019b) for evaluation on these datasets. We finetune these pre-trained language models for 15 epochs for the smaller datasets (SNIPS, ATIS) 50 epochs for the larger datasets (HWU, BANKING, CLINC) and with a learning rate of 2e-05 and Adam optimizer[4]. Early stopping was employed to stop training. For all methods, we provide the same number of gold annotated data obtained using our pipeline and report its performance.

Baselines: We compare the performance of our method using two annotation techniques for choosing $B - \|D_{init}\|$ data points: 1) Gl_F: This is the ideal scenario where we are given F (=10) data points for each of the new classes - *Gold*$_{Few}$, abbreviated as 'Gl_F'. 2) Rn_F : Here, we randomly choose $B - \|D_{init}\|$ data points from the unlabelled data - *Random*$_{Few}$, abbreviated as 'Rn_F'.

Clustering Algorithms: One of the building blocks of **MNID** is to cluster datapoints, so the efficacy of **MNID** depends on employing an efficient clustering algorithm. We do a detailed study by employing several unsupervised and semi-supervised clustering algorithms and choose the best.

The unsupervised algorithms are: (i) **K-Means (KM)** (MacQueen et al., 1967) (ii) **Agglomera-**

Table 3: Overall Accuracy (A) and Macro F1 in (%) across all datasets for different scenarios - ideal (Gl_F), random (Rn_F) and MNID (The best outcomes among three scenarios in **Bold**). *Casanueva et al. (2020) report accuracy of 90.15 with OOS and 92.14 without OOS.

tive Clustering (AG) (Gowda and Krishna, 1978) (iii) **Deep Clustering Network (DCN)** (Yang et al., 2017) and (iv) **Deep Embedded Clustering (DEC)** (Xie et al., 2016) which uses the stacked auto-encoder based reconstruction loss. The semi-supervised algorithms are: (i) **DeepAligned (DAL)** (Zhang et al., 2021) which uses limited data for pre-training and cluster assignments as pseudo labels for cluster refinement. (ii) **DTC** (Han et al., 2019) develops on the DCN algorithm by scaling it to the transfer learning setting and can estimate the number of known classes in unlabelled data. It is however highly dependent on availability of labelled data (iii) **KCL** (Hsu et al., 2017) which transfers the knowledge to target dataset considering KL-divergence based distance loss (iv) **MCL** (Hsu et al., 2019) which uses meta-classification based likelihood criterion for pairwise similarity evaluation (v) **CDAC+** (Lin et al., 2020) which uses prior data to refine the clustering process and KL-divergence based loss [5].

Other than KM and AG, all the other unsupervised methods along with some of the semi-supervised methods such as DTC and CDAC need the information of the ground truth number of clusters for training and we provide them so (it is an extra advantage for them). For semi-supervised methods such as KCL, MCL, DTC and DAL, we start with double the number of ground truth clusters and let the method determine the number of clusters.

Hyper-parameters and Settings: For Post-Processing annotation strategy of MNID, we set the cosine similarity threshold, τ as 0.8 and the confidence threshold, $\mathcal{TH}$ as 0.5 [6]. For all datasets, we use a setting similar to κ-shot with κ = 10. For N intents, we define our total budget $B = \kappa \times N$. We use same budget for all our experiments. We experiment on NVIDIA Tesla K40m GPU with 12 GB RAM, 6 Gbps clock cycle and GDDR5 memory. All the methods took less than 8 GPU hours for training.

6 Experimental Results

In this section, we discuss the experimental outcomes for MNID and competing baselines. We also show results of different clustering algorithms and variations of distinct components of MNID.

(A) Class Discovery: MNID is very effective in identifying almost all new intents. For HWU, BANKING and CLINC, 54 out of 54 (100%), 66 out of 67 (98.5%) and 139 out of 140 (99.3%) new intents from the unknown intent set were discovered, respectively. For SNIPS and ATIS, we could discover 2 out of 2 (100%) and 7 out of 8 (87.5%) new intent classes, respectively. Due to data skewness (ATIS) and high intent similarity (BANKING, CLINC) MNID misses one intent.

(B) Performance of MNID: Table 3 shows the performance of different models - IFSTC, PolyAI, BERT and RoBERTa when trained with datasets provided by MNID. In order to maintain the fairness, MNID, Rn_F and Gl_F use the (overall) same number of gold-annotated data points. Besides MNID uses silver-annotated data points, while the others do not have any way of creating high quality silver annotated data. Each cell in the table consists of values from Gl_F, Rn_F and MNID. As expected, Rn_F performs the worst across all settings. However, except two scenarios, we observe that MNID consistently performs better than the Gl_F dataset. For all these four different settings across five datasets, MNID improvements over Gl_F predictions are statistically significant ($p < 0.05$) as

---

[5] Code: `https://github.com/thuiar/TEXTOIR`

[6] This combination of τ and $\mathcal{TH}$ provides the best results among different experimented results.

per McNemar's Test. It is observed that our approach also works well on the highly imbalanced ATIS dataset in which some of the classes have less than 10 data points and highly similar BANKING dataset in which the intents are closely related eg., 'top-up-reverted' and 'top-up-failed'. This is because although Gl_F chooses uniformly across all classes, MNID selectively labels datapoints having high uncertainty thus providing the classifier with the right ingredient to perform better. In IFSTC on SNIPS dataset, MNID underperforms as compared to Gl_F but with a very small margin. This happens because in the case of SNIPS dataset, the number of new classes is very less, hence Gl_F can choose ideal candidates. The best performance of MNID as well as the two baselines is in the PolyAI setting when it is used with Universal Sentence Encoders (USE). Since PolyAI performs the best, all our subsequent results are provided on PolyAI (USE).

(C) Distribution of gold annotated points: Fig 2 shows the count of the gold annotated points ($Y-axis$) for new classes (class indices on $X-axis$). The dotted line is at the frequency of 10, corresponding to the average annotations per class. For 76.2% (HWU), 81.5% (BANKING) and 67.3% (CLINC) classes in good clusters require '$\leq$ 10' annotations. More than 10 annotations are needed for 65.4% (HWU), 68.5% (BANKING) and 54.5% (CLINC) classes in bad clusters.

(D) Budgets: For novel intent class discovery, a minimum number of human annotation is necessary. For NCD to work, at least 4 shot, 6-shot and 7-shot annotations are required for HWU, BANKING and CLINC datasets respectively.

Different Variations of MNID

MNID consists of three steps (a). novel class detection (NCD), (b). cluster quality based annotation (CQBA) and (c). post-processing annotation strategy (PPAS). In each of these steps, certain parameters can be varied. We systematically discuss the impact of these parameters on MNID performance.

Variations at NCD

(a) Performance of Clustering Algorithms: We explore different unsupervised and semi-supervised clustering algorithms in our **MNID** framework. Overall accuracy and F1-Score for open intent discovery by different approaches are shown in Table 4. From Table 4, it is seen that unsupervised approaches perform better than semi-supervised models. The semi-supervised techniques get biased by the initial seed and fail to discover diverse clusters needed to detect all the new intent classes. K-Means (KM) performs the best across all datasets in terms of accuracy and F1 score except for HWU dataset where DEC and DTC (F1 only) outperforms it. This is most probably due to its robustness and absence of any outlier in the dataset. So we use K-Means as the clustering algorithm for MNID.

(b) Class Discovery with number of clusters: From Fig 3a, we observe an increasing trend in the number of classes discovered with increasing number of clusters which show that classes get evenly distributed across clusters as the number of clusters increases. The rate at which new classes are discovered is linear with the new clusters until significant classes are detected. The horizontal lines represent the gold number of new intents.

(c) Effect of number of points (x) used in clustering: Fig 3b shows that the accuracy on all datasets drops as we increase the number of points used for new class discovery in clustering beyond $x = 2$. This is because most of the budget gets exhausted while clustering and we have a very small budget to annotate low-confidence points in the next steps. Note that at least two points from a cluster need to be annotated for new class discovery.

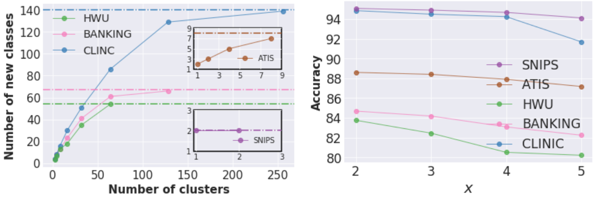
Table 6: Accuracy (%) based on point selections from Good and Bad clusters



(a) Class discovery with number of clusters

(b) Accuracy vs points annotated (x) for clustering

Figure 3: Variations of NCD

Variations at CQBA

(a) Effect of number of points selected from Good and Bad clusters: We experiment with different values of point selection (p, q) for the module CQBA (Algo 4) and observe how accuracy changes for three larger datasets - HWU, BANKING and CLINC. We get the best accuracy for (p, q) = (3, 2) i.e 3 (p) points from good cluster and 5 ($p + q$) points from bad cluster as shown in Table 6. Since, we perform gold annotation strategy on the bad clusters, a higher number of point selection is required to identify classes.

(b) Distribution of good and bad clusters: For CLINC, BANKING and HWU we obtain 256, 128 and 64 clusters respectively by NCD. The percentage of good clusters obtained for CLINC, BANKING and HWU are 70.70% (181 out of 256), 46.88% (60 out of 128) 56.25 % (36 out of 64), respectively. For BANKING, since the entire dataset is from a single domain with multiple intents being similar among themselves, we obtain more bad clusters than the good clusters. For SNIPS and ATIS, however, all the clusters are good clusters.

Variations at PPAS

(a) Different Variations of Gold and Silver Strategies: The results for different variations of MNID methods (based on Silver and Gold Strategy applications) for all the datasets are provided in Table 5. We observe that the best result is obtained on MNID-9, i.e., choosing high confidence points from the good clusters for silver strategy and low confidence points from the bad clusters (if detected or else from the good clusters) only for gold strategy. This strategy ensures that during silver annotation we choose points with high fidelity and side by side for gold annotation choose points with high uncertainty, both of which help in developing a highly accurate classifier. Silver strategy on

high confidence points from good cluster (7 vs 9) and gold strategy on low confidence points from bad cluster (4 vs 9) alone enhances ∼1- 3% accuracy and F1 for the three large datasets.MNID-9 corresponds to our proposed approach, MNID.

(b) Silver Strategy Analysis: We inspect silver strategy based on cosine similarity, confidence score and strategy accuracy.

(i) Effect of Cosine Similarity and Confidence Score (CS): We study the effect of cosine similarity of silver strategy for MNID. From Fig. 4a, we observe that the best results are always obtained using a higher threshold of 0.8 cosine similarity. In case of BANKING, HWU and ATIS accuracy drops at 0.9 whereas for other datasets it remains almost identical. Fig. 4b shows how accuracy varies for different confidence scores. We observe that for all the datasets the best results are obtained at a threshold of 0.5. This is because a lower threshold allows more diverse datapoints to be selected using cosine similarity and this in turn improves the model performance. In both the cases if the cosine similarity or the threshold is increased beyond the optimal point, that results in selection of too less datapoints which is not enough for the classifier to do a meaningful learning. Hence accuracy drops. So we choose the parameters - cosine similarity = 0.8 and τ = 0.5 - while choosing *high confidence* point to be annotated by silver strategy.

(ii) Strategy Accuracy: The accuracy of data point selection by silver strategy for different MNID variations is shown in Table 7. We see the strategy of choosing high-confidence points from good clusters produce points with high fidelity. Table 7 also shows the average number of points per class as selected by this strategy for various datasets. Here we see that enough number of silver points are annotated even after considering a very strict criterion. Note, average points per intent class count is the highest for BANKING because multiple intents are very similar to each other and hence more points qualify the cosine similarity threshold, τ.

.

7 Conclusion

We have developed MNID (**M**ultiple **N**ovel **I**ntent **D**etection), an end-to-end framework to identify multiple novel intents within a fixed annotation cost. The algorithm intelligently uses the concept of clusters to first discover the classes and then estimate the nature in which datapoints of a class is distributed, that is, whether the datapoints of a class congregate strongly within themselves and separate from other classes or are entangled with datapoints of other classes. In the two types of situations, we propose two different strategies, silver strategy to take advantage of the clusters so that we can annotate many points without any extra human cost and gold strategy to annotate highly uncertain points. This two-pronged approach helps us to annotate highly precise points automatically while annotating the most uncertain (with respect to the class it belongs) points using human assistance. We have done a very rigorous analysis/experimentation to establish the core idea of our algorithm. We observe that the accuracy of classifiers when fed with the dataset created by MNID can beat the standard best few-shot setting where it is assumed that 'κ' instances of each class are provided and annotated by human whereas in our case we have to first discover the classes and then have to find the instances of each class.

One limitation of MNID is that it is not able to detect intents where classes are very similar to each other. For example, the query "Can you explain why my payment is still pending?" in BANKING dataset is from the "pending transfer" category but our system detects as "pending card payment" intent as both intents are quite similar. We shall try to address this issue in future. We have presently worked on a setting where novel intents appear in one step, we would strive to extend this framework to explore the dynamics of periodically evolving intents.

Abstract

It is challenging to train a good intent classifier for a task-oriented dialogue system with only a few annotations. Recent studies have shown that fine-tuning pre-trained language models with a small amount of labeled utterances from public benchmarks in a supervised manner is extremely helpful. However, we find that supervised pre-training yields an anisotropic feature space, which may suppress the expressive power of the semantic representations. Inspired by recent research in isotropization, we propose to improve supervised pre-training by regularizing the feature space towards isotropy. We propose two regularizers based on contrastive learning and correlation matrix respectively, and demonstrate their effectiveness through extensive experiments. Our main finding is that it is promising to regularize supervised pre-training with isotropization to further improve the performance of few-shot intent detection. The source code can be found at `https://github.com/fanolabs/isoIntentBert-main`.

1 Introduction

Intent detection is a core module of task-oriented dialogue systems. Training a well-performing intent classifier with only a few annotations, i.e., few-shot intent detection, is of great practical value. Recently, this problem has attracted considerable attention (Vulić et al., 2021; Zhang et al., b; Dopierre et al., b) but remains a challenge.

To tackle few-shot intent detection, earlier works employ induction network (Geng et al., 2019), generation-based methods (Xia et al., a), metric learning (Nguyen et al., 2020), and self-training (Dopierre et al., b), to design sophisticated algorithms. Recently, pre-trained language models (PLMs) have emerged as a simple yet promising solution to a wide spectrum of natural language processing (NLP) tasks, triggering the surge of PLM-based solutions for few-shot intent detection (Wu et al., 2020; Zhang et al., a,b; Vulić et al., 2021; Zhang et al., b), which typically fine-tune PLMs on conversation data.

A PLM-based fine-tuning method (Zhang et al., a), called IntentBERT, utilizes a small amount of labeled utterances from public intent datasets to fine-tune PLMs with a standard classification task, which is referred to as *supervised pre-training*. Despite its simplicity, supervised pre-training has been shown extremely useful for few-shot intent detection even when the target data and the data used for fine-tuning are very different in semantics. However, as will be shown in Section 3.2, IntentBERT suffers from severe anisotropy, an undesirable property of PLMs (Gao et al., a; Ethayarajh, 2019; Li et al., 2020).

Anisotropy is a geometric property that semantic vectors fall into a narrow cone. It has been identified as a crucial factor for the sub-optimal performance of PLMs on a variety of downstream tasks (Gao et al., a; Arora et al., b; Cai et al., 2020; Ethayarajh, 2019), which is also known as the representation degeneration problem (Gao et al., a). Fortunately, isotropization techniques can be applied to adjust the embedding space and yield significant performance improvement in many tasks (Su et al., 2021; Rajaee and Pilehvar, 2021a).

Hence, this paper aims to answer the question:

- Can we improve supervised pre-training via *isotropization* for few-shot intent detection?

Many isotropization techniques have been developed based on transformation (Su et al., 2021; Huang et al., 2021), contrastive learning (Gao et al., b), and top principal components elimination (Mu and Viswanath, 2018). However, these methods are designed for off-the-shelf PLMs. When applied on PLMs that have been fine-tuned on some NLP task such as semantic textual similarity or intent classification, they may introduce an adverse effect,

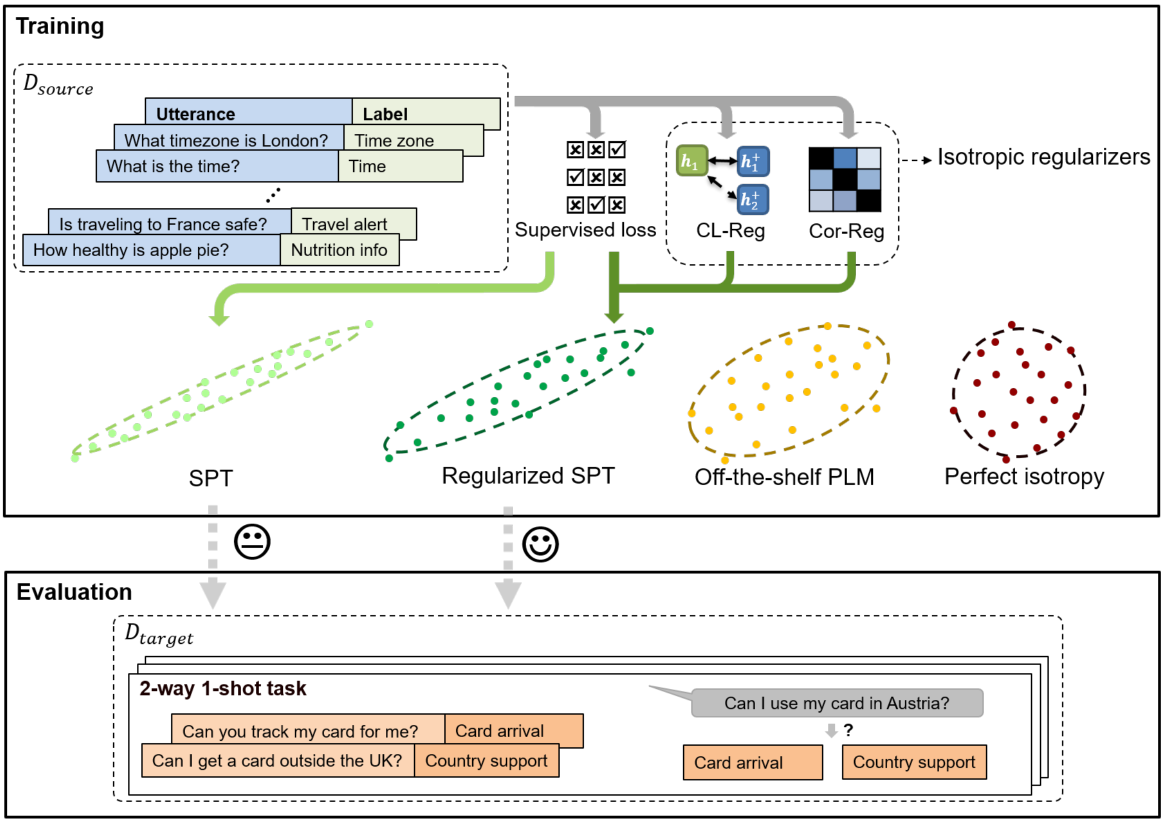

Figure 1: Illustration of our proposed regularized supervised pre-training. SPT denotes supervised pre-training (fine-tuning an off-the-shelf PLM on a set of labeled utterances), which makes the feature space more anisotropic. CL-Reg and Cor-Reg are designed to regularize SPT and increase the isotropy of the feature space, which leads to better performance on few-shot intent detection.

as observed in Rajaee and Pilehvar (2021c) and our pilot experiments.

In this work, we propose to regularize supervised pre-training with isotropic regularizers. As shown in Fig. 1, we devise two regularizers, a contrastive-learning-based regularizer (CL-Reg) and a correlation-matrix-based regularizer (Cor-Reg), each of which can increase the isotropy of the feature space during supervised training. Our empirical study shows that the regularizers can significantly improve the performance of standard supervised training, and better performance can often be achieved when they are combined.

The contributions of this work are three-fold:

- We present the first study on the isotropy property of PLMs for few-shot intent detection, shedding light on the interaction of supervised pre-training and isotropization.
- We improve supervised pre-training by devising two simple yet effective regularizers to increase the isotropy of the feature space.
- We conduct a comprehensive evaluation and analysis to validate the effectiveness of the proposed approach.

2 Related Works

2.1 Few-shot Intent Detection

With a surge of interest in few-shot learning (Finn et al., 2017; Vinyals et al., 2016; Snell et al., 2017), few-shot intent detection has started to receive attention. Earlier works mainly focus on model design, using capsule network (Geng et al., 2019), variational autoencoder (Xia et al., a), or metric functions (Yu et al., 2018; Nguyen et al., 2020). Recently, PLMs-based methods have shown promising performance in a variety of NLP tasks and become the model of choice for few-shot intent detection. Zhang et al. (c) cast few-shot intent detection into a natural language inference (NLI) problem and fine-tune PLMs on NLI datasets. Zhang et al. (b) propose to fine-tune PLMs on unlabeled utterances by contrastive learning. Zhang et al. (a) leverage a small set of public annotated intent detection benchmarks to fine-tune PLMs with standard supervised training and observe promising performance on cross-domain few-shot intent detection. Meanwhile, the study of few-shot intent detection has been extended to other settings including semi-supervised learning (Dopierre et al., b,a), generalized setting (Nguyen et al., 2020), multi-label classification (Hou et al., 2021), and incremental learning (Xia et al., b). In this work, we consider standard few-shot intent detection, following the setup of Zhang et al. (a) and aiming to improve supervised pre-training with isotropization.

2.2 Further Pre-training PLMs with Dialogue Corpora

Recent works have shown that further pre-training off-the-shelf PLMs using dialogue corpora (Henderson et al., b; Peng et al., 2020, 2021) are beneficial for task-oriented downstream tasks such as intent detection. Specifically, TOD-BERT (Wu et al., 2020) conducts self-supervised learning on diverse task-oriented dialogue corpora. ConvBERT (Mehri et al., 2020) is pre-trained on a 700 million open-domain dialogue corpus. Vulić et al. (2021) propose a two-stage procedure: adaptive conversational fine-tuning followed by task-tailored conversational fine-tuning. In this work, we follow Zhang et al. (a) to further pre-train PLMs using a small amount of labeled utterances from public intent detection benchmarks.

2.3 Anisotropy of PLMs

Isotropy is a key geometric property of the semantic space of PLMs. Recent studies identify the anisotropy problem of PLMs (Cai et al., 2020; Ethayarajh, 2019; Mu and Viswanath, 2018; Rajaee and Pilehvar, 2021c), which is also known as the representation degeneration problem (Gao et al., a): word embeddings occupy a narrow cone, which suppresses the expressiveness of PLMs. To resolve the problem, various methods have been proposed, including spectrum control (Wang et al., 2019), flow-based mapping (Li et al., 2020), whitening transformation (Su et al., 2021; Huang et al., 2021), contrastive learning (Gao et al., b), and cluster-based methods (Rajaee and Pilehvar, 2021a). Despite their effectiveness, these methods are designed for off-the-shelf PLMs. The interaction between isotropization and fine-tuning PLMs remains under-explored. A most recent work by Rajaee and Pilehvar shows that there might be a conflict between the two operations for the semantic textual similarity (STS) task. On the other hand, Zhou et al. (2021) propose to fine-tune PLMs with isotropic batch normalization on some supervised tasks, but it requires a large amount of training data. In this work, we study the interaction between isotropization and supervised pre-training (fine-tuning) PLMs on intent detection tasks.

Dataset	BERT	IntentBERT

HINT3	.95	$.72_{(.03)}$
HWU64	.96	$.72_{(.04)}$

Table 1: The impact of fine-tuning on isotropy. Fine-tuning renders the semantic space notably more anisotropic. The mean and standard deviation of 5 runs with different random seeds are reported.

3 Pilot Study

Before introducing our approach, we present pilot experiments to gain some insights into the interaction between isotropization and fine-tuning PLMs.

3.1 Measuring isotropy

Following Mu and Viswanath (2018); Biś et al. (2021), we adopt the following measurement of isotropy:

$$\mathrm{I}(\mathbf{V}) = \frac{\min_{\mathbf{c} \in C} \mathrm{Z}(\mathbf{c}, \mathbf{V})}{\max_{\mathbf{c} \in C} \mathrm{Z}(\mathbf{c}, \mathbf{V})}, \tag{1}$$

where $\mathbf{V} \in \mathbb{R}^{N \times d}$ is the matrix of stacked embeddings of N utterances (note that the embeddings have zero mean), C is the set of unit eigenvectors of $\mathbf{V}^\top \mathbf{V}$, and $\mathrm{Z}(\mathbf{c}, \mathbf{V})$ is the partition function (Arora et al., b) defined as:

$$\mathrm{Z}(\mathbf{c}, \mathbf{V}) = \sum_{i=1}^{N} \exp\left(\mathbf{c}^\top \mathbf{v}_i\right), \tag{2}$$

where $\mathbf{v}_i$ is the i_{th} row of $\mathbf{V}$. $\mathrm{I}(\mathbf{V}) \in [0, 1]$, and 1 indicates perfect isotropy.

3.2 Fine-tuning Leads to Anisotropy

To observe the impact of fine-tuning on isotropy, we follow IntentBERT (Zhang et al., a) to fine-tune BERT (Devlin et al., 2019) with standard supervised training on a small set of an intent detection benchmark OOS (Larson et al., 2019) (details are given in Section 4.1). We then compare the isotropy of the original embedding space (BERT) and the embedding space after fine-tuning (IntentBERT) on target datasets. As shown in Table 1, after fine-tuning, the isotropy of the embedding space is notably decreased on all datasets. Hence, it can be seen that *fine-tuning may render the feature space more anisotropic*.

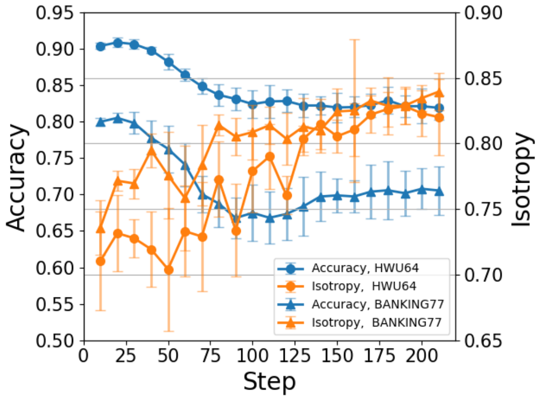

Figure 2: The impact of contrastive learning on IntentBERT with experiments on HWU64 and BANKING77 datasets. The performance (blue) drops while the isotropy (orange) increases.

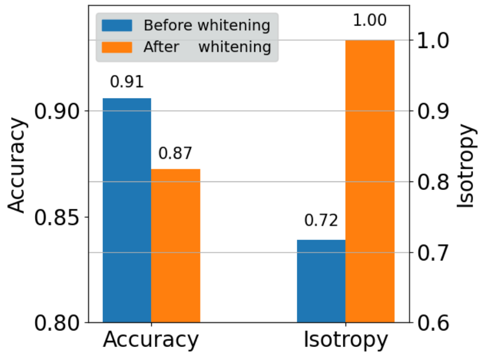
3.3 Isotropization after Fine-tuning May Have an Adverse Effect

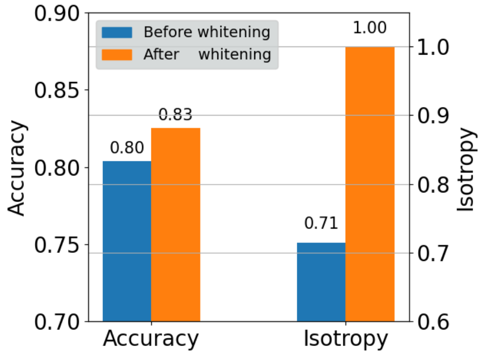
To examine the effect of isotropization on a fine-tuned model, we apply two strong isotropization techniques to IntentBERT: dropout-based contrastive learning (Gao et al., b) and whitening transformation (Su et al., 2021). The former fine-tunes PLMs in a contrastive learning manner[1], while the latter transforms the semantic feature space into an isotropic space via matrix transformation. These methods have been demonstrated highly effective (Gao et al., b; Su et al., 2021) when applied to off-the-shelf PLMs, but things are different when they are applied to fine-tuned models. As shown in Fig. 2, contrastive learning improves isotropy, but it significantly lowers the performance on two benchmarks. As for whitening transformation, it has inconsistent effects on the two datasets, as shown in Fig. 3. It hurts the performance on HWU64 (Fig. 3a) but yields better results on BANKING77 (Fig. 3b), while producing nearly perfect isotropy on both. The above observations indicate that *isotropization may hurt fine-tuned models*, which echoes the recent finding of Rajaee and Pilehvar.

4 Method

The pilot experiments reveal the anisotropy of a PLM fine-tuned on intent detection tasks and the



(a) HWU64.



(b) BANKING77.

Figure 3: The impact of whitening on IntentBERT with experiments on HWU64 and BANKING77 datasets. Whitening transformation leads to perfect isotropy but has inconsistent effects on the performance.

challenge of applying isotropization techiniques on the fine-tuned model. In this section, we propose a joint fine-tuning and isotropization framework. Specifically, we propose two regularizers to make the feature space more isotropic during fine-tuning. Before presenting our method, we first introduce supervised pre-training.

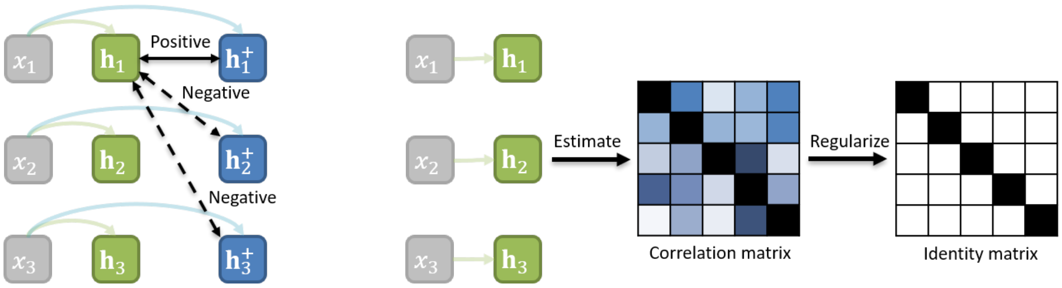
4.1 Supervised Pre-training for Few-shot Intent Detection

Few-shot intent detection targets to train a good intent classifier with only a few labeled data $\mathcal{D}_{\text{target}} = \{(x_i, y_i)\}_{N_t}$, where N_t is the number of labeled samples in the target dataset, x_i denotes the i_{th} utterance, and y_i is the label.

To tackle the problem, Zhang et al. (a) propose to learn intent detection skills (fine-tune a PLM) on a small subset of public intent detection benchmarks by supervised pre-training. Denote by $\mathcal{D}_{\text{source}} = \{(x_i, y_i)\}_{N_s}$ the source data used for pre-training, where N_s is the number of examples. The fine-tuned PLM can be directly used on the target dataset. It has been shown that this method

---

[1] We refer the reader to the original paper for details.



(a) CL-Reg.

(b) Cor-Reg.

Figure 4: Illustration of CL-Reg (contrastive-learning-based regularizer) and Cor-Reg (correlation-matrix-based regularizer). x_i is the i_{th} utterance in a batch of size 3. In (a), x_i is fed to the PLM twice with built-in dropout to produce two different representations of x_i: $\mathbf{h}_i$ and $\mathbf{h}_i^+$. Positive and negative pairs are then constructed for each x_i. For example, $\mathbf{h}_1$ and $\mathbf{h}_1^+$ form a positive pair for x_1, while $\mathbf{h}_1$ and $\mathbf{h}_2^+$, and $\mathbf{h}_1$ and $\mathbf{h}_3^+$, form negative pairs for x_1. In (b), the correlation matrix is estimated from $\mathbf{h}_i$, feature vectors generated by the PLM, and is regularized towards the identity matrix.

can work well when the label spaces of $\mathcal{D}_{\text{source}}$ and $\mathcal{D}_{\text{target}}$ are disjoint.

Specifically, the pre-training is conducted by attaching a linear layer (as the classifier) on top of the utterance representation generated by the PLM:

$$\text{p}(y|\mathbf{h}_i) = \text{softmax}\left(\mathbf{W}\mathbf{h}_i + \mathbf{b}\right) \in \mathbb{R}^L, \qquad (3)$$

where $\mathbf{h}_i \in \mathbb{R}^d$ is the representation of the i_{th} utterance in $\mathcal{D}_{\text{source}}$, $\mathbf{W} \in \mathbb{R}^{L \times d}$ and $\mathbf{b} \in \mathbb{R}^L$ are the parameters of the linear layer, and L is the number of classes. The model parameters $\theta = \{\phi, \mathbf{W}, \mathbf{b}\}$, with ϕ being the parameters of the PLM, are trained on $\mathcal{D}_{\text{source}}$ with a cross-entropy loss:

$$\theta = \arg\min_{\theta} \mathcal{L}_{\text{ce}}\left(\mathcal{D}_{\text{source}};\theta\right). \qquad (4)$$

After supervised pre-training, the linear layer is removed, and the PLM can be immediately used as a feature extractor for few-shot intent classification on target data. As shown in Zhang et al. (a), a parametric classifier such as logistic regression can be trained with only a few labeled samples to achieve good performance.

However, our analysis in Section 3.2 shows the limitation of supervised pre-training, which yields a anisotropic feature space.

4.2 Regularizing Supervised Pre-training with Isotropization

To mitigate the anisotropy of the PLM fine-tuned by supervised pre-training, we propose a joint training objective by adding a regularization term $\mathcal{L}_{\text{reg}}$ for isotropization:

$$\mathcal{L} = \mathcal{L}_{\text{ce}}(\mathcal{D}_{\text{source}};\theta) + \lambda\mathcal{L}_{\text{reg}}(\mathcal{D}_{\text{source}};\theta), \qquad (5)$$

where λ is a weight parameter. The aim is to learn intent detection skills while maintaining an appropriate degree of isotropy. We devise two different regularizers introduced as follows.

Contrastive-learning-based Regularizer. Inspired by the recent success of contrastive learning in mitigating anisotropy (Yan et al., 2021; Gao et al., b), we employ the dropout-based contrastive learning loss used in Gao et al. (b) as the regularizer:

$$\mathcal{L}_{\text{reg}} = -\frac{1}{N_b}\sum_{i}^{N_b}\log\frac{e^{\text{sim}(\mathbf{h}_i,\mathbf{h}_i^+)/\tau}}{\sum_{j=1}^{N_b} e^{\text{sim}(\mathbf{h}_i,\mathbf{h}_j^+)/\tau}}. \qquad (6)$$

In particular, $\mathbf{h}_i \in \mathbb{R}^d$ and $\mathbf{h}_i^+ \in \mathbb{R}^d$ are two different representations of utterance x_i generated by the PLM with built-in standard dropout (Srivastava et al., 2014), i.e., x_i is passed to the PLM twice with different dropout masks to produce $\mathbf{h}_i$ and $\mathbf{h}_i^+$. $\text{sim}(\mathbf{h}_1, \mathbf{h}_2)$ denotes the cosine similarity between $\mathbf{h}_1$ and $\mathbf{h}_2$. τ is the temperature parameter. N_b is the batch size. Since $\mathbf{h}_i$ and $\mathbf{h}_i^+$ represent the same utterance, they form a positive pair. Similarly, $\mathbf{h}_i$ and $\mathbf{h}_j^+$ form a negative pair, since they represent different utterances. An example is given in Fig. 4a. By minimizing the contrastive loss, positive pairs are pulled together while negative pairs are pushed away, which in theory enforces an isotropic feature space (Gao et al., b). In Gao et al. (b), the contrastive loss is used as the single objective to fine-tune off-the-shelf PLMs in an unsupervised manner, while in this work we use it jointly with supervised pre-training to fine-tune PLMs for few-shot learning.

Correlation-matrix-based Regularizer. The above regularizer enforces isotropization implicitly.

Here, we propose a new regularizer that explicitly enforces isotropization. The perfect isotropy is characterized by zero covariance and uniform variance (Su et al., 2021; Zhou et al., 2021), i.e., a covariance matrix with uniform diagonal elements and zero non-diagonal elements. Isotropization can be achieved by endowing the feature space with such statistical property. However, as will be shown in Section 5.3, it is difficult to determine the appropriate scale of variance. Therefore, we base the regularizer on *correlation matrix* :

$$\mathcal{L}_{\text{reg}} = \|\mathbf{\Sigma} - \mathbf{I}\|, \tag{7}$$

where $\|\cdot\|$ denotes Frobenius norm, $\mathbf{I} \in \mathbb{R}^{d \times d}$ is the identity matrix, $\mathbf{\Sigma} \in \mathbb{R}^{d \times d}$ is the correlation matrix with $\mathbf{\Sigma}_{ij}$ being the Pearson correlation coefficient between the i_{th} dimension and the j_{th} dimension. As shown in Fig. 4b, $\mathbf{\Sigma}$ is estimated with utterances in the current batch. By pushing the correlation matrix towards the identity matrix during training, we can learn a more isotropic feature space.

Moreover, the proposed two regularizers can be used together as follows:

$$\begin{aligned} \mathcal{L} = \mathcal{L}_{\text{ce}}(\mathcal{D}_{\text{source}};\theta) + \lambda_1 \mathcal{L}_{\text{cl}}(\mathcal{D}_{\text{source}};\theta) \\ + \lambda_2 \mathcal{L}_{\text{cor}}(\mathcal{D}_{\text{source}};\theta), \end{aligned} \tag{8}$$

where λ_1 and λ_2 are the weight parameters, and $\mathcal{L}_{\text{cl}}$ and $\mathcal{L}_{\text{cor}}$ denote CL-Reg and Cor-Reg, respectively. Our experiments show that better performance is often observed when they are used together.

5 Experiments

To validate the effectiveness of the approach, we conduct extensive experiments.

5.1 Experimental Setup

Datasets. To perform supervised pre-training, we follow Zhang et al. to use the OOS dataset (Larson et al., 2019) which contains diverse semantics of 10 domains. Also following Zhang et al., we exclude the domains "Banking" and "Credit Cards" since they are similar in semantics to one of the test dataset BANKING77. We then use 6 domains for training and 2 for validation, as shown in Table 2. For evaluation, we employ three datasets: **BANKING77** (Casanueva et al., 2020) is an intent detection dataset for banking service. **HINT3** (Arora et al., a) covers 3 domains, "Mattress Products Retail", "Fitness Supplements Retail", and "Online Gaming". **HWU64** (Liu et al., 2019a) is a large-scale dataset containing 21 domains. Dataset statistics are summarized in Table 3.

Training	Validation
"Utility", "Auto commute", "Work", "Home", "Meta", "Small talk"	"Travel", "Kitchen dining"

Table 2: Split of domains in OOS.

Dataset	#domain	#intent	#data
OOS	10	150	22500
BANKING77	1	77	13083
HINT3	3	51	2011
HWU64	21	64	10030

Table 3: Dataset statistics.

Our Method. Our method can be applied to fine-tune any PLM. We conduct experiments on two popular PLMs, BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019b). For both of them, the embedding of $[CLS]$ is used as the utterance representation in Eq. 3. We employ logistic regression as the classifier. We select the hyperparameters $\lambda, \lambda_1, \lambda_2$, and τ by validation. The best hyperparameters are provided in Table 4.

Method	Hyperparameter
CL-Reg	$\lambda = 1.7, \tau = 0.05$
Cor-Reg	$\lambda = 0.04$
CL-Reg + Cor-Reg	$\lambda_1 = 1.7, \lambda_2 = 0.04, \tau = 0.05$

(a) BERT-based.

Method	Hyperparameter
CL-Reg	$\lambda = 2.9, \tau = 0.05$
Cor-Reg	$\lambda = 0.06$
CL-Reg + Cor-Reg	$\lambda_1 = 2.9, \lambda_2 = 0.13, \tau = 0.05$

(b) RoBERTa-based.

Table 4: Hyperparameters selected via validation.

Baselines. We compare our method to the following baselines. First, for BERT-based methods, **BERT-Freeze** freezes BERT; **CONVBERT** (Mehri et al., 2020), **TOD-BERT** (Wu et al., 2020), and **DNNC-BERT** (Zhang et al., c) further pre-train BERT on conversational corpus or natural language inference tasks. **USE-ConveRT** (Henderson et al., a; Casanueva et al., 2020) is a transformer-based dual-encoder pre-trained on conversational corpus. **CPFT-BERT** is the re-implemented version of CPFT (Zhang

Table 6: 5-way few-shot intent detection using RoBERTa. We report the mean and standard deviation of our methods and IntentBERT variants. CL-Reg, Cor-Reg, and CL-Reg + CorReg denote supervised pre-training regularized by the corresponding regularizer. The top 3 results are highlighted.

et al., b), by further pre-training BERT in an unsupervised manner with mask-based contrastive learning and masked language modeling on the same training data as ours. **IntentBERT** (Zhang et al., a) further pre-trains BERT via supervised pre-training described in Section 4.1. To guarantee a fair comparison, we provide **IntentBERT-ReImp**, the re-implemented version of IntentBERT, which uses the same random seed, training data, and validation data as our methods. Second, for RoBERTa-based baselines, **RoBERTa-Freeze** freezes the model. **WikiHowRoBERTa** (Zhang et al., d) further pre-trains RoBERTa on synthesized intent detection data. **DNNC-RoBERTa** and **CPFT-RoBERTa** are similar to DNNC-BERT and CPFT-BERT except the PLM. **IntentRoBERTa** is the re-implemented version of IntentBERT based on RoBERTa, with uses the same random seed, training data, and validation data as our method. Finally, to show the superiority of the joint fine-tuning and isotropization, we compare our method against whitening transformation (Su et al., 2021). **BERT-White** and **RoBERTa-White** apply the transformation to BERT and RoBERTa, respectively. **IntentBERT-White** and **IntentRoBERTa-White** apply the transformation to IntentBERT-ReImp and IntentRoBERTa, respectively.

All baselines use logistic regression as classifier except DNNC-BERT and DNNC-RoBERTa, wherein we follow the original work[2] to train a pairwise encoder for nearest neighbor classification.

Training Details. We use PyTorch library and Python to build our model. We employ Hugging Face implementation[3] of *bert-base-uncased* and *roberta-base*. We use Adam (Kingma and Ba,

---

[2] https://github.com/salesforce/DNNC-few-shot-intent

[3] https://github.com/huggingface/transformers

2015) as the optimizer with learning rate of $2e-05$ and weight decay of $1e-03$. The model is trained with Nvidia RTX 3090 GPUs. The training is early stopped if no improvement in validation accuracy is observed for 100 steps. The same set of random seeds, $\{1, 2, 3, 4, 5\}$, is used for IntentBERT-ReImp, IntentRoBERTa, and our method.

Evaluation. The baselines and our method are evaluated on C-way K-shot tasks. For each task, we randomly sample C classes and K examples per class. The $C \times K$ labeled examples are used to train the logistic regression classifier. Note that we do not further fine-tune the PLM using the labeled data of the task. We then sample another 5 examples per class as queries. Fig. 1 gives an example with $C = 2$ and $K = 1$. We report the averaged accuracy of 500 tasks randomly sampled from $\mathcal{D}_{\text{target}}$.

5.2 Main Results

The main results are provided in Table 5 (BERT-based) and Table 6 (RoBERTa-based). The following observations can be made. First, our proposed regularized supervised pre-training, with either CL-Reg or Cor-Reg, consistently outperforms all the baselines by a notable margin in most cases, indicating the effectiveness of our method. Our method also outperforms whitening transformation, demonstrating the superiority of the proposed joint fine-tuning and isotropization framework. Second, Cor-Reg slightly outperforms CL-Reg in most cases, showing the advantage of enforcing isotropy explicitly with the correlation matrix. Finally, CL-Reg and Cor-Reg show a complementary effect in many cases, especially on BANKING77. The above observations are consistent for both BERT and RoBERTa. It can be also seen that higher performance is often attained with RoBERTa.

Method	BANKING77	HINT3	HWU64
IntentBERT-ReImp	.71$_{(.04)}$	.72$_{(.03)}$	.72$_{(.03)}$
SPT+CL-Reg	.77$_{(.01)}$	.78$_{(.01)}$	.75$_{(.03)}$
SPT+Cor-Reg	.79$_{(.01)}$	.76$_{(.06)}$	.80$_{(.03)}$
SPT+CL-Reg+Cor-Reg	.79$_{(.01)}$	.76$_{(.05)}$	.80$_{(.02)}$

Table 7: Impact of the proposed regularizers on isotropy. The results are obtained with BERT. SPT denotes supervised pre-training.

The observed improvement in performance comes with an improvement in isotropy. We report the change in isotropy by the proposed regularizers in Table 7. It can be seen that both regularizers and their combination make the feature space more isotropic compared to IntentBERT-ReImp that only uses supervised pre-training. In addition, in general, Cor-Reg can achieve better isotropy than CL-Reg.

5.3 Ablation Study and Analysis

Moderate isotropy is helpful. To investigate the relation between the isotropy of the feature space and the performance of few-shot intent detection, we tune the weight parameter λ of Cor-Reg to increase the isotropy and examine the performance. As shown in Fig. 5, a common pattern is observed: the best performance is achieved when the isotropy is moderate. This observation indicates that it is important to find an appropriate trade-off between learning intent detection skills and learning an isotropic feature space. In our method, we select the appropriate λ by validation.

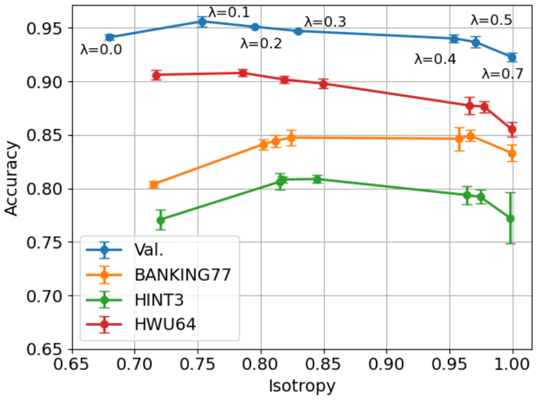

Figure 5: Relation between performance and isotropy. The results are obtained with BERT on 5-way 2-shot tasks.

Correlation matrix is better than covariance matrix as regularizer. In the design of Cor-Reg (Section 4.2), we use the correlation matrix, rather than the covariance matrix, to characterize isotropy, although the latter contains more information – variance. The reason is that it is difficult to determine the proper scale of the variances. Here, we conduct experiments using the covariance matrix, by pushing the non-diagonal elements (covariances) towards 0 and the diagonal elements (variances) towards 1, 0.5, or the mean value, which are denoted by Cov-Reg-1, Cov-Reg-0.5, and Cov-Reg-mean respectively in Table 8. It can be seen that all the variants perform worse than Cor-Reg.

Our method is complementary with batch normalization. Batch normalization (Ioffe and Szegedy, 2015) can potentially mitigate the

Method	BANKING77	Val.
Cov-Reg-1	82.19(.84)	94.52(.19)

✓		✓	✓	**84.67(.51)**
✓	✓	✓		85.21(.58)
✓	✓	✓	✓	**85.64(.41)**

Table 9: Effect of combining batch normalization and our method. The experiments are conducted with BERT and evaluated on 5-way 2-shot tasks. SPT denotes supervised pre-training. BN denotes batch normalization.

The performance gain is not from the reduction in model variance. Regularization techniques such as L1 regularization (Tibshirani, 1996) and L2 regularization (Hoerl and Kennard, 1970) are often used to improve model performance by reducing model variance. Here, we show that the performance gain of our method is ascribed to the improved isotropy (Table 7) rather than the reduction in model variance. To this end, we compare our method against L2 regularization with a wide range of weights, and it is observed that reducing model variance cannot achieve comparable performance to our method, as shown in Fig. 6.

The computational overhead is small. To analyze the computational overheads incurred by CL-Reg and Cor-Reg, we decompose the duration of one epoch of our method using the two regularizers jointly. As shown in Fig. 7, the overheads of CL-Reg and Cor-Reg are small, only taking up a small portion of the time.

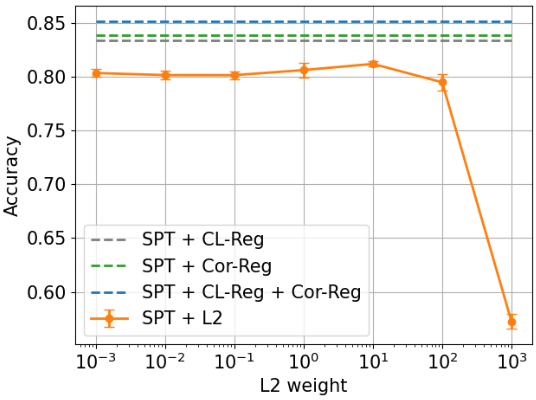

Figure 6: Comparison between our methods and L2 regularization. The experiments are conducted with BERT and evaluated on 5-way 2-shot tasks on BANKING77. SPT denotes superivsed pre-training.

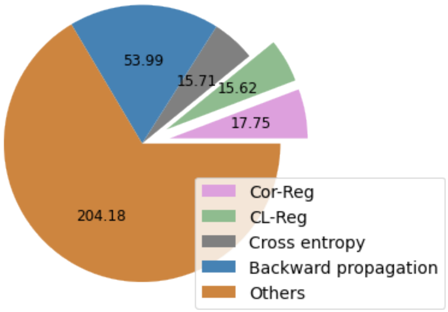

Figure 7: Run time decomposition of a single epoch. The unit is second.

6 Conclusion

In this work, we have identified and analyzed the anisotropy of the feature space of a PLM fine-tuned on intent detection tasks. Further, we have proposed a joint training framework and designed two regularizers based on contrastive learning and correlation matrix respectively to increase the insotropy of the feature space during fine-tuning, which leads to notably improved performance on few-shot intent detection. Our findings and solutions may have broader implications for solving other natural language understanding tasks with PLM-based models.

Cross-document Misinformation Detection based on Event Graph Reasoning

Xueqing Wu, Kung-Hsiang Huang, Yi R. Fung, Heng Ji
University of Illinois Urbana-Champaign
`{xueqing8,khhuang3,yifung2,hengji}@illinois.edu`

Abstract

For emerging events, human readers are often exposed to both real news and fake news. Multiple news articles may contain complementary or contradictory information that readers can leverage to help detect fake news. Inspired by this process, we propose a novel task of **cross-document misinformation detection**. Given a cluster of topically related news documents, we aim to detect misinformation at both *document level* and a more fine-grained level, *event level*. Due to the lack of data, we generate fake news by manipulating real news, and construct 3 new datasets with 422, 276, and $1,413$ clusters of topically related documents, respectively. We further propose a graph-based detector that constructs a cross-document knowledge graph using cross-document event coreference resolution and employs a heterogeneous graph neural network to conduct detection at two levels. We then feed the event-level detection results into the document-level detector. Experimental results show that our proposed method significantly outperforms existing methods by up to 7 F1 points on this new task.[1]

1 Introduction

The dissemination of fake news has become an important social issue. For emergent complex events, human readers are usually exposed to multiple news documents, where some are real and others are fake. News documents from different sources naturally form a cluster of topically related documents. We notice that articles about the same topic may contain conflicting or complementary information, which can benefit the task of misinformation detection. An example is shown in Figure 1. As shown in the knowledge graph, the death of Rosanne Boyland in 2021 US Capitol attack is a shared event across all four documents. Each document is internally consistent, making it difficult to identify misinformation when judging each news separately. However, the three real news documents complement each other's statements regarding the death of Boyland, while the fake news document contradicts the other stories. Such cross-document connections can be leveraged to help detect misinformation.

Most of the existing work on fake news detection is limited to judging each document in isolation. In contrast, we propose a novel task of **cross-document misinformation detection** that aims to detect fake information from a cluster of topically related news documents. We perform the task at both the document level and event level. Each event describes a specific type of real-world event mentioned in the text (e.g., the death of Boyland in Figure 1), and usually involves certain participants to represent different aspects of the event (e.g., the cause of death and the victim of the death event). **Document-level detection** aims to detect fake news documents. **Event-level detection** is a more fine-grained task that aims to detect fake events, thereby pinpointing specific fake information in news documents.

Existing work on fine-grained misinformation detection detects triplets of false knowledge (Fung et al., 2021). However, we focus on identifying false events instead of relations or entities, because events are more important for storytelling and easier to compare across multiple documents through cross-document coreference resolution.

To the best of our knowledge, there are no fake news detection datasets with clusters of topically related documents. Therefore, we construct 3 new benchmark datasets based on existing real news corpus with such clusters. Following Fung et al. (2021), we train a generator that generates a document from a knowledge graph (KG), and feed manipulated KGs into the generator to generate fake news documents. Tracking the manipulation operations, we also obtain supervision for event-

Real News 1

…Rosanne Boyland, a 34-year-old Trump supporter from Georgia who died during the attack on the Capitol on Jan. 6, appears to have been killed in a crush of fellow rioters…The chief medical examiner of Washington, D.C., said Boyland’s cause and manner of death are “pending”. …

Real News 2

…The medical examiner ruled that Rosanne Boyland, 34, of Kennesaw, Ga., died of accidental acute amphetamine intoxication. …The drug cited in Boyland’s death is addictive and can be prescribed to treat attention-deficit disorder and narcolepsy. …

Real News 3

…Officer A.W. stepped out of a tunnel where police were congregated and into the crowd to help Rosanne Boyland, 34, a rioter and QAnon supporter who was trampled by the mob. She died of an accidental drug overdose, according to Washington, DC's chief medical examiner. …

Fake News

Newly-released video from the Jan. 6 U.S. Capitol display appears to show U.S. Capitol police kicking 34-year-old Rosanne Boyland to death. …This video seems to confirm previous reports from The Gateway Pundit suggesting that Boyland was killed by U.S. Capitol police. …

Figure 1: An example of cross-document misinformation detection, including the texts and knowledge graphs for four news documents. The three real news documents complement each other, while the fake news contradicts the other news. News 1 falsely speculates that Boyland was crushed to death, but it admits that the cause of death was not yet verified. News 2 and 3 complete the story by reporting that Boyland died of drug overdose. The fake news claims that Boyland was killed by police, which contradicts the other news. Additionally, the fake news states that the police attacked Boyland, which is inconsistent with News 3’s claim that the police was trying to help her.

level detection.

We further propose a detection approach as shown in Figure 2. Given a cluster of documents, we first use an information extraction (IE) system (Lin et al., 2020) to construct a within-document KG for each document. Then, we connect the within-document KGs to form a cross-document KG using cross-document event coreference resolution (Lai et al., 2021; Wen et al., 2021). Eventually, we use a heterogeneous graph neural network (GNN) to encode the cross-document KG and conduct detection at two levels.

Our contributions are summarized as follows:

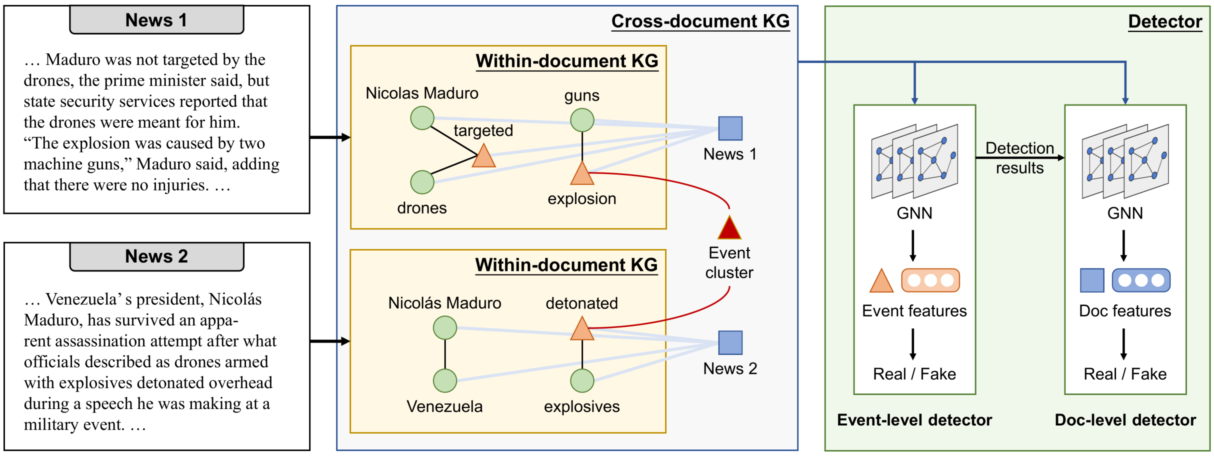
1. We propose the novel task of cross-document misinformation detection, and conduct the task at two levels, document level and the more fine-grained event level.
2. We construct 3 new datasets for our proposed task based on existing document clusters categorized by topics.
3. We propose a detector that leverages cross-document information and improve document-level detection by utilizing features produced by the event-level detector. Experiments on three datasets demonstrate that our method significantly outperforms existing methods.

2 Related Work

Fake News Detection: Early work on fake news detection uses hand-crafted features to perform document classification (Rubin et al., 2016; Wang, 2017; Rashkin et al., 2017; Pérez-Rosas et al., 2018; Sarkar et al., 2018; Atanasova et al., 2019). Recent work uses neural networks such as recurrent neural networks (Karimi et al., 2018; Nasir et al., 2021) and Transformer (Zellers et al., 2019) to encode the news document. To model the internal structure of a news document, Karimi and Tang (2019) model the inter-sentence dependency tree, Vaibhav et al. (2019); Hu et al. (2021) model the interactions between sentences; and Pan et al. (2018) and Fung et al. (2021) model the knowledge graph extracted by IE systems. Similar to our work, Hu et al. (2021) compare each news with external knowledge base (KB) to check for inconsistencies. However, the correlation between news and KB is not as close as the correlation between related news documents due to the incompleteness of these KBs. Other work utilizes additional information such as user engagements and behaviors on social media (Shu et al., 2019; Nguyen et al., 2020) and multi-modal features (Khattar et al., 2019; Tan et al., 2020; Fung et al., 2021). However, to the best of our knowledge, no published work has considered using cross-document inference for misinformation detection.

In addition to document-level detection, the task of fine-grained detection is also important but rarely explored. The most relevant work detects fake knowledge triplets extracted from each individual news article (Fung et al., 2021).

Another related task is fact verification which aims to verify a statement based on retrieved evidence. Fact verification has been explored in multiple domains such as general domain (Thorne et al., 2018), climate change (Diggelmann et al., 2020)



… Maduro was not targeted by the drones, the prime minister said, but state security services reported that the drones were meant for him. "The explosion was caused by two machine guns," Maduro said, adding that there were no injuries. …

… Venezuela' s president, Nicolás Maduro, has survived an apparent assassination attempt after what officials described as drones armed with explosives detonated overhead during a speech he was making at a military event. …

Figure 2: An overview of our approach. We first construct a within-document KG for each document based on IE output, where ○ represents an entity and △ represents an event. Then, we construct a cross-document KG by (1) adding a node for each cross-document event cluster and connecting it with events in the cluster, and (2) introducing a document node □ for each document and connecting it with all entities and events in the given document. Finally, we use GNN to encode the cross-document KG, and use the event and document features to conduct misinformation detection at two levels. The two detectors are trained and deployed in a pipeline fashion, where event-level detection results are leveraged to improve document-level detection.

and COVID-19 (Wadden et al., 2020; Saakyan et al., 2021). However, fact verification focuses on short single-sentence statements and cannot model the complicated internal structure of a news document.

Fake News Datasets: The main difficulty in constructing a fake news dataset is to obtain annotations. Rashkin et al. (2017) and Rubin et al. (2016) obtain labels from the source information and consider news from reliable sources as real news, and unreliable sources as fake news. A potential issue is that the detector may only learn to distinguish the style of different news sources, rather than the authenticity of the content. Shu et al. (2020) collect annotations from fact-checking websites, and Pérez-Rosas et al. (2018) collect annotations via crowd-sourcing. These approaches produce datasets of higher quality, but require extensive manual efforts. With the development of powerful generative models capable of mimicking human-written news (Zellers et al., 2019), recent work has constructed datasets by using generative models to generate fake news (Tan et al., 2020; Fung et al., 2021). Fung et al. (2021) further generate fake news from manipulated KG, which we follow to construct our dataset.

3 Task Formulation

Given a cluster of documents about the same story, the task of cross-document misinformation detection aims to detect the fake information included in the cluster.

Formally, let $\mathbf{S} = \{\mathbf{d}_1, \cdots, \mathbf{d}_N\}$ be the document cluster, and $N = |\mathbf{S}|$ be the size of the cluster. Some documents in $\mathbf{S}$ are real, while others are fake. From each document $\mathbf{d} \in \mathbf{S}$, we extract events $\mathbf{E}(\mathbf{d}) = \{e_1, \cdots, e_m\}$, where $m = |\mathbf{E}(\mathbf{d})|$ is the number of events in document $\mathbf{d}$. In an extracted event set $\mathbf{E}(\mathbf{d})$, some events are real and others are fake.

We conduct the task of misinformation detection at two levels, document level and event level. **Document-level detection** aims to predict whether each document $\mathbf{d} \in \mathbf{S}$ is real or fake. **Event-level detection** is a more fine-grained task that aims to predict whether each event $e \in \mathbf{E}(\mathbf{d}), \mathbf{d} \in \mathbf{S}$ is real or fake. In the example in Figure 1, the *die* event in the fake news is fake, since it falsely describes Boyland being killed by the police, but she actually died of drug overdose.

4 Approach

An overview of our approach is shown in Figure 2. Given a cluster of documents, we first construct a within-document KG for each document using an IE system (Lin et al., 2020), and then connect the within-document KGs into a cross-document KG using cross-document event coreference resolution. Based on the cross-document KG, we use a hetereogeneous GNN (Schlichtkrull et al., 2018;

Hu et al., 2019) to perform detection. We further incorporate the results of event-level detection to help the document-level detector.

4.1 Knowledge Graph Construction

Within-document KG: We first construct a within-document IE-based knowledge graph for each document. We leverage OneIE (Lin et al., 2020), a joint IE system, to extract the entities, relations, and events contained in a given document. Then, we conduct entity linking (Pan et al., 2017) and entity coreference resolution (Lee et al., 2017) to merge multiple mentions of the same entities together. Eventually, we obtain a within-document KG where entities and events are nodes, relations are edges between entities, and arguments are edges between events and entities.

Cross-document KG: We leverage cross-document event coreference resolution to connect the within-document KGs into a cross-document KG as illustrated in Figure 2. We employ a cross-document event coreference resolution system (Lai et al., 2021; Wen et al., 2021) to identify clusters of events from multiple documents that refer to the same real-world events. The system utilizes both textual contexts of the event mentions and symbolic features such as the event type information. An example of the detected event cluster is shown in Table 1, where the four events of four documents all refer to the same explosion attack on Venezuela's President Nicolas Marduro. These four events contain complementary or contradictory details, which can be used for misinformation detection. For each event cluster, we add a node to represent the overall information of the real-world complex event corresponding to the cluster. Then, an edge is added between each event node and corresponding cluster node to allow reasoning among cross-document coreferential events.

To indicate which document each entity or event belongs to and capture the global information of each document, we further introduce a document node and connect it to the associated entity and event nodes for each document.

The resulting KG contains 4 types of nodes (i.e. entity nodes, event nodes, document nodes, and event cluster nodes) and 5 types of edges (i.e. relation edges, event argument edges, document-to-entity edges, document-to-event edges, and edges connecting event nodes to event cluster nodes). Since all edges are directional, we add an inverse edge for each edge to propagate features along both directions, and the final KG contains 10 edge types, accounting for the inverse of existing edge types.

Real	· · · Venezuela' s president, Nicolás Maduro, has survived an apparent assassination attempt after what officials described as drones armed with explosives$_{\text{arg1}}$ **detonated**$_{\text{trig}}$ overhead during a speech he was making at a military event. · · ·
Real	· · · The BBC quotes anonymous firefighters at the scene who say "the incident was actually a gas tank **explosion**$_{\text{trig}}$ inside an apartment$_{\text{arg2}}$, but did not provide further details." · · ·
Fake	· · · Maduro was not targeted by the drones, the prime minister said, but state security services reported that the drones were meant for him. "The **explosion**$_{\text{trig}}$ was caused by two machine guns$_{\text{arg1}}$," Maduro said, adding that there were no injuries. · · ·
Fake	· · · Two drones armed with explosives **detonated**$_{\text{trig}}$ near PuntoDeCorte$_{\text{arg2}}$, where the Venezuelan Foreign Minister, Jorge Rodríguez, was performing, and near the stage where he was giving a speech. · · ·

Table 1: An example of cross-document event cluster from IED dataset, where **trig**, arg1 and arg2 represent the trigger, *ExplosiveDevice* argument and *Place* argument respectively. The four events from four documents all refer to the explosion attack on Nicolas Marduro. The two real news articles complement each other by providing different aspects of the event (*ExplosiveDevice* argument in the first news and *Place* argument in the second news), while the two fake news articles contradict the real news with different details (i.e., different *ExplosiveDevice* and *Place* arguments).

KG representation: We use BERT (Devlin et al., 2019) to initialize the node and edge embeddings in the KG. For a document node, we use BERT to encode the entire document and take the embeddings of `[CLS]` tokens. Similarly, for an entity node, we encode its canonical mention. For an event node, we encode the sentence where the event trigger occurs. For an event cluster node, we take the average of the embeddings of all events in the cluster. For a relation edge or an event argument role edge, we encode the linearized representation of the relation tuple. For example, the *Leadership* relation between "Nicolas Maduro" and "Venezuelan" is represented by "*Nicolas Maduro, Leadership, Venezuelan*" , and "guns" as the *ExplosiveDevice* argument of the *DetonateExplode* event is represented by "*DetonateExplode, ExplosiveDevice, guns*".

4.2 Knowledge Graph Encoder

Heterogeneous GNN: Given the heterogeneous nature of the cross-document KG, we adopt a heterogeneous GNN to encode the KG.

Formally, let $\mathcal{G}$ denote KG and $\mathcal{V}$ denote the nodes in $\mathcal{G}$. We use $\mathcal{R}$ to denote the 10 types of edges as discussed in the previous section, and for each edge type $r \in \mathcal{R}$, we use $\mathcal{G}_r$ to denote the subgraph of $\mathcal{G}$ that only contains edges of type r. At the l-th layer, the inputs are output features produced by the previous layer denoted as $\mathbf{h}_i^{(l-1)}, i \in \mathcal{V}$. For each edge type $r \in \mathcal{R}$, we apply a separate GNN to encode $\mathcal{G}_r$ and produce a set of features denoted as $\mathbf{h}_{i,r}^{(l)}$. Then, we aggregate the outputs for all edge types into the final output as follows:

$$\mathbf{h}_i^{(l)} = \sum_{r \in \mathcal{R}} \mathbf{h}_{i,r}^{(l)} / |\mathcal{R}| \tag{1}$$

For document-to-entity edges, document-to-event edges, and edges connecting event nodes to event cluster nodes, we use standard graph attention network (GAT). For relation edges and event argument edges, we apply edge-aware GAT to leverage the edge features. Here, the edge features refer to the BERT embeddings of text descriptions such as "*Nicolas Maduro, Leadership, Venezuelan*" or "*DetonateExplode, ExplosiveDevice, guns*" as described in Section 4.1. The remainder of Section 4.2 presents details of GAT and edge-aware GAT, i.e., how to produce $\mathbf{h}_{i,r}^{(l)}$ based on $\mathbf{h}_i^{(l-1)}$.

Graph attention network: For each given node, GAT aggregates the node features of its neighbors via attention mechanism (Velickovic et al., 2018). For a given edge type $r \in \mathcal{R}$, let $\mathcal{N}_{i,r}$ denote the neighbors of node i in $\mathcal{G}_r$. At the l-th layer, the attention weights α_{ij} are calculated as follows:

$$e_{ij} = \text{LeakyReLU}\left(\mathbf{a}^\top \left[\mathbf{W}\mathbf{h}_i^{(l-1)} \| \mathbf{W}\mathbf{h}_j^{(l-1)}\right]\right) \tag{2}$$

$$\alpha_{ij} = \text{softmax}_j(e_{ij}) = \frac{\exp(e_{ij})}{\sum_{k \in \mathcal{N}_{i,r}} \exp(e_{ik})} \tag{3}$$

where $\mathbf{a}$ and $\mathbf{W}$ are trainable parameters, and $\|$ denotes the feature concatenation. The output features $\mathbf{h}_{i,r}^{(l)}$ for node i in $\mathcal{G}_r$ are calculated as follows:

$$\mathbf{h}_{i,r}^{(l)} = \sum_{j \in \mathcal{N}_{i,r}} \alpha_{ij} \mathbf{W}\mathbf{h}_j^{(l-1)} \tag{4}$$

Edge-aware graph attention network: Edge-aware GAT is an extension of GAT that considers edge features in addition to node features (Huang et al., 2020; Yasunaga et al., 2021). Let $\mathbf{r}_{ij}$ denote the features of the edge between nodes i and j. For a given edge type $r \in \mathcal{R}$, at the l-th layer, the attention weights α_{ij} are computed as follows:

$$\mathbf{r}'_{ij} = \mathbf{W}^r \left[\mathbf{h}_i^{(l-1)} \| \mathbf{h}_j^{(l-1)} \| \mathbf{r}_{ij}\right] \tag{5}$$

$$\alpha_{ij} = \text{softmax}_j \left((\mathbf{W}^Q \mathbf{h}_i^{(l-1)})(\mathbf{W}^K \mathbf{r}'_{ij})^\top\right) \tag{6}$$

where $\mathbf{W}^r$, $\mathbf{W}^Q$ and $\mathbf{W}^K$ are trainable parameters. The output features $\mathbf{h}_{i,r}^{(l)}$ for node i in $\mathcal{G}_r$ are computed as follows:

$$\mathbf{h}_{i,r}^{(l)} = \sum_{j \in \mathcal{N}_{i,r}} \alpha_{ij} \mathbf{W}^V \mathbf{r}'_{ij} \tag{7}$$

where $\mathbf{W}^V$ is a learnable matrix.

4.3 Misinformation Detector

Using the previously described graph encoder, we are able to obtain representations of the document and event nodes. We conduct document-level detection using the document node representations, and event-level detection using the event node representations. We separately train two detectors for these two levels of tasks.

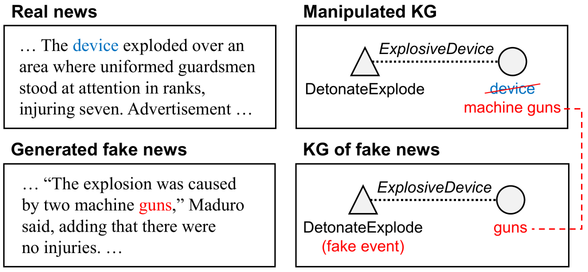
However, these two tasks are not mutually independent. Intuitively, document-level detection can benefit from the results of event-level detection, because the presence of a large number of false events indicates that the document is more likely to be fake. Therefore, we feed the results produced by a well-trained event-level detector into each layer of the document-level detector. Let $\mathbf{e}_i$ denote the representations of node i produced by the event-level detector. At the l-th layer of the document-level detector, instead of using the output features of the previous layer $\mathbf{h}_i^{(l-1)}$ as input features, we use a linear projection of the concatenation of $\mathbf{e}_i$ and $\mathbf{h}_i^{(l-1)}$ calculated as follows:

$$\mathbf{W}_{\text{proj}}^{(l)} \left[\mathbf{e}_i \| \mathbf{h}_i^{(l-1)}\right] \tag{8}$$

where $\mathbf{W}_{\text{proj}}^{(l)}$ is a learnable matrix.

5 Dataset Construction

Currently, there are no existing resources for cross-document misinformation detection. We propose to construct datasets based on real news datasets with clustering information. For each cluster, we randomly sample 50% real news and replace them with manipulated fake news. Figure 3 shows an



… The device exploded over an area where uniformed guardsmen stood at attention in ranks, injuring seven. Advertisement …

… "The explosion was caused by two machine guns," Maduro said, adding that there were no injuries. …

Figure 3: An overview of the fake news generation process. Based on the real news and its IE output, we select a high-frequency "*DetonateExplode*" event and replace its argument entity "device" with "machine guns". We then generate the fake news from the manipulated KG. In the KG of generated fake news, the manipulated entity "guns" is an argument of the "*DetonateExplode*" event, so we consider the event as fake.

overview of the fake news generation process, and more examples are presented in Appendix D.

Following Fung et al. (2021), we train a KG-to-text generator from the real news in our datasets, and generate fake news from manipulated KGs. The main differences between Fung et al. (2021)'s method and ours in terms of manipulating KG are: (1) we only conduct entity swapping, and do not adopt other types of manipulation including adding relations or events and subgraph replacement; (2) since we focus on events, we select entities to be replaced that are arguments of high-frequency events, instead of based on entity node degree; (3) we select entities from other documents in the same document cluster to replace the original entities, so that the entities before and after replacement are more similar.

We record the manipulation operations, and use a heuristic rule to obtain supervision for event-level detection as explained below. In a fake document, if an event involves manipulated entities as arguments, we consider this event as fake.

6 Experiments

6.1 Data

We constructed three new benchmark datasets based on three datasets that naturally have clusters of topically related documents. **IED** is a complex event corpus, where each complex event refers to a real-world story (e.g., Boston bombing) and is described by multiple documents (Li et al., 2021). Therefore, a complex event can be considered as a document cluster. **TL17** and **Crisis** are two timeline summarization datasets containing multiple news timelines. Each timeline contains multiple documents describing an evolving long-term event such as Influenza H1N1 and Egypt Revolution (Tran et al., 2013, 2015), and thus can be regarded as a document cluster. The detailed statistics of the original datasets are shown in Appendix A.

		# Cluster	**# Doc**	**# Fake event per doc (%)**
IED	**Train**	422	3865	3.99 (9.91%)
	Dev	140	1297	3.66 (9.14%)
	Test	140	1262	3.68 (9.51%)
TL17	**Train**	276	2610	2.97 (12.70%)
	Dev	92	879	2.69 (12.31%)
	Test	92	892	2.85 (12.13%)
Crisis	**Train**	1413	13337	4.54 (13.95%)
	Dev	177	1648	4.21 (13.29%)
	Test	177	1701	4.38 (13.80%)

Table 2: Statistics of the resulting datasets.

However, documents within the same cluster may not be closely related as the story described by a cluster can span up to three years. To obtain smaller and more closely related clusters, we split each timeline into smaller clusters of approximately size 10 based on publication dates[2]. Then, we employ the methods described in Section 5 to generate fake documents. The statistics of the constructed datasets are in Table 2.

6.2 Experimental Settings

For our proposed method, we use a 4-layered heterogeneous GAT and use `bert-base-uncased` to initialize the node and edge embeddings. For comparison, on the document-level detection task, we compare our method against two baselines: **HDSF** that models the inter-sentence dependency tree (Karimi and Tang, 2019), and **GROVER** (Zellers et al., 2019), a Transformer-based detector. On the event-level detection task, we compare our method against **random guessing**, **logistic regression** and **BERT**. For logistic regression, we use hand-crafted features to represent the event including the event type, the number of arguments, and the size of the event cluster. The detailed settings are presented in Appendix C.

For evaluation, we use F1 to evaluate document-level detection. Considering the label imbalance of event-level detection, we use F1 and the area under the ROC curve (AUC) to evaluate event-level

---

[2] For IED, we randomly split the clusters due to the lack of publication dates.

	IED	**TL17**	**Crisis**
HDSF	78.42	80.62	82.14
GROVER-medium	79.06	79.40	86.84
GROVER-mega	82.90	90.00	87.13
Ours	**86.76**	**90.21**	**93.89**

Table 3: F1 results (in %) of document-level detection. We report the F1 scores of HDSF (Karimi and Tang, 2019), GROVER of two settings (Zellers et al., 2019), and our proposed method.

Cross-document event coreference	Event-level detection results	**IED**	**TL17**	**Crisis**
✗	✗	80.59	86.55	93.64
✓	✗	84.57	88.99	93.67
✓	Random	83.63	84.86	92.18
✓	✓	**86.76**	**90.21**	**93.89**

Table 4: F1 results (in %) of ablation study over document-level detection. We analyze the use of cross-document event coreference resolution and event-level detection results. We further experiment with random features for event-level detection results. Results of our full method are presented in the last row.

detection. For the F1 metric, we select the optimal threshold on the validation set.

6.3 Document-level Detection Results

Table 3 shows the results of document-level detection. Our method yields consistent improvements on all three datasets and significantly outperforms the baselines that judge the authenticity for each document in isolation. To understand the effectiveness of each component, we conducted an ablation study and show the results in Table 4. We have the following findings:

(1) We remove the edges between event nodes and event center nodes to analyze the impact of cross-document event coreference resolution, and find that such information significantly improves the performance on IED and TL17. We also train our detector with smaller clusters on TL17 and get worse performance (84.53% and 87.37% on clusters with size 1 and 2 respectively), which verifies that our model benefits from more cross-document information. The benefit of cross-document event coreference resolution is less significant on the large-scale Crisis dataset containing $1.7k$ documents. This may imply that cross-document misinformation detection is more useful for emerging new events where large-scale training data is not available.

(2) Using the event-level detection results consistently improves the performance by 1-3 points on all datasets. Since the projection modules introduce additional parameters, we further train a detector utilizing random features and find that using random features reduces the performance. This verifies that the improvement is brought by utilizing the knowledge learnt by the event-level detector rather than additional parameters.

	IED		**TL17**		**Crisis**	
	F1	AUC	F1	AUC	F1	AUC
Random	16.31	50.44	19.44	49.65	21.70	50.41
LR	31.26	77.87	29.14	68.19	31.67	68.17
BERT	26.43	71.12	31.95	71.42	33.89	71.86
Ours	44.86	**88.46**	**41.56**	**82.59**	**48.48**	**85.60**
Ours$^{\text{(ABLATION)}}$	**45.00**	**88.54**	**41.66**	82.28	47.78	85.17

Table 5: Results (in %) of event-level detection. We report the F1 and AUC scores of random guessing (Random), logistic regression (LR), BERT, and our method. We further conduct an ablation study and report the results of our method without cross-document event coreference information, denoted as Ours$^{\text{(ABLATION)}}$.

6.4 Event-level Detection Results

We track the manipulation operations during the dataset construction process, which allows us to obtain supervision for event-level detection. The results are shown in Table 5. We compare our method with random guessing, logistic regression with hand-crafted event features, and BERT. We find that random guessing performs the worst, logistic regression and BERT achieve satisfactory performance, and our method significantly outperforms all baselines by a large margin. As in document-level detection, we conduct an ablation study on the use of cross-document event coreference resolution by removing edges between event nodes and event cluster nodes, and find that such information brings slight improvements in the AUC metric.

6.5 Analysis and Discussion

To demonstrate the benefits of using cross-document event coreference resolution, we show an example in Figure 4, with 4 documents from the same cluster. As shown in Figure 4, by performing cross-document reasoning on events in the same event cluster, our model achieves better performance compared to Ours$^{\text{(ABLATION)}}$, i.e., our model without edges between event nodes and event cluster nodes.

We further analyze the remaining errors in our model. Figure 5 shows two representative cases

Figure 4: An example of four documents from the same cluster in the IED dataset. **Event triggers** are bolded and marked in gold, and fake information is marked in red. The tables report the detection results of our model with and without cross-document event coreference resolution, denoted by "Ours" and "Ours$^{\text{(ABLATION)}}$" respectively, and better results are bolded. The use of cross-document event coreference resolution significantly enhances both levels of detection, especially for detecting fake news 1.

where both document-level and event-level detectors fail to detect misinformation. In the first example, the manipulated entity is not captured by the IE system, and the error of IE system is propagated into the detector. A potential solution is to use an OpenIE system (Stanovsky et al., 2018) that is able to cover more event and entity types. The second example is a more challenging case where the event containing fake information is not mentioned in any other document. This makes it difficult to either verify or disprove via cross-document reasoning, and may require the detector to actively search for external information related to the event.

There are some remaining challenges and limitations in our proposed methodology. First, some cross-document contradictions are difficult to capture by coreference resolution only. In the example in Figure 1, knowing that the police are unlikely to help and attack Boyland at the same time requires commonsense reasoning, which we leave as our future work. Second, an underlying assumption of our framework is that real news articles are consistent and complementary with each other, while fake news often contradicts each other. This assumption is true for our constructed datasets because we manipulate the KGs via random entity swapping. However, certain types of human-written fake news documents, such as conspiracy theories, tend to be closely related to each other and convey highly similar information because they share the same biases or aim to manipulate readers in the same way. This may limit the performance of our proposed system in real-world scenarios.

Text	KG	Prediction
…Smoke is seen following a fire at an oil processing facility in Abqaiq City, Saudi Arabia, following an **attack** on Saudi Aramco's Abaqaiq facility on September 14, 2019. …		p(doc is fake) $= 0.2639$ p(event is fake) $= 0.3573$
…Prime Minister Atal Bihari Vajpayee, during a **visit** to Mumbai, ordered the Indian consulate to be put on high alert and the police to beef up security at all Indian diplomatic missions in Mumbai. …		p(doc is fake) $= 0.2169$ p(event is fake) $= 0.0716$

Figure 5: Two examples where our detector fails to detect the fake information. **Event triggers** are bolded and marked in gold, and fake information is marked in red. In the first example, the fake event argument Abqaiq City is not captured by the IE system and thus cannot be detected. In the second example, the visit of Vajpayee to Mumbai is fake information but not mentioned by any other documents, and no coreference is detected for the *Transportation* event. Therefore, our detector does not have enough information to detect the fake information.

6.6 Human Evaluation on Fake News Generation

To evaluate the quality of the generated fake news, we conducted a Turing Test by 13 human readers as in Fung et al. (2021). We randomly select 100 documents from the IED dataset, half real and half fake, and ask the human readers to assess the authenticity for each document. The overall accuracy achieved by human readers is 66.88%, with 77.44% accuracy on real documents but only 56.32% accuracy on fake documents. This shows that it is difficult for human readers to detect the generated fake news.

7 Conclusions and Future Work

We are the first to study the new task of cross-document misinformation detection. We conduct the task at two levels, document level and the more fine-grained event level, and construct three new datasets to handle the lack of training data. We further propose a graph-based cross-document detector that conducts reasoning over a cross-document knowledge graph and feed the event-level detection results into document-level detector. The experimental results show that our proposed method significantly outperforms existing methods.

For future work, we intend to extend our method to conduct cross-document reasoning over more types of information (e.g., entities and relations) in addition to events. We also plan to extend our method to multi-media news including texts, images, audios and videos, which requires the construction of cross-document multi-modal knowledge graphs. Finally, a challenging but important task is to construct a large-scale fake news detection corpus with human-written fake news containing document clusters and study our method in this scenario.

8 Ethical Considerations

The goal of this work is to advance state-of-the-art research in the field of misinformation detection by analyzing multiple documents on the same topic. We build new benchmark datasets using a fake news generator, and propose a detector that achieves high performance in such scenarios. We have released the constructed datasets and detector codes in this submission as a useful reference for future research. We hope that our work will encourage more efforts in this direction and benefit the community.

However, as with any work that utilizes text generation, our work involves the risk of being applied to produce false information to mislead or manipulate readers. Therefore, we promise not to share codes or checkpoints of our generator to avoid potential negative consequences. To improve reproducibility, we describe the general idea and a few crucial details of the fake news generator.

A Statistics of Original Datasets

Statistics of the original IED, TL17 and Crisis dataset are presented in Table 6.

	# Cluster	**# Doc**	**# Doc per cluster**
IED	433	7403	17
TL17	17	4650	273
Crisis	4	20463	5116

Table 6: Statistics of the original datasets.

B Method Details

B.1 Information Extraction

We use **OneIE** (Lin et al., 2020), a BERT-based end-to-end IE system to extract entities, relations, and events. OneIE conducts IE in four steps: (1) encode a sentence with a pre-trained BERT encoder, (2) identify entity mentions and event triggers using a conditional random fields layer, (3) classify types of entity mentions, events, entity relations, and event arguments using feed-forward networks, and (4) search for a globally optimal IE graph via beam search. In this work, we use the model released by Wen et al. (2021). The model achieves 64.1, 49.7, and 49.5 F1 on trigger extraction, argument extraction and relation extraction respectively on ACE 2005 and ERE (Song et al., 2015).

In addition, we use entity linking and entity coreference resolution to identify coreferential entity mentions. For **entity linking**, we use an LSTM-based entity linker to link (Pan et al., 2017) to link entity mentions to WikiData entries. The entity linker achieves 91.8 F1 and 84.3 accuracy. For **entity coreference resolution**, we use an extension of the e2e-coref model (Lee et al., 2017) based on XLM-RoBERTa (Conneau et al., 2020). The model is released by Wen et al. (2021) and achieves a 92.4 CoNLL score on OntoNotes (Pradhan et al., 2012). Eventually, entity mentions that are linked to the same WikiData entry or identified as coreferences will be considered as the same entity, and their entity nodes in the KG will be merged.

B.2 Event Coreference Resolution

For event coreference resolution, we use Lai et al. (2021), a within-document coreference resolution model. We extend it to the cross-document scenario following Wen et al. (2021). Given a cluster containing N documents, we concatenate each pair of documents into a "mega-document". The model then conducts coreference resolution on each mega-document. More specifically, for each event mention, the model uses SpanBERT (Joshi et al., 2020) to extract contextualized text embeddings and builds manually designed symbolic features such as event types, attributes, and arguments. Then, the two features are combined selectively using a gated mechanism. Eventually, for each pair of event mentions in a mega-document, the model predicts whether they are coreferential. In this work, we use the model released by Wen et al. (2021). The model achieves 84.8 CoNLL score on ACE 2005.

B.3 KG-to-Text Generator

We train the KG-to-text generator by following Fung et al. (2021).

We first linearize the IE-based KG. For example, the *Leadership* relation between "Nicolas Maduro" and "Venezuelan" is represented by "*Nicolas Maduro, Leadership, Venezuelan*", and the *DetonateExplode* event with "drone" as *ExplosiveDevice* argument and "flat" as *Place* argument is represented by "*[DetonateExplode | ExplosiveDevice = drone, Place = flat]*". We represent the entire KG in graph by concatenating the text representations of all relations and events.

Since generating the entire document is very challenging, we fine-tune a sentence-level KG-to-text generator from BART (Lewis et al., 2020). The generator takes the linearized KG and the previous sentence as input and generates the next sentence. Here, the KG only contains information presented in the sentence rather than in the entire document. During inference, the generator generates the entire document sentence-by-sentence in an autoregressive manner.

C Experiment Details

Detailed settings of our method: For our proposed method, we use a 4-layered heterogeneous GNN, where each GAT layer contains 8 heads. To initialize the node and edge embeddings, we use `bert-base-uncased` model with the feature dimension of 768. Our model contains 233M parameters.

For hyperparameters, we use a batch size of 16, and search the learning rate from $\{10^{-3}, 10^{-4}, 10^{-5}\}$ and the number of layers within $\{2, 4, 8\}$. Our best-found hyperparameters are a learning rate of 10^{-5} and a number of layers of 4. We train our model with Adam optimizer until convergence. To reduce computation cost, we freeze BERT's parameters. The training process takes approximately 6 hours on a Tesla P100 GPU.

Detailed settings of KG-to-text generator: We fine-tune the model from `bart-large` model containing 24 layers, 1024 hidden dimensions, 16 heads, and 406M parameters. on the three datasets respectively. We train the model on a Tesla P100 GPU using the batch size of 1024 tokens, the gradient accumulation step of 16, the learning rate of 3×10^{-5}, the warmup steps of 500 steps, and the total training steps of 12000.

Document-level baselines: For document-level detection, we compare our method against two baselines: HDSF that models inter-sentence dependency tree (Karimi and Tang, 2019), and GROVER (Zellers et al., 2019), a Transformer-based detector. For HDSF, we use the implementation at `https://github.com/hamidkarimi/HDSF/`. We train the model on our datasets using their default hyper-parameters. For GROVER, we use the implementation at `https://github.com/rowanz/grover` and experiment with two settings, medium setting and mega setting. Since fine-tuning the GROVER model is computationally expensive, we use GROVER in the zero-shot setting.

Event-level baselines: For event-level detection, since there are no existing methods, we use three baselines, random guessing, logistic regression, and BERT. In random guessing, for each event, we randomly draw a value from a uniform distribution between $[0, 1]$ as the probability that the event is false. In logistic regression, we use the following features: event type (represented by one-hot feature), number of arguments, and the size of the event cluster that the given event belongs to. The features are normalized on the training set. We use the implementation of logistic regression and default parameters provided by `sklearn`. In the BERT baseline, we use the same BERT-based event features as our method, and replace the 4-layer GNN in our model with a feed-forward network. We use the same hyper-parameters to train the model.

D Examples of Fake News Generation

We present two examples of generated fake news in Figure 6 and 7, including the original real news, manipulated KG, and generated fake news. The generated fake news conveys the manipulated misinformation and meanwhile is stylistically similar to real news.

E Scientific Artifacts

In this work, we use three datasets including IED (Li et al., 2021), TL17 (Tran et al., 2013) and Crisis (Tran et al., 2015). There are no licenses or terms of use associated with all three datasets.

We use five software. Among them, HDSF (Karimi and Tang, 2019), OneIE (Lin et al., 2020) and RESIN (Wen et al., 2021) have no license or terms of use. GROVER (Zellers et al., 2019) and huggingface are licensed under the Apache License 2.0. Fairseq (Ott et al., 2019) is licenced under the MIT License.

We use two models, BERT (Devlin et al., 2019) and BART (Lewis et al., 2020), licenced under the Apache License 2.0 and the MIT License respectively.

In summary, all artifacts involved either have no associated licenses or terms of use, or are licensed under the Apache License 2.0 or the MIT License. Both the Apache License 2.0 or the MIT License permit commercial and private use. Therefore, our use is consistent with their intended use. We will release the datasets and software with licenses compatible with the original access conditions.

Real News

Amia bombing: Argentina and Iran agree truth commission Published duration 28 January 2013. image caption The two foreign ministers signed the agreement in Addis Ababa on Sunday. Argentina and Iran are to jointly set up a commission to investigate the 1994 bombing of the Israeli-Argentine Mutual Association (Amia) Jewish community centre in Buenos Aires. The commission will be made up of five independent judges, none of whom will be from either Argentina or Iran. Argentine courts have blamed Iran for the attack, which killed 85 people. Iran has always denied any involvement. Israel's foreign ministry said it was "surprised" by news of the commission. Spokesman Yigal Palmor told the AFP news agency that it was waiting "to receive full details" from Argentina. Amia and another key Argentina Jewish organisation were meanwhile reported to be vehemently opposed to the move. High-profile suspect. Iran agreed last July to co-operate with Argentina in the investigation, which it said "was going down the wrong way". Such negotiations have alarmed Israel's government and Argentina's sizeable Jewish community, who fear Argentina is weakening in its resolve to put suspects on trial. "We warned the Argentines from the start that the Iranians would try to set a trap for them and that they should beware," Mr Palmor was quoted by AFP as saying on Monday. The news agency also quoted a joint statement by Amia and the Delegation of Israelite Argentine Associations as saying that the new move would "imply a decline in our sovereignty". image caption The seven-storey Amia building was destroyed in the attack on 18 July 1994. "To ignore everything that Argentine justice has done and to replace it with a commission that, in the best of cases, will issue, without any defined deadline, a 'recommendation' to the parties constitutes, without doubt, a reversal in the common objective of obtaining justice," the statement said. However, Argentine President Cristina Fernandez de Kirchner called the agreement "historic". "It guarantees the right to due process of law, a fundamental principle of international criminal law," Ms Fernandez said. She said Argentine Foreign Minister Hector Timerman and his Iranian counterpart had signed a memorandum of understanding on the sidelines of an African Union summit in Addis Ababa, in Ethiopia. It still has to be ratified by the parliaments of both countries. The commission would "analyse all the documentation presented to date by the judicial authorities of Argentina and Iran", Ms Fernandez wrote on her Twitter account. According to Mr Timerman, the agreement will make it possible for Argentine legal officials to question Iranian suspects in Tehran. Among the suspects named by Argentine prosecutors when they made their case in 2007 is Iran's current Defence Minister, Gen Ahmed Vahidi. At the time of the attack, Gen Vahidi was the commander of a special unit of Iran's Revolutionary Guards. Argentine prosecutors said Iran planned and financed the attack, and that the Lebanese militant group Hezbollah carried it out.

Generated Fake News

Israel's foreign ministry said in a statement that it was "shocked and saddened" by the news. The foreign ministers met in Addis Ababa on Tuesday to discuss the two countries' efforts to promote peace in the Horn of Africa. Argentina and Ethiopia have been close allies in the fight against terrorism since the 1994 bombing of a Jewish community centre in Buenos Aires that left 85 people dead. The commission's judges, none of whom are from Argentina or Iran, were appointed by President Cristina Fernández de Kirchner, who has close ties with Iran. Argentine courts have blamed Kenya for the attack, which killed 85 people, but it has been blamed on Iran. Another bombing in Bolivia, in 1994, was also blamed on Iran, but that has not been proven. Argentina's main Jewish organisation, the Argentina-based Jewish Organisation of Argentina, said it was convinced that Iran was behind the attack. The Jewish community in Argentina has long accused the government of Israel of not doing enough to bring the suspects to trial, and of obstructing efforts to bring them to justice. In an interview with AFP, Palmor said: "We've been asking the Iranians and the Argentines for a long time to do something. We're still waiting for the Iranians to acknowledge that the Amia building was attacked and to take responsibility for it." Argentine President Cristina Fernandez de Kirchner, who was in office from 2007 to 2015, has accused Iran of being behind the attack, but Tehran has repeatedly denied any involvement. Argentine Foreign Minister Hector Timerman, on his way to an African Union summit in Addis Ababa, Ethiopia, spoke with his Iranian counterpart, Mohammad Javad Zarif, by phone on Monday, according to a statement released by the Iranian Foreign Ministry. Timerman "expressed Argentina's solidarity with the African Union," the statement said. Iran's Foreign Minister said Iran "condemns in the strongest terms" the decision by Argentine prosecutors to issue an arrest warrant for former intelligence chief Ahmad Vahidi in connection with a case that Argentine prosecutors have been investigating for years. "We call on the authorities of Iran and Argentina to immediately comply with the decision of the judicial authorities of both countries," Mohammad Javad Zarif said in a statement. Argentine officials met with the Iranian suspects in Tehran last month, and Argentine officials said they had "sufficient evidence" to proceed with the extradition. Both countries' parliaments have to approve the extradition, which is expected to happen in the coming weeks. Vahidi, the commander of an elite unit of Iran's Revolutionary Guards known as the Quds Force, is believed to have masterminded the attack, which Vahidi said was carried out with the help of a "cousin," Maj. Gen. Mohammad Ali Jafari. Argentine prosecutors have said that Iran paid more than $400 million for the attack, a claim that Iran has repeatedly denied.

KG manipulation

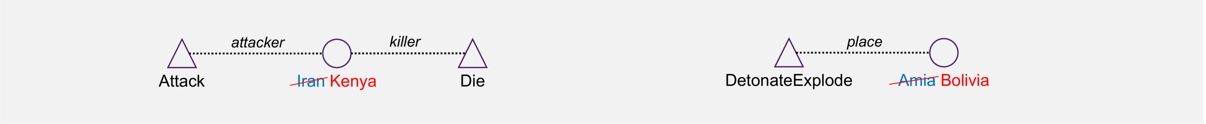

Figure 6: An example of generated fake news, including the original real news, manipulated KG, and generated fake news. Real and fake information are marked in blue and red respectively. To save space, we only show some parts of the KG that are manipulated.

Real News

An IRA member who was part of the group behind the Birmingham pub bombings has apologised. Michael Christopher Hayes – a self-confessed bomb maker – said he was sorry for the killing of innocent people in the 1974 blasts. Speaking to the BBC, Mr Hayes said he hoped his apology on behalf of all active republicans will help grieving relatives find "closure". He said: "My apologies and my heartfelt sympathies to all of you, for the terrible, tragic loss that you've been put through. And all these years you've been trying to find closure. I hope at last God will be merciful and bring you closure. "And I apologise not only for myself ... I apologise for all active republicans who had no intention of hurting anybody and sympathise with you." An eight-minute delay before police were warned of the bombs' location led to the death of 21 people and the injury of 182 others, when they exploded in a pair of city centre pubs. Mr Hayes said the bombs had not been intended to kill people. On the evening of the 21 November 1974, a man with an Irish accent called the Birmingham Post and Evening Mail newspapers to say two bombs were planted in the town centre. He finished the call by giving the official code used by the Provisional IRA to authenticate a warning call and allow civilians to be evacuated. Former IRA officials have since said there was an unintentional delay in issuing the warning. Mr Hayes said the IRA unit in Birmingham had been shocked by the death toll. "That wasn't meant. It wouldn't have been done if that was the case," he said. The wreckage left at the Mulberry Bush pub in Birmingham after a bomb exploded on 21 November 1974 (PA) The Birmingham pub bombings caused the worst single losses of life in the Troubles. Six men were wrongfully convicted for the blasts but no-one has ever been brought to justice. Mr Hayes, 69, who now lives in south Dublin, said he personally defused a third bomb on Birmingham's Hagley Road after he became aware of the death toll in the first two blasts. He refused to say who planted the bombs in the Mulberry Bush and the Tavern in the Town but he said he wanted to speak out to give "the point of view of a participant". But relatives of those who were killed said the apology was "gutless and spineless". Mr Hayes' apology came as an inquest into the bombings was reopened by a coroner stating "a wealth of evidence" had not yet been heard. West Midland Police said their investigation remained open but that no further comments on the suspects' identities will be provided until the proceedings have concluded. Victims' families have repeatedly asked for the names of the suspects to be disclosed. Mr Hayes was arrested and questioned by West Midlands Police about the bombings in 1974 but he was released. He said he had been a member of the IRA for more than 30 years in both Ireland and England and had participated in the group's activities in Birmingham as "an active volunteer". AFP via Getty UK news: Benita Stipp (centre) and Mimi Ferguson (left) react as students at Norwich School receive their A-Level results. PA UK news: A train derailment near Stonehaven has left three people dead.

Generated Fake News

A man with an Irish accent made a telephone call to the Birmingham Post and Evening Mail, claiming to be from the town centre and claiming to have information about the whereabouts of an Irish Republican Army (IRA) bomb which had been planted in the town. The caller claimed that the bomb had been intended to cause an explosion which would have killed all the "scrubbers". A niece was killed and nine others were injured when they were caught up in the bombs which exploded in the two pubs. The Birmingham pub bombings were believed to have been carried out by a member of the IRA's Provisional IRA group. Image copyright Getty Images Image caption Twenty-one people were killed. Only two men have been convicted of the bombing, but no - one has been brought to justice. It has been suggested that IRA officials may have been involved in the planning of the atrocity, but this has been denied. It has been suggested that the IRA unit responsible for the Birmingham killings may have been involved in the planning and execution. The relatives of those killed have been campaigning for a full public inquiry into the killings for more than 20 years. Image copyright Pacemaker Image caption The death toll from the County Antrim pub bombings was the highest in a single day in the Troubles. In a statement, he said: "It is not known who planted the bombs in the Mulberry Bush and the Tavern in the Town but it is clear who placed the bombs at the Tavern. "It is known that Mr Hayes, who was living in south Dublin at the time, defused a bomb in Birmingham's Hagley Road the day before he carried out the Mulberry Bush bombing but it is not known if he was involved in the Tavern in the Town explosion." A number of civilians were evacuated from the scene. Victims' families have expressed their shock and grief. Image copyright Getty Images Image caption The attack has been described as a "heinous act of terrorism" Image copyright Getty Images Image caption Corporation Street in Birmingham was the scene of one of the Birmingham bomb attacks in 1974. In County Antrim, Benita Stipp and Mimi Ferguson, who were students at the time of the bombing, were the two people who died in the blast, as were two other students. The attack was condemned by the Irish Republican Army (IRA) and Sinn Féin. During his time at Elvington Airfield, near York, York, in the UK, Carl Thomas had been involved in the construction of a radar station, which was to be used by the Royal Ulster Constabulary (RUC) and the British Army. The pair, who were born and raised in the UK but grew up in the mountains of the north-west of England, were home-schooled students who had studied in Belgium before going to the Department for Education in London, but after finishing their studies in the Albanian mountains, the pair returned to their home country to work as teaching candidates in the Department of Education in the country, and to work with their teachers. After the attack, James Boyle was arrested by West Midlands Police but he was released after being questioned by the police and released on bail, and was due to appear before a judge on Monday. Police believe he was a member of the IRA in Ireland and in England, and that he was based in Birmingham, but that he had been active in the IRA both in England and in Ireland. 2 of the 3 men convicted of the bombings have been released on appeal. They had their convictions quashed on appeal after serving 16 years in prison and their trial was heard by the Court of Appeal. They were released on compassionate grounds after a judge ruled that they had suffered a miscarriage of justice.

Abstract

Action in video usually involves the interaction of human with objects. Action labels are typically composed of various combinations of verbs and nouns, but we may not have training data for all possible combinations. In this paper, we aim to improve the generalization ability of the compositional action recognition model to novel verbs or novel nouns that are unseen during training time, by leveraging the power of knowledge graphs. Previous work utilizes verb-noun compositional action nodes in the knowledge graph, making it inefficient to scale since the number of compositional action nodes grows quadratically with respect to the number of verbs and nouns. To address this issue, we propose our approach: Disentangled Action Recognition with Knowledge-bases (DARK), which leverages the inherent compositionality of actions. DARK trains a factorized model by first extracting disentangled feature representations for verbs and nouns, and then predicting classification weights using relations in external knowledge graphs. The type constraint between verb and noun is extracted from external knowledge bases and finally applied when composing actions. DARK has better scalability in the number of objects and verbs, and achieves state-of-the-art performance on the Charades dataset. We further propose a new benchmark split based on the Epic-kitchen dataset which is an order of magnitude bigger in the numbers of classes and samples, and benchmark various models on this benchmark.

1 Introduction

Understanding human-object interaction is crucial for modeling human behavior, and plays a key role in developing robotic agents that interact with humans. In videos, many of these interactions can be described using the combination of verbs and nouns, e.g, *move chair*, *peel apple*. Recently researchers have been focusing on the task of compositional action recognition with the goal of recognizing actions represented by such verb-noun pairs. The key challenge comes from the extremely large label space of various combinations. The number of possible verb-noun pairs grows quadratically with respect to the number of verbs and nouns. It is infeasible to collect training data for all possible actions. This motivates us to study the problem of zero-shot compositional action recognition, which aims to predict action with components beyond the vocabularies in train data.

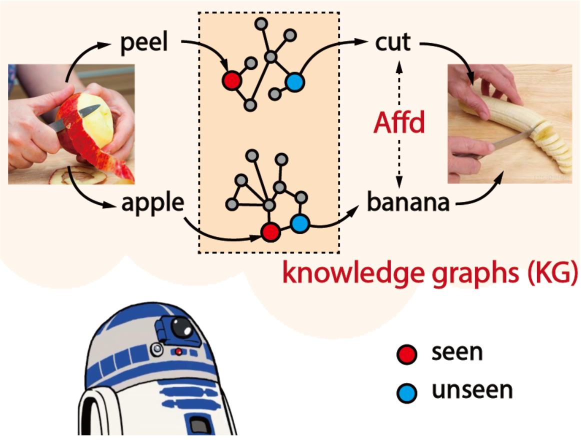

Figure 1: DARK extracts disentangled features of verbs/nouns and leverages knowledge graphs (KG) to generate classifiers for unseen verbs and nouns. Predictions are then composed under constraints of object affordance priors (Affd) from knowledge bases (e.g. *banana can be cut*).

To conduct zero-shot learning, we propose our Disentangled Action Recognition with Knowledge-bases (DARK), which leverages knowledge graphs. A knowledge graph (KG) encodes semantic relationships between verb or noun nodes. We apply graph convolutional network (GCN) on KG to predict classifier weights for unseen nodes in graphs.

July 10-15, 2022

Previous work (Kato et al., 2018) has explored using knowledge graphs for zero-shot compositional action learning. However, their model builds a graph containing verb, noun and compositional action nodes (which link verbs and nouns). It learns features of novel action nodes by propagating information from connected verb/noun nodes. The number of compositional action nodes during training is in the order of $\mathcal{O}(n^2)$, and the memory consumption may become prohibitively expensive as we scale this approach to large vocabularies. To overcome this issue, we propose to learn separate classifiers for verbs and nouns, which scales linearly with respect to the vocabulary size.

Specifically, DARK extracts verb and noun features separately, and relies on separate verb and noun knowledge graphs to predict unseen concepts before composing the action label. Activity recognition is particularly well-suited for such a factorized approach, because nouns may be better captured using object detection-based approaches and verbs may be represented by motion. Compared to prior work (Kato et al., 2018; Zhukov et al., 2019) that use the same feature representation for both verb and noun, our separate features model noun and verb more precisely. In addition, we adopt disentanglement between the learned verb and noun features, so they compose more readily and improve generalization on unseen actions.

Though scalability is achieved using our factorized approach, verbs and nouns are actually not fully independent. For instance, the process of $sanding$ an object and $scrubbing$ an object are visually similar, however you are more likely to be $scrubbing$ a car than $sanding$ it. Prior work (Kato et al., 2018) models the verb-noun relationships by constructing quadratic compositional action nodes. In our model, when composing action labels, we take object affordances (Gibson, 1978), namely the commonsense relationship of verbs and nouns, into consideration. We extract affordance knowledge from a caption corpus and build a scoring component to consider the relationship between verbs and nouns, to further improve the generalization ability. The basic idea of our proposed model is illustrated in Figure 1.

Furthermore, we investigate the evaluation of zero-shot compositional action recognition task and identify the drawback of existing metrics. With N_v verbs, N_n nouns, it constructs a $N_v \times N_n$ label space for possible actions. Among these actions, some are $invalid$ (e.g. $peel\ a\ car$) and some are $valid\ but\ not\ presented$ in the dataset. In real-world applications, the model would need to make predictions in the whole $N_v \times N_n$ label space. But current evaluation protocols, implicitly or explicitly, only evaluate on compositional classes that are $valid\ and\ presented$ in the dataset, which does not reflect the real difficulty of this task. We propose a new setting, where predictions are made and evaluated in the full $N_v \times N_n$ label space.

The Charades (Sigurdsson et al., 2016) dataset is relatively small scale for testing zero-shot compositional action recognition (Kato et al., 2018). To promote further research, we propose a new benchmark based on the Epic-kitchen (Damen et al., 2018, 2020) dataset, which is an order of magnitude bigger both in number of classes and sample size. The key contributions of our paper are:

1. We propose a novel factorized model that learns disentangled representation separately for verbs and nouns, facilitating scalability.
2. We further improve the model's generalization performance by learning the interaction constraints between verbs and nouns (affordance priors) from an external corpus.
3. We propose a new evaluation protocol for zero-shot compositional learnings, which better reflects the real-world application setting.
4. We propose a new large-scale benchmark based on the Epic-Kitchen dataset and achieve state-of-the-art results.

2 Related Work

Zero-shot learning with knowledge graphs: Zero-shot learning has been widely studied in computer vision (Akata et al., 2015; Lampert et al., 2013; Lee et al., 2018; Sahu et al., 2020; Wang et al., 2019; Xian et al., 2018). We will focus on related work relevant to our approach. (Wang et al., 2018) proposes to distill both the implicit knowledge representations (e.g., word embedding) and explicit relationships (e.g., knowledge graph) to learn a visual classifier for new classes through GCN (Kipf and Welling, 2016). (Kampffmeyer et al., 2019) later proposes to augment the knowledge graph (KG) with dense connections which directly connects multi-hop relationship and distinguishes between parent and children nodes. The graph learning of our model mostly follows their work. Recently there have been improvements on GCN models. (Nayak and Bach, 2020) designs a novel transformer GCN to learn representations based on common-sense KGs. (Geng et al., 2020b) uses an attentive GCN together with an explanation generator to conduct explainable zero-shot learning. Instead of generating classifier for unseen classes directly, (Geng et al., 2020a) uses a generative adversarial network to synthesize features for unseen classes to conduct classification. These directions could be potentially explored in our problem setting to further improve performance. (Gao et al., 2019) conducts zero-shot action recognition based on KGs, but unlike our problem setting, their verb-noun relationship is not compositional and objects are used as attributes to infer action.

Compositional action recognition: Many prior works aim to understand actions through interaction with objects. (Wang et al., 2020; Xu et al., 2019) tackle zero-shot human-object interaction in images. (Zhukov et al., 2019) conduct weakly-supervised action recognition, leveraging compositionality of verb-noun pairs to decompose tasks into a set of verb/noun classifiers. This shares certain similarities with our factorized model, but it is not a zero-shot setting, nor does it enforce feature disentanglement. (Materzynska et al., 2020) conduct zero-shot compositional action recognition, where individual verb/noun concepts have been seen during training but not in the same interaction with each other. Although it cannot deal with unseen verbs or nouns, using object detector to explicitly model object features inspires our approach. One of the closest works to our proposed approach is (Kato et al., 2018). It constructs a KG that contains verb nodes, noun nodes and compositional action nodes, and learns the feature representation for each action node to match visual features. Novel actions' features are inferred jointly during training through GCN. The number of action nodes grows quadratically with respect to the number of nouns or verbs, which makes this approach difficult to scale, especially considering that GCN's forward pass needs to learn all features simultaneously.

3 Method

We propose DARK – Disentangled Action Recognition with Knowledge-bases (Figure 2). It extracts disentangled feature representations for verbs and nouns, then predicts classifier weights for unseen components using knowledge graphs, and composes them under object affordance priors.

3.1 Factorized verb-noun classifier

Given a video X, we first use a verb feature extractor $\mathcal{F}_v$ to extract verb feature, and a noun feature extractor $\mathcal{F}_n$ for noun feature. Subsequently, we learn one-layer predictors $\mathcal{W}_v^{seen}$ and $\mathcal{W}_n^{seen}$ for predicting the final verb/noun class. $\mathcal{F}_v$, $\mathcal{F}_n$ and $\mathcal{W}_v^{seen}$, $\mathcal{W}_n^{seen}$ are trained via cross entropy (CE) losses $\mathcal{L}_{cls}^v$ and $\mathcal{L}_{cls}^n$ with verb / noun labels y_v, y_n.

$$\mathcal{L}_{cls}^v = \mathbf{CE}(\mathcal{F}_v; \mathcal{W}_v^{seen}; y_v) \tag{1}$$

$$\mathcal{L}_{cls}^n = \mathbf{CE}(\mathcal{F}_n; \mathcal{W}_n^{seen}; y_n) \tag{2}$$

We extract disentangled features for verbs and nouns, so that verbs and nouns can be treated as separate entities. If verb features contain much information about nouns, it would overfit to seen actions and would not generalize to unseen compositions. Standard networks like Inception3D (I3D) (Carreira and Zisserman, 2017) can rely on scene or object information to predict verbs (Battaglia et al., 2018; Materzynska et al., 2020). To decouple verb's representation from noun's, we add explicit regularization to the model input. We first used an off-the-shelf class-agnostic object detector to detect the bounding box of interacting objects. Then, we crop the object from videos and use I3D backbone to extract verb features from the cropped videos. (Yun et al., 2019; DeVries and Taylor, 2017; Choi et al., 2019; Singh and Lee, 2017) use similar cropping technique to remove bias in other tasks. We also detect hand masks and add hand regions separately to the verb input because the class-agnostic detector tends to crop out the hands as well. Adding hand gesture information back provides hints for verbs. Disentanglement method on Charades dataset (Sigurdsson et al., 2016) is different as it contains third-person view videos, and relevant details are discussed in Section 4.5.

3.2 GCN for learning novel concept

After training on seen concepts, we can infer the classifier for unseen ones. In this subsection, we drop the subscript v/n as the same process applies for both verb and noun. After learning feature extractor $\mathcal{F}$ and classifier of seen concept $\mathcal{W}^{seen}$, learning classifier for unseen concepts is equivalent to learning the weight $\mathcal{W}^{unseen}$. This step leverages graph convolution network (GCN) following previous work (Kampffmeyer et al., 2019; Kato

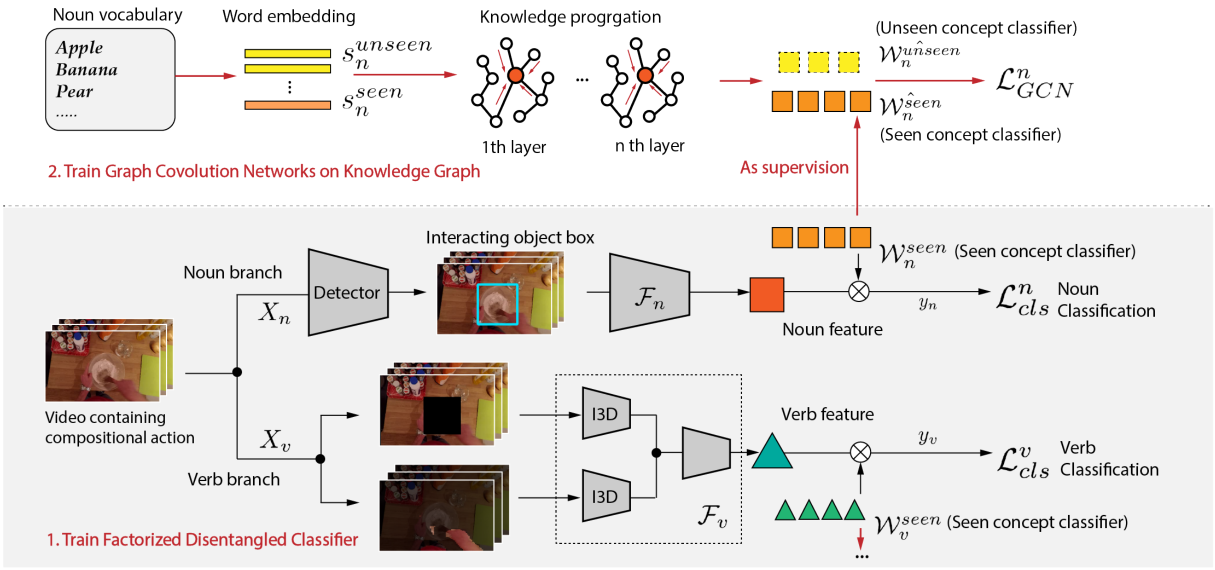

Figure 2: Overall training process. We first jointly train factorized disentangled feature extractor $\mathcal{F}_v$, $\mathcal{F}_n$, and classifier weights for seen class $\mathcal{W}_n^{seen}$, $\mathcal{W}_v^{seen}$. We then take word embedding s_{seen}, s_{unseen} as input, and use GCN to predict classifier weights of unseen class $\hat{\mathcal{W}}_n^{unseen}$, $\hat{\mathcal{W}}_v^{unseen}$ based on knowledge graphs (KGs). Note that the same GCN learning applies to both verbs / nouns, and in the figure we only show the noun's part for brevity.

et al., 2018; Xian et al., 2017). It takes the word embedding of unseen/seen concepts s_{seen}, s_{unseen}, and conducts graph convolution on the KG, with previously learned classifier weight $\mathcal{W}^{seen}$ as supervision. In each layer, it calculates:

$$Z_{i+1} = \hat{A} Z_i W_i \tag{3}$$

Z_i and Z_{i+1} are input and output of the layer i, $\hat{A}$ is the adjacency matrix of the graph. Following (Kampffmeyer et al., 2019; Kato et al., 2018; Wang et al., 2018), we normalize the adjacency matrix. W_i is a learnable parameter. GCN first transforms features linearly, then aggregates information between nodes via graph edges. The 0^{th} layer's input Z_0 is the word embedding $[s_{seen}, s_{unseen}]$. The last layer's output Z_n is the classifier weight $[\hat{\mathcal{W}}^{seen}, \hat{\mathcal{W}}^{unseen}]$. We use the $\mathcal{W}^{seen}$ learned previously as supervision, and calculate the mean square error loss between $\mathcal{W}^{seen}$ and $\hat{\mathcal{W}}^{seen}$. The training process is illustrated in Figure 2. Only the GCN learning of nouns is shown for brevity.

$$\mathcal{L}_{GCN} = \mathcal{L}_{mse}(\hat{\mathcal{W}}^{seen}, \mathcal{W}^{seen}) \tag{4}$$

3.3 Incorporating affordance prior

Not all verb-noun pairs are equally important — some objects can only admit certain actions but not others. (Gibson, 1978) proposed the notion of "affordance" — the shape of an object may provide hints on how humans should use it, which induces the set of suitable actions. Affordance can be extracted from the language source, e.g. we will often say *peel the apple* but rarely *peel the chair*. Prior works (Zhuang et al., 2017; Lu et al., 2016) used language information as prior to improve their performance. In this paper, we use captions of HowTO100M dataset (Miech et al., 2019) which records human-object interaction. We run the Standford NLP parser (Chen and Manning, 2014) to extract nouns/verbs from captions automatically.

After extracting verb-noun pairs, we train a scoring function $\mathcal{A}$ to calculate the verb-noun affordance matching score. We project verb embedding s_v to the noun embedding space and calculate cosine distance with s_n, followed by sigmoid to output a scalar value indicating whether this verb-noun compositional action is plausible. For training, we generate positive/negative pairs and use binary cross-entropy loss $\mathcal{L}_{affd}$. Note that there underlies an open-world assumption (Nickel et al., 2015): the verb-noun pairs missing are not entirely infeasible, but could be unobserved. Further research can be explored to develop a more precise way of modeling the affordance constraint.

A scoring function based on only word-embedding is similar to a static look-up table for verb-noun pairs, and may fail to encode diverse action visual features. Thus we train a mapping function $\mathcal{M}$ to transform verb's visual input to its word embedding s_v using mean square error loss.

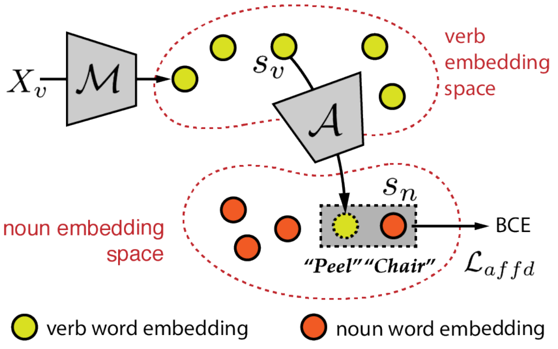

Figure 3: We train a scoring function $\mathcal{A}$ to calculate the affordance matching between verb and noun. In test time, the matching score is computed between mapped verb visual feature $\mathcal{M}(X_v)$ and s_n.

Algorithm 1 Training process of our DARK model

1. Train the feature extractor and corresponding classification weight ($\mathcal{F}_v$, $\mathcal{W}_v$), ($\mathcal{F}_n$, $\mathcal{W}_n$) via classification loss $\mathcal{L}_v$, $\mathcal{L}_n$ separately.

2. Use the word embeddings s_v, s_n as input and the learned classification weight $\mathcal{W}_v$, $\mathcal{W}_n$ as supervision, to train the GCN model ($\mathcal{G}_v$, $\mathcal{G}_n$) with mean square error (MSE) loss (Equation 4).

3. Use extracted affordance pairs to train scoring function $\mathcal{A}(s_v, s_n)$ (Figure 3), via binary cross entropy (BCE) loss $\mathcal{L}_{affd}$.

4. Train mapping function $\mathcal{M}$ to map visual verb inputs to semantic embedding space (Equation 5).

$$\mathcal{L}_{mse}(\mathcal{M}(X_v), s_v) \tag{5}$$

The separation of $\mathcal{A}$, $\mathcal{M}$ also adds interpretability and allows learning from different data. $\mathcal{A}$ can be trained on a language corpus without video data. Also, $\mathcal{A}$ deals with textual affordance relationship directly and adds interpretability. In test time we map verb's visual input to verb embedding space and calculate affordance score with target noun's embedding s_n (Figure 3). The model is asymmetric, since we use object proposals with false detection and verb visual input is more reliable.

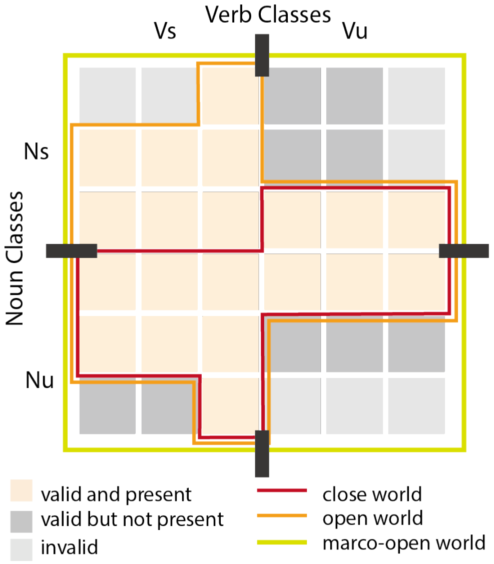

Figure 4: The seen compositional actions correspond to V_sN_s (the upper left part), and unseen actions include V_sN_u, V_uN_s and V_uN_u (the rest). We visualize the scope of close / open / macro-open world settings.

3.4 Overall algorithm and inference

The training of our DARK model is shown in Algorithm 1. During inference, we calculate the probability of a video containing the compositional action (v, n) using following equations:

$$\mathcal{P}(v, n) = \mathcal{P}(v) * \mathcal{P}(n) * \mathcal{A}(\mathcal{M}(X_v), s_n) \tag{6}$$
$$\mathcal{P}(v) = \sigma(\mathcal{W}_v * \mathcal{F}_v(X)) \tag{7}$$

σ is sigmoid function. For the classification weights $\mathcal{W}_v$ used in verb prediction $\mathcal{P}(v)$, we use the learned classification weight $\mathcal{W}_v^{seen}$ for seen classes, and $\mathcal{W}_v^{\hat{unseen}}$ predicted by GCN for unseen classes. Similar equation applies for noun prediction $\mathcal{P}(n)$, which is omitted.

4 Experiments

In this section, we discuss experiment evaluation, setup and results. Some implementation details are in appendix. [1]

4.1 Evaluation of zero-shot compositional task

Following previous work (Kato et al., 2018), we partition verbs into two disjoint sets for seen/unseen classes, V_s / V_u, and same for nouns, N_s / N_u. Thus, "seen compositional actions" correspond to V_sN_s, while "unseen (zero-shot) actions" correspond to V_sN_u, V_uN_s and V_uN_u.

Prior to (Chao et al., 2016), most works (e.g. (Norouzi et al., 2013)) on zero-shot learning adopt an evaluation protocol where predictions are made and evaluated only among unseen classes.

---

[1] Code and proposed benchmark are in `https://github.com/airmachine/DARK`.

This is later denoted as **close world** setting. (Chao et al., 2016) points out that it does not reflect the difficulty of recognition in practice, and there exists a trade-off between classification accuracies of seen / unseen classes. They propose **generalized zero-shot learning (GZL)** setting — test set contains samples of both seen / unseen classes. Predictions are made and evaluated on both categories. By adding different biases to unseen classes' prediction, one can draw a curve depicting the trade-off between accuracies of seen/unseen samples. They use area under the curve (AUC) to better reflect model's overall performance on both seen and unseen classes. Our evaluation follows this setup.

Currently, relatively few prior works tackle zero-shot compositional action recognition (Kato et al., 2018; Materzynska et al., 2020). Taking other zero-shot compositional learning tasks such as zero-shot attribute-object classification (Misra et al., 2017; Nagarajan and Grauman, 2018; Purushwalkam et al., 2019; Yang et al., 2020) and image-based zero-shot human-object interaction (Wang et al., 2020; Xu et al., 2019) into consideration, we find that zero-shot compositional learning task poses extra challenges due to its combinatorial label space: not all compositional labels are valid, and for the valid ones, there may be no samples in the dataset. For brevity, we continue to use the term "verb" and "noun", but the following discussion could be also applied to other zero-shot compositional learning tasks (e.g., attribute-object). As in Figure 4, with N_v verbs, N_n nouns, we can construct a $N_v \times N_n$ action label space. Among these actions, some are $invalid$, because the verb-noun pair contradicts our common sense (e.g. $peel\ a\ car$). And some are $valid\ but\ not\ presented$ in the dataset. Most previous works only consider labels that contain samples in the dataset, namely compositional classes that are $valid\ and\ presented$ in the dataset.

Prior works (Materzynska et al., 2020; Misra et al., 2017; Nagarajan and Grauman, 2018; Yang et al., 2020) use disjoint label spaces in training and test sets, which corresponds to the **close world setting**. (Purushwalkam et al., 2019)'s test set contains both seen and unseen classes (GZL setting) and uses the AUC metric like ours, but their prediction is made and evaluated only among compositional classes with samples in dataset. (Kato et al., 2018; Wang et al., 2020) also follow GZL setting, but they use mean average precision (mAP) over compositional classes presented in dataset, which implicitly only considers $valid\ and\ presented$ classes. We denote this as **open world setting**: test set contains samples from seen/unseen classes, but prediction is made and/or evaluated among $valid\ and\ presented$ classes.

Neither close world setting nor open word setting reflects the difficulty of zero-shot compositional action recognition task. When deploying recognition models in the real world, it would need to make predictions in the whole $N_v \times N_n$ label space. Thus, compositional constraints between verbs and nouns (affordance) should be properly modeled to exclude $invalid$ classes. In addition, the evaluation protocol should not distinguish between classes that are $valid\ but\ not\ presented$ and $valid\ and\ presented$ in the dataset, because models would not have access to that information beforehand. We propose the **marco open world setting**. In test time, sample can be from all seen/unseen classes, including V_sN_s, V_sN_u, V_uN_s and V_uN_u, and model receives no information about where the sample comes from. Predictions are made and evaluated in the whole $N_v \times N_n$ label space, and the AUC metric (Chao et al., 2016) considering the trade-off between seen/unseen classes is reported. Figure 4 compares these three settings.

4.2 Experimental setup

Dataset and split: We conduct experiments on two datasets, Epic-kitchen v-2 (Damen et al., 2020, 2018) and Charades (Sigurdsson et al., 2016). On Epic-kitchen benchmark, we create the compositional split for compositional action recognition. To avoid inductive bias brought by pretrained backbones (e.g. Faster R-CNN (Girshick, 2015) pretrained on ImageNet (Deng et al., 2009), or Inception3D (I3D) (Carreira and Zisserman, 2017) pretrained on Kinetics (Kay et al., 2017)) as discussed in (Wang et al., 2020), we ensure all nouns/verbs seen during pre-training stay in V_sN_s when creating compositional split on Epic-kitchen benchmark. For Charades, we follow the same splits in (Kato et al., 2018) for fair comparison.

Charades dataset (Sigurdsson et al., 2016) contains 9848 videos, and many involve compositional human-object interaction. We use the compositional benchmark proposed by (Kato et al., 2018): they remove "no interaction" action categories, leaving 9625 videos with 34 verbs and 37 nouns. Those verbs and nouns are further partitioned into two verb splits V_s, V_u (number of classes being

Table 1: DARK's results on Epic-Kitchen dataset, compared with baselines and GCNCL (Kato et al., 2018)

Table 2: Dataset statistics of proposed benchmark based on Epic-kitchen and previous benchmark on Charades.

	V_sN_s	V_sN_u	V_uN_s	V_uN_u	samples
Epic-	840	896	1073	820	76605
Charades	49	47	22	31	9625

20 / 14), and two noun splits N_s, N_u (18 / 19). The total number of compositional actions is 149.

Epic-kitchen version 2 dataset (Damen et al., 2020, 2018) contains videos recorded in kitchens, where people demonstrate their interaction with objects like pan, etc. The diversity of actions in this dataset makes it especially challenging. We follow the steps in similar previous works (Rahman et al., 2018; Wang et al., 2020) to create our compositional split. We first make sure that classes seen in pre-training stay in the seen split. Then for the remaining classes we sort them based on the number of instances in descending order, and pick the last 20% to be unseen classes, because (Rahman et al., 2018) pointed out that zero-shot learning targets the classes not easy to collect (especially those in the tail part of the long tail class distribution). We show dataset statistics in Table 2. We get a total number of 76605 videos, including 90 verbs, 249 nouns, and 3629 compositional actions. Compared to Charades, our proposed benchmark is at a larger scale in terms of classes involved and sample size.

Baselines: We establish our baselines following previous work (Kato et al., 2018). Here we briefly summarize their architectures, and readers can refer to (Kato et al., 2018) or original papers for details. These baselines are based on Inception3D features.

Triplet Siamese Network (Triplet) by (Kato et al., 2018): verb/noun embeddings are concatenated, and transformed by fully connected (FC) layers. The output is concatenated with visual features to predict scores through one FC layer with the training of BCE loss.

Semantic Embedding Space (SES) (Xu et al., 2015): The model projects visual features into embedding space through FC layers and then matches output with corresponding action embeddings (average of verb/noun embeddings) using L2 loss.

Deep Embedding Model (DEM) (Zhang et al., 2017): Verb/noun embeddings are transformed separately via FC layers and summed together. Then output is matched with visual features via L2 loss.

4.3 Results on Epic-kitchen dataset

The results of the proposed DARK model, as well as the aforementioned baselines (Triplet, SES and DEM) and previous model GCNCL (Kato et al., 2018) on the Epic-kitchen dataset are listed in Table 1. We report the results in the proposed AUC metric (Chao et al., 2016) with precision calculated at top 1/2/3 prediction for both open world and macro open world settings, which evaluates the overall trade-off between seen/unseen class. We also report the mean average precision (mAP) used in (Kato et al., 2018) on all and zero-shot compositional action classes for reference.

Our best performing DARK model outperforms all baselines and GCNCL by a large margin under all metrics, illustrating the benefit of disentangled action representation for compositional action recognition. DARK is also more scalable, and reduces the number of graph nodes from 22749 (GCNCL with no external knowledge) to 339 (ours).

DARK considers the type constraint of verbs and nouns when composing verb and noun into compositional action label by training an affordance scoring module, while GCNCL considers the constraint when building compositional action nodes by collecting the existing verb-noun pairs from NEIL (Chen et al., 2013). For fair comparison, we re-implement three versions of KG in GCNCL model. In "GT", we use the ground-truth verb-noun relationships that are presented in the dataset

Table 3: Combination for zero-shot learning in verb and noun classifiers. The top1 "open world" AUC is reported on the Epic-kitchen dataset.

	Verb-KG	Verb-SES	Verb-ConSE
Noun-KG	1.81	1.24	0.49
Noun-SES	0.40	0.44	0.32
Noun-ConSE	0.25	0.18	0.13

(open world setting). In "Affd", we only consider relationships in the same corpus with DARK. We use the relationships as a hard look-up since GCNCL only contains unweighted "hard" edges in its knowledge graph. In "Both", we use the union of the constraints in "GT" and "Affd". Under all the three circumstances, our DARK model outperforms other models by a large margin. For all experiments, we report the best results.

4.4 Ablations on different components

Zero-shot learning in verb/noun classifier: In DARK model, we do separate verb and noun classification in two branches. We investigate different implementations of zero-shot learning in verb/noun classifier. Specifically, we consider three options for both verb and noun, namely "KG", "SES" and "ConSE". "KG" stands for zero-shot learning by using knowledge graph to predict classification weights for unseen component with GloVe embedding (Pennington et al., 2014) as in (Kato et al., 2018). "SES" (Xu et al., 2015) is the best common embedding baseline in Table 1 using better BERT word embedding (Devlin et al., 2018) (based on observation in Table 5, BERT tends to have better performance). "ConSE" (Norouzi et al., 2013) learns a semantic structure aware embedding space compared to original word embeddings, which is modeled with graph. "ConSE" (Norouzi et al., 2013) is used as the zero-shot learning component in previous image-based action recognition task (Xu et al., 2019). It learns a semantic structure aware embedding space and we also use GloVe embedding. For better comparison of zero-shot learning component, we report the "open world" AUC on the Epic-kitchen dataset without using affordance (same as "ground-truth" affordance in macro open setting), thus excluding the influence of affordance prior. Different zero-shot learning combinations for verbs and nouns are reported in Table 3. Using "KG" for both verb / noun outperforms others by a large margin, and we take this approach in the rest experiments.

Table 4: Different verb knowledge graphs. We report the top1 AUC for verbs under GZL setting.

	WN dis	VN group	VN tree
one-way	1.86	0.83	1.93
two-way	×	×	1.79

Construction of verb knowledge graph: Compared to nouns, the concept of verb is relatively abstract and the relationship between verbs is hard to capture. We explore different ways of constructing the verb KG, namely, "WN dis", "VN group" and "VN tree". (The details of noun KG are discussed in the appendix.) In "WN dis", we use WordNet (Miller, 1995) structure and add edges between nodes if their LCH (Leacock and Chodorow, 1998) distance is bigger than a threshold. We also explore VerbNet (Kipper et al., 2008) which is designed to capture the semantic similarity of verbs. VerbNet categorizes verbs into different classes, and each class contains multiple verb members. To resolve the duplication in each class, we add edges between verbs in the same class, and denote this as "VN group". We also try adding a meta node for each class and connecting all its members to the meta node, denoted as "VN tree". Graphs of "WN dis" and "VN group" are naturally undirected. For "VN tree", we consider an additional "two-way" setting as in (Kampffmeyer et al., 2019), where a GCN model separates the parent-to-children and children-to-parent knowledge propagation into two stages to better model hierarchical graph structure. However, we do not observe performance improvement in this setting. In Table 4, we report top1 AUC for verbs using different KGs under the GZL(Chao et al., 2016) setting. "VN tree" in "one-way" gives the best prediction for verb, and we keep this configuration in rest experiments.

Affordance learning: We consider the compositional constraints between verbs and nouns (affordance) when composing the compositional action. We explore various ways of learning affordance in Table 5. In "Word-only" we train a word-embedding only model. And "Visual" represents the approach in method section where an additional projection module maps visual features to embedding space. For each, we explore two word embeddings, GLoVe (Pennington et al., 2014) and BERT (Devlin et al., 2018). In terms of score calculation, we try three different methods each. In "Concat-Scoring", we concatenate verb/noun features, and

Table 5: Top1 “marco open world" AUC on Epic-kitchen based on different affordance learning methods.

	Word-only		Visual	
	GLoVe	BERT	GLoVe	BERT
Concat-Scoring	1.49	1.59	1.48	1.60
Context-Scoring	1.49	1.59	1.49	×
Proj-Cosine	1.42	1.59	1.42	1.69
Lookup Table	1.35			
Uniform	1.46			
Ground Truth	1.81			

Table 6: Results (mAP) on Charades under GZL setting. Baselines and GCNCL results from (Kato et al., 2018).

	Model	All	Zero-shot
Baseline	Chance	1.37	1.00
	Triplet	10.41	7.82
	SES	10.14	7.81
	DEM	9.57	7.74
GCNCL	GCNCL-I+A	10.48	7.95
	GCNCL+A	10.53	8.09
Ours	DARK	11.21	8.38

train a scoring model. In “Context-Scoring", instead of concatenating, for BERT the scoring model embeds verb-noun phrase together and averages their embeddings, and for GloVe we simply average their embeddings. In “Proj-Cosine", we project verb embedding to noun embedding space and calculate the cosine distance. We also try a lookup table, where affordance is one if the compositional pair exists in train set or knowledge bases, and zero otherwise. “Uniform" sets all affordance to be one, which means no weighting is applied. “Ground Truth" sets one for pairs existing in the dataset (train/test), equivalent to “open world". In all experiments, we use best configuration from Table 3, and label compositional pairs seen in training to one. BERT constantly improve affordance relationships in different methods. Lookup table performs worse than “Uniform" (no affordance) since some valid pairings are missing in knowledge bases.

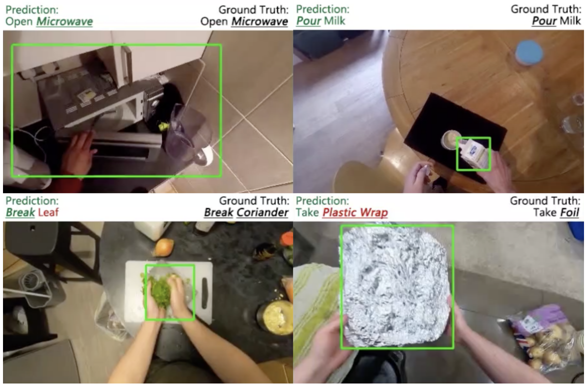

Figure 5: Qualitative Analysis. Underlines are unseen concepts, green for right predictions and red for wrong.

4.5 Results on Charades dataset

We report results on Charades in Table 6. Following (Kato et al., 2018), we report mean average precision (mAP) and compare our model to theirs and baselines. We also report zero-shot classes ($V_sN_u + V_uN_s + V_uN_u$) separately but all predictions are made under GZL setting. Unlike Epic-Kitchen which contains ego-centric actions, Charades contains third-person view videos and cannot detect the mask of person’s hand. Thus we directly learn the verb and noun feature disentanglement leveraging a discriminator and a disentanglement loss. Following (Peng et al., 2018), discriminator tries to adversarially classify noun label y_n from its verb feature, and feature extractor $\mathcal{F}$ goes against it. To better capture the multi-label property in Charades, we use an un-factorized classification model for actions in V_sN_s so they can be treated separately. Since we report the mAP results for fair comparison with GCNCL, we do not use affordance in our model. As indicated in (Kato et al., 2018), we also notice that the amount of improvement over baselines is not large, possibly because Charades is relatively small and easy to overfit. And this motivated us to propose a large-scale zero-shot compositional action recognition benchmark.

4.6 Qualitative error analysis

We also visualize some examples in Figure 5. The model misclassifies *coriander* as *leaf*, and *foil* as *plastic wrap* due to visual similarity.

5 Conclusion

In this paper, we propose DARK, a novel compositional action recognition model that reduces complexity from quadratic to linear, making the training more scalable. DARK generalizes to unseen verb-noun pairs, and can be combined with knowledge bases to produce state-of-the-art compositional action recognition results.

A Implementation Detail

To build the object feature extractor $\mathcal{F}_n$, we first use an off-the-shelf class-agnostic object detector to detect the bounding box of interacting objects. For the Charades (Sigurdsson et al., 2016) dataset, we use the detected object boxes generated by HOID (Wang et al., 2020). HOID model first detects the box of human, then based on the human's bounding box it detects interacting objects. We use the code publicly released by (Wang et al., 2020), with the default parameters provided by the author. We use the weights of the class-agnostic object detector provided on the project page. For the Epic-kitchen dataset (Damen et al., 2020, 2018), we use the pre-computed class-agnostic boxes provided by the authors. They use the model from (Shan et al., 2020), which detects human hands and locates the interacting objects. We use different models for object detection because Epic-kitchen (Damen et al., 2018) contains mostly ego-centric action videos while Charades (Sigurdsson et al., 2016) contains third-person view videos. For the Epic-kitchen dataset, we additionally use its pre-computed detected masks of human hands.

After the object boxes are detected, we run the Faster-RCNN (Girshick, 2015) model with the ResNet-101 backbone to extract the object features. We use the implementation provided by the Detectron2 (Wu et al., 2019) library, with the weights pre-trained on ImageNet (Deng et al., 2009). We obtain the features before the classifier layer in the Faster-RCNN model, which results in 2048 dimension object features. If we detect multiple boxes in one frame, we conduct max-pooling over their extracted features to obtain one feature representation for each frame. If no box is detected for a particular frame, we then extract the feature of the whole image as its object feature.

We sample several frames along the temporal axis of the video to conduct object detection. Since videos in the Charades (Sigurdsson et al., 2016) dataset may contain more than one action, we treat each frame in Charades dataset as one sample for training. For the Epic-kitchen (Damen et al., 2020, 2018) dataset whose videos contain only one action, we instead simply apply mean pooling over object features of sampled frames to obtain one feature representation for the whole video. We add fully-connected (FC) layers upon the fixed Faster-RCNN backbone to conduct feature extraction.

For verb features, we build our feature extractor $\mathcal{F}_v$ based on a standard two-stream Inception3D (Carreira and Zisserman, 2017) backbone pre-trained on the Kinetics dataset (Kay et al., 2017). We use both the RGB branch and the optical-flow branch, each producing a 1024 dimension feature in the layer Mixed_5c. We then concatenate them, resulting in a feature representation of 2048 dimension. For the Epic-kitchen dataset, we generate features first using the video input with the object cropped out. Then we do the same using the video input with everything cropped except for the detected hands in order to obtain hand gesture movement information. We further concatenate these two features to get a 4096 dimension feature. Similar to the object feature extractor, we add FC layers to features generated by the fixed Inception3D backbone. For the Charades dataset, since another disentanglement approach is used, we simply use the 2048 dimension feature.

Following common practice, we split the whole video into video clips with a small duration, and generate features for each clip during training and inference. For the Charades dataset, we sample 10 clips per video to conduct training and we treat each clip as a sample. Whereas for the Epic-kitchen dataset, we apply max pooling to the features of all the clips generated from one video to obtain one feature representation for the whole video.

Our model is implemented in PyTorch with Adam optimizer. We used in total around 20 GPUs through out the experiments. But a single run only needs 5 GPUs. (we launch parallel experiments)

B The Proposed Epic-kitchen Benchmark

We build our compositional action recognition benchmark based on the Epic-kitchen(Damen et al., 2020, 2018) dataset version two. We take the class that overlaps with pre-trained backbones into consideration when creating seen/unseen class splits. We find that there are 95 noun classes overlapping with ImageNet classes, and 23 verb classes overlapping with Kinetics classes, where the backbones that we use have been pre-trained. We make sure these overlapping classes stay in the seen split.

We then remove the tail verb and noun classes with less than 10 instances. The remaining dataset contains a total number of 76605 videos, including 90 verbs, 249 nouns, and 3629 compositional actions. We have 29 verbs in the seen category, and 61 verbs in the unseen category. On the other hand, 102 nouns are seen and 147 nouns are unseen.

The V_sN_s split contains 840 compositional actions, and 51228 samples. The V_uN_s split has 1073 compositional actions, and 10105 samples. For the V_sN_u split, there are 896 compositional actions and 11073 samples. And for the V_uN_u split, there are 820 compositional actions and 4199 samples.

Epic-Kitchen dataset is realized under the Creative Commons Attribution-NonCommercial 4.0 International License. The licence for non-Commercial use of Charades dataset can be found at http://vuchallenge.org/charades.html. We follow the intended usage of these two dataset.

C Noun Knowledge Graph Construction

We discuss the construction of the verb knowledge graph in the paper, due to the space limit, we present the details of the noun knowledge graph in this section. We construct the noun knowledge graph following (Wang et al., 2018)'s approach. We begin from the nouns presented in the dataset, and recursively search their hyper-norms using WordNet (Miller, 1995)'s lexical relationship to add to the graph. In addition, we augment the knowledge graph by adding nouns from ImageNet's ((Deng et al., 2009)) class labels.

When building noun knowledge graphs, we add an edge if two entities are direct synonyms or hyper-norms. Our model is built upon the graph convolution model implemented by (**?**). We use its plain GCN version without attention. And we use the "two-way" approach, which separates parent-to-children and children-to-parent knowledge propagation into two stages to better model the hierarchical graph structure. For noun knowledge graph learning, we use 300d GloVe (Pennington et al., 2014) embeddings as input.

D Disentanglement in Charades Dataset

Let X_v denote the input to the verb feature extractor $\mathcal{F}_v$, and X'_v denote the extracted verb features. Similarly, X_n is the input to $\mathcal{F}_n$ and X'_n is the extracted noun features.

$$X'_v = \mathcal{F}_v(X_v) \tag{8}$$
$$X'_n = \mathcal{F}_n(X_n) \tag{9}$$

To obtain disentangled verb / noun features, we take the idea from the previous paper (Peng et al., 2018). We use a discriminator to limit the information verb and noun features contain. The discriminator $\mathcal{D}_v$ tries to adversarially classify noun label y_n from its verb feature X'_v, and the feature extractor $\mathcal{F}_v$ goes against it via a minimax process. The discriminator helps to limit the information which verb feature X'_v contains about the nouns in the video. The same procedure happens for $\mathcal{D}_n$. We use one layer linear classifier for discriminator $\mathcal{D}_v$ and $\mathcal{D}_n$ and they output class predictions for the opposite branch. This leads to the disentanglement loss:

$$\mathcal{L}^v_{dis} = -\mathbf{CE}(\mathcal{D}_v(X'_v); y_n) \tag{10}$$
$$\mathcal{L}^n_{dis} = -\mathbf{CE}(\mathcal{D}_n(X'_n); y_v) \tag{11}$$

The **CE** refers to the cross-entropy loss. The overall loss for training the feature extractor $\mathcal{F}_v$, $\mathcal{F}_n$ and the classifier for seen classes $\mathcal{W}^{seen}_v$, $\mathcal{W}^{seen}_n$ is:

$$\mathcal{L}_v = \mathcal{L}^v_{cls} + \mathcal{L}^v_{dis} \tag{12}$$
$$\mathcal{L}_n = \mathcal{L}^n_{cls} + \mathcal{L}^n_{dis} \tag{13}$$

The definitions of $\mathcal{L}^v_{cls}$, $\mathcal{L}^n_{cls}$ are the same as discussed in the main paper.

Disentangled Action Recognition with Knowledge Bases

Abstract

Action in video usually involves the interaction of human with objects. Action labels are typically composed of various combinations of verbs and nouns, but we may not have training data for all possible combinations. In this paper, we aim to improve the generalization ability of the compositional action recognition model to novel verbs or novel nouns that are unseen during training time, by leveraging the power of knowledge graphs. Previous work utilizes verb-noun compositional action nodes in the knowledge graph, making it inefficient to scale since the number of compositional action nodes grows quadratically with respect to the number of verbs and nouns. To address this issue, we propose our approach: Disentangled Action Recognition with Knowledge-bases (DARK), which leverages the inherent compositionality of actions. DARK trains a factorized model by first extracting disentangled feature representations for verbs and nouns, and then predicting classification weights using relations in external knowledge graphs. The type constraint between verb and noun is extracted from external knowledge bases and finally applied when composing actions. DARK has better scalability in the number of objects and verbs, and achieves state-of-the-art performance on the Charades dataset. We further propose a new benchmark split based on the Epic-kitchen dataset which is an order of magnitude bigger in the numbers of classes and samples, and benchmark various models on this benchmark.

1 Introduction

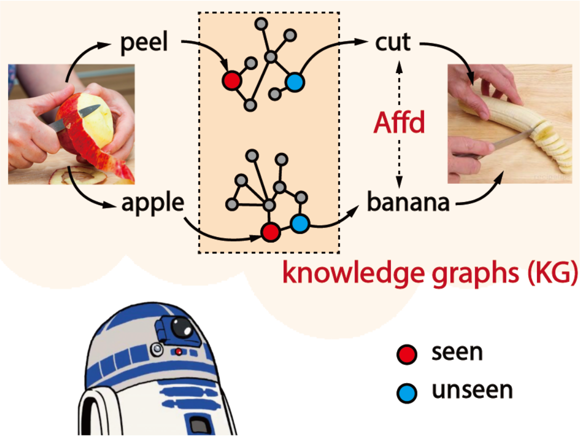

Figure 1: DARK extracts disentangled features of verbs/nouns and leverages knowledge graphs (KG) to generate classifiers for unseen verbs and nouns. Predictions are then composed under constraints of object affordance priors (Affd) from knowledge bases (e.g. *banana can be cut*).

Understanding human-object interaction is crucial for modeling human behavior, and plays a key role in developing robotic agents that interact with humans. In videos, many of these interactions can be described using the combination of verbs and nouns, e.g, *move chair*, *peel apple*. Recently researchers have been focusing on the task of compositional action recognition with the goal of recognizing actions represented by such verb-noun pairs. The key challenge comes from the extremely large label space of various combinations. The number of possible verb-noun pairs grows quadratically with respect to the number of verbs and nouns. It is infeasible to collect training data for all possible actions. This motivates us to study the problem of zero-shot compositional action recognition, which aims to predict action with components beyond the vocabularies in train data.

To conduct zero-shot learning, we propose our Disentangled Action Recognition with Knowledge-bases (DARK), which leverages knowledge graphs. A knowledge graph (KG) encodes semantic relationships between verb or noun nodes. We apply graph convolutional network (GCN) on KG to predict classifier weights for unseen nodes in graphs.

Previous work (Kato et al., 2018) has explored using knowledge graphs for zero-shot compositional action learning. However, their model builds a graph containing verb, noun and compositional action nodes (which link verbs and nouns). It learns features of novel action nodes by propagating information from connected verb/noun nodes. The number of compositional action nodes during training is in the order of $\mathcal{O}(n^2)$, and the memory consumption may become prohibitively expensive as we scale this approach to large vocabularies. To overcome this issue, we propose to learn separate classifiers for verbs and nouns, which scales linearly with respect to the vocabulary size.

Specifically, DARK extracts verb and noun features separately, and relies on separate verb and noun knowledge graphs to predict unseen concepts before composing the action label. Activity recognition is particularly well-suited for such a factorized approach, because nouns may be better captured using object detection-based approaches and verbs may be represented by motion. Compared to prior work (Kato et al., 2018; Zhukov et al., 2019) that use the same feature representation for both verb and noun, our separate features model noun and verb more precisely. In addition, we adopt disentanglement between the learned verb and noun features, so they compose more readily and improve generalization on unseen actions.

Though scalability is achieved using our factorized approach, verbs and nouns are actually not fully independent. For instance, the process of $sanding$ an object and $scrubbing$ an object are visually similar, however you are more likely to be $scrubbing$ a car than $sanding$ it. Prior work (Kato et al., 2018) models the verb-noun relationships by constructing quadratic compositional action nodes. In our model, when composing action labels, we take object affordances (Gibson, 1978), namely the commonsense relationship of verbs and nouns, into consideration. We extract affordance knowledge from a caption corpus and build a scoring component to consider the relationship between verbs and nouns, to further improve the generalization ability. The basic idea of our proposed model is illustrated in Figure 1.

Furthermore, we investigate the evaluation of zero-shot compositional action recognition task and identify the drawback of existing metrics. With N_v verbs, N_n nouns, it constructs a $N_v \times N_n$ label space for possible actions. Among these actions, some are $invalid$ (e.g. $peel\ a\ car$) and some are $valid\ but\ not\ presented$ in the dataset. In real-world applications, the model would need to make predictions in the whole $N_v \times N_n$ label space. But current evaluation protocols, implicitly or explicitly, only evaluate on compositional classes that are $valid\ and\ presented$ in the dataset, which does not reflect the real difficulty of this task. We propose a new setting, where predictions are made and evaluated in the full $N_v \times N_n$ label space.

The Charades (Sigurdsson et al., 2016) dataset is relatively small scale for testing zero-shot compositional action recognition (Kato et al., 2018). To promote further research, we propose a new benchmark based on the Epic-kitchen (Damen et al., 2018, 2020) dataset, which is an order of magnitude bigger both in number of classes and sample size. The key contributions of our paper are:

1. We propose a novel factorized model that learns disentangled representation separately for verbs and nouns, facilitating scalability.
2. We further improve the model's generalization performance by learning the interaction constraints between verbs and nouns (affordance priors) from an external corpus.
3. We propose a new evaluation protocol for zero-shot compositional learnings, which better reflects the real-world application setting.
4. We propose a new large-scale benchmark based on the Epic-Kitchen dataset and achieve state-of-the-art results.

2 Related Work

Zero-shot learning with knowledge graphs: Zero-shot learning has been widely studied in computer vision (Akata et al., 2015; Lampert et al., 2013; Lee et al., 2018; Sahu et al., 2020; Wang et al., 2019; Xian et al., 2018). We will focus on related work relevant to our approach. (Wang et al., 2018) proposes to distill both the implicit knowledge representations (e.g., word embedding) and explicit relationships (e.g., knowledge graph) to learn a visual classifier for new classes through GCN (Kipf and Welling, 2016). (Kampffmeyer et al., 2019) later proposes to augment the knowledge graph (KG) with dense connections which directly connects multi-hop relationship and distinguishes between parent and children nodes. The graph learning of our model mostly follows their work. Recently there have been improvements on GCN models. (Nayak and Bach, 2020) designs a novel transformer GCN to learn representations based on common-sense KGs. (Geng et al., 2020b) uses an attentive GCN together with an explanation generator to conduct explainable zero-shot learning. Instead of generating classifier for unseen classes directly, (Geng et al., 2020a) uses a generative adversarial network to synthesize features for unseen classes to conduct classification. These directions could be potentially explored in our problem setting to further improve performance. (Gao et al., 2019) conducts zero-shot action recognition based on KGs, but unlike our problem setting, their verb-noun relationship is not compositional and objects are used as attributes to infer action.

Compositional action recognition: Many prior works aim to understand actions through interaction with objects. (Wang et al., 2020; Xu et al., 2019) tackle zero-shot human-object interaction in images. (Zhukov et al., 2019) conduct weakly-supervised action recognition, leveraging compositionality of verb-noun pairs to decompose tasks into a set of verb/noun classifiers. This shares certain similarities with our factorized model, but it is not a zero-shot setting, nor does it enforce feature disentanglement. (Materzynska et al., 2020) conduct zero-shot compositional action recognition, where individual verb/noun concepts have been seen during training but not in the same interaction with each other. Although it cannot deal with unseen verbs or nouns, using object detector to explicitly model object features inspires our approach. One of the closest works to our proposed approach is (Kato et al., 2018). It constructs a KG that contains verb nodes, noun nodes and compositional action nodes, and learns the feature representation for each action node to match visual features. Novel actions' features are inferred jointly during training through GCN. The number of action nodes grows quadratically with respect to the number of nouns or verbs, which makes this approach difficult to scale, especially considering that GCN's forward pass needs to learn all features simultaneously.

3 Method

We propose DARK – Disentangled Action Recognition with Knowledge-bases (Figure 2). It extracts disentangled feature representations for verbs and nouns, then predicts classifier weights for unseen components using knowledge graphs, and composes them under object affordance priors.

3.1 Factorized verb-noun classifier

Given a video X, we first use a verb feature extractor $\mathcal{F}_v$ to extract verb feature, and a noun feature extractor $\mathcal{F}_n$ for noun feature. Subsequently, we learn one-layer predictors $\mathcal{W}_v^{seen}$ and $\mathcal{W}_n^{seen}$ for predicting the final verb/noun class. $\mathcal{F}_v$, $\mathcal{F}_n$ and $\mathcal{W}_v^{seen}$, $\mathcal{W}_n^{seen}$ are trained via cross entropy (CE) losses $\mathcal{L}_{cls}^v$ and $\mathcal{L}_{cls}^n$ with verb / noun labels y_v, y_n.

$$\mathcal{L}_{cls}^v = \mathbf{CE}(\mathcal{F}_v; \mathcal{W}_v^{seen}; y_v) \tag{1}$$

$$\mathcal{L}_{cls}^n = \mathbf{CE}(\mathcal{F}_n; \mathcal{W}_n^{seen}; y_n) \tag{2}$$

We extract disentangled features for verbs and nouns, so that verbs and nouns can be treated as separate entities. If verb features contain much information about nouns, it would overfit to seen actions and would not generalize to unseen compositions. Standard networks like Inception3D (I3D) (Carreira and Zisserman, 2017) can rely on scene or object information to predict verbs (Battaglia et al., 2018; Materzynska et al., 2020). To decouple verb's representation from noun's, we add explicit regularization to the model input. We first used an off-the-shelf class-agnostic object detector to detect the bounding box of interacting objects. Then, we crop the object from videos and use I3D backbone to extract verb features from the cropped videos. (Yun et al., 2019; DeVries and Taylor, 2017; Choi et al., 2019; Singh and Lee, 2017) use similar cropping technique to remove bias in other tasks. We also detect hand masks and add hand regions separately to the verb input because the class-agnostic detector tends to crop out the hands as well. Adding hand gesture information back provides hints for verbs. Disentanglement method on Charades dataset (Sigurdsson et al., 2016) is different as it contains third-person view videos, and relevant details are discussed in Section 4.5.

3.2 GCN for learning novel concept

After training on seen concepts, we can infer the classifier for unseen ones. In this subsection, we drop the subscript v/n as the same process applies for both verb and noun. After learning feature extractor $\mathcal{F}$ and classifier of seen concept $\mathcal{W}^{seen}$, learning classifier for unseen concepts is equivalent to learning the weight $\mathcal{W}^{unseen}$. This step leverages graph convolution network (GCN) following previous work (Kampffmeyer et al., 2019; Kato

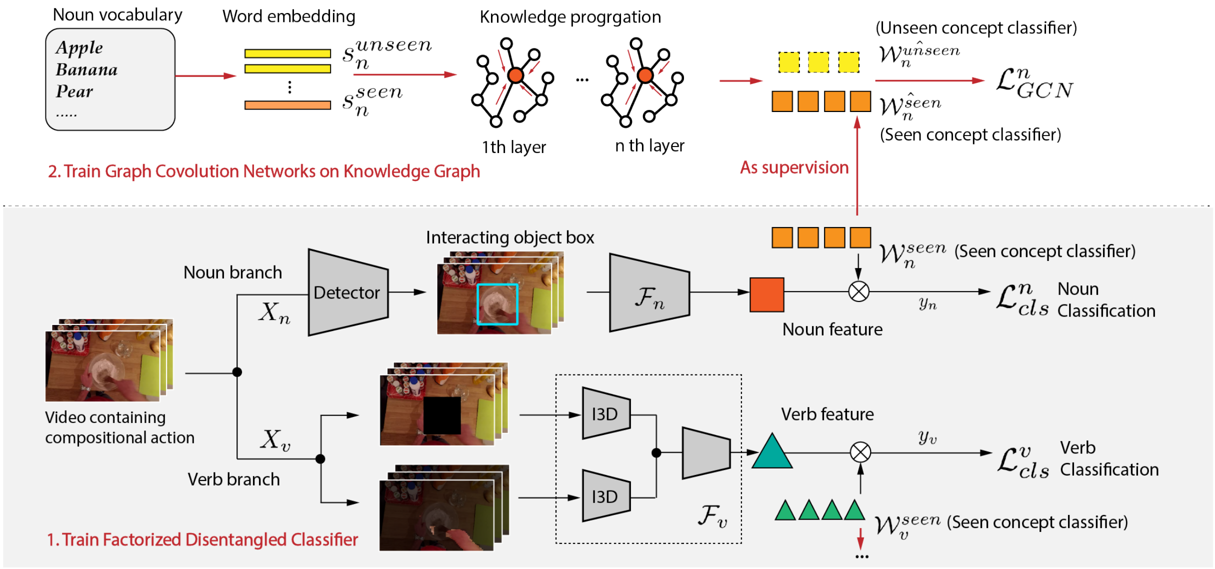

Figure 2: Overall training process. We first jointly train factorized disentangled feature extractor $\mathcal{F}_v$, $\mathcal{F}_n$, and classifier weights for seen class $\mathcal{W}_n^{seen}$, $\mathcal{W}_v^{seen}$. We then take word embedding s_{seen}, s_{unseen} as input, and use GCN to predict classifier weights of unseen class $\mathcal{W}_n^{un\hat{s}een}$, $\mathcal{W}_v^{un\hat{s}een}$ based on knowledge graphs (KGs). Note that the same GCN learning applies to both verbs / nouns, and in the figure we only show the noun's part for brevity.

et al., 2018; Xian et al., 2017). It takes the word embedding of unseen/seen concepts s_{seen}, s_{unseen}, and conducts graph convolution on the KG, with previously learned classifier weight $\mathcal{W}^{seen}$ as supervision. In each layer, it calculates:

$$Z_{i+1} = \hat{A} Z_i W_i \tag{3}$$

Z_i and Z_{i+1} are input and output of the layer i, $\hat{A}$ is the adjacency matrix of the graph. Following (Kampffmeyer et al., 2019; Kato et al., 2018; Wang et al., 2018), we normalize the adjacency matrix. W_i is a learnable parameter. GCN first transforms features linearly, then aggregates information between nodes via graph edges. The 0^{th} layer's input Z_0 is the word embedding $[s_{seen}, s_{unseen}]$. The last layer's output Z_n is the classifier weight $[\mathcal{W}^{\hat{s}een}, \mathcal{W}^{un\hat{s}een}]$. We use the $\mathcal{W}^{seen}$ learned previously as supervision, and calculate the mean square error loss between $\mathcal{W}^{seen}$ and $\mathcal{W}^{\hat{s}een}$. The training process is illustrated in Figure 2. Only the GCN learning of nouns is shown for brevity.

$$\mathcal{L}_{GCN} = \mathcal{L}_{mse}(\mathcal{W}^{\hat{s}een}, \mathcal{W}^{seen}) \tag{4}$$

3.3 Incorporating affordance prior

Not all verb-noun pairs are equally important — some objects can only admit certain actions but not others. (Gibson, 1978) proposed the notion of "affordance" — the shape of an object may provide hints on how humans should use it, which induces the set of suitable actions. Affordance can be extracted from the language source, e.g. we will often say *peel the apple* but rarely *peel the chair*. Prior works (Zhuang et al., 2017; Lu et al., 2016) used language information as prior to improve their performance. In this paper, we use captions of HowTO100M dataset (Miech et al., 2019) which records human-object interaction. We run the Standford NLP parser (Chen and Manning, 2014) to extract nouns/verbs from captions automatically.

After extracting verb-noun pairs, we train a scoring function $\mathcal{A}$ to calculate the verb-noun affordance matching score. We project verb embedding s_v to the noun embedding space and calculate cosine distance with s_n, followed by sigmoid to output a scalar value indicating whether this verb-noun compositional action is plausible. For training, we generate positive/negative pairs and use binary cross-entropy loss $\mathcal{L}_{affd}$. Note that there underlies an open-world assumption (Nickel et al., 2015): the verb-noun pairs missing are not entirely infeasible, but could be unobserved. Further research can be explored to develop a more precise way of modeling the affordance constraint.

A scoring function based on only word-embedding is similar to a static look-up table for verb-noun pairs, and may fail to encode diverse action visual features. Thus we train a mapping function $\mathcal{M}$ to transform verb's visual input to its word embedding s_v using mean square error loss.

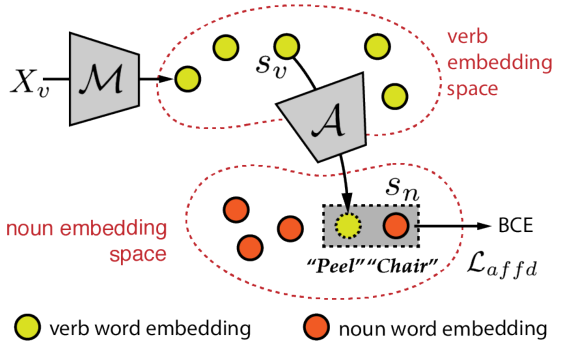

Figure 3: We train a scoring function $\mathcal{A}$ to calculate the affordance matching between verb and noun. In test time, the matching score is computed between mapped verb visual feature $\mathcal{M}(X_v)$ and s_n.

Algorithm 1 Training process of our DARK model

1. Train the feature extractor and corresponding classification weight ($\mathcal{F}_v$, $\mathcal{W}_v$), ($\mathcal{F}_n$, $\mathcal{W}_n$) via classification loss $\mathcal{L}_v$, $\mathcal{L}_n$ separately.

2. Use the word embeddings s_v, s_n as input and the learned classification weight $\mathcal{W}_v$, $\mathcal{W}_n$ as supervision, to train the GCN model ($\mathcal{G}_v$, $\mathcal{G}_n$) with mean square error (MSE) loss (Equation 4).

3. Use extracted affordance pairs to train scoring function $\mathcal{A}(s_v, s_n)$ (Figure 3), via binary cross entropy (BCE) loss $\mathcal{L}_{affd}$.

4. Train mapping function $\mathcal{M}$ to map visual verb inputs to semantic embedding space (Equation 5).

$$\mathcal{L}_{mse}(\mathcal{M}(X_v), s_v) \tag{5}$$

The separation of $\mathcal{A}$, $\mathcal{M}$ also adds interpretability and allows learning from different data. $\mathcal{A}$ can be trained on a language corpus without video data. Also, $\mathcal{A}$ deals with textual affordance relationship directly and adds interpretability. In test time we map verb's visual input to verb embedding space and calculate affordance score with target noun's embedding s_n (Figure 3). The model is asymmetric, since we use object proposals with false detection and verb visual input is more reliable.

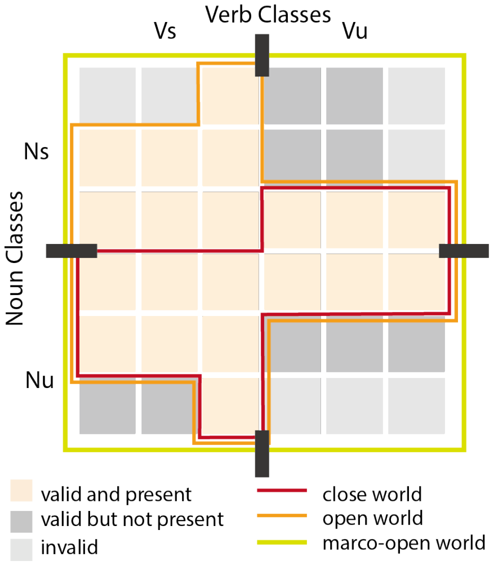

Figure 4: The seen compositional actions correspond to V_sN_s (the upper left part), and unseen actions include V_sN_u, V_uN_s and V_uN_u (the rest). We visualize the scope of close / open / macro-open world settings.

3.4 Overall algorithm and inference

The training of our DARK model is shown in Algorithm 1. During inference, we calculate the probability of a video containing the compositional action (v, n) using following equations:

$$\mathcal{P}(v, n) = \mathcal{P}(v) * \mathcal{P}(n) * \mathcal{A}(\mathcal{M}(X_v), s_n) \tag{6}$$

$$\mathcal{P}(v) = \sigma(\mathcal{W}_v * \mathcal{F}_v(X)) \tag{7}$$

σ is sigmoid function. For the classification weights $\mathcal{W}_v$ used in verb prediction $\mathcal{P}(v)$, we use the learned classification weight $\mathcal{W}_v^{seen}$ for seen classes, and $\mathcal{W}_v^{un\widehat{s}een}$ predicted by GCN for unseen classes. Similar equation applies for noun prediction $\mathcal{P}(n)$, which is omitted.

4 Experiments

In this section, we discuss experiment evaluation, setup and results. Some implementation details are in appendix. [1]

4.1 Evaluation of zero-shot compositional task

Following previous work (Kato et al., 2018), we partition verbs into two disjoint sets for seen/unseen classes, V_s / V_u, and same for nouns, N_s / N_u. Thus, "seen compositional actions" correspond to V_sN_s, while "unseen (zero-shot) actions" correspond to V_sN_u, V_uN_s and V_uN_u.

Prior to (Chao et al., 2016), most works (e.g. (Norouzi et al., 2013)) on zero-shot learning adopt an evaluation protocol where predictions are made and evaluated only among unseen classes.

---

[1] Code and proposed benchmark are in `https://github.com/airmachine/DARK`.

This is later denoted as **close world** setting. (Chao et al., 2016) points out that it does not reflect the difficulty of recognition in practice, and there exists a trade-off between classification accuracies of seen / unseen classes. They propose **generalized zero-shot learning (GZL)** setting — test set contains samples of both seen / unseen classes. Predictions are made and evaluated on both categories. By adding different biases to unseen classes' prediction, one can draw a curve depicting the trade-off between accuracies of seen/unseen samples. They use area under the curve (AUC) to better reflect model's overall performance on both seen and unseen classes. Our evaluation follows this setup.

Currently, relatively few prior works tackle zero-shot compositional action recognition (Kato et al., 2018; Materzynska et al., 2020). Taking other zero-shot compositional learning tasks such as zero-shot attribute-object classification (Misra et al., 2017; Nagarajan and Grauman, 2018; Purushwalkam et al., 2019; Yang et al., 2020) and image-based zero-shot human-object interaction (Wang et al., 2020; Xu et al., 2019) into consideration, we find that zero-shot compositional learning task poses extra challenges due to its combinatorial label space: not all compositional labels are valid, and for the valid ones, there may be no samples in the dataset. For brevity, we continue to use the term "verb" and "noun", but the following discussion could be also applied to other zero-shot compositional learning tasks (e.g., attribute-object). As in Figure 4, with N_v verbs, N_n nouns, we can construct a $N_v \times N_n$ action label space. Among these actions, some are $invalid$, because the verb-noun pair contradicts our common sense (e.g. $peel\ a\ car$). And some are $valid\ but\ not\ presented$ in the dataset. Most previous works only consider labels that contain samples in the dataset, namely compositional classes that are $valid\ and\ presented$ in the dataset.

Prior works (Materzynska et al., 2020; Misra et al., 2017; Nagarajan and Grauman, 2018; Yang et al., 2020) use disjoint label spaces in training and test sets, which corresponds to the **close world setting**. (Purushwalkam et al., 2019)'s test set contains both seen and unseen classes (GZL setting) and uses the AUC metric like ours, but their prediction is made and evaluated only among compositional classes with samples in dataset. (Kato et al., 2018; Wang et al., 2020) also follow GZL setting, but they use mean average precision (mAP) over compositional classes presented in dataset, which implicitly only considers $valid\ and\ presented$ classes. We denote this as **open world setting**: test set contains samples from seen/unseen classes, but prediction is made and/or evaluated among $valid\ and\ presented$ classes.

Neither close world setting nor open word setting reflects the difficulty of zero-shot compositional action recognition task. When deploying recognition models in the real world, it would need to make predictions in the whole $N_v \times N_n$ label space. Thus, compositional constraints between verbs and nouns (affordance) should be properly modeled to exclude $invalid$ classes. In addition, the evaluation protocol should not distinguish between classes that are $valid\ but\ not\ presented$ and $valid\ and\ presented$ in the dataset, because models would not have access to that information beforehand. We propose the **marco open world setting**. In test time, sample can be from all seen/unseen classes, including V_sN_s, V_sN_u, V_uN_s and V_uN_u, and model receives no information about where the sample comes from. Predictions are made and evaluated in the whole $N_v \times N_n$ label space, and the AUC metric (Chao et al., 2016) considering the trade-off between seen/unseen classes is reported. Figure 4 compares these three settings.

4.2 Experimental setup

Dataset and split: We conduct experiments on two datasets, Epic-kitchen v-2 (Damen et al., 2020, 2018) and Charades (Sigurdsson et al., 2016). On Epic-kitchen benchmark, we create the compositional split for compositional action recognition. To avoid inductive bias brought by pretrained backbones (e.g. Faster R-CNN (Girshick, 2015) pretrained on ImageNet (Deng et al., 2009), or Inception3D (I3D) (Carreira and Zisserman, 2017) pretrained on Kinetics (Kay et al., 2017)) as discussed in (Wang et al., 2020), we ensure all nouns/verbs seen during pre-training stay in V_sN_s when creating compositional split on Epic-kitchen benchmark. For Charades, we follow the same splits in (Kato et al., 2018) for fair comparison.

Charades dataset (Sigurdsson et al., 2016) contains 9848 videos, and many involve compositional human-object interaction. We use the compositional benchmark proposed by (Kato et al., 2018): they remove "no interaction" action categories, leaving 9625 videos with 34 verbs and 37 nouns. Those verbs and nouns are further partitioned into two verb splits V_s, V_u (number of classes being

Table 1: DARK's results on Epic-Kitchen dataset, compared with baselines and GCNCL (Kato et al., 2018)

DARK (ours)	1.69	3.64	5.45	2.04	4.67	7.05	2.39	1.22

Table 2: Dataset statistics of proposed benchmark based on Epic-kitchen and previous benchmark on Charades.

	V_sN_s	V_sN_u	V_uN_s	V_uN_u	samples
Epic-	840	896	1073	820	76605
Charades	49	47	22	31	9625

20 / 14), and two noun splits N_s, N_u (18 / 19). The total number of compositional actions is 149.

Epic-kitchen version 2 dataset (Damen et al., 2020, 2018) contains videos recorded in kitchens, where people demonstrate their interaction with objects like pan, etc. The diversity of actions in this dataset makes it especially challenging. We follow the steps in similar previous works (Rahman et al., 2018; Wang et al., 2020) to create our compositional split. We first make sure that classes seen in pre-training stay in the seen split. Then for the remaining classes we sort them based on the number of instances in descending order, and pick the last 20% to be unseen classes, because (Rahman et al., 2018) pointed out that zero-shot learning targets the classes not easy to collect (especially those in the tail part of the long tail class distribution). We show dataset statistics in Table 2. We get a total number of 76605 videos, including 90 verbs, 249 nouns, and 3629 compositional actions. Compared to Charades, our proposed benchmark is at a larger scale in terms of classes involved and sample size.

Baselines: We establish our baselines following previous work (Kato et al., 2018). Here we briefly summarize their architectures, and readers can refer to (Kato et al., 2018) or original papers for details. These baselines are based on Inception3D features.

Triplet Siamese Network (Triplet) by (Kato et al., 2018): verb/noun embeddings are concatenated, and transformed by fully connected (FC) layers. The output is concatenated with visual features to predict scores through one FC layer with the training of BCE loss.

Semantic Embedding Space (SES) (Xu et al., 2015): The model projects visual features into embedding space through FC layers and then matches output with corresponding action embeddings (average of verb/noun embeddings) using L2 loss.

Deep Embedding Model (DEM) (Zhang et al., 2017): Verb/noun embeddings are transformed separately via FC layers and summed together. Then output is matched with visual features via L2 loss.

4.3 Results on Epic-kitchen dataset

The results of the proposed DARK model, as well as the aforementioned baselines (Triplet, SES and DEM) and previous model GCNCL (Kato et al., 2018) on the Epic-kitchen dataset are listed in Table 1. We report the results in the proposed AUC metric (Chao et al., 2016) with precision calculated at top 1/2/3 prediction for both open world and macro open world settings, which evaluates the overall trade-off between seen/unseen class. We also report the mean average precision (mAP) used in (Kato et al., 2018) on all and zero-shot compositional action classes for reference.

Our best performing DARK model outperforms all baselines and GCNCL by a large margin under all metrics, illustrating the benefit of disentangled action representation for compositional action recognition. DARK is also more scalable, and reduces the number of graph nodes from 22749 (GCNCL with no external knowledge) to 339 (ours).

DARK considers the type constraint of verbs and nouns when composing verb and noun into compositional action label by training an affordance scoring module, while GCNCL considers the constraint when building compositional action nodes by collecting the existing verb-noun pairs from NEIL (Chen et al., 2013). For fair comparison, we re-implement three versions of KG in GCNCL model. In "GT", we use the ground-truth verb-noun relationships that are presented in the dataset

Table 3: Combination for zero-shot learning in verb and noun classifiers. The top1 “open world" AUC is reported on the Epic-kitchen dataset.

	Verb-KG	Verb-SES	Verb-ConSE
Noun-KG	1.81	1.24	0.49
Noun-SES	0.40	0.44	0.32
Noun-ConSE	0.25	0.18	0.13

(open world setting). In “Affd", we only consider relationships in the same corpus with DARK. We use the relationships as a hard look-up since GCNCL only contains unweighted “hard" edges in its knowledge graph. In “Both", we use the union of the constraints in “GT" and “Affd". Under all the three circumstances, our DARK model outperforms other models by a large margin. For all experiments, we report the best results.

4.4 Ablations on different components

Zero-shot learning in verb/noun classifier: In DARK model, we do separate verb and noun classification in two branches. We investigate different implementations of zero-shot learning in verb/noun classifier. Specifically, we consider three options for both verb and noun, namely “KG", “SES" and “ConSE". “KG" stands for zero-shot learning by using knowledge graph to predict classification weights for unseen component with GloVe embedding (Pennington et al., 2014) as in (Kato et al., 2018). “SES" (Xu et al., 2015) is the best common embedding baseline in Table 1 using better BERT word embedding (Devlin et al., 2018) (based on observation in Table 5, BERT tends to have better performance). “ConSE" (Norouzi et al., 2013) learns a semantic structure aware embedding space compared to original word embeddings, which is modeled with graph. “ConSE" (Norouzi et al., 2013) is used as the zero-shot learning component in previous image-based action recognition task (Xu et al., 2019). It learns a semantic structure aware embedding space and we also use GloVe embedding. For better comparison of zero-shot learning component, we report the “open world” AUC on the Epic-kitchen dataset without using affordance (same as “ground-truth" affordance in macro open setting), thus excluding the influence of affordance prior. Different zero-shot learning combinations for verbs and nouns are reported in Table 3. Using “KG" for both verb / noun outperforms others by a large margin, and we take this approach in the rest experiments.

Table 4: Different verb knowledge graphs. We report the top1 AUC for verbs under GZL setting.

	WN dis	VN group	VN tree
one-way	1.86	0.83	1.93
two-way	×	×	1.79

Construction of verb knowledge graph: Compared to nouns, the concept of verb is relatively abstract and the relationship between verbs is hard to capture. We explore different ways of constructing the verb KG, namely, “WN dis", “VN group" and “VN tree". (The details of noun KG are discussed in the appendix.) In “WN dis", we use WordNet (Miller, 1995) structure and add edges between nodes if their LCH (Leacock and Chodorow, 1998) distance is bigger than a threshold. We also explore VerbNet (Kipper et al., 2008) which is designed to capture the semantic similarity of verbs. VerbNet categorizes verbs into different classes, and each class contains multiple verb members. To resolve the duplication in each class, we add edges between verbs in the same class, and denote this as “VN group". We also try adding a meta node for each class and connecting all its members to the meta node, denoted as “VN tree". Graphs of “WN dis" and “VN group" are naturally undirected. For “VN tree", we consider an additional “two-way" setting as in (Kampffmeyer et al., 2019), where a GCN model separates the parent-to-children and children-to-parent knowledge propagation into two stages to better model hierarchical graph structure. However, we do not observe performance improvement in this setting. In Table 4, we report top1 AUC for verbs using different KGs under the GZL(Chao et al., 2016) setting. “VN tree" in “one-way" gives the best prediction for verb, and we keep this configuration in rest experiments.

Affordance learning: We consider the compositional constraints between verbs and nouns (affordance) when composing the compositional action. We explore various ways of learning affordance in Table 5. In “Word-only" we train a word-embedding only model. And “Visual" represents the approach in method section where an additional projection module maps visual features to embedding space. For each, we explore two word embeddings, GLoVe (Pennington et al., 2014) and BERT (Devlin et al., 2018). In terms of score calculation, we try three different methods each. In “Concat-Scoring", we concatenate verb/noun features, and

Table 5: Top1 “marco open world" AUC on Epic-kitchen based on different affordance learning methods.

	Word-only		Visual	
	GLoVe	BERT	GLoVe	BERT
Concat-Scoring	1.49	1.59	1.48	1.60
Context-Scoring	1.49	1.59	1.49	×
Proj-Cosine	1.42	1.59	1.42	1.69
Lookup Table	1.35			
Uniform	1.46			
Ground Truth	1.81			

Table 6: Results (mAP) on Charades under GZL setting. Baselines and GCNCL results from (Kato et al., 2018).

	Model	All	Zero-shot
Baseline	Chance	1.37	1.00
	Triplet	10.41	7.82
	SES	10.14	7.81
	DEM	9.57	7.74
GCNCL	GCNCL-I+A	10.48	7.95
	GCNCL+A	10.53	8.09
Ours	DARK	11.21	8.38

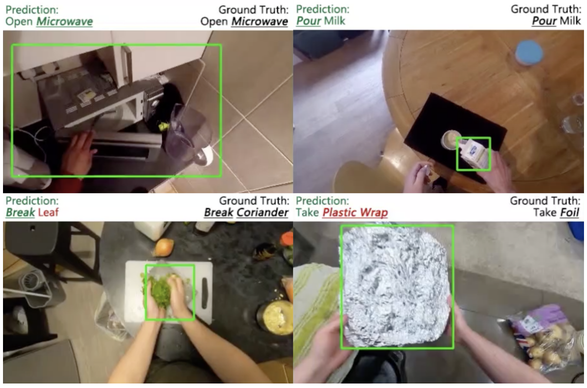

Figure 5: Qualitative Analysis. Underlines are unseen concepts, green for right predictions and red for wrong.

train a scoring model. In “Context-Scoring", instead of concatenating, for BERT the scoring model embeds verb-noun phrase together and averages their embeddings, and for GloVe we simply average their embeddings. In “Proj-Cosine", we project verb embedding to noun embedding space and calculate the cosine distance. We also try a lookup table, where affordance is one if the compositional pair exists in train set or knowledge bases, and zero otherwise. “Uniform" sets all affordance to be one, which means no weighting is applied. “Ground Truth" sets one for pairs existing in the dataset (train/test), equivalent to “open world". In all experiments, we use best configuration from Table 3, and label compositional pairs seen in training to one. BERT constantly improve affordance relationships in different methods. Lookup table performs worse than “Uniform" (no affordance) since some valid pairings are missing in knowledge bases.

4.5 Results on Charades dataset

We report results on Charades in Table 6. Following (Kato et al., 2018), we report mean average precision (mAP) and compare our model to theirs and baselines. We also report zero-shot classes ($V_sN_u + V_uN_s + V_uN_u$) separately but all predictions are made under GZL setting. Unlike Epic-Kitchen which contains ego-centric actions, Charades contains third-person view videos and cannot detect the mask of person's hand. Thus we directly learn the verb and noun feature disentanglement leveraging a discriminator and a disentanglement loss. Following (Peng et al., 2018), discriminator tries to adversarially classify noun label y_n from its verb feature, and feature extractor $\mathcal{F}$ goes against it. To better capture the multi-label property in Charades, we use an un-factorized classification model for actions in V_sN_s so they can be treated separately. Since we report the mAP results for fair comparison with GCNCL, we do not use affordance in our model. As indicated in (Kato et al., 2018), we also notice that the amount of improvement over baselines is not large, possibly because Charades is relatively small and easy to overfit. And this motivated us to propose a large-scale zero-shot compositional action recognition benchmark.

4.6 Qualitative error analysis

We also visualize some examples in Figure 5. The model misclassifies *coriander* as *leaf*, and *foil* as *plastic wrap* due to visual similarity.

5 Conclusion

In this paper, we propose DARK, a novel compositional action recognition model that reduces complexity from quadratic to linear, making the training more scalable. DARK generalizes to unseen verb-noun pairs, and can be combined with knowledge bases to produce state-of-the-art compositional action recognition results.

A Implementation Detail

To build the object feature extractor $\mathcal{F}_n$, we first use an off-the-shelf class-agnostic object detector to detect the bounding box of interacting objects. For the Charades (Sigurdsson et al., 2016) dataset, we use the detected object boxes generated by HOID (Wang et al., 2020). HOID model first detects the box of human, then based on the human's bounding box it detects interacting objects. We use the code publicly released by (Wang et al., 2020), with the default parameters provided by the author. We use the weights of the class-agnostic object detector provided on the project page. For the Epic-kitchen dataset (Damen et al., 2020, 2018), we use the pre-computed class-agnostic boxes provided by the authors. They use the model from (Shan et al., 2020), which detects human hands and locates the interacting objects. We use different models for object detection because Epic-kitchen (Damen et al., 2018) contains mostly ego-centric action videos while Charades (Sigurdsson et al., 2016) contains third-person view videos. For the Epic-kitchen dataset, we additionally use its pre-computed detected masks of human hands.

After the object boxes are detected, we run the Faster-RCNN (Girshick, 2015) model with the ResNet-101 backbone to extract the object features. We use the implementation provided by the Detectron2 (Wu et al., 2019) library, with the weights pre-trained on ImageNet (Deng et al., 2009). We obtain the features before the classifier layer in the Faster-RCNN model, which results in 2048 dimension object features. If we detect multiple boxes in one frame, we conduct max-pooling over their extracted features to obtain one feature representation for each frame. If no box is detected for a particular frame, we then extract the feature of the whole image as its object feature.

We sample several frames along the temporal axis of the video to conduct object detection. Since videos in the Charades (Sigurdsson et al., 2016) dataset may contain more than one action, we treat each frame in Charades dataset as one sample for training. For the Epic-kitchen (Damen et al., 2020, 2018) dataset whose videos contain only one action, we instead simply apply mean pooling over object features of sampled frames to obtain one feature representation for the whole video. We add fully-connected (FC) layers upon the fixed Faster-RCNN backbone to conduct feature extraction.

For verb features, we build our feature extractor $\mathcal{F}_v$ based on a standard two-stream Inception3D (Carreira and Zisserman, 2017) backbone pre-trained on the Kinetics dataset (Kay et al., 2017). We use both the RGB branch and the optical-flow branch, each producing a 1024 dimension feature in the layer Mixed_5c. We then concatenate them, resulting in a feature representation of 2048 dimension. For the Epic-kitchen dataset, we generate features first using the video input with the object cropped out. Then we do the same using the video input with everything cropped except for the detected hands in order to obtain hand gesture movement information. We further concatenate these two features to get a 4096 dimension feature. Similar to the object feature extractor, we add FC layers to features generated by the fixed Inception3D backbone. For the Charades dataset, since another disentanglement approach is used, we simply use the 2048 dimension feature.

Following common practice, we split the whole video into video clips with a small duration, and generate features for each clip during training and inference. For the Charades dataset, we sample 10 clips per video to conduct training and we treat each clip as a sample. Whereas for the Epic-kitchen dataset, we apply max pooling to the features of all the clips generated from one video to obtain one feature representation for the whole video.

Our model is implemented in PyTorch with Adam optimizer. We used in total around 20 GPUs through out the experiments. But a single run only needs 5 GPUs. (we launch parallel experiments)

B The Proposed Epic-kitchen Benchmark

We build our compositional action recognition benchmark based on the Epic-kitchen(Damen et al., 2020, 2018) dataset version two. We take the class that overlaps with pre-trained backbones into consideration when creating seen/unseen class splits. We find that there are 95 noun classes overlapping with ImageNet classes, and 23 verb classes overlapping with Kinetics classes, where the backbones that we use have been pre-trained. We make sure these overlapping classes stay in the seen split.

We then remove the tail verb and noun classes with less than 10 instances. The remaining dataset contains a total number of 76605 videos, including 90 verbs, 249 nouns, and 3629 compositional actions. We have 29 verbs in the seen category, and 61 verbs in the unseen category. On the other hand, 102 nouns are seen and 147 nouns are unseen.

The V_sN_s split contains 840 compositional actions, and 51228 samples. The V_uN_s split has 1073 compositional actions, and 10105 samples. For the V_sN_u split, there are 896 compositional actions and 11073 samples. And for the V_uN_u split, there are 820 compositional actions and 4199 samples.

Epic-Kitchen dataset is realized under the Creative Commons Attribution-NonCommercial 4.0 International License. The licence for non-Commercial use of Charades dataset can be found at http://vuchallenge.org/charades.html. We follow the intended usage of these two dataset.

C Noun Knowledge Graph Construction

We discuss the construction of the verb knowledge graph in the paper, due to the space limit, we present the details of the noun knowledge graph in this section. We construct the noun knowledge graph following (Wang et al., 2018)'s approach. We begin from the nouns presented in the dataset, and recursively search their hyper-norms using WordNet (Miller, 1995)'s lexical relationship to add to the graph. In addition, we augment the knowledge graph by adding nouns from ImageNet's ((Deng et al., 2009)) class labels.

When building noun knowledge graphs, we add an edge if two entities are direct synonyms or hyper-norms. Our model is built upon the graph convolution model implemented by (**?**). We use its plain GCN version without attention. And we use the "two-way" approach, which separates parent-to-children and children-to-parent knowledge propagation into two stages to better model the hierarchical graph structure. For noun knowledge graph learning, we use 300d GloVe (Pennington et al., 2014) embeddings as input.

D Disentanglement in Charades Dataset

Let X_v denote the input to the verb feature extractor $\mathcal{F}_v$, and X'_v denote the extracted verb features. Similarly, X_n is the input to $\mathcal{F}_n$ and X'_n is the extracted noun features.

$$X'_v = \mathcal{F}_v(X_v) \tag{8}$$
$$X'_n = \mathcal{F}_n(X_n) \tag{9}$$

To obtain disentangled verb / noun features, we take the idea from the previous paper (Peng et al., 2018). We use a discriminator to limit the information verb and noun features contain. The discriminator $\mathcal{D}_v$ tries to adversarially classify noun label y_n from its verb feature X'_v, and the feature extractor $\mathcal{F}_v$ goes against it via a minimax process. The discriminator helps to limit the information which verb feature X'_v contains about the nouns in the video. The same procedure happens for $\mathcal{D}_n$. We use one layer linear classifier for discriminator $\mathcal{D}_v$ and $\mathcal{D}_n$ and they output class predictions for the opposite branch. This leads to the disentanglement loss:

$$\mathcal{L}^v_{dis} = -\mathbf{CE}(\mathcal{D}_v(X'_v); y_n) \tag{10}$$
$$\mathcal{L}^n_{dis} = -\mathbf{CE}(\mathcal{D}_n(X'_n); y_v) \tag{11}$$

The **CE** refers to the cross-entropy loss. The overall loss for training the feature extractor $\mathcal{F}_v$, $\mathcal{F}_n$ and the classifier for seen classes $\mathcal{W}^{seen}_v$, $\mathcal{W}^{seen}_n$ is:

$$\mathcal{L}_v = \mathcal{L}^v_{cls} + \mathcal{L}^v_{dis} \tag{12}$$
$$\mathcal{L}_n = \mathcal{L}^n_{cls} + \mathcal{L}^n_{dis} \tag{13}$$

The definitions of $\mathcal{L}^v_{cls}$, $\mathcal{L}^n_{cls}$ are the same as discussed in the main paper.

A Word is Worth A Thousand Dollars:
Adversarial Attack on Tweets Fools Stock Prediction

Abstract

More and more investors and machine learning models rely on social media (e.g., Twitter and Reddit) to gather real-time information and sentiment to predict stock price movements. Although text-based models are known to be vulnerable to adversarial attacks, whether stock prediction models have similar vulnerability is underexplored. In this paper, we experiment with a variety of adversarial attack configurations to fool three stock prediction victim models. We address the task of adversarial generation by solving combinatorial optimization problems with semantics and budget constraints. Our results show that the proposed attack method can **achieve consistent success rates** and cause **significant monetary loss** in trading simulation by simply concatenating a perturbed but semantically similar tweet.

1 Introduction

The advance of deep learning based language models are playing a more and more important role in the financial context, including convolutional neutral network (CNN) (Ding et al., 2015), recurrent neutral network (RNN) (Minh et al., 2018), long short-term memory network (LSTM) (Hiew et al., 2019; Sawhney et al., 2021; Hochreiter and Schmidhuber, 1997), graph neutral network (GNN) (Sawhney et al., 2020a,b), transformer (Yang et al., 2020), autoencoder (Xu and Cohen, 2018), etc. For example, Antweiler and Frank (2004) find that comments on Yahoo Finance can predict stock market volatility after controlling the effect of news. Cookson and Niessner (2020) also show that sentiment disagreement on Stocktwits is highly related to certain market activities. Readers can refer to these survey papers for more details (Dang et al., 2020; Zhang et al., 2018; Xing et al., 2018).

Figure 1: An example of word-replacement adversarial attack. (Top) benign tweet leads `Stocknet` to predict stock going UP; (Bottom) adding an adversarial retweet leads **Stocknet** to predict stock going DOWN.

It is now known that text-based deep learning models can be vulnerable to adversarial attacks (Szegedy et al., 2014; Goodfellow et al., 2015). The perturbation can be at the sentence level (e.g., Xu et al., 2021; Iyyer et al., 2018; Ribeiro et al., 2018), the word level (e.g., Zhang et al., 2019; Alzantot et al., 2018; Zang et al., 2020; Jin et al., 2020; Lei et al., 2019; Zhang et al., 2021; Lin et al., 2021), or both (Chen et al., 2021). We are interested in whether such adversarial attack vulnerability also exists in stock prediction models, as these models embrace more and more human-generated media data (e.g., Twitter, Reddit, Stocktwit, Yahoo News (Xu and Cohen, 2018; Sawhney et al., 2021)). The adversarial robustness is a more critical issue in the context of stock prediction as anyone can post perturbed tweets or news to influence forecasting models. For example, a fake news ("Two Explosions in the White House and Barack Obama is Injured") posted by a hacker using the Associated-Press's Twitter account on 04/23/2013 erased $136

July 10-15, 2022

billion market value in just 60 seconds (Fisher, 2013). Although the event doesn't fall into the category of adversarial attack, it rings the alarm for traders who use (social) media information for their trading decisions.

To our best knowledge, it is the first paper to consider the adversarial attack in the financial NLP literature. Many attacks modify benign text directly (*manipulation attack*) and use them as model input; However, in our case, adversarial retweets enter the model along with benign tweets (*concatenation attack*), which is more realistic as malicious Twitter users can not modify others' tweets. In other words, we formulate the task as a text-concatenating attack (Jia and Liang, 2017; Le et al., 2021): we implement the attack by injecting new tweets instead of manipulating existing benign tweets. Our task is inspired and mimics the retweet function on social media, and uses it to feed the adversarial samples into the dataset. Despite various algorithms are proposed to generate manipulation attack, literature of concatenation attack on classification models is rare, with exceptions Le et al. (2021), Song et al. (2021) and Wang et al. (2020). Our paper provides extra evidence of their difference by investigating their performances in the financial domain.

The main challenge is to craft new and effective adversarial tweets. We solve the task by aligning the semantics with benign tweets so that the potential human and machine readers can't detect our adversarial tweets. To achieve that, we consider the generation task as a combinatorial optimization problem (Zang et al., 2020; Guo et al., 2021). Specific tweets are first selected, which are used as the target of perturbation on a limit number of words within the tweets. We then examine our attack method on three financial forecast models with *attack success rate*, *F1* and potential *profit and loss* as evaluation metrics. Results show that our attack method consistently achieves good success rate on the victim models. More astonishingly, the attack can cause additional loss of 23% to 32% if an investor trades on the predictions of the victim models (Fig. 4).

2 Adversarial Attack on Stock Prediction Models with Tweet Data

Attack model: Adversarial tweets. In the case of Twitter, adversaries can post malicious tweets which are crafted to manipulate downstream models that take them as input. We propose to attack by posting semantically similar adversarial tweets as retweets on Twitter, so that they could be identified as relevant information and collected as model input. For example, as shown in Fig 1, the original authentic tweet by the user *wallstreetbet7821* was "*$BHP announces the demerger of its non-core assets - details expected to be filled in on Tuesday.*" An adversarial sentence could be "*$BHP announces the demerger of its non-core assets - details expected to be exercised in on Tuesday.*". The outcome of the victim model switches to negative prediction from positive prediction when the retweet is added to the input.

The proposed attack method takes the practical implementation into its design consideration, thus has many advantages. First, the adversarial tweets are crafted based on carefully-selected relevant tweets, so they are more likely to pass the models' tweet filter and enter the inference data corpus. Secondly, adversarial tweets are optimized to be semantically similar to the original tweets so that they are not counterfactual and very likely to fool human sanity checks as well as the Twitter's content moderation system.

Attack generation: Hierarchical perturbation. The challenge of our attack method centers around how to select the optimal tweets and the token perturbations with the constraints of semantic similarity. In this paper, we formulate the task as a *hierarchical perturbation* consisting of three steps: *tweet selection*, *word selection* and *word perturbation*. In the first step, a set of optimal tweets is first selected as the target tweets to be perturbed and retweeted. For each selected tweet in the pool, the word selection problem is then solved to find one or more optimal words to apply perturbation. Word and tweet budgets are also introduced to quantify the strength of the perturbation.

We consider the **word replacemen**t and **deletion** for word perturbation (Garg and Ramakrishnan, 2020; Li et al., 2020). In the former case, the final step is to find the optimal candidate as replacement. A synonym as replacement is widely adopted in the word-level attack since it is a natural choice to preserve semantics (Zang et al., 2020; Dong et al., 2021; Zhang et al., 2019; Jin et al., 2020). Therefore, we replace target words with their synonyms chosen from synonym sets which contain the semantically closest words measured by the similarity of the GLOVE embedding (Jin et al., 2020).

Mathematical Formulation. We consider a multimodal stock forecast model $f(\cdot)$ that takes tweet collections $\{\boldsymbol{c_t}\}_{t=1}^{T}$ and numerical factors $\{\boldsymbol{p_t}\}_{t=1}^{T}$ as input, where t indexes the date when the data is collected. Peeking into the tweet collection, it contains $|\boldsymbol{c_t}|$ tweets for date t, namely, $\boldsymbol{c_t} = \{\boldsymbol{s_t^1}, \boldsymbol{s_t^2}, ..., \boldsymbol{s_t^{|c_t|}}\}$. Each tweet $\boldsymbol{s_t^i}$ is a text-based sentence of length $|\boldsymbol{s_t^i}|$, denoted as $\boldsymbol{s_t^i} = (w_t^{i,1}, ..., w_t^{i,j}, ..., w_t^{i,|\boldsymbol{s_t^i}|})$, for $i = 1, ..., |\boldsymbol{c_t}|$. A directional financial forecast model takes domains of tweets and numerical factors as input, and yields prediction for stocks' directional movement $y \in \{-1, 1\}$:

$$\hat{y}_{t+1} = f(\boldsymbol{c_{t-h:t}}, \boldsymbol{p_{t-h:t}}), \quad (1)$$

h is the looking-back window for historical data.

The hierarchical perturbation can be cast as a combinatorial problem for tweet selection $\boldsymbol{m}$, word selection $\boldsymbol{z}$ and replacement selection $\boldsymbol{u}$. The boolean vector $\boldsymbol{m}$ indicates the tweets to be selected. For i-th tweet, vector $\boldsymbol{z_i}$ indicates the word to be perturbed. As for the word perturbation task, another boolean vector $\boldsymbol{u_{i,j}}$ selects the best replacement. It follows that the hierarchical perturbation can be formulated as

$$\boldsymbol{c_t'} = (\boldsymbol{1} - \boldsymbol{m} \cdot \boldsymbol{z}) \cdot \boldsymbol{c_t} + \boldsymbol{m} \cdot \boldsymbol{z} \cdot \boldsymbol{u} \cdot S(\boldsymbol{c_t}), \quad (2)$$

where $\cdot$ denotes element-column wise product, $\boldsymbol{m} \cdot \boldsymbol{z}$ indicates the selected words in selected tweets, $\boldsymbol{m} \cdot \boldsymbol{z} \cdot \boldsymbol{u}$ indicates selected synonyms for each selected word, and $S(\cdot)$ is a element-wise synonym generating function. Consequently, given attack loss $\mathcal{L}$, generation of adversarial retweets can be formulated as the optimization program $\min_{\boldsymbol{m},\boldsymbol{z},\boldsymbol{u}} \mathcal{L}(\boldsymbol{c_t'} \cup \boldsymbol{c_{t-h:t}}, \boldsymbol{c_{t-h:t}} | \boldsymbol{p_{t-h:t}}, f)$, subject to the budget constraints: *a)* $\boldsymbol{1}^T \boldsymbol{m} \leq b_s$, *b)* $\boldsymbol{1}^T \boldsymbol{z_i} \leq b_w, \forall i$ and *c)* $\boldsymbol{1}^T \boldsymbol{u_{i,j}} = 1, \forall i, j$, where b_s and b_w denote the tweet and word budgets. It is worth to stress that perturbation is only applied to the date (t) when the attack is implemented to preserve the temporal order.

To solve the program, we follow the convex relaxation approach developed in (Srikant et al., 2021). Specifically, the boolean variables (for tweet and word selection) are relaxed into the continuous space so that they can be optimized by gradient-based methods over a convex hull. Two main implementations of the optimization-based attack generation method are proposed: *joint optimization* (JO) solver and *alternating greedy optimization* (AGO) solver. JO calls projected gradient descent method to optimize the tweet and word selection variables and word replacement variables simultaneously. AGO uses an alternative optimization procedure to sequentially update the discrete selection variables and the replacement selection variables. More details on the optimization program and the solvers can be found in Appendix A.

3 Experiments

Dataset & victim models. We evaluate our adversarial attack on a stock prediction dataset consisting of 10,824 instances including relevant tweets and numerical features of 88 stocks from 2014 to 2016 (Xu and Cohen, 2018). Three models (**`Stocknet`** (Xu and Cohen, 2018), **`FinGRU`** based on GRU (Cho et al., 2014) and **`FinLSTM`** based on LSTM (Hochreiter and Schmidhuber, 1997)) of binary classification are considered as victims in this paper. We apply our attack to instances on which the victim models make correct predictions.

Evaluation metrics. Attack performance is evaluated by two metrics: *Attack Success Rate* (ASR) and victim model's *F1* drop after attack. ASR is defined as the percentage of the attack efforts that changes the model output. The two metrics gauge the efficacy of the attack and its impact on model performance: More efficient attack leads to higher ASR and more decline of F1. Moreover, we simulate a ***Long-Only Buy-Hold-Sell*** strategy (Sawhney et al., 2021; Feng et al., 2019) with victim models, and calculate the *Profit and Loss* (PnL) for each simulation. Assume a portfolio starts with initial net value \$10000 (100%), its net value at the end of test period reflects the profitability of the trading strategy and the underlying model. Consequently, the change in PnLs measures the monetary impact of our attack. More details on the dataset, victim models and evaluation metrics are housed in Appendix B.

4 Results

Attack performance with single perturbation. The experiment results for the concatenation attack with word replacement perturbation is shown in Table 1 (with tweet and word budgets both as 1). For both JO and AGO, ASR increases by roughly 10% and F1 drops by 0.1 on average in comparison to the random attack. Such performance drop is considered significant in the context of stock prediction given that the state-of-the-art prediction accuracy of interday return is only about 60%.

Model	ASR(%)				F1			
	NA	RA	JO	AGO	NA	RA	JO	AGO
Stocknet	0	4.5	**16.8**	11.8	1	0.96	**0.84**	0.88
FinGRU	0	5.1	**16.4**	14.1	1	0.95	**0.85**	0.87
FinLSTM	0	11.9	16.5	**19.7**	1	0.89	0.85	**0.78**

Table 1: Performance of the various adversarial attacks. NA: no attack; RA: random attack; JO: joint optimization; and AGO: alternating greedy optimization.

Effect of attack budget. We report the effect of different attack budgets on the attack performance in Fig. 2. We observe that the more budgets allowed (perturbing more tweets and words), the better the attack performance, but the increase is not significant. It appears that the attack performance becomes saturated if we keep increasing the attack budgets. In fact, the attack with budget of one tweet and one word is the most cost effective, provided that it introduces minimum perturbation but achieves a relatively similar ASR.

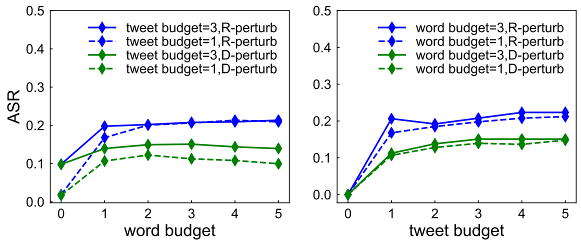

Figure 2: Effect of attack budgets on ASR with Stocknet as victim model and with JO solver. r-perturb: word replacement; d-perturb: word deletion.

Manipulation vs concatenation attack. We focus on concatenation attack in this paper since we believe it is distinct from manipulation attack. We investigate the difference by applying the same method of tweet generation to implement manipulation attack, where the adversarial tweets replace target tweets instead. The experiment runs with one word budget and one twee budget, and the results are reported in Fig. 3.

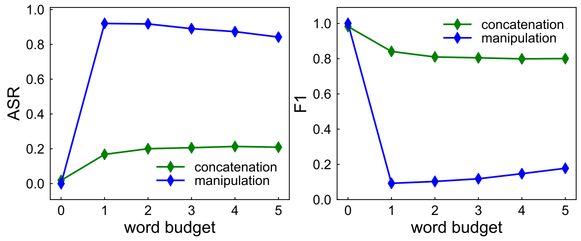

Figure 3: Comparison between **manipulation** and **concatenation** attacks with **word-replacement** perturbation method. `Stocknet` is the victim model.

It is clear that manipulation attack remarkably outperforms concatenation attack in terms of ASR and F1. Even though the success rate of concatenation attack lags behind the state-of-the-art textual attack, the manipulation attack achieves performance of the same ballpark, which demonstrates the efficacy of optimization-based attack and our solvers. More importantly, it implies that the attack is not transferable between the two tasks, documenting more evidence on language attack transferability (Yuan et al., 2021; He et al., 2021). The bottom line is that they are two different tasks under different assumptions. Researchers should take downstream scenarios into account when develop attack models.

Trading simulation. The ultimate measure of a stock prediction model's performance is profitability. Fig. 4 plots the *profit and loss* of the same trading strategy with `Stocknet` as the prediction model with or without the attack – JO is used to generate adversarial retweets. For each simulation, the investor has $10K (100%) to invest; the results show that the proposed attack method with a retweet with only a single word replacement can cause the investor an additional $3.2K (75%-43%) loss to their portfolio after about 2 years.

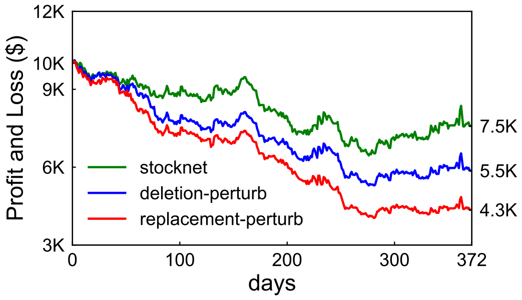

Figure 4: *Profit and Loss* with `Stocknet` as the victim model using *Long-Only Buy-Hold-Sell* strategy for 2 years with $10K initial investment. Green line: trading using `Stocknet` without attack; Blue line: concatenation attack with **deletion perturbation**; Red line: concatenation attack with **replacement perturbation**.

5 Conclusion

This work demonstrates that our adversarial attack method consistently fools various financial forecast models even with physical constraints that the raw tweet can not be modified. Adding a retweet with only one word replaced, the attack can cause 32% additional loss to our simulated investment portfolio. Via studying financial model's vulnerability, **our goal is to raise financial community's awareness of the AI model's risks**, so that in the future we can develop more robust human-in-the-loop AI architecture (Wang et al., 2019) to cope with this and other real-world attacks, including black-box attack, unknown input domains, etc.

A Mathematical Formation

A.1 Financial Forecast Model

Massive amounts of text data are generated by millions of users on Twitter every day. Among a variety of discussion, stock analysis, picking and prediction are consistently one of the trending topics. And investors often use the Twitter *cashtag* function (a $ symbol followed by a ticker) to organize their particular thoughts around one single stock, e.g., $AAPL, so that users can click and see the ongoing discussions. Textual data on Twitter is collectively generated by all of its users via posting tweets. Financial organizations and institutional investors often ingest the massive text data in real time and incorporate them or their latent representation into their stock prediction models.

We consider the multimodal stock forecast models that take tweet collections $\{\boldsymbol{c_t}\}_{t=1}^{T}$ and numerical factors $\{\boldsymbol{p_t}\}_{t=1}^{T}$ as input,where t indexes the date when the data is collected. The numerical factors are usually mined from historical price, fundamentals and other alternative data sources. In this paper, we assume that the domain of numerical factors is unassailable since they are directly derived from public records. Therefore, the objective of adversary is to manipulate model output by injecting perturbation to the textual domain $\{\boldsymbol{c_t}\}_{t=1}^{T}$. Peeking into the tweet collection, it contains $|\boldsymbol{c_t}|$ tweets for date t, namely, $\boldsymbol{c_t} = \{\boldsymbol{s_t^1}, \boldsymbol{s_t^2}, ..., \boldsymbol{s_t^{|c_t|}}\}$. Each tweet $\boldsymbol{s_t^i}$ is a text-based sentence of length $|\boldsymbol{s_t^i}|$, denoted as $\boldsymbol{s_t^i} = (w_t^{i,1}, ..., w_t^{i,j}, ..., w_t^{i,|\boldsymbol{s_t^i}|})$, for $i = 1, ..., |\boldsymbol{c_t}|$. A directional financial forecast model takes domains of tweets and numerical factors as input, and yields prediction for stocks' directional movement $y \in \{-1, 1\}$:

$$\hat{y}_{t+1} = f(\boldsymbol{c_{t-h:t}}, \boldsymbol{p_{t-h:t}}), \tag{3}$$

where h is the looking-back window for historical data.

A.2 Attack Model

Let $\boldsymbol{c'_t}$ be the perturbed tweet collection at time t created by solving the hierarchical perturbation problem. To formalize the perturbation task, we introduce boolean vector variable $\boldsymbol{m} \in \{0,1\}^{n_m}$ to indicate the tweets to be selected. If $m_i = 1$, then i-th tweet is the target tweet to be perturbed and retweeted. Besides, for i-th tweet, vector $\boldsymbol{z_i} \in \{0,1\}^{n_z}$ indicates the word to be perturbed. As for the word perturbation task, another boolean vector $\boldsymbol{u_{i,j}} \in \{0,1\}^{n_u}$ selects the best replacement. n_m and n_z and n_u denote the maximum amount of tweets, maximum amount of words in each tweet, and the amount of synonyms for each word, respectively. We identify deletion perturbation as a special case of replacement with $u_{i,j,k} = 1$ only for padding token, so that the task degenerates to tweet selection and word selection. Let vector $\boldsymbol{z} \in \{0,1\}^{n_m \times n_z}$ denote n_m different $\boldsymbol{z_i}$ vector, and $\boldsymbol{u} \in \{0,1\}^{n_m \times n_z \times n_u}$ denote $n_m \times n_z$ different $u_{i,j}$ vectors. It follows that the hierarchical perturbation can be defined as

$$\begin{aligned} \boldsymbol{c'_t} &= (\mathbf{1} - \boldsymbol{m} \cdot \boldsymbol{z}) \cdot \boldsymbol{c_t} + \boldsymbol{m} \cdot \boldsymbol{z} \cdot \boldsymbol{u} \cdot S(\boldsymbol{c_t}) \\ s.t. \quad & \mathbf{1}^T \boldsymbol{m} \le b_s, \\ & \mathbf{1}^T \boldsymbol{z_i} \le b_w, \forall i, \\ & \mathbf{1}^T \boldsymbol{u_{i,j}} = 1, \forall i, j, \end{aligned} \tag{4}$$

where $\cdot$ denotes element-column wise product, b_s denotes tweet budget, b_w denotes word budget and $S(\cdot)$ is element-wise synonym generating function.

Adversarial retweets are the then passed into downstream financial forecast model $f(\cdot)$ along with benign tweets. Attack success is achieved if the adversarial tweets manage to fool the downstream model, and change the model output. Financial forecast model usually takes observation of multiple steps as input to appreciate the temporal dependence. However, adversary can only inject adversarial retweets at present time. That is, when run the model on day t to predict price movement on day $t+1$, retweets only enter tweet collection for day t; collections for days prior to t remain static. Consequently, generation of successful adversarial retweets is formulated as the following optimization program:

$$\begin{aligned} \min_{\boldsymbol{m,z,u}} \quad & \mathcal{L}(\boldsymbol{c'_t} \cup \boldsymbol{c_{t-h:t}}, \boldsymbol{c_{t-h:t}} | \boldsymbol{p_{t-h:t}}, f) \\ s.t. \quad & \text{constraint in (4)}, \end{aligned} \tag{5}$$

where $\mathcal{L}$ denotes the attack loss. We adopt the cross-entropy loss for our attack since it is untargeted attack (Srikant et al., 2021). Other classification-related loss may be applied according to adversary's objective. Furthermore, we also add entropy-based regularization to encourage sparsity of optimization variables (Dong et al., 2021).

A.3 Methodology

The challenge of solving program (5) lies in the combinatorial and hierarchical nature. We first relax the boolean variables into continuous space so that they can be solved by gradient-based solvers. A common workaround for combinatorial optimization is to solve an associated continuous optimization over convex hull (Dong et al., 2021; Srikant et al., 2021). An computationally efficient fashion is to optimize over a convex hull constructed with linear combination of candidate set, and the optimal replacement goes with word with highest weight (Dong et al., 2021). However, this approach doesn't fit in the hierarchical tweet and word selection problem. For example, in order to select the optimal target word, one need to sum over the embedding of all words in the tweet, so the tweet collapses into embedding for one hypothetical word. Similarly, different tweets collapse to one hypothetical tweet, or one hypothetical word when one jointly selects tweets and words.

Joint optimization solver (JO). As a remedy, we propose a *joint optimization solver* that combines projected gradient descent and convex hull to jointly optimize $\boldsymbol{m}$, $\boldsymbol{z}$ and $\boldsymbol{u}$. Replacement selection is optimized over the convex hull:

$$\boldsymbol{c}'_{\boldsymbol{t}} = (1 - \boldsymbol{m} \cdot \boldsymbol{z}) \cdot \boldsymbol{c}_{\boldsymbol{t}} + \boldsymbol{m} \cdot \boldsymbol{z} \cdot conv(\boldsymbol{u}, S(\boldsymbol{c}_{\boldsymbol{t}})),$$

where

$$conv(\boldsymbol{u}, S(\boldsymbol{c}_{\boldsymbol{t}})) = \{\sum_k \hat{u}_{i,j,k} S(w_{i,j,k}), \forall i, j\},$$

and

$$\hat{u}_{i,j,k} = \frac{exp(u_{i,j,k})}{\sum_k exp(u_{i,j,k})}.$$

The problem of (5) is then solved by optimizing $\hat{\boldsymbol{u}}$. Unlike $\boldsymbol{u}$, $\boldsymbol{m}$ and $\boldsymbol{z}$ are optimized directly via projected gradient descent (PGD). Moreover, when $\boldsymbol{m}$ is one-hot vector, it determines the tweets to be retweeted, and those retweets are then added into tweet collection. However, $\boldsymbol{m}$ is continuous during optimization, so we retweet all the collected tweets and add them into tweet collection, which helps generate and back-propagate gradients for all the entries of $\boldsymbol{m}$. After the optimization is solved, we map the continuous solution into one-hot vector by selecting top b_s highest m_i.

Alternating greedy optimization solver (AGO). Greedy optimization is usually computational ineffective since a vast amount of inquiries is required when we collect large amount of tweets and have high attack budget. To mitigate the problem, we alternate the optimization over $\boldsymbol{m}$, $\boldsymbol{z}$ and $\boldsymbol{u}$. The aforementioned convex hull approach is adopted for finding optimal $\boldsymbol{u}$. The difference lies on the path to solve tweet and word selection problems. More specifically, we alternatively search the optimal target tweets and words which achieve the highest increases in prediction loss. For tweet selection, we mimic the physical attack scenario, and new retweets are added into tweet collection during the greedy search. Depending on the adversary's objective, different metrics may be used to measure the importance of each tweet and word. For example, Alzantot et al. (2018) use predicting probability to determine the selection of words; Ren et al. (2019) propose probability weighted word saliency as criterion for word selection; Jin et al. (2020) calculate the prediction change before and after deletion as word importance.

B Experimental Settings

B.1 Dataset

We evaluate our adversarial attack on a stock prediction dataset (Xu and Cohen, 2018). The dataset contains both tweets and historical prices (e.g., open, close, high, etc) for 88 stocks of 9 industries: *Basic Materials, Consumer Goods, Healthcare, Services, Utilities, Conglomerates, Financial, Industrial Goods and Technology.* Since we consider the task of binary classification, data instances are supposed to labelled positive and negative for upward and downward movement respectively.

Moreover, it is observed that the dataset contains a number of instances with exceptionally minor price movements. In practice, minor movement is hard to be monetized due to the existence of transaction cost. Therefore, an upper threshold of 0.55% and a lower threshold of -0.5% are introduced. Specifically, stocks going up more than 0.55% in a day are labeled as positive, those going down more than -0.5% are labeled as negative, and the minor moves in between are filtered out. As argued in (Xu and Cohen, 2018), the particular thresholds are carefully selected to balance the two classes.

In addition, the sampling period spans from 01/01/2014 to 01/01/2016. We split the dataset into train and test set on a rolling basis. This special program improves the similarity between distributions of train set and test set, which is widely adopted on temporal dataset. It leaves us 9416 train instances and 1408 test instances in 7 nonconsecutive periods. For the text domain, the dataset contains

57533 tweets in total.

B.2 Victim Models

Stocknet. A variational Autoencoder (VAE) that takes both tweets and price as input (Xu and Cohen, 2018). Tweets are encoded in hierarchical manner within days, and then modeled sequentially along with price features. It consists of three main components in bottom-up fashion. Market Information Encoder first encodes tweets and prices to a latent representation of 50 dimensions for each day. Variational Movement Decoder infers latent vectors of 150 dimensions and then decodes stock movements. At last, a module called Attentive Temporal Auxiliary integrates temporal loss through an attention mechanism. We train the model on the dataset from scratch with the same configurations as Xu and Cohen (2018).

FinGRU. A binary classifier that takes numerical features and tweets as input. All features are encoded sequentially by GRU (Cho et al., 2014) to exploit the temporal dependence. The model adopts the same Market Information Encoder as Stocknet. Latent representation of tweets and prices are then fed into a layer of GRU with attention mechanism to integrate temporal information. We train the model with an Adam optimizer (Kingma and Ba, 2015) and learning rate of 0.005. The checkpoint achieves the best performance on test dataset among 100 epochs is adopted as the victim model.

FinLSTM. A binary classifier identical to FinGRU, but utilizes LSTM (Hochreiter and Schmidhuber, 1997) to encode temporal dependence. The model is trained in the same manner as FinGRU.

B.3 Evaluation Metrics

Following Srikant et al. (2021), we evaulate the attack on those examples in the test set that are correctly classified by the target models. It provides direct evidence of the adversarial effect of the input perturbation and the model robustness. In the specific application of financial forecast, it makes more sense to manipulate correct prediction than incorrect ones. The following two common metrics are adopted to evaluate attack performance.

Attack Success Rate. ASR is defined as the percentage of the attack efforts that make the victim model misclassify the instances that are originally correctly classified. Mathematically, $ASR = \frac{\sum_t \delta(\hat{y}'_t \neq y_t)}{\sum_t \delta(\hat{y}_t = y_t)}$, where $\hat{y}_t$ is the unperturbed model prediction, $\hat{y}'_t$ the model prediction with perturbation, and y_t the ground-truth label. ASR characterizes the capability of the attack model, and higher the ASR, the better the attack.

F1 Score. F1 gauges the prediction performance of the victim models. Since we only consider the samples that are correctly predicted, the F1 score in the case of no attack is 1. Apparently, the drop of the F1 score of caused by the perturbation demonstrates the performance of the attack method. Unlike ASR, the drops of F1 score gauge the direct impact on the model performance: more successful attack leads to lower post-attack F1 score.

Profit and Loss. This widely-used financial indicator measures the profitability of a trading strategy. Assume that the initial net values are \$10K (100%), accumulate profit and loss for each trade, we can then calculate the final net value of the portfolio and *profit and loss*. A binary financial forecast model can be exploited in many ways, and support various trading strategies, which usually lead to different PnLs. In this paper, we use a simple ***Long-Only Buy-Hold-Sell*** strategy (Sawhney et al., 2021; Feng et al., 2019). More specifically, we *buy* stock(s) on Day T if the model predicts these stocks go up on Day $T+1$, *hold* for one day, and *sell* these stocks the next day no matter what prices will be, and repeat it. We do not *short* a stock even if the model predicts a negative move in the second day.

Besides, when the model makes positive prediction on more than one stocks, the money is evenly invested to the stock pool of positive prediction. For example, suppose that we stand on day 4 with portfolio value \$12K. If the model gives positive prediction on 10 of 88 stocks for day 5, we invest 10% of the total wealth (\$1.2K) to each stock, and sell them at closing prices of day 5. The process continues until the end of the test periods, and the resulting net value of the portfolio is used to calculate the profit and loss of the underlying model.

The buy-hold-sell strategy monetizes the prediction performance of financial forecast models by betting on the their predictions. The PnL reflects the profitability of the underlying models, even if it is usually influenced by many other confounding factors. Most importantly, the changes of PnLs caused by perturbation on the victim models only gauge the monetary consequence of our attack,

Model	**ASR(%)**				**F1**			
	NA	RA	JO	AGO	NA	RA	JO	AGO
Stocknet	0	3.6	12.1	11.0	1	0.97	0.89	0.89
FinGRU	0	4.0	10.2	10.6	1	0.96	0.85	0.91
FinLSTM	0	11.9	12.1	11.6	1	0.89	0.89	0.89

Table 2: Results for concatenation attack with deletion perturbation and budgets 1. NA and RA stand for no attack and random attack respectively, serving as benchmarks.

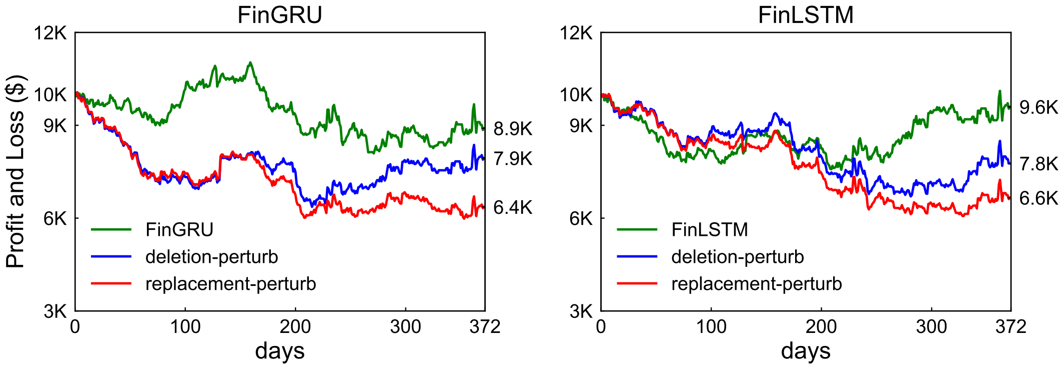

Figure 5: Effect on *Profit and Loss* of various perturbation methods on FinGRU and FinLSTM.

since all else are equal.

C Supplemental Experiment Results

C.1 Replacement vs deletion perturbation.

We report results for concatenation attack with only the *replacement perturbation* in the main text in Table 1. Here we also report results for the *deletion perturbation* in Table 2. Attacks conducted via deletion perturbation in general perform worse than the results of replacement perturbation. We observe ASRs via JO and AGO fall by 5.1% and 4.1% respectively compared with the replacement perturbation. Accordingly, F1 slightly increases as attack performance worsens. There is no significant difference between the two optimizers (JO and AGO) in the case of deletion perturbation, but JO is preferable in terms of optimization efficiency.

Moreover, we also simulate the trading profit and loss based on FinGRU and FinLSTM. For the sake of consistency, the two models are under concatenation attack with replacement perturbation. Same as our main results, the attack is optimized by JO solver. The simulation results are reported in Figure 5, which provides further evidence for the potential monetary loss caused by our adversarial attack. Replacement perturbation again outperforms deletion perturbation in the case of FinGRU and FinLSTM.

C.2 Effect of Iteration Number

We experiment with the optimizer to perform gradient descent or greedy search for up to 10 rounds before yielding the final solution. To visualize the effect of iteration, we plot the loss trajectory and ASR along with the optimization iterations in Figure 6. We also collect the average model loss of attack instances at each iteration, and then normalize the loss to set the initial loss as 1. Therefore, the loss trajectory visualization reveals the percentage loss drop during the optimization. We consider two different perturbations (replacement and deletion) under concatenation attacks. The attack is optimized with the JO solver.

The three charts on the first row of Figure 6 show that optimizations on all three victim models quickly converge after 4 iterations in our experiment. Accordingly, ASRs rise gradually during the first 4 iterations, but then flattens or even slides afterward. Such results suggest that our solvers can find the convergence in just a few iterations. Therefore, it makes our attack computationally effective, and insensitive to hyperparameter of iteration number.

D Regularization on Attack Loss.

The experiment results reported in the main text are generated with the sparsity regularization. We

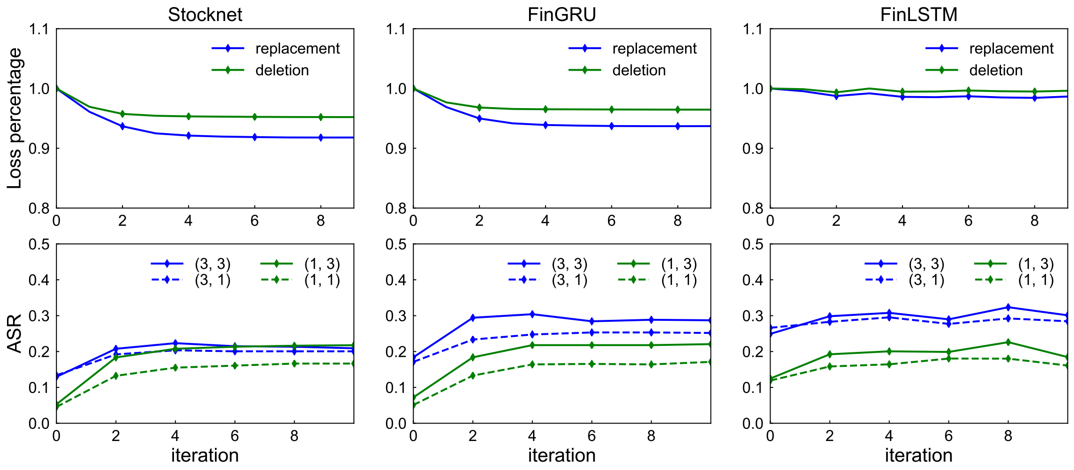

Figure 6: Iteration number effect on prediction loss and attack success rate. The three plots on the first row show the loss trajectory during optimization for the three victim models, and the bottom row reports the ASRs trajectory. The legends for the bottom-row charts read as (tweet budget, word budget).

also run ablation experiments that remove sparsity regularization. The results are consistent with our conclusion. Furthermore, inspired by (Srikant et al., 2021), we try smoothing attack loss to stabilize the optimization. We add Gaussian noise to optimization variables and evaluate the attack 10 times. The loss average is then used as the final loss for backpropagation. The results show that loss smoothing does not contribute to attack performance in our experiment as it does in Srikant et al. (2021).

E Attack Word Analysis

To qualitatively understand what kinds of words and tweets are being selected in the perturbation and retweet, we compare our tweet corpus and the selected word replacements with 15 corpora of different genres in Brown corpus via Linguistic Inquiry and Word Count program (LIWC) (Tausczik and Pennebaker, 2010). As Brown corpus does not have a financial genre, we also use Financial Phrase Bank (Malo et al., 2014). We then run K-means clustering on these 18 corpora based on the feature matrix from LIWC. As shown in Figure 7, financial corpora (red), Brown general word corpus (green), and attack words (blue) are grouped into three clusters, indicating the inherent difference of those text genres. Moreover, we observe that target words identified by our solvers (red "tweet" and blue "attack words" dots) are closer to financial corpora than "random attack words".

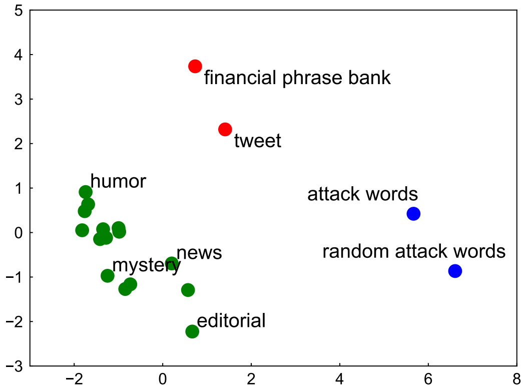

Figure 7: Corpora clusters. 18 corpora are grouped into 3 clusters based on features from LIWC. In order to visualize the clusters, principal component analysis is applied to the features to find the first 2 principal components, which are then used as x-axis and y-axis to generate this figure.

F Example of Adversarial Retweet

Table 3 reports 10 adversarial retweets generated in concatenation attack mode with JO and AGO solver and replacement perturbation. For all the examples, the victim model predicts positive outcomes originally, and but predicts negative outcomes after adding the adversarial retweet.

Building Multilingual Machine Translation Systems That Serve Arbitrary *X*-*Y* Translations

Akiko Eriguchi[*] [†], **Shufang Xie**[*] [‡], **Tao Qin**[‡], and **Hany Hassan Awadalla**[†]
[†]Microsoft [‡]Microsoft Research Asia

Abstract

Multilingual Neural Machine Translation (MNMT) enables one system to translate sentences from multiple source languages to multiple target languages, greatly reducing deployment costs compared with conventional bilingual systems. The MNMT training benefit, however, is often limited to many-to-one directions. The model suffers from poor performance in one-to-many and many-to-many with zero-shot setup. To address this issue, this paper discusses how to practically build MNMT systems that serve arbitrary `X-Y` translation directions while leveraging multilinguality with a two-stage training strategy of pretraining and finetuning. Experimenting with the WMT'21 multilingual translation task, we demonstrate that our systems outperform the conventional baselines of direct bilingual models and pivot translation models for most directions, averagely giving +6.0 and +4.1 BLEU, without the need for architecture change or extra data collection. Moreover, we also examine our proposed approach in an extremely large-scale data setting to accommodate practical deployment scenarios.

1 Introduction

Multilingual Neural Machine Translation (MNMT), which enables one system to serve translation for multiple directions, has attracted much attention in the machine translation area (Zoph and Knight, 2016; Firat et al., 2016). Because the multilingual capability hugely reduces the deployment cost at training and inference, MNMT has actively been employed as a machine translation system backbone in recent years (Johnson et al., 2017; Hassan et al., 2018).

Most MNMT systems are trained with multiple English-centric data for both directions (e.g., English → {French, Chinese} (`En-X`) and {French, Chinese} → English (`X-En`)). Recent work (Gu et al., 2019; Zhang et al., 2020; Yang et al., 2021b) pointed out that such MNMT systems severely face an off-target translation issue, especially in translations from a non-English language X to another non-English language Y. Meanwhile, Freitag and Firat (2020) have extended data resources with multi-way aligned data and reported that one complete many-to-many MNMT can be fully supervised, achieving competitive translation performance for all `X-Y` directions. In our preliminary experiments, we observed that the complete many-to-many training is still as challenging as one-to-many training (Johnson et al., 2017; Wang et al., 2020), since we have introduced more one-to-many translation tasks into the training. Similarly reported in the many-to-many training with zero-shot setup (Gu et al., 2019; Yang et al., 2021b), the complete MNMT model also suffers from capturing correlations in the data for all the `X-Y` directions as one model training, due to highly imbalanced data.

In this paper, we propose a two-stage training for complete MNMT systems that serve arbitrary `X-Y` translations by 1) pretraining a complete multilingual many-to-many model and 2) finetuning the model to effectively transfer knowledge from pretraining to task-specific multilingual systems. Considering that MNMT is a multi-task learner of translation tasks with "multiple languages", the complete multilingual model learns more diverse and general multilingual representations. We transfer the representations to a specifically targeted task via many-to-one multilingual finetuning, and eventually build multiple many-to-one MNMT models that cover all `X-Y` directions. The experimental results on the WMT'21 multilingual translation task show that our systems have substantial improvement against conventional bilingual approaches and many-to-one multilingual approaches for most directions. Besides, we discuss our proposal in the

light of feasible deployment scenarios and show that the proposed approach also works well in an extremely large-scale data setting.

2 Two-Stage Training for MNMT Models

To support all possible translations with $|L|$ languages (including English), we first train a complete MNMT system on all available parallel data for $|L| \times (|L| - 1)$ directions. We assume that there exist data of $(|L| - 1)$ English-centric language pairs and remaining $\frac{(|L|-1)\times(|L|-2)}{2}$ non-English-centric language pairs, which lets the system learn multilingual representations across all $|L|$ languages. Usually, the volume of English-centric data is much greater than non-English-centric one. Then, we transfer the multilingual representations to one target language L by finetuning the system on a subset of training data for many-to-L directions (i.e., **multilingual many-to-one finetuning**). This step leads the decoder towards the specifically targeted language L rather than multiple languages. As a result, we obtain $|L|$ multilingual many-to-one systems to serve all `X-Y` translation directions. We experiment with our proposed approach in the following two settings: 1) WMT'21 large-scale multilingual translation data with 972M sentence pairs and 2) our in-house production-scale dataset with 4.1B sentence pairs.

3 WMT'21 Multilingual Translation Task

We experiment with two small tasks of the WMT'21 large-scale multilingual translation task. The tasks provide multilingual multi-way parallel corpora from the Flores 101 data (Wenzek et al., 2021). The parallel sentences are provided among English (en), five Central and East European languages of {Croatian (hr), Hungarian (hu), Estonian (et), Serbian (sr), Macedonian (mk)} for the task 1, and five Southeast Asian languages of {Javanese (jv), Indonesian (id), Malay (ms), Tagalog (tl), Tamil (ta)} for the task 2. We removed sentence pairs either of whose sides is an empty line, and eventually collected the data with (English-centric, Non-English-centric)=(321M, 651M) sentence pairs in total. The data size per direction varies in a range of 0.07M-83.9M. To balance the data distribution across languages (Kudugunta et al., 2019), we up-sample the low-resource languages with temperature=5. We append language ID tokens at the end of source sentences to specify a target language (Johnson et al., 2017). We tokenize the data with the SentencePiece (Kudo and Richardson, 2018) and build a shared vocabulary with 64k tokens.

We train Transformer models (Vaswani et al., 2017) consisting of a m-layer encoder and n-layer decoder with (hidden dim., ffn dim.) =(768, 3072) in a complete multilingual many-to-many fashion. We have two settings of (m, n) = (12, 6)

Table 1: Average sacreBLEU scores for many-to-L directions on both Task 1 and 2, and the data statistics of the corresponding L-centric training data (L={en, hu, hr, sr, et, id, ms, tl, mk, jv, ta}). All the multilingual systems including many-to-one baselines and the proposed model are 12E6D. Note that the "Pivot-based" system for many-to-English directions is identical to "Bilingual".

for "12E6D" and (24, 12) for "24E12D" , to learn diverse multilingual dataset. The model parameters are optimized by using RAdam (Liu et al., 2020) with an initial learning rate of 0.025, and warm-up steps of 10k and 30k for the 12E6D and 24E12D model training, respectively. The systems are pretrained on 64 V100 GPUs with a mini-batch size of 3072 tokens and gradient accumulation of 16. After the pretraining, the models are finetuned on a subset of `X`–L training data. We finetune the model parameters gently on 8 V100 GPUs with the same mini-batch size, gradient accumulations, and optimizer with different learning rate scheduling of (init_lr, warm-up steps)=({1e-4, 1e-5, 1e-6}, 8k). The best checkpoints are selected based on development loss. The translations are obtained by a beam search decoding with a beam size of 4, unless otherwise stated.

Baselines For system comparison, we build three different baselines: 1) direct bilingual systems, 2) pivot translation systems via English (only applicable for non-English `X–Y` evaluation) (Utiyama and Isahara, 2007), and 3) many-to-one multilingual systems with the 12E6D architecture. The bilingual and pivot-based baselines employ the Transformer base architecture. The embedding dimension is set to 256 for jv, ms, ta, and tl, because of the training data scarcity. For the `X–Y` pivot translation, a source sentence in language `X` is translated to English with a beam size of 5 by the `X–En` model, then the best output is translated to the final target language `Y` by the `En–Y` model.

Results All results on the test sets are displayed in Figure 1 and Table 1, where we report the case-sensitive sacreBLEU score (Post, 2018) for translation accuracy. Overall, our best systems ("24E12D+FT") are significantly better by $\geq +0.5$ sacreBLEU for 83% and 88% directions against the bilingual baselines and the pivot translation baselines, respectively. In Table 1, we present the average sacreBLEU scores for many-to-L directions, showing that our proposed approach successfully achieved the best performance in most targeted languages. Compared to the many-to-one multilingual baselines, the proposed approach of utilizing the complete MNMT model transfers multilingual representations more effectively to the targeted translation directions, as the L-centric data size are smaller. We also note that the winning system of the shared task achieved (task1, task2)=(37.6, 33.9) BLEU with a 36-layer encoder and 12-layer decoder model (Yang et al., 2021a) that is pretrained on extra language data including parallel and monolingual data, while our best system with a 24-layer encoder and 12-layer decoder obtained (task1, task2)=(25.7, 22.8) sacreBLEU, without using those extra data.

4 In-house Extremely Large-Scale Setting

Deploying a larger and larger model is not always feasible. We often have limitations in the computational resources at inference time, which leads to a trade-off problem between the performance and the decoding cost caused by the model architecture. In this section, we validate our proposed approach in an extremely large-scale data setting and also discuss how we can build lighter NMT models without the performance loss, while distilling the proposed MNMT systems (Kim and Rush, 2016). We briefly touch the following three topics of 1) multi-way multilingual data collection, 2) English-centric vs. multi-centric pretraining for `X–Y` translations, and 3) a lighter NMT model that addresses the trade-off issue between performance and latency. Then,

	xx-de	xx-fr	xx-es	xx-it	xx-pl
Pivot-based baselines	35.7	39.8	38.0	33.0	26.2
Pretrained model on en-xx data	14.2	33.1	—	—	—
+ Many-to-one multilingual finetuning	36.6	41.3	—	—	—
Pretrained model on {en, de, fr}-xx data	37.5	42.1	20.0	16.6	11.1
+ Many-to-one multilingual finetuning	**38.3**	**42.6**	**39.3**	**34.6**	**28.3**

Table 2: Average sacreBLEU scores of the proposed two-stage MNMT training for the many-to-one directions, with the English-centric pretrained model and the multi-centric model pretrained on {en, de, fr}-xx data.

we report the experimental results in the extremely large-scale setting.

Multilingual Data Collection We build an extremely large-scale data set using our in-house English-centric data set, consisting of 10 European languages, ranging 24M-192M sentences per language. This contains available parallel data and back-translated data between English and {German (de), French (fr), Spanish (es), Italian (it), Polish (pl), Greek (el), Dutch (nl), Portuguese (pt), and Romanian (ro)}. From these English-centric corpora, we extract a multi-way multilingual `X-Y` data, by aligning `En-X` and `En-Y` data via pivoting English. Specifically, we extracted {de, fr, es, it, pl}-centric data and concatenate them to the existent direct `X-Y` data, providing 78M-279M sentence pairs per direction. Similarly as in Section 3, we build a shared SentencePiece vocabulary with 128k tokens to address the large-scale setting.

En-centric vs Multi-centric Pretraining In a large-scale data setting, a question might come up; *Which pretrained model provides generalized multilingual representations to achieve better* `X-Y` *translation quality?* Considering English is often a dominant text data, e.g., 70% tasks are English-centric in the WMT'21 news translation task, the model supervised on English-centric corpora might learn representations enough to transfer for `X-Y` translations. To investigate the usefulness of the multi-centric data training, we pretrain our Transformer models with deeper 24-12 layers described in Section 3, on the English-centric data and the L-centric data (L={en,de,fr}), individually. After pretraining, we apply the multilingual many-to-one finetuning with a subset of the training data and evaluate each system for the fully supervised `X-Y` directions, i.e., xx-{`en`,`de`,`fr`}, and the partially supervised `X-Y` directions, i.e., xx-{`es`,`it`,`pl`}. We followed the same training and finetuning settings as described in Section 3, unless otherwise stated.

MNMT with Light Decoder At the practical level, one drawback of the large-scale models would be latency at inference time. This is mostly caused by the high computational cost in the decoder layers due to auto-regressive models and the extra cross-attention network in each block of the decoder. Recent studies (Kasai et al., 2021; Hsu et al., 2020; Li et al., 2021) have experimentally shown that models with a deep encoder and a shallow decoder can address the issue, without losing much performance. Fortunately, such an architecture also satisfies demands of the many-to-one MNMT training, which requires the encoder networks to be more complex to handle various source languages. To examine the light NMT model architecture, we train the Transformer base architecture modified with 9-3 layers (`E9D3`) in a bilingual setting and compare it with a standard Transformer base model, with 6-6 layers (`E6D6`), as a baseline. Additionally, we also report direct `X-Y` translation performance, when distilling the best large-scale MNMT models alongside the light NMT models as a student model. More specifically, following Kim and Rush (2016), we train light NMT student models (`E9D3`) that serve many-to-L translations (L={de, fr, es, it, pl}).

Results Table 2 reports average sacreBLEU scores for many-to-one directions in our in-house X-Y test sets. For the `xx-{de,fr}` directions, the proposed finetuning helps both English-centric and multi-centric pretrained models to improve the accuracy. Overall, the finetuned multi-centric models achieved the best, largely outperforming the English pivot-based baselines by +2.6 and +2.8 points. For the comparison among the multilingual systems, the multi-centric model without finetuning already surpasses the finetuned English-centric systems with a large margin of +0.9 and +0.8 points for both `xx-{de,fr}` directions. This suggests

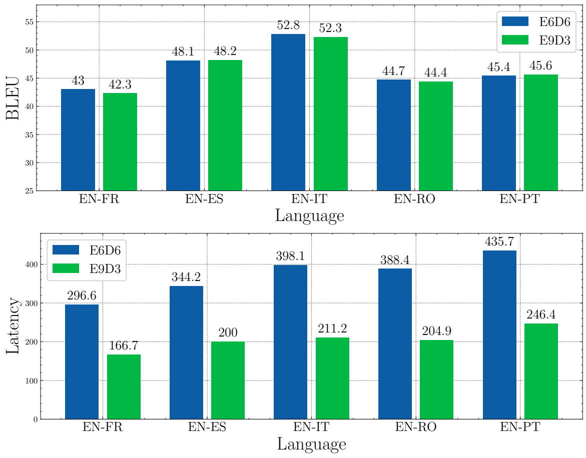

Figure 2: The BLEU score and latency in milliseconds of standard (`E6D6`) and light (`E9D3`) architecture.

that, by pretraining a model on more multi-centric data, the model learns better multilinguality to transfer. For the `xx-{es,it,pl}` directions[1], the fineutned multi-centric systems gain similar accuracy improvement, averagely outperforming the conventional pivot-based baselines.

Figure 2 shows the effectiveness of our light NMT model architecture for five bilingual `En-X` directions, reporting the translation performance in sacreBLEU scores and the latency measured on CPUs. Our light NMT model (`E9D3`) successfully achieves almost 2x speed up, without much drop of the performance for all directions. Employing this light model architecture as a student model, we report the distilled many-to-one model performance in Table 3, measured by sacreBLEU and COMET scores (Rei et al., 2020). For consistent comparison, we also built English bilingual baselines (`E6D6`) that are distilled from the bilingual Teachers, then we obtained the English pivot-based translation performance. For all the many-to-L directions (L={de,fr,es,it,pl}), the light NMT models that are distilled from the best MNMT models show the best performance in both metrics. Besides that, we also note that our direct `X-Y` light NMT systems successfully save the decoding cost with 75% against the pivot translation[2].

	Models	BLEU	COMET
xx-de	Pivot-based baselines	38.1	60.8
	Ours	**39.5**	**67.2**
xx-fr	Pivot-based baselines	41.5	69.3
	Ours	**42.9**	**73.2**
xx-es	Pivot-based baselines	37.4	73.9
	Ours	**38.0**	**74.4**
xx-it	Pivot-based baselines	32.6	77.2
	Ours	**33.7**	**80.9**
xx-pl	Pivot-based baselines	26.7	77.8
	Ours	**28.0**	**88.5**

Table 3: Average direct `X-Y` translation performance of our proposed light NMT models. All "Our" NMT systems employ the light models (`E9D3`) that are distilled from the best systems reported in Table 2.

5 Conclusion

This paper proposes a simple but effective two-stage training strategy for MNMT systems that serve arbitrary `X-Y` translations. To support translations across languages, we first pretrain a complete multilingual many-to-many model, then transfer the representations via finetuning the model in a many-to-one multilingual fashion. In the WMT'21 translation task, we experimentally showed that the proposed approach substantially improve translation accuracy for most `X-Y` directions against the strong conventional baselines of bilingual systems, pivot translation systems, and many-to-one multilingual systems. We also examined the proposed approach in the extremely large-scale setting, while addressing the practical questions such as multi-way parallel data collection, the usefulness of multilinguality during the pretraining and finetuning, and how to save the decoding cost, achieving the better `X-Y` quality.

Abstract

Variational Autoencoder (VAE) is an effective framework to model the interdependency for non-autoregressive neural machine translation (NAT). One of the prominent VAE-based NAT frameworks, LaNMT, achieves great improvements to vanilla models, but still suffers from two main issues which lower down the translation quality: (1) mismatch between training and inference circumstances and (2) inadequacy of latent representations. In this work, we target on addressing these issues by proposing posterior consistency regularization. Specifically, we first perform stochastic data augmentation on the input samples to better adapt the model for inference circumstance, and then conduct consistency training on posterior latent variables to construct a more robust latent representations without any expansion on latent size. Experiments on En<->De and En<->Ro benchmarks confirm the effectiveness of our methods with about 1.5/0.7 and 0.8/0.3 BLEU points improvement to the baseline model with about 12.6× faster than autoregressive Transformer.

1 Introduction

Neural Machine Translation (NMT) achieves great success in recent years, and typical sequence-to-sequence frameworks like Transformer (Vaswani et al., 2017) achieved state-of-the-art performance on the task of NMT. In this framework, source sentences are translated in an autoregressive (AT) manner where each token is generated depending on previously generated tokens. Inevitably, such sequential decoding strategy results in a high inference latency. To alleviate this issue, Non-autoregressive translation (NAT; Gu et al., 2018) was proposed to speed-up decoding procedure by generating target tokens in parallel. However, the translation quality of vanilla NAT is compromised, one of the most significant problems is multi-modality and it usually results in multiple translation results, duplicate or missing words in target sentences of NAT models (Gu et al., 2018). This situation results from the conditional independence proposed by NAT, since models are trained to maximize the log-probability of target tokens at each position while the interdependency is omitted.

The key to alleviate the multi-modality issue is to model the dependency information of targets implicitly or explicitly so decoder can easily learn and capture the information between target tokens and generate more accurate translations. For example, Ghazvininejad et al. (2019) and (2020b) model the target dependency by providing observed target tokens in training and performing iterative inference. Ran et al. (2021) generates intermediate representations by permuting the source sentences in the target order. Libovickỳ and Helcl (2018), Shao et al. (2020) and Ghazvininejad et al. (2020a) model the target dependency by introducing objective functions with alignment. Guo et al. (2020) and Wang et al. (2019) improve the translation quality by proposing additional regularizations. Zhou and Keung (2020) and Liu et al. (2021) utilize the external information like monolingual data or semantic structure to help the training.

Previous studies have validated the effectiveness of applying VAE on AT (Zhang et al. 2016; McCarthy et al. 2019; Su et al. 2018) and NAT (Kaiser et al. 2018; Shu et al. 2020) frameworks. A prominent NAT model is LaNMT[1](Shu et al., 2020) which encodes the source and target tokens into intermediate Gaussian distribution latent variables and outperforms vanilla NAT with about 5.0 BLEU points on WMT14 En-De task with 12.5× speedup to base Transformer. However, there exists a slight lag behind the state-of-the-art fully NAT models. It may be attributed to two reasons: (1) The inadequate representations of latent variables. Figure 1 shows the effect of latent size to translation qualities. Obviously, the optimal capacity of latent variables is significantly lower than the model's hid-

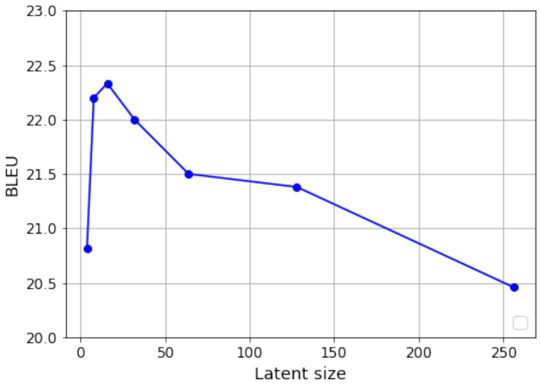

Figure 1: Effect of latent size. Values are obtained by our experiments on WMT14 En-De benchmark

den size (512) while high-capacity latent variables conversely deteriorate the performance because the minimization between prior and posterior becomes difficult (Shu et al., 2020). (2) The mismatch between training and inference circumstances that the posterior module receives the gold sentence as inputs during training but imperfect initial translation instead during inference. Thus, in this paper, we aim to improve the robustness of the latent representation and move the training circumstance close to inference circumstance.

To this end, we propose a consistency regularized posterior network for better latent representations and closer training-inference circumstance with no extended latent size. Specifically, it can be split into two main steps: we first apply stochastic data augmentation methods to inject stochastic noises in posterior inputs x and y to get two different views (x_1, y_1) and (x_2, y_2), which are then transformed to corresponding latent variables z_1, z_2 by the posterior network. Secondly, the consistency regularization step tries to minimise the gap between z_1 and z_2 since they are derived from the same pair of input x and y. These two steps enable the sequences better represented by the size-limited latent variables which is trained to be more robust to the noises in input samples. Meanwhile, posterior module receives noisy views instead of gold samples during training, it is more adaptive to the inference time which receives imperfect initial translations as inputs.

We verified the performance and effectiveness of our methods on WMT14 En<->De and WMT16 En<->Ro benchmarks. Our methods outperform the latent variable baseline with about 1.5/0.7 and 0.8/0.3 BLEU points improvement on four benchmarks. With these improvements, we achieve the comparable performance to the state-of-the-art fully NAT approaches: 25.65/30.23 and 31.56/31.20 of BLEU scores with similar decoding speed, and it can be improved further with latent search. The contributions of our work can be summarized as follows:

- For better latent representations, we propose consistency regularization optimized posterior network, which improves the translation quality by training more robust latent variables to noises.
- We apply four data augmentation methods to cooperate with posterior consistency regularization, where all of them are also benefit to the translation quality by alleviating the mismatch between training and inference circumstances.
- We show our strategy is capable of improving the translation quality of the base latent-variable NAT model to be comparable with the state-of-the-art fully NAT frameworks.

2 Background

2.1 Non-Autoregressive Translation

Traditional sequence-to-sequence NMT models generate target sentences in an autoregressive manner. Specifically, given a source sentence x, AT frameworks model the conditional probability of $y = \{y_1, y_2, \cdots, y_{l_y}\}$ by the following form:

$$\log p(y|x) = \sum_{i=1}^{l_y} \log p(y_i|y_{<i}, x) \quad (1)$$

where $y_{<i}$ indicates the target tokens already generated before y_i. Hence, the target tokens are generated sequentially which results in a high decoding latency. To alleviate this issue, vanilla NAT (Gu et al., 2018) breaks the conditional dependency by conditional independence assumption so that all tokens can be generated independently. Following its probability form:

$$\log p(y|x) = \sum_{i=1}^{l_y} \log p(y_i|x) \quad (2)$$

where each target token y_i now only depends on the source sentence x. Benefit from the parallel computing capability of hardware accelerators like GPU or TPU, all tokens can be generated with one iteration in an ideal circumstance.

2.2 Latent-Variable Model

We mainly focus on performing optimization on the variational NAT framework proposed by Shu et al. (2020). The network architecture is constructed by four main components. An encoder $p_\omega(z|x)$ encodes the source representation of input x and computes the prior latent variable. An approximate posterior network $q_\phi(z|x,y)$ accepts both the source sentence x and target sentence y as the input and computes the posterior latent variable. A length predictor $p(l_y|z)$ predicts the length of target sentence y, and finally a decoder $p_\theta(y|x,z,l_y)$ with a length transform module to transform the latent variables z to the target length l_y at first and reconstruct y from z with the source representations of x. Note that the l_y here is the gold length in training. Hence, the training objective is aiming to maximize the evidence lowerbound (ELBO):

$$\begin{aligned}\mathcal{L}(x,y) &= \mathbb{E}_{z\sim q_\phi}[\log p_\theta(y|x,z)] \\ &\quad -\mathrm{KL}\left[q_\phi(z|x,y)||p_\omega(z|x)\right] \\ p_\theta(y|x,z) &= p_\theta(y|x,z,l_y)p(l_y|z)\end{aligned} \tag{3}$$

where the latent variables z is constrained with the same length as x and the value is modeled as spherical Gaussian distribution. KL denotes Kullback-Leibler divergence.

2.3 Consistency Regularization

Consistency regularization is considered as an effective method on semi-supervised learning to capture the potential features from unlabeled samples (Sajjadi et al., 2016; Laine and Aila, 2017; Tarvainen and Valpola, 2017; Xie et al., 2020). It is also utilized as a complementary regularization tool with other regularization methods to prevent model from overfitting (Liang et al., 2021). In a nutshell, consistency regularization assumes a well trained model should be robust enough to any small changes in the input samples or hidden states and generate invariant outputs (Xie et al., 2020). To this end, it regularizes model's final outputs to be invariant to input samples with small stochastic noises injected by minimizing the gap between two augmented views of one sample.

In this paper, we focus on the posterior module of the variational framework and apply consistency regularization on it instead of the whole network. Along with data augmentation for noise injection, consistency regularization is capable to improve the representation of this module and result in better translation quality.

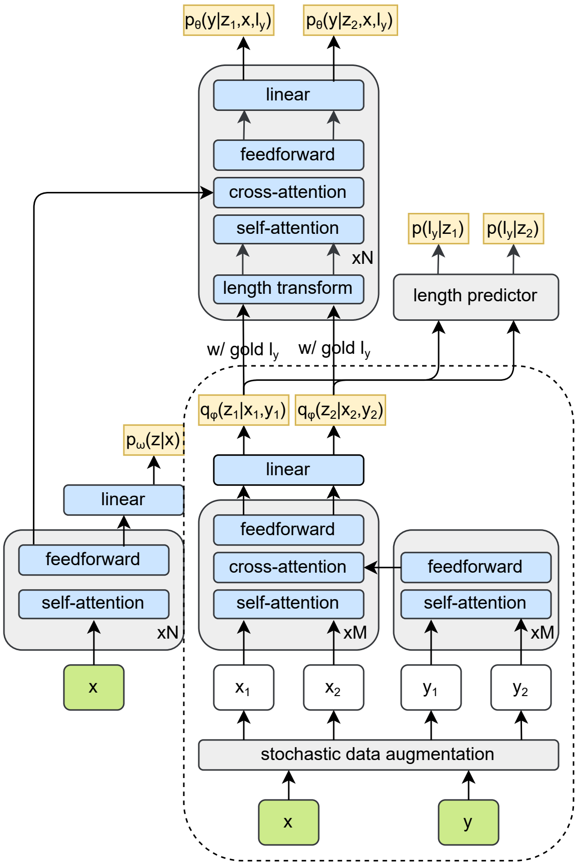

Figure 2: The overall pipeline of training with posterior consistency regularization

3 Approach

The posterior module is considered to train with consistency regularization and data augmentation for better translation quality. In this section, we will introduce the details of our method, including the overall network architecture, the objective and procedure of training with consistency regularization, four data augmentation methods and three decoding strategies applied for inference.

3.1 Model Architecture

We follow the variational model architecture proposed by Shu et al. (2020) with four main components: encoder, posterior, length predictor and decoder module. Since we apply consistency regularization on the posterior, an additional stochastic data augmentation module is added for noise injection on posterior input samples. With two augmented views derived from one sample, each sample thus appears twice in a training batch. Figure 2 shows the brief model architecture and training pipeline of our work. The part in the dashed box is the major difference to the base model.

3.2 Posterior Consistency Regularization

As discussed above, consistency regularization is applied on the posterior module to improve its robustness. Given a training sample with a pair of source sentence x with l_x tokens and target sentence y with l_y tokens, we first apply data augmentation on both x and y twice to inject stochastic noises and obtain two different views (denoted as x_1, y_1 and x_2, y_2). Both views are forwarded to the posterior network $q_\phi(z|x,y)$ to predict the mean and variance vectors of two latent variables z_1 and z_2. Since the latent variables derive from the same input sample, the consistency regularization method tries to minimize the difference between these two latent variables by measuring bidirectional KL-divergence as follows:

$$\begin{aligned}\mathcal{L}_{cons} = \frac{1}{2}(\mathrm{KL}(z_1||z_2) + \mathrm{KL}(z_2||z_1)),\\ z_1 = q_\phi(Z|X = x_1, Y = y_1),\\ z_2 = q_\phi(Z|X = x_2, Y = y_2)\end{aligned} \tag{4}$$

Combining with the basic negative log-likelihood (NLL) objective on the decoder, since there are two different z for the same sample, it is evaluated by averaging them:

$$\mathcal{L}_{nll} = -\frac{1}{2}(\log p_\theta(y|x, z_1, l_y) + \log p_\theta(y|x, z_2, l_y)) \tag{5}$$

Note that the gold length l_y of target sentence y is used which is known during training. Similarly, the objective of the length predictor is calculated by:

$$\mathcal{L}_{len} = -\frac{1}{2}(\log p(l_y|z_1) + \log p(l_y|z_2)) \tag{6}$$

To back propagate the gradient information from the decoder and length predictor to posterior, reparameterization trick is applied to sample z from q_ϕ where $z = \mu + \theta * \mathcal{N}(0, 1)$ in Eq.(6) and (5). Here, μ and θ indicate mean and variance vector. For encoder, it not only generates representations of source sentence x but also computes the prior latent variables. Thus, we close the KL-divergence between prior and two posterior latent variables by:

$$\mathcal{L}_{prior} = \frac{1}{2}(\mathrm{KL}(z_1||z_p) + \mathrm{KL}(z_2||z_p)) \tag{7}$$

where $z_p = p_\omega(Z|X = x)$, z_1 and z_2 are obtained from (4). Finally, to achieve the similar goal of maximizing (3), we minimize the loss function by combining (4), (5), (6) and (7) as follows:

$$\mathcal{L}_{loss} = \mathcal{L}_{nll} + \mathcal{L}_{len} + \mathcal{L}_{prior} + \alpha\mathcal{L}_{cons} \tag{8}$$

where α here is the only hyperparameter to weight the consistency regularization loss.

3.3 Data Augmentation Methods

Given an embedding matrix $\mathbb{R}^{L\times d}$ with L tokens embedded into d-dimensions vectors, to generate different views for the posterior network inputs and perform posterior consistency regularization, as well as to close the gap between training and inference circumstances, we explore four data augmentation methods for this purpose including dropout, feature cutoff, token cutoff and replacement as presented in Figure 3.

Dropout Dropout (Srivastava et al., 2014) is widely used as a regularization method to prevent neural networks from overfitting. But in this paper, we found that it is also an effective data augmentation method for noise injection. Specifically, we randomly choose values on token embeddings by a specific proportion and force them to zero.

Cutoff This is a simple but effective augmentation method proposed by Shen et al. (2020). The cutoff methods we adopt include token cutoff and feature cutoff. For token cutoff, a specific proportion of tokens are chosen from the token dimension L and dropped by setting the vectors to zero. For feature cutoff, the dropped values are chosen from feature dimension d instead.

Replacement This is similar to the token replacement adopted by BERT pre-training (Devlin et al., 2019) where the chosen token vectors are replaced by the embedding of new tokens that randomly selected from the vocabulary instead of setting them to zero or any special tokens directly.

3.4 Decoding Strategies

Non-refinement For this strategy, we completely follow the original design (Shu et al., 2020) where the posterior network is discarded since the target sentence y is unknown during inference. The foremost step is to obtain the representations of x and the prior latent variable z from encoder with source input x. The latent variable is then used to determine the target length and generate target sentence.

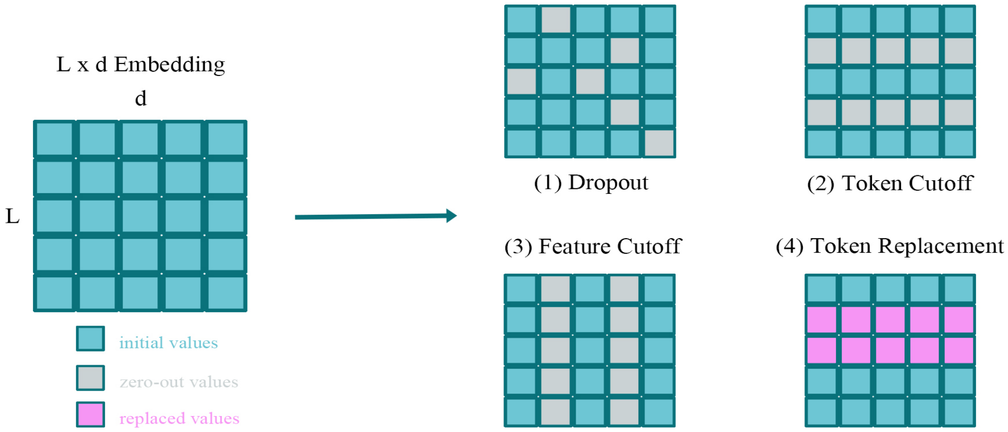

Figure 3: Four stochastic data augmentation methods we used for noise injection

Note that to avoid randomness during inference, z is set to its mean value μ instead of reparameterization sampling. This can be summarized as follows:

$$\begin{aligned}\mu_0 &= \mathbb{E}_{p_\omega(z|x)}[z], \\ l_{y_0} &= \arg\max_{l_y} p(l_y|z=\mu_0), \\ y_0 &= \arg\max_{y} p_\theta(y|x, l_{y_0}, z=\mu_0)\end{aligned} \tag{9}$$

Deterministic Refinement The posterior network q_ϕ can be reused to take refinement on the initial output y_0 above. According to Shu et al. (2020), its original design allows multi-step iterative refinement for more precise translations, but sacrifices huge cost in decoding speed for a tiny quality improvement. Thus, we consider one-step only refinement in this paper:

$$\begin{aligned}\mu_1 &= \mathbb{E}_{q_\phi(z|x,y_0)}[z], \\ l_{y_1} &= \arg\max_{l_y} p(l_y|z=\mu_1), \\ y_1 &= \arg\max_{y} p_\theta(y|x, l_{y_1}, z=\mu_1)\end{aligned} \tag{10}$$

Here the y_1 is the final output after refinement.

Latent Search Since reparameterization is disabled in above two strategies to generate deterministic results, it is also able to search the best latent variable from Gaussian distribution. Specifically, m prior latent variables are sampled by reparameterization and decoded in parallel, result in m target candidates for each source sentence. To get the best result, we select the candidate with the highest score by averaging the log-probability of tokens as the final output. This is different from Shu et al. (2020) or Noisy Parallel Decoding (NPD; Gu et al. 2018) which rescore the candidates by autoregressive teacher and at least cuts the decoding speed by half, our no-rescoring strategy is still effective and much faster.

4 Experiments

In this section, we will introduce the settings of our experiments, report the main results and compare our model to the representative NAT frameworks. Our experiments mainly focus on (1) the improvement benefit from our optimization to former VAE-based NAT model. (2) The effectiveness of consistency regularization and different data augmentation methods.

4.1 Experimental Setup

Dataset Four of the commonly used machine translation benchmarks are adopted to evaluate our proposed method: WMT14 English<->German[2] (En-De and De-En, 4.5M) and WMT16 English<->Romanian[3] (En-Ro and Ro-En, 610K). We follow previous works' data preprocessing configurations to preprocess the data (En-De: Shu et al., 2020, En-Ro: Ghazvininejad et al. 2019). To learn the subword vocabulary, we apply SentencePiece (Kudo and Richardson, 2018) to generate joint subword vocabulary of 32K tokens for each dataset respectively.

Knowledge Distillation Following previous studies on NAT that models are trained on distilled data generated by autoregressive teacher, we also apply sentence-level knowledge distillation for all datasets to obtain less noisy and more deterministic data. In this work, Transformer (Vaswani et al.,

2017) with base settings is adopted and reproduced as the teacher model for data distillation.

Implementation Details The model is trained by the objective function illustrated on Eq.(8). To avoid posterior collapse, freebits annealing (Chen et al., 2017) is applied on KL terms in Eq.(7) to keep a distance between prior and posterior. Its threshold is fixed to 1 for the first half training steps, and linearly decay to 0 on the second half. For both dataset, we train the model with a batch of approximate 40K tokens for overall 100K steps on four Tesla V100 GPUs and conduct fine-tuning for additional 20K steps with annealing disabled.

For network settings, we use 6 layers encoder and decoder with $d_{model}/d_{feedforward} = 512/2048$. Following Shu et al. (2020), the posterior network contains 3 transformer layers and the dimension of latent variable is set to 8. We set L2 weight decay of 0.01 and dropout between attention layers with rate of 0.1/0.3 for WMT14 En<->De and WMT16 En<->Ro respectively as well as label smoothing rate $\epsilon = 0.1$ on target tokens. Models are trained by AdamW (Loshchilov and Hutter, 2017) with settings of $\beta = (0.9, 0.98)$ and $\epsilon = 1e-4$. The learning rate is warmed up for first 4000 steps to 1.4e-3 and decayed by inverse-square-root scheduler. To obtain the final model, we average 5 best checkpoints chosen by validation BLEU score. For the rate of noise injection, all four augmentation strategies are evaluated with rates from 0.1 to 0.3 on WMT14 En-De benchmark and the settings for other experiments are determined according to these results.

Evaluation For all benchmarks, we use sacreBLEU[4] (Post, 2018) to evaluate BLEU score of

---

[4] `https://github.com/mjpost/sacrebleu`

translation results. Following Lee et al. (2018) and Shu et al. (2020), repetition tokens are removed before generating the final outputs for evaluation. The results of latent search is obtained by the mean score of 5 independent runs on the test set of each benchmark to get more precise measures since reparameterization causes randomness in decoding.

To evaluate the decoding speed, following previous works (e.g. Gu et al. 2018, Lee et al. 2018), models are run on WMT14 En-De test set with batch size of 1 under the environment with one GPU only. The mean value of decoding latency among all samples is collected and represent as the decoding speed. Meanwhile, base Transformer is reproduced and evaluated on the same machine to obtain the speed up rates.

Baselines We set former VAE based NAT frameworks proposed by Kaiser et al. (2018) and Shu et al. (2020) as the main baselines to present the improvement of our method. We also compare our model with base Transformer and other representative NAT frameworks including iterative and fully approaches. Due to the lack of computing resources, experiments and comparison with connectionist temporal classification (CTC) based frameworks like Libovickỳ and Helcl (2018) or Gu and Kong (2021) are not considered in this paper since the decoder output is many times the length of the target sequence, which extremely consumes extra GPU storage in training. The performance measures including BLEU score and speedup rate of other models are directly obtained from the figures reported on their original paper, while some unreported measures are obtained by our implementation.

4.2 Results and Analysis

The main results on the benchmarks are illustrated on Table 1, we report the best scores of our experiments among different tested combinations of data augmentation methods with consistency regularization. As the performance measure shown in Table 1, our methods significantly outperform former VAE-based baselines, with about 5.8 BLEU points improvement to the discrete latent variable model (Kaiser et al., 2018) and 1.7/1.5, 0.6/0.7, 0.7/0.8, 0.1/0.3 points improvement on non-refinement/refinement decoding to continuous latent variable baseline (Shu et al., 2020) on WMT14 En<->De, and WMT16 En<->Ro benchmarks without latent search. All measures indicate that our posterior consistency regularization method greatly enhances the robustness of the latent representations and results in an improved translation quality.

Comparing to other representative AT and NAT models, our method shows the superiority of decoding speed to AT and iterative NAT models while there are less than 2 BLEU points lag behind. With the refinement decoding, our model also achieves a comparable translation quality to the state-of-the-art fully-NAT approaches with similar decoding latency.

The results of latent search is encouraging. Benefit from the parallel computing capability of GPU, latent search sacrifices very small decoding speed to achieve about 0.5/1.0/0.9/0.9 BLEU improvements for refinement decoding and 1.6/2.7/1.5/2.6 BLEU improvements for non-refinement decoding on four benchmarks with $m = 9$ candidates.

Table 2: BLEU scores for baseline and our models with different data augmentation methods. * denotes the results obtained by our implementation. **Baseline** indicates Shu et al. (2020)

Effectiveness of Data Augmentation Methods In this work, we adopt four different data augmentation strategies as the stochastic noise injection method to cooperate with consistency regularization. To evaluate their effectiveness and the impact for translation quality, all data augmentation methods are tested on the benchmarks. The results are reported on Table 2. The method we adopt combining posterior consistency regularization with data augmentation is effective and capable to achieve higher BLEU scores than the baseline. Specifically, token replacement achieves the highest score on all of benchmarks with refinement decoding since the posterior network is trained on sentences with incorrect tokens, this is more similar to the inference circumstance. With the non-refinement decoding, even the posterior module is disabled, the improvement is still exist for all strategies.

Effectiveness of Consistency Regularization Consistency regularization should work together with stochastic data augmentation which is widely known as a trick to train robust neural networks (Shorten and Khoshgoftaar 2019; Shen et al. 2020). Thus, to confirm that the model is not just benefit from data augmentation but the contribution of posterior consistency regularization, we perform the experiments by disabling (setting $\alpha = 0$ in eq.(8)) consistency training module and train the model with four data augmentation methods respectively on WMT14 En-De dataset. The results illustrate on Table 3. Without consistency regularization, the data augmentation methods still result in improvement to baseline, but a slight lag exists behind the model with consistency regularization enabled. In other words, consistency regularization can improve the translation quality further. Thus, it is confirmed that our posterior consistency regularization method is effective and capable to train better latent representations in this work.

Method	w/o Reg.	w/ Reg.
Baseline	24.10	
Dropout	24.85	25.39
Token Cutoff	25.38	25.58
Feature Cutoff	25.02	25.44
Token Replacement	25.36	25.65

Table 3: BLEU scores on WMT14 En-De for baseline and our methods with consistency regularization enabled and disabled.

Effect of Augmentation Rate To investigate the impact of augmentation rate and choose the optimal hyperparameter, we train and evaluate the models by different augmentation rates from 0.1 to 0.3 on WMT14 En-De dataset. Results are illustrated on Figure 4. The best augmentation rate is different for each augmentation methods, alone with the increase of noise injection level, the performance of each method increases firstly and then gradually drops down. Token cutoff and replacement achieves the outstanding peak performance to others, it could be attribute to the mechanism that model can potentially learn from the incomplete sentences with incorrect or missing tokens and revise them, which mostly benefits to the refinement decoding at inference where there are massive incorrect tokens from initial translations.

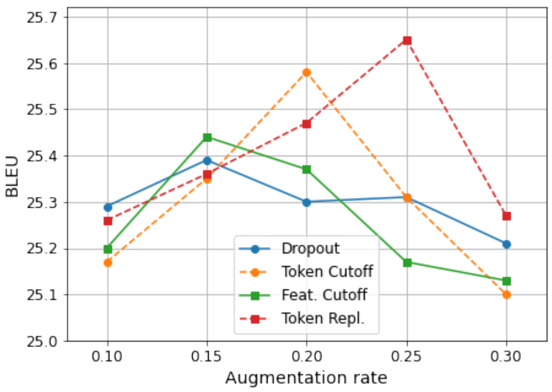

Figure 4: Effect of the rate for augmentation methods on WMT14 En-De benchmark.

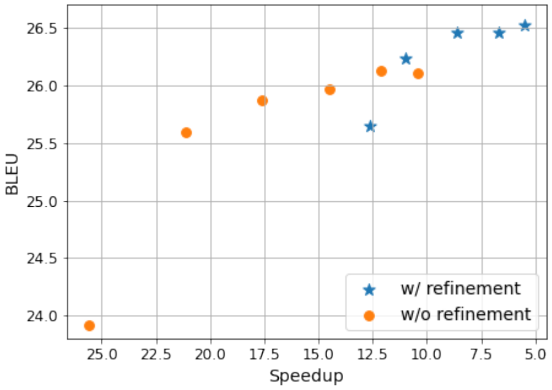

Figure 5: Tradeoff between decoding speed and translation quality on WMT14 En-De benchmark.

Tradeoff between Speed and Quality The tradeoff between the speedup rate and translation quality on WMT14 En-De dataset is shown in Figure 5. We draw the scatter points by evaluating the proposed model on various number of candidates from 9 to 59 sampled for latent search. It can be observed that both decoding with or without refinement can benefit from latent search. Since the excellent parallel computation capability of GPU, and no autoregressive scorer is required in our framework, the decoding speed remains acceptable. Specifically, the non-refinement decoding with more latent candidates can reach the similar quality level of refinement approach. However, refinement decoding can achieve further improvements and reaches the peak of about 26.5 BLEU points.

Summary Summarizing from the experiments and corresponding results illustrated on Table 2, 3 and Figure 4, the mechanism of data augmentation and consistency regularization in this paper can be explained in two ways: firstly, data augmentation, especially token-level strategies, help the posterior network learn the capability of encoding correct latent variables from incomplete, incorrect or noisy sentences, which narrows the gap between training and inference circumstances. Thus, our posterior network can do better refinement on the initial translation y_0 from Eq.(9) which is relatively noisy and imperfect. Secondly, consistency regularization helps the posterior network learn to be more consistent on latent variables under the impact of noises in input samples, this potentially improves the robustness of latent representations which result in further improvements. In addition to the ability of sample multiple translations in parallel from latent distribution, all of these cooperate together and maximize the overall translation quality.

Conclusion

In this work, we introduce posterior consistency regularization along with a series of data augmentation methods on the posterior module of a variational NAT model to improve its performance of translation quality. This method trains the posterior network to be consistent to stochastic noises in inputs and potentially improves its representations. Meanwhile, data augmentation closes the gap between training and inference circumstances. Both are highly benefit to decoding and refinement step. Experiments on WMT14 En<->De and WMT16 En<->Ro benchmarks show that our approach achieves a significant improvement to the baseline model and a comparable translation quality to other state-of-the-art fully NAT models with fast decoding speed. As the effectiveness of consistency regularization and data augmentation is verified by our experiments, it is promising to be applied on other models and tasks in the future.

Abstract

In this paper, we define the task of gender rewriting in contexts involving two users (I and/or You) – first and second grammatical persons with independent grammatical gender preferences. We focus on Arabic, a gender-marking morphologically rich language. We develop a multi-step system that combines the positive aspects of both rule-based and neural rewriting models. Our results successfully demonstrate the viability of this approach on a recently created corpus for Arabic gender rewriting, achieving 88.42 M^2 $F_{0.5}$ on a blind test set. Our proposed system improves over previous work on the first-person-only version of this task, by 3.05 absolute increase in M^2 $F_{0.5}$. We demonstrate a use case of our gender rewriting system by using it to post-edit the output of a commercial MT system to provide personalized outputs based on the users' grammatical gender preferences. We make our code, data, and pretrained models publicly available.[1]

1 Introduction

Gender bias is a fundamental problem in natural language processing (NLP) and it has been receiving an increasing attention across a variety of core tasks such as machine translation (MT), co-reference resolution, and dialogue systems. Research has shown that NLP systems have the ability to embed and amplify gender bias (Sun et al., 2019), which not only degrades users' experiences but also creates representational harm (Blodgett et al., 2020). The embedded bias within NLP systems is usually attributed to training models on biased data that reflects the social inequalities of the world we live in. However, even the most balanced of models can still exhibit and amplify bias if they are designed to produce a single text output without taking their users' gender preferences into consideration. Therefore, to provide the correct user-aware output, NLP systems should be designed to produce outputs that are as gender-specific as the users information they have access to. Users information could be either embedded as part of the input or provided externally by the users themselves. In cases where this information is unavailable to the system, generating all gender-specific forms or a gender-neutral form is more appropriate.

Producing user-aware outputs becomes more challenging for systems targeting multi-user contexts (first and second persons, with independent grammatical gender preferences), particularly when dealing with gender-marking morphologically rich languages. In this paper, we define the task of gender rewriting in contexts involving two users (I and/or You) – first and second grammatical persons with independent grammatical gender preferences and we focus on Arabic, a gender-marking morphologically rich language. The main contributions of our work are as follows:

1. We introduce a multi-step gender rewriting system that combines the positive aspects of rule-based and neural models.
2. We demonstrate our approach's effectiveness by establishing a strong benchmark on a publicly available multi-user Arabic gender rewriting corpus.
3. We show that our best system yields state-of-the-art results on the first-person-only version of this task, beating previous work.
4. We demonstrate a use case of our system by post-editing the output of an MT system to match users' grammatical gender preferences.

This paper is organized as follows. We first discuss related work (§2) as well as relevant Arabic linguistic facts (§3). We then define the gender rewriting task in §4 and describe the data we use and the gender rewriting model we build in §5 and §6. Lastly, we present our experimental setup (§7) and results (§8) and conclude in §9.

2 Background and Related Work

Substantial research has targeted the problem of gender bias in various NLP tasks such as MT (Rabinovich et al., 2017; Vanmassenhove et al., 2018; Stafanovičs et al., 2020; Savoldi et al., 2021), dialogue systems (Cercas Curry et al., 2020; Dinan et al., 2020; Liu et al., 2020a,b; Sheng et al., 2021), language modeling (Lu et al., 2018; Bordia and Bowman, 2019; Sheng et al., 2019; Vig et al., 2020; Nadeem et al., 2021), co-reference resolution (Rudinger et al., 2018; Zhao et al., 2018a), and named entity recognition (Mehrabi et al., 2019). While the majority of research has focused on tackling gender bias in English by debiasing word embeddings (Bolukbasi et al., 2016; Zhao et al., 2018b; Gonen and Goldberg, 2019; Manzini et al., 2019; Zhao et al., 2020) or by training systems on gender-balanced corpora built using counterfactual data augmentation techniques (Lu et al., 2018; Hall Maudslay et al., 2019; Zmigrod et al., 2019), our work falls under text rewriting through the controlled generation of gender alternatives for morphologically rich languages.

Within text rewriting, Vanmassenhove et al. (2021) and Sun et al. (2021) recently presented rule-based and neural rewriting models to generate gender-neutral sentences in English. For morphologically rich languages and specifically Arabic, Habash et al. (2019) introduced the Arabic Parallel Gender Corpus v1.0 (APGC v1.0) of first-person-singular constructions and designed a two-step gender identification and reinflection system to generate masculine and feminine grammatical gender alternatives. Alhafni et al. (2020) used APGC v1.0 to create a joint gender identification and reinflection model. They treated the problem as a user-aware grammatical error correction task and showed improvements over Habash et al. (2019)'s results. Both efforts modeled gender reinflection using character-level Seq2Seq models. More recently, Alhafni et al. (2022) extended APGC v1.0 to APGC v2.0 by including contexts involving first and second grammatical persons covering singular, dual, and plural constructions; and adding six times more sentences.

In our work, we use APGC v2.0 to build a multi-step gender rewriting system to generate gender alternatives in multi-user contexts. We also show improvements over both Habash et al. (2019)'s and Alhafni et al. (2020)'s results on APGC v1.0.

3 Arabic Linguistic Facts

We highlight two of the many challenges that face Modern Standard Arabic (MSA) NLP systems dealing with gender expressions.

Morphological Richness and Complexity Arabic has a rich and complex morphological system that inflects for many morphological features (gender, number, person, case, state, aspect, mood, voice), in addition to several attachable clitics (prepositions, particles, pronouns) (Habash, 2010). Arabic nouns, adjectives, and verbs inflect for gender: masculine (*M*) and feminine (*F*), and for number: singular (*S*), dual (*D*) and plural (*P*).

Changing the grammatical gender of Arabic words involves either changing the form of the *base word*, changing the *pronominal enclitics* that are attached to the *base word*, or a combination of both. A *base word* in Arabic refers to the stem along with its attachable affixes (prefixes, suffixes, circumfixes). Changing the *base word* gender requires either a suffix change, a pattern change, or a lexical change as shown in Table 1(a-c). Arabic also has clitics that attach to the stem after affixes. A clitic is a morpheme that has the syntactic characteristics of a word but shows evidence of being phonologically bound to another word. In this respect, a clitic is distinctly different from an affix, which is phonologically and syntactically part of the word. Proclitics are clitics that precede the word (like a prefix), whereas enclitics are clitics that follow the word (like a suffix). *Pronominal enclitics* are pronouns that cliticize to previous words (Table 1(d)). It is worth noting that multiple affixes and clitics can appear in a single word in Arabic and changing the grammatical gender of such words requires changing the genders of both the base word and its clitics (Table 1(f-g)).

Orthographic Ambiguity Arabic uses diacritics to specify short vowels. However, these optional diacritics are usually omitted in Arabic orthography, leaving readers to infer the meaning of certain words based on the context (Habash, 2010). This increases the degree of word ambiguity as gender-specific words could only differ in terms of diacritics. For instance, the verb لعبت *lςbt*[2] can be diacritized as لَعِبْتَ *laςibta* 'you [masc.] played' or as لَعِبْتِ *laςibti* 'you [fem.] played'.

---

[2] Arabic transliteration is in the HSB scheme (Habash et al., 2007).

Paired Gender Alternatives		Rewrite Type	
أمير *Âmyr (NOUN.MS)* prince	أميرة *Âmyrħ (NOUN.FS)* princess	Suffix Change	(a)
أحمر *ÂHmr (ADJ.MS)* red	حمراء *HmrA' (ADJ.FS)* red	Pattern Change	(b)
أخ *Âx (NOUN.MS)* brother	أخت *Âxt (NOUN.FS)* sister	Lexical Change	(c)
أمير+كم *Âmyr+km* (*NOUN.MS+PRON.2MP*) your (*MP*) prince	أمير+كن *Âmyr+kn* (*NOUN.MS+PRON.2FP*) your (*FP*) prince	Enclitic Change	(d)
أمراء *ÂmrA' (NOUN.MP)* princes	أميرات *ÂmyrAt (NOUN.FP)* princesses	Pattern Change + Suffix Change	(e)
أمير+كم *Âmyr+km* (*NOUN.MS+PRON.2MP*) your (*MP*) prince	أميرت+كن *Âmyrt+kn* (*NOUN.FS+PRON.2FP*) your (*FP*) princess	Suffix Change + Enclitic Change	(f)
أمراء+هم *ÂmrA'+hm (NOUN.MP+PRON.3MP)* their (*MP*) princes	أميرات+هن *ÂmyrAt+hn (NOUN.FP+PRON.3FP)* their (*FP*) princesses	Pattern Change + Suffix Change + Enclitic Change	(g)

Table 1: Examples of the changes needed to generate gender alternative forms of gender-specific words in Arabic.

4 The Gender Rewriting Task

We define the task of gender rewriting as generating alternatives of a given Arabic sentence to match different *target user gender contexts* (e.g., female speaker with a male listener, a male speaker with a male listener, etc.). This requires changing the grammatical gender (masculine or feminine) of certain words referring to the users (speaker/1st person and listener/2nd person). Previous work done by Habash et al. (2019) and Alhafni et al. (2020) refer to this task as gender reinflection, but we believe that gender rewriting is a more appropriate term given that it goes beyond reinflection.[3]

Notation We will use four elementary symbols to facilitate the discussion of this task: 1M, 1F, 2M and 2F. The digit part of the symbol refers to the grammatical persons (1st or 2nd) and the letter part refers to the grammatical genders (masculine or feminine). Additionally, we will use B to refer to invariant/ambiguous gender.

We define the ***sentence-level*** gender using the following four labels: 1M/2F, 1F/2M, 1M/2F, and 1F/2F. These four labels indicate the grammatical persons and genders of the user contexts we are modeling.

We define the ***word-level*** gender based on the genders of the word's base form and its attachable pronominal enclitics (§3) using the notation: *base form gender + enclitic gender*. This results in 25 word-level gender labels (e.g., B+1F, 1F+2M). We use B to refer to gender invariant/ambiguous words. Examples of the word-level gender labels are shown in Table 2.

Task Definition Given an Arabic sentence and a sentence-level target gender, the goal is to rewrite the input sentence to match the target users' gender preferences.

Some of the models we explore only use sentence-level gender labels; while other models use word-level gender labels to identify which input words need to be rewritten to match the target users' gender preferences.

5 Data

For our experiments, we use the publicly available Arabic Parallel Gender Corpus (APGC) – a parallel corpus of Arabic sentences with gender annotations and gender rewritten alternatives of sentences selected from OpenSubtitles 2018 (Lison and Tiedemann, 2016). The corpus comes in two versions: APGC v1.0 and APGC v2.0. APGC v1.0 was introduced by Habash et al. (2019) and it contains 12,238 first-person-singular Arabic parallel gender-annotated sentences. Alhafni et al. (2022) expanded APGC v1.0 by including contexts involving first and second grammatical persons covering singular, dual, and plural constructions to create v2.0, which contains 80,326 gender-annotated parallel sentences (596,799 words). Both versions of APGC include the original English parallels of the Arabic sentences.

---

[3] Morphological reinflection usually refers to reinflecting either a lemma or an already inflected form to produce a desired form of a particular word (Cotterell et al., 2016, 2017).

	English	Input	Target 1M/2M	Target 1F/2M	Target 1M/2F	Target 1F/2F
(a)	I want to talk to you	أريد أن أتحدث معك B B B B	أريد أن أتحدث معك B B B B	أريد أن أتحدث معك B B B B	أريد أن أتحدث معك B B B B	أريد أن أتحدث معك B B B B
(b)	Dad, I am here	أبي أنا هنا B B 2M+B	أبي أنا هنا B B 2M+B	أبي أنا هنا B B 2M+B	أمي أنا هنا B B 2F+B	أمي أنا هنا B B 2F+B
(c)	I will tell you [*plural*] something	سأخبركن شيئا B B+2F	سأخبركم شيئا B B+2M	سأخبركم شيئا B B+2M	سأخبركن شيئا B B+2F	سأخبركن شيئا B B+2F
(d)	I am going to my office	أنا ذاهب لمكتبي B 1M+B B	أنا ذاهب لمكتبي B 1M+B B	أنا ذاهبة لمكتبي B 1F+B B	أنا ذاهب لمكتبي B 1M+B B	أنا ذاهبة لمكتبي B 1F+B B
(e)	Because I am an idiot	ولأني حمقاء 1F+B B	ولأني أحمق 1M+B B	ولأني حمقاء 1F+B B	ولأني أحمق 1M+B B	ولأني حمقاء 1F+B B
(f)	I am glad to know you [*plural*]	أنا سعيدة بمعرفتكم B+2M 1F+B B	أنا سعيد بمعرفتكم B+2M 1M+B B	أنا سعيدة بمعرفتكم B+2M 1F+B B	أنا سعيد بمعرفتكن B+2F 1M+B B	أنا سعيدة بمعرفتكن B+2F 1F+B B

Table 2: Examples from the Arabic Parallel Gender Corpus v2.0 including the extended word-level annotations for each sentence and its rewrite to the opposite grammatical gender forms where appropriate. First person gendered words are in purple and second person gendered words are in red. M is Masculine; F is Feminine; and B is invariant.

In all of our experiments, we use an extended version of APGC v2.0 to train and test our systems. We also report results on the test set of APGC v1.0 to compare with previous work.

Annotations Each sentence in APGC v2.0 has word-level gender labels where each word is labeled as B, 1F, 2F, 1M, or 2M. All sentences containing gender-specific words referring to human participants have parallels representing their opposite gender forms. For the sentences without any gender-specific words, their parallels are trivial copies. Out of the 80,326 sentences in APGC v2.0, 46% (36,980) do not contain any gendered words, whereas sentences with gendered references constitute 54% (43,346). In terms of the word-level statistics, 9.7% (58,066) are gender-specific, whereas 90.3% (538,733) are marked as B.

Moreover, APGC v2.0 is organized into five parallel corpora that are fully aligned (1-to-1) at the word level: Input, Target 1M/2M, Target 1F/2M, Target 1M/2F, and Target 1F/2F. All five corpora are balanced in terms of gender, i.e., the number of words marked as 1F and 1M is the same; and the number of words marked as 2F and 2M is the same. The Input corpus contains sentences with all possible word types (B, 1F, 2F, 1M, 2M). The Target 1M/2M corpus contains sentences that consist of B, 1M, 2M words; the Target 1F/2M corpus contains sentences that consist of B, 1F, 2M words; the Target 1M/2F corpus contains sentences that consist of B, 1M, 2F words; and the Target 1F/2F corpus contains sentences that consist of B, 1F, 2F words. The four target corpora are intended to model the target users' gender preferences for a particular input.

Splits We use Alhafni et al. (2022)'s splits: 57,603 sentences (427,523 words) for training (TRAIN), 6,647 sentences (49,257 words) for development (DEV), and 16,076 sentences (120,019 words) for testing (TEST).

Preprocessing the Word-Level Annotations Since gender information could be expressed at different parts of Arabic words (§3), we automatically extend the APGC v2.0 word-level annotations to mark the genders of both the base words and their pronominal enclitics.

Our preprocessing pipeline considers the labeled gendered words across the five parallel forms of each sentence in APGC v2.0. If the word ends with a gender marking pronominal enclitic, we label the gender of the enclitic based on predefined rules as 1F, 1M, 2F, or 2M. If the gendered word does not end with a gender-marking enclitic, then we label the enclitic as B. Once the enclitic is labeled, we compare the base form of the word across its parallel forms. If the base form is the same, we label it as B. Otherwise, we assign the base form the same label that is provided as part of APGC v2.0. All gender ambiguous words will be labeled as B. Table 2 presents some examples from APGC v2.0 with the extended word-level gender annotations.

The extended word-level statistics are presented in Appendix B. We make the extended word-level gender annotations publicly available as a new release of APGC (APGC v2.1).[4]

---

6 The Multi-step Model Approach

Most of the recent work on gender rewriting rely on using Seq2Seq models (Habash et al., 2019; Alhafni et al., 2020; Sun et al., 2021; Jain et al., 2021; Vanmassenhove et al., 2021). However, the lack of large gender-annotated parallel datasets presents a challenge when training Seq2Seq models, and especially when dealing with morphologically rich languages. This issue is highlighted by Alhafni et al. (2020), who report that most of the errors (68%) produced by their character-level Seq2Seq model are due to not making any changes to gender-specific words in the input sentences. Given the complexity of the gender rewriting task in Arabic and the relatively small training data size, we model the gender rewriting task using a multi-step system the combines the positive aspects of rule-based and neural models. Our system consists of three components: *Gender identification*, *Out-of-context word gender rewriting*, and *In-context ranking and selection*.

6.1 Gender Identification (GID)

We first identify the word-level gender label (base word + pronominal enclitic) for each word in the input sentence. We build a word-level classifier by leveraging a Transformer-based pretrained language model. There are many Arabic monolingual BERT models available such as AraBERT (Antoun et al., 2020), ARBERT (Abdul-Mageed et al., 2021), and QARIB (Abdelali et al., 2021). However, we chose to use CAMeLBERT MSA (Inoue et al., 2021) as it was pretrained on the largest MSA dataset to date. Following the work of Devlin et al. (2019), we fine-tune CAMeLBERT MSA using Hugging Face's transformers (Wolf et al., 2020) by adding a fully-connected linear layer with a softmax on top of its architecture. During fine-tuning, we use the representation of the first sub-token as an input to the linear layer.

6.2 Out-of-context Word Gender Rewriting

Given the desired sentence-level target gender as an input and the identified gender label for each word in the input sentence, we decide if a word-level gender rewrite is needed based on the compatibility between the provided sentence-level target gender and the predicted word-level gender labels. We implement three word-level gender alternative generation models: *Corpus-based Rewriter*, *Morphological Rewriter*, and *Neural Rewriter*.

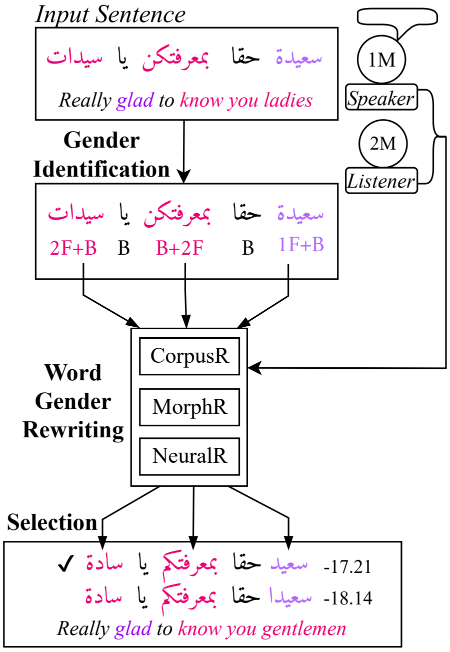

Figure 1: The multi-step gender rewriting system. First person gendered words are in purple and second person gendered words are in red. The sentence-level target gender is 1M/2M. The input words *glad* (1F+B), *know you* (B+2F), and *ladies* (2F+B) are rewritten to their masculine forms.

Corpus-based Rewriter (CorpusR) We build a simple word-level lookup rewriting model by exploiting the fully aligned words in APGC v2.1. We implement this model as a bigram maximum likelihood estimator: given an input word with its bigram surrounding context (w_i, w_{i-1}), a gender alternative target word (y_i), and a desired word-level target gender (g), the CorpusR model is built by computing $P(y_i|w_i, w_{i-1}, g)$ over the training examples. During inference, we generate all possible gender alternatives for the given input word (w_i). If the bigram context (w_i, w_{i-1}) was not observed in the training data, we backoff to a unigram context. If the input word was not observed during training, we pass it to the output as it is.

Morphological Rewriter (MorphR) For the morphological rewriter, we use the morphological analyzer and generator provided by CAMeL Tools (Obeid et al., 2020). We extend the Standard Arabic Morphological Analyzer database (SAMA) (Graff et al., 2009) used by the morphological generator to produce controlled gender alternatives. We make our extensions to the database publicly available.[5]

---

[5] We provide code to reconstruct our extended database from the original SAMA 3.1 database (LDC2010L01) which can be obtained from the LDC.

Given an input word and a desired word-level target gender, the morphological generator has the ability to produce gender alternatives by either rewriting the base word, its pronominal enclitics, or both. If an input word does not get recognized by the morphological analyzer and generator, we pass it to the output as it is. It is worth noting that this rewriting model does not require any training data.

Neural Rewriter (NeuralR) Inspired by work done on out-of-context morphological reinfection (Kann and Schütze, 2016; Cotterell et al., 2018), we design a character-level encoder-decoder model with attention. Given an input word and word-level target gender, the encoder-decoder model would generate gender alternatives of the input word. For the encoder, we use a two-layer bidirectional GRU (Cho et al., 2014) and for the decoder we use a two-layer GRU with additive attention (Bahdanau et al., 2015). Furthermore, we employ *side constraints* (Sennrich et al., 2016) to control for the generation of gender alternatives. That is, we add the word-level target gender as a special token (e.g., <1F+B>) to the beginning of the input word and we feed that entire sequence to the model (i.e., <1F+B>سعيد). The intuition here is that the attentional encoder-decoder model would be able to learn to pay attention to the side constraints to generate the desired gender alternative of the input word. During inference, we use beam search to generate the top 3-best hypotheses.

6.3 In-Context Ranking and Selection

Since the three word-level gender alternative generation models we implement are out-of-context and given Arabic's morphological richness, we expect to get multiple output words when generating a single gender alternative for a particular input word. This leads to producing multiple candidate gender alternative output sentences. To select the best candidate output sentence, we rank all candidates in full sentential context based on their *pseudo-log-likelihood* (PLL) scores (Salazar et al., 2020). We first use Hugging Face's transformers to fine-tune the CAMeLBERT MSA model on the Input corpus of APGC v2.1 by using a masked language modeling (Devlin et al., 2019) objective. This helps in mitigating the domain shift (Gretton et al., 2006) issue between CAMeLBERT's pretraining data and APGC v2.1. We then compute the PLL score for each sentence using the fine-tuned CAMeLBERT MSA model by masking the sentence tokens one by one.[6] We will refer to the in-context ranking and selection as simply *selection* throughout the paper.

Figure 1 presents an overview of our gender rewriting model. We describe the training settings and the model's hyperparameters in Appendix A.

7 Experimental Setup

7.1 Evaluation Metrics

We follow Alhafni et al. (2020) by treating the gender rewriting problem as a user-aware grammatical error correction task and use the MaxMatch (M^2) scorer (Dahlmeier and Ng, 2012) as our evaluation metric. The M^2 scorer computes the precision (P), recall (R), and $F_{0.5}$ by maximally matching phrase-level edits made by a system to gold-standard edits. The gold edits are computed by the M^2 scorer based on provided gold references. Moreover and to be consistent with previous work, we also report BLEU (Papineni et al., 2002) scores which are obtained using SacreBLEU (Post, 2018). We report the gender rewriting results in a normalized space for Alif, Ya, and Ta-Marbuta (Habash, 2010).

7.2 Baselines

Do Nothing Our first baseline trivially passes the input sentences to the output as they are. This baseline highlights the level of similarity between the inputs and the outputs.

Joint Baseline Model Our second baseline uses a variant of the sentence-level linguistically enhanced joint gender identification and rewriting model introduced by Alhafni et al. (2020). The main difference between this model and the one introduced by Alhafni et al. (2020) is that we model four multi-user target genders, whereas they only modeled two single-user target genders (1M, 1F). We implement this joint baseline model using a character-level GRU encoder-decoder with additive attention, where the learned input character-level representations are enriched with word-level morphological features obtained from the extended morphological analyzer that is part of CAMeL Tools. The representation of the input sentence-level target gender (1M/2M, 1F/2M, 1M/2F, 1F/2F) is learned as part of the model and used during decoding when generating gender alternatives. We refer to this baseline as **Joint+Morph**.

---

[6] We use Salazar et al. (2020)'s implementation to compute the PLL scores: `https://github.com/awslabs/mlm-scoring`

Extended Joint Baseline Models Our third and fourth baseline models reduce the complexity of the **Joint+Morph** model by not learning a representation for the input sentence-level target gender as part of the model. Instead, we provide the sentence-level target gender information as side constraints. We add the target gender as a special token to the beginning of the input sentence (e.g., <1M/2F>Input Sentence) when we feed it to the model. Moreover, we explore the effectiveness of enriching the input character representations with word-level morphological features. To do so, we omit the morphological features from the first joint variant, and we use them in the second. We refer to these models as **Joint+Side Constraints** and **Joint+Morph+Side Constraints**, respectively.

7.3 Our Multi-step Models

We explore five variants of the gender rewriting multi-step model described in §6. All five variants use the same gender identification (**GID**) and in-context selection models, but they differ in their out-of-context word-level gender rewriting generation setup. The first three variants use one word-level gender rewriting model each – **CorpusR**, **MorphR**, or **NeuralR**. The fourth multi-step model uses **MorphR** as a backoff if the input words that need to be rewritten are not observed by the **CorpusR** model during training (**CorpusR»MorphR**). The fifth system uses all three word-level gender alternative generation models in a backoff cascade: **CorpusR»MorphR»NeuralR**.

7.4 Data Augmentation

Given the relatively small size of APGC v2.1 and motivated by recent work on using data augmentation to improve grammatical error correction (Wan et al., 2020; Stahlberg and Kumar, 2021), we investigate adding additional training examples through data augmentation. We randomly selected 800K sentences from the English-Arabic portion of the OpenSubtitles 2018 dataset, which was used to build APGC. We ensured that all extracted pairs include either first or second (or both) person pronouns on the English side: *I, me, my, mine, myself,* and *you, your, yours, yourself*. To generate gender alternatives of the selected Arabic sentences, we pass each sentence four times through our best gender rewriting system to generate all four user gender contexts (1M/2M, 1F/2M, 1M/2F, 1F/2F). We add the 800K selected Arabic sentences and their 1M/2M, 1F/2M, 1M/2F, 1F/2F generated gender alternatives to the Input, Target 1M/2M, Target 1F/2M, Target 1M/2F, and Target 1F/2F corpora of the training split of APGC v2.1, respectively. At the end, we end up with 857,603 Arabic parallel sentences (6,209,958 words). We make the synthetically generated data publicly available.

8 Results

Table 3 presents the DEV set results. **Joint+Side Constraints** and **Joint+Morph+Side Constraints** significantly improve over the **Joint+Morph** baseline with up to 13.87 increase in $F_{0.5}$. The best performing system overall is our multi-step model using all rewrite components – Table 3(i), henceforth, *Our Best Model*. It improves over all the joint models in every compared metric, including a 22.84 increase in $F_{0.5}$ when compared to the **Joint+Morph** baseline. *Our Best Model*'s biggest advantages seem to come from combining the three word-level out-of-context gender alternative generation models in a cascaded setup to deal with OOV words during the generation. Comparing (i) with (e,f,g) in Table 3, we observe improvements ranging from 3.91 to 6.02 $F_{0.5}$.

We used *Our Best Model* to conduct the data augmentation experiments as discussed in §7.4. The full set of augmentation experiment results are presented in Appendix C. The best augmented model's results, which benefits from augmentation in the **GID** and **NeuralR** components, are also presented in Table 3(j). However, its increase of 0.19 points in $F_{0.5}$ is not statistically significant with McNemar's (McNemar, 1947) test at $p > 0.05$.

The results of our best models on the TEST sets of APGC v2.1 and APGC v1.0 are presented in Table 4. The results on APGC v2.1 TEST show consistent conclusions with the DEV results. Our best augmented model improves over its non-augmented variant in every compared metric, including a 0.25 absolute increase in $F_{0.5}$ that is statistically significant with McNemar's test at $p < 0.05$. For APGC v1.0, we do not report results with augmentation for fair comparison to previous results. In both TEST sets, we establish new SOTAs.

Error Analysis We conducted an error analysis over the output of our best augmented system on APGC v2.1 DEV. In total, there were 1,475 (5.5% out of 26,588) sentences with errors across the four target corpora. Table 5 presents a summary of the error types our best augmented gender rewriting model makes.

		P	R	$F_{0.5}$	BLEU
(a)	**Do Nothing**	100.0	0.0	0.0	89.36
(b)	**Joint + Morph**	64.76	67.40	65.27	93.31
(c)	**Joint + Side Constraints**	77.10	77.71	77.22	95.60
(d)	**Joint + Morph + Side Constraints**	78.97	79.84	79.14	96.17
(e)	**GID + CorpusR + Selection**	88.22	71.22	84.20	96.54
(f)	**GID + MorphR + Selection**	84.48	75.29	82.47	96.96
(g)	**GID + NeuralR + Selection**	84.62	73.32	82.09	96.75
(h)	**GID + CorpusR » MorphR + Selection**	**88.59**	85.84	88.02	97.96
(i)	**GID + CorpusR » MorphR » NeuralR + Selection**	88.46	**86.74**	**88.11**	**98.04**

Table 4: Gender rewriting results on the TEST sets of APGC v2.1 and APGC v1.0.

	1M/2M	1F/2M	1M/2F	1F/2F
GID	150 56%	194 70%	325 68%	324 72%
Rewrite	69 26%	50 18%	82 17%	66 15%
Select	49 18%	35 13%	73 15%	58 13%
Total	268	279	480	448

Table 5: Error type statistics of our best augmented system's performance on APGC v2.1 DEV.

Target	1M/2M	1F/2M	1M/2F	1F/2F
Google Translate	13.59	13.15	11.38	10.96
$\text{Best System}_{\text{Aug}}$	**13.71**	**13.64**	**13.30**	**13.23**

Table 6: BLEU results on the post-edited Google Translate output of APGC v2.1 TEST using our best augmented system.

The majority of errors (67.3%) were caused by **GID** which achieves a word-level accuracy of 98.9% on DEV. The gender-rewriting errors constituted 18.1% and selection errors 14.6%. Considering different target corpora, we observe that every time an F target is added, the number of errors increases. The 1M/2M target outputs has the lowest number of errors (268 or 18%), while the 1M/2F targets outputs has the highest number of errors (480 or 33%).

Use Case: Post-Editing MT Output We demonstrate next how our proposed gender rewriting model could be used to personalize the output of user-unaware MT systems through post-editing. We use the English to Arabic Google Translate output sentences that are part of APGC v2.1. We evaluate Google Translate's output against all four target corpora (1M/2M, 1F/2M, 1M/2F, 1F/2F) separately. To re-target Google Translate's Arabic output for the four user gender contexts we model, we pass each Arabic sentence four times through our best augmented system (Table 3(j)). We present the evaluation in terms of BLEU in Table 6 over APGC v2.1 TEST. All the results are reported in an orthographically normalized space for Alif, Ya, and Ta-Marbuta.

Again, we observe that every time an M participant is switched to F, the BLEU scores drop for Google Translate's output. This is consistent to what have been reported by Alhafni et al. (2022) and highlights the bias the machine translation output has towards masculine grammatical gender preferences. The post-edited outputs generated by our best augmented system improves over Google Translate's across the four target user contexts, achieving the highest increase in 2.27 BLEU points for 1F/2F.

9 Conclusion and Future Work

We defined the task of gender rewriting in contexts involving two users (I and/or You), and developed a multi-step system that combines the positive aspects of both rule-based and neural rewriting models. Our best models establish the benchmark for this newly defined task and the SOTA for a previously defined first person version of it. We further demonstrated a use case of our gender rewriting system by post-editing the output of a commercial MT system to provide personalized outputs based on the users' grammatical gender preferences.

In future work, we plan to explore the use of other pretrained models, and to work on the problem of gender rewriting in other languages and dialectal varieties.

Ethical Considerations

Gender Rewriting Our underlying intention of developing a gender rewriting model for Arabic is to increase the inclusiveness of NLP applications that deal with gender-marking morphologically rich languages. Our work aims at empowering and allowing users to interact with NLP technology in a way that is consistent with their social identities. We acknowledge that by limiting the choice of gender expressions to the grammatical gender choices in Arabic, we exclude other alternatives such as non-binary gender or no-gender expressions. However, we are not aware of any sociolinguistics published research that discusses such alternatives for Arabic. We stress on the importance of adapting Arabic NLP models to new gender alternative forms as they emerge as part of the language usage. We further recognize the limitations of the gender identification component we use as part of our multi-step gender rewriting model as it relies on a language model that was pretrained on a large monolingual Arabic corpus, which could possibly contain biased text. We realize the potential risks of our proposed gender rewriting model if it is intentionally maliciously misused to produce gender alternatives that do not match the target users' gender preferences.

Data We use the publicly available Arabic Parallel Gender Corpus (APGC).[7] It is subject to its creators' own Copy Rights and User Agreement and we strictly adhere to its intended usage. It is worth noting that APGC does not contain any hetero-centric assumptions as part of its annotations (e.g., the word زوجي 'my husband' is labeled as gender-ambiguous (B)). Moreover, all proper names are labeled as B, even when they have strong gender-specific association (Alhafni et al., 2022). The Arabic data we use for our data augmentation experiments was randomly sampled from OpenSubtitles 2018 (Lison and Tiedemann, 2016), which is publicly available.[8] OpenSubtitles is distributed under a Creative Commons license.[9]

A Detailed Experimental Setup

Gender Identification We fine-tune CAMeLBERT MSA on a single GPU for 10 epochs with a learning rate of 5e-5, batch size of 32, a seed of 12345, and a maximum sequence length of 128. For the augmentation experiments, we use the same hyperparamters but we run the fine-tuning for 3 epochs. At the end of the fine-tuning, we pick the best checkpoint based on the performance on the DEV set. Our gender identification model has 108,506,901 parameters.

In-Context Ranking and Selection We fine-tune CAMeLBERT MSA on a single GPU for 3 epochs with a learning of 5e-5, batch size of 32, and a seed of 88. The fine-tuned CAMeLBERT MSA model has 109,112,880 parameters.

Neural Rewriter (NeuralR) For the character-level encoder-decoder neural rewriter model we use a character embedding size of 128, a hidden size of 256, a dropout probability of 0.2 on the outputs of each GRU layer, and gradient clipping with a maximum norm of 1. We train for 50 epochs on a single GPU with early stopping after 6 epochs if the loss does not decrease on the DEV set. We use the Adam (Kingma and Ba, 2014) optimizer with an initial learning rate of 5e-4, decaying by a factor of 0.5 if the loss on the DEV set does not decrease after 2 epochs. We train with greedy decoding and a batch size of 32. We also apply scheduled sampling (teacher forcing) (Bengio et al., 2015) with a constant sampling probability (0.3) during training. During inference, we use beam search with a beam width of 10 to produce the top 3-best hypotheses. Our **NeuralR** model has 3,287,110 parameters.

Joint Models The training settings and the hyperparameters of the joint models are identical to the ones we use in our **NeuralR** model.

The crucial difference between the **Joint+Morph** model and its extended variants (**Joint+Side Constraints** and **Joint+Morph+Side Constraints**) is that the rewriting in the **Joint+Morph** model is conditioned on the sentence-level target gender. The representation of the sentence-level target gender in the baseline model is learned as an embedding of size 10 during training and only used in the decoder.

Our **Joint+Morph** model has 3,481,178 parameters; the **Joint+Side Constraints** model has 3,293,258 parameters; and the **Joint+Morph+Side Constraints** model has 3,480,926 parameters.

Training Time The **CorpusR** model was trained on a single CPU and it took ≈2 minutes to be trained. All our neural models were trained on a single GPU. Fine-tuning CAMeLBERT MSA on the gender identification task took ≈1 hour; fine-tuning CAMeLBERT MSA on the MLM objective took ≈1 hour. Training the **NeuralR** model with different settings took ≈12 hours in total. All the baseline joint models took ≈29 hours to be trained.

It is worth noting that all the results presented in this work are reported over a single run and the hyperparameters of our neural models were manually tuned based on the performance on the DEV set.

B Arabic Parallel Gender Corpus v2.1: Extended Word-Level Annotations

Word Gender Label	Train	Dev	Test	
B	385,693	44,629	108,411	538,733

Table 8: Results of the data augmentation experiments on the DEV set of APGC v2.1. **Aug** indicates that the component of the system is trained on the augmented data.

C Augmentation Experiments

When it comes to the data augmentation experiments, we took the best performing system (Table 3(i)) and explored training its different components on the augmented training data. Evaluation results on the DEV set of APGC v2.1 using data augmentation are presented in Table 8. Starting off with training the **CorpusR** model on the augmented data (Table 8(a)), we notice a decrease in performance by 0.23 $F_{0.5}$ compared to *Our Best Model* (Table 3(i)). This is attributed to the noisy coverage increase in the **CorpusR** model and can be observed by the decrease in precision (88.19) and recall (86.66). When we train the **GID** and the **NeuralR** models on the augmented data (Table 8(b-c)), we get an increase in $F_{0.5}$ reaching 88.28 and 88.12, respectively. However, using both the augmented **GID** and **CorpusR** models (Table 8(d)) decreases the performance slightly as it achieves 88.10 in $F_{0.5}$. The best performing system was the one that uses both the augmented **GID** and **NeuralR** models (Table 8(e)) as it improves over its non-augmented variant reaching 88.30 (0.19 increase) in $F_{0.5}$. Combining the three augmented **GID**, **CorpusR**, and **NeuralR** models (Table 8(f)) achieves 88.08 in $F_{0.5}$.

Reframing Human-AI Collaboration for Generating Free-Text Explanations

Abstract

Large language models are increasingly capable of generating fluent-appearing text with relatively little task-specific supervision. But can these models accurately explain classification decisions? We consider the task of generating free-text explanations using human-written examples in a few-shot manner. We find that (1) authoring higher quality prompts results in higher quality generations; and (2) surprisingly, in a head-to-head comparison, crowdworkers often prefer explanations generated by GPT-3 to crowdsourced explanations in existing datasets. Our human studies also show, however, that while models often produce factual, grammatical, and sufficient explanations, they have room to improve along axes such as providing novel information and supporting the label. We create a pipeline that combines GPT-3 with a supervised filter that incorporates binary acceptability judgments from humans in the loop. Despite the intrinsic subjectivity of acceptability judgments, we demonstrate that acceptability is partially correlated with various fine-grained attributes of explanations. Our approach is able to consistently filter GPT-3-generated explanations deemed acceptable by humans.

1 Introduction

As natural language understanding tasks have become increasingly complex, the field of explainable NLP has embraced explanations written in free-form natural language. In contrast to extractive explanations that highlight tokens in the input, free-text explanations provide a natural interface between machine computation and human end-users (Hendricks et al., 2016; Camburu et al., 2018). The dominant paradigm for producing free-text explanations is via direct supervision, i.e., training an autoregressive, generative language model to predict human-authored explanations directly (Kim et al., 2018; Park et al., 2018; Ehsan et al., 2018; Narang et al., 2020; Wiegreffe et al., 2021, *i.a.*).

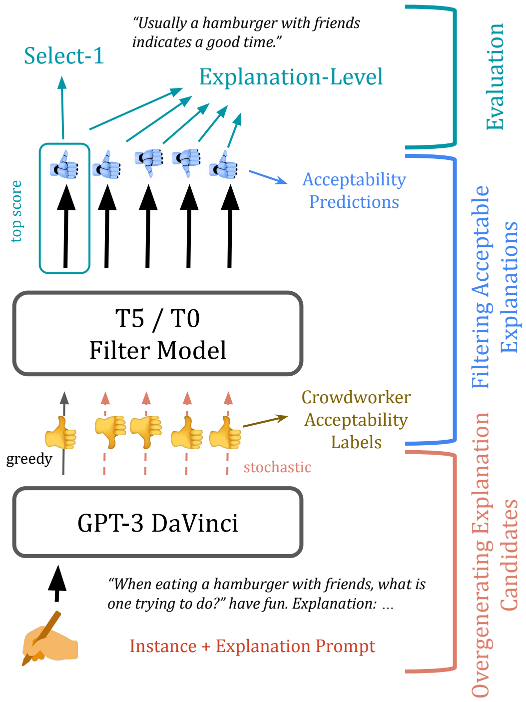

Figure 1: Illustration of our overgeneration + filtration pipeline for producing human acceptable explanations for CommonsenseQA and SNLI (see examples in Table 1). Authors of this work write explanations to prompt GPT-3, generating 5 explanations per instance. An acceptability filter, trained on human binary acceptability judgments, determines which of these generated explanations are plausible. Evaluation is performed at both the explanation and the instance level.

However, collecting high-quality written explanations to serve as supervision is difficult and expensive. More than 70% of existing free-text explanation datasets are crowdsourced (Wiegreffe and Marasović, 2021), and even the most meticulous crowdsourcing efforts frequently fail to elicit logically consistent and grammatical explanations (Narang et al., 2020). Furthermore, a lack of standardized crowdsourcing design has resulted in highly varied datasets, which are hard to compare or combine (Tan, 2021).

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 632 - 658
July 10-15, 2022

Recent progress in prompting large language models (LLMs) provides a potentially promising alternate to large-scale crowdsourcing. The *in-context learning* paradigm, wherein powerful language models are prompted in a few-shot manner with just a few examples, has proven surprisingly effective across a range of NLP tasks (Radford et al., 2019; Brown et al., 2020; Shin et al., 2020; Schick and Schütze, 2021a, *i.a.*). In this work we ask: can LLMs also generate reliable *explanations*? In human subjects studies, we find that GPT-3 (Brown et al., 2020) can be readily made to generate explanations via prompting, and surprisingly, humans often prefer GPT-3 generated explanations to crowdsourced explanations in existing datasets (§2).

Two additional human subjects studies, however, demonstrate that GPT-3-generated explanations still have significant room for improvement along axes such as providing new information (i.e., avoiding repetition) and supporting the label; human subjects found less than half of greedily-decoded GPT-3-generated explanations to be *acceptable* with 100% agreement. To improve upon this, we *re-frame* the role of crowd annotators: instead of asking them to write explanations as in prior work, we (1) repeatedly query GPT-3 to generate multiple candidate explanations for each input instance, and (2) ask crowdworkers to rate the acceptability of each candidate generation. After showing that GPT-3 can usually generate an explanation that humans unanimously find acceptable within as few as five queries (§3), we use a small number of these binary crowdworker judgments to supervise an acceptability filtering model, which can be applied to select high quality candidates among GPT-3's outputs (Figure 1; §4).

Despite intrinsic subjectivity in acceptability ratings, our supervised model improves upon the already-competitive few-shot paradigm by consistently selecting (human-identified) high quality explanations better than strong baselines. Human evaluations reveal that the filtration model not only improves acceptability, but also other axes like supporting the label and providing novel information.

In summary, our main findings are:

i. few-shot prompting with GPT-3 produces surprisingly competitive explanations, providing a promising alternative to crowd-authored free-text explanation corpora;
ii. binary human labeling can instead be leveraged to train a filter that selects high-quality machine-generated explanations; and
iii. in areas where GPT-3 struggles, including information content, supporting the label, and overall acceptability, our proposed overgenerate-and-filter pipeline improves generated explanations.

We publicly release our code and data.[1]

2 GPT-3 is Competitive with Crowdsourced Explanation Datasets

We investigate three research questions:

1. Are GPT-3-generated explanations preferable to crowdsourced ones in existing datasets? (§2.1)
2. Can improving prompt quality improve GPT-3-generated explanations? (§2.2)
3. Along what fine-grained dimensions are GPT-3-generated explanations preferred, and do these correlate with overall acceptability? (§2.3)

Explanation tasks and datasets. We consider two English tasks: CommonsenseQA and natural language inference (NLI), shown in Table 1. CommonsenseQA (Talmor et al., 2019) is a multiple choice task posed over commonsense questions. Crowdsourced free-text explanations for instances in CommonsenseQA are provided in the CoS-E v1.11 (Rajani et al., 2019) and ECQA (Aggarwal et al., 2021) datasets. ECQA explanations are counterfactual, i.e., annotators were instructed to explain not only the correct answer choice but also why the others are incorrect. ECQA was released to address the quality issues of CoS-E (Narang et al., 2020); for completeness, we experiment with both. Our second task is NLI, which involves inferring whether a given hypothesis sentence entails, contradicts, or is neutral towards a premise. This task is instantiated with the SNLI dataset (Bowman et al., 2015) and crowdsourced explanations from e-SNLI (Camburu et al., 2018). For each task, we report results on a fixed, randomly-sampled 250-instance test set not observed during prompt design.

Few-shot prompting for explanations. We use GPT-3 Davinci[2] (Brown et al., 2020), an autoregressive language model with ~175B parameters trained on a large dataset of text scraped from the internet. We prompt the model with several (question, gold answer, explanation) triplets followed by an unexplained question-gold answer instance for

---

[1] https://github.com/allenai/few_shot_explanations/

[2] Non-instruct version, available in Summer 2021.

SNLI (Bowman et al., 2015)

Premise: Dark-haired man wearing a watch and oven mitt about to cook some meat in the kitchen.
Hypothesis: A man is cooking something to eat.
Label: entailment

e-SNLI (Camburu et al., 2018): Meat is cooked in a kitchen, and is a food that you eat. Using an oven mitt implies you're about to cook with hot utensils.
GPT-3: Cooking is usually done to prepare food to eat.

CommonsenseQA (Talmor et al., 2019)

Question: What is the result of applying for job?
Answer Choices: anxiety and fear, increased workload, praise, less sleep, or being employed
Correct Choice: being employed

CoS-E (Rajani et al., 2019): being employed applying for job
ECQA (Aggarwal et al., 2021): Applying for a job is followed by attending interview which results in being employed. Applying for a job may not result in the other options.
GPT-3: Applying for a job can result in being employed, which is a positive outcome.

Table 1: Task-specific instances, along with their crowdsourced explanations from the respective datasets, shown alongside explanations generated greedily by GPT-3. In our experiments, the SNLI GPT-3 explanation was preferred over its corresponding e-SNLI explanation by $2/3$ annotators. For CommonsenseQA, $3/3$ preferred the GPT-3 explanation to the CoS-E explanation, and $2/3$ to the ECQA one.

Let's explain classification decisions.
A young boy wearing a tank-top is climbing a tree.
question: A boy was showing off for a girl.
true, false, or neither? neither
why? A boy might climb a tree to show off for a girl, but he also might do it for fun or for other reasons.
###
A person on a horse jumps over a broken down airplane.
question: A person is outdoors, on a horse.
true, false, or neither? true
why? Horse riding is an activity almost always done outdoors. Additionally, a plane is a large object and is most likely to be found outdoors.
###
There is a red truck behind the horses.
question: The horses are becoming suspicious of my apples.
true, false, or neither? false
why? The presence of a red truck does not imply there are apples, nor does it imply the horses are suspicious.
###
A dog carries an object in the snow.
question: A dog is asleep in its dog house.
true, false, or neither? false
why?

Table 2: Example of a prompt with 3 training examples for SNLI: presented are the premise/hypothesis pairs, the gold labels, and the explanations (written by us) that act as input to GPT-3 (in practice, we use 8-24 examples per prompt). The text generated by the model acts as the free-text explanation. In this case, the model greedily auto-completes (given 12 examples): *"A dog cannot carry something while asleep"*.

which we expect the model to generate an explanation.[3] We use a total of 115 randomly sampled train instances to create our prompts; each prompt consists of 8-24 randomly selected examples from this set. For each instance, we generate a single explanation with greedy decoding. More details about prompt construction are in Appendix A; example prompts are given in Tables 2 and 11.

Crowdsourcing evaluation. Given that existing automatic metrics often do not correlate well with human judgements of explanation quality (Clinciu et al., 2021; Kayser et al., 2021), we conduct human studies for evaluation.[4] We ensure each experiment has a substantial number of distinct crowdworkers to mitigate individual annotator bias (Table 17).

We present workers with a dataset instance, its gold label, and two explanations for the instance generated under different conditions ("head-to-head"). We then ask them to make a preferential selection, collecting 3 annotations per data point. We report inter-annotator agreement (IAA) using Krippendorff's α (Krippendorff, 2011). We find low-to-moderate agreement across studies, indicating the subjective nature of the task; see Tables 3, 4, and 5. Appendix B contains further details on quality control.

---

[3] We condition on the gold label as a *methodological control* to ensure reliable human evaluation. In pilot studies, we found it hard to avoid bias against explanations when we disagreed with the predicted label. Prior work (Kayser et al., 2021; Marasović et al., 2021) has removed this confounder by only considering explanations for *correctly-predicted* instances, which may overestimate explanation quality. Our method allows us to report results on a truly representative sample. We experiment with incorrect vs. correct predictions in Appendix C, finding that GPT-3 can competitively explain gold labels for instances it predicted incorrectly.

[4] Our studies were conducted on the Amazon Mechanical Turk platform, at the Allen Institute for AI. We selected workers located in Australia, Canada, New Zealand, the UK, or the US, with a past HIT approval rate of >98% and >5000 HITs approved, and compensated them at a rate of $15/hour. Each worker completed qualifying exams on explanation evaluation and the NLI task.

	Preferred Explanation (%)			
Dataset	**Crowd**	**Tie**	**GPT-3**	α
CoS-E	20.3	34.9	**44.8**	0.5
ECQA	**52.7**	12.9	34.4	0.2
e-SNLI	**63.6**	11.6	24.8	0.3

Table 3: Head-to-head human evaluation for 250 explanations generated by GPT-3 vs. written by crowdworkers in the datasets, along with Krippendorff's α for IAA. Results are shown as % preferences. We prompted GPT-3 with crowd explanations *from the corresponding datasets*.

2.1 Are GPT-3 explanations preferred over crowdsourced ones?

We perform a head-to-head comparison of explanations generated by GPT-3 with greedy decoding vs. gold human-written explanations in the original datasets. The crowdsourced explanations serve as a reasonable upper bound for what a supervised explanation generation model trained on them could produce. Table 1 contains examples of GPT-3-preferred explanations.

Results are shown in Table 3. GPT-3 greedily-decoded explanations are frequently preferred or comparable to crowdsourced explanations in CoS-E, which is not too surprising given the dataset has many ungrammatical explanations (Narang et al., 2020). And, while ECQA and e-SNLI explanations are strongly preferred to GPT-3, there are still a non-trivial number of cases where GPT-3 explanations are competitive (47.3% and 36.4%, respectively).

2.2 Can improving prompt quality improve GPT-3-generated explanations?

	Preferred GPT-3 Explanation (%)			
Dataset	**Crowd Prompts**	**Tie**	**Our Prompts**	α
CoS-E	6.9	13.5	**79.6**	0.2
ECQA	15.9	9.5	**74.7**	0.3
e-SNLI	30.8	26.8	**42.4**	0.5

Table 4: Head-to-head human evaluation for 250 explanations generated by GPT-3 prompted with either author-written explanations or crowdsourced explanations from the associated datasets, along with Krippendorff's α for IAA.

Given that low-quality training instances may result in low-quality predictions (especially in a few shot setting),[5] we ask: can we improve GPT-3 generations simply by conditioning on higher-quality instances? To this end, we replace the 115 crowdsourced explanations from the original datasets for prompting GPT-3 with explanations carefully written by the authors of this paper (see Table 12 for examples). Our prompts are used to generate a different set of GPT-3 explanations on the same test data.

	Preferred Explanation (%)			
Dataset	**Crowd**	**Tie**	**GPT-3**	α
CoS-E	7.2	13.9	**78.9**	0.5
ECQA	44.5	9.7	**45.7**	0.4
e-SNLI	**49.6**	9.7	40.7	0.2

Table 5: Head-to-head human evaluation for 250 explanations generated by GPT-3 vs. written by crowdworkers in the datasets, along with Krippendorff's α for IAA. GPT-3 explanations were prompted with explanations *written by the authors*.

We perform a head-to-head human evaluation of the GPT-3 generations conditioned on the explanations we wrote vs. those conditioned on the crowdsourced explanations. Results in Table 4 show that, for all three corpora, generations conditioned on our explanations outperform generations conditioned on crowdsourced ones, illustrating the importance of good-quality prompts for GPT-3.

We repeat the experiment of §2.1, but with our prompts instead of dataset prompts. With this change, GPT-3 generations are even more competitive (Table 5). For all three datasets, more than half the time, few-shot prompting results in an explanation *at least as good as* a human-written explanation. For subsequent experiments, we prompt GPT-3 with the author-written explanations.

2.3 What types of explanations does GPT-3 generate?

Pairwise evaluations can only offer perspective on the relative quality of generated explanations. Are crowd annotators simply comparing explanations on surface-level features like grammaticality?

To understand finer-grained characteristics of explanations, we design a second human study to collect absolute Likert-scale judgments across seven axes of quality (with each explanation judged by 3 annotators). The first three axes capture surface-level features: generality, grammaticality, and factuality. The next three capture richer aspects of explanation quality: whether new information is introduced (a requirement for non-vacuous explana-

---

[5] For example, GPT-3 reproduces known data artifacts in the CoS-E corpus when prompted with explanations from it, such as the recurring phrase "rivers flow trough (sp) valleys".

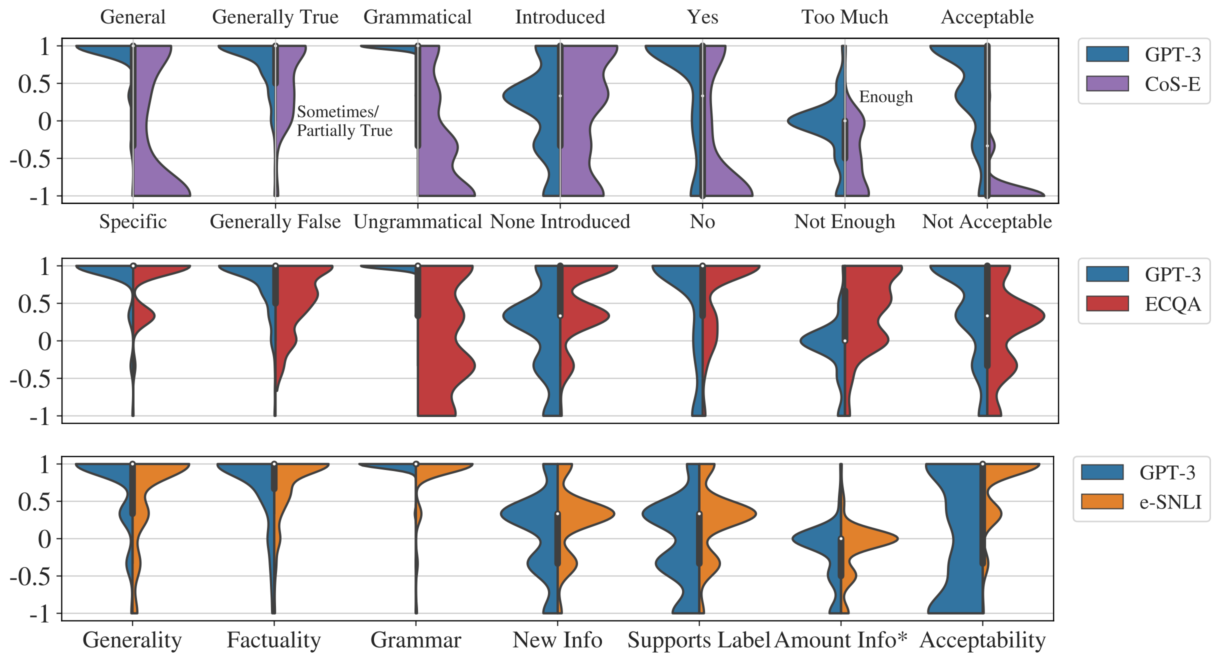

Figure 2: Absolute evaluation for GPT-3 and crowdsourced explanations for CommonsenseQA via CoS-E (top) and ECQA (middle) datasets, and for NLI via the e-SNLI dataset (bottom). The distribution of mean scores of 3 annotators for each instance in the test set is plotted. All attributes besides **Factuality** and **Amount Info** are binary. ***Amount Info** is the only attribute for which a value of 0 is preferred to a value of 1. See Table 18 for more details.

tions), whether explanations support the gold label, and whether the amount of information given is sufficient. Finally, we ask for an overall judgement of quality: *is the explanation acceptable*? We explain our design process in Appendix B.3. Results on the crowdsourced and GPT-3 explanations for both tasks are given in Figure 2.[6]

For both tasks, GPT-3 explanations do well in all 3 surface-level categories, with statistically significantly greater ratings in generality and grammaticality (and factuality for CommonsenseQA) compared to crowdsourced explanations, and distributional means close to 1. In these categories, there is little room for improvement.

On the other hand, GPT-3 explanations do not contain as much new information as ECQA and e-SNLI explanations, indicating substantial room for improvement (mean=0.1 for both tasks compared to 0.6 for ECQA and 0.2 for SNLI; these differences are statistically significant at $p \leq 0.01$). GPT-3 explanations are substantially more supportive of the label vs. CoS-E, but not as supportive as ECQA or e-SNLI (all statistically significant at $p \leq 0.1$). Indeed, the mean rating of GPT-3 explanations for label support is 0.5 for CommonsenseQA and -0.1 for NLI, demonstrating room for improvement. These axes are crucial to ensuring explanations are not vacuous and are on-topic. Finally, GPT-3 explanations are judged as acceptable at higher rates than CoS-E or ECQA explanations, but not e-SNLI explanations. Mean scores of 0.5 (CommonsenseQA) and 0.0 (NLI) indicate that GPT-3 explanations have room to improve overall.[7]

Correlation between acceptability and other attributes To understand what factors are important for the overall "acceptability" judgement, we compute Spearman correlation (ρ; Spearman, 1987) between acceptability and all other attributes (Table 6). Each is positively correlated with acceptability, though with varying degrees of magnitude. Acceptability is least correlated with "new information," and most correlated with grammaticality, generality, and the explanation's support for the label. Overall, the results indicate that human preference for explanations is not fully explained by any one attribute, and is not limited to surface-level features.

---

[6] Krippendorff's α is 0.48 for CommonsenseQA annotations and 0.31 for SNLI; see Table 15.

[7] We do not evaluate explanations counterfactually, which may explain why ECQA explanations are often labeled as having "too much information". See Appendix B.1.

Attribute	ρ	n
Generality	0.25	3750
Factuality	0.17	2958
Grammar	0.31	3750
New Info	0.05	3750
Supports Label	0.22	2943
*Amount Info	0.16	1761

Table 6: Spearman's correlation (ρ) between acceptability and other attributes in Figure 2. For *Amount Info*, a value of 0 is preferred to a value of 1. All results are statistically significant at p <0.01.

3 Beyond Greedy Explanations

While GPT-3 explanations demonstrate strength across surface-level features and are surprisingly competitive in head-to-head settings, they can still be improved. One might imagine a setting with multiple end-users in which we wish to provide the most **unambiguously acceptable** explanation as output from a system. When considering the data from §2.3, we find that only 46.3% of the greedily-decoded GPT-3-generated explanations for CommonsenseQA and 31.5% for NLI are rated acceptable **by 3/3 annotators**.[8]

Inspired by work in other generation tasks (Holtzman et al., 2020; Massarelli et al., 2020; Holtzman et al., 2021), we hypothesize that equally or more informative explanations can be generated by sampling stochastically. We sample 4 additional generations from GPT-3 for each instance to complement the greedy generation. We crowdsource 3 acceptability annotations for each new explanation.

As expected, sampled explanations exhibit lower 3/3 acceptability than greedy explanations (25.1% for CommonsenseQA; 11.3% for SNLI). However, this results in a surprisingly higher proportion of instances that have *at least one* acceptable explanation in the set of 5. The greedy explanation was judged to be 3/3 acceptable in 46.3% of instances for CommonsenseQA and 31.5% for NLI; this increases to 79.5% and 51.2%, respectively, when sampled explanations are included.[9]

4 Improving Explanation Generation with Acceptability Filtering

The challenge of overgeneration is that GPT-3 alone cannot discern *which* of its stochastic samples are acceptable. Inspired by West et al. (2021), we explore training a supervised filter on the collected labels. Our key intuition is that by re-framing the role of annotators from explanation authors to binary judges, we can alleviate the need to collect a large-scale explanations dataset—the result is a simpler, cheaper, and easier crowdsourcing setup to administer (§4.1). Namely, we can (1) aggregate ratings over multiple annotators to produce more reliable labels, (2) use numerical metrics of annotator agreement to remove annotators contributing noisy data, and (3) collect annotations more quickly and cheaply than asking annotators to hand-write explanations. Moreover, we find that the filter can be trained with a relatively small amount of binary human judgments (§4.2). We demonstrate that the trained model is not simply taking advantage of surface-level features (§4.4). Figure 1 presents an overview of our pipeline.

4.1 Acceptability Annotations

We generate train and validation sets by repeating the procedure of generating 1 greedy and 4 sampled explanations for 991 and 1K instances, respectively, of the CommonsenseQA and SNLI training sets. Combining these with the annotated test sets from previous experiments results in a dataset of 1241/1250 instances in a 72/8/20% train/val/test ratio for each task. We again collect 3 binary acceptability ratings for each instance, resulting in ~6200 instance-explanation pairs and ~19K individual annotations per task. Table 13 contains statistics. To ensure that models trained on these corpora do not overfit to specific annotators (Geva et al., 2019), we collect an additional set of judgments for the test set of SNLI from a group of annotators who did not participate in any of our previous annotation tasks ("Test2"). Figure 9 and Figure 10 show the user interface.[10]

While we evaluate at test-time with the schema that only instances that 3/3 annotators deem acceptable are considered acceptable, preliminary experiments show that treating both 2/3 and 3/3 agreement instances as acceptable during training performs best on the 3/3 evaluation criterion at test-time.[11] We also train a variant where we randomly select one annotation from the three as the gold label ("without human agreement").

---

[8] In §4, we show that these are not upper-bounds caused by intrinsic subjectivity, and that they can be improved upon.

[9] Appendix D provides similar results for the 2/3 acceptability threshold.

[10] Krippendorff's α for all acceptability annotations is 0.34 for CommonsenseQA and 0.39 for SNLI (see Table 14).

[11] Our results don't significantly change if a 2/3 cutoff is used at test time instead: Appendix F contains the results.

4.2 Acceptability Filter

Concretely, given the problem instance, the gold label, and a generated explanation, the acceptability filter predicts whether the explanation is acceptable. We fine-tune two sequence-to-sequence architectures, T5-Large (Raffel et al., 2020) and T0-3B (Sanh et al., 2022). Each model is trained 5x with different random seeds. Further training details are given in Appendix E.

Baselines. We train an **explanation-only** baseline, which receives as input only the explanation; similar baselines have been proposed for NLI (Poliak et al., 2018; Gururangan et al., 2018). These models represent the hypothesis that annotator ratings can be reconstructed with only surface features of the explanation candidates, e.g., grammaticality. We also consider a **negative log-likelihood (NLL)** baseline, which uses GPT-3's estimated probability as the acceptability classification score. This is a slightly more competitive baseline than greedy; greedy usually (but not always) produces the highest-likelihood explanation.[12]

4.3 Evaluation

We consider three evaluation settings. The first is **instance-level** ("select-1"), where the system returns 1 explanation selected from the set of 5 for each instance. We return the explanation with the highest model-estimated probability and report instance-level accuracy, i.e., the % of instances for which a gold acceptable explanation is selected.

We also evaluate at the **explanation-level**, where we treat each explanation independently and compute metrics over the full dataset. This aligns with the binary classification training of the models (cross-entropy on the explanation labels) and is suited for the setting in which we want to return *all* of the acceptable explanations per instance. In this setting, we report **average precision (AP)**, an estimate of area under the precision-recall curve.

Finally, we perform an absolute human evaluation (§2.3) on the subset of instances where the filter model does *not* select the greedy explanation as the best, i.e., comparing "select-1" performance to a greedy baseline on the instances where it differs. We additionally re-perform the head-to-head comparison of Table 5, replacing the greedy GPT-3 explanations with those selected by the filter.

	"Select-1" Acc@3/3		Expl.-level AP@3/3	
	Dev	**Test**	**Dev**	**Test**
Random	$26.8_{3.2}$	$30.6_{2.1}$	$27.4_{1.1}$	$31.6_{0.4}$
Constant	—	—	27.9	31.8
NLL	41.8	52.0	42.4	45.6

Table 8: Results for SNLI explanation acceptability; all model results are on T0-3B. See Table 7's caption.

4.4 Results

Classifier performance is given in Tables 7-8.

Effect of model size. On CommonsenseQA, T0-3B outperforms T5-Large by ~2-4% select-1 accuracy and ~5-6% explanation-level AP across splits. We use T0-3B in subsequent experiments.

NLL baseline vs. full model. For both tasks on both validation and test sets, T0-3B outperforms the NLL baseline substantially. On CommonsenseQA, we observe a 7-8% gain in instance-level accuracy, and a gain of 18% explanation-level AP on the test set. This provides strong evidence that the supervised model is able to incorporate binary human feedback to predict acceptable explanations at a level much higher that GPT-3 achieves on its own. We present examples where "select-1" predictions differ between NLL and our filter model in Table 10 and Table 16.

Explanation only vs. full model. Our results suggest that our models are leveraging feature interactions between the instance and explanation to make their predictions: without instance-level context, the explanation-only baselines are on average more than 5 points worse across metrics. Though

---

[12] According to GPT-3, a sampled explanation from the set of 5 has a lower NLL than greedy for only 2.8% and 3.6% of instances, respectively, of our Com.QA and SNLI test sets.

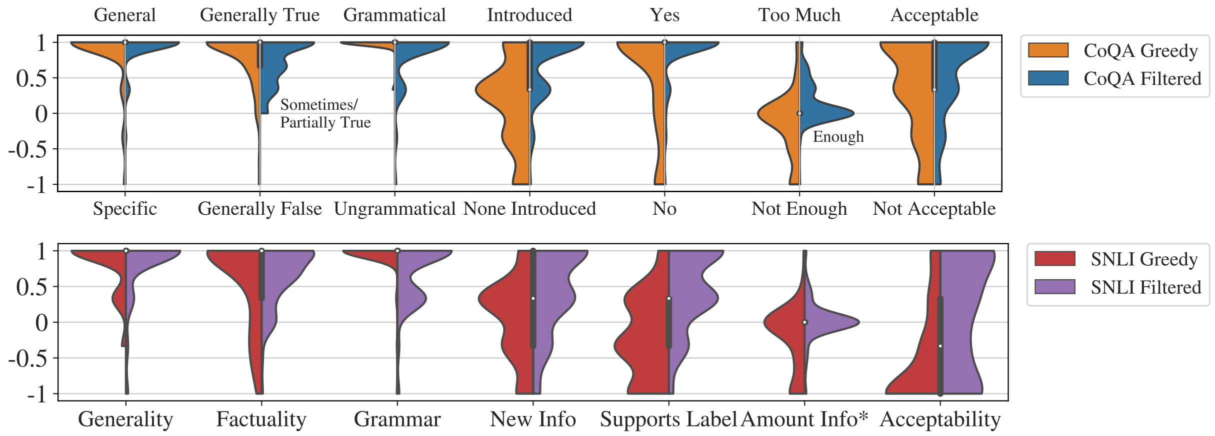

Figure 3: Absolute evaluation results in the "select-1" setting for the instances where our best-performing filter model does *not* select the greedy explanation (156 instances for CommonsenseQA (top); 91 for NLI (bottom)). See caption of Figure 2 and the Appendix-Table 20 for more details and statistical significance results.

	Preferred Explanation (%)			
Dataset	**Gold-Standard**	**Tie**	**GPT-3**	α
CoS-E	2.9	3.6	**93.5**	0.25
ECQA	19.9	10.0	**70.1**	0.05
e-SNLI	**49.9**	6.9	43.2	0.14

Table 9: A replication of Table 5, except the GPT-3 explanations are now the top-1 of our filter system.

they under-perform significantly relative to the full model, explanation-only baselines do fare surprisingly well, indicating that shallow features like factuality and grammaticality may represent latent factors in human acceptability judgments.

The effect of multiple training annotations. In some cases, performance improves if the training instances are labeled with the consensus of three annotators (vs. the singularly annotated case "w/o HA"), though the effects are inconsistent. In most cases, using consensus labels results in reduced variance across random seeds. However, the gains may not outweigh the 3x annotations required.

Our model doesn't overfit to specific annotators. The performance of our model when evaluated on the NLI test set labeled by separate annotators ("Test2") is comparable to the original test set (instance-level accuracy drops a few points, but explanation-level AP slightly rises).

Our model improves generated explanations along desirable traits. We present our absolute human evaluation for greedy vs. filtered explanations from GPT-3 in Figure 3— for both tasks, explanations filtered by our model more readily introduce new information, support the label, and contain at least enough information for both tasks (in addition to being more acceptable). Interestingly, greedy explanations still prevail in surface-level features (grammaticality and, in the case of CommonsenseQA, factuality; differences are statistically significant with low p, see Table 20).[13]

SNLI
Premise: An officer in a black uniform and hat stands to the left of a large structure with other officers in the background. **Hypothesis:** An officer enjoys coffee in a shop. **Label:** contradiction **NLL-Predicted Explanation:** An officer in a black uniform and hat is not necessarily an officer enjoying coffee in a shop. **Filter-Predicted Explanation:** An officer in a structure standing to one side is not the same as enjoying coffee in a shop.
CommonsenseQA
Question: Where would there be an auditorium with only a single person speaking? **Answer choices:** theater, park, university campus, crowd, or lights **NLL-Predicted Explanation:** An auditorium is a large room used for lectures, and a single person speaking is likely to be a lecture. **Filter-Predicted Explanation:** On university or university-like campuses, the auditoriums are often used for lectures or other University events, where a single person might be speaking.

Table 10: Randomly-selected instances that our filter model predicts differently than NLL at the "select-1" task and got **correct**, but NLL got incorrect.

We additionally find in our head-to-head study

---

[13] Krippendorff's α for these experiments is 0.32 for CommonsenseQA and 0.33 for SNLI.

(Table 9) that, compared to Table 5, using filtered GPT-3 explanations instead of greedy increases the preference for GPT-3 explanations by 15-24% for both CommonsenseQA datasets. We do not see an increase in the SNLI case, which may be due to the fact that fewer GPT-3 explanations change after filtering (36.4%, compared to 62.4% for CommonsenseQA), and GPT-3 explanations for SNLI tend to be less acceptable overall, resulting in a lower upper-bound oracle of instances where an acceptable explanation can be selected (§3).

In summary. We have demonstrated the effectiveness of modeling binary crowd judgements of acceptability as a means to select candidates from GPT-3 which are deemed acceptable with unanimous agreement. For the method that does not leverage human agreement, this is done with only ~5k binary annotations. We additionally demonstrate that our filtered explanations improve upon greedy generations in fine-grained categories that probe their topical relevance and meaningful content. The gap between our best model and the upper-bound oracle indicates that there is still substantial room for improvement in both task settings (but especially for SNLI). Future work may investigate sampling more explanations, or incorporating other sources of supervision signal.

5 Related Work

Free-text explanation generation. The earliest neural free-text explanation models did so for computer vision applications (Hendricks et al., 2016; Park et al., 2018; Kim et al., 2018) and NLI (Camburu et al., 2018). These methods relied on supervised datasets to train the explanation generator. Others have proposed to generate explanations or clarifications to improve task performance in a supervised (Rajani et al., 2019; Lampinen et al., 2022) or unsupervised (Shwartz et al., 2020) manner. Yordanov et al. (2021) study transfer learning between datasets for few-shot generation.

Latcinnik and Berant (2020) proposed a method to generate free-text explanations supervised only on task signal, and Brahman et al. (2021) used sources of weak supervision to generate explanations for defeasible inference. Paranjape et al. (2021) design hand-crafted templates which they use with mask-infilling to produce contrastive explanations from pretrained language models.

Concurrent work (Marasović et al., 2021) studies the effect of prompt format and model size on crowdworker judgements of prompted explanation plausibility. They find that GPT-3 Davinci outperforms other smaller pretrained models, but that crowdworkers find these explanations less plausible than those from the datasets, aligning with our first experimental result (Table 3). We perform a more in-depth study of the fine-grained criteria comprising human acceptability, and demonstrate that with higher-quality prompts and filtering, GPT-3's performance can be significantly improved.

Supervising on human preferences. Prior and concurrent work has used binary judgements from crowdworkers to fit models to human preferences for non-XAI tasks such as summarization (Ziegler et al., 2020; Stiennon et al., 2020), creating commonsense knowledge bases (West et al., 2021), and building natural language inference datasets (Liu et al., 2022). Unlike these works, we apply human preference modeling to increase the human acceptability of model-generated free-text explanations. West et al. (2021) demonstrate that GPT-3 + a supervised acceptability filter can generate a high-quality causal knowledge graph: in addition to their work being conducted in a different domain, our success conditions and evaluation metrics differ because we *must* produce a prediction for each instance (whereas they can simply discard bad generations).

6 Conclusion

We demonstrate GPT-3's capacity to generate free-text explanations for NLP task instances in a few-shot setting. We further improve this capability via an overgenerate + filter approach, where the filter is trained on supervision from human acceptability ratings. We hope our results can guide future work on free-text explanations via neural or neuro-symbolic systems (Brahman et al., 2021; Majumder et al., 2021; Saha et al., 2021). Future work may also further investigate the benefits of counterfactual explanations.

While human rationales for decision making are not necessarily the same as model rationales, the goal behind modeling human acceptability is often to build trust with a human user. This trust may or may not be warranted (Jacovi et al., 2021); future work would be well-suited to further investigate generated explanations for incorrect label predictions such as in Appendix C, which could mislead end users.

Acknowledgements

We thank Jena Hwang for helpful advice in designing our human user studies and Peter West for sharing GPT-3 prompting scripts. We thank other members of the Mosaic team at the Allen Institute for AI for valuable suggestions, as well as both our anonymous annotators and reviewers. This work was done while SW was an intern on Mosaic.

7 Ethics & Broader Impacts

All datasets used in this work are public, and we plan to release the machine-generated explanations and annotations we collected. We do not collect any personal information from our human participants.

Models that produce explanations in the means used in our experimental protocol (i.e., by conditioning on the gold labels) have the possibility to cause humans to place unwarranted trust in an AI system. This line of research is complementary to works investigating the faithfulness of model-generated free-text explanations (Hase et al., 2020; Wiegreffe et al., 2021). We demonstrate in Appendix C that GPT-3's explanations lack reliability because the model can explain answer choices that were not its prediction equally well. This may be due in part to the fact that decoding algorithms for generating predictions from language models are sub-optimal (e.g., Zhao et al., 2021; Holtzman et al., 2021) and GPT-3 may have factual knowledge stored in its parameters about other answer choices that allow it to provide reasonably acceptable explanations. Until this phenomenon is better understood, we do not condone using GPT-3-generated explanations in real-world deployment.

Lastly, our model of human acceptability is based on the aggregate judgements of participants from primarily Western, English-speaking countries working on crowdsourcing platforms. The subjective judgements of explanation acceptability may vary significantly among different population groups.

A Prompt Construction

Following Perez et al. (2021), we avoid prompt tuning on the full training and development sets of the datasets studied, in order to ensure that our methods represent a true few-shot setting. To develop the initial prompt design, we experimented with no more than 10 different layouts in the GPT-3 Sandbox platform using 15 training examples on the CoS-E and e-SNLI datasets. For subsequent prompt design, we again used these 15 training examples for each dataset from which we sampled 6 prompts,

Let's explain classification decisions.
question: When remembering a tragedy in the past, what do many people feel?
pain, depression, knowing, knowledge, or nostalgia?
depression
why? Remembering a past tradedy can resurface feelings that arose in response to that tragedy. Because tragedies are not positive events, it's possible that sadness and depression could arise from remembering it.
###
question: What do people do sometimes when they find a good deal?
race cars, murder each other, believe in god, fight each other, or fear death?
fight each other
why? Malls sometimes have sales, e.g., on black friday, when they offer good deals; however, the items are sometimes in limited supply, which can cause altercations between folks, each trying to buy the same item.
###
question: What does someone who has a greed for energy do?
buy food, lie, get, cause businesses to grow, or win?
buy food
why? When consumed, food provides energy and satisfies the greed for it.
###
question: Immediately after peeing, a person's bladder is what?
full, empty, filled, stretchable, or collapsed?
empty
why?

Table 11: Example of a prompt with 3 training examples for CommonsenseQA: presented are the question and answer choices, the gold labels, and the explanations (written by us) that act as input to GPT-3 (in practice, we use 8-24 examples per prompt). The text generated by the model acts as the free-text explanation. In this case, the model greedily auto-completes (given 8 examples): *"After peeing, the bladder is empty."*

along with a fixed 100-example "development set" randomly drawn from the training set. We preserve the "few-shot" approach by using a maximum of these same 115 instances to develop our prompting methods. For these 115 examples, the authors of this paper manually wrote high-quality explanations to be used as prompt examples (Table 12). As presented in Table 2, we found that structuring SNLI as a question-answering task achieved the best performance, similarly to Zhao et al. (2021). We provide an example of our SNLI prompt in Table 2 and CommonsenseQA in Table 11.

In-context learning methods have been shown to have high variance based on hyperparameters including example order, number of examples given, and which examples are given (Jiang et al., 2020; Zhao et al., 2021; Lu et al., 2022). While these values have not been standardized, two prominent papers, Schick and Schütze (2021b) and Brown et al. (2020), use 32 and 64 prompt examples, respectively. Due to the 2049-token limit of the OpenAI GPT-3 API and the fact that the addition of explanations elongates each prompt instance, we find the maximum number of examples the API can accommodate is 24 for CoS-E, e-SNLI, and our handwritten explanations and 16 for ECQA.

The focus of this work is not on finding the optimal prompt, but on developing a general strategy for few-shot explanation generation that could be successful when no additional (large) validation set for tuning is available. Therefore, to provide as robust of an expected performance estimate as possible, we do not tune the additional hyperparameters, instead sampling them to approximate performance.[14] Namely, while prior work uses one fixed prompt for all instances and varies the random seed, we approximate the same expected performance by sampling a new set of prompts for each instance. We also sample the number of prompts for each instance (and shuffle their order) from the values $\{8, 16, 24\}$ for CommonsenseQA experiments, $\{8, 16\}$ for experiments using ECQA explanations, and $\{12, 18, 24\}$ for SNLI experiments (to maintain label balance). To overcome label bias in prompt ordering, for tasks with distinct answer choices per instance (CommonsenseQA), we shuffle the answer choices. For tasks with fixed answer choices (SNLI), we sample an equal number of prompt instances for each label (so number of prompt instances is a multiple of 3).

Table 12 shows a few non-cherry-picked examples of our handwritten explanations used as prompts relative to the datasets.

B Crowdsourcing Details

We discuss shared details of the study designs in §B.1. We discuss the head-to-head interface in §B.2, the absolute interface in §B.3, and the acceptability interface in §B.4. Finally, we present details on quality control and payment in §B.5 and annotator statistics in §B.6.

B.1 Shared Interface Details

For all three human subjects study designs designs, we show the user the input instance (e.g.,

---

[14] Perez et al. (2021) show that performing cross-validation or tuning via maximum description length over a small validation set does not significantly outperform random sampling of these values.

SNLI (Bowman et al., 2015)
Premise: A person on a horse jumps over a broken down airplane. **Hypothesis:** A person is training his horse for a competition. **Label:** neutral **Our Explanation:** While it is possible that jumping a horse over an obstacle is part of a training routine for a competition, it is also possible that the horse ride is being done for pleasure, not necessarily for a competion (sp). **e-SNLI Explanation:** the person is not necessarily training his horse
Premise: Children smiling and waving at camera **Hypothesis:** There are children present **Label:** entailment **Our Explanation:** Since the children are part of the event of smiling at the camera, they are present at the event under discussion. **e-SNLI Explanation:** The children must be present to see them smiling and waving.

CommonsenseQA (Talmor et al., 2019)
Question: A cat can't talk, but a cat can what? **Answer choices:** sleep all day, meow, shed fur, see king, live many years **Our Explanation:** A cat can meow as a way to vocalize. **CoS-E Explanation:** the cat is a small carnivorous mammal **ECQA Explanation:** A cat can meow but cannot see the king. Meowing is how a cat communicates and not by sleeping all day, shedding fur or by living many years.
Question: "There are 10 apples on an apple tree. Three fall off. Now there are X apples." What is this an example of? **Answer choices:** park, coloring book, garden center, math problem, gravity **Our Explanation:** A math problem is usually posed as a question that requires some operation such as subtraction or addition to answer. **CoS-E Explanation:** webmath is designed to help you solve **ECQA Explanation:** Math problem is an arithmetical problem of addition, subtraction, multiplication or division. So “There are 10 apples on an apple tree. Three fall off. Now there are X apples.” is a math problem. All the other options aren't problems to be examples of the given question.

Table 12: Examples of explanations used as prompts from various sources, including our handwritten explanations. Correct answers for CommonsenseQA are underlined.

premise+hypothesis) and the gold label in addition to the explanation(s). We explain our motivation for using the gold label as a methodological control in §2.

For a similar reason, we do not show the other incorrect label choices to the user, which is particularly of note for the CommonsenseQA task which has different answer choices per instance. Some instances in CommonsenseQA have multiple correct or very similar answer choices, due to noise in the dataset and the fact that the wrong answer choices were deliberately collected to make the task challenging. We (the authors) again found we struggled to accurately judge explanation quality when we disagreed with the selected answer choice or found multiple answer choices to be correct. To remove this possible confounder, we instruct participants to pretend the gold label is correct even if they disagree with it, and make this easier by hiding the other answer choices. This may result in a slight bias in judgements against the ECQA dataset due to its unique counterfactual nature, though our goal was not to study the benefits and downsides of counterfactual explanations in this work.

B.2 Head-to-Head Interface Details

We show the user the task input and gold label, and ask them to select which of two explanations best explains the answer. We instruct workers to consider the gold label to be correct even if they disagree with it (CommonsenseQA instances can be subjective) and to ignore minor grammar and spelling mistakes such as improper upper-casing. Figures 5 and 6 show the evaluation interface.

B.3 Absolute Interface Details

Figures 7 and 8 show the absolute evaluation interface (minus the acceptability attribute, which is collected in a separate run of the study). Our interface is inspired by prior work from psychology and the social sciences (Leake, 1991; Gopnik, 1998; Lombrozo, 2007; Zemla et al., 2017; Chiyah Garcia et al., 2018; Clinciu et al., 2021; Sulik et al., 2021). We iterated over 3-4 versions of the questions and UI design until we had optimized agreement rates as much as possible. Our resulting two-part evaluation consists of 7 questions:

Part 1: Context-Independent Evaluation We first assess the explanation in isolation, i.e., these questions are presented to the user without revealing the question/context that the explanation is attempting to address:

1. *How factual is this statement?* (generally false, sometimes or partially true, generally true, or need more information to judge). This question is designed to test both generality (can the explanation's truthfulness be ascertained or is more in-

formation needed?) and factuality, which aligns with "compatibility with receiver's existing beliefs" and that the best explanation is the "most likely" explanation from the receiver/user's perspective (Lombrozo, 2007; Zemla et al., 2017; Sulik et al., 2021). Generality is coded based on whether a truthfulness answer is selected (considered to be general) or whether the "need more information to judge" choice is selected (considered not to be general).

2. *Is this statement grammatical?* (yes or no) This question is designed to test for clarity, aligning with characteristics such as coherence (Lei et al., 2016) and human-likeness and understandability (Ehsan et al., 2019).

Part 2: Context-Dependent Evaluation We next show the user the question (premise and hypothesis for SNLI) and gold answer that the explanation was conditioned on. We then ask:

1. *Does the explanation provide new facts, information or reasoning not stated in the question and answer?* (yes or no) In our preliminary experiments, we found some explanations simply restate the question declaratively with the answer filled in. This question addresses the distinction between "validity" and "utility" (Leake, 1991): an explanation can be valid (i.e., a restatement of the question with the answer filled-in might be correct), but not useful; utility is defined by whether an explanation "satisfies an explainer's need for information". And while utility is best understood in the context of real-world applications (Lai et al., 2020), we nonetheless aim to identify vacuous explanations that do not provide new information.
2. *Is the new information relevant to justifying the answer? (yes or no)* New information, if provided, "should be compatible with our existing beliefs, and consistent with the evidence and with itself" (Zemla et al., 2017). This question is designed to test whether the information provided supports the label. The specific interpretation of "relevance" is purposefully left to the annotator.[15]
3. *How much information does the explanation have to justify the answer?* (not enough, enough, or too much) This question is designed to test the extent to which the provided novel information is *adequate* or *sufficient* (Kim et al., 2016; Lei et al., 2016; Ehsan et al., 2019).[16]
4. *Is the explanation acceptable?* (yes or no) The final question is designed to assess annotators' overall judgement of the explanation as a whole.

We only ask Question 2 if the answer to Question 1 is "yes" and Question 3 if the answer to Question 2 is yes, because they regard the new facts, information, or reasoning. We found that most prior work tends to lump added-value, relevance, and adequacy judgements into one "informativeness" judgement (Clinciu et al., 2021), which we felt was too course to allow for meaningful error analysis.

B.4 Acceptability Interface Details

Figures 9 and 10 show the binary acceptability interface used to collect training and test data for the overgeneration filter model.

Spearman's rank-order correlation coefficients (Table 6) are computed using scipy (Virtanen et al., 2020) on the 250 test explanations from the 5 data sources in Figure 2. Each instance is annotated by 3 annotators for a total of 3750 datapoints (some criteria are only evaluated conditionally, resulting in less total annotations– see Appendix B.3). Statistical significance is computed using the built-in two-sided non-parametric test.

B.5 Quality Control and Payment

We use Amazon Mechanical Turk (AMT), and calculate pay on a rate of \$15/hour. Every few batches, we check to ensure that the median time taken per-annotator amounts to approximately this pay rate. While annotators do tend to speed up the more HITs we released, first-round median times were approximately 30 seconds per head-to-head evaluation HIT (thus paid at \$0.12 each), 1 minute per absolute evaluation HIT (thus paid at \$0.25 each), and 35-39 seconds per acceptability HIT (5 explanations; paid at \$0.20 each).

We require annotators to be located in either Australia, Canada, New Zealand, the United Kingdom, or the United States, as a proxy for English competency.[17] We require a past HIT approval rate of >

---

[15] This decision is inspired by prior work in psychology, which finds that explanations are only good "to the extent that people find [them] satisfying" (Gopnik, 1998; Sulik et al., 2021).

[16] In practice, we do not find Turkers use the "too much information" option often, except in the case of ECQA dataset explanations. We included the option because succinctness is an oft-cited explanatory virtue (Lombrozo, 2007; Zemla et al., 2017; Chiyah Garcia et al., 2018).

[17] We realize this is a broad assumption and likely suboptimal. However, colleagues have found that broadening

98% and > 5000 HITs approved. We do not allow annotators to participate who were previously on a block list from our past AMT studies.

Annotators must complete a qualifying exam in order to participate in the main annotation tasks. The qualifying exam consists of 3 HITs in the same format as the main absolute evaluation task for CommonsenseQA We pay $2.25 for the qualifying exam. There are 9-18 questions in total (3-6 questions per HIT), some of which are only answerable conditioned on previous answers. A user who answers “no” to question 3, for example, will not be asked to answer questions 4 and 5. Given the challenging and sometimes ambiguous nature of some of the questions, for the first run of the qualification exam, we manually awarded qualifications by inspecting the annotators’ answers. Scores for the first run compared to our answers (out of 17 annotators attempting) ranged from 5 to 14 out of 18. The median accuracy was 11 out of 18, and we find that awarding the qualification to those with scores at or above the median aligns closely with our manual inspection. We thus use this score to assign qualifications in future iterations.

Because it is necessary that annotators understand the task before they can evaluate explanation quality (Wiegreffe and Marasović, 2021), for tasks that are more difficult, i.e., NLI, we additionally require annotators to pass (score of 7 or above) a task-specific qualification exam with 8 questions, paid at $1.25.

In order to track quality throughout evaluation, we compute inter-annotator agreement using Krippendorff’s α and use a hidden built-in Javascript function to compute time per HIT spent. If any annotator completed the tasks in an unreasonably low time, or removing their annotations substantially improves Krippendorff’s α, we remove their annotations and re-annotate their instances. We additionally ensure that each experiment has a substantial number of distinct crowdworkers to mitigate individual annotator bias, reporting this as well as the mean and median number of HITs completed by each in Table 17.

B.6 Statistics

The number of distinct crowd annotators and the median and mean number of HITs completed for each experiment can be found in Table 17. More detailed breakdowns of inter-annotator agreement for some experiments are in Tables 14 and 15.

Dataset	**Split**	**# Instances by Agreement**				**Total**
		0/3	**1/3**	**2/3**	**3/3**	
Com.QA	Train	932	1078	1194	1296	4500
	Dev	105	91	132	127	455
	Test	298	227	328	397	1250
SNLI	Train	2372	805	621	702	4500
	Dev	272	87	65	76	500
	Test	678	225	166	181	1250
	Test2	666	234	179	171	1250

Table 13: Statistics of our acceptability annotations.

C Absolute Evaluation by Label Accuracy

Can GPT-3 produce convincing explanations even for instances it cannot predict correctly? This has implications for model-generated explanations being “right for the right reasons”. To produce label predictions, we follow the same prompt format as in Tables 2 and 11, removing the WHY? token and the gold explanations so that the model generates a label prediction instead. GPT-3 achieves 50.8% accuracy on CommonsenseQA compared to a 20% random baseline, and 46% accuracy on SNLI compared to a 33.33% random baseline.[18]

Figure 4 presents absolute evaluation results broken down by whether GPT-3 correctly predicts the instance label. The results show little variation between the correctly-predicted and incorrectly-predicted groups in most attributes. This indicates that GPT-3 explanations are not faithful enough to use in real-world applications in their current form.

D 2/3 Acceptability Statistics

When we treat explanations rated by at least $2/3$ annotators as “acceptable”, for CommonsenseQA, 77.9% of greedily-decoded explanations are acceptable; for SNLI, 51.0%. 50.5% of sampled explanations are acceptable; for SNLI, 23.5%. Out of the set of 5 (1 greedy + 4 stochastic), 97.7% of CommonsenseQA instances have *at least one* acceptable explanation, and 79.5% of SNLI.

---

the geographical requirements often still leads to >90% of annotators in the US or Canada, due to AMT’s pay structure being optimal in these countries.

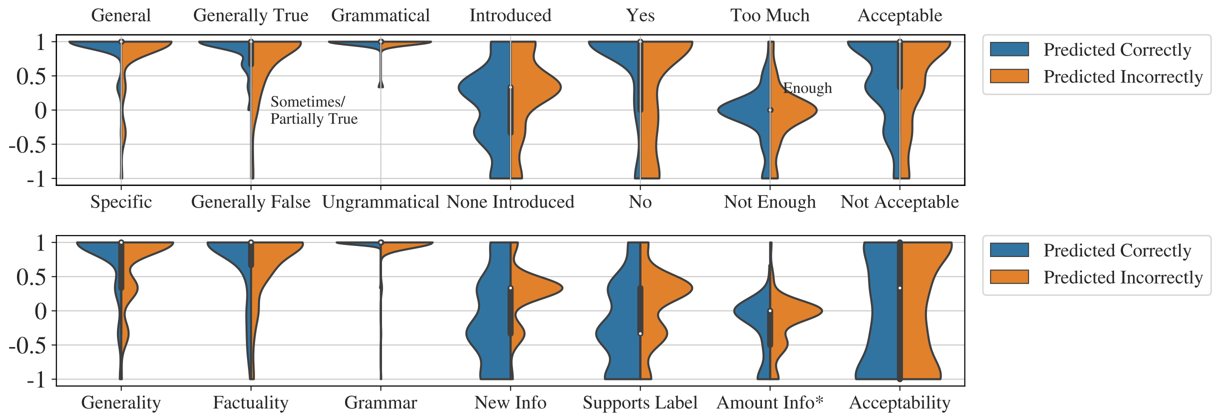

Figure 4: Absolute evaluation results for explanations generated by GPT-3 based on whether GPT-3 predicted the instance label correctly or not. CommonsenseQA (top) and SNLI (bottom). See caption of Figure 2 and the Appendix-Table 19 for more details.

E Filter Model Details

We split the 4,955 distinct annotated explanations for CommonsenseQA (5000 for SNLI) into a train/dev set of 4500/455 (4500/500 for SNLI), where all 5 explanations for a given instance are placed in the same set to avoid leakage. We present statistics on the label distribution in Table 13. Along with the metric settings reported in the paper ("select-1" and explanation-level), we computed a metric that is instance-level but considers all explanations by computing metrics over the 5 explanations of an instance and then averaging across instances, finding in practice that the results are highly similar to the explanation-level evaluation.

We use Huggingface Datasets (Lhoest et al., 2021) and Huggingface Transformers (Wolf et al., 2020) for implementation. We format inputs to the models as follows, where `expl` is one of the five explanations and the `gold_label` is either 0 (not acceptable) or 1 (acceptable):

```
if explanation_only:
  input_string = (f"explanation: {expl}.
    Is this explanation good or bad?")
else:
  input_string = (
    "{question} answer: {gold_label}. "
    "explanation: {expl}. "
    Is this explanation good or bad?")
```

The T5-Large model is trained using a learning rate of $1E-4$ with linear decay, a batch size of 64, and default values for Adam (Kingma and Ba, 2015), gradient clipping, and dropout. We train for a maximum 200 epochs, performing early stopping on the validation loss with a patience of 10 epochs. For T0-3B, we train with a batch size of 50. We use AdaFactor (Shazeer and Stern, 2018) with a linear warmup of 500 steps. We conduct an initial hyperparameter sweep over learning rate, considering $1E-5, 5E-05, 5E-06$. The learning rate that achieves the best validation loss for the full-information model and the explanation-only model is $1E-5$, which we use for all training experiments.

Dataset	**Split**	**Krippendorff's α**
CommonsenseQA	Training + Validation	0.32
	Test	0.40
SNLI	Training + Validation	0.51
	Test	0.50
	Test2	0.47

Table 14: Inter-annotator agreement for acceptability AMT studies.

F Additional Filter Results

In the main experiments, at evaluation time, we labelled an explanation as acceptable if $3/3$ annotators agreed on it. Here, we report results if this threshold is relaxed to $2/3$. Overall, the results are comparable: T0-3B outperforms the baselines according to both select-1 accuracy and AP (see Table 21 and Table 22).

---

[18] Low SNLI performance aligns with previous findings that GPT-3 struggles with sentence-comparison tasks (Brown et al., 2020; Zhao et al., 2021).

AMT Study	Dataset	Generality	Factuality	Grammar	New Info	Supports Label	Amount Info	Acceptability	Aggregate
GPT-3 Greedy	Com.QA	0.37	0.32	-0.01	0.09	0.45	0.21	0.28	**0.38**

Table 15: Inter-annotator agreement for absolute-comparison AMT studies, using Krippendorff's α computed on an interval scale from -1 to 1. The aggregate score is computed by treating the annotations along each attribute as separate instances and computing agreement across the entire set.

SNLI (Bowman et al., 2015)
Premise: There are two kilted men, one of them older and is holding bagpipes with the other one with a drum. **Hypothesis:** Two kiled (sp) men hold bagpipes **Label:** contradiction **NLL-Predicted Explanation:** The two kilted men are not holding bagpipes, they are holding a bagpipe and a drum. **Filter-Predicted Explanation:** Just because there are kilted men does not necessarily mean that they are holding bagpipes. This can be seen from the older kilted man is holding the bagpipes rather than the kilder (sp) one.
CommonsenseQA (Talmor et al., 2019)
Question: The hardcovers were especially tall, so he removed a shelf on the what to make room? **Answer choices:** hold alcohol, grocery store, <u>bookcase</u>, nightstand, or chest of drawers **NLL-Predicted Explanation:** Bookcases are tall, and so if they are full of hardcover books, they might need to be removed to make room for other things. **Filter-Predicted Explanation:** People keep books on bookshelves, and bookcases are very commonly used to hold books. Since hardcover books can be pretty tall, it takes up extra vertical space which would require removal of an upper shelf of the bookcase.

Table 16: Randomly-selected instances that our filter model predicts differently than NLL at the "select-1" task, and got **incorrect** but NLL got correct.

AMT Study	Task/Dataset	# Annotators	Median # HITs (Mean)

Instructions (click to expand/collapse)

Thanks for participating in this HIT!

You will read multiple-choice questions about daily life. For each question, an answer has been selected and 2 explanations for the answer have been given. Your task is to select the explanation that best explains the answer.

Each HIT contains 3 parts:

Question	A question such as "If a lantern is not for sale, where is it likely to be?"
Answer	A selected answer, such as "house" (may or may not be correct).
Explanations	Two explanations for the ***Answer***.

A couple of notes:

- **You may disagree with the *Answer*, but you should pretend it is correct when selecting the best *Explanation*.**
- **You can ignore minor grammar and spelling mistakes. Some sentences will be lowercased incorrectly; please ignore this.**
- If you find the ***Explanations*** similarly good (or bad), select the one you think is the best and then select ***"I voted, but this one is close because the explanations are similar."***
- If you find the ***Explanations*** equally good (or bad) and cannot choose, select ***"Both equally good."*** or ***"Both equally bad."***

Examples (click to expand/collapse)

Question: **${question}**
Answer: **${gold_label}**

Which explanation better explains the answer?

${explanation_1}

${explanation_2}

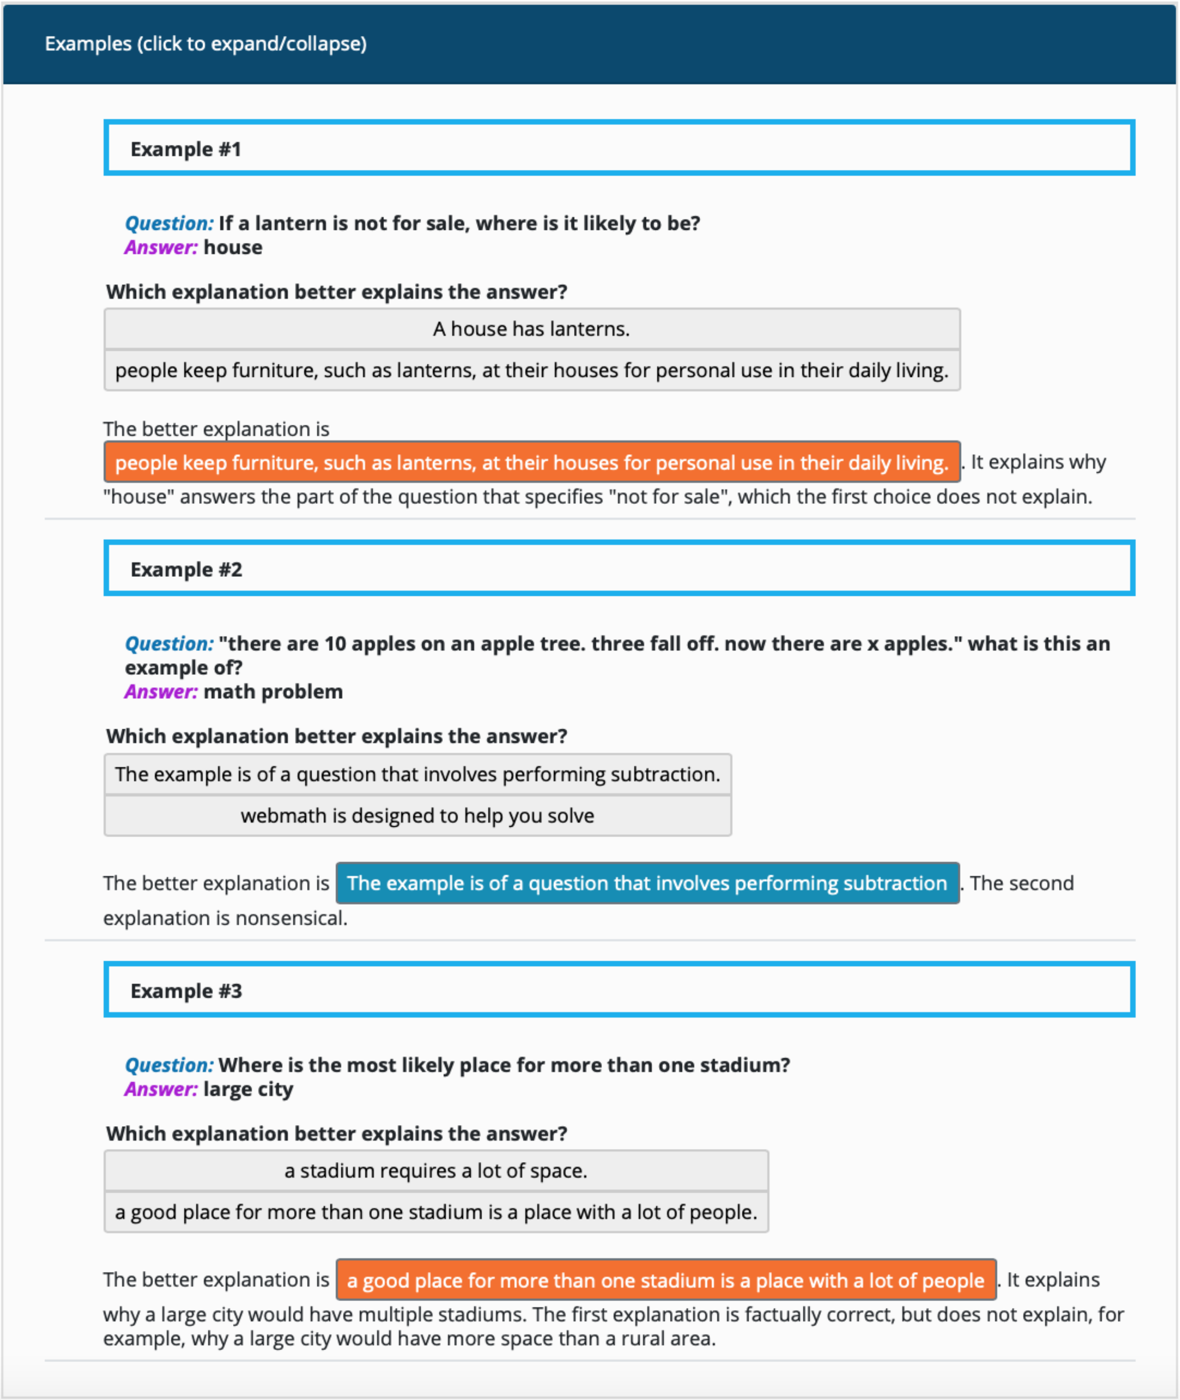
☐ Both equally good.

☐ Both equally bad.

☐ I voted, but this one is close because the explanations are similar.

(Optional) Please let us know if anything was unclear, if you experienced any issues, or if you have any other feedback for us.

Figure 5: An overview of the user interface of our head-to-head comparison AMT studies for CommonsenseQA. The top shows the instructions and the bottom the actual task. The Examples tab is collapsed here; shown in full in Figure 6.



Examples (click to expand/collapse)

Example #1

Question: **If a lantern is not for sale, where is it likely to be?**
Answer: **house**

Which explanation better explains the answer?

A house has lanterns.

people keep furniture, such as lanterns, at their houses for personal use in their daily living.

The better explanation is people keep furniture, such as lanterns, at their houses for personal use in their daily living. . It explains why "house" answers the part of the question that specifies "not for sale", which the first choice does not explain.

Example #2

Question: **"there are 10 apples on an apple tree. three fall off. now there are x apples." what is this an example of?**
Answer: **math problem**

Which explanation better explains the answer?

The example is of a question that involves performing subtraction.

webmath is designed to help you solve

The better explanation is The example is of a question that involves performing subtraction . The second explanation is nonsensical.

Example #3

Question: **Where is the most likely place for more than one stadium?**
Answer: **large city**

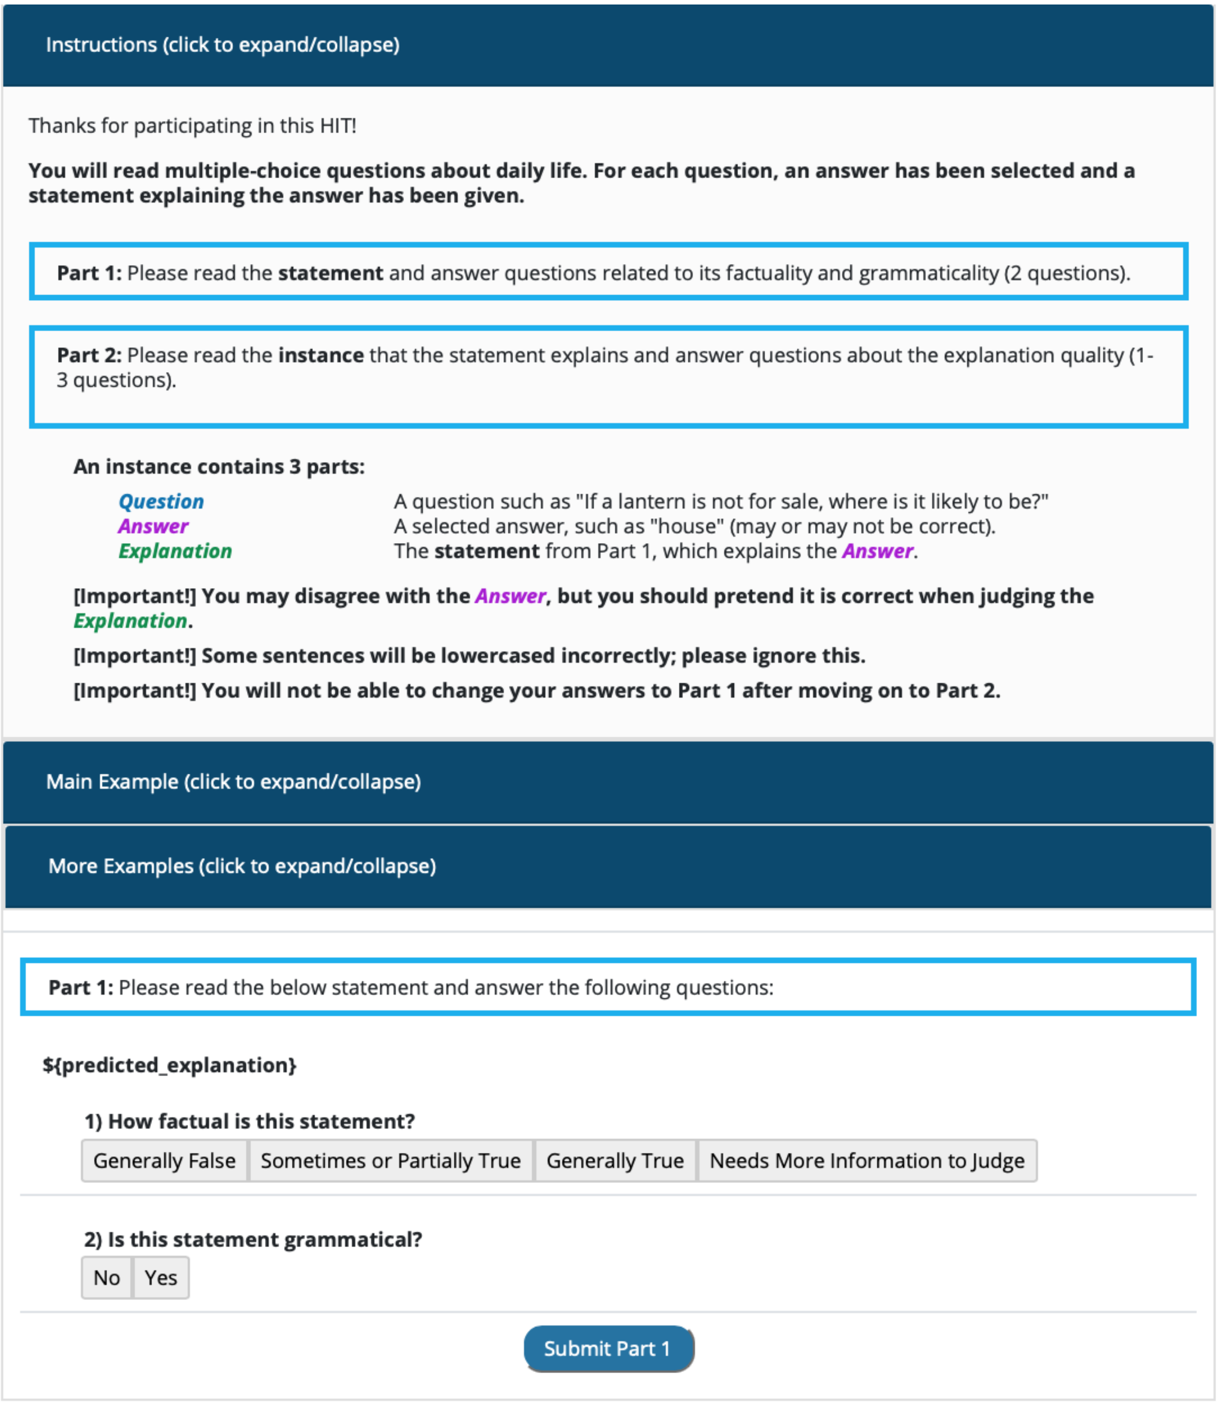
Which explanation better explains the answer?

a stadium requires a lot of space.

a good place for more than one stadium is a place with a lot of people.

The better explanation is a good place for more than one stadium is a place with a lot of people . It explains why a large city would have multiple stadiums. The first explanation is factually correct, but does not explain, for example, why a large city would have more space than a rural area.

Figure 6: The Examples tab given in the user interface of our head-to-head comparison AMT studies for CommonsenseQA. The full interface is shown in Figure 5.



Thanks for participating in this HIT!

You will read multiple-choice questions about daily life. For each question, an answer has been selected and a statement explaining the answer has been given.

Part 1: Please read the **statement** and answer questions related to its factuality and grammaticality (2 questions).

Part 2: Please read the **instance** that the statement explains and answer questions about the explanation quality (1-3 questions).

An instance contains 3 parts:

Question	A question such as "If a lantern is not for sale, where is it likely to be?"
Answer	A selected answer, such as "house" (may or may not be correct).
Explanation	The **statement** from Part 1, which explains the ***Answer***.

[Important!] You may disagree with the *Answer*, but you should pretend it is correct when judging the *Explanation*.

[Important!] Some sentences will be lowercased incorrectly; please ignore this.

[Important!] You will not be able to change your answers to Part 1 after moving on to Part 2.

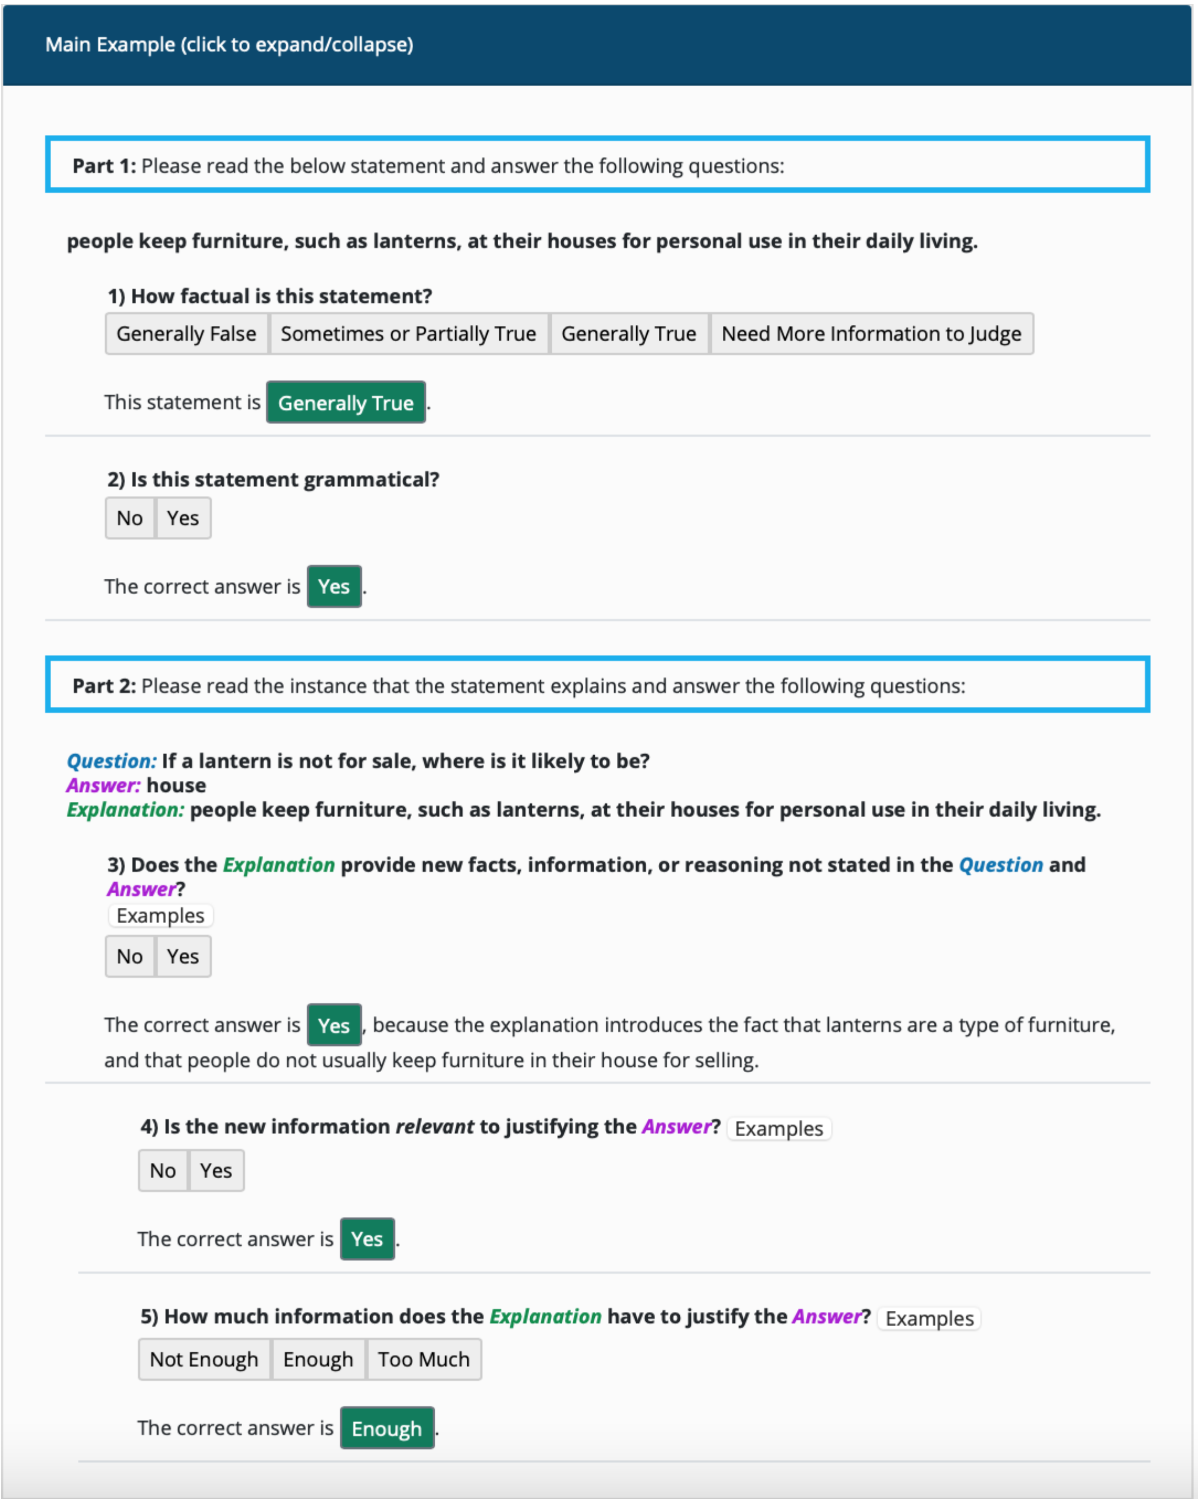
Part 1: Please read the below statement and answer the following questions:

${predicted_explanation}

1) How factual is this statement?

2) Is this statement grammatical?

Figure 7: An overview of the user interface template of our absolute comparison AMT studies for CommonsenseQA. The top shows the instructions and the bottom the actual task. Only part 1 of the task is shown here (part 2 appears once part 1 is submitted). The Main Example and More Examples tabs illustrating both parts 1 and 2 are collapsed here; see Figure 8.



Part 1: Please read the below statement and answer the following questions:

people keep furniture, such as lanterns, at their houses for personal use in their daily living.

1) How factual is this statement?

This statement is **Generally True**.

2) Is this statement grammatical?

The correct answer is **Yes**.

Part 2: Please read the instance that the statement explains and answer the following questions:

Question: **If a lantern is not for sale, where is it likely to be?**
Answer: **house**
Explanation: **people keep furniture, such as lanterns, at their houses for personal use in their daily living.**

3) Does the *Explanation* provide new facts, information, or reasoning not stated in the *Question* and *Answer*?

The correct answer is **Yes**, because the explanation introduces the fact that lanterns are a type of furniture, and that people do not usually keep furniture in their house for selling.

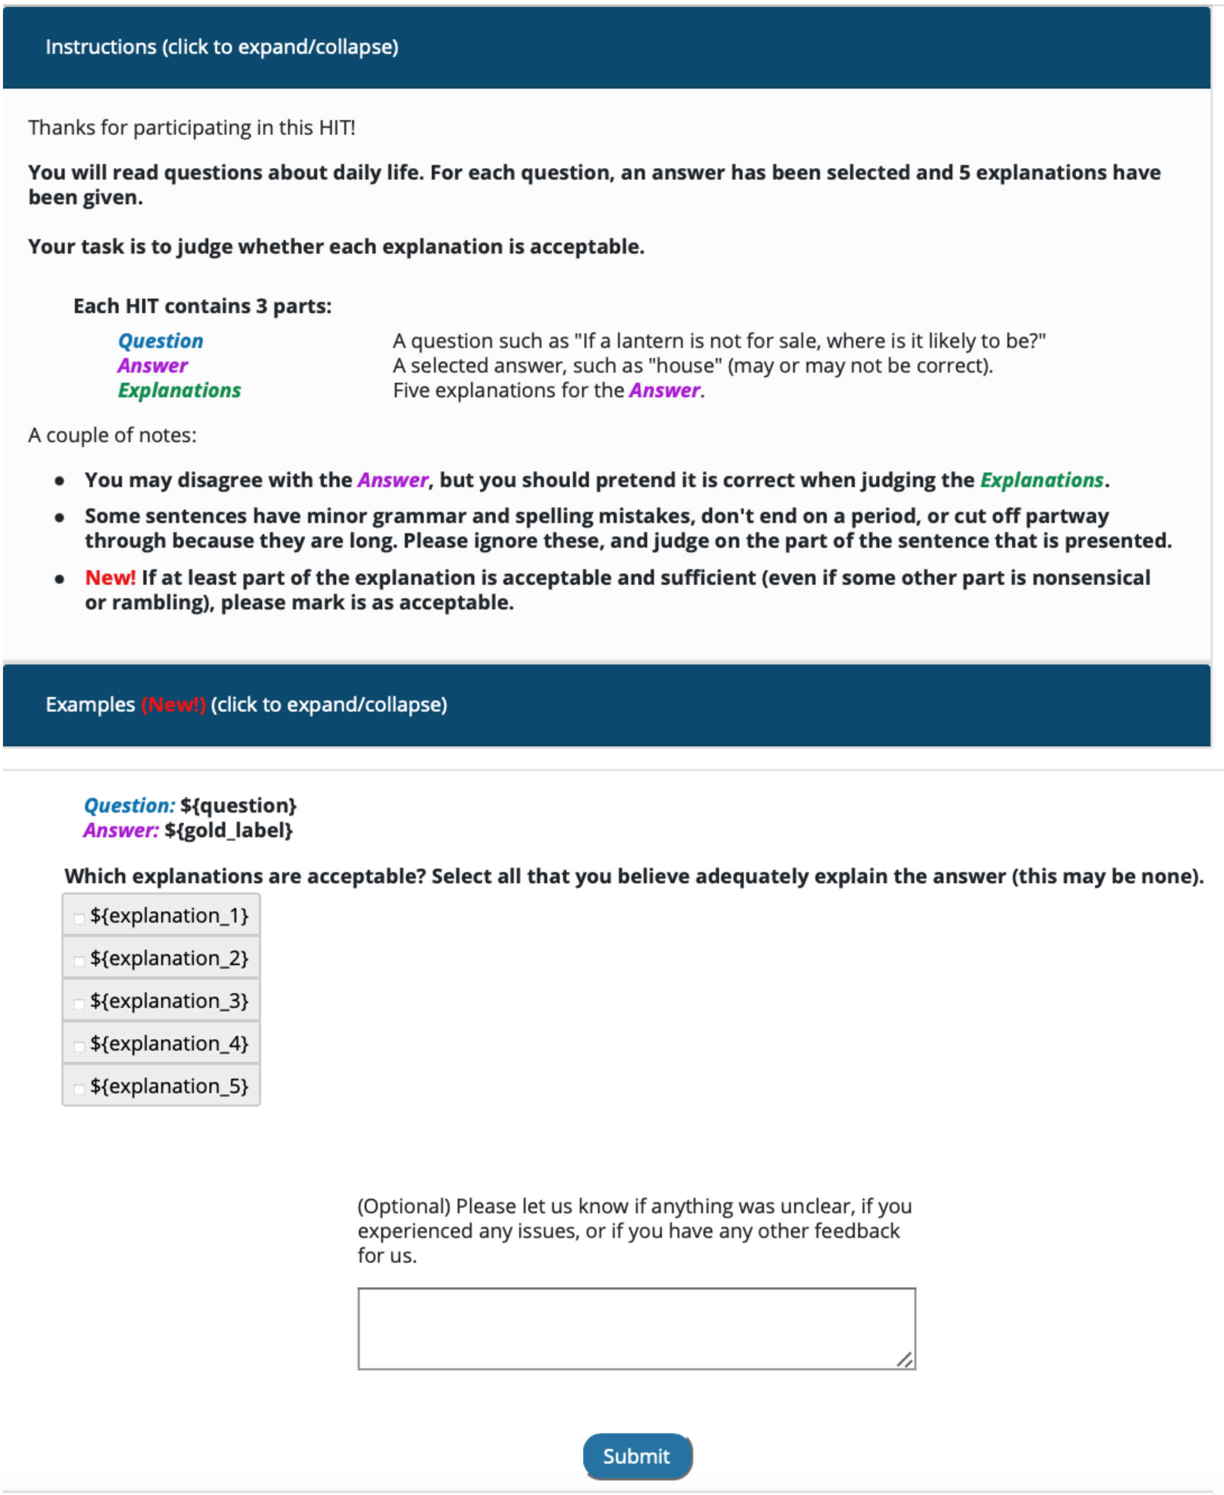
4) Is the new information *relevant* to justifying the *Answer*?

The correct answer is **Yes**.

5) How much information does the *Explanation* have to justify the *Answer*?

The correct answer is **Enough**.

Figure 8: The Main Example given in the user interface template of our absolute comparison AMT studies for CommonsenseQA. This format follows the actual task layout. The full interface is shown in Figure 7.



Instructions (click to expand/collapse)

Thanks for participating in this HIT!

You will read questions about daily life. For each question, an answer has been selected and 5 explanations have been given.

Your task is to judge whether each explanation is acceptable.

Each HIT contains 3 parts:

Question	A question such as "If a lantern is not for sale, where is it likely to be?"
Answer	A selected answer, such as "house" (may or may not be correct).
Explanations	Five explanations for the ***Answer***.

A couple of notes:

- **You may disagree with the *Answer*, but you should pretend it is correct when judging the *Explanations*.**
- **Some sentences have minor grammar and spelling mistakes, don't end on a period, or cut off partway through because they are long. Please ignore these, and judge on the part of the sentence that is presented.**
- **New! If at least part of the explanation is acceptable and sufficient (even if some other part is nonsensical or rambling), please mark is as acceptable.**

Examples (New!) (click to expand/collapse)

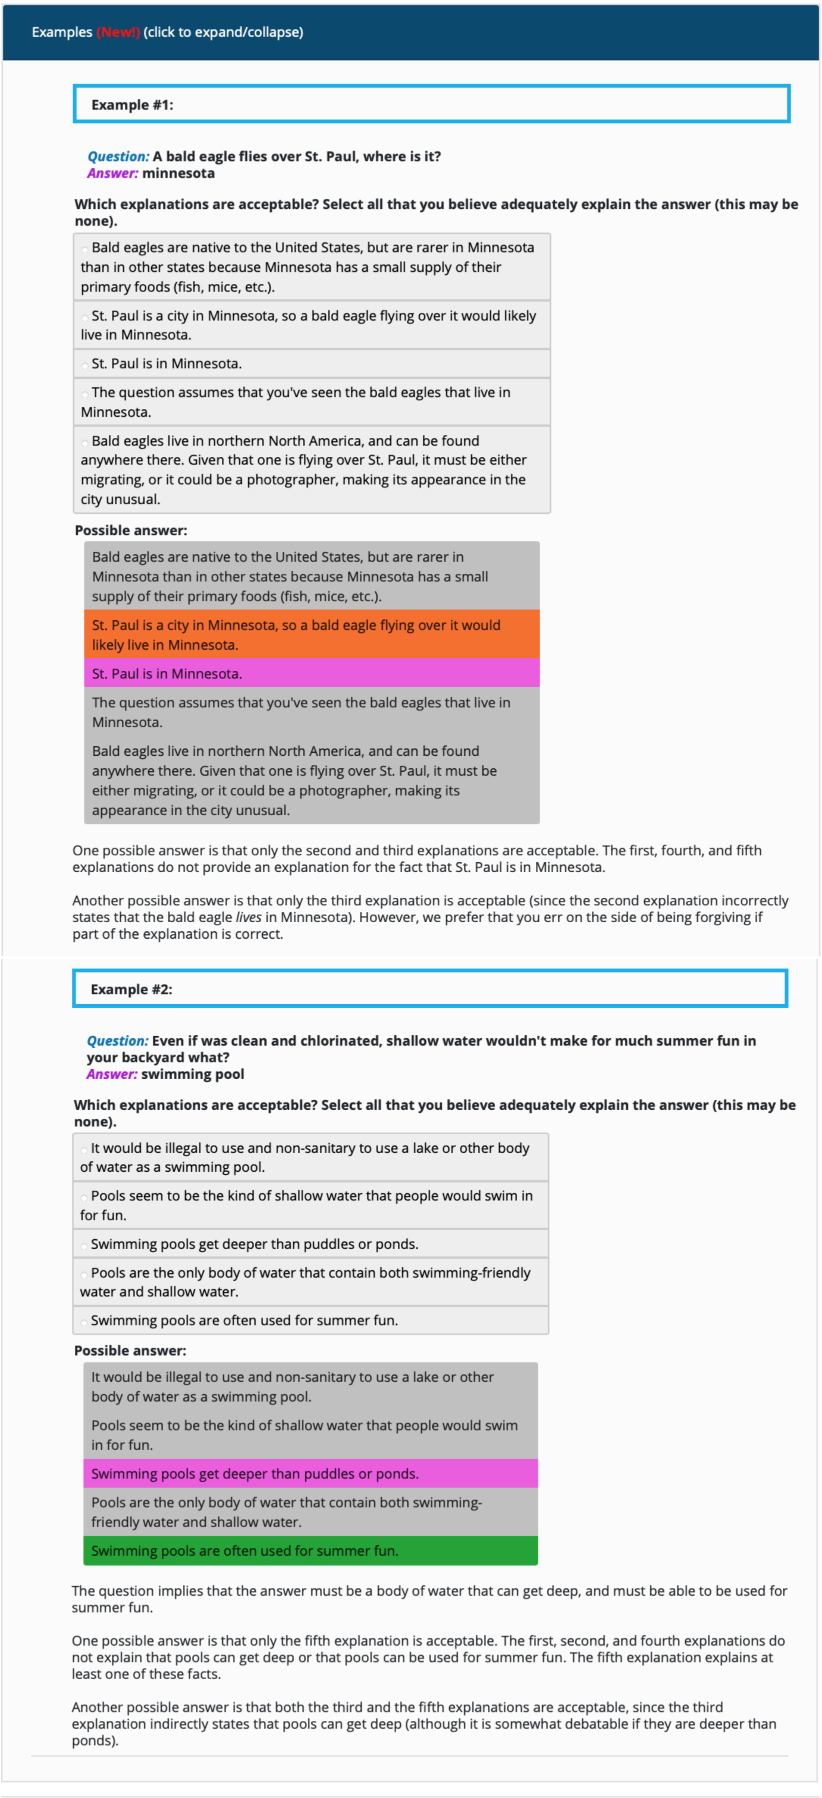
Question: **${question}**
Answer: **${gold_label}**

Which explanations are acceptable? Select all that you believe adequately explain the answer (this may be none).

☐ ${explanation_1}
☐ ${explanation_2}
☐ ${explanation_3}
☐ ${explanation_4}
☐ ${explanation_5}

(Optional) Please let us know if anything was unclear, if you experienced any issues, or if you have any other feedback for us.

Figure 9: An overview of the user interface of our explanation acceptability AMT studies for CommonsenseQA. The top shows the instructions and the bottom the actual task. The "examples" tab is collapsed here; shown in full in Figure 10.



Examples (New!) (click to expand/collapse)

Example #1:

Question: **A bald eagle flies over St. Paul, where is it?**
Answer: **minnesota**

Which explanations are acceptable? Select all that you believe adequately explain the answer (this may be none).

○ Bald eagles are native to the United States, but are rarer in Minnesota than in other states because Minnesota has a small supply of their primary foods (fish, mice, etc.).

○ St. Paul is a city in Minnesota, so a bald eagle flying over it would likely live in Minnesota.

○ St. Paul is in Minnesota.

○ The question assumes that you've seen the bald eagles that live in Minnesota.

○ Bald eagles live in northern North America, and can be found anywhere there. Given that one is flying over St. Paul, it must be either migrating, or it could be a photographer, making its appearance in the city unusual.

Possible answer:

Bald eagles are native to the United States, but are rarer in Minnesota than in other states because Minnesota has a small supply of their primary foods (fish, mice, etc.).

St. Paul is a city in Minnesota, so a bald eagle flying over it would likely live in Minnesota.

St. Paul is in Minnesota.

The question assumes that you've seen the bald eagles that live in Minnesota.

Bald eagles live in northern North America, and can be found anywhere there. Given that one is flying over St. Paul, it must be either migrating, or it could be a photographer, making its appearance in the city unusual.

One possible answer is that only the second and third explanations are acceptable. The first, fourth, and fifth explanations do not provide an explanation for the fact that St. Paul is in Minnesota.

Another possible answer is that only the third explanation is acceptable (since the second explanation incorrectly states that the bald eagle *lives* in Minnesota). However, we prefer that you err on the side of being forgiving if part of the explanation is correct.

Example #2:

Question: **Even if was clean and chlorinated, shallow water wouldn't make for much summer fun in your backyard what?**
Answer: **swimming pool**

Which explanations are acceptable? Select all that you believe adequately explain the answer (this may be none).

○ It would be illegal to use and non-sanitary to use a lake or other body of water as a swimming pool.

○ Pools seem to be the kind of shallow water that people would swim in for fun.

○ Swimming pools get deeper than puddles or ponds.

○ Pools are the only body of water that contain both swimming-friendly water and shallow water.

○ Swimming pools are often used for summer fun.

Possible answer:

It would be illegal to use and non-sanitary to use a lake or other body of water as a swimming pool.

Pools seem to be the kind of shallow water that people would swim in for fun.

Swimming pools get deeper than puddles or ponds.

Pools are the only body of water that contain both swimming-friendly water and shallow water.

Swimming pools are often used for summer fun.

The question implies that the answer must be a body of water that can get deep, and must be able to be used for summer fun.

One possible answer is that only the fifth explanation is acceptable. The first, second, and fourth explanations do not explain that pools can get deep or that pools can be used for summer fun. The fifth explanation explains at least one of these facts.

Another possible answer is that both the third and the fifth explanations are acceptable, since the third explanation indirectly states that pools can get deep (although it is somewhat debatable if they are deeper than ponds).

Abstract

Multi-triple extraction is a challenging task due to the existence of informative inter-triple correlations, and consequently rich interactions across the constituent entities and relations. While existing works only explore entity representations, we propose to explicitly introduce *relation* representation, jointly represent it with entities, and novelly align them to identify valid triples. We perform comprehensive experiments[1] on document-level relation extraction and joint entity and relation extraction along with ablations to demonstrate the advantage of the proposed method.

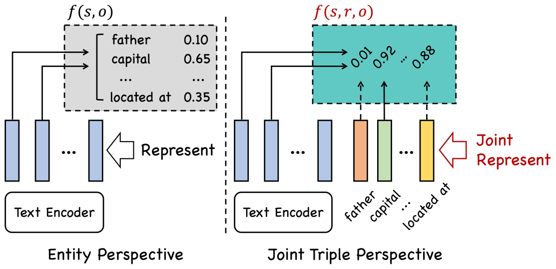

Figure 1: Different formulations for multi-triple extraction. 1) *entity perspective* constructs only entity representation and feed them into a relation-specific classifier. 2) *joint triple perspective* constructs both entity representation and relation representation to model comprehensive correlations across all components.

1 Introduction

Relation extraction aims at discovering structured knowledge in the form of <*subject-relation-object*> triples from plain text. It is an essential task towards constructing knowledge bases. Although a lot of efforts have been made in building advanced relation extraction systems, it is still a challenging problem under certain practical scenarios where multiple entities and relations are involved, *e.g.*, document-level relation extraction (Yao et al., 2019) and joint entity and relation extraction (Riedel et al., 2010; Gardent et al., 2017).

Existing works mostly take the *entity perspective* that focuses on exploring cross-entity interactions (Xu et al., 2021; Zeng et al., 2020). They either treat relations as atomic labels specified in a final classifier (Xu et al., 2021; Zeng et al., 2020; Wang et al., 2020), or simply search subjects and objects for each individual relation(Wei et al., 2020; Zheng et al., 2021). However, as an essential component, relations also interact with entities and context, which jointly exhibit informative inter-triple correlations. e.g., the two relations *capital of* and *located at* often co-occur between the same pair of entities but with different probabilities conditioned on specific contextual clues. As a consequence, the capability to model and make full use of rich interactions across relations, entities, and context is crucial for the task.

In this paper, we advocate a novel *joint triple perspective* for relation extraction (see Figure 1 for illustration). Different from previous works that only seek to represent entities, we propose ***EmRel*** that creates, refines and leverages the ***Em***bedded representations of ***Rel***ations. Specifically, we first explicitly create relation representations as embedded vectors; then refine these relation (as well as entity) representations by modeling rich relation-entity-context interactions via an attention-based fusion module; and finally identify valid triples by aligning the representation of entities and relations in a joint space, with a novel alignment function based on Tucker Decomposition. This joint triple perspective actually considers entities along with relations as components of a small, in-context knowledge graph, and completes this graph by aligning and reasoning to extract multiple valid triples.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 659 - 665
July 10-15, 2022 ©2022 Association for Computational Linguistics

To demonstrate the advantage of the proposed *EmRel* framework, we conduct experiments on two specific scenarios of multi-triple extraction: document-level relation extraction(RE) and joint entity and relation extraction, with three popular datasets including DocRED (Yao et al., 2019), NYT (Riedel et al., 2010) and WebNLG (Gardent et al., 2017). The results verify the superiority of the joint triple perspective over the traditional entity perspective in multi-triple extraction. We also provide further ablation study to show the effectiveness of our fusion module and alignment function.

2 Related Works

Document-level Relation Extraction Extracting multi-triples from document-level text has recently aroused increasing interests (Yao et al., 2019). Existing methods take the entity perspective that proposes various techniques to model entity interactions. Nan et al. (2020) and Zeng et al. (2020) construct an entity graph, and perform graph-level reasoning to refine the entity node representations. Xu et al. (2021) introduces entity structure as useful prior, and models such information within the transformer attention layer. Zhang et al. (2021) utilizes a segmentation network to model the interdependency among entity pairs. Therefore, inter-triple correlations are only captured at the entity level while relation-based ones are neglected.

Joint Entity and Relation Extraction Joint entity and relation extraction is a popular task that extracts multi-triples along with their entities. Existing works can be concluded into two frameworks: one that searches subjects and objects for each individual relation (Liu et al., 2020; Wang et al., 2020; Wei et al., 2020), and the other that directly see each word as a candidate entity and assign them with relation labels (Gupta et al., 2016; Zheng et al., 2021). Both formulations do not explicitly include inter-triple correlations. Very recently, Wu and Shi (2021) propose to model the interdependencies between entity labels and relation labels. However, such correlation is constrained within a specific word position, while *EmRel* exploits the global correlations among all triples and across entities, context, and relations. Li et al. (2021) introduces a translation-based function that predicts object from subject and relation, while *EmRel* proposes a more expressive alignment function that models the ternary interaction of subject, relation and object.

Relation Embedding There is one specific previous work (Chen and Badlani, 2020) that also considers modeling relation representations. CRE uses the sentence representation as relation embeddings, and scores them with the entity embeddings trained along with the knowledge base. This raises significant differences with *EmRel* in both 1) technical design, *EmRel* constructs and models independent relation representations that are not inherited from specific context, and 2) task settings, CRE requires all entities be aligned to an existing knowledge base to train their embedding.

3 Methodology

3.1 Task Formulation

We first formulate the multi-triple extraction task to suitably contain both document-level RE and joint entity and relation extraction. Given a sequence of text $\{w_i\}$, a set of candidate entities $E = \{e_i\}$ and the pre-defined relations $R = \{r_i\}$, the candidate triples can be derived as:

$$T = \{< s, r, o > | s, o \in \{e_i\}, r \in \{r_i\}\} \quad (1)$$

the target is to assign each t in T a binary label that discriminates its validity. The candidate entities can either be pre-annotated, as in document-level relation extraction, or be jointly recognized, as in joint entity and relation extraction. In the latter scenario, one prevailing solution is to directly see each word as a candidate entity, such as tagging-based methods (Wang et al., 2020) or table filling methods (Gupta et al., 2016). Here we follow Wang et al. (2020) as our baseline, and thus formulate both tasks under a unified framework that extracts multi-triples from a given candidate entity set.

3.2 EmRel

EmRel consists of three modules: *Representation Construction* for both entities and relations, *Representation Fusion* that captures multi-triple correlations by modeling the informative interactions across entities, context and relations, and *Representation Alignment* that leverages these representations to extract triples by aligning their ternary structures (see Figure 2 for illustration).

Representation Construction The entity representation is constructed similar to existing practices. We employ a text encoder, *e.g.*, pretrained language models like BERT (Devlin et al., 2019), and obtain

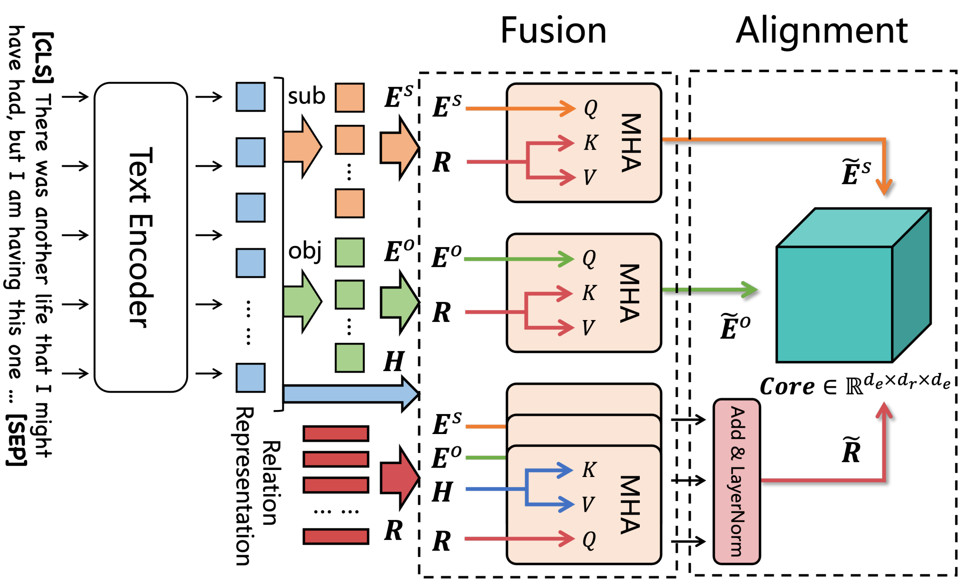

Figure 2: The overall framework of EmRel. It explicitly introduces relations embedding, and jointly represents it with entities to identify all valid triples.

the output from its last layer on corresponding position as the contextualized representation:

$$(h_1, h_2, ...h_n) = \texttt{encoder}(w_1, w_2, ...w_n) \qquad (2)$$

which we denote as $\mathbf{H} \in \mathbb{R}^{|\{w_i\}| \times d_h}$. Then we construct each entity representation $\mathbf{e}_i \in \mathbb{R}^{d_e}$ by applying a pooling operation on its corresponding mention positions, and further map it into respective subject and object representation $\mathbf{e}_i^s$, $\mathbf{e}_i^o$. We thus denote all extracted entity representations as $\mathbf{E}^s, \mathbf{E}^o \in \mathbb{R}^{|E| \times d_e}$.

We embed the target relations R into an embedding matrix $\mathbf{R} \in \mathbb{R}^{|R| \times d_r}$, where each row $\mathbf{R}_{i,:}$ represents a vectorized relation r_i. This matrix is maintained as part of the model parameter and trained accordingly.

Representation Fusion In order to jointly represent entities and relations in a shared knowledge representation space, we fuse them to be aware of each other. We adopt the attention network (Bahdanau et al., 2015) to model inter-component interactions, which has proven to be very successful in modeling rich interactions across contexts (Yu et al., 2018) or modalities (Lu et al., 2016). Specifically, we employ the canonical multi-head attention (MHA) network (Vaswani et al., 2017). Given the target representation $\mathbf{X}_Q$ and the source representation $\mathbf{X}_S$, each head of MHA operates them as:

$$\begin{aligned} \widehat{\mathbf{X}}_Q &= \texttt{Att}(\mathbf{X}_Q W^Q, \mathbf{X}_S W^K, \mathbf{X}_S W^V) \\ &= \texttt{softmax}(\frac{(\mathbf{X}_Q W^Q)(\mathbf{X}_S W^K)^T}{\sqrt{d_k}}) \mathbf{X}_S W^V \end{aligned} \qquad (3)$$

where $\widehat{\mathbf{X}}_Q$ is the updated representation of $\mathbf{X}_Q$ w.r.t. $\mathbf{X}_S$, all heads operate in parallel and will be concatenated together.

In *EmRel*, to exploit the comprehensive interactions across all components, we first construct entity/context-aware relation representation:

$$\begin{aligned} \widehat{\mathbf{R}}^s &= \texttt{Att}_{s2r}(\mathbf{R}W^Q, \mathbf{E}^s W^K, \mathbf{E}^s W^V) \\ \widehat{\mathbf{R}}^o &= \texttt{Att}_{o2r}(\mathbf{R}W^Q, \mathbf{E}^o W^K, \mathbf{E}^o W^V) \\ \widehat{\mathbf{R}}^c &= \texttt{Att}_{c2r}(\mathbf{R}W^Q, \mathbf{H}W^K, \mathbf{H}W^V) \end{aligned} \qquad (4)$$

which are then aggregated together using layer normalization:

$$\widehat{\mathbf{R}} = \texttt{LayerNorm}(\widehat{\mathbf{R}}^s + \widehat{\mathbf{R}}^o + \widehat{\mathbf{R}}^c) \qquad (5)$$

we symmetrically construct relation-aware entity representation:

$$\begin{aligned} \widehat{\mathbf{E}}^s &= \texttt{Att}_{r2s}(\mathbf{E}^s W^Q, \mathbf{R}W^K, \mathbf{R}W^V) \\ \widehat{\mathbf{E}}^o &= \texttt{Att}_{r2o}(\mathbf{E}^o W^Q, \mathbf{R}W^K, \mathbf{R}W^V) \end{aligned} \qquad (6)$$

s, o, c are abbreviations for $subject$, $object$ and $context$. Each attention module is wrapped with residual connection, feedforward layer, layer normalization, and is instantiated with different parameters of W_Q, W_K, W_V to model distinguished attending patterns. The outputs of fusion module are refined representations $\widehat{\mathbf{R}}$, $\widehat{\mathbf{E}}^s$, $\widehat{\mathbf{E}}^o$ for relations, subjects and objects.

Representation Alignment *EmRel* extracts triples by aligning their ternary components $\widehat{\mathbf{R}}$, $\widehat{\mathbf{E}}^s$, and $\widehat{\mathbf{E}}^o$. In order to fully leverage their expressiveness, we propose factorization-based alignment using Tucker decomposition (Tucker et al., 1964). We introduce a core tensor $\mathcal{Z} \in \mathbb{R}^{d_e * d_r * d_e}$, and the validity for each $< s_i, r_k, o_j >$ is scored as:

$$\phi(s_i, r_k, o_j) = \sigma(\mathcal{Z} \times_1 \hat{\mathbf{e}}_i^s \times_2 \hat{\mathbf{r}}_k \times_3 \hat{\mathbf{e}}_j^o + b_k) \quad (7)$$

where $\hat{\mathbf{e}}_i^s = \widehat{\mathbf{E}}_{i,:}^s$, $\hat{\mathbf{r}}_k = \widehat{\mathbf{R}}_{k,:}$, $\hat{\mathbf{e}}_i^o = \widehat{\mathbf{E}}_{j,:}^o$, and $\times_n$ indicates tensor product along the n-th mode, σ denotes sigmoid function. We compute ϕ for all triples in parallel using batched tensor product, and train them using cross-entropy loss:

$$\begin{aligned} L = \sum_{<s_i, r_k, o_j>}^{T} & [-\mathbb{1}^{True}(< s_i, r_k, o_j >) \log \phi(s_i, r_k, o_j) \\ & - \mathbb{1}^{False}(< s_i, r_k, o_j >) \log(1 - \phi(s_i, r_k, o_j))] \end{aligned} \quad (8)$$

where $\mathbb{1}$ indicates the ground truth validity.

4 Experiments

4.1 Main Results

We conduct comprehensive experiments on document-level RE dataset DocRED (Yao et al., 2019) and joint entity and relation extraction dataset NYT (Riedel et al., 2010) and WebNLG (Gardent et al., 2017). We use BERT-Base-Cased (Devlin et al., 2019) as the context encoder and we also provide results with RoBERTa (Liu et al., 2019) on DocRED. The dimension of embedded relation representation is set as 768 for Base models, 1024 for Large models on DocRED, and 128 on NYT / WebNLG. The number of attention heads in the fusion module is simply set as 4. We provide our reproduced results of TPLinker (Wang et al., 2020) and the baseline system of Xu et al. (2021). Both are competitive baselines based on the entity perspective, and are directly comparable with *EmRel*. Further specifics about these datasets and implementation details can be referred to Appendix.

The results (see Table 1 and Table 2) show that *EmRel* universally outperforms its baselines on all datasets. Respectively, **+0.3 F1** for NYT*, **+0.8 F1** for WebNLG*, **+1.0 F1** for NYT and **+1.1 F1** for WebNLG. On DocRED, *EmRel* improves the baseline by **+0.95 Dev F1**, **+1.47 Test F1**, and also outperforms several previous studies including BERT-TS (Wang et al., 2019), CorefBERT (Ye et al., 2020), LSR (Nan et al., 2020), and SSAN (Xu et al., 2021). On stronger backbone encoders like RoBERTa, similar improvements over baselines can also be observed.

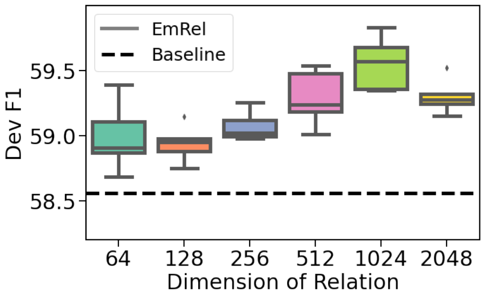

Figure 3: Ablation on dimensions of relations.

4.2 Ablation Studies

On EmRel Modules We first varify the design of *EmRel* modules. Table 3 shows that both fusion and alignment module contribute to the improvements. We also observe that *EmRel* has more robust performance across multiple runs. This can be attributed to our alignment function, which, once removed, would result in an increased standard deviation from ±0.20 to ±0.47.

On the Dimensionality of Relation Representations We investigate the effects of choices for d_r in Fig 3. First of all, the advantage of *EmRel* is general across variant choices comparing to the baseline. As we gradually set a higher d_r from 64 to 1024, we get improved performance for its stronger expressive capability. While we further increase d_r to 2048, the performance starting to degrades, which might attribute to overfitting. Overall, the optimal dimension lies within [512, 2048], which is quite robust and also computationally acceptable.

5 Conclusion

In this paper, we propose *EmRel* for multi-triple extraction. Distinguished from existing works, *EmRel* explicitly creates, refines, and leverages the embedded representation of relations. Notably, we design a novel alignment function that discriminates triple validity by aligning its components in a joint representation space. We conduct experiments on both document-level relation extraction and joint entity and relation extraction, to demonstrate the advantage of *EmRel* over its baselines.

EmRel also provides a new joint triple perspective, where multi-triple extraction is formulated as completion of a small, context-dependent knowledge graph, with candidate entities and relations as its components. In the future, we think more intricate techniques *e.g.*, graph-based reasoning, can be explored following such formulation.

Table 4: Statistics of used datasets. * denotes task settings that only annotate the last word. N denotes the number of valid triples within an instance. We can see that these selected benchmarks all involve multiple triples, thus pose significant challenge for relation extraction systems.

A Benchmarks

We introduce the benchmarks used in this work. Table 4 gives their detailed statistics. **DocRED** is constructed from Wikipedia document. It provides comprehensive human annotations for entity mentions, entity types, relational triples, along with their supporting evidences. Each document is a semantically integrate unit that centers in one concept (the title of the wiki page), resulting multiple triples with rich correlations. **NYT** is constructed from New York Times news articles and annotated through distant supervision. **WebNLG** is originally created for natural language generation task, and the sentences are written by humans to cover given triples. Both datasets have the other version denoted as NYT* and WebNLG*. The texts in NYT and WebNLG are much shorter than DocRED documents. These two datasets also feature in multiple triples. In this paper, we solve all three datasets under a unified multi-triple extraction formulation with *EmRel*.

B Implementation Details

To provide comparable results, we set hyper-parameters following previous works (Wang et al., 2020; Xu et al., 2021). On NYT / WebNLG, we set learning rate as 5e-5, batch size as 24 / 6, and epoch as 100, as each word is seen as a candidate entity, we directly take the word representation as entity representation. On DocRED, we set learning rate as 3e-5, batch size as 4, and search epochs in {40, 60, 80, 100}. Each document is truncated by 512 sequence length. Entity representation is constructed by pooling from all its mention positions. To produce more robust results, we further perform multiple searches using 5 different seeds, resulting a grid search on both epochs and random seeds. The mean and standard deviation results across different seed are reported on development set. All experiments are conducted on a single NIVDIA V100 or A100 GPU machine.

C Grouped Alignment

The WebNLG dataset has up to 216 relations, which requires increased computational cost. Inspired by (Zheng et al., 2019), we split the alignment tensors into N groups across its dimensions to reduce the computational overhead, and re-write Eq. 7 as:

$$\phi(s_i, p_k, o_j) = \sum_{n=1}^{N} \mathcal{Z}^n \times_1 \hat{\mathbf{e}}_i^{s,n} \times_2 \hat{\mathbf{r}}_k^n \times_3 \hat{\mathbf{e}}_j^{o,n} + b_k \tag{9}$$

$$\begin{aligned} \hat{\mathbf{e}}_i^{s,n} &= \widehat{\mathbf{E}}^s_{i,[(n-1)\frac{d_e}{N}:n\frac{d_e}{N}]} \\ \hat{\mathbf{r}}_k^n &= \widehat{\mathbf{R}}_{k,[(n-1)\frac{d_r}{N}:n\frac{d_r}{N}]} \\ \hat{\mathbf{e}}_i^{o,n} &= \widehat{\mathbf{E}}^o_{j,[(n-1)\frac{d_e}{N}:n\frac{d_e}{N}]} \end{aligned} \tag{10}$$

We set group N to 4 for WebNLG, and 1 for other datasets (that is, without further spliting).

Meta Learning for Natural Language Processing: A Survey

Abstract

Deep learning has been the mainstream technique in natural language processing (NLP) area. However, the techniques require many labeled data and are less generalizable across domains. Meta-learning is an arising field in machine learning studying approaches to learn better learning algorithms. Approaches aim at improving algorithms in various aspects, including data efficiency and generalizability. Efficacy of approaches has been shown in many NLP tasks, but there is no systematic survey of these approaches in NLP, which hinders more researchers from joining the field. Our goal with this survey paper is to offer researchers pointers to relevant meta-learning works in NLP and attract more attention from the NLP community to drive future innovation. This paper first introduces the general concepts of meta-learning and the common approaches. Then we summarize task construction settings and application of meta-learning for various NLP problems and review the development of meta-learning in NLP community.

1 Introduction

Recently, deep learning (DL) based natural language processing (NLP) has been one of the research mainstreams and yields significant performance improvement in many NLP problems. However, DL models are data-hungry. The downside limits such models' application to different domains, languages, countries, or styles because collecting in-genre data for model training are costly.

To address the challenges, meta-learning techniques are gaining attention. Meta-learning, or Learning to Learn, aims to learn better learning algorithms, including better parameter initialization (Finn et al., 2017), optimization strategy (Andrychowicz et al., 2016; Ravi and Larochelle, 2017), network architecture (Zoph and Le, 2017; Zoph et al., 2018; Pham et al., 2018a), distance metrics (Vinyals et al., 2016; Gao et al., 2019a; Sung et al., 2018), and beyond (Mishra et al., 2018). Meta-learning allows faster fine-tuning, converges to better performance, yields more generalizable models, and it achieves outstanding results for few-shot image classificaition (Triantafillou et al., 2020). The benefits alleviate the dependency of learning algorithms on labels and make model development more scalable. Image processing is one of the machine learning areas with abundant applications and established most of the examples in the previous survey papers on meta-learning (Hospedales et al., 2021; Huisman et al., 2021).

On the other hand, there are works showing benefits of meta-learning techniques in performance and data efficiency via applying meta-learning to NLP problems. Please refer to Tables 2 and 3 in the appendix for NLP applications improved by meta-learning. Tutorial (Lee et al., 2021b) and Workshop (Lee et al., 2021a) are organized at ACL 2021 to encourage exchange and collaboration among NLP researchers interested in these techniques. To facilitate more NLP researchers and practitioners benefiting from the advance of meta-learning and participating in the area, we provide a systematic survey of meta-learning to NLP problems in this paper. There is another survey paper on meta-learning in NLP (Yin, 2020). While Yin (2020) describes meta-learning methods in general, this paper focuses on the idea of making meta-learning successful when applied to NLP and provides a broader review of publications on NLP meta-learning. This paper is organized as below.

- A brief introduction of meta-learning backgrounds, general concepts, and algorithms in Section 2.
- Common settings for constructing meta-learning tasks in Section 3.

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 666 - 684
July 10-15, 2022

- Adaptation of general meta-learning approaches to NLP problems in Section 4.
- Meta-learning approaches for special topics, including knowledge distillation and life-long learning for NLP applications in Section 5.

Due to space constraints, we will not give too many detailed descriptions of general meta-learning techniques in this survey paper. For general concepts of meta-learning, we encourage readers to read the previous overview paper (Yin, 2020; Hospedales et al., 2021; Huisman et al., 2021).

2 Background Knowledge for Meta Learning

The goal of machine learning (ML) is to find a function $f_\theta(x)$ parametrized by model parameters θ for inference from training data. For machine translation (MT), the input x is a sentence, while $f_\theta(x)$ is the translation of x; for automatic speech recognitoin (ASR), x is an utterance, while $f_\theta(x)$ is the transcription; In DL, θ are the network parameters, or weights and biases of a network. To learn θ, there is a loss function $l(\theta;\mathcal{D})$, where $\mathcal{D}$ is a set of paired examples for training,

$$\mathcal{D} = \{(x_1, y_1), (x_2, y_2), ..., (x_K, y_K)\}, \qquad (1)$$

where x_k is function input, y_k is the ground truth, and K is the number of examples in $\mathcal{D}$. The loss function $l(\theta;\mathcal{D})$ is defined as below:

$$l(\theta;\mathcal{D}) = \sum_{k=1}^{K} d(f_\theta(x_k), y_k). \qquad (2)$$

where $d(f_\theta(x_k), y_k)$ is the "distance" between the function output $f_\theta(x_k)$ and the ground truth y_k. For classification problem, $d(.,.)$ can be cross-entropy; for regression, it can be L1/L2 distance. The following optimization problem is solved to find the optimal parameter set θ^* for inference via minimizing the loss function $l(\theta;\mathcal{D})$.

$$\theta^* = \arg\min_\theta l(\theta;\mathcal{D}). \qquad (3)$$

In meta-learning, what we want to learn is a learning algorithm. The learning algorithm can also be considered as a function, denoted as $F_\phi(.)$. The input of $F_\phi(.)$ is the training data, while the output of the function $F_\phi(.)$ is the learned model parameters, or θ^* in (3). The learning algorithm $F_\phi(.)$ is parameterized by *meta-parameters* ϕ, which is what we want to learn in meta-learning. If $F_\phi(.)$ represents gradient descent for deep network, ϕ can be initial parameters, learning rate, network architecture, etc. Different meta-learning approaches focus on learning different components. For example, model-agnostic meta-learning (MAML) focuses on learning initial parameters (Finn et al., 2017), which will be further descried in Section 4.1. Learning to Compare methods like Prototypical Network (Snell et al., 2017) in Section 4.2 learn the latent representation of the inputs and their distance metrics for comparison. Network architecture search (NAS) in Section 4.3 learns the network architecture (Zoph and Le, 2017; Zoph et al., 2018; Pham et al., 2018a).

To learn meta-parameters ϕ, *meta-training tasks* $\mathcal{T}_{train}$ are required.

$$\mathcal{T}_{train} = \{\mathcal{T}_1, \mathcal{T}_2, ..., \mathcal{T}_N\}, \qquad (4)$$

where $\mathcal{T}_n$ is a task, and N is the number of tasks in $\mathcal{T}_{train}$. Usually, all the tasks belong to the same NLP problem; for example, all the $\mathcal{T}_n$ are QA but from different corpora, but it is also possible that the tasks belong to various problems. Each task $\mathcal{T}_n$ includes a *support set* $\mathcal{S}_n$ and a *query set* $\mathcal{Q}_n$. Both $\mathcal{S}_n$ and $\mathcal{Q}_n$ are paired examples as $\mathcal{D}$ in (1). The support set plays the role of training data in typical ML, while the query set can be understood as the testing data in typical ML. However, to not confuse the reader, we use the terms support and query sets in the context of meta-learning instead of training and testing sets.

In meta-learning, there is a loss function $L(\phi;\mathcal{T}_{train})$, which represents how "bad" a learning algorihtm paramereized by ϕ is on $\mathcal{T}_{train}$. $L(\phi;\mathcal{T}_{train})$ is the performance over all the tasks in $\mathcal{T}_{train}$,

$$L(\phi;\mathcal{T}_{train}) = \sum_{n=1}^{N} l(\theta^n;\mathcal{Q}_n). \qquad (5)$$

The definition of the function $l(.)$ above is the same as in (2). $l(\theta^n;\mathcal{Q}_n)$ for each task $\mathcal{T}_n$ is obtained as below. For each task $\mathcal{T}_n$ in $\mathcal{T}_{train}$, we use a support set $\mathcal{S}_n$ to learn a model by the learning algorihtm F_ϕ. The learned model is denoted as θ^n, where $\theta^n = F_\phi(\mathcal{S}_n)$. This procedure is equivalent to typical ML training. We called this step *within-task training*. Then θ^n is evaluated on $\mathcal{Q}_n$ to obtain $l(\theta^n;\mathcal{Q}_n)$ in (5). We called this step *within-task testing*. One execution of within-task training and followed by one execution of within-task testing is called an *episode*.

The optimization task below is solved to learn meta-parameteres ϕ.

$$\phi^* = \arg\min_{\phi} L(\phi; \mathcal{T}_{train}). \quad (6)$$

If ϕ is differentiable with respect to $L(\phi; \mathcal{T}_{train})$, then we can use gradient descent to learn meta-parameters; if not, we can use reinforcement learning algorithm or evolutionary algorithm. Solving (6) is called *cross-task training* in this paper, which usually involves running many episodes on meta-training tasks. To evaluate ϕ^*, we need *meta-testing tasks* $\mathcal{T}_{test}$, tasks for evaluating algorithms parameterized by meta-parameters ϕ^*[1]. We do *cross-task testing* on $\mathcal{T}_{test}$, that is, running an episode on each meta-testing task to evaluate algorithms parameterized by meta-parameters ϕ^*.

In order to facilitate the reading of our paper, we summarize the most important terminologies and their meanings in Table 1 in the appendix.

3 Task Construction

In this section, we discuss different settings of constructing meta-training tasks $\mathcal{T}_{train}$ and meta-testing tasks $\mathcal{T}_{test}$.

3.1 Cross-domain Transfer

A typical setting for constructing the tasks is based on domains (Qian and Yu, 2019; Yan et al., 2020; Li et al., 2020a; Park et al., 2021; Chen et al., 2020b; Huang et al., 2020a; Dai et al., 2020; Wang et al., 2021b; Dingliwal et al., 2021; Qian et al., 2021). In this setting, all the tasks, no matter belonging to $\mathcal{T}_{train}$ or $\mathcal{T}_{test}$, are the same NLP problems. In each task $\mathcal{T}_n$, the support set $\mathcal{S}_n$ and the query set $\mathcal{Q}_n$ are from the same domain, while different tasks contain the examples from different domains. In each task, the model is trained on the support set of a domain (usually having a small size) and evaluated on the query set in the same domain, which can be considered as *domain adaptation*. From the meta-training tasks $\mathcal{T}_{train}$, cross-task training finds meta-parameters ϕ^* parameterizing the learning algorithm F_{ϕ^*}. With a sufficient number of tasks in $\mathcal{T}_{train}$, cross-task training should find a suitable ϕ^* for a wide range of domains, and thus also works well on the tasks in $\mathcal{T}_{test}$ containing the domains unseen during cross-task training. Hence, meta-learning can be considered as one way to improve *domain adaptation*. If the support set in each task includes only a few examples, the meta-learning has to find the meta-parameters ϕ^* that can learn from a small support set and generalize well to the query set in the same domain. Therefore, meta-learning is considered one way to achieve *few-shot learning*.

The cross-domain setting is widespread. We only provide a few examples in this subsection. In MT, each meta-training task includes the documents from a specific domain (e.g., news, laws, etc.), while each meta-testing task also contains documents from one domain but not covered by the meta-training tasks (e.g., medical records) (Li et al., 2020a). For another example, both meta-training and meta-testing tasks are DST. The meta-training tasks include hotel booking, flight ticket booking, etc., while the testing task is taxi booking (Huang et al., 2020a; Wang et al., 2021b; Dingliwal et al., 2021). Domain has different meanings in different NLP problems. For example, in speech processing tasks, the domains can refer to accents (Winata et al., 2020b; Huang et al., 2021) or speakers (Klejch et al., 2019; Wu et al., 2021b; Huang et al., 2022).

3.2 Cross-lingual Transfer

If we consider different languages as different domains, then the cross-lingual transfer can be regarded as a special case of cross-domain transfer. Suppose each task contains the examples of an NLP problem from one language, and different tasks are in different languages. In this case, cross-task training finds meta-parameters ϕ^* from the languages in $\mathcal{T}_{train}$, and cross-task testing evaluate the meta-parameters ϕ^* on new langauges in $\mathcal{T}_{test}$. This setting aims at finding the learning algorithm $F_{\phi^*}(.)$ that works well on the NLP problem of any language given the support set of the language. Cross-language settings have been applied to NLI and QA in X-MAML (Nooralahzadeh et al., 2020), documentation classification (van der Heijden et al., 2021), dependency parsing (Langedijk et al., 2021), MT (Gu et al., 2018), and ASR (Hsu et al., 2020; Winata et al., 2020a; Chen et al., 2020d; Xiao et al., 2021).

For the meta-learning methods aiming at learning the initial parameters like MAML (will be intro-

---

[1] If the learning processing of ϕ also involve some hyperperparameter selection, then *meta-validation tasks* are needed, but in this paper, we ignore the discussion of meta-validation tasks for simplicity.

duced in Section 4.1), the network architecture used in all tasks must have the same network architecture. A unified network architecture across all tasks is not obvious in cross-lingual learning because the vocabularies in different tasks are different. Before multilingual pretrained models are available, unified word embeddings across languages are required. Gu et al. (2018) uses the universal lexical representation to overcome the input-output mismatch across different languages. Recently, by using multilingual pretrained models as encoders, such as M-BERT (Devlin et al., 2019) or XLM-R (Conneau et al., 2020), all languages can share the same network architecture (Nooralahzadeh et al., 2020; van der Heijden et al., 2021).

3.3 Cross-problem Training

Here the meta-training and meta-testing tasks can come from different problems. For example, the meta-training tasks include MT and NLI, while the meta-testing tasks include QA and DST. The cross-problem setting is not usual, but there are still some examples. In Bansal et al. (2020a), the meta-training tasks are the GLUE benchmark tasks (Wang et al., 2018), while the meta-testing tasks are NLP problems, including entity typing, NLI, sentiment classification, and various other text classification tasks, not in the GLUE. All the meta-training and meta-testing tasks can be formulated as classification but with different classes. In Indurthi et al. (2020), the meta-training tasks are MT and ASR, while the meta-testing task is speech translation (ST). CrossFit is a benchmark corpus for this cross-problem setting (Ye et al., 2021).

The intrinsic challenge in the cross-problem setting is that different NLP problems may need very different meta-parameters in learning algorithms, so it may be challenging to find unified meta-parameters on the meta-training tasks that can generalize to meta-testing tasks. In addition, the meta-learning algorithms learning initial parameters such as MAML require all the tasks to have a unified network architecture. If different problems need different network architecture, then the original MAML cannot be used in the cross-problem setting. LEOPARD (Bansal et al., 2020a) and ProtoMAML (van der Heijden et al., 2021) are the MAML variants that can be used in the classification tasks with different class numbers. Both approaches use the data of a class to generate the class-specific head, so only the parameters of the head parameter generation model are required. The head parameter generation model is shared across all classes, so the network architecture becomes class-number agnostic. On the other hand, recently, universal models for a wide range of NLP problems have been emgered (Raffel et al., 2019; Chen et al., 2021; Ao et al., 2021). We believe the development of the universal models will intrigue the cross-problem setting in meta-learning.

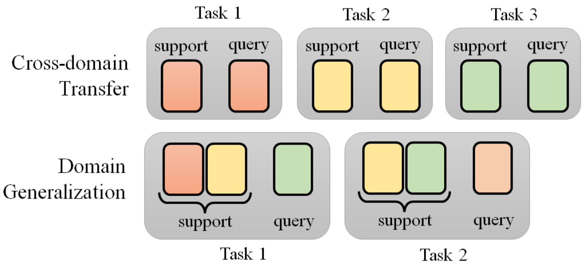

Figure 1: The task construction of cross-domain transfer in Section 3.1 and domain generalization in Section 3.4. Different colors represents data from different domains.

3.4 Domain Generalization

Traditional supervised learning assumes that the training and testing data have the same distribution. Domain shift refers to the problem that a model performs poorly when training data and testing data have very different statistics. Domain adaptation in Section 3.1 uses little domain-specific data to adapt the model[2]. On the other hand, *domain generalization* techniques attempt to alleviate the domain mismatch issue by producing models that generalize well to novel testing domains.

Meta-learning can also be used to realize domain generalization by learning an algorithm that can train from one domain but evaluate on the other. To simulate the domain generalization scenario, a set of meta-training tasks are constructed by sampling data from different domains as the support and query sets. With the meta-training tasks above, cross-task training will find the meta-parameters ϕ^* that work well on the scenario where the training (support) and testing (query) examples are from different domains. Fig. 1 shows how to construct tasks for domain generalization and compares the construction with the cross-domain transfer setting. The setting has been used to improve the domain generalization for semantic parsing (Wang et al.,

---

[2] The domain-specific data are usually labelled, but unlabelled domain-specific data can be leveraged as well (Kouw and Loog, 2021), which is out of scope here.

2021a) and language generalization[3] for sentiment classification and relevance classification (Li et al., 2020c).

3.5 Task Augmentation

In meta-learning, it is critical to have a large number of diverse tasks in the meta-training tasks $\mathcal{T}_{train}$ to find a set of meta-parameters ϕ^* that can generalize well to the meta-testing tasks. However, considering the setting in the previous subsections, different tasks contain examples in various domains, language, or even NLP problems, so a large and diverse $\mathcal{T}_{train}$ are often not available. In typical ML, data augmentation comes in handy when data is lacking. In meta-learning, augmenting tasks is similarly understood as data augmentation in ML. Data augmentation becomes task augmentation because the "training examples" in meta-learning are a collection of tasks. Task augmentation approaches in meta-learning can be categorized into two main directions: a) Inventing more tasks (without human labeling efforts) to increase the number and diversity of the meta-training tasks $\mathcal{T}_{train}$. b) Splitting training data from one single dataset into homogenous partitions that allow applying meta-learning techniques and therefore improve the performance. NLP-specific methods have been proposed in both categories.

Inventing more tasks The main question is how to construct a massive amount of tasks efficiently. There is already some general task augmentation approahces proposed for general meta-learning (Yao et al., 2021a; Ni et al., 2021; Rajendran et al., 2020; Yao et al., 2021b). Here we only focus on NLP-specific approaches. Inspired from the self-supervised learning, Bansal et al. (2020b) generates a large number of cloze tasks, which can be considered as multi-class classification tasks but obtained without labeling effort, to augment the meta-training tasks. Bansal et al. (2021) further explores the influence of unsupervised task distribution and creates task distributions that are inductive to better meta-training efficacy. The self-supervised generated tasks improve the performance on a wide range of different meta-testing tasks which are classification problems (Bansal et al., 2020b), and it even performs comparably with supervised meta-learning methods on FewRel 2.0 benchmark (Gao et al., 2019b) on 5-shot evaluation (Bansal et al., 2021).

Generating tasks from a monolithic corpus Many tasks can be constructed with one monolithic corpus (Huang et al. (2018); Guo et al. (2019); Wu et al. (2019); Jiang et al. (2019); Chien and Lieow (2019); Li et al. (2020b); MacLaughlin et al. (2020); Wang et al. (2020a); Pasunuru and Bansal (2020); Xu et al. (2021a); Murty et al. (2021)). First, the training set of the corpus is split into support partition, $\mathcal{D}_s$, and query partition, $\mathcal{D}_q$. Two subsets of examples are sampled from $\mathcal{D}_s$ and $\mathcal{D}_q$ as the support set, $\mathcal{S}$, and query set, $\mathcal{Q}$, respectively. In each episode, model parameters θ are updated with $\mathcal{S}$, and then the losses are computed with the updated model and $\mathcal{Q}$. The meta-parameters ϕ are then updated based on the losses, as the meta-learning framework introduced in Section 2. The test set of the corpus is used to build $\mathcal{T}_{test}$ for evaluation. As compared to constructing $\mathcal{T}_{train}$ from multiple relevant corpora, which are often not available, building $\mathcal{T}_{train}$ with one corpus makes meta-learning methodology more applicable. Besides, results obtained from one corpus are more comparable with existing NLP studies. However, only using a single data stream makes the resulting models less generalizable to various attributes such as domains and languages.

How to sample the data points to form a task[4] is the key in such category. In NAS research in Section 4.3, the support and query sets are usually randomly sampled. Learning to Compare in Section 4.2 splits the data points of different classes in different tasks based on some predefined criteria. There are some NLP-specific ways to construct the tasks. In Huang et al. (2018), a relevance function is designed to sample the support set $\mathcal{S}$ based on its relevance to the query set $\mathcal{Q}$. In Guo et al. (2019), a retrieval model is used to retrieve the support set $\mathcal{S}$ from the whole dataset. DReCa (Murty et al., 2021) applies clustering on BERT representations to create tasks.

4 Meta-Learning for NLP Tasks

This section shows the most popular meta-learning methods for NLP and how they fit into NLP tasks. Due to space limitations, only the major trends are mentioned. Please refer to Table 2 and 3 in the appendix for a complete survey.

---

[3] if a language is considered as a domain

[4] If a corpus includes data from different domains, and we sample the data in the same domain to create a task, then the setting here becomes cross-domain in Section 3.1.

4.1 Learning to Initialize

In typical DL, gradient descent is widely used to solve (3). Gradient descent starts from a set of initial parameters θ^0, and then the parameters θ are updated iteratively according to the directions of the gradient. There is a series of meta-learning approaches targeting at learning the initial parameters θ^0. In these learn-to-init approaches, the meta-parameters ϕ to be learned are the initial parameters θ^0 for gradient descent, or $\phi = \theta^0$. MAML (Finn et al., 2017) and its first-order approximation, FO-MAML (Finn et al., 2017), Reptile (Nichol et al., 2018), etc., are the representative approaches of learn-to-init. We surveyed a large number of papers using MAML-based approaches to NLP applications in the last three years and summarized them in Table 4 in the appendix.

Learning to Initialize v.s. Self-supervised Learning The learn-to-init approaches aim at learning a set of good initial parameters. On the other hand, self-supervised approaches like BERT also have the same target. There is a natural question: are they complementary? Based on the survey in Table 4 in the appendix, it is common to use the self-supervised models to "initialize" the meta-parameters ϕ in learn-to-init approaches. To find the optimal ϕ^* in (5), gradient descent is used as well, and thus the "initial parameters for initial parameters", or ϕ^0 is required. A self-supervised model usually serves the role of ϕ^0, and the learn-to-init approaches further update ϕ^0 to find ϕ^*.

Learn-to-init and self-supervised learning are complementary. The self-supervised objectives are different from the objective of the target NLP problem, so there is a "learning gap". On the other hand, learn-to-init approaches learn to achieve good performance on the query sets of the meta-training tasks, so it directly optimizes the objective of the NLP problems. The benefit of self-supervised learning is that it does not require labeled data, while labeling is still needed to prepare the examples in meta-training tasks.

Learning to Initialize v.s. Multi-task Learning Multi-task learning is another way to initialize model parameters, which usually serves as the baseline of learn-to-init in the literature. In multi-task learning, all the labelled data from the meta-training tasks is put together to train a model. That is, all the support sets $\mathcal{S}_n$ and query sets $\mathcal{Q}_n$ in the meta-training tasks $\mathcal{T}_{train}$ are put together as a training set $\mathcal{D}$, and the loss (3) is optimized to find a parameter θ^*. Then θ^* is used as initial parameters for the meta-testing tasks.

Both multi-task learning and meta-learning leverage the examples in the meta-training tasks, but with different training criteria. Learn-to-init finds the initial parameters suitable to be updated by updating the model on the support sets and then evaluating it on the query sets. In contrast, multi-task learning does not consider that the initial parameters would be further updated at all during training. Therefore, in terms of performance, learn-to-init is usually shown to be better than multi-task learning (Dou et al., 2019; Chen et al., 2020b). On the other hand, in terms of training speed, meta-learning, which optimizes (5), is more computationally intensive than multi-task learning optimizing (3).

Three-stage Initialization Since learn-to-init, multi-task, self-supervised learning all have their pros and cons, they can be integrated to draw on the strong points of each other. A common way to integrate the three approaches is "three-stage initialization" as below. a) First, initialize a model by self-supervised learning, which leverages unlabeled data. Its objective is usually not directly related to the target NLP problem. b) Then, multi-task learning is used to fine-tune the self-supervised model. The objective of multi-task learning is the target NLP problem but does not consider the update procedure in gradient descent. c) Finally, learn-to-init, which finds the initial parameters suitable for update, is used to fine-tune the multi-task model.

Learn-to-init is chosen to be the last stage because its training objective is closest to the target of looking for good initial parameters, but it is the most computationally intensive method, and thus it is only used to change the model a little bit. The three-stage initialization has been tested in several works (Nooralahzadeh et al., 2020; Wu et al., 2021b; van der Heijden et al., 2021; Langedijk et al., 2021), but it does not always improve the performance (Wu et al., 2021b; van der Heijden et al., 2021).

Challenges Learn-to-init is an essential paradigm for few-shot learning and usually achieves outstanding results in the few-shot learning benchmarks of image classification (Triantafillou et al., 2020). However, it has fallen short of yielding state-of-the-art results on NLP few-shot learning benchmarks (Ye et al., 2021; Chen et al., 2022; Bragg et al., 2021). For example, on the cross-task few-shot learning benchmark, CrossFit, simple multi-task learning outperforms existing learn-to-init in many cases (Ye et al., 2021). One possible reason is meta-learning methods are susceptible to hyper-parameters and even random seeds (Antoniou et al., 2019). Hence, it is difficult to obtain decent performance without exhaustively tuning hyperparameters. The research about developing more stable learn-to-init methods may lead to more practical real-world applications for the approaches. There is a study about stabilizing the cross-task training of learn-to-init methods by reducing the variance of gradients for NLP (Wang et al., 2021b).

4.2 Learning to Compare

Learning to Compare methods are widely applied to NLP tasks. Among many others, we find applications of Learning to Compare methods in text classification (Yu et al., 2018; Tan et al., 2019; Geng et al., 2019; Sun et al., 2019b; Geng et al., 2020), sequence labeling (Hou et al., 2020; Oguz and Vu, 2021), semantic relation classification (Ye and Ling, 2019; Chen et al., 2019a; Gao et al., 2019a; Ren et al., 2020), knowledege completion (Xiong et al., 2018; Wang et al., 2019b; Zhang et al., 2020; Sheng et al., 2020) and speech recognition (Lux and Vu, 2021) tasks.

Most of the proposed methods are based on Matching Network (Vinyals et al., 2016), Prototypical Network (Snell et al., 2017) and Relation Network (Sung et al., 2018), and extend these architectures in two aspects: a) how to embed text input in a vector space with/without context information, and b) how to compute the distance/similarity/relation between two inputs in this space. Since these questions have had deep roots in the computation linguistics research for many years (Schütze, 1992; Manning and Schutze, 1999), Learning to Compare methods is one of the most important methods among other meta-learning methods in the context of NLP despite their simplicity. Notably, to date, such family of methods is mainly applied to classification tasks.

4.3 Neural Network Architecture Search

Neural network architecture search (NAS) is another common meta-learning technique applied to NLP including language modeling (WikiText-103 (Merity et al., 2017), PTB (Mikolov et al., 2010)), NER (CoNLL-2003 (Sang and De Meulder, 2003)), TC (GLUE (Wang et al., 2019a)), and MT (WMT'14 (Bojar et al., 2014)). As discussed in Section 3.5, these techniques are often trained/evaluated with a single, matched dataset, which is different from other meta-learning approaches.

Moreover, in contrast to conventional NAS methods that focus on learning the topology in an individual recurrent or convolutional cell, NAS methods have to be redesigned in order to make the search space suitable for NLP problems, where contextual information often plays an important role. Jiang et al. (2019) pioneers the application of NAS to NLP tasks beyond language modeling (NER in this case), and improves differentiable NAS by redesigning its search space for natural language processing. Li et al. (2020b) extends the search space of NAS to cover more RNN architectures and allow the exploring of intra- and inter-token connection to increase the expressibility of searched networks. As the popularity of pre-trained language models (PLM) grows in NLP area, researchers also apply NAS to discover better topology for PLM such as BERT. Wang et al. (2020a) introduces Hardware-Aware Transformers (HAT) to search Transformer architecture optimized for inference speed and memory footprint in different hardware platforms. NAS-BERT (Xu et al., 2021b) and AdaBERT (Chen et al., 2020a) explores task-agnostic and task-dependent network compression techniques with NAS respectively. EfficientBERT (Dong et al., 2021) applies NAS to search for more efficient architecture of feed-forward network that is suitable for edge device deployment.

To show the efficacy of NAS, we summarize the performance of several state-of-the-art NAS approaches on GLUE benchmarks (Wang et al., 2019a) in Table 5 in the appendix. These approaches are applied to BERT to discover architectures with smaller sizes, faster inference speed, and better model accuracy. For comparison, performance from original and manually compressed BERT models is also presented. The results show that the BERT architecture improved by NAS yields performance competitive to BERT (c.f., 82.3 from EfficientBERT vs 82.5 from BERT) and is 6.9x smaller and 4.4x faster. The searched architecture also outperforms manually designed, parameter- and inference-efficient model (MobileBERT$_{\text{TINY}}$) at similar size and speed. These results suggest the efficacy of NAS in discovering more efficient network architectures. As NLP researchers continue to design even larger PLMs while the need of deployment on edge devices grows, we expect there will be increasing investment in innovating NAS techniques to make PLM networks more compact and accelerate inference.

Challenges The main bottleneck for NAS being widely applied is the prohibitive requirement in computation resources for architecture search. Approaches such as Efficient Neural Architecture Search (ENAS, Pham et al. (2018b)) and Flexible and Expressive Neural Architecture Search (FENAS, Pasunuru and Bansal (2020)) are proposed to improve the search efficiency. As PLMs usually have bulky sizes and slow training speed, search efficiency is even more critical when applying NAS to PLM. Weight-sharing techniques are often applied to accelerate searching (Wang et al., 2020a; Dong et al., 2021; Xu et al., 2021b).

4.4 Meta-learning for Data Selection

Multi-linguality, multi-task, and multi-label see many impacts on NLP problems due to the diversity of human languages. To learn models with balanced performance over attributes (e.g., languages, tasks, labels), a common approach is to weight the training examples for data selection to learn models with balanced performance over the attributes, and it is a natural assumption that meta-learning techniques derive more generalizable weighting than manually tuned hyperparameters. For example, Wu et al. (2019) add another gradient update step wrapping the conventional classifier update for training meta-parameters that controls the weight when aggregating losses from different labels to update classifier's parameters. In addition to gradient update, meta-learned weights are also applied directly to training examples for data selection to address the issue of noisy labeling. Shu et al. (2019) propose a technique to jointly learn a classifier and a weighting function, where a conventional gradient update for the classifier and a meta-learning update for the weighting is performed alternatively. The function weights examples to mitigate model overfitting towards biased training data caused by corrupted labels or class imbalance. Zheng et al. (2021) apply a similar framework but extend the weighting with a label correction model. Both techniques show improvement over SOTA in text classification with biased training data.

Additionally, as the progress in the research of pre-training and transfer learning, there is a trend of leveraging datasets in multiple languages, domains, or tasks to jointly pre-train models to learn transferable knowledge. A meta-learned data selector can also help in this scenario by choosing examples that benefit model training and transferability. For instance, Wang et al. (2020b) investigate the common challenge of imbalanced training examples across languages in multilingual MT, which is conventionally addressed by tuning hyperparameters manually to up-sample languages with less resources. The authors propose Differentiable Data Selection (DDS) to parameterize the sampling strategies. DDS is trained with episodes and REINFORCE algorithm to optimize parameters of sampler and MT models in an alternating way for the MT models to converge with better performance across languages. Pham et al. (2021) formulate data sampling for multilingual MT as a problem of back-translation to generate examples of parallel utterances from unlabeled corpora in target language. The back-translation is jointly trained with MT models to improve translation result through better distribution of training examples and data augmentation. Tarunesh et al. (2021) further study knowledge transferring across tasks and languages. The authors combine Reptile and DDS to meta-learn samplers with six different languages (en, hi, es, de, fr, and zh) and five different tasks (QA, NLI, paraphrase identification, POS tagging, and NER) and demonstrate competitive performance on XTREME multilingual benchmark dataset (Hu et al., 2020).

5 Meta-learning beyond Accuracy

In the previous sections, meta-learning is used to obtain better evaluation metrics for NLP applications. This section illustrates how meta-learning can improve NLP applications from more aspects beyond performance.

5.1 Learn to Knowledge Distillation

Knowledge distillation method was proposed in (Hinton et al., 2015). The main goal is to transfer knowledge from a so-called teacher model, e.g., a vast neural network trained with a lot of training data, to a more compact student model, e.g., a neural network with much less trainable parameters. The main weaknesses of this method are as follows: a) the number of teacher models is fixed to one that could limit the power of the transferring process; b) the teacher model is not optimized for the transferring process and c) the teacher model is not aware of the student model during the transferring process. Meta-learning methods can be applied to partially fix these issues. The high-level idea is to increase the number of teacher models and the number of student models and consider each pair of a teacher model and a student model as a task in the meta-learning framework. By doing so, we can train a meta teacher model that works better than a single teacher model (Pan et al., 2020), and we can optimize the transferring process and force the teacher model to be aware of the student model (Zhou et al., 2022).

5.2 Learn to Life-long learning

This subsection discusses how to use meta-learning to improve *lifelong learning* (LLL) (Chen and Liu, 2018). The real world is changing and evolving from time to time, and therefore machines naturally need to update and adapt to the new data they receive. However, when a trained deep neural network is adapted to a new dataset with a different distribution, it often loses the knowledge previously acquired and performs the previous seen data worse than before. This phenomenon is called *catastrophic forgetting* (McCloskey and Cohen, 1989). There is a wide range of LLL approaches aiming for solving catastrophic forgetting (Parisi et al., 2019). Among them, the following directions apply meta-learning: [5]

Meta-learning for Regularization-based LLL methods Regularization-based LLL methods aim to consolidate essential parameters in a model when adapting models with new data (Kirkpatrick et al., 2017; Zenke et al., 2017; Schwarz et al., 2018; Aljundi et al., 2018; Ehret et al., 2021). Meta-learning targets "how to consolidate" and has some successful examples in NLP applications. KnowledgeEditor (De Cao et al., 2021) learns the parameter update strategies that can learn the new data and simultaneously retain the same predictions on the old data. KnowledgeEditor has been applied to fact-checking and QA. Editable Training (Sinitsin et al., 2020) employs learn-to-init approaches to find the set of initial parameters, ensuring that new knowledge can be learned after updates without harming the performance of old data. Editable Training empirically demonstrates the effectiveness on MT.

Meta-learning for Data-based LLL Methods The basic idea of data-based methods is to store a limited number of previously seen training examples in memory and then use them for empirical replay, that is, training on seen examples to recover knowledge learned (Sprechmann et al., 2018; de Masson d'Autume et al., 2019; Sun et al., 2019a) or to derive optimization constraints (Lopez-Paz and Ranzato, 2017; Li and Hoiem, 2017; Saha and Roy, 2021). A hurdle for data-based approaches is the need to store an unrealistically large number of training examples in memory to achieve good performance. To achieve sample efficiency, Obamuyide and Vlachos (2019a); Wang et al. (2020c); Wu et al. (2021a) uses meta-learning to learn a better adaptation algorithm that recovers the knowledge learned with a limited amount of previously seen data. Experiments on text classification and QA benchmarks validate the effectiveness of the framework, achieving state-of-the-art performance using only 1% of the memory size (Wang et al., 2020c).

6 Conclusion

This paper investigates how meta-learning is used in NLP applications. We review the task construction settings (Section 3), the commonly used methods including learning to initialize, learning to compare and neural architecture search (Section 4), and highlight research directions that go beyond improving performance (Section 5). We hope this paper will encourage more researchers in the NLP community to work on meta-learning.

A Appendx

Table 1: Terminologies and their meanings.

Terminologies	Meaning
(NLP) Problem	a type of NLP problems like QA, POS, or MT
Model Parameter	parameters of models making inference for underlying problems
Meta-parameter	parameters of learning algorithms (e.g., model init, optimizers) that are shared across tasks
Support Set	a set of training examples for updating model parameters
Query Set	a set of testing examples for evaluating model parameters
Task	combination of one support set and one query set
Within-task Training	learning model parameter with support set
Within-task Testing	using query set to evaluate model parameters
Episode	one execution of within-task training and followed by one execution of within-task testing
Meta-training Tasks	tasks generated for learning meta-parameter
Meta-testing Tasks	tasks generated for evaluating algorithms parameterized by meta-parameter
Cross-task Training	learning meta-parameter, which usually involves running many episodes on meta-training tasks
Ccross-task Testing	running an episode on each meta-testing task to evaluate algorithms parameterized by meta-parameter

Table 2: An organization of works on meta-learning in NLP. The **Application** column lists the applications that are performed in corresponding papers. We use the following abbreviations. **QA**: Question Answering. **MT**: Machine Translation. **TC**: Text Classification (including Natural Langauge Inference). **IE**: Information Extraction (including Relation Classificaiton and Knowledge Graph Completion). **WE**: Word Ebedding **TAG**: Sequence Tagging. **PAR**: Parsing. **DST**: Dialgoue State Tracking. **DG**: Dialgoue Generation (including Natural Language Generation). **MG**: Multimodal Grounding. **ASR**: Automatic Speech Recognition. **SS**: Source Separation. **KS**: Keyword Spotting. **VC**: Voice Cloning. **SED**: Sound Event Detection. The **Method** column lists the involving meta-learning methods. **INIT** is learning to initialize; **COM** is learning to compare; **NAS** is network architecture search; **OPT** is learning to optimize; **ALG** is learning the learning algorithm; **SEL** is learning to select data. **Task construction** column lists the way each work is built for training meta-parameters. Please refer to Section 3 for the description about task construction.

Table 4: Summary of learn-to-init variants. This table contains the following information. (1) **Method**: There are many variants in the learn-to-init family. The most representative one is MAML. Typical MAML (Finn et al., 2017) has large computation intensity, so the first-order approximations like FOMAML (Finn et al., 2017) and Reptile (Nichol et al., 2018) are widely used. DG-MAML (Li et al., 2018) is for domain generalization. Typical learn-to-init assumes that all the tasks use the same network architecture, but LEOPARD (Bansal et al., 2020a) and Proto(FO)MAML (Triantafillou et al., 2020) are proposed to overcome the limitation. (2) **How to Initialize the Initialization**: Learn-to-init approaches aim at learning the initial parameters. But where does the initialization of MAML come from? We found that using self-supervised pre-training as initialization is common. The table specifies the pre-trained models used to initialize the learn-to-init methods. '-' means the initial parameters are learned from random initialization or cannot tell based on the descriptions in the papers.

Abstract

Building robust multimodal models are crucial for achieving reliable deployment in the wild. Despite its importance, less attention has been paid to identifying and improving the robustness of Multimodal Sentiment Analysis (MSA) models. In this work, we hope to address that by (i) Proposing simple diagnostic checks for modality robustness in a trained multimodal model. Using these checks, we find MSA models to be highly sensitive to a single modality, which creates issues in their robustness; (ii) We analyze well-known robust training strategies to alleviate the issues. Critically, we observe that robustness can be achieved *without* compromising on the original performance. We hope our extensive study–performed across five models and two benchmark datasets–and proposed procedures would make robustness an integral component in MSA research. Our diagnostic checks and robust training solutions are simple to implement and available at `https://github.com/declare-lab/MSA-Robustness`

1 Introduction

Multimodal Sentiment Analysis (MSA) is a burgeoning field of research that has seen accelerated developments in recent years. Numerous models have been proposed that utilize multiple modalities such as audio, visual, and language signals to predict sentiments, emotions, and other forms of affect. While progress in MSA has been driven mainly by improvements in multimodal performance, we call for attention towards an equally important aspect in multimodal systems – *multimodal robustness*. Robustness is crucial when models are deployed in the wild, where it is common to encounter inadvertent errors in the source modalities due to data loss, data corruption, jitter, privacy issues, amongst others.

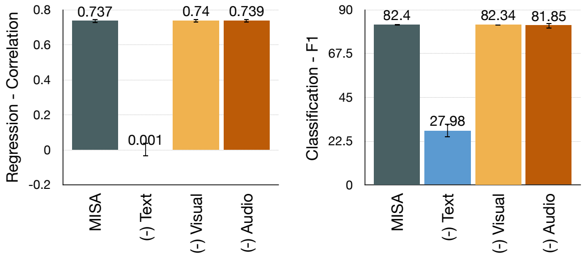

Figure 1: Removing modalities one at a time from the testing set of CMU-MOSI (Zadeh et al., 2016) on a trained MISA (Hazarika et al., 2020).

A well-known fact in the MSA research is that *language* modality tends to be the most effective, which has prompted models to utilize language as its core modality (Wu et al., 2021; Han et al., 2021a; Zeng et al., 2021). In this work, we focus on skewed dependence on language and try to understand how it affects the robustness of MSA models. Specifically, we ask,

RQ1: *Are models in MSA over-reliant on a subset of modalities, particularly language?*

RQ2: *If yes, what implications does it have on modality robustness?*

To answer **RQ1**, we look at Fig. 1. The figure illustrates a setup where we fully remove one modality during testing on the MISA model (Hazarika et al., 2020). Here, we observe a sharp drop in performance when language modality is removed but

---

[*] Equal Contribution.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 685 - 696
July 10-15, 2022 ©2022 Association for Computational Linguistics

do not see statistically significant drops when audio or visual modalities are removed. This observation aligns with recent findings in the MSA literature highlighting the dominance of language.

This brings us to **RQ2** where we try to understand the robustness implications over this dominance. We design an elaborate study in § 3—over five state-of-the-art (SOTA) MSA models and across two benchmark datasets—where we propose diagnostic checks to understand *modality robustness*, i.e., how robust are models against modality errors such as missing or noisy modalities.

Based on our findings, we then proceed to ask,

RQ3: *How can we improve the robustness of these models?*

RQ4: *Does robust training lead to a performance trade-off?*

For **RQ3**, we study well-known robust training methods, that act as a pre-emptive strategy to reduce the performance drops. Critically, our training is *model-agnostic* and can be easily included in any existing multimodal model (§ 4). For **RQ4**, we observe that our method to improve robustness *does not* trade-off with the final performance on the clean testing set, thus achieving similar performance as the original model.

2 Related Works

While MSA has received increased attention in recent times, the topic of robustness has not taken center stage. Fortunately, few works have started changing this trend. (Gat et al., 2020) reveals how multimodal classifiers often utilize a subset of modalities, which they addressed by inducing uniform contribution from all input modalities. In MSA, multiple works over-rely on language modality to improve the performance. (Wu et al., 2021) constructs a text-centered shared-private framework for multimodal fusion, and (Han et al., 2021a) obtains two text-related modal pairs and iteratively push the interaction between modalities to supplement information for better performance. While this has enabled performance boosts, our goal is to explore the double-edged nature of this feature and how it impacts robustness. Our motivation for diagnostics is similar to (Frank et al., 2021), but unlike them, we do not perturb the raw data (such as image patches). Instead, we intervene on modality representations, which is easier to integrate with existing models and do not require prior knowledge of the modality structure.

To address robustness in MSA, (Tsai et al., 2018) proposes a factored model that can accommodate modality drops. Also, (Ma et al., 2021) introduces modality drops during training and testing and uses meta-learning to make models robust. However, our work comprises some crucial distinctions: i) Unlike these works, our diagnostics and robust training do not require sophisticated architecture and can be easily integrated into existing models. ii) We perform an exhaustive analysis of robustness across multiple models, which is previously not done in the MSA literature.

3 Testing Robustness via Diagnostic Checks

In this section we perform an elaborate study on modality robustness by simulating potential issues with modality signals during testing (or deployment) of MSA models.

3.1 Experiment Setup

Models. In order to fully verify the universality of our experiments, we select a series of diverse SOTA models, ranging from RNN-based to Transformer-based architectures. These models work across different granularities from word-level to sentence-level variants:

(i) **MISA** (Hazarika et al., 2020) is a popular model that generates modality-invariant and -specific features of multimodal data, to learn both shared and unique characteristics of each modality. (ii) **BBFN** (Han et al., 2021a) in a similar vein performs fusion and separation to increase cross-modal relevances and differences. This work acknowledges the dominance of text modality in MSA and proposes two text-centric bi-modal transformers to increase performance. (iii) **Self-MM** (Yu et al., 2021) focuses on the relationship between multi- and uni-modal predictions by multi-tasking consistencies and differences between them. (iv) **MMIM** (Han et al., 2021b) incorporates mutual information (MI) into MSA by maximizing MI at the input and fusion level. (v) **MulT** (Tsai et al., 2019) merges multimodal time series through multiple sets of directional pairwise cross-modal transformers. It accounts for long-range dependencies across modality elements to create a strong baseline (see Appendix B).

Datasets. We consider two benchmark datasets widely used in the field of multimodal sentiment analysis, CMU-MOSI (Zadeh et al., 2016), which

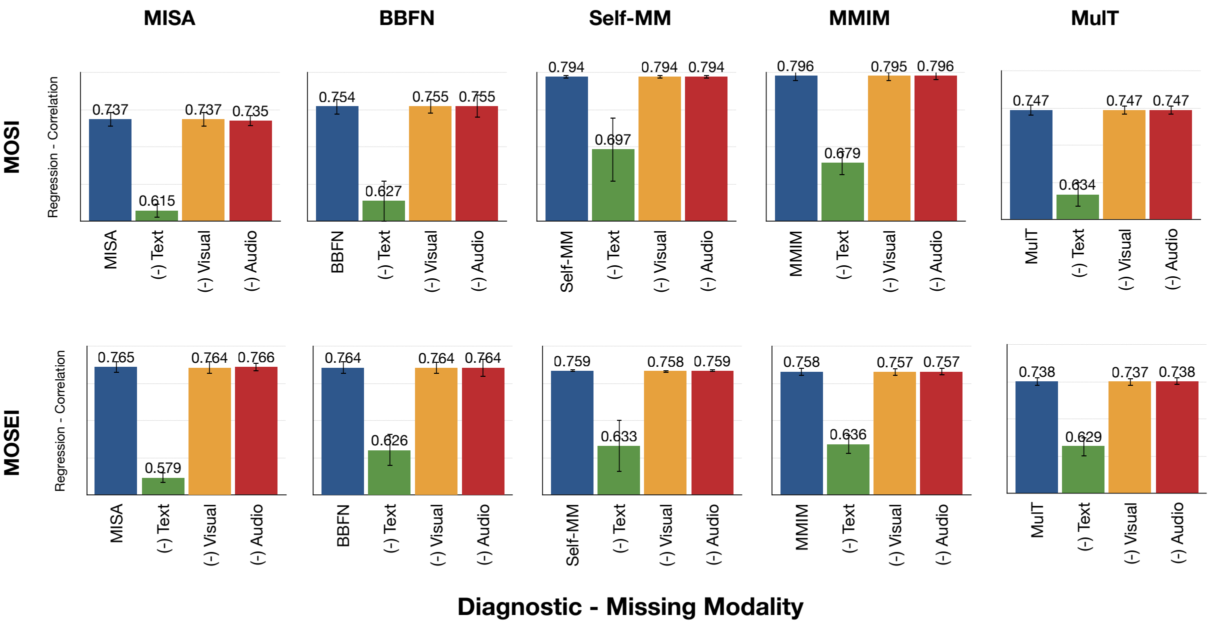

Figure 2: Diagnostic checks (missing modality) for modality robustness in MOSI and MOSEI datasets. Results are averaged over three independent runs. Each modality error is applied to 30% of testing data.

is a popular dataset for studying the intensity of multimodal sentiment in the MSA field and CMU-MOSEI (Bagher Zadeh et al., 2018) which is a larger counterpart of MOSI with richer annotations and more diverse samples. Both these datasets contain short utterance videos and provide language, audio, and visual modality features.

3.2 Proposed Diagnostic Checks

We propose two diagnostic checks that introduce i) *Missing Modalities*, which drops (or nullifies) a modality from the input and ii) *Noisy Modalities* which include random changes to the modality representations, introduced via white Gaussian noise to the respective modality representations[1]. To simulate a realistic scenario, we apply these checks to 30% of the testing data set[2]. Given the increased dependence on language modality in MSA models, we limit our study to errors introduced only in language modality without loss of generality.

Procedure. We aim to intervene on modality representations to simulate modality errors. For the language modality l, all models map the sequence of tokens $U_l \in R^{T_l}$ to its low-level embedding $\mathbf{U}_l \in R^{T_l \times d_l}$ with T_l tokens and d_l embedding dimension. This low-level sequence is then encoded into hidden representations using an encoder of choice, such as BERT (Devlin et al., 2019), to achieve the language representation vector $\mathbf{u}_l = enc_{\theta_l}(U_l) \in \mathbb{R}^d$. We intervene on this representation and apply our diagnostics as follows.

We sample 30% of u_l from the testing set and modify them as $\hat{\mathbf{u}}_l = f(\mathbf{u}_l)$, where $f(\mathbf{x})$ is defined as either $f(\mathbf{x}) = \mathbf{x} \odot \mathbf{0}$ for modality dropping (nulling the vector to 0s by element-wise multiplication) or $f(\mathbf{x}) = \mathbf{x} + \mathcal{N}(\mathbf{0}, \mathbf{1})$ to add white noise. The modified $\hat{\mathbf{u}}_l$ is then fed to the rest of the network as usual.

In the selected models, we apply diagnostics at different network locations. These include the representations before the hidden projection, such as in MISA, or fusion operation, such as in Self-MM. For MulT and BBFN, we apply the interventions right after the word embeddings. Detailed discussion on the location of interventions is provided in Appendix A.

Observations. Figs. 2 and 3 presents the results, where across both MOSI and MOSEI datasets, we find that language modality is highly sensitive to modality errors in the language source (across all models). This trend is observed for both missing and noisy modality checks, thus highlighting the concerns over robustness of these SOTA models. These diagnostic checks are easy to analyze, and we hope they will become an integrated part of the model-development pipeline in MSA.

---

[1] While missing and noisy errors are predominant in the wild, we leave other potential forms of errors, such as affine transformations to the representations for future work.

[2] We set 30% arbitrarily to simulate modality errors to a proportion of the input signals.

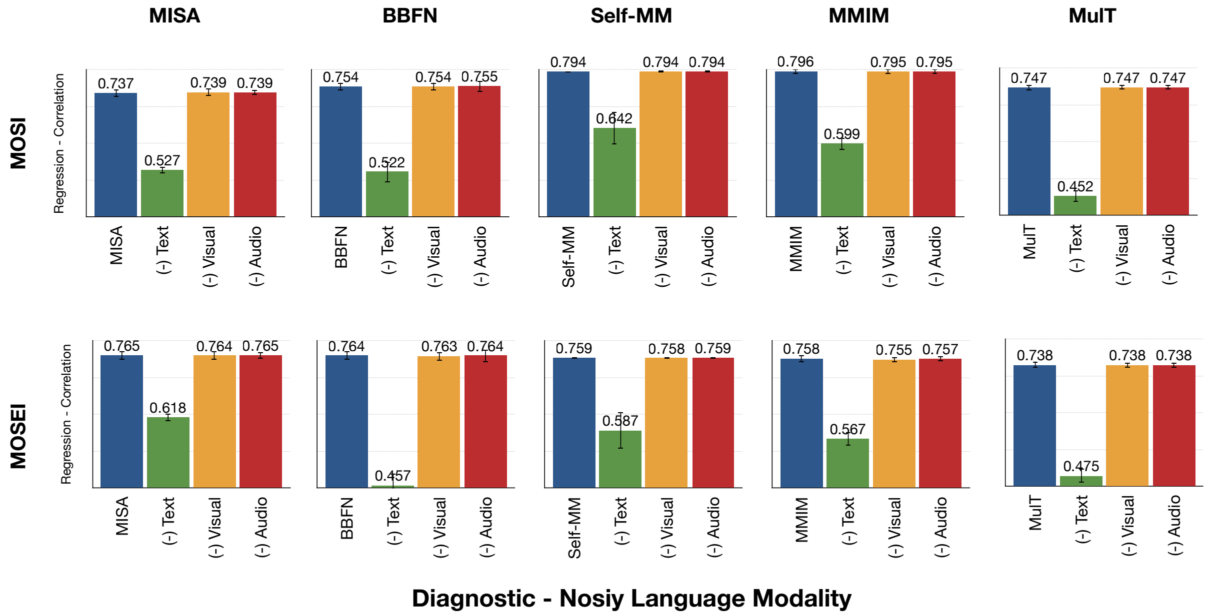

Figure 3: Diagnostic checks (noisy modality) for modality robustness in MOSI and MOSEI datasets. Results are averaged over three independent runs. Each modality error is applied to 30% of testing data.

4 Robust Training

In this section, we explore how to reduce the sensitivity of the models to the dominant modality, i.e., language. One of the popular ways to alleviate such issues is to *teach* the model such scenarios during training. We dub this approach as *modality-perturbation*, which is conceptually similar to removing or masking modalities in (Ma et al., 2021; Georgiou et al., 2021) or adding noise in (Miyato et al., 2018). It simulates the modality errors during training so that the model learns to expect such events during testing/deployment. The procedure is as follows,

1. **Training:**
   (a) For a particular batch of data, sample a proportion of the data to be perturbed.
   (b) Similar to the diagnostic checks in § 3, perturb the dominant modality (in our case, language) of half of this data with *missing* and the other half with *noisy* perturbation. Repeat both these steps for the next batch.
2. **Testing:** Apply the diagnostic checks as in § 3.

This simple approach can be interpreted as regularization akin to dropouts or noising strategies used in de-noising auto-encoders.

4.1 Results

Robustness. Table 1 presents the results, where we perform *balanced* perturbation between missing and noisy modalities. For the 30% perturbable data in training, we drop the language modality on 15% and for the other 15%, we add noise. This setting improves the diagnostics in both kinds of errors. Appendix C presents results on other proportions of the training data.

With balanced perturbation, (BBFN-MOSI) reduces the relative drop on *missing* language diagnostic by 31% (in F1) and 98% on *noise*. Also, *missing* drop reduces by 11% in Corr and by 99% for *noisy* diagnostic. (Self-MM, MOSI) increases the relative drop in Corr slightly on *missing* diagnostic, but in all other cases, it is significantly reduced. For example, the F1 drop on MOSI for *noisy* diagnostic reduces significantly by 93%. Table 1 also shows that our method performs well on both RNN-based and Transformer-based models, demonstrating the wide applicability of our method.

Performance Trade-off. While alleviating robustness via regularization is well-known in the literature, there is often a trade-off with absolute performance in the original testing setup. Most approaches that achieve robustness take a hit at their best performance on clean input (Zhang et al., 2022) (Nakkiran, 2019) (Su et al., 2018) (Tsipras et al., 2019). This raises the question of whether introducing *modality-perturbation* reduces the performance of the model on the original testing set.

We find the answer to this is *No*. Surprisingly, our robust training procedure *does not* degrade in

	Diagnostic (30%)	Robust Training	MOSI		MOSEI

Table 1: Robust Training is performed with 15% missing and 15% noise perturbation. Results are averaged over 3 random runs. More perturbation results are provided in Appendix C. Higher drops between Non-robust and robust training (consecutive rows) are highlighted.

its original performance and can perform similar to the original model variants. This is highly ideal as we achieve robustness without compromising on performance in clean data.

5 Conclusion

In this work, we performed a systematic study that demonstrate the double-edged nature of dominant modality in SOTA MSA models. Our analysis using diagnostic checks reveal high susceptibility to performance drops when presented with unwanted errors in their representations.

To alleviate the issues, we also study robust training methods that uses modality perturbations. Critically, we find that robustness and performance can co-exist without an explicit trade-off. These improvements demonstrate a positive nudge in the effort to achieve robustness and we believe there remains significant room for improvement. With this work, by proposing simple and easy-to-integrate diagnostic checks and training methods, we hope to permeate discussions on robustness into mainstream MSA research.

A Model Details

MISA: We get the MISA model from its official repository [3]. In this model, we apply the interventions at the following encoded language representation from the original paper:

$$\mathbf{u}_l = \text{Bert}\left(\mathbf{U}_l; \theta_l^{bert}\right) \quad (1)$$

$$\hat{\mathbf{u}}_l = f(\hat{\mathbf{u}}_l) \quad (2)$$

$$\mathbf{h}_l^c = E_c\left(\hat{\mathbf{u}}_l; \theta^c\right), \quad \mathbf{h}_l^p = E_p\left(\hat{\mathbf{u}}_l; \theta_l^p\right) \quad (3)$$

That is, the interventions are applied before the language representation is projected to its shared and private subspaces.

BBFN: We get the BBFN model from its official repository [4]. In this model, we execute the interventions after the following language embedding from the original paper.

$$\mathbf{M}_l = (m_0, m_1, \ldots, m_{n+1}) \quad (4)$$

$$\hat{\mathbf{M}}_l = f(\mathbf{M}_l) \quad (5)$$

Self-MM: We get the Self-MM model from its official repository[5]. In this model, we set the interventions after the language features encoded below from the original paper.

$$\mathbf{F}_l = BERT\left(I_l; \theta_l^{bert}\right) \in R^{d_l} \quad (6)$$

$$\hat{\mathbf{F}}_l = f(\mathbf{F}_l) \quad (7)$$

MMIM: We get the MMIM model from its official repository [6]. For this model, we perform the interventions after the following encoded language representation from the original paper.

$$\mathbf{x}_l = \text{BERT}\left(X_l; \theta_l^{BERT}\right) \quad (8)$$

$$\hat{\mathbf{x}}_l = f(\mathbf{x}_l) \quad (9)$$

MulT: We get the MulT model from its official repository [7]. We intervene in this model after the following encoded language representation:.

$$\mathbf{x}_l = \text{Conv1D}(X_l, k_l) \in \mathbb{R}^{T_l \times d} \quad (10)$$

$$\hat{\mathbf{x}}_l = f(\mathbf{x}_l) \quad (11)$$

Table 2: Hyper-parameter config used to train the models.

B Reproducing Results

For each model we train the models to achieve performances close to reported in the respective papers. Table 2 presents the hyper-parameters we used to reproduce their results.

C Additional Results on Modality-Perturbation

We also analyze with varying proportions of perturbations in the training and testing phase, respectively. As seen in Table 3, as the noise gradually increases from 5% to 15%, the drop of Corr in MOSI is gradually reduced , which shows the robustness is getting better, until it reaches the optimum at 30% perturbation (15% missing + 15% noise). In other models, 30% perturbation is also advantageous. For example, in Table 7, (Mult, MOSEI) reduces Corr drop while improving F1 performance in 30% perturbation. Although it is only a small improvement at present, we believe that there will be more meaningful improvements in the future.

Abstract

The past several years have witnessed Variational Auto-Encoder's superiority in various text generation tasks. However, due to the sequential nature of the text, auto-regressive decoders tend to ignore latent variables and then reduce to simple language models, known as the *KL vanishing* problem, which would further deteriorate when VAE is combined with Transformer-based structures. To ameliorate this problem, we propose DELLA, a novel variational Transformer framework. DELLA learns a series of layer-wise latent variables with each inferred from those of lower layers and tightly coupled with the hidden states by low-rank tensor product. In this way, DELLA forces these posterior latent variables to be fused deeply with the whole computation path and hence incorporate more information. We theoretically demonstrate that our method can be regarded as entangling latent variables to avoid posterior information decrease through layers, enabling DELLA to get higher non-zero KL values even without any annealing or thresholding tricks. Experiments on four unconditional and three conditional generation tasks show that DELLA could better alleviate KL vanishing and improve both quality and diversity compared to several strong baselines.

1 Introduction

Variational Autoencoder (VAE) (Kingma and Welling, 2014; Rezende et al., 2014) has proven to be successful in generating various kinds of text, such as stylistic text (Hu et al., 2017; John et al., 2019), dialogue (Zhao et al., 2017), story (Yu et al., 2020) and poetry (Yi et al., 2020). The sequential nature of the text leads to typically used auto-regressive decoders in VAE for language generation. However, such strong decoders tend to evade the difficulty of learning meaningful latent codes by heavily relying on previously generated words and hence ignore latent variables (Bowman et al., 2016), known as *KL vanishing* or *posterior collapse*. This problem causes two drawbacks: (a) the posterior distribution quickly turns into the prior one (usually standard Gaussian), falling to build expressive latent representations; (b) the decoder reduces to a naive language model, resulting in monotonous generated text (Fu et al., 2019).

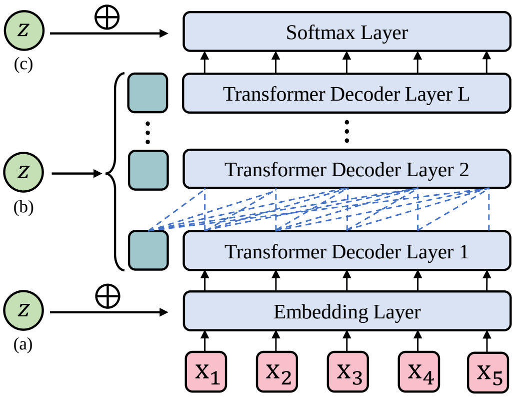

Figure 1: Existing paradigms of Transformer VAE.

To ameliorate this problem, researchers have designed various techniques. Among them, three broadly used methods include weakening decoders (Bowman et al., 2016; Semeniuta et al., 2017; Zhao et al., 2017), KL annealing (Bowman et al., 2016; Fu et al., 2019) and KL threshold (Kingma et al., 2016; Higgins et al., 2017; Li et al., 2019). Nonetheless, the weakening of decoders restrains models' language modelling capability; annealing hyperparameters are hard to tune; KL threshold introduces a non-smooth objective with some optimization difficulties.

In the era of RNN, VAE can be easily incorporated by using the latent variable as the initial decoder state, while how to combine VAE with recently prevalent Transformer (Vaswani et al., 2017) architectures, which have made a breakthrough in text generation, still remains an open challenge.

July 10-15, 2022

As shown in Fig.1, existing methods of integrating Transformer into VAE fall into three main paradigms: (a) directly adding latent variables to input token embeddings (abbr. *Embedding*) (Li et al., 2020a); (b) using latent variables as a separate memory token vector to be attended by self-attention in each layer (abbr. *Memory*) (Fang et al., 2021); (c) combining latent variables with the last-layer decoder states before output softmax (abbr. *Softmax*) (Wang and Wan, 2019). However, paradigm (a) brings noise for self-attention. In paradigm (b), memory vectors tend to be ignored by attention, even exacerbating KL vanishing. In paradigm (c), latent variables couldn't deeply interfere with the whole computation path. Sec.3.3 presents more detailed analyses.

To better incorporate Transformer into VAE and theoretically ameliorate the *KL vanishing* problem, we propose DELLA[1], a novel variational transformer framework. DELLA learns a series of layer-wise latent variables in a Transformer encoder, and each is inferred from those of lower layers and then tightly coupled with the hidden states in the corresponding decoder layer by low-rank tensor product. Our method theoretically stimulates the entanglement of latent variables and hence allows propagation of undiminished latent information through layers. As a result, DELLA forces posterior latent variables to be deeply fused with the entire computation path and encode richer information of input text, achieving higher KL values even without any annealing or threshold training tricks.

In summary, our contributions are as follow: (i) We are the first to propose layer-wise inferred latent variables in Transformer-based architecture to mitigate KL vanishing; We (ii) innovatively inject latent variables using low-rank tensor product, (iii) provide a theoretical validity of our method and (iv) demonstrate its effectiveness on four unconditional and three conditional generation tasks. Our codes are available at https://github.com/OpenVLG/DELLA.git.

2 Related Work

Thanks to the representation capacity of latent space, VAE has been widely adopted for both image generation (van den Oord et al., 2017; Vahdat and Kautz, 2020) and text generation (Bowman et al., 2016; Hu et al., 2017). In the early stage, VAE was combined with RNN decoders for generating a broad range of text, varying from dialogue (Serban et al., 2016), image caption (Wang et al., 2017), text summarization (Gupta et al., 2017) to story (Yu et al., 2020) and poetry (Yi et al., 2020). In this case, latent variables are usually utilized as either the initial decoder state (Li et al., 2018) or input at each time step (Gupta et al., 2017).

In spite of extensive applications, VAE suffered from *KL vanishing* in the scenario of text generation (Bowman et al., 2016). Several lines of techniques have been proposed to alleviate this problem. The first line is to avoid a too fast decrease of the KL divergence by re-weighting. KL annealing (Bowman et al., 2016) linearly increased the weight of KL term from 0 to 1 during the warm-up period. Fu et al. (2019) further proposed cyclical annealing, which repeats the warm-up process multiple times. The second line guarantees a positive lower bound of the KL term. KL thresholding (Kingma et al., 2016) achieved a fixed minimum by combining a hinge loss, while BN-VAE (Zhu et al., 2020) learned more flexible ones via batch normalization. δ-VAE (Razavi et al., 2019) chose to restrain the family of posterior distributions. The third line aims to constraint decoders to force a more informative latent variable. Wang et al. (2017) introduced an auxiliary BOW (bag-of-words) loss. He et al. (2019) added additional training loops for the encoder. Yang et al. (2017) adopted dilated CNN as decoder, and Dieng et al. (2019) added skip connections to the decoder. Although the above methods mitigate *KL vanishing* to some extent, it is still challenging for either tuning or optimization.

In these years, the powerful Transformer has been integrated with VAE to benefit diverse tasks, including text classification (Gururangan et al., 2019), story generation (Wang and Wan, 2019; Fang et al., 2021) and dialogue generation (Lin et al., 2020). Optimus (Li et al., 2020a) further bridged the pre-trained BERT (Devlin et al., 2019) and GPT-2 (Radford et al., 2019) with VAE for pre-training. Most existing works inject latent variables into the Transformer decoder by the three paradigms, Embedding (Li et al., 2020a), Memory (Li et al., 2020a; Fang et al., 2021) and Softmax(Wang and Wan, 2019), as discussed in Sec. 1, while these methods shallowly fuse the latent variables with hidden states. To achieve deeper fusion and ameliorate KL vanishing, we propose DELLA.

The most relevant architecture to our model is hierarchical VAE (Sønderby et al., 2016; Klushyn

---

[1] DELLA: **DE**eply Fused **L**ayer-wise **LA**tent Variables

et al., 2019; Vahdat and Kautz, 2020; Child, 2020), which is mainly designed for image generation and not suitable for text. For text generation, hierarchical latent variables are either independent of each other (Serban et al., 2016), or corresponding to different text granularities (sentence or word level), while our DELLA learns conditionally inferred and layer-wise latent variables based on Transformer.

3 Preliminaries

3.1 Transformer

Transformer (Vaswani et al., 2017) represents an input sequence $\boldsymbol{x} = \{x_1, \ldots, x_i, \ldots, x_n\}$ as contextualized distributed hidden states $\boldsymbol{h} = \{h_1, \ldots, h_i, \ldots, h_n\}$ by a series of stacked layers, and states in the l-th layer, $\boldsymbol{h}^{(l)}$, are calculated with scaled dot-product attention:

$$\text{Attention}(Q, K, V) = \text{softmax}\left(\frac{Q^T K}{\sqrt{d}}\right) V^T, \tag{1}$$

where Q, K, V stand for Query, Key, Value, respectively, which are projected from outputs of the previous layer: $Q = W^q \boldsymbol{h}^{(l-1)}$, $K = W^k \boldsymbol{h}^{(l-1)}$, $V = W^v \boldsymbol{h}^{(l-1)}$. d is the dimension of hidden states. In practice, multiple groups of states are calculated with different attention parameters and then concatenated, known as multi-head attention.

3.2 VAE

As a kind of generative model, VAE estimates the intractable data distribution $p(\boldsymbol{x})$ by deriving and maximizing its lower bound as:

$$\begin{aligned}&\log p(\boldsymbol{x}) \geq \mathcal{L}_{ELBO}(\boldsymbol{x}; \boldsymbol{\theta}, \boldsymbol{\phi}) = \\ &\mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})}[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})] - \text{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) || p(\boldsymbol{z})),\end{aligned} \tag{2}$$

where $\boldsymbol{z}$ is the latent variable and $p(\boldsymbol{z})$ is the prior distribution of latent variable which is commonly assumed as standard Gaussian; the posterior distribution $p(\boldsymbol{z}|\boldsymbol{x})$ is approximated by an inference network (encoder) $q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})$; $p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})$ is a generator (decoder) to generate text $\boldsymbol{x}$ from the latent variable $\boldsymbol{z}$; $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ are corresponding parameters.

The whole lower bound in Eq.(2), called Evidence Lower BOund (ELBO), consists of two terms: the reconstruction loss,

$$\mathcal{L}_E = -\mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x})}\left[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z})\right], \tag{3}$$

which helps reconstruct the input given the posterior latent variable $\boldsymbol{z}$, and the KL divergence,

$$\mathcal{L}_R = \text{KL}\left(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x}) \| p(\boldsymbol{z})\right). \tag{4}$$

In practice, VAE is considered as a regularized Auto-encoder, and a hyper-parameter β is introduced to control the strength of KL, $\beta\mathcal{L}_R$, usually used in KL annealing methods (Fu et al., 2019).

3.3 Incorporate Transformer into VAE

For Transformer encoder, the posterior $\boldsymbol{z}$ is mapped from the text representation, which can be the pooling of all hidden states in the last layer (Fang et al., 2021), or state of a special token (Li et al., 2020a), *e.g.*, [CLS]. Then $\boldsymbol{z}$ is injected into Transformer decoder by the paradigms discussed in Sec. 1.

Now we take a further step and investigate why intrinsically these three paradigms, namely Embedding, Memory and Softmax, would perform poorly.

Embedding: Define $\boldsymbol{e}_i, \boldsymbol{e}_j$ as two token embeddings and $\alpha_{i,j}$ as the attention weight of i-th and j-th tokens. From Eq.(1), we have $\alpha_{i,j} = (W^q \boldsymbol{e}_i)^T (W^k \boldsymbol{e}_j) = \boldsymbol{e}_i^T (W^q)^T W^k \boldsymbol{e}_j$, which is further abbreviated as $\langle \boldsymbol{e}_i, \boldsymbol{e}_j \rangle$. Such Embedding paradigm directly adds $\boldsymbol{z}$ to token embeddings as:

$$\begin{aligned}\alpha'_{i,j} &= \left[W^q(\boldsymbol{e}_i + \boldsymbol{z})\right]^T \left[W^k(\boldsymbol{e}_j + \boldsymbol{z})\right] \\ &= \langle \boldsymbol{e}_i, \boldsymbol{e}_j \rangle + \langle \boldsymbol{e}_i, \boldsymbol{z} \rangle + \langle \boldsymbol{z}, \boldsymbol{e}_j \rangle + \langle \boldsymbol{z}, \boldsymbol{z} \rangle,\end{aligned} \tag{5}$$

where we can find that a redundant term, $\langle \boldsymbol{z}, \boldsymbol{z} \rangle$, is introduced, bringing extra noise for attention mechanism. Moreover, information in $\boldsymbol{z}$ could diminish with propagation through layers (Fig. 2), aggravating KL vanishing.

Memory: This paradigm treats $\boldsymbol{z}$ as an additional memory token and places it at the beginning of $\boldsymbol{x}$ to be attended by other tokens via attention. Nevertheless, as mentioned in Sec. 1, the powerful Transformer decoder may only rely on preceding decoded tokens. Consequently, with no explicit constraints (*e.g.*, auxiliary loss), such a memory token is more likely to be ignored by self-attention (Fig. 6 & 7), even exacerbating KL vanishing.

Softmax: This paradigm first adds $\boldsymbol{z}$ to the last-layer hidden states $\boldsymbol{h}$, and then projects $\boldsymbol{z} + \boldsymbol{h}$ into a logit vector $\boldsymbol{p} \in \mathbb{R}^v$ over the vocabulary, where v is vocab size. In this method, latent variables do not interact with hidden states until the last layer, which erodes the effect of latent variables (see Fig. 2).

4 Methodology

As demonstrated in Sec. 3, existing three paradigms make latent variables gradually diminish through layers, be ignored by self-attention or inadequately interact with hidden states, which would not mitigate but even worsen the KL vanishing problem.

To deeply fuse latent variables with the whole computation path of Transformer, we propose DELLA to learn a series of layer-wise posterior latent variables which are conditionally inferred in encoder, and injected into hidden states in decoder by low-rank tensor product. We present layer-wise latent variables in Sec. 4.1, describe the tensor product fusion in Sec. 4.2, give the theoretical verification of DELLA's effectiveness for ameliorating KL vanishing in Sec. 4.3, and then extend DELLA to Conditional VAE (CVAE) in Sec. 4.4.

4.1 Layer-wise Latent Variables

Different from previous work where only one latent variable $\boldsymbol{z}$ is calculated and shared by (Li et al., 2020a) or projected to (Fang et al., 2021) decoder layers, we involve a series of latent variables $\boldsymbol{z} = \{\boldsymbol{z}_1, \boldsymbol{z}_2, \dots, \boldsymbol{z}_L\}$, where L is the number of Transformer layers. Then we reformulate the prior and posterior distributions as $p(\boldsymbol{z}) = \prod_{l=1}^{L} p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})$, $q(\boldsymbol{z}|\boldsymbol{x}) = \prod_{l=1}^{L} q(\boldsymbol{z}_l|\boldsymbol{z}_{<l}, \boldsymbol{x})$, respectively, with each $\boldsymbol{z}_l$ still following Gaussian distribution. Then we rewrite $\mathcal{L}_R$ in Eq.(4) similar to Vahdat and Kautz (2020):

$$\begin{aligned}&\mathcal{L}_R = \mathrm{KL}(q(\boldsymbol{z}|\boldsymbol{x})||p(\boldsymbol{z}))\\ =&\sum_{l=1}^{L} \mathbb{E}_{q(\boldsymbol{z}_{<l}|\boldsymbol{x})}\left[\mathrm{KL}(q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l})||p(\boldsymbol{z}_l|\boldsymbol{z}_{<l}))\right].\end{aligned} \tag{6}$$

When $l = 1$, $p(\boldsymbol{z}_1|\boldsymbol{z}_{<1}) = p(\boldsymbol{z}_1)$ is the standard Gaussian distribution, $q(\boldsymbol{z}_1|\boldsymbol{x}, \boldsymbol{z}_{<1}) = q(\boldsymbol{z}_1|\boldsymbol{x})$. We give detailed derivations in Appendix B.1.

These latent variables $\boldsymbol{z}_l$ are calculated (inferred) layer by layer using representations of the corresponding layer. Concretely, in l-th layer, we use the hidden state of the first token in text $\boldsymbol{x}$, as its l-th-layer representation, denoted as $\boldsymbol{x}^{(l)} \in \mathbb{R}^d$, where d is hidden size. Then we represent latent variables in lower layers as $\boldsymbol{z}_{<l}$ and obtain it by:

$$\boldsymbol{z}_{<l} = \tanh(\boldsymbol{W}_{hh}^{(l)} \boldsymbol{z}_{<l-1} + \boldsymbol{W}_{ih}^{(l)} \boldsymbol{z}_{l-1}), \tag{7}$$

where $W_{hh}, W_{ih} \in \mathbb{R}^{p \times p}$, so $\boldsymbol{z}_{<l} \in \mathbb{R}^p$ and p is the dimension of latent variable. $\boldsymbol{z}_0$ and $\boldsymbol{z}_{<0}$ are set as zero vector. We calculate the mean and variance vectors of $p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})$ and $q(\boldsymbol{z}_l|\boldsymbol{z}_{<l}, \boldsymbol{x})$ by:

$$\begin{aligned}\begin{pmatrix}\boldsymbol{\mu}_p\\ \log(\boldsymbol{\sigma}_p^2)\end{pmatrix} &= \boldsymbol{W}_p^{(l)} \boldsymbol{z}_{<l},\\ \begin{pmatrix}\boldsymbol{\mu}_q\\ \log(\boldsymbol{\sigma}_q^2)\end{pmatrix} &= \boldsymbol{W}_q^{(l)} \begin{pmatrix}\boldsymbol{z}_{<l}\\ \boldsymbol{x}^{(l)}\end{pmatrix},\end{aligned} \tag{8}$$

where $\boldsymbol{W}_p \in \mathbb{R}^{p \times 2p}$, $\boldsymbol{W}_p \in \mathbb{R}^{p \times 2p}$.

The latent variable $\boldsymbol{z}_l$ is sampled from the posterior distribution $q(\boldsymbol{z}_l|\boldsymbol{z}_{<l}, \boldsymbol{x}) = \mathcal{N}(\boldsymbol{\mu}_q, \boldsymbol{\sigma}_q^2 \boldsymbol{I})$ for training, and from the prior one $q(\boldsymbol{z}_l|\boldsymbol{z}_{<l}) = \mathcal{N}(\boldsymbol{\mu}_p, \boldsymbol{\sigma}_p^2 \boldsymbol{I})$ for testing. Since hidden states in each layer belong to different vector spaces, the parameters to calculate each $\boldsymbol{z}_{<l}$, *e.g.*, $\boldsymbol{W}_p^{(l)}$ and $\boldsymbol{W}_q^{(l)}$, *do not* share throughout different layers.

4.2 Low-rank Tensor Product

We inject the latent variable $\boldsymbol{z}_l$, which is obtained based on l-th encoder layer, into the corresponding l-th decoder layer. Instead of simply using $\boldsymbol{z}_l$ as a memory token as discussed in Sec. 3.3, we resort to low-rank tensor product, which has been successfully utilized for fusing multimodal representations (Liu et al., 2018), to deeply fuse latent variables with hidden states in the decoder.

In detail, we conduct low-rank tensor product on $\boldsymbol{z}_l$ and $\boldsymbol{x}_i$'s l-th-layer value vector $\boldsymbol{v}_i^{(l)}$ as:

$$\widetilde{\boldsymbol{v}}_i^{(l)} = (\sum_{j=1}^{r} \boldsymbol{W}_v^{(l,j)} \boldsymbol{v}_i^{(l)}) \circ (\sum_{j=1}^{r} \boldsymbol{W}_z^{(l,j)} \boldsymbol{z}_l), \tag{9}$$

where r is a hyper-parameter, $\circ$ means element-wise multiplication, $\boldsymbol{W}_v \in \mathbb{R}^{d \times d}.\boldsymbol{W}_z \in \mathbb{R}^{p \times d}$ are learnable parameters which are shared across all positions (i) but not shared with layers (l), considering distinct vector spaces in different layers, as mentioned in Sec. 4.1. Then the fused Value $\widetilde{V}^{(l)} = \{\widetilde{\boldsymbol{v}}_1^{(l)}, \dots, \widetilde{\boldsymbol{v}}_n^{(l)}\}$ is used in Eq.(1)

In this way, layer-wise $\boldsymbol{z}_l$ is conditionally inferred from latent variables in previous encoder layers, together with l-th-layer text representation, and then explicitly fused with the corresponding decoder layer, yielding a deeper intervention throughout the whole computation path of Transformer.

4.3 Why Could DELLA Work Well?

To theoretically interpret the advantage of layer-wise latent variables which contributes most to DELLA (Table 4), we give the following theorem:

Theorem 1 *For an observation $\boldsymbol{x}$ and a sequence of latent variables $\boldsymbol{z}_1, \boldsymbol{z}_2, \dots \boldsymbol{z}_L$, satisfying $p(\boldsymbol{z}) = \prod_{l=1}^{L} p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})$, and $q(\boldsymbol{z}|\boldsymbol{x}) = \prod_{l=1}^{L} q(\boldsymbol{z}_l|\boldsymbol{z}_{<l}, \boldsymbol{x})$, then the expectation of the KL term, $\mathbb{E}_{p(\boldsymbol{x})}[\mathcal{L}_R]$ is an upper bound of:*

$$-\sum_{i=2}^{L-1} I(\boldsymbol{z}_L; \dots; \boldsymbol{z}_i|\boldsymbol{z}_{i-1}) - I(\boldsymbol{z}_L; \dots; \boldsymbol{z}_1|\boldsymbol{x}), \tag{10}$$

where I is the interaction information[2].

See Appendix B.2 for proof. Based on Theorem 1, minimizing $\mathcal{L}_R$ approximatively means maximizing each interaction information term in Eq.(10), which forces the entanglement of all latent varibles $\boldsymbol{z}_1; \dots; \boldsymbol{z}_L$ given the observation $\boldsymbol{x}$, alleviating the diminishing of information encoded in latent variables when propagating through layers.

4.4 Extension to CVAE

DELLA could also be applied to CVAE for conditional generation tasks like storytelling. Given an observation $\boldsymbol{x}$ and its condition $\boldsymbol{c}$, we can optimize:

$$\log p(\boldsymbol{x}|\boldsymbol{c}) \geq \mathbb{E}_{q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x},\boldsymbol{c})}[\log p_{\boldsymbol{\theta}}(\boldsymbol{x}|\boldsymbol{z},\boldsymbol{c})] - \mathrm{KL}(q_{\boldsymbol{\phi}}(\boldsymbol{z}|\boldsymbol{x},\boldsymbol{c})||p(\boldsymbol{z}|\boldsymbol{c})), \quad (11)$$

and then replace the prior distribution $q(\boldsymbol{z}_l|\boldsymbol{x},\boldsymbol{z}_{<l})$ and posterior distribution $p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})$ in Eq.(6) with $q(\boldsymbol{z}_l|\boldsymbol{x},\boldsymbol{c},\boldsymbol{z}_{<l})$ and $p(\boldsymbol{z}_l|\boldsymbol{z}_{<l},\boldsymbol{c})$, respectively.

In this case, we encode the condition $\boldsymbol{c}$ with the same encoder. Similarly, we can obtain the representation of $\boldsymbol{c}$ at l-th layer, denoted as $\boldsymbol{c}^{(l)} \in \mathbb{R}^d$, and then calculate the mean and log variance of $p(\boldsymbol{z}_l|\boldsymbol{z}_{<l},\boldsymbol{c})$ and $q(\boldsymbol{z}_l|\boldsymbol{z}_{<l},\boldsymbol{x},\boldsymbol{c})$ by:

$$\begin{aligned} \begin{pmatrix} \boldsymbol{\mu}_p \\ \log(\boldsymbol{\sigma}_p^2) \end{pmatrix} &= \hat{\boldsymbol{W}}_p^{(l)} \begin{pmatrix} \boldsymbol{z}_{<l} \\ \boldsymbol{c}^{(l)} \end{pmatrix}, \\ \begin{pmatrix} \boldsymbol{\mu}_q \\ \log(\boldsymbol{\sigma}_q^2) \end{pmatrix} &= \hat{\boldsymbol{W}}_q^{(l)} \begin{pmatrix} \boldsymbol{z}_{<l} \\ \boldsymbol{x}^{(l)} \\ \boldsymbol{c}^{(l)} \end{pmatrix}, \end{aligned} \quad (12)$$

where $\hat{\boldsymbol{W}}_p^{(l)} \in \mathbb{R}^{(p+d)\times 2p}$, $\hat{\boldsymbol{W}}_q^{(l)} \mathbb{R}^{(p+2d)\times 2p}$.

5 Experiment

5.1 Dataset

We consider four datasets for language modelling and unconditional generation, including the Yelp, and Yahoo (Yang et al., 2017; He et al., 2019), Penn Treebank (PTB) (Marcus et al., 1993), and SNLI (Bowman et al., 2015), and three datasets for conditional generation tasks, including summarization generation with CNN/DailyMail (CNN/DM) (See et al., 2017), story generation with WritingPrompts (WP) (Fan et al., 2018) and paraphrase generation with Quora [3]. Detailed data statistics are listed in Table 7. Due to the limited computation capability, we use 165,157 samples in CNN/DM and 22,2614 in WP with the max length of 900 for training.

5.2 Implementation Details

We use pretrained language models as the backbone and fine-tune them on each task mentioned above with our DELLA as in (Li et al., 2020a). For unconditional generation and story generation, encoder and decoder **shared** the same parameters initialized with 12-layer GPT-2 (Radford et al., 2019). For summarization and paraphrase generation, parameters are **not shared** and initialized with BART-base (Lewis et al., 2020). We set the dimension of latent variable as 32 for all VAE-based models and use cyclical annealing for training, following (Li et al., 2020a). More details are given in Appendix A.1.

5.3 Baseline

We make a comprehensive comparison with strong Transformer-based baselines. We do not consider RNN-based models that are inferior to Transformer for text generation as shown in (Li et al., 2020a).

Finetuned Pretrained Models. To manifest the suitability of DELLA for different pretrained language models, we compare it with fine-tuned GPT2 on unconditional generation and story generation, and with fine-tuned BART-base on summarization generation and paraphrase generation.

Optimus (Li et al., 2020a): a large-scale VAE model which takes a pre-trained BERT as encoder and pretrained GPT-2 as decoder. This model is first pretrained as a VAE, which simultaneously utilizes the two paradigms, Embedding and Memory as introduced in Sec. 3.3, for injecting latent variables, with both KL annealing and KL threshold tricks, and then fine-tuned on downstream tasks.

Transformer-based VAE. Besides Optimus, we also compre the three paradigms, namely **Embedding** (Li et al., 2020a), **Memory** (Fang et al., 2021) and **Softmax** (Wang and Wan, 2019), and incorporate each paradigm into the same pre-trained model as DELLA on each dataset for fair comparison.

5.4 Metrics

For unconditional generation tasks, we consider three types of metrics. **(a) Representation Learning Capability**: we report PPL, ELBO, KL, mutual information (MI) (Alemi et al., 2016) and activate units (AU) (Burda et al., 2016). These metrics measure VAE's ability to mitigate KL vanishing and learn meaningful representations. Different from traditional language models like GPT-2, VAE-based models could not produce exact PPL due to randomness, so we use importance-weighted sam-

ples to estimate PPL, following He et al. (2019). We set the threshold in AU to 0.2 to further distinguish different models. **(b) Generation Quality**: we report BLEU (Papineni et al., 2002), CND (Li et al., 2020b) and MAUVE (Pillutla et al., 2021). CND and MAUVE measure the divergence between human-authored text and the generated one. **(c) Generation Diversity**: we report Self-BLEU (Zhu et al., 2018), Dist (Li et al., 2016) and JS (Jaccard similarity) (Wang and Wan, 2018) to assess the diversity and novelty of generated text.

For conditional generation tasks, we report BLEU, Rouge-1, Rouge-2, Rouge-L (Lin and Hovy, 2002), and BERTScore (Zhang et al., 2020) to evaluate the quality of generated texts, as well as the same diversity metrics used in unconditional generation. We also report KL and AU value to present representation learning capability. More details of metrics are provided in Appendix A.3.

5.5 Results

5.5.1 Unconditional Generation

We present results on Yelp and Yahoo in Table 1 and leave the those on PTB and SNLI in the Appendix A.5 due to space limitations. We also show the learning curves of ELBO and KL in Fig. 5.

As shown in Table 1, Della achieves notably improvement on almost all the metrics, especially superior on representation learning metrics. Much higher KL, MI and AU, and a big gap in PPL obtained by Della indicate the latent variables encode more meaningful text information and won't diminish when propagating through Transformer layers, which strongly supports our motivation that fusing latent variables with hidden states more deeply could effectively alleviate the KL vanishing problem. Such results also empirically verify the theoretical advantage of our model (Theorem 1), demonstrating entangled layer-wise latent variables can preserve more encoded knowledge for decoder. We will show that $\boldsymbol{z}$ can involve more information when injected into more layers in Sec. 5.8.

Besides, Della also gets good performance (comparable BLEU and much better CND and MAUVE) on generation quality. With more informative latent variables, Della could achieve a better ELBO and hence further boost the learning of data distribution $p(\boldsymbol{x})$ in Eq.(2), leading to satisfactory quality of generated texts.

Generally, Della also outperforms baseline models on generation diversity. The reason is twofold: randomly sampled latent variables $\boldsymbol{z}$ should bring diversity, while the VAE-based baselines tend to ignore $\boldsymbol{z}$ as mentioned before, losing some randomness. In contrast, latent variables are deeply fused in Della, maintaining enough randomness. Besides, each latent variable is sampled in corresponding layer, and thus such a sampling process accumulates and enhances randomness, further benefiting diversity while keeping good quality.

5.5.2 Conditional Generation

We report the results of WP and CNN/DM in Table 2, and leave those of Quora in Appendix A.5. As we can see, Della performs better on most quality metrics, but gets a little worse on diversity

compared to GPT-2. This is because GPT-2 may produce some ill-formed contents which 'improve' diversity by cheating the metrics but also lead to much worse quality (lower BLEU and Rouge). Even so, on both WP and CNN/DM, DELLA still beats all previous VAE paradigms in diversity, manifesting the effectiveness of our DELLA.

In addition, all baselines methods suffer from severer KL vanishing problems on conditional generation tasks than on the unconditional ones. This is because the given condition text could aggravate the reliance of these models on preceding generated tokens and the condition, and therefore bypass latent variables. By contrast, DELLA could learn more informative $\boldsymbol{z}$ and hence keep a relatively higher KL value even given the condition text.

Model	PPL↓	ELBO↓	KL↑	MI ↑	AU↑

Softmax(384)	20.15	330.24	5.04	7.15	0

Table 4: Ablation study on Yelp dataset. LTP: low-rank tensor product. LW: layer-wise latent variables. Separate: latent variables in each layer are independent. $l = 1$ or 4 KL means we only compute KL loss on $\boldsymbol{z}_1$ or $\boldsymbol{z}_L$, respectively. 384 means the dimension of latent variable used in baseline are $12 \times 32 = 384$.

5.6 Human Evaluation

To better verify the effectiveness of DELLA, we also conduct human evaluation on the two conditional generation tasks. For each model, we generated 30 samples on each task, and invite 5 competent annotators to score these samples in terms of three criteria, **Fluency**, **Coherence** and **Novelty** for story generation, and **Informativeness**, **Coherence** and **Novelty** for summarization generation.

As shown in Table 3, DELLA obtains satisfactory performance in quality, and is consistently superior to all baselines on diversity and novelty. See Appendix A.4 for more detailed evaluation protocols.

5.7 Ablation Study

Table 4 shows the results of ablation study on Yelp. We can find both tensor product and the layer-wise latent variables benefit the learning of informative

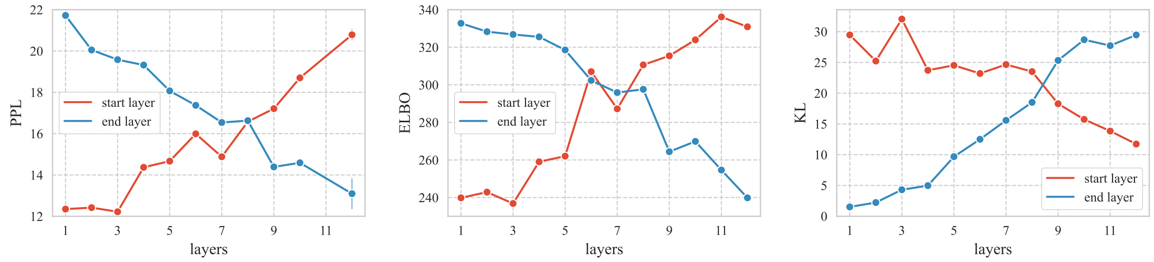

Figure 2: PPL, ELBO end KL on Yelp with different numbers of latent variables. The values *start layer* i and *end layer* j means latent variables are produces and utilized only from i-th layer to the last layer, or from the first layer to j-th layer of the encoder respectively.

latent variables, while the latter contributes the most to DELLA. To further verify the performance gain originating from Theorem 1 instead of simply increasing the number or the dimension of latent variables, we conduct two groups of experiments.

First, we remove the conditional dependence between layer-wise latent variables by independently sampling each z_l in both training and testing. We can see that removing dependence causes a significant performance drop. Besides, we keep the dependence between z_l but optimize only one of the KL terms in Eq.(6), and find all representation capability metrics deteriorate, especially KL, MI and AU. Such results effectively demonstrate the necessity of using and optimizing the conditional inference of layer-wise latent variables, supporting our theoretical interpretation of DELLA.

Second, we enlarge the dimension of z_l used in the three paradigms to 384 (12×32), equal to the total latent dimension used in DELLA. The results show that simply increasing the dimension of latent variables brings a more sparse latent space, even exacerbating the KL vanishing problem.

5.8 Analysis

Training Tricks To reveal the robustness of our model, we evaluate the influence of three commonly used training tricks to relieve KL vanishing, *i.e.*, BOW (bag-of-words) loss (Wang et al., 2017), batch normalization (Zhu et al., 2020) and KL annealing (Fu et al., 2019), to the performance of DELLA and the three paradigms. As shown in Table 5, previous methods suffer KL vanishing seriously without annealing or BOW loss, getting KL, MI and AU almost 0. Though not good as using annealing, DELLA still maintains acceptable performance and mitigates KL vanishing even without any training tricks. Bow and batch normalization dramatically prevent low KL divergence, but obstruct the optimization and thus cause higher PPL.

Number of Latent Variables We observe the change of PPL, KL and ELBO with different numbers of latent variables. We conduct two groups of experiments where we produce and utilize layer-wise latent variables starting from and ending at different layers. As shown in Fig. 2, incorporating more latent variables could continuously improve performance, consistent to our claim in Sec. 4. With the same number of latent variables, starting from a higher layer is better than ending at a lower layer, which indicates that latent variables

Prompt: After receiving perfect score on your final exam, your school is asking you to give a speech on the subject of the exam. Little does anyone know you guessed every single answer.

Memory: The room was silent except for me. I could hear some whispering behind us as we continued to pace about campus, but there was no need. We knew better than that any moment that would come, and at least if they were around, we wouldn't have to be so paranoid.

DELLA: "Hey mister!" I just got back from work and the whole class was already ready for question. So go ahead I **took the stage**. The teacher **smiled encouragingly**. Standing up in the front of desk, I started talking about all sorts of things about **answering test question**.

Figure 4: Generation examples of Memory and DELLA based on the prompt from test set of WritingPrompts.

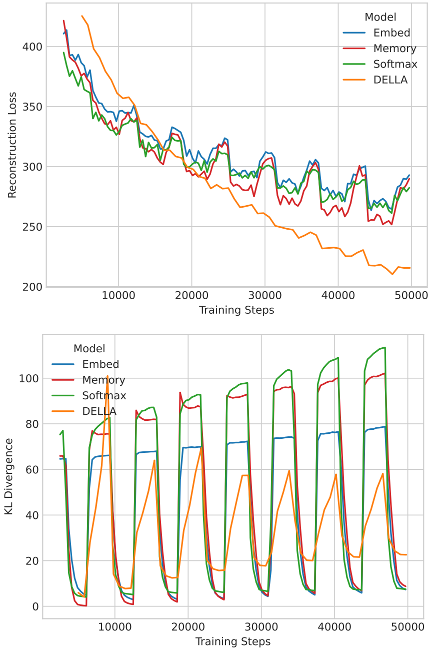

Figure 5: Reconstruction loss and KL Divergence throughout training process.

generated from higher layers encode more helpful information compared to those from lower layers, manifesting disadvantages of the two previous paradigms, Softmax (starting from the last layer) and Embedding (ending at the first layer).

Model size We compare the performance of DELLA and three paradigms with 24-layer GPT2-medium as backbone. As shown in Table 5, with the increasing of model size, DELLA consistently achieves better performance than baselines.

5.9 Case Study

VAE captures text representations in a smooth latent space. We take two sentences $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ and sample two posterior latent variables $\boldsymbol{z}^{(1)}$ and $\boldsymbol{z}^{(2)}$ from $p(\boldsymbol{z}^{(1)}|\boldsymbol{x}_1)$ and $p(\boldsymbol{z}^{(2)}|\boldsymbol{x}_2)$, and get interpolated latent variables with $\boldsymbol{z} = \tau\boldsymbol{z}^{(1)} + (1-\tau)\boldsymbol{z}^{(2)}$. We generate multiple sentences with a continuously changed τ from 0 to 1. As shown in Fig. 3, sentences generated from interpolated $\boldsymbol{z}$ mix the semantics of the two initial sentences and smoothly change from $\boldsymbol{x}_1$ to $\boldsymbol{x}_2$, showing DELLA's ability of learning a flexible latent space.

Fig. 4 shows the generation examples of DELLA and one of baseline, Memory, given the same prompt WritingPrompts. We observe that the generated text of Memory is irrelevant to the prompt, while DELLA generates coherent and vivid text.

6 Conclusion

In this paper, we propose a novel variational Transformer framework DELLA. Our framework learns a series of layer-wise latent variables with iterative dependence. These latent variables are conditionally inferred and injected into corresponding decoder layers by low-rank tensor product for deeper fusion. The experiments on both unconditional and conditional generation tasks demonstrate DELLA's ability to significantly mitigate KL vanishing and improve generated text's quality and diversity. In the future, we plan to explore further the potential of DELLA in larger pretrained language models.

A Experiment Details

A.1 Implementation Details

We load pretrained model GPT-2 (Radford et al., 2019) as initial parameters for unconditional generation and story generation, and pretrained BART-base (Lewis et al., 2020) for summarization and paraphrasing generation tasks. For the summarization and paraphrasing generation, we keep the encoder-decoder attention block. No encoder-decoder attention is used in unconditional generation and story generation tasks. The number of layers and dimensions of hidden states in DELLA is consistent with the configurations of corresponding pretrained models (GPT-2 has 12 layers and Bart-base has 6-layer encoder and 6-layer decoder. The hidden size of both is 768). We use the state of a special token to obtain the representation in the encoder. We utilize cyclical annealing tricks to train DELLA and other VAE baselines. Specifically, two epochs are one annealing period. In one period, β (the weight of KL term in ELBO) keeps 1e-5 in the first half, then linearly increases to 1 in the next quarter, then keeps at 1 for the last quarter. We select batch size over $\{16, 32\}$ and learning rate over $\{$5e-5, 7e-5$\}$. We use beam search for DELLA and top-k sampling for compared baseline models for the unconditional generation and story generation. For the summarization and paraphrasing generation, we use beam search in all the models.

We implement DELLA and other VAE baselines based on Huggingface Transformers (Wolf et al., 2020) library of v4.10.0 and use NVIDIA GeForce RTX 3090 to train our model. The total number of training GPU hours on different datasets is in Table 6. The number of parameters for our model is 193,353,984 in the unconditional generation setting and 195,180,114 in the conditional generation one. All experimental results are trained and tested in a single run.

Dataset	Training Time
Yelp	20h
Yahoo	20h
PTB	6h
SNLI	12h
CNN/DM	40h
WP	170h
Quora	5h

Table 6: GPU hours of training DELLA with RTX3090

Dataset	# Train	# Dev	# Test	Avarage Length	
Yelp	100k	10k	10k	96	
Yahoo	100k	10k	10k	79	
PTB	42k	3k	3k	21	
SNLI	100k	10k	10k	10	
CNN/DM	287k	13k	11k	S: 790	T: 61
WP	272k	15k	15k	S: 28	T: 674
Quora	134k	5k	10k	S: 10	T: 10

Table 7: **Statistics of datasets**. We present the size of train/dev/test sets and the average length for 7 datasets. S means source text and T means target text.

A.2 Datasets Details

The detailed dataset statistics are in Table 7. For the licenses of the datasets we use, CNN/DM and WritingPrompts use MIT License, while SNLI uses CC BY-SA 4.0. Meanwhile, PTB, Quora, and Yelp use their own license: LDC User Agreement, Yelp Data Agreement, and Quora's Terms of Service, respectively. All of these licenses and agreements allow their data for academic use. Unfortunately, we did not find the license for the Yahoo Dataset.

A.3 Metrics Details

Here we provide more details of the metrics used in our experiments.

Perplexity (PPL). PPL $= p(\boldsymbol{x})^{-1/n}$ is commonly used to evaluate the performance of language models, where n is number of tokens $\boldsymbol{x}$ contains. For VAE-based model, we can only obtain the lower bound of $\log p(\boldsymbol{x})$. We consider k latent variables $z_1, z_2, \ldots, z_k$ sampled from the posterior distribution $q(\boldsymbol{z}_i|\boldsymbol{x})$. Based on the fact that average importance weights are an unbiased estimator of $\log p(\boldsymbol{x})$ (Burda et al., 2016) and Jensen's Inequality, we have:

$$\begin{aligned} \mathcal{L}_k &= \mathbb{E}\left[\log \frac{1}{k}\sum_{i=1}^{k}\frac{p(\boldsymbol{x}, \boldsymbol{z}_i)}{q(\boldsymbol{z}_i|\boldsymbol{x})}\right] \\ &\leq \log \mathbb{E}\left[\frac{1}{k}\sum_{i=1}^{k}\frac{p(\boldsymbol{x}, \boldsymbol{z}_i)}{q(\boldsymbol{z}_i|\boldsymbol{x})}\right] = \log p(\boldsymbol{x}). \end{aligned} \tag{13}$$

We use $\mathcal{L}_k$ to estimate $\log p(\boldsymbol{x})$ and calculate PPL.

ELBO. The ELBO is the sum of reconstruction loss and KL divergence.

KL. The KL divergence of the posterior and prior distribution.

Mutual Information(MI) (Alemi et al., 2016).

Mutual Information $\mathcal{I}(\boldsymbol{x}, \boldsymbol{z})$ is defined as:

$$\mathcal{I}_q(\boldsymbol{x}, \boldsymbol{z}) \tag{14}$$
$$=\mathbb{E}_{p(\boldsymbol{x})}\mathbb{E}_{q(\boldsymbol{z}|\boldsymbol{x})} \log q(\boldsymbol{z}|\boldsymbol{x}) - \mathbb{E}_{q(\boldsymbol{z})} \log q(\boldsymbol{z})$$

where $q_(\boldsymbol{z}) = \mathbb{E}_{p(\boldsymbol{x})} q(\boldsymbol{z}|\boldsymbol{x})$ is called the aggregated posterior.

Activate Units(AU) (Burda et al., 2016). AU is the active units in latent varibles, defined as $A_{\boldsymbol{z}} = \mathrm{Cov}_{\boldsymbol{x}}(\mathbb{E}_{z\sim q(z|\boldsymbol{x})}[z]) > \delta$, where δ is a threshold, commonly set as 0.01. However, we find that with $\delta = 0.01$, all VAE models in our experiments have full active unit. So we increase the threshold to 0.2 to distinguish the performance of different models on this metric. **Please note** that DELLA incorporates latent variables in all layers, and hence we calculate AU for the latent variable in each layer and then report the average.

BLEU (Papineni et al., 2002). BLEU measures the n-gram overlap of generated sequences and the reference ones. For unconditional setting, we regard all samples in the test set as references to each generated example.

CND (Li et al., 2020b). CND approximates the divergence of the empirical reference distribution and generated text distribution in n-gram spaces.

MAUVE (Pillutla et al., 2021). MAUVE measures the gap between reference text and generated text using divergence frontiers.

Self-BLEU (Zhu et al., 2018). Self-Bleu calculates the BLEU score on the generated samples, which averages the BLEU score of each generated sequence calculated with other generated ones as references. This metric measures the diversity of a set of generated sequences. Higher Self-BLEU means these generated sequences are more distinguishable from each other.

Dist (Li et al., 2016). Dist measures the proportion of distinct n-grams on generated samples.

Jaccard Similarity(JS) (Wang and Wan, 2018). JS calculates the average n-gram Jaccard similarity between every two generated sequences.

Rouge (Lin and Hovy, 2002). Rouge computes n-gram overlap of generated examples with given target samples. We use rouge-score v0.0.4 to evaluate the rouge score of our model and the baselines.

BERTScore (Zhang et al., 2020). BERTScore uses pre-trained BERT (Devlin et al., 2019) to obtain the vector representations of generated and reference text and calculates their cosine similarity. We use bert-score v0.3.10 to calculate the BERTScore of our model and the baselines.

A.4 Human Evaluation Details

Due to the relatively long length of generated text, we randomly sample 30 examples in the test set of WP and CNN/DM as input to DELLA and other compared baseline models to generate the target. We invite five graduate students proficient in English to score the generated text. The criteria for story generation include fluency, coherence, and novelty, and the criteria for summarization generation include informativeness, consistency, and novelty. Specifically, fluency measures whether the generated sentences are syntactically fluent; coherence measures whether the generated text is logically structured and consistent with the input text; novelty measures whether the content is novel and attractive; informativeness measures to what extent the generated summarization summarizes the general idea of the article.

When conducting the human evaluation, we informed the participants as follows:

- The following contents are generated by the automatic models. Some of them may be offensive or contain improper arguments. Please be conscious of these risks and evaluate these contents equitably and adequately.
- The evaluation you provide will be used only for academic use and will never be used commercially.

Every evaluator will sign their signature below these warnings to confirm that they have read those words. After finishing the annotation, they will receive $25. This amount is determined by the time of the whole annotation process and the estimation of average hourly income. The ethics review board for data collection protocol is not essential in our country, so we did not conduct this review for our data collection protocol.

A.5 Additional Experimental Result

Table 8 and Table 9 report the results on PTB, SNLI and Quora dataset.

A.6 Case Study Details

We take two sentences $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$ and sample two groups of latent variables $\boldsymbol{z}^{(1)} = \{\boldsymbol{z}_1^{(1)}, \boldsymbol{z}_2^{(1)}, \ldots, \boldsymbol{z}_L^{(1)}\}$ and $\boldsymbol{z}^{(2)} = \{\boldsymbol{z}_1^{(2)}, \boldsymbol{z}_2^{(2)}, \ldots, \boldsymbol{z}_L^{(2)}\}$ from posterior distributions $p(\boldsymbol{z}^{(1)}|\boldsymbol{x}_1)$ and $p(\boldsymbol{z}^{(2)}|\boldsymbol{x}_2)$. We obtain the weighted latent variables $\hat{\boldsymbol{z}} = \{\hat{\boldsymbol{z}}_1, \hat{\boldsymbol{z}}_2, \ldots, \hat{\boldsymbol{z}}_L\}$ by taking weighted sum at each corresponding element in two groups, i.e. $\hat{\boldsymbol{z}}_i = \tau * \boldsymbol{z}_i^{(1)} + (1-\tau) * \boldsymbol{z}_i^{(2)}$. The mixed sentence $\hat{\boldsymbol{x}}$ is generated conditioned on $p(\hat{\boldsymbol{x}}|\hat{\boldsymbol{z}})$ by the decoder.

A.7 Potential Risks and Limitations of our work

Due to the unclean corpus (especially in the WP dataset) we use where slang repeatedly appears, the model training on this corpus may also output some rude expressions during generation. Also, the text generated in the unconditional generation task is not controllable, which may contain some bias or politically sensitive expression. Besides, since our model significantly improves the quality and diversity of generated, it can produce more plausible texts like news, which could be possibly utilized to create fake news or disinformation. However, on the other hand, our model could benefit fairness in language generation. Previous text generation models tend to produce biases like gender or nationality biases, which means only the majority would be appropriately described while the minority may be ignored. These biases are mainly caused by the biased training corpus. With the same data, our model can improve the diversity of generated text, which is also potential for mitigating these biased. We will try to develop debiased language generation systems in future work to avoid these risks harming society.

While DELLA shows good performance on text generation, it has one limitation: training efficiency. DELLA brings more parameters compared with three baseline methods. Training efficiency needs to be considered if we further explore the performance of DELLA on the large pretrained model.

Table 9: Results on Quora dataset. Because the sentences in Quora are quite short and constrained, the results of the three diversity metrics on all baselines are almost the same. So we omit them here.

B Additional Proof

B.1 Derivation of KL Divergence of Layer-Wise Latent Variables

KL divergence of layer-wise latent variables

$$
\begin{aligned}
&KL(q(\boldsymbol{z}|\boldsymbol{x})||p(\boldsymbol{z})) \\
=&\int q(\boldsymbol{z}|\boldsymbol{x}) \log \frac{q(\boldsymbol{z}|\boldsymbol{x})}{p(\boldsymbol{z})} \,\mathrm{d}\boldsymbol{z} \\
=&\int \prod_{l=1}^{L} q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l}) \log \frac{\prod_{l=1}^{L} q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l})}{\prod_{l=1}^{L} p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{z}_1 \,\mathrm{d}\boldsymbol{z}_2 \ldots \mathrm{d}\boldsymbol{z}_L \\
=&\sum_{i=1}^{L} \int \prod_{l=1}^{L} q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l}) \log \frac{q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l})}{p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{z}_1 \,\mathrm{d}\boldsymbol{z}_2 \ldots \mathrm{d}\boldsymbol{z}_L \\
=&\sum_{l=1}^{L} \int q(\boldsymbol{z}_{<l}|\boldsymbol{x}) q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l}) \log \frac{q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l})}{p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{z}_1 \,\mathrm{d}\boldsymbol{z}_2 \ldots \mathrm{d}\boldsymbol{z}_l \\
=&\sum_{l=1}^{L} \mathbb{E}_{q(\boldsymbol{z}_{<l}|\boldsymbol{x})} \mathrm{KL}(q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l})||p(\boldsymbol{z}_l|\boldsymbol{z}_{<l}))
\end{aligned}
\tag{15}
$$

B.2 Proof of Theorem 1

First, we consider on term in the summation and can obtain:

$$
\begin{aligned}
&\mathbb{E}_{p(\boldsymbol{x})} \mathbb{E}_{q(\boldsymbol{z}_{<l}|\boldsymbol{x})} [\mathrm{KL}(q(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{z}_{<l})||p(\boldsymbol{z}_l|\boldsymbol{z}_{<l}))] \\
=&\int q(\boldsymbol{x}) q(\boldsymbol{z}_{<l}|\boldsymbol{x}) q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{<l}) \log \frac{q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{\boldsymbol{l}})}{p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{x} \,\mathrm{d}\boldsymbol{z}_l \,\mathrm{d}\boldsymbol{z}_{<l} \\
=&\int q(\boldsymbol{x}, \boldsymbol{z}_l, \boldsymbol{z}_{<l}) \log \frac{q(\boldsymbol{z}_l|\boldsymbol{x}, \boldsymbol{z}_{\boldsymbol{l}})}{p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{x} \,\mathrm{d}\boldsymbol{z}_l \,\mathrm{d}\boldsymbol{z}_{<l} \\
=&\int q(\boldsymbol{x}, \boldsymbol{z}_l, \boldsymbol{z}_{<l}) \log \Big(\frac{q(\boldsymbol{z}, \boldsymbol{x}|\boldsymbol{z}_{<l})}{q(\boldsymbol{x}|\boldsymbol{z}_{<l}) q(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \frac{q(\boldsymbol{z}_l|\boldsymbol{z}_{<l})}{p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \Big) \,\mathrm{d}\boldsymbol{x} \,\mathrm{d}\boldsymbol{z}_l \,\mathrm{d}\boldsymbol{z}_{<l} \\
=&\int q(\boldsymbol{z}_{<l}) q(\boldsymbol{x}, \boldsymbol{z}_l|\boldsymbol{z}_{<l}) \log \frac{q(\boldsymbol{z}, \boldsymbol{x}|\boldsymbol{z}_{<l})}{q(\boldsymbol{x}|\boldsymbol{z}_{<l}) q(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{x} \,\mathrm{d}\boldsymbol{z}_l \,\mathrm{d}\boldsymbol{z}_{<l} + \\
&\int q(\boldsymbol{x}|\boldsymbol{z}_l, \boldsymbol{z}_{<l}) q(\boldsymbol{z}_l|\boldsymbol{z}_{<l}) q(\boldsymbol{z}_{<l}) \log \frac{q(\boldsymbol{z}_l|\boldsymbol{z}_{<l})}{p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{x} \,\mathrm{d}\boldsymbol{z}_l \,\mathrm{d}\boldsymbol{z}_{<l} \\
=&\int q(\boldsymbol{x}, \boldsymbol{z}_l|\boldsymbol{z}_{<l}) \log \frac{q(\boldsymbol{z}, \boldsymbol{x}|\boldsymbol{z}_{<l})}{q(\boldsymbol{x}|\boldsymbol{z}_{<l}) q(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{x} \,\mathrm{d}\boldsymbol{z}_l + \\
&\int q(\boldsymbol{z}_l|\boldsymbol{z}_{<l}) q(\boldsymbol{z}_{<l}) \log \frac{q(\boldsymbol{z}_l|\boldsymbol{z}_{<l})}{p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})} \,\mathrm{d}\boldsymbol{z}_l \,\mathrm{d}\boldsymbol{z}_{<l} \\
=&H(\boldsymbol{z}_l|\boldsymbol{z}_{<l}) - H(\boldsymbol{z}_l|\boldsymbol{z}_{<l}, \boldsymbol{x}) + \mathbb{E}_{q(\boldsymbol{z}_{<l})} \mathrm{KL}(q(\boldsymbol{z}_l|\boldsymbol{z}_{<l}||p(\boldsymbol{z}_l|\boldsymbol{z}_{<l})) \\
\geq&H(\boldsymbol{z}_l|\boldsymbol{z}_{<l}) - H(\boldsymbol{z}_l|\boldsymbol{z}_{<l}, \boldsymbol{x})
\end{aligned}
\tag{16}
$$

where H is the Shannon entropy. Then, the summation has a lower bound:

$$
\begin{aligned}
&\sum_{i=1}^{L} \mathbb{E}_{p(\boldsymbol{x})} \mathbb{E}_{q(\boldsymbol{z}_{<l}|\boldsymbol{x})} [\mathrm{KL}(q(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{z}_{<l})||p(\boldsymbol{z}_l|\boldsymbol{z}_{<l}))] \\
\geq&\sum_{i=1}^{L} H(\boldsymbol{z}_l|\boldsymbol{z}_{<l}) - H(\boldsymbol{z}_l|\boldsymbol{z}_{<l}, \boldsymbol{x}) \\
=&H(\boldsymbol{z}_1, \ldots, \boldsymbol{z}_L) - H(\boldsymbol{z}_1, \ldots, \boldsymbol{z}_L|\boldsymbol{x}) \\
=&I(\boldsymbol{x}; \boldsymbol{z}_1, \ldots, \boldsymbol{z}_L)
\end{aligned}
\tag{17}
$$

where I is mutual information. Next, we prove the following inequality with induction:

$$I(\boldsymbol{x}; \boldsymbol{z}_1, \ldots, \boldsymbol{z}_L) \geq I(\boldsymbol{x}; \boldsymbol{z}_1; \ldots; \boldsymbol{z}_L) \tag{18}$$

When $L = 2$, we proof $I(\boldsymbol{x}; \boldsymbol{z}_1, \boldsymbol{z}_2) \geq I(\boldsymbol{x}; \boldsymbol{z}_1; \boldsymbol{z}_2)$. Actually, we have the following facts:

$$\begin{aligned} &I(\boldsymbol{x}; \boldsymbol{z}_1, \boldsymbol{z}_2) \\ =&H(\boldsymbol{x}) + H(\boldsymbol{z}_1, \boldsymbol{z}_2) - H(\boldsymbol{x}, \boldsymbol{z}_1, \boldsymbol{z}_2) \end{aligned} \tag{19}$$

$$\begin{aligned} &I(\boldsymbol{x}; \boldsymbol{z}_1; \boldsymbol{z}_2) \\ =&H(\boldsymbol{x}) + H(\boldsymbol{z}_1) + H(\boldsymbol{z}_2) + H(\boldsymbol{x}, \boldsymbol{z}_1, \boldsymbol{z}_2) \\ &- H(\boldsymbol{z}_1, \boldsymbol{z}_2) - H(\boldsymbol{x}, \boldsymbol{z}_1) - H(\boldsymbol{x}, \boldsymbol{z}_2) \end{aligned} \tag{20}$$

Based on the facts above, we have:

$$I(\boldsymbol{x}; \boldsymbol{z}_1, \boldsymbol{z}_2) \geq I(\boldsymbol{x}; \boldsymbol{z}_1; \boldsymbol{z}_2) \tag{21}$$

$$\Leftrightarrow 2H(\boldsymbol{z}_1, \boldsymbol{z}_2) + H(\boldsymbol{x}, \boldsymbol{z}_1) + H(\boldsymbol{x}, \boldsymbol{z}_2) \geq H(\boldsymbol{z}_1) + H(\boldsymbol{z}_2) + 2H(\boldsymbol{x}, \boldsymbol{z}_1, \boldsymbol{z}_2) \tag{22}$$

It's true because we have:

$$\begin{aligned} &H(\boldsymbol{z}_1, \boldsymbol{z}_2) + H(\boldsymbol{x}, \boldsymbol{z}_1) \\ =&H(\boldsymbol{z}_2|\boldsymbol{z}_1) + H(\boldsymbol{x}|\boldsymbol{z}_1) + 2H(\boldsymbol{z}_1) \\ \geq&H(\boldsymbol{x}, \boldsymbol{z}_2|\boldsymbol{z}_1) + 2H(\boldsymbol{z}_1) \\ =&H(\boldsymbol{x}, \boldsymbol{z}_1, \boldsymbol{z}_2) + H(\boldsymbol{z}_1) \end{aligned} \tag{23}$$

Similarly, the following inequality also holds true:

$$H(\boldsymbol{z}_1, \boldsymbol{z}_2) + H(\boldsymbol{x}, \boldsymbol{z}_2) \geq H(\boldsymbol{x}, \boldsymbol{z}_1, \boldsymbol{z}_2) + H(\boldsymbol{z}_2) \tag{24}$$

Therefore, making sum to Eq.(23) and Eq.(24), we conclude that $I(\boldsymbol{x}; \boldsymbol{z}_1, \boldsymbol{z}_2) \geq I(\boldsymbol{x}; \boldsymbol{z}_1; \boldsymbol{z}_2)$. Hence, we finish the proof of the $L = 2$ case.

When $L = k$, suppose $I(\boldsymbol{x}; \boldsymbol{z}_1, \ldots, \boldsymbol{z}_k) \geq I(\boldsymbol{x}; \boldsymbol{z}_1; \ldots; \boldsymbol{z}_k)$, we consider $L = k + 1$. In this case, based on the inductive assumption, we have:

$$I(\boldsymbol{x}; \boldsymbol{z}_1, \ldots, \boldsymbol{z}_{k+1}) \geq I(\boldsymbol{x}; \boldsymbol{z}_1, \ldots, \boldsymbol{z}_k) \geq I(\boldsymbol{x}; \boldsymbol{z}_1; \ldots; \boldsymbol{z}_k) \geq I(\boldsymbol{x}; \boldsymbol{z}_1; \ldots; \boldsymbol{z}_{k+1}) \tag{25}$$

Hence, the case of $L = k + 1$ also holds true. Therefore, we conclude that $I(\boldsymbol{x}; \boldsymbol{z}_1, \ldots, \boldsymbol{z}_L) \geq I(\boldsymbol{x}; \boldsymbol{z}_1; \ldots; \boldsymbol{z}_L)$.

Now, we consider the interaction information and can obtain:

$$\begin{aligned} &I(\boldsymbol{x}; \boldsymbol{z}_1; \ldots; \boldsymbol{z}_L) \\ =&I(\boldsymbol{z}_L, \boldsymbol{z}_{L-1}) - \sum_{i=2}^{L-1} I(\boldsymbol{z}_L; \ldots; \boldsymbol{z}_i|\boldsymbol{z}_{i-1}) - I(\boldsymbol{z}_L; \ldots; \boldsymbol{z}_1|\boldsymbol{x}) \\ \geq&\sum_{i=2}^{L-1} I(\boldsymbol{z}_L; \ldots; \boldsymbol{z}_i|\boldsymbol{z}_{i-1}) - I(\boldsymbol{z}_L; \ldots; \boldsymbol{z}_1|\boldsymbol{x}) \end{aligned} \tag{26}$$

Finally, based on Eq.(16), (17), (25), (26), we can conclude:

$$\begin{aligned} \mathbb{E}_{p(\boldsymbol{x})}[\mathcal{L}_R] &= \sum_{i=1}^{L} \mathbb{E}_{p(\boldsymbol{x})}\mathbb{E}_{q(\boldsymbol{z}_{<l}|\boldsymbol{x})}[\mathrm{KL}(q(\boldsymbol{z}|\boldsymbol{x}, \boldsymbol{z}_{<l})||p(\boldsymbol{z}_l|\boldsymbol{z}_{<l}))] \\ &\geq I(\boldsymbol{x}; \boldsymbol{z}_1, \ldots, \boldsymbol{z}_L) \\ &\geq I(\boldsymbol{x}; \boldsymbol{z}_1; \ldots; \boldsymbol{z}_L) \\ &\geq \sum_{i=2}^{L-1} I(\boldsymbol{z}_L; \ldots; \boldsymbol{z}_i|\boldsymbol{z}_{i-1}) - I(\boldsymbol{z}_L; \ldots; \boldsymbol{z}_1|\boldsymbol{x}) \end{aligned} \tag{27}$$

Easy Adaptation to Mitigate Gender Bias in Multilingual Text Classification

Xiaolei Huang
Department of Computer Science, University of Memphis
xiaolei.huang@memphis.edu

Abstract

Existing approaches to mitigate demographic biases evaluate on monolingual data, however, multilingual data has not been examined. In this work, we treat the gender as domains (e.g., male vs. female) and present a standard domain adaptation model to reduce the gender bias and improve performance of text classifiers under multilingual settings. We evaluate our approach on two text classification tasks, hate speech detection and rating prediction, and demonstrate the effectiveness of our approach with three fair-aware baselines.

1 Introduction

Recent research raises concerns that document classification models can be discriminatory and can perpetuate human biases (Dixon et al., 2018; Borkan et al., 2019; Sun et al., 2019; Blodgett et al., 2020; Liang et al., 2020). Building *fairness*-aware classifiers is critical for the text classification task, such as hate speech detection and online reviews due to its rich demographic diversity of users. The fairness-aware classifiers aim to provide fair and non-discriminatory outcomes towards people or groups of people based on their demographic attributes, such as gender, age, or race. Fairness has been defined in different ways (Hardt et al., 2016) across downstream tasks; for mitigating biases in the text classification, existing research (Dixon et al., 2018; Heindorf et al., 2019; Han et al., 2021) has focused on *group fairness* (Chouldechova and Roth, 2018), under which document classifiers are defined as biased if the *classifiers perform better for documents of some groups than for documents of other groups*.

Methods to mitigate demographic biases in text classification task focus on four main directions, data augmentation (Dixon et al., 2018; Park et al., 2018; Garg et al., 2019), instance weighting (Zhang et al., 2020; Pruksachatkun et al., 2021), debiased pre-trained embeddings (Zhao et al., 2017; Pruksachatkun et al., 2021), and adversarial training (Zhang et al., 2018; Barrett et al., 2019; Han et al., 2021; Liu et al., 2021). The existing studies have been evaluated on English datasets containing rich demographic variations, such as Wikipedia toxicity comments (Cabrera et al., 2018), sentiment analysis (Kiritchenko and Mohammad, 2018), hate speech detection (Huang et al., 2020). However, the methods of reducing biases in text classifiers have not been evaluated under multilingual settings.

In this study, we propose a domain adaptation approach using the idea of "easy adaptation" (Daumé III, 2007) and evaluate on the text classification task of two multilingual datasets, hate speech detection and rating prediction. We experiment with non-debiased classifiers and three fair-aware baselines on the gender attribute, due to its wide applications and easily accessible resources. The evaluation results of both non-debiased and debiased models establish important benchmarks of group fairness on the multilingual settings. To our best knowledge, this is the first study that proposes the adaptation method and evaluates fair-aware text classifiers on the multilingual settings.

2 Multilingual Data

We retrieved two public multilingual datasets that have gender annotations for hate speech classification (Huang et al., 2020) and rating reviews (Hovy et al., 2015).[1] The hate speech (*HS*) data collects online tweets from Twitter and covers four languages, including English (en), Italian (it), Portuguese (pt), and Spanish (es). The rating review (*Review*) data collects user reviews from Trustpilot website and covers four languages, including English, French (fr), German (de), and Danish (da). The HS data is annotated with binary labels indicating whether the tweet is related to hate speech

---

[1] The number of languages is limited by the availability of the data providers.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 717 - 723
July 10-15, 2022 ©2022 Association for Computational Linguistics

or not. The Review data has five ratings from 1 to 5. To keep consistent, we removed reviews with the rating 3 and encoded the review scores into two discrete categories: score > 3 as positive and < 3 as negative. All the data has the same categories for the gender/sex, male and female. We anonymized tweets, lowercased all documents, and tokenized each document by NLTK (Loper and Bird, 2002), which supports processing English and the other six languages.

Source	Lang	Docs	Tokens	F-Ratio	L-Ratio
HS	EN	44,253	20.533	.498	.355
	IT	2,361	19.848	.310	.235
	PT	1,852	20.007	.554	.222
	ES	4,831	20.660	.455	.357
Review	EN	358,219	48.553	.398	.930
	FR	324,358	37.102	.429	.931
	DE	115,367	38.224	.430	.928
	DA	882,080	49.829	.475	.886

Table 1: Summary of multilingual Hate Speech (HS) and Online Review data. F-Ratio and L-Ratio indicate female ratios and positive / hate speech label ratios respectively.

We summarize the data statistics in Table 1. The HS data is comparatively smaller than the review data, and both datasets have a skewed label distributions. For example, most of the reviews have positive labels, and most of tweets are not hate speech. Notice that the review data comes from a consumer review website in Denmark, and therefore, Danish reviews are more than the other languages of the review data. We can find that all documents are short, and the HS data from Twitter is comparatively shorter. For the gender ratio, most of the data has a relatively lower female ratios.

Ethic and Privacy consideration. We only use the text documents and gender information for evaluation purposes without any other user profile, such as user IDs. All experimental information has been anonymized before training text classifiers. Specifically, we hash document IDs and replace any user mentions and URLs by two generic symbols, "user" and "url", respectively. To preserve user privacy, we will only release aggregated results presented in this manuscript and will not release the data. Instead, we will provide experimental code and the public access links of the datasets to replicate the proposed methodology.

3 Easy Adaptation Framework

Previous work has shown that applying domain adaptation techniques, specifically the "Frustratingly Easy Domain Adaptation" (**FEDA**) approach (Daumé III, 2007), can improve document classification when demographic groups are treated as domains (Volkova et al., 2013; Lynn et al., 2017). Based on these results, we investigate whether the same technique can also improve the fairness of classifiers, as shown in Figure 1. With this method, the feature set is augmented such that each feature has a domain-specific version for each domain, as well as a domain-independent (general) version. Specifically, the features values are set to the original feature values for the domain-independent features and the domain-specific features that apply to the document, while domain-specific features for documents that do not belong to that domain are set to 0. We implement this via a feature mask by the element-wise matrix multiplication. For example, a training document with a female author would be encoded as $[F_{general}, F_{domain,female}, 0]$, while a document with a male author would be encoded as $[F_{general}, 0, F_{domain,male}]$. At test time we only use the domain-independent features. While the FEDA applies to non-neural classifiers, we treat neural models as feature extractors and apply the framework on neural classifiers (e.g., RNN). We denote models with the easy adaptation with the suffix -DA.

4 Experiments

Demographic variations root in documents, especially in social media data (Volkova et al., 2013; Hovy, 2015). In this study, we present a standard domain adaptation model on the gender factor, and we treat each demographic group as a domain (e.g., male and female domains). We show the domain adaptation method can effectively reduce the biases of document classifiers on the two multilingual corpora. Each corpus is randomly split into training (80%), development (10%), and test (10%) sets. We train the models on the training set and find the optimal hyperparameters on the development set. We randomly shuffle the training data at the beginning of each training epoch.

4.1 Regular Baselines (B-Reg)

We experimented with three popular classifiers, Logistic Regression (LR), Recurrent Neural Network (RNN), and BERT (Devlin et al., 2019). For the LR,

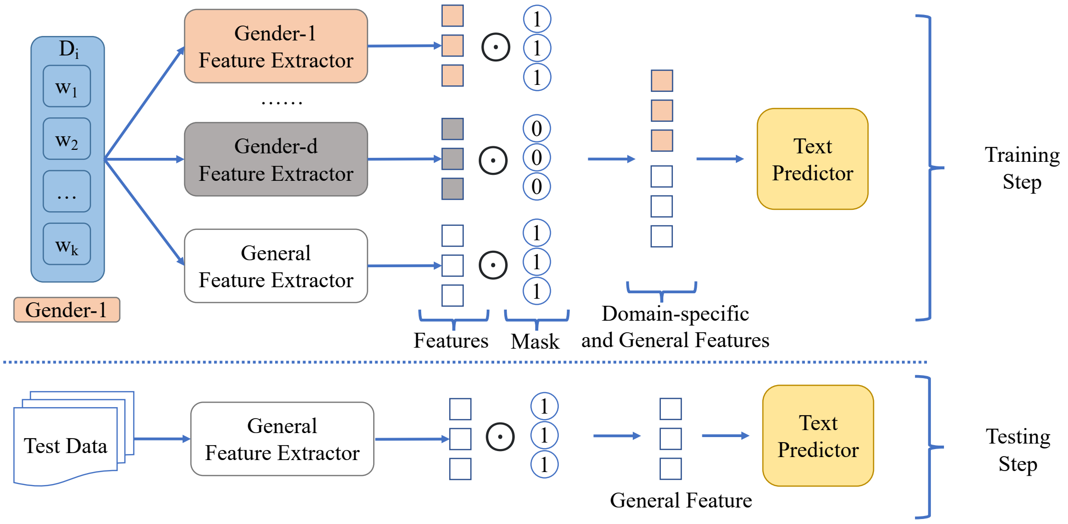

Figure 1: Framework illustrations for training and testing steps. The training step uses domain-independent (general in no color) and -specific (in color) features, while the testing step only uses the general features.

we extract Tf-IDF-weighted features for uni-, bi-, and tri-grams on the corpora with the most frequent 15K features with the minimum feature frequency as 3. We then train a `LogisticRegression` from scikit-learn (Pedregosa et al., 2011). We left other hyperparameters as their defaults. For the RNN classifier, we follow existing work (Park et al., 2018) and build a bi-directional model with the Gated Recurrent Unit (GRU) (Chung et al., 2014) as the recurrent unit. We set the output dimension of RNN as 200 and apply a dropout on the output with rate .2. We optimize the RNN with RMSprop (Tieleman and Hinton, 2012). To encode the multilingual tokens, we utilize the pre-trained fastText multilingual embeddings (Mikolov et al., 2018) to encode the top 15K frequent tokens. For the BERT classifier, we build two new linear layers upon on pretrained BERT models (Devlin et al., 2019) including both English and multilingual versions. The multilingual version supports 104 languages that cover all languages in this work. The first layer transforms the BERT-encoded representations into 200-dimension vectors and feeds the vectors for the the final prediction layer. We optimize the model parameters by the Adam (Kingma and Ba, 2015). For the neural classifiers, we train them with the batch size as 64, the max length as 200, and the learning rate within the range of $[1e-4, 1e-6]$. The classifiers in the following sections apply the same hyperparameter settings for fair comparison.

4.2 Fair-aware Baselines

Blind augments data by masking out tokens that are associated with the demographic groups (Dixon et al., 2018; Garg et al., 2019). We apply the Blind strategy on the regular baselines and denote the classifiers as LR-Blind, RNN-Blind, and BERT-Blind respectively. We retrieved the gender-sensitive tokens from the Conversation AI project (ConversationAI, 2021), which contains individual tokens. However, the existing resource (Dixon et al., 2018; Garg et al., 2019) only focused on English instead of the other languages. Therefore, we use the multilingual lexicon, PanLex (Kamholz et al., 2014), to translate the gender-sensitive English tokens into the other six languages.

RNN-IW applies the instance weighting to reduce impacts of gender-biased documents (Zhang et al., 2020) during training classifiers. The method learns each training instance with a numerical weight $\frac{P(Y)}{P(Y|Z)}$ based on explicit biases counted by gender-sensitive tokens (ConversationAI, 2021). Then the method utilizes a random forest classifier to estimate the conditional distribution $P(Y|Z)$ and the marginal distribution $P(Y)$. Finally, the method applies the classifier on training instances to obtain weight scores and assign the weights to training instances during optimization loss calculation. The approach achieves the best results using RNN models, and we keep the same settings. We extend the approach to multilingual settings using the translated resources.

Delta-R (%)		-0.1	-0.4	-32.1	7.1	1.9	-25.2	10.7	0.8	-14.0	7.5	1.6	-57.7
Delta-F (%)		-0.6	-2.5	-15.5	15.2	11.8	6.6	10.7	-1.3	-16.1	6.4	2.5	-50.9

Table 2: Performance on the HS and Review Data in percentage. A lower fair score is better. The Delta-R and -F are improvements over the regular (-R) and fair (-F) baselines respectively. Negative Delta scores over the fair indicate percentage of mitigating biases, and lower scores means more bias mitigation.

RNN-Adv utilizes adversarial training (Han et al., 2021) to mitigate (Liu et al., 2021) gender biases by two prediction tasks, document and gender predictions. Instead of learning to better separate gender labels, the adversarial training aims to confuse the gender predictions to reduce gender sensitiveness. We adapt the RNN module which achieved promising results (Han et al., 2021; Liu et al., 2021).

4.3 Evaluation Metrics

We use F1-macro score (fit for skewed label distribution) and area under the ROC curve (AUC) to measure overall performance. To evaluate group fairness, we measure the *equality differences* (ED) of false positive/negative rates (Dixon et al., 2018) for the fair evaluation. Existing study shows the FP-/FN-ED is an ideal choice to evaluate fairness in classification tasks (Czarnowska et al., 2021). Taking the false positive rate (FPR) as an example, we calculate the equality difference by $FPED = \sum_{g \in G} |FPR_d - FPR|$, where G is the gender and d is a gender group (e.g., female). We report the sum of FP-/FN-ED scores and denote the score as "Fair". This metric sums the differences between the rates within specific gender groups and the overall rates.

4.4 Results

We present the averaged results after running evaluations three times of both baselines and our approach in Table 2. Fair-aware classifiers have significantly reduced the gender bias over regular classifiers across the multilingual datasets, and our approaches have better scores of the group fairness by a range of 14% to 57.7% improvements over the baselines. The data augmentation approach achieves better fair scores across multiple languages, which indicates that the translated resources of English gender-sensitive tokens can also be effective on the evaluated languages. The neural fair-aware RNNs usually achieve worse performance than the BERT-based models, but the RNN-based models is more likely to achieve better fairness scores. Note that the BERT and fastText embeddings were pretrained on the same text corpus, Wikipedia dumps, and the performance indicates that fine-tuning the more complex models is a practical approach to reduce gender bias under the multilingual settings. Overall, our approach appears promising to reduce the gender bias under the multilingual setting.

Considering model performance, we can generally find that the fair-aware methods do not significantly improve the model performance, which aligns with findings in a previous study (Menon and Williamson, 2018). For example, fair-aware classifiers promote classification performance by around 1%, and fair-aware classifiers slightly decrease on the English hate speech data. However, we also find that all fair-aware models achieve better performance on the Spanish, Italian, and Portuguese hate speech data. We infer this due to the data size, as for the three corpora are much smaller than the corpora in other languages.

5 Conclusion

We present an easy adaptation method to reduce gender bias on two downstream tasks (hate speech detection and user rating prediction) under the multilingual setting. The experiments show that by treating demographic groups as domains, we can reduce biases while keeping relatively good performance. Our future work will solve the limitations of this study, including non-binary genders, multiple demographic factors, embedding sources, and label imbalance. Code and data instructions of our work are available at `https://github.com/xiaoleihuang/DomainFairness`.

5.1 Limitations

While we have proved the effectiveness of our proposed framework, limitations must be acknowledged in order to appropriately interpret our evaluations. First, our experiments are based on coarse-grained gender categories (binary gender groups) and the multilingual datasets fail to provide fine-grained information. Using coarse-grained attributes would ignore people with non-binary gender. Expanding evaluations of existing methods may require enriching categories of demographic attributes. In this study, we include two major data sources and experiment the six languages aiming to evaluate gender-bias-mitigation algorithms in a diverse and multilingual scenario. We keep the same experimental settings with the baselines (Dixon et al., 2018; Zhang et al., 2020; Han et al., 2021; Liu et al., 2021) to ensure fair comparisons, such as data sources and binary labels. Second, the multilingual pretrained embeddings (fastText and BERT), which were not trained on the social media data, may not achieve the best performance overall. We may expect a performance boost if utilizing in-domain pretrained embeddings. However, our focus is on the augmentation framework to reduce demographic (gender) biases.

Acknowledgements

The author wants to thank for reviewers' valuable comments. The experiments on the English hate speech data was adopted from his Ph.D. thesis, Section 5.6 (Huang, 2020). The author also wants to thank Dr. Michael J. Paul for the initial idea discussion and Dr. Shijie Wu for his suggestions on selecting the multilingual lexicon.

A Implementation Details

While we have presented experimental and hyperparameter settings in the Section 4, we report implementation tools in this section. We implement neural models by PyTorch (Paszke et al., 2019) and non-neural models by scikit-learn (Pedregosa et al., 2011). For the BERT model, we use the Hugging Face Transformers (Wolf et al., 2020). The Keras (Chollet et al., 2015) helped preprocess text documents for neural models, including padding and tokenization. We trained models on an NVIDIA RTX 3090 and evaluated the models on CPUs.

On the Use of External Data for Spoken Named Entity Recognition

Abstract

Spoken language understanding (SLU) tasks involve mapping from speech signals to semantic labels. Given the complexity of such tasks, good performance is expected to require large labeled datasets, which are difficult to collect for each new task and domain. However, recent advances in self-supervised speech representations have made it feasible to consider learning SLU models with limited labeled data. In this work, we focus on low-resource spoken named entity recognition (NER) and address the question: Beyond self-supervised pre-training, how can we use external speech and/or text data that are not annotated for the task? We consider self-training, knowledge distillation, and transfer learning for end-to-end (E2E) and pipeline (speech recognition followed by text NER) approaches. We find that several of these approaches improve performance in resource-constrained settings beyond the benefits from pre-trained representations. Compared to prior work, we find relative improvements in F1 of up to 16%. While the best baseline model is a pipeline approach, the best performance using external data is ultimately achieved by an E2E model. We provide detailed comparisons and analyses, developing insights on, for example, the effects of leveraging external data on (i) different categories of NER errors and (ii) the switch in performance trends between pipeline and E2E models.

1 Introduction

Named entity recognition (NER) is a popular task in natural language processing. It involves detecting the named entities and their categories from a text sequence. NER can be used to extract information from unstructured data, which can also be used as features for other tasks like question answering (Chen et al., 2017) and slot filling for task-oriented dialogues (Louvan and Magnini, 2018).

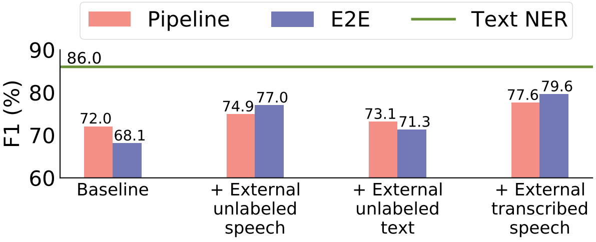

Figure 1: *Improvements in spoken NER with 100 hours of external data of different types. "Pipeline" refers to approaches consisting of speech recognition followed by a text NER model; "E2E" refers to approaches that directly map from speech to NER-tagged text. The "Baseline" and "Text NER" numbers are from previously established baselines (Shon et al., 2022).*

Thanks to pre-trained text representations such as BERT (Devlin et al., 2019), text-based NER has recently improved greatly (Wang et al., 2021b; Li et al., 2020b). *Spoken* NER, on the other hand, is not as well-studied. It has the added challenges of continuous-valued and longer input sequences and, at the same time, provides opportunities to take advantage of acoustic cues in the input. A recent study (Shon et al., 2022) shows that there is still 10-20% absolute degradation in the F1 scores of spoken NER models compared to text-based NER using gold transcripts (see Figure 1) despite using large pre-trained speech representation models. Closing this gap remains a critical challenge.

In this work, we study the potential benefits of using a variety of external data types: (a) plain speech audio, (b) plain text, (c) speech with transcripts, and (d) text-based NER data. We benchmark our findings against recently published baselines for NER on the VoxPopuli dataset of European Parliament speech recordings (Shon et al., 2022) and also introduce baselines of our own. We observe improvement from leveraging every type of external data. Our analysis also quantifies the pros and cons of the pipeline (speech recognition followed

by text NER) and end-to-end (E2E) approaches. The key improvements are summarized in Figure 1. Specific contributions include:

(i) Unlike previous work, we devote equal effort to improving both pipeline and E2E approaches.

(ii) We present experiments using various external data types and modeling approaches.

(iii) Overall, we obtain F1 improvements of up to 16% for the E2E model and 6% for the pipeline model over previously published baselines, setting a new state of the art for NER on this dataset.

(iv) We benchmark the advantage of self-supervised representations (SSR) over a baseline that uses standard spectrogram features. SSR gives relative improvements of 36%/31% for pipeline/E2E models, respectively. To our knowledge, prior work has not directly measured this improvement over competitive baselines tuned for the task.

(v) We establish that E2E models outperform pipeline approaches on this task, given access to external data, while the baseline models without the external data have the opposite relationship.

(vi) We provide a detailed analysis of model behavior, including differences in error types between pipeline and E2E approaches and the reasoning for the superiority of E2E over pipeline models when using external data but not in the baseline setting.

2 Related work

2.1 Spoken named entity recognition

Relatively little work has been conducted on spoken NER (Kim and Woodland, 2000; Sudoh et al., 2006; Parada et al., 2011; Ghannay et al., 2018; Caubrière et al., 2020; Yadav et al., 2020; Shon et al., 2022) as compared to the extensively studied task of NER on text (Nadeau and Sekine, 2007; Ratinov and Roth, 2009; Yadav and Bethard, 2018; Li et al., 2020a). While spoken NER is commonly done through a pipeline approach (Sudoh et al., 2006; Raymond, 2013; Jannet et al., 2015), there is rising interest in E2E approaches in the speech community (Ghannay et al., 2018; Caubrière et al., 2020; Yadav et al., 2020; Shon et al., 2022). These two approaches are depicted in Fig. 2.

An early E2E spoken NER model was introduced by Ghannay et al. (2018). The approach is based on the DeepSpeech2 (Amodei et al., 2016) architecture, with the addition of special characters for NER labels around the named entities in the transcription, and is trained with character-level connectionist temporal classification (CTC) (Graves et al., 2006). Yadav et al. (2020) introduced an English speech NER dataset and proposed an E2E approach similar to Ghannay et al. (2018). They show that LM fusion improves the performance of the E2E approach. Caubrière et al. (2020) provided a detailed comparison between E2E and pipeline models; however, they focused on small RNN/CNN models and did not use state-of-the-art SSR models. All these approaches use at least 100 hours of annotated data.

These previous efforts have shown that E2E models can outperform pipeline approaches in a fully supervised setting. Borgholt et al. (2021) also made the same observation on a simplified NER task. However, these studies do not account for improvements in NLP from self-supervised text representations for their pipeline counterparts. Shon et al. (2022) introduced and worked with a low-resource NER corpus and showed that E2E models still do not rival pipeline approaches when state-of-the-art pre-trained models are used.

When using pre-trained representations, E2E models are at a disadvantage since the pipeline model also has access to a text model trained on >50GB of text, in addition to the same speech representation model as E2E. This inspires us to study the benefits of using additional unlabeled data.

We choose to work with the NER-annotated VoxPopuli corpus (Wang et al., 2021a; Shon et al., 2022). VoxPopuli consists of naturally spoken speech, unlike Bastianelli et al. (2020), and is annotated manually, unlike Yadav et al. (2020) and Borgholt et al. (2021) who obtain ground-truth labels using text model predictions. The SLUE benchmark (Shon et al., 2022) is aimed at low-resource SLU and includes annotations for only 15 hours of data; this matches with the goals of our work, making it an ideal choice to benchmark our findings.

2.2 Self-supervised pre-training

There is a long history of using unsupervised pre-training in NLP to improve performance over limited-data supervised training on a broad range of tasks. SSRs have started to make an impact on speech tasks as well, with the first improvements seen in large-scale ASR with wav2vec (Schneider et al., 2019). More recently, improvements have been seen on more tasks with wav2vec 2.0 (Baevski et al., 2020) and other models (Yang et al., 2021).

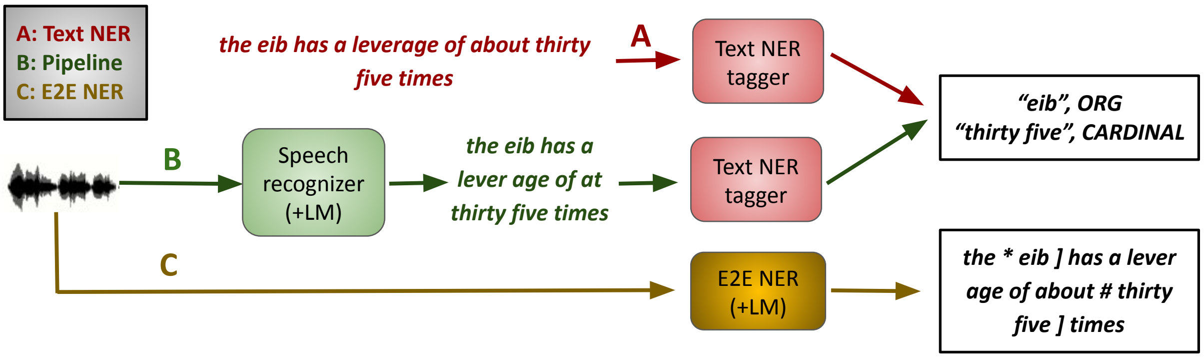

Figure 2: *High-level summary of approaches typically used to solve spoken and textual NER tasks. Optional LM decoding is applied in ASR and E2E-NER models.*

However, it is not yet clear how universal these pre-trained representations are for speech tasks, particularly for semantic understanding tasks like NER. Some pre-trained models achieve impressive performance across a variety of tasks, including some understanding tasks (Yang et al., 2021) and analyses suggest that they contain at least some word meaning information (Pasad et al., 2021). However, these pre-trained models have not yet been tested on a broad range of challenging understanding tasks. We believe our work is the first to quantify the improvements from SSR, specifically on spoken NER.

2.3 Leveraging external data

Self-training (Scudder, 1965; Yarowsky, 1995; Riloff, 1996) is a popular approach to improve supervised models when some additional unannotated data is available. Self-training has been observed to improve ASR (Parthasarathi and Strom, 2019; Xu et al., 2021) and is also complementary to pre-training (Xu et al., 2021). To the best of our knowledge, this is the first work to introduce it to spoken NER while also studying its effects on both E2E and pipeline approaches.

Knowledge distillation is widely used in model compression research. In this approach, some intermediate output from a teacher model is used to train a smaller student model (Hinton et al., 2014). In the context of our work, the teacher and student networks are two different approaches to solving NER tasks, and the latter is trained on the final output tags of the former.

Transfer learning has been widely employed for SLU tasks (Lugosch et al., 2019; Jia et al., 2020), including E2E spoken NER (Ghannay et al., 2018; Caubrière et al., 2020). Automatic speech recognition (ASR) is a typically chosen task for pre-training a model before fine-tuning it for SLU. This choice is facilitated by the wider availability of transcribed speech than SLU annotations. Specifically for NER, ASR pre-training is expected to help since the accuracy of decoded texts can directly affect the final NER predictions.

3 Methods

Spoken NER involves detecting the entity phrases in a spoken utterance along with their tags. The annotations include the text transcripts for the audio and the entity phrases with their corresponding tags. Spoken NER, like any other SLU task, is typically tackled using one of two types of approaches: (i) Pipeline and (ii) End-to-end (E2E). As shown in Fig. 2, a pipeline approach decodes speech to text using ASR and then passes the decoded text through a text NER module, whereas an E2E system directly maps the input speech to the output task labels. Each approach has its own set of advantages and shortcomings. Pipeline systems can enjoy the individual advances from both the speech and the text research communities, whereas combining two modules increases inference time, and propagation of ASR errors can have unexpected detrimental effects on the text NER module performance. On the other hand, E2E models directly optimize a task-specific objective and tend to have faster inference. However, such models typically require a large amount of task-specific labeled data to perform well. This can be seen from previous papers on E2E NER (Yadav et al., 2020; Ghannay et al., 2018), where using at least 100 hours of labeled data is typical.

3.1 Baseline models

The baselines we use for E2E and pipeline models are taken from Shon et al. (2022). Similarly to previous work (Shon et al., 2022; Ghannay et al., 2018; Yadav et al., 2020), we formulate E2E NER as character-level prediction with tag-specific special characters delimiting entity phrases. For example, the phrases "irish" and "eu" are tagged as NORP[1] ($) and GPE[2] (%) respectively in "*the $ irish] system works within a legal and regulatory policy directive framework dictated by the % eu]*".

The E2E NER and ASR modules are initialized with the wav2vec2.0 base (Baevski et al., 2020) pre-trained speech representation, while the text NER module is pre-trained with DeBERTa base (He et al., 2021). These pre-trained models are then fine-tuned for ASR/NER after adding a linear layer on top of the final hidden-state output.

Since text transcripts are typically a part of the NER annotations, we can also train an NER model that uses the ground-truth text as input. This text NER model serves roughly as a topline and is further used in experiments with external data. The E2E NER and ASR models are trained with a character-level CTC objective. The text NER model is trained for token-level classification with cross-entropy loss.

It is expected that using self-supervised representations gives a significant boost in limited labeled data settings. In order to quantify the benefits of the pre-trained representations in our setting, we also report the performance of E2E and pipeline baselines that are trained from scratch, not utilizing any pre-trained models.

3.2 Evaluation metrics

Similarly to previous work (Ghannay et al., 2018; Yadav et al., 2020), we evaluate performance using *micro-averaged F1* scores on an unordered list of tuples of named entity phrase and tag pairs predicted for each sentence. An entity prediction is considered correct if both the entity text and the entity tag are correct.

Spoken NER introduces an added variability to the possible model errors due to speech-to-text conversion. We report word error rate (WER) to evaluate this aspect. *WER* is the word-level Levenshtein distance between the ground-truth text and the decoded text generated by the model. Additionally, to get an idea of the errors made by the model specifically on named entities, we also evaluate *NE ACC*, the proportion of entity phrases correctly decoded in the speech-to-text conversion. An entity phrase is considered accurate only if all the words in the phrase are correctly decoded in the right order.

3.3 Utilizing external data

Next, we describe our approaches that use data external to the task-specific labeled data to improve both the pipeline and the E2E models for spoken NER. We consider four types of external data: (i) unlabeled speech (*Un-Sp*), (ii) unlabeled text (*Un-Txt*), (iii) transcribed speech (*Sp-Txt*), and (iv) text-based NER data.

External data type	**Method**	**Target model**
Un-Sp	SelfTrain-ASR	ASR
Un-Txt	SelfTrain-txtNER	text NER
Sp-Txt	Pre-ASR	ASR

Table 1: Methods for using external data for pipeline models. For "SelfTrain" approaches, the *labeling model* is the same as the *target model*. The method for external transcribed data (*Sp-Txt*) is based on transfer learning and thus there is no *labeling model*. More details are provided in Sec. 3.3.

The majority of techniques we consider involve labeling the external data with a *labeling model* (typically one of the baseline models) to produce *pseudo-labels*. The *target model* is then trained on these generated pseudo-labels along with the original labeled NER data. Tables 1 and 2 present a detailed list of all methods we consider for improving pipeline and E2E models respectively. The methods we include use the first three kinds of external data listed above. The fourth kind, external text-based NER data, is used in experiments attempting to improve the text NER model; since it does not succeed (Sec. 5.2.1), this data source is not explored further for the pipeline and E2E models.

When the labeling model is the same as the target model, this is a well-established process called self-training (Scudder, 1965; Yarowsky, 1995; Riloff, 1996; Xu et al., 2020, 2021). In our setting, a word-level language model (LM) is used for decoding both the ASR and E2E NER models. Shon et al. (2022) observed that a LM consistently improves performance of all of the baseline models.

---

[1] NORP: Nationalities or religious or political groups

[2] GPE: Countries, cities, states

External data type	Method	Labeling model	Target model	LM for decoding
Un-Sp	SelfTrain-E2E	E2E-NER	E2E-NER	pLabel 4-gram
	Distill-Pipeline	Pipeline-NER (after SelfTrain-ASR)	E2E-NER	pLabel 4-gram
Un-Txt	Distill-txtNER-lm	text NER	n/a	pLabel 4-gram
Sp-Txt	Distill-txtNER	text NER	E2E-NER	pLabel 4-gram
	Pre-ASR	n/a	n/a	ftune 4-gram

Table 2: Methods for using external data for E2E models. Details are provided in Sec. 3.3.

So we may expect self-training from pseudo-labels to improve the target models by distilling the LM information into all model layers.

When the two models are different, we refer to it as knowledge distillation (Hinton et al., 2014), where the information is being distilled from the labeling model to the target model. This approach enables the target model to learn from the better-performing labeling model via pseudo-labels. Among the baseline models, the pipeline performs better than E2E approaches, presumably since the former uses strong pre-trained text representations. So, for instance, distilling from the pipeline (labeling model) into the E2E model (target model) is expected to boost the performance of the E2E model.

The LMs used for decoding in different approaches are mentioned in Tab. 2. All the ASR experiments use language models trained on the TED-LIUM 3 LM corpus (Hernandez et al., 2018) as in Shon et al. (2022). The language model used in baseline E2E NER experiments is trained on the 15hr fine-tune set (*ftune 4-gram*). The generated pseudo-labels also provide additional annotated data for LM training, which can be used in E2E models. These are referred to as *plabel 4-gram*) (for "pseudo-label 4-gram").

Unlabeled speech: The unlabeled speech is used to improve the ASR module of the pipeline approach via self-training (*SelfTrain-ASR*).

For improving the E2E model, the improved pipeline can be used as the labeling model, followed by training the E2E model on the generated pseudo-labels (*Distill-Pipeline*). Alternatively, the unlabeled audio can be directly used to improve the E2E model via self-training (*SelfTrain-E2E*).

Unlabeled text: The text NER module in the pipeline approach is improved by self-training using the unlabeled text data (*SelfTrain-txtNER*). The E2E model uses the pseudo labels generated from the text NER baseline module on the unlabeled text to update the LM used for decoding (*Distill-txtNER-lm*).

Transcribed speech: The pipeline approach is improved by using the additional transcribed speech data to improve the ASR module (*Pre-ASR*). The E2E model uses this updated ASR as an initialization in a typical transfer learning setup. Alternatively, for paired speech text data, the pseudo-labels generated from the text NER model can be paired with audio and used for training the E2E model, thus distilling information from a stronger text NER model into it (*Distill-txtNER*).

Text NER data: In addition to improving the pipeline and E2E models using the approaches mentioned above, we also look for any possible improvements in the text NER model by leveraging a larger external annotated text NER corpus. The DeBERTa base model is first fine-tuned on the larger external corpus, and then further fine-tuned on the in-domain labeled data. The first fine-tuning step is expected to help avoid shortcomings in performance due to the limited size of the in-domain labeled data.

This approach is limited by the availability of external datasets with the same annotation scheme as the in-domain corpus. We use the OntoNotes5.0 (Pradhan et al., 2013) corpus, whose labeling scheme inspired that of VoxPopuli (Shon et al., 2022). See Tab. 3 for more information on OntoNotes5.0.

4 Experimental setup

4.1 Dataset

VoxPopuli (Wang et al., 2021a) is a large multilingual speech corpus consisting of European Parliament event recordings with audio, transcripts, and timestamps from the official Parliament website. The English subset of the corpus has 540 hours of

Data split	**# utt**	**Duration (hours)**	**# entity phrases**
fine-tune	5k	15	5820
dev	1.7k	5	1862
test	1.8k	5	2006
ext-100h	350k	101	N/A
ext-500h	177k	508	
ext-NER (ontonotes-train)	66.6k	N/A	81.8k

Table 3: Data statistics. The "ext-" prefix denotes external datasets. The external data doesn't have named entity annotations, except for OntoNotes 5.0.

spoken data with text transcripts. Shon et al. (2022) recently published NE annotations for a 15-hour subset of the train set and the complete standard dev set. Test set annotations are not public, but we obtain test set results by submitting model outputs following the SLUE site instructions.[3] For our experiments with external in-domain data, we use uniformly sampled 100-hour and 500-hour subsets of the remainder of the VoxPopuli train set. The statistics for these splits are reported in Tab. 3. For more information on NE tags and label distribution, we direct the reader to the dataset and annotation papers (Pradhan et al., 2013; Shon et al., 2022).

4.2 Baseline models

We closely follow the setup for E2E and pipeline baselines in Shon et al. (2022).[4] We use wav2vec 2.0 base (Baevski et al., 2020) and DeBERTa-base (He et al., 2021) as the unsupervised pre-trained models, which have 95M and 139M parameters respectively. The publicly available wav2vec2.0 base model is pre-trained on 960 hours of the LibriSpeech audiobooks corpus (Panayotov et al., 2015).

For baselines that do not use pre-trained representations, we utilize the DeepSpeech2 (DS2) toolkit[5] (Amodei et al., 2016). DS2 first converts audio files into spectrogram features. The model processes the spectrogram features through two 2-D convolutional layers followed by five bidirectional 2048-dim LSTM layers and a softmax layer. The softmax layer outputs the probabilities for a sequence of characters. The model has 26M parameters and is trained with SpecAugment data augmentation (Park et al., 2019) and a character-level CTC objective. Following Shon et al. (2022), we train on the finer label set (18 entity tags) and evaluate on the combined version (7 entity tags).

4.3 Utilizing external data

We use fairseq library (Ott et al., 2019) to fine-tune wav2vec 2.0 models for the E2E NER and ASR tasks. We fine-tune the model for 80k (160k) updates on 100 (500) hours of pseudo-labeled data. It takes 20 (40) hours (wall clock time) to fine-tune on 100 (500) hours of data using 8 TITAN RTX GPUs. We use HuggingFace's transformers toolkit (Wolf et al., 2020) for training the text NER model on pseudo-labels. Detailed config files will be provided in the public codebase.[6]

5 Results

5.1 Baseline models

NER system	**Pretrained model**		**F1**
	Speech	**Text**	
Pipeline	✗	DeBERTa-B	52.4
E2E	✗	✗	51.8
Pipeline	W2V2-B	DeBERTa-B	72.0
E2E	W2V2-B	✗	68.1
Text NER	✗	DeBERTa-B	86.0

Table 4: Dev set % f-score performance of baseline models. All models here are trained on the 15hr fine-tune set. The pre-trained speech and text models are mentioned wherever used or applicable. The last three rows are from previously established baselines (Shon et al., 2022).

Results from all the baseline models are reported in Tab. 4. The models here are trained on the 15hr fine-tune set. We see that self-supervised pre-training gives a significant performance boost over no pre-training. The text NER model (which uses ground-truth transcripts) is far better than the pipeline method, which is better than the E2E model.

5.2 Leveraging external data

We report F1 scores on the dev set using different pipeline and E2E approaches in Tables 5 and 6 re-

	Pre-ASR	70.7	73.2

Table 6: Dev set % f-score performance of the E2E models. Note the baseline E2E (68.1) and text NER (86.0) performances without using any additional data from Tab. 4.

spectively. Fig. 1 presents key results when using each external data type for both E2E and pipeline models. The key findings are:
(i) Using external data reduces the gap between spoken NER baselines and text NER.
(ii) With access to either unlabeled speech or transcribed speech, E2E models outperform pipeline models, whereas, for the baselines, the opposite holds.
(iii) Using unlabeled text gives the smallest boost among the three types of external data, and the pipeline approach performs better in that setting.

A summary of test set results is presented in Appendix A.1. The results follow the same trend as on the dev set.

5.2.1 External text NER data

We try to improve the text NER model by using the OntoNotes5.0 NER corpus (Pradhan et al., 2013). Fine-tuning DeBERTa-base on OntoNotes5.0 produces an F1 of 60% on the VoxPopuli dev set. Fine-tuning it further on VoxPopuli gives F1 86% on the dev set. Since we do not see any boost over the existing vanilla approach (86%, see Tab. 4), we retain the original text NER model using only in-domain data and do not perform further experiments using the OntoNotes-finetuned model.

6 Discussion and analysis

The baseline results are not surprising: The limited labeled data is not enough for the baseline E2E approach, but the pipeline model can leverage a strong text representation model, which gives it an edge. Improvements to these models can be attributed to either (i) a better speech-to-text conversion or (ii) a better semantic understanding of the input content. Next, we use this distinction to understand the observed improvements from using external data.

6.1 Improved E2E results

When using external data with the E2E model, the best performing methods use either (a) external unlabeled speech (*Distill-Pipeline*) or (b) transcribed speech (*Distill-txtNER*). The labeling models have a stronger semantic component than the E2E baseline in both of these scenarios because of their strong text NER module. The same cannot be said for the other competing approaches for these external data categories, *SelfTrain-NER* and *Pre-ASR*, which provide much lower improvements. *SelfTrain-NER* distills information from the LM into the model layers, but the n-gram LM is much less powerful than the transformer-based text NER module used in *Distill-Pipeline*. The *Pre-ASR* approach has no means to improve the semantic component in the updated model.

In the presence of unlabeled text data, the modification comes from a better 4-gram LM trained on pseudo-labels. Note that the baseline E2E model parameters do not change, unlike when using the other two types of external data. This can explain why this approach only has a small improvement over the baseline.

6.2 Improved pipeline results

The baseline pipeline model already takes advantage of the text NER module, which leaves little room for improvement in the semantic understanding component. Specifically, using unlabeled text data to improve the text NER module (*SelfTrain-txtNER*) gives a small boost of 0.4%. For comparison, note that the improvement from using unlabeled speech is 2.5% over baseline. So, the hope with pipeline models is for the external data to improve the speech-to-text conversion, which can then help reduce error propagation between the independent pipeline modules.

6.3 Amount of external data

Almost all experiments produce a larger improvement when using 500 hours of external data than 100 hours. Only *SelfTrain-txtNER* has a reverse trend (see Tab. 5). The higher amount of external data naturally increases the fraction of noisy data that the target model is trained on, and that may lead to a poorer model. We hypothesize that methods for balancing between the effects of manually annotated and pseudo-labeled examples could help tackle this issue (Park et al., 2020). However, we leave an in-depth investigation of this phenomenon to future work.

6.4 Error analysis

For analysis, we choose the best-performing models within each category.

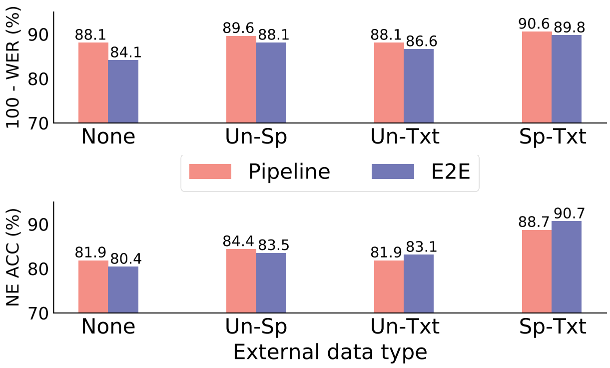

Figure 3: 100−*WER (%) and NE ACC (%) values on the dev set for the best-performing models in each category with access to 100 hours of external data.*

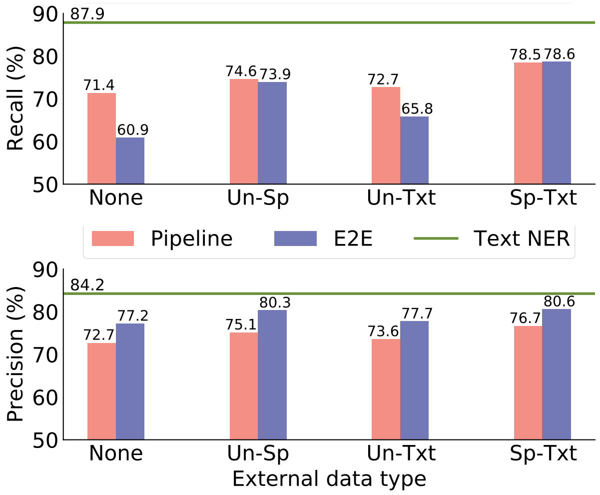

Figure 4: *Recall and precision on the dev set for the best-performing models in each category with access to 100 hours of external data.*

Fig. 3 presents the NE accuracy and word error rates (WER). We strip off the tag-specific special character tokens when evaluating WER for the E2E NER models. Note that we report 100− WER so that higher is better in both plots. We observe that the ASR used in pipeline models typically performs better than the speech-to-text conversion of E2E models, even when the former has a poorer F1 (Fig. 1). This may lead us to hypothesize that the E2E model recognizes NE words better while doing worse for other words. However, this hypothesis is not supported by the *NE-ACC* results (Fig. 3).

Next, we look at the breakdown of F1 into precision and recall (Fig. 4). We see that pipeline models have worse precision, thus suggesting that these suffer from a higher false-positive rate than the E2E models. This explains why *NE-ACC* is not predictive of F1; the former can inform us about errors due to false negatives, but not false positives.

6.4.1 Error categories

For a more detailed understanding of model behavior, we categorize the NER errors into an exhaustive list of types (details in Appendix A.2). We focus on four major categories showing noteworthy differences between pipeline and E2E approaches. We provide this analysis for the baselines, *Distill-Pipeline*, and *SelfTrain-ASR* models using external unlabeled speech data. The trends and observations presented here are consistent with the other two external data types.

The major error categories, along with examples, are presented in Fig. 5. We observe that:
(i) False detections are 1.5 times more common in pipeline models than in E2E models, as expected based on the lower precision for the former. This happens even when the falsely detected text is not a speech-to-text conversion error.
(ii) Over-detections are 3.5 to 4 times more common in the pipeline models even when the entity phrase is decoded correctly.
(iii) Missed detections for the E2E *Distill-Pipeline* model are drastically reduced compared to the E2E baseline. Missed detections refer to cases where the entity phrases are correctly transcribed but are not labeled as named entities. The improvement here therefore suggests that *Distill-Pipeline* improves the understanding capability of the E2E model, in addition to its speech-to-text capability. Also, note that the pipeline model does not enjoy the same benefit from unlabeled speech since this only involves self-training (instead of knowledge distillation from a much richer model for E2E).

Overall, the pipeline models suffer disproportionately from false positives. This seems to stem

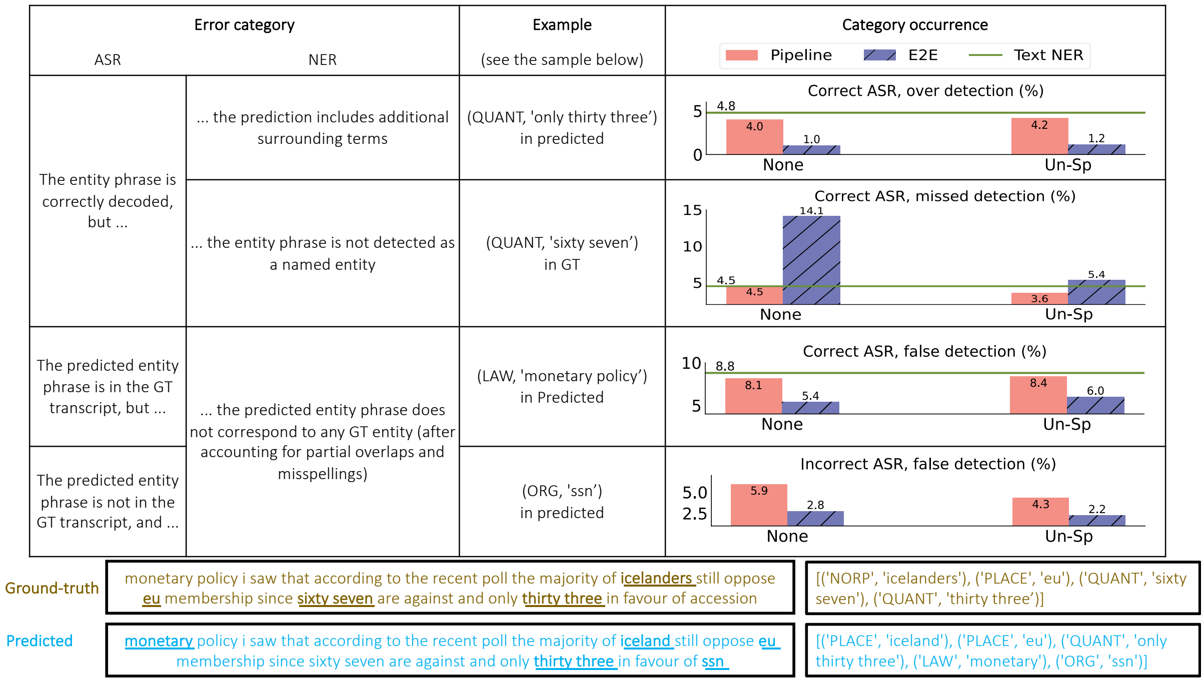

Figure 5: *NER error category distribution on the dev set. The category-specific error rates in the plots are normalized by the total number of ground-truth (GT) entities. The examples here are artificially created from the same ground-truth example for ease of presentation. Actual examples of these categories are presented in Appendix A.2.*

from the text NER model, which has even higher over-detection and false detection rates than the pipeline baseline models (Fig. 5). The reasons behind this difference between E2E and pipeline models need further investigation.

7 Conclusion

We have explored various ways to use different external data types that improve both pipeline and E2E methods for spoken NER. The best-performing model when using external data is an E2E approach. This is one of the few results in the literature thus far showing better performance for E2E over pipeline methods that use state-of-the-art modules for spoken language understanding. We develop some insights into this difference; we notice that pipeline models are adversely affected by false positives and that leveraging external data improves the semantic understanding capability of the E2E models.

We hope that our work provides guiding principles for researchers working on SLU tasks in similar low-resource domains when some form of external data is abundant. This work also leaves some interesting research questions for future work. For example, we see minor improvements between 100h and 500h of external data (see Tab. 5 and 6), which suggests the question: What is the smallest amount of external data needed to obtain significant improvements in NER performance? Additionally, one preliminary experiment with external, out-of-domain text NER data (OntoNotes 5.0) fails to improve the text NER performance, suggesting the challenges of dealing with out-of-domain datasets. The scenario where we have access to out-of-domain external data is common but challenging, and warrants further study. From the modeling perspective, better fine-tuning strategies for wav2vec2.0 in low supervision settings have been proposed for ASR (Pasad et al., 2021); it would be interesting to explore how these findings may transfer to an SLU task.

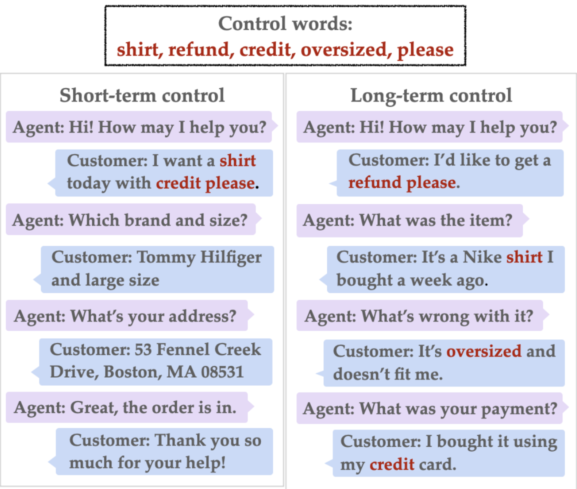
Abstract

Current approaches for controlling dialogue response generation are primarily focused on high-level attributes like style, sentiment, or topic. In this work, we focus on *constrained long-term* dialogue generation, which involves more fine-grained control and requires a given set of control words to appear in generated responses. This setting requires a model to not only consider the generation of these control words in the immediate context, but also produce utterances that will encourage the generation of the words at some time in the (possibly distant) future. We define the problem of constrained long-term control for dialogue generation, identify gaps in current methods for evaluation, and propose new metrics that better measure long-term control. We also propose a retrieval-augmented method that improves performance of long-term controlled generation via logit modification techniques. We show through experiments on three task-oriented dialogue datasets that our metrics better assess dialogue control relative to current alternatives and that our method outperforms state-of-the-art constrained generation baselines. [1]

1 Introduction

Despite recent advances in dialogue systems (Serban et al., 2016; Ham et al., 2020), *controlling* dialogue generation remains a significant challenge. Response generation in dialogue can be controlled towards different topics and styles (Madotto et al., 2020) or towards a set of hard constraints (i.e., lexical control words need to appear in the generated text) (Sha, 2020). We focus on the hard constraint setting, also known as *constrained* generation, as this provides a more fine-grained method of controlling dialogues.

For example, consider a customer service use case (Figure 1), in which an agent speaks to a customer about an issue. The goal is to generate a given set of control words in the responses of one of the speakers (agent or customer). Naive constrained generation approaches (Pascual et al., 2020; Miao et al., 2019) use methods like beam search and stochastic search to force the generation of these control words for short-term control, where control words need to appear in a single utterance or phrase. Because they do not consider the future, these approaches may generate the words all at once in a single response or not generate them at natural places in the conversation (Figure 1, left).



Control words:
shirt, refund, credit, oversized, please

Short-term control
Agent: Hi! How may I help you?
Customer: I want a shirt today with credit please.
Agent: Which brand and size?
Customer: Tommy Hilfiger and large size
Agent: What's your address?
Customer: 53 Fennel Creek Drive, Boston, MA 08531
Agent: Great, the order is in.
Customer: Thank you so much for your help!

Long-term control
Agent: Hi! How may I help you?
Customer: I'd like to get a refund please.
Agent: What was the item?
Customer: It's a Nike shirt I bought a week ago.
Agent: What's wrong with it?
Customer: It's oversized and doesn't fit me.
Agent: What was your payment?
Customer: I bought it using my credit card.

Figure 1: Examples of short vs. long-term control for dialogue generation. **(Left)** In short-term control, many control words are generated initially, but the conversation is led away from the desired future. **(Right)** In long-term control, responses are generated with the future in mind with words generated at natural points in the conversation.

The above example highlights the challenges of applying existing constrained generation methods to long-term dialogue generation. First, since another speaker is involved in the dialogue, the model does not have full control of the generated text. Instead, the model can only control the dialogue indirectly. Second, dialogues can be long and

thus, controlling utterances several time steps into the future is non-trivial. In this work, we propose the problem of long-term dialogue control, where the goal is to generate a set of control words over many utterances in a dialogue, which requires appropriately timing the generation of control words (Figure 1, right). To the best of our knowledge, we are the first work to constrain *long-term dialogue generation* through lexical control words.

We begin by highlighting challenges with evaluation for this problem. Successful long-term control of dialogue can be difficult to measure. We describe current evaluation metrics for constrained text generation and show that these metrics can be gamed by generating all or many control words early in the conversation. To resolve this and measure how natural the control is, we propose a new set of metrics: long-term success rate, which measures the percentage of control words in simulated roll-outs of the conversation, and precision, recall, and F1-score, which compare control words in generated responses to those in reference responses from a historical dataset. The second set of metrics specifically help to capture whether the control words are generated at the right time.

Next, we propose a novel method to explicitly address long-term control. Prior methods are unable to handle this task as the number of possible future sequences is exponential. To alleviate this issue, we retrieve similar conversations from training and condition on them during generation. We first identify similar neighbors using a kNN-based approach and then guide the language model towards generating similar responses, inspired by plug-and-play methods (Madotto et al., 2021; Dathathri et al., 2019; Pascual et al., 2020). The motivation for this is that retrieved conversations guide the model to generate the control words at more natural points in the conversation.

We conduct experiments on multiple task-oriented dialogue datasets and show that our method outperforms several constrained text generation baselines on automated evaluation metrics as well as human evaluation. Specifically, we are able to generate 30-40% more control words on long-term success rate compared with baselines, while preserving fluency (scores of ≥ 4.3 out of 5), as measured by human evaluation.

2 Related work

Controllable text generation. Prior work has developed many methods for controllable text generation. These approaches can be categorized into three general areas. The first is altering decoding strategies (Grover et al., 2019; Deng et al., 2020), in which the sampling distribution can be modified (Ghazvininejad et al., 2017; Baheti et al., 2018) or hidden states in the models can be changed (Gu et al., 2017). The second area involves including prompts to guide text generation (Ribeiro et al., 2018; Jiang et al., 2020; Li and Liang, 2021), for example through universal trigger tokens (Wallace et al., 2019; Shin et al., 2020). Finally, fine-tuning can be used to guide language model outputs through the use of a latent variable (Fan et al., 2018; Peng et al., 2018) or through CTRL codes (Keskar et al., 2019). Our work differs from the broad area of controllable language generation in that 1) we require more fine-grained generation through lexical control words and 2) we focus on dialogue settings where another speaker can also change the course of the conversation.

Constrained text generation. The key difference between constrained text generation and controllable text generation is the focus on hard rather than soft constraints. Typically, there are two general methods for constrained generation: beam search (Hokamp and Liu, 2017; Post and Vilar, 2018; Pascual et al., 2020) and stochastic search (Miao et al., 2019; Sha, 2020). Directed Beam Search (DBS) (Pascual et al., 2020), modifies language model logits to encourage generation of a specified set of “guide words", or control words. A method based on stochastic search (Miao et al., 2019) uses Metropolis-Hastings with the constraint of keyword inclusion. These approaches do not apply to the dialogue setting where these constraints need to hold for many utterances into the future.

Dialogue response generation. While many works develop methods for unconstrained response generation (Budzianowski and Vulić, 2019; Peng et al., 2020; Cao et al., 2020; Hosseini-Asl et al., 2020; Yavuz et al., 2019), there is a subset of work more related to our problem focused on *controlling* response generation. In one work, transformer models are fine-tuned for dialogue through modifications of the inputs, for example by adding information about the user’s persona (Wolf et al., 2019). The work of Lippe et al. (2020) generates utterances by paraphrasing templated responses. Several works control generation through exemplar-guided methods (Cai et al., 2020; Gupta et al., 2020), which is a different setting from ours since we want to guide generation based on a set of control words rather than through a prototype. One work (Xu et al., 2019) controls response generation through meta-words that include desired attributes of the response (e.g., response length and specificity). Another work controls response generation through control words by adding inductive biases into training to guide generation (Wu et al., 2020). However, this work only controls generation for a single response, rather than controlling several utterances into the future. The closest work to ours is work by (Tang et al., 2019), which proposes a similar problem of long-term control towards a target subject. While the setup is similar, we learn to constrain dialogue responses given a set of control words rather than a target attribute, which also results in a different approach.

Retrieval-augmented generation. Another related area is retrieval-augmented language generation, which inspires our approach of using retrieval to control dialogue generation. REALM (Guu et al., 2020) uses a latent knowledge retriever to identify relevant documents and backpropagates through this retrieval step. In another work (Fan et al., 2020), relevant information is retrieved from an external knowledge base to guide dialogue generation. Several works by Khandelwal et al leverage nearest neighbor approaches to improve performance with no additional training (Khandelwal et al., 2019, 2020). While these works condition on retrieval for uncontrolled generation, we leverage ideas from this space specifically for control in dialogue.

3 Problem definition

We first define the problem of long-term constrained dialogue generation. A conversation $\mathcal{X} = \{s_1, u_1, s_2, u_2, ..., s_T, u_T\}$ is defined as a list of utterances generated by two speakers: the system s that we are trying to control and the user u, which we don't have explicit control over. T denotes the total number of turns in the conversation. Given the current dialogue context of a conversation $x = \{s_1, u_1, ..., s_t, u_t\}$ up until timestep t and a set of control words $\mathcal{W} = \{w_1, w_2, ..., w_M\}$, our goal is to generate the remaining responses of the conversation $\mathcal{R}_{t+1:T} = \{s_{t+1}, ..., s_T\}$ such that the control words $\mathcal{W}$ appear in the future generated responses. We consider a scenario in which someone provides a set of control words to be included in the conversation without assumptions on their order. This means methods need to handle control words given in any order.

We additionally assume access to a historical dataset of conversations $\mathcal{D} = \{x^{(i)}\}$, $i \in [1, ..., N]$ and a fine-tuned language model M on this dataset. We can leverage these inputs in order to control future responses $\mathcal{R}_{t+1:T}$. We focus on the plug-and-play setting (Pascual et al., 2020), in which approaches simply guide the given language model M towards generating the control words without any additional re-training.

4 Proposed metrics for evaluation

Directly evaluating the generated responses in terms of prior evaluation methods can lead to misleading results. Previous works on constrained text generation (Pascual et al., 2020) have used metrics like perplexity to measure fluency and success rate to measure the percentage of control words generated. However, these metrics are more relevant for short-term generation, as they can be gamed in settings where the control words would be naturally distributed across the full conversation. As shown in the left-hand side of Figure 1, when several words are forced into the first response, the conversation may move away from the desired future and control word generation could be inappropriately timed. To better evaluate how well the model generates the right words at the right time, we propose the following new metrics.

The first metric we propose is long-term success rate, which involves simulating conversations with a user language model and computing the percentage of generated control words in the system responses of these simulated roll-outs. Prior work (Ghandeharioun et al., 2019) has used self-play for evaluation, but they do not propose roll-outs as a way to measure dialogue control.

Long-term success rate: Our modified success rate metric is computed as the fraction of control words generated in a full simulated roll-out of the conversation. We compute this as: $s = \frac{n_w}{|\mathcal{W}|}$, where n_w is the number of control words that appear in all of the future system responses $\mathcal{R}_{t+1:T}$.

One limitation of long-term success rate is that it doesn't measure the timing of control words in the conversation. So next, we want to evaluate whether the methods generate control words at appropriate

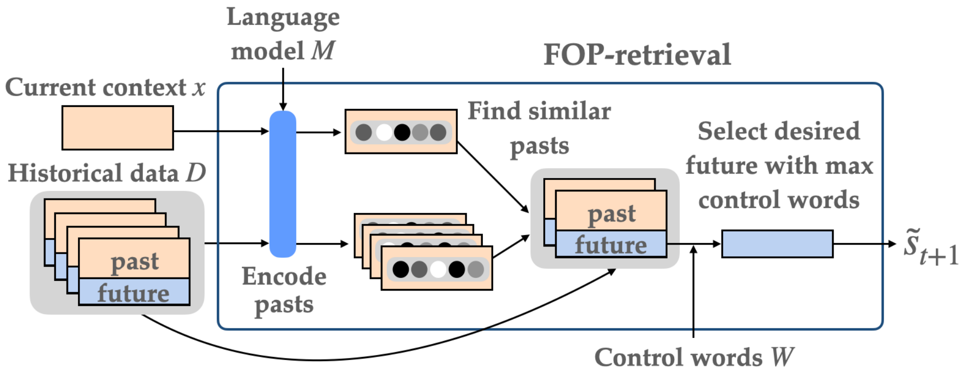

Figure 2: Visualization of FOP-retrieval. First, each conversation in the historical dataset $\mathcal{D}$ is split into many past-future conversation pairs. The current context x and the pasts are encoded using language model M. We use kNN search to identify pasts similar to context x and then select a desired future with the highest number of control words. The output is the first response in the selected future $\tilde{s}_{t+1}$.

points in the conversation. To measure this, we propose computing precision, recall, and F1-score for control words. This particular evaluation is not done in simulation. Instead, we consider each true system response in the evaluation dataset in isolation and generate a response for each, given the conversation history up until that point. We compute the number of generated control words that are correctly predicted, when compared with the control words in the ground truth response *in the same time step*.

For example, on the right side of Figure 1, when generating the second customer response (given the true conversation history up until then), we would count a “correct" prediction for P/R/F1 as a response that includes the word “shirt" (in any position in the response), as it is a control word that appears in the ground truth response in that time step. It is true that control words can also appear later in the conversation, but this setting is already evaluated by long-term success rate in simulated rollouts. After counting the number of correctly predicted control words for each response individually, we aggregate across all responses.

Precision: Precision is calculated at the corpus-level as the number of correctly predicted control words over the total number of predicted control words ($p = \frac{|\text{correct}|}{|\text{predicted}|}$).

Recall: Recall is similarly computed at the corpus-level as the number of correctly predicted control words over the total number of actual control words ($r = \frac{|\text{correct}|}{|\text{actual}|}$).

F1-score: Finally, F1-score combines precision and recall into one metric ($f1 = \frac{(2*p*r)}{(p+r)}$).

These metrics penalize models that condense all control words into one response. Instead, we want the models to naturally generate control words when they are relevant. These metrics evaluate whether control words are generated at the appropriate position in a conversation. To introduce some flexibility, an extension could be to compute a soft version of precision, recall, and F1-score that scores utterances based on whether control words appear within N utterances of the ground truth position.

Finally, we use human evaluation to evaluate how realistic and relevant the generated responses are. Specifically, we evaluate each conversation on fluency, consistency of control word generation, relevance, coherence, and diversity.

5 Retrieval-based Control

We now present our proposed approach for constrained dialogue generation. Inspired by work in retrieval-augmented generation (Guu et al., 2020; Fan et al., 2020), we retrieve similar pasts based on the current context x and use their futures to control dialogue response generation. The key insight here is that by looking at how people have used these control words in similar conversations in the past, we can bias the models towards more natural dialogues. In other words, we use futures of the past conversations to guide the current response generation. To better motivate the use of retrieval in our problem, consider the example conversation in Figure 1. The agent asks which item the customer wants to return, and there are many possible answers (e.g., “I want my pant refunded.", “I want to return gloves I bought yesterday."). Keyword-

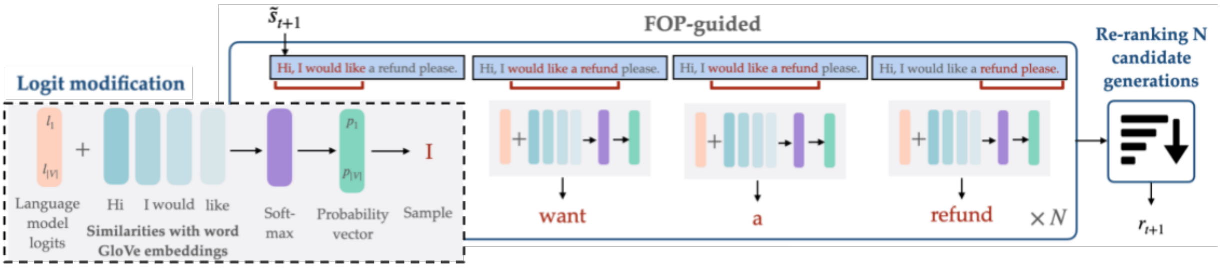

Figure 3: Visualization of FOP-guided. Language model logits are first modified using a window-based approach. All words (and similar words based on GloVe vector similarity) within the window are upweighted with a weight decay. Once any word in the window is generated, the window shifts until the full response is generated. After N generations, a re-ranking step selects the response with the highest number of control words and lowest loss.

based retrieval will surface a response about shirts, a control word, which encourages the model to generate a natural response with that word: “It’s a Nike shirt I bought a week ago."

We present two variants of our retrieval-inspired Futures of the Past (FOP) approach: 1) FOP-retrieval: we retrieve the desired future from historical data and simply use the retrieved utterance as the generated response and 2) FOP-guided: we use the utterance from FOP-retrieval as a reference sentence to guide the model towards similar responses.

The simple variant of our approach, FOP-retrieval, is shown in Figure 2. It focuses on identifying what the model should say now that will lead to the control words in the future. The reason we need to determine what to say now is that control words in our problem are distributed across a long dialogue conversation. One possible approach to generate the current response is to run many roll-outs of the conversation and select the response that leads to the highest number of control words. However, this brute force approach is computationally expensive and will not be effective for rich, diverse conversations. Instead, we leverage historical conversation data to identify the most relevant futures given the current context and control words. The retrieved futures can guide the model towards what to say now that will lead to the desired future. The guided variant, shown in Figure 3, involves guiding the language model towards generating a response similar to the retrieved utterance.

Our proposed approaches address some of the challenges of long-term control for dialogue generation. First, another speaker can change the course of the conversation, which is why we retrieve a new set of similar past contexts at each time step to re-align with the current context. Second, to control responses many steps into the future, we retrieve historical conversations with the desired future (high percentage of control words) and gently nudge the conversation in that direction, thus controlling not only the current utterance but also the future of the conversation.

5.1 Retrieval Futures of the Past (FOP-retrieval)

For the retrieval component, the goal is to select futures that have relevant past contexts as well as desired futures based on the control words. To do this, we employ a multi-step approach. First, we split each conversation $x^{(i)}$ in the historical dataset $\mathcal{D}$ into a set of past-future conversation pairs $x^{(i)} = \{(p, f)^{(i,j)}\}$. We encode the current context $M(x)$ and each past conversation $M(p^{(i,j)})$ using the language model M. Then, we use kNN search based on FAISS, a library for fast nearest neighbor retrieval (Johnson et al., 2019), to identify k similar pasts from the historical data that closely match the current context x. We then filter the futures of these past conversations based on which have the highest percentage of control words.

$$\begin{aligned}\mathtt{KNN_x} &= \mathtt{faiss}(M(x), M(p^{(i,j)}), k)\\ f^* &= \mathtt{argmax}([\mathtt{count}(f^{(i,j)}, \mathcal{W})]_{f^{(i,j)} \in \mathtt{KNN_x}})\\ \tilde{s}_{t+1} &= f^*[0], f^* = \{s_1, u_1, ..., s_T, u_T\}\end{aligned}$$

In the above equations, the `count` function counts the number of control words $\mathcal{W}$ in the future $f^{(i,j)}$. The reference response $\tilde{s}_{t+1}$ is simply the first utterance of the retrieved future.

5.2 Guided Futures of the Past (FOP-guided)

Now that we have a candidate reference response $\tilde{s}_{t+1}$, we can guide the language model towards generating a similar response. To do this, we modify the logits from the language model to encourage generation of the control words or similar words. We start with the first word w_0 in $\tilde{s}_{t+1}$ and upweight logits in a way similar to DBS (Pascual et al., 2020) using similarity of GloVe vector embeddings:

$$l'_i = l_i + \lambda \cdot \texttt{min}(0, \texttt{cos}(\gamma(t_i), \gamma(w_j)))^2,$$

where γ represents GloVe embeddings, t_i is the ith token of the language model's vocabulary V, w_j is the current reference word, and λ is a hyperparameter specifying how much weight to put on generating words similar to w_j.

With this approach, we observed that sometimes the model got stuck on the first word and never moved on to later words. To enable more flexible control, instead of requiring every word to be generated before moving on to the next word, we include a window of size q and increase the logits of each word in the window, with a decay multiplier of $\frac{1}{2^i}$, $i \in q$. If any of the words in the window have been generated, the window is shifted beginning from the generated word with the same window size of q. The process repeats until the full response has been generated.

The decay multiplier is used to encourage the model to generate earlier words in the reference response and not skip words unless it's highly likely. We generate N such responses using this method and include an additional ranking step to select the best one. We first sort by the number of control words in the generated response. If multiple responses generate the highest number of control words, we sort by the loss from the model and select the response with the lowest loss l:

$$\begin{aligned}
\tilde{\mathcal{R}}_{t+1} &= \{M^j(l') | j \in [1, ..., N]\} \\
s^* &= \texttt{max}([\texttt{count}(r, \mathcal{W})]_{r \in \tilde{\mathcal{R}}_{t+1}}) \\
\hat{\mathcal{R}}_{t+1} &= \{r | \texttt{count}(r, \mathcal{W}) = s^*, r \in \tilde{\mathcal{R}}_{t+1}\} \\
r_{t+1} &= \texttt{argmin}([\texttt{loss}(r)]_{r \in \hat{\mathcal{R}}_{t+1}}),
\end{aligned}$$

where $\tilde{\mathcal{R}}_{t+1}$ is the set of N generated responses, using a model with logits l'. The final generated response r_{t+1} is selected based on the two-step ranking process. None of the other approaches include this ranking component.

6 Experimental setup

6.1 Task-Oriented Dialogue Datasets

Our problem and approach are applicable to any general dialogue control setting. In our experiments, we controlled the customer in task-oriented dialogue. This is useful for constructing a customer bot that imitates real-life customers. By controlling the customer simulator (for example through control words), we can develop a training environment for coaching customer service agents in a variety of diverse situations. For all datasets, we select control words from the utterances of the customer by selecting the top M ranked words based on tf-idf. For some real-world applications, control words can also be manually selected by a designer.

MultiWoz 2.3: The first dataset we evaluate on is MultiWoz 2.3 (Han et al., 2020), which is widely used in the dialogue community. The dataset has over 10K dialogues and 5 domains.

TaskMaster-3: The second is another commonly used task-oriented dialogue dataset TaskMaster-3 (Byrne et al., 2019). This dataset has 23,757 dialogues in the movie ticketing domain.

Action-Based Conversations Dataset (ABCD): The final dataset (Chen et al., 2021) includes a set of agent-customer conversations focused on solving customer problems. The dataset contains over 10k dialogues and is also focused on one domain.

6.2 Baselines

$\mathcal{W}_{\text{first}}$: The first baseline is a naive approach that outputs all control words in the first response of the conversation and nothing afterwards, which means words are not appropriately timed.

Fine-tuned: This approach simply generates responses using the fine-tuned language model M.

Prompt: This method is based on prompting approaches (Li and Liang, 2021; Ribeiro et al., 2018; Jiang et al., 2020; Madotto et al., 2021). Because we focus on the plug-and-play setting, we simply append control words to the beginning of the context and generate using this modified input.

Directed Beam Search (DBS): This is a constrained text generation approach (Pascual et al., 2020), in which keywords are generated using logit modification and beam search. It is not optimized for long-term control and is highly dependent on the ordering of control words.

Constrained Sentence Generation by Metropolis-Hastings Sampling (CGMH): This method (Miao et al., 2019) is based on stochastic search methods that insert, delete, and replace words in a sentence with the requirement

Methods	LT-SR	$f1$-score	Human eval	Overall average
Prompt	0.23	0.34	**0.87**	0.48
DBS	0.42	0.28	0.72	0.47
CGMH	**0.90**	0.17	0.3	0.46
FOP-retrieval	0.82	0.39	0.82	**0.68**
FOP-guided	0.74	**0.41**	0.81	0.67

Table 1: Summary table of results, including long-term success rate (LT-SR) from Figure 4 averaged over datasets for 9 control words, F1-score from the overall F1 column of Table 2 that averages F1 over datasets, and human eval from Table 3 averaged over all metrics and divided by 5 to get a number between 0 and 1.

that control words need to be present. It is neither optimized for long-term generation of control words nor forward generation and is particularly susceptible to aggressively generating all control words in a single response. It was also originally applied to the task of keyword-to-phrase generation so we adapted it to dialogue generation by prompting the language model with the dialogue context and also replaced a bidirectional RNN model with our transformer-based model.

7 Results

7.1 Aggregated Results

We begin by presenting a top-level overview of our main baselines and methods because each evaluation metric captures a different aspect of performance. Table 1 includes averaged scores across tasks, parameters, and/or metrics for the main results in Tables 2 and 3 and Figure 4. These include results of our two proposed automatic metrics of long-term success rate and control word F1-score (Section 4) as well as human-evaluated quality metrics (Section 7.4). In subsequent sections, we will examine each of these results more closely.

The key insight in these aggregated results is that while FOP-based methods are not always the best-performing system for each metric, they are consistently the most reliable. Specifically, CGMH has high success rate, but lowest F1 and human scores. Prompt, on the other hand has the highest human evaluation scores but the worst success rate. This is not too surprising. It is, after all, an unmodified language model, so it should be fluent and on topic when viewed by a human. However, given its extremely low success rate, it is not viable for long-form controlled generation. In contrast, FOP-based methods are either the top 1 or 2 performing system across all summary statistics.

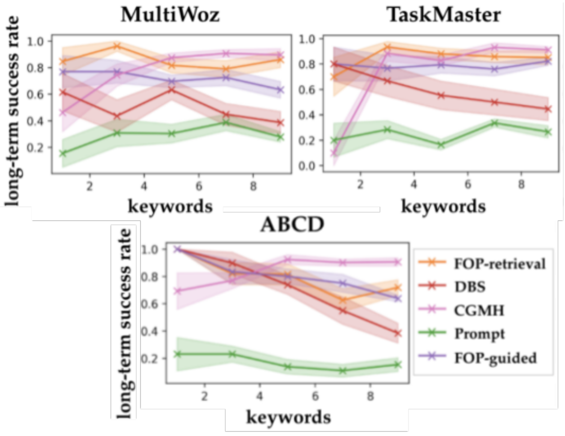

Figure 4: Long-term success rate computed on simulated roll-outs for MultiWoz, TaskMaster, and ABCD. Details on hyperparameters are in Appendix A.3.

7.2 Long-term Success Rate

The first analysis involves comparing all methods on long-term success rate, which measures the percentage of control words in generated simulated roll-outs. To do this, we train a separate user model with the training dataset. We perform a roll-out per test example with 10 generated system responses and 10 generated user responses and compute the percentage of control words in the generated system responses. When counting the number of generated words, we compare word stems.

Figure 4 shows the performance of all approaches when varying the number of control words. Both of our approach variants (FOP-retrieval and FOP-guided) have higher success rates than Prompt and DBS. Prompt is the method with the lowest performance because including the control words at the beginning without any re-training doesn't provide the model with sufficient information to generate the control words. DBS does well when there is only a few control words but struggles as the number of control words increases. This is because DBS is not able to filter out words that are irrelevant at the current time step and instead simply tries to generate the words one by one. This method is also unable to handle words when not in the exact order it should appear.

FOP-retrieval, in some cases, has higher performance than FOP-guided because it will get all keywords in the retrieved response correct. FOP-guided can choose to ignore these keywords if the LM overrides it. So, we would expect FOP-retrieval to do better on this metric, compared to

Methods	MultiWoz 2.3			TaskMaster-3			ABCD			Overall
	p	r	$f1$	p	r	$f1$	p	r	$f1$	avg($f1$)
$\mathcal{W}_{first}$	0.25	0.18	0.21	0.22	0.19	0.2	0.29	0.24	0.27	0.23
Fine-tuned	**0.64**	**0.23**	**0.34**	**0.82**	0.34	0.48	0.68	0.13	0.22	0.35
Prompt	0.45	0.18	0.25	0.81	0.36	0.49	**0.69**	0.18	0.29	0.34
DBS	0.4	0.2	0.27	0.43	0.27	0.33	0.39	0.17	0.24	0.28
CGMH	0.27	0.18	0.21	0.17	0.03	0.05	0.27	0.22	0.24	0.17
FOP-retrieval	0.38	0.18	0.25	0.68	0.38	0.49	0.65	0.33	0.44	0.39
FOP-guided	0.36	0.18	0.24	0.62	**0.48**	**0.54**	0.6	**0.36**	**0.45**	**0.41**

Table 2: Precision, recall, and F1-score for all methods on Multiwoz, TaskMaster, and ABCD. These metrics capture whether the approaches generate control words at the right time by using the control words in the ground truth response as a proxy. The last column is the macro $f1$-score average across all datasets.

Methods	FL	CC	RL	CO	DV
DBS	4.60^{*}	$3.65^{\dagger}$	**3.80**	2.90	$3.10^{\dagger}$
CGMH	$1.70^{\dagger}$	$1.24^{\dagger}$	$1.52^{\dagger}$	$1.12^{\dagger}$	$1.82^{\dagger}$
FOP-retrieval	**4.81**	**4.77**	3.63	2.82	4.35
FOP-guided	$4.36^{\dagger}$	4.53^{*}	3.77	**3.12**	**4.47**
Prompt	4.87	4.98	4.30	4.22	3.42
True	4.88	4.90	4.83	4.92	4.80

Table 3: Human evaluation of simulated roll-outs. **FL**: fluency; **CC**: control-consistency; **RL**: relevance; **CO**: Coherence; **DV**: diversity. * and † indicate significant differences from the best result in that column (bolded, excluding True and Prompt) with p-value < 0.05 and < 0.001 respectively, using Welch's t-test. Annotators rated fluency, control-consistency, and relevance per response, while coherence and diversity were annotated per conversation. All metrics are on a scale of 1 to 5.

FOP-guided. We also include an ablation experiment in Appendix A.1.1 to analyze the effect of removing the sliding window in FOP-guided. CGMH seems to do well on long-term success rate, but human evaluation (Section 7.4) results reveal that the generated responses are not very fluent. This method is one that can game previous evaluation metrics, as it tends to condense many or all control words into one utterance. Thus, these approaches are better evaluated through the next set of metrics: precision, recall, and F1-score.

7.3 Control Word P/R/F1

We now measure how well the approaches generate control words at the right time using precision, recall, and F1-score. Table 2 compares these metrics on all datasets. We see that, on average across all datasets, FOP-guided gets higher F1-scores compared with baseline methods. This is because by retrieving similar futures, we are able to guide the language model towards generating control words at appropriate points in the conversation. FOP-guided does worse on MultiWoz because the dataset contains more domains and has much more variety in the conversations. This diversity makes it hard for retrieval-based methods to successfully find similar conversations to guide generation.

The naive approach $\mathcal{W}_{\text{first}}$ gets low recall and precision since it only outputs the control words at the first utterance. Similar to $\mathcal{W}_{\text{first}}$, CGMH gets low F1-scores because it generates many control words early in the conversation rather than at a natural time. DBS also does not do well on these evaluation metrics as it is highly affected by the order of control words, while our method is able to retrieve similar futures to generate appropriate words at the current time step. Finally, Prompt does well on precision but not on recall as it's not explicitly guided to generate the control words.

7.4 Human Evaluation

Finally, we rate all methods on human evaluation. We follow recent work on good evaluation practices for text generation approaches (Karpinska et al., 2021). Further details are in Appendix A.4.

Fluency: Is the response fluent and grammatical?
Control consistency: *When* control words appear in the response, are they appropriately used?
Relevance: Is the response a natural reply to the previous utterance in the conversation?
Coherence: Are all of the system responses in the conversation coherent with respect to each other?
Diversity: Is there diversity in the system responses of the conversation?

Two raters annotated each example, and agreement was measured using Krippendorff's alpha for each of the 5 metrics (0.84, 0.74, 0.82, 0.76, 0.67). We present results in Table 3 for all five approaches as well as for the ground truth conversation. We focus on comparisons between DBS, CGMH, and the FOP methods, as these were the methods that performed comparably on control metrics (at least 40% on long-term success rate) and thus are reasonable baselines for long-term control.

CGMH consistently gets low scores across all metrics. Compared to DBS, FOP-guided performs similarly on fluency, relevance, and coherence but much better on control-consistency and diversity, which could be because retrieval helps decide naturally what to say throughout the conversation. FOP-guided is at least as good as FOP-retrieval on relevance, coherence, and diversity, while only slightly worse on fluency and control-consistency. This is because FOP-guided uses the context and retrieved sentence to *generate* a response, while FOP-retrieval selects an already fluent historical response. Overall, human evaluation results highlight that both of our proposed methods generate realistic, coherent text, while also generating a high percentage of control words.

8 Conclusion

In this paper, we propose the problem of constrained dialogue generation, which involves controlling dialogue responses such that a set of control words appear at some point in the future of the conversation. We propose a new set of metrics as well as a novel method that leverages retrieval of relevant conversations to control future generated responses. We show on three datasets that our method outperforms several constrained text generation baselines on quantitative metrics as well as human evaluation. As far as we are aware, this is the first work to address the problem of long-term control for dialogue generation.

9 Acknowledgments

We thank S.R.K Branavan and Derek Chen for their insightful feedback. We thank Tianyi Zhang for his starting code that we built upon in this work. We also want to thank Ethan Elenberg, Felix Wu, Clemens Rosenbaum, Sam Altschul, David Sontag, and the rest of the ASAPP research team for all of their feedback in making this work stronger.

A Appendix

A.1 Additional results

A.1.1 Ablation of window in FOP-guided

We ran ablation experiments comparing FOP-guided with a version without the sliding window. Table 4 includes the results for all of the baselines on the most difficult setting for ABCD (9 control words).

Methods	**Long-term success rate**
Prompt	0.15
DBS	0.38
CGMH	0.91
FOP-retrieval	0.72
FOP-guided	0.69
FOP-guided (no-window)	0.56

Table 4: Ablation experiment for the most difficult setting in ABCD (9 control words). FOP-guided without a sliding window performs worse on long-term success rate.

Our approach FOP-guided gets more than 10% more control words in simulated rollouts, compared with FOP-guided without the window approach, which highlights the usefulness of the sliding window component. We also compare the two FOP-guided variants when varying the number of control words and see that FOP-guided consistently performs better (Figure 5).

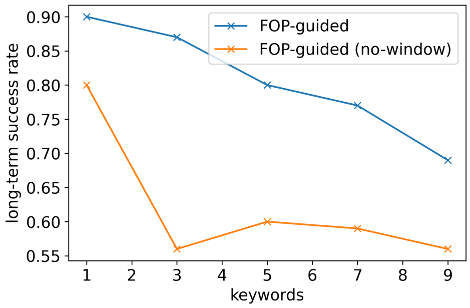

Figure 5: Long-term success rate on ABCD, comparing FOP-guided and FOP-guided without a sliding window.

A.2 Example simulations on ABCD

In Tables 5, 6, 7, 8, and 9, we show some example simulations on the ABCD dataset using a trained agent model for each of the methods.

A.3 Experiment details

We did a hyperparameter search over the following lambda values $\{0, 5, 10, 15, 20, 25\}$ for all datasets. On both ABCD and MultiWoz, the best hyperparameter for FOP-guided was $\lambda = 15$ and for DBS, it was $\lambda = 20$. For TaskMaster, the best hyperparameter for FOP-guided was $\lambda = 10$ and for DBS, it was $\lambda = 15$. CGMH was run with the recommended hyperparameters from the authors.

For all datasets, we used the number of candidate generations for FOP-guided as $N = 10$ and the window size for logit modification as $q = 4$. The number of examples used for multiple splits of each dataset is as follows: For the ABCD dataset, we used 8034 conversations for training and 1004 conversations each for dev and test splits. In the Multiwoz dataset, we used 8438, 1000, 1000 as train, dev and test splits respectively. Finally, for the Taskmaster-3 dataset, we used 16629, 3564, 3564 as train, dev and test datasets respectively.

We used the GPT2-medium model from the hugging-face repository as the pre-trained language model for all of our experiments. This model contains 345M parameters.

For all our experiments, we used a p3.2xlarge EC2 instance. This instance has one GPU with 16GB capacity and 61GB of RAM. Out of all of our experiments, simulated long-term success rate experiments took the most amount of GPU hours to run. Altogether it took somewhere between 24-36 GPU hours to complete all the experiments.

A.4 Human evaluation setting details

We recruited four trained annotators to evaluate generated conversations on the following five metrics, each on a scale of 1 to 5. We split up the examples across the four annotators such that each example was judged by two annotators. We included the ground truth conversation as an additional baseline to act as an upper bound. To ensure the ratings would be high-quality, we provided a rubric, included below, for each metric with examples for different ratings, did an initial pilot for a few sample conversations, and provided a reference sheet to help calibrate the ratings across annotators.

A.4.1 Rubric

Evaluate generated conversations on a few metrics, each on a scale of 1 to 5:

[utterance-level] Fluency: Is this response fluent and grammatical?

- 1: Generated responses do not make any sense, English-wise and grammar-wise, which could include misspelled words, no transition words, limited punctuation, skipped words, etc (e.g., “the figh help order”)
- 3: Generated responses have some good English so you can make out what is being said but it’s not well-formed sentences (e.g., “will you help order”)
- 5: Generated responses have perfect English and perfect grammar. Customers can use lower-case text as less-formal style so first-letter capitalization is not necessary (e.g., “can you help me refund my order?”)

[utterance-level] Relevance: Is this response a natural reply to the previous utterance in the conversation?

- 1: The generated response is not at all relevant to the conversation context/history (e.g., when asked for account id: “I can’t get my promo code”)
- 3: The generated response is somewhat relevant to the conversation context/history but not the best fit (e.g., when asked for account id: “No”)
- 5: The generated response is perfectly relevant and a great response to the conversation context/history (e.g., when asked for account id: “Account ID: 3425435”)

[utterance-level] Control-consistency: If control words appear in this response, are they appropriately used?

- 1: When used, the control words (which are uppercased) make no sense in the generated responses. They are fully forced into the responses (e.g., “TODAY account id: 435650”)
- 3: When used, the control words (which are uppercased) make some sense in the generated responses but are not super smooth (e.g., “I need help with my order, can you help TODAY?“)
- 5: When used, the control words (which are uppercased) are perfectly and naturally used in the generated responses (e.g., “TODAY, I want to buy a shirt. Can you help me?”)

[conversation-level] Diversity: Is there diversity in the customer responses of the conversation?

- 1: Almost all of the responses are repetitive and have no diversity (e.g., “ok” “ok” “ok” “thanks”)
- 3: Some of the generated responses provide diversity while many do not (e.g., “I want to buy a shirt” “can you help me with this?” “ok” “thanks”)
- 5: All of the generated responses are diverse and provide a variety of interesting words through the conversation. The customer can still say ok and thanks but it shouldn’t happen all the time and has to be appropriate for that point in the conversation (e.g., “I want to buy a shirt” “can you help me with this?” “ok sure” “thank you very much for your help!”)

[conversation-level] Coherence: Are all of the customer responses in the conversation coherent with respect to each other?

- 1: All of the responses have very little relation when seen together (e.g., “I want to buy a shirt”, “can you help me with my promo code”, “my subscription expired”)
- 3: Some of the generated responses in a conversation make sense together and some don’t (e.g., “I want to buy a shirt” “I have a promo code for buying this shirt” “my subscription expired”)
- 5: All generated responses make complete sense together (e.g., “I want to buy a shirt”, “I have a promo code for buying this shirt”, “thank you for helping me with this purchase!”)

Learning Dialogue Representations from Consecutive Utterances

*Northwestern University †AWS AI Labs

Abstract

Learning high-quality dialogue representations is essential for solving a variety of dialogue-oriented tasks, especially considering that dialogue systems often suffer from data scarcity. In this paper, we introduce Dialogue Sentence Embedding (DSE), a self-supervised contrastive learning method that learns effective dialogue representations suitable for a wide range of dialogue tasks. DSE learns from dialogues by taking consecutive utterances[1] of the same dialogue as positive pairs for contrastive learning. Despite its simplicity, DSE achieves significantly better representation capability than other dialogue representation and universal sentence representation models. We evaluate DSE on five downstream dialogue tasks that examine dialogue representation at different semantic granularities. Experiments in few-shot and zero-shot settings show that DSE outperforms baselines by a large margin. For example, it achieves 13% average performance improvement over the strongest unsupervised baseline in 1-shot intent classification on 6 datasets. [2] We also provide analyses on the benefits and limitations of our model.

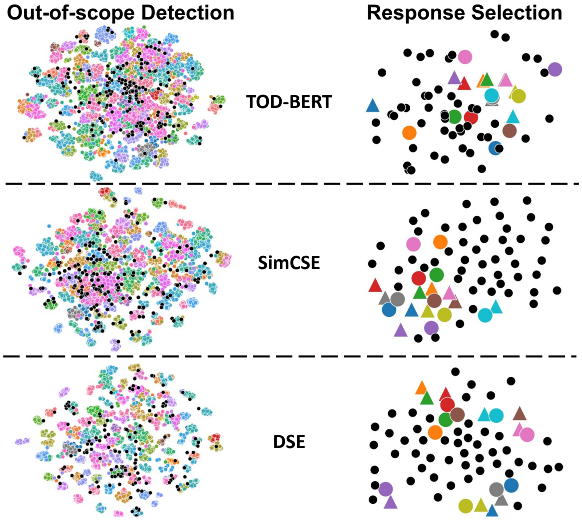

Figure 1: TSNE visualization of the dialogue representations provides by `TOD-BERT`, `SimCSE`, and `DSE`. **Left**: each color indicates one intent category, while the black circles represents out-of-scope samples. **Right**: items with the same color stands for query-response pairs, where triangles represent queries. The black circles represents randomly sampled responses.

1 Introduction

Due to the variety of domains and the high cost of data annotation, labeled data for task-oriented dialogue systems is often scarce or even unavailable. Therefore, learning universal dialogue representations that effectively capture dialogue semantics at different granularities (Hou et al., 2020; Krone et al., 2020; Yu et al., 2021) provides a good foundation for solving various downstream tasks (Snell et al., 2017; Vinyals et al., 2016).

Contrastive learning (Chen et al., 2020; He et al., 2020) has achieved widespread success in representations learning in both the image domain (Hjelm et al., 2018; Lee et al., 2020; Bachman et al., 2019) and the text domain (Gao et al., 2021; Zhang et al., 2021a,b; Wu et al., 2020a). Contrastive learning aims to reduce the distance between semantically similar (positive) pairs and increase the distance between semantically dissimilar (negative) pairs. These positive pairs can be either human-annotated or obtained through various data augmentations, while negative pairs are often collected through negative sampling in the mini-batch.

In the supervised learning regime, Gao et al. (2021); Zhang et al. (2021a) demonstrate the effectiveness of leveraging the Natural Language Inference (NLI) datasets (Bowman et al., 2015; Williams et al., 2018) to support contrastive learning. Inspired by their success, a natural choice of dialogue representation learning is utilizing the

Pair 1: I am looking for restaurants. | What type of food do you like?
Pair 2: What type of food do you like? | I want some pizza.
Pair 3: I want some pizza. | Domino's is a good place for pizza.

Pair 4: Find me some restaurants. | What type of food do you like?
Pair 5: What type of food do you like? | Korean food, please.
Pair 6: Korean food, please. | There is no Korean restaurant.

Figure 2: Illustration of the positive pair construction from dialogues.

Dialogue-NLI dataset (Welleck et al., 2018) that consists of both semantically entailed and contradicted pairs. However, due to its relatively limited scale and diversity, we found learning from this dataset leads to less satisfying performance, while the high cost of collecting additional human annotations precludes its scalability. On the other extreme, unsupervised representation learning has achieved encouraging results recently, among which SimCSE (Gao et al., 2021) and TOD-BERT (Wu et al., 2020a) set new state-of-the-art results on general texts and dialogues, respectively.

SimCSE uses Dropout (Srivastava et al., 2014) to construct positive pairs from any text by passing a sentence through the encoder twice to generate two different embeddings. Although SimCSE outperforms common data augmentations that directly operate on discrete text, we find it performs poorly in the dialogue domain (see Sec. 4.3). This motivates us to seek better positive pair constructions by leveraging the intrinsic properties of dialogue data. On the other hand, TOD-BERT takes an utterance and the concatenation of all the previous utterances in the dialogue as a positive pair. Despite promising performance on same tasks, we found TOD-BERT struggles on many other dialogue tasks where the semantic granularities or data statistics are different from those evaluated in their paper.

In this paper, inspired by the fact that dialogues consist of consecutive utterances that are often semantically related, we use consecutive utterances within the same dialogue as positive pairs for contrastive learning (See Figure 2). This simple strategy works surprisingly well. We evaluate DSE on a wide range of task-oriented dialogue applications, including intent classification, out-of-scope detection, response selection, and dialogue action prediction. We demonstrate that DSE substantially outperforms TOD-BERT, SimCSE, and some other sentence representation learning models in most scenarios. We assess the effectiveness of our approach by comparing DSE against its variants trained on other types of positive pairs (e.g., Dropout and Dialogue-NLI). We also discuss the trade-off in learning dialogue representation for tasks focusing on different semantic granularities and provide insights on the benefits and limitations of the proposed method. Additionally, we empirically demonstrate that using consecutive utterances as positive pairs can effectively improve the training stability (Appendix A.3).

2 Why Contrastive Learning on Consecutive Utterances?

When performing contrastive learning on consecutive utterances, we encourage the model to treat an utterance as similar to its adjacent utterances and dissimilar to utterances that are not consecutive to it or that belong to other dialogues.

On the one hand, this training process directly increases an utterance's similarity with its *true* response and decreases its similarities with other randomly sampled utterances. The ability to identify the appropriate response from many similar utterances is beneficial for dialogue ranking tasks (e.g., response selection). On the other hand, consecutive utterances also contain implicit categorical information, which benefits dialogue classification tasks (e.g., intent classification and out-of-scope detection). Consider pairs 1 and 4 in Figure 2: we implicitly learn similar representations of *I am looking for restaurants* and *Find me some restaurants*, since they are both consecutive with *What type of food do you like?*.

In contrast, SimCSE does not enjoy these benefits by simply using Dropout as data augmentation. Although TOD-BERT also leverages the intrinsic dialogue semantics by combining an utterance with its dialogue context as positive pair, the context is often the concatenation of 5 to 15 utterances.

Due to the large discrepancy in both semantics and data statistics between each utterance and its context, simply optimizing the similarity between them leads to less satisfying representations on many dialogue tasks. As shown in Section 4, TOD-BERT can even lead to degenerated representations on some downstream tasks when compared to the original BERT model.

3 Model

3.1 Notation

Let $\{(x_i, x_{i^+})\}_{i=1}^{M}$ be a batch of positive pairs, where M is the batch size. In our setting, each (x_i, x_{i^+}) denotes a pair of consecutive utterances sampled from a dialogue. Let e_i denote the representation of the text instance x_i that is obtained through an encoder. In this paper, we use mean pooling to obtain representations.

3.2 Training Target

Contrastive learning aims to maximize the similarity between positive samples and minimize the similarity between negative samples. For a contrastive anchor x_i, the contrastive loss aims to increase its similarity with its positive sample x_{i^+} and decrease its similarity with the other $2M - 2$ negative samples within the same batch.

We adopt the *Hard-Negative* sampling strategy proposed by Zhang et al. (2021a), which puts higher weights on the samples that are close to the anchor in the representation space. The underlying hypothesis is that hard negatives are more likely to occur among those that are located close to the anchor in the representation space. Specifically, the Hard-Negative sampling based contrastive loss regarding anchor x_i is defined as follows:

$$\ell^{i,i^+} = -\log \frac{\exp(\mathrm{sim}(e_i, e_{i^+})/\tau)}{\sum_{j\neq i} \exp(\alpha_{ij} \cdot \mathrm{sim}(e_i, e_j)/\tau)} . \tag{1}$$

As mentioned above, here i and i^+ represent the indices of the anchor and its positive sample. We use τ to denote the temperature hyperparameter and $\mathrm{sim}(e_i, e_j)$ represent the cosine similarity of e_i and e_j. In the above loss, α_{ij} is defined as follows,

$$\alpha_{ij} = \frac{\exp(\mathrm{sim}(e_i, e_j)/\tau)}{\frac{1}{2M-2} \sum_{k\neq i^+} \exp(\mathrm{sim}(e_i, e_k)/\tau)} . \tag{2}$$

Noted here, the denominator is averaged over all the other $2M$-2 negatives of x_i. Intuitively, samples that are close to the anchor in the representation space are assigned with higher weights. In other words, α_{ij} denotes the relative importance of instance x_j for optimizing the contrastive loss of the anchor x_i among all $2M$-2 negatives. For every positive pair (x_i, x_{i^+}), we respectively take x_i and x_{i^+} as the contrastive anchor to calculate the contrastive loss. Thereby, the contrastive loss over the batch is calculated as:

$$\mathcal{L} = \frac{1}{2M} \sum_{i=1}^{M} (\ell^{i,i^+} + \ell^{i^+,i}) \tag{3}$$

Here $\ell^{i^+,i}$ is defined by exchanging the roles of instances i and i^+ in Equation (1), respectively.

4 Experiments

We run experiments with five different backbones: BERT$_{\texttt{base}}$, BERT$_{\texttt{large}}$ (Devlin et al., 2018), RoBERTa$_{\texttt{base}}$, RoBERTa$_{\texttt{large}}$ (Liu et al., 2019b), DistilBERT$_{\texttt{base}}$ (Sanh et al., 2019). Due to the space limit, we only present the results on BERT$_{\texttt{base}}$ in the main text. The results of other models are summarized in Appendix D. We use the same training data as TOD-BERT for a fair comparison. We summarize the implementation details and data statistics of both pre-training and evaluation in Appendices A and B, respectively.

4.1 Baselines

We compare DSE against several representation learning models that attain state-of-the-art results on both general text and dialogue languages. We categorize them into the following two categories.

Supervised Learning `SimCSE-sup` (Gao et al., 2021) is the supervised version of SimCSE, which uses entailment and contradiction pairs in the NLI datasets (Bowman et al., 2015; Williams et al., 2018) to construct positive pair and hard negative pair accordingly. In a similar vein, `PairSupCon` (Zhang et al., 2021a) leverages the entailment pairs as positive pairs only while proposing an unsupervised hard negative sampling strategy that we summarized in Section 3.2. Following this line, we also evaluate DSE against its variant `DSE-dianli` trained on the Dialogue Natural Language Inference dataset (Welleck et al., 2018) by taking all the *entail* pairs as positive pairs.

Task	Dataset	Evaluation Setting	Num.
Intent Classification	`Clinc150`, `Snips`, `Hwu64`, `Bank77`, `Appen-A`, `Appen-H`	1-shot & 5-shot fine-tune 1-shot & 5-shot similarity	10 10
Out-of-scope Detection	`Clinc150`	1-shot & 5-shot similarity	10
Utterance-level Response Selection	`AmazonQA`	0-shot similarity 500-shot & 1000-shot fine-tune	1 5
Dialogue-level Response Selection	`DSTC7-Ubuntu`	0-shot similarity	1
Dialogue Action Prediction	`DSTC2`, `GSIM`	10-shot & 20-shot fine-tune	5

Table 1: Summarization of all the experimental settings. Please see Appendix B.2 for details of each dataset. The last column (**Num**) indicates the number of independent experiments with different random seeds (we report the averaged results). Since there is no randomness in 0-shot evaluations, we only run them once.

Unsupervised Learning `TOD-BERT` (Wu et al., 2020a) optimizes a contrastive response selection objective by treating an utterance and its dialogue context as positive pair. `DialoGPT` (Zhang et al., 2019) is a dialogue generation model that learns from consecutive utterance by optimizing a language modeling target.[3] `SimCSE-unsup` (Gao et al., 2021) uses Dropout (Srivastava et al., 2014) to construct positive pairs. In the general text domain, `SimCSE-unsup` has attained impressive performance over several explicit data augmentation strategies that directly operate on the discrete texts. To test its effectiveness in the dialogue domain, we compare DSE against its variant `DSE-dropout` where augmentations of every single utterance are obtained through Dropout.

The evaluations on `DSE-dropout` and `DSE-dianli` allow us to fairly compare our approach against the state-of-the-art approaches in both the supervised learning and the unsupervised learning regimes.

4.2 Evaluation Setting

To accommodate the fact that obtaining a large number of annotations is often time-consuming and expensive for solving the task-oriented dialogue applications, especially considering the variety of domains and certain privacy concerns, we mainly focus on few-shot or zero-shot based evaluations.

4.2.1 Evaluation Methods

Considering that only a few annotations are available in our setting, we mainly focus on the **similarity-based** evaluations, where predictions are made based on different similarity metrics applied in the embedding space without requiring updating the model.

We use different random seeds to independently construct multiple (See Table 1) few-shot train and validation sets from the original training data and use the original test data for performance evaluation. To examine whether the performance gap reported in the similarity-based evaluations is consistent with the associated fine-tuning approaches, we also report the **fine-tuning** results. We perform early stopping according to the validation set and report the testing performance averaged over different data splits.

4.2.2 Tasks and Metrics

We evaluate all models considered in this paper on two types of tasks: **utterance-level** and **dialogue-level**. The utterance-level tasks take a single dialogue utterance as input, while the dialogue-level tasks take the dialogue history as input. These two types of tasks assess representation quality on dialogue understanding at different semantic granularities, which are shared across a variety of downstream tasks.

Intent Classification is an utterance-level task that aims to classify user utterances into one of the pre-defined intent categories. We use Prototypical Networks (Snell et al., 2017) to perform the similarity-based evaluation. Specifically, we calculate a prototype embedding for each category by averaging the embedding of all the training samples that belong to this category. A sample is classified into the category whose prototype embedding is the most similar to its own. We report the classification accuracy for this task.

Out-of-scope Detection advances intent classification by detecting whether the sample is out-of-

---

[3] We use mean pooling of its hidden states as sentence representation, which leads to better performance than using only the last token. We use its *Medium* version that has twice as many parameters as $\textbf{BERT}_{\textbf{base}}$, since we found its *Small* version performs dramatically worse under our settings.

scope, *i.e.,* does not belong to any pre-defined categories. We adapt the aforementioned Prototypical Networks to solve it. For a test sample, if its similarity with its most similar category is lower than a threshold, we classify it as out-of-scope. Otherwise, we assign it to its most similar category. For each model, we calculate the `mean` and `std` (standard deviation) of the similarity scores between every sample and its most similar prototype embedding, and take `mean−std` and `mean` as the threshold, respectively. The evaluation set contains both in-scope and out-of-scope examples. We evaluate this task with four metrics: 1) Accuracy: accuracy of both in-scope and out-of-scope detection. 2) In-Accuracy: accuracy reported on 150 in-scope intents. 3) OOS-Accuracy: out-of-scope detection accuracy. 4) OOS-Recall: recall of OOS detection.

Utterance-level Response Selection is an utterance-level task that aims to find the most appropriate response from a pool of candidates for the input user query, where both the query and response are single dialogue utterances. We formulate it as a ranking problem and evaluate it with Top-k-100 accuracy (a.k.a., k-to-100 accuracy), a standard metric for this ranking problem (Wu et al., 2020a). For every query, we combine its ground-truth response with 99 randomly sampled responses and rank these 100 responses based on their similarities with the query in the embedding space. The Top-k-100 accuracy represents the ratio of the ground-truth response being ranked at top-k, where k is an integer between 1 and 100. We report the Top-1, Top-3, and Top-10 accuracy of the models.

Dialogue-Level Response Selection is a dialogue-level task. The only difference with the *Utterance-level Response Selection* is that query in this task is dialogue history (e.g., concatenation of multiple dialogue utterances from different speakers). We also report the Top-1, Top-3, and Top-10 accuracy for this task.

Dialogue Action Prediction is a dialogue-level task that aims to predict the appropriate system action given the most recent dialogue history. We formulate it as a multi-label text classification problem and evaluate it with model fine-tuning. We report the Macro and Micro F1 scores for this task.

4.3 Main Results

Intent Classification & Out-of-scope Detection Tables 2 and 3 show the results of similarity-based intent classification and out-of-scope detection. The fine-tuning based results are presented in Appendix C. As we can see, DSE substantially outperforms all the baselines. In intent classification, it attains 13% average accuracy improvement over the strongest unsupervised baseline. More impor-

Table 4: Results on 0-shot response selection on `AmazonQA` (utterance-level) and `DSTC7-Ubuntu` (dialogue-level).

tantly, DSE achieves a 5%–10% average accuracy improvement over the supervised baselines that are trained on a large amount of expensively annotated data. The same trend was observed in out-of-scope detection, where DSE achieves 13%-20% average performance improvement over the strongest unsupervised baseline. The comparison between DSE, DSE-dropout, and DSE-dianli further demonstrates the effectiveness of using consecutive utterances as positive pairs in learning dialogue embeddings.

The left panel of Figure 1 visualizes the embeddings on the `Clinc150` dataset given by TOD-BERT, SimCSE, and DSE, which provides more intuitive insights into the performance gap. As shown in the figure, with the DSE embeddings, in-scope samples belonging to the same category are closely clustered together. Clusters of different categories are clearly separated with a large margin, while the out-of-scope samples are far away from those in-scope clusters.

Response Selection Table 4 shows the the results of similarity-based 0-shot response selection on utterance-level (AmazonQA) and dialogue-level (DSTC7-Ubuntu). Results of finetune-based evaluation on AmazonQA show similar trend and we summarize in Table 9 in Appendix. In Table 4, the large improvement attained by DSE over the baselines indicate our model's capability in dialogue response selection, in presence of both single-utterance query or using long dialogue history as query. The right panel of Figure 1 further illustrates this. It visualizes the embeddings of questions and

answers in the AmazonQA dataset calculated by DSE, SimCSE, and TOD-BERT. With the DSE embedding, each question is placed close to its real answer while far away from other candidates.

Dialogue Action Prediction Table 5 shows that DSE outperforms all baselines except TOD-BERT, which indicates its capability in capturing dialogue-level semantics. To better understand TOD-BERT's superiority over DSE on this task, we further investigate this task and find its data format is special. Concretely, here each input consists of multiple utterances explicitly concatenated by using two special tokens [SYS] and [USR] to indicate the system and user inputs, respectively. For example, ([SYS] hi [USR] how are you? [SYS] I'm good). It follows the same format as the queries[4] used for training TOD-BERT, while DSE uses a single utterance as the query.

4.4 Trade-off in Query Construction

To understand the impact of using multiple utterances as queries, we train three new variants of DSE. Specifically, we construct positive pairs as: $(u_1$ [SEP] $u_2, u_3)$, $(u_2$ [SEP] $u_3, u_4)$, where u_i represents the i-th utterance in a dialogue. We use the [SEP] token to concatenate two consecutive utterances as query. We refer DSE trained with this data as $\mathtt{DSE}_{2-1}$ since it uses 2 utterances as the query and 1 utterance as the response. Similarly, we train another variant $\mathtt{DSE}_{3-1}$. Lastly, we also combine the positive pairs constructed for training DSE, DSE$_{2\text{-}1}$, and DSE$_{3\text{-}1}$ together to train another variant named $\mathtt{DSE}_{123-1}$.

As shown in Table 5, by simply increasing the number of utterances within each query to three, DSE again outperforms TOD-BERT, and the improvement further expands when trained with the combined set, *i.e.,* $\mathtt{DSE}_{123-1}$. Our results demonstrate that using long queries that consist of 5 to 15 utterances as what TOD-BERT does is not necessary even for dialogue action prediction. We further demonstrate this by evaluating DSE and its variants on all the other four tasks in Table 6, where our model outperforms TOD-BERT by a large margin. As it indicates, by using a single utterance as a query, DSE achieves a good balance among different dialogue tasks. In cases where dialogue action prediction is of great importance, augmenting the original training set of DSE with positive pairs constructed by using query consisting of 2 to 3 utterances is good enough to attain better performance while only incurring a slight performance drop on other tasks.

4.5 Potential Limitation

Considering the effectiveness of using consecutive utterances as positive pairs, a natural yet important question is: what are the potential limitations of

---

[4] We use *query* to refer the first utterance in a positive pair and use *response* to refer the other one

our proposed approach? When using consecutive utterances as positive pairs for contrastive learning, an assumption is that responses to the same query are semantically similar. Vice versa, queries that prompt the same answer are similar. This assumption holds in many scenarios, yet it fails sometimes.

It may fail when answers have different semantic meanings. Take the pairs 2 and 5 in Figure 2 as an example. Through our data construction, we implicitly consider *I want some pizza* and *Korean food, please* to be semantically similar since they are both positively paired with *What type of food do you like*. Although this may be correct in some coarse-grained classification tasks since these two sentences generally represent the same intent (e.g., order food), using them as positive pairs can introduce some noise when considering more fine-grained semantics. This problem is further elaborated when answers are general and ubiquitous, *e.g., Thank you*. Since these utterances can be used to respond to countless types of dissimilar queries, *e.g., I have booked a ticket for you* v.s. *Happy birthday*, we may implicitly increase the similarities among highly dissimilar utterances when training on these samples, which is undesirable.

We verify this on the NLI datasets, where the the task is to identify whether one sentence semantically entails or contradicts the anchor sentence. For each anchor sentence, we calculate its cosine similarities with both the true *entailment*, *contradiction* sentences in the representation space. We classify the sentence with higher cosine similarity with the anchor as entailment and the other as the contradiction. Despite DSE achieves better classification accuracy (76.62) than BERT (69.40) and TOD-BERT (70.51), it underperforms SimCSE-unsup (80.31). Although using dropout to construct positive pairs is not as effective as ours in many dialogue scenarios, this method better avoids introducing fine-grained semantic noise.

Despite the limitations, using consecutive utterances as positive pairs still leads to better dialogue representation than the elaborately labeled NLI datasets, indicating the great value of the information contained in dialogue utterances.

5 Related Work

Positive Pair Construction Popular supervised sentence representation learning often takes advantage of the human-annotated natural language inference (NLI) datasets (Bowman et al., 2015; Williams et al., 2018) for contrastive learning (Gao et al., 2021; Zhang et al., 2021a; Reimers and Gurevych, 2019; Cer et al., 2018). These sentence pairs either entail or contradict each other, making them the great choice for constructing positive and negative training pairs. Unsupervised sentence representation learning often relies on variant data augmentation strategies. Logeswaran and Lee (2018) and Giorgi et al. (2020) propose using sentences and their surrounding context as positive pairs. Other works resort to popular NLP augmentation methods such as word permutation (Wu et al., 2020b) and back-translation (Fang et al., 2020). Recently, Gao et al. (2021) demonstrates the superiority of using Dropout over other data augmentations that directly operate on the discrete texts.

Contrastive Learning Methods Contrastive learning is key to recent advances in learning sentence embeddings. Many contrastive learning approaches utilize memory-based methods, which draw negative samples from a memory bank of embeddings (Hjelm et al., 2018; Bachman et al., 2019; He et al., 2020). On the other hand, Chen et al. (2020) introduces a memory-free contrastive framework, SimCLR, that takes advantage of negative sampling within large mini-batches. Promising results were also reported in the NLP domain. To name a few, Gao et al. (2021) leverages both within batch negatives and the 'contradiction' annotations in NLI; and Zhang et al. (2021a) propose an unsupervised hard-negative sampling strategy.

Dialogue Language Model Learning dialogue-specific language models has attracted a lot of attention. Along this line, Zhang et al. (2019) adapts the pre-trained GPT-2 model (Radford et al., 2019) on Reddit data to perform open-domain dialogue response generation. Bao et al. (2019) evaluates multiple dialogue generation tasks after training on Twitter and Reddit data (Wolf et al., 2019; Peng et al., 2020). For dialogue understanding, Henderson et al. (2019b) propose a response selection approach using a dual-encoder model. They pre-train the response selection model on Reddit and then fine-tune it for different response selection tasks. Following this, Henderson et al. (2019a) introduces a more efficient conversational model that is pre-trained with a response selection target on the Reddit corpus. However, they did not release code or pre-trained models for comparison. Wu et al. (2020a) combines nine dialogue datasets to obtain a large and high-quality task-oriented dialogue corpus. They introduce the TOD-BERT model by further pre-training BERT on this corpus with both the masked language modeling loss and the contrastive response selection loss.

6 Conclusion

In this paper, we introduce a simple contrastive learning method DSE that learns dialogue representations by leveraging consecutive utterances in dialogues as positive pairs. We conduct extensive experiments on five dialogue tasks to show that the proposed method greatly outperforms other state-of-the-art dialogue representation models and universal sentence representation methods. We provide ablation study and analysis on our proposed data construction from different perspectives, investigate the trade-off between different data construction variants, and discuss the potential limitation to motivate further exploration in representation learning on unlabeled dialogues. We believe DSE can serve as a drop-in replacement of the dialogue representation model (e.g., the text encoder) for a wide range of dialogue systems.

A Pre-train

In this section, we present the training data, implementation details, and training stability of model pre-training.

A.1 Data

We utilize the corpus collected by TOD-BERT (Wu et al., 2020a) to construct positive pairs. This dataset is the combination of 9 publicly available task-oriented datasets: MetaLWOZ (Lee et al., 2019), Schema (Rastogi et al., 2020), Taskmaster (Byrne et al., 2019), MWOZ (Budzianowski et al., 2018), MSR-E2E (Li et al., 2018), SMD (Eric and Manning, 2017), Frames (Asri et al., 2017), WOZ (Mrkšić et al., 2016), CamRest676 (Wen et al., 2017). The combined dataset contains 100707 dialogues with 1388152 utterances over 60 domains. We filter out sentences with less or equal to 3 words and end up with 892835 consecutive utterances (for DSE) and 879185 unique sentences (for DSE-dropout). Note that, the training data of SimCSE-unsup consists of 1 million sentences from Wikipedia. That says, on the one hand, we use the same dataset as TOD-BERT but with our proposed data construction. On the other hand, we use a similar number of training samples as SimCSE-unsup. We believe such data construction makes the comparisons fair enough.

A.2 Hyperparameters

We add a contrastive head after the Transformer model and use the outputs of the contrastive head to perform contrastive learning. We use a two-layer MLP with size $(d \times d, d \times 128)$ as the contrastive head. We use Adam (Kingma and Ba, 2014) with a batch size of 1024 and a constant learning rate as the optimizer. We set the learning rate for contrastive head as $3e-4$ and the learning rate for the Transformer model as $3e-6$. The temperature hyperparameter τ is set as 0.05. We train the model for 15 epochs (see Appendix A.3 for more details) and save the model at the end for evaluation. We use the same hyperparameters across all the experiments for BERT$_{\texttt{base}}$, RoBERTa$_{\texttt{base}}$, and DistilBERT$_{\texttt{base}}$ models. For BERT$_{\texttt{large}}$ and RoBERTa$_{\texttt{large}}$, we change the batch size to 512 to fit it into the GPUs. Pre-training of the DistilBERT$_{\texttt{base}}$, BERT$_{\texttt{base}}$, and BERT$_{\texttt{large}}$ model respectively takes 3, 4, and 13 hours on 8 NVIDIA® V100 GPUs[5].

---

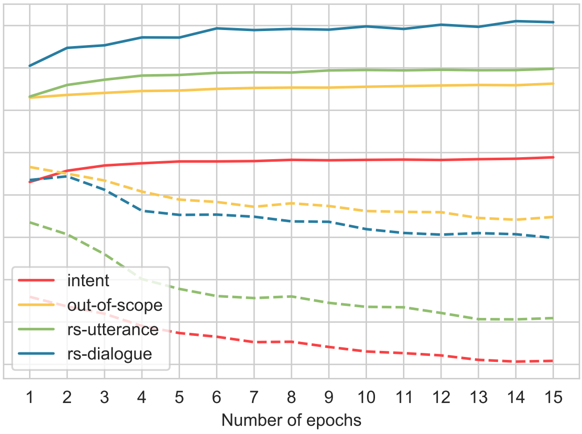

Figure 3: `DSE` and `DSE-dropout`'s performance on each task at every epoch. The dashed lines represent the results of `DSE-dropout`.

A.3 Training Stability

In this section, we analyze the model's stability in terms of training steps when training with different type of positive pairs. We compare two data construction methods: consecutive utterances (DSE) and dropout (DSE-dropout). We first train each model for 15 epochs, save the checkpoint at the end of each epoch and evaluate each checkpoint with similarity-based methods. Figure 3 shows the two model's average performances on intent classification, out-of-scope detection, utterance-level response selection and dialogue-level response selection.

This result further illustrates the effectiveness of using consecutive utterances as positive pairs for learning dialogue representation. As shown in the figure, DSE's performance on all the tasks consistently improves during the training process, while DSE-dropout achieves the best performance at the first epoch and significantly loses performance afterwards. Besides, DSE's performance is less sensitive to the training steps. It achieves stable performance after about 5 epochs. In contrast, DSE-dropout's performance drops dramatically during the training process, yet it never surpasses DSE's performance. Therefore, we report DSE-dropout's performance at the first epoch in all the tables.

B Evaluation Setup

In this section, we present evaluation details and introduction to the evaluation dataset. Throughout this paper, we use *cosine similarity* as the similarity metric and *mean pooling of token embeddings* as the sentence representation. For baseline models, we report the better results of using its default setting (e.g., last hidden state of the [CLS] token as sentence embedding for SimCSE) and mean pooling.

B.1 Hyperparameters

We use the same hyperparameters for all the models. For similarity-based methods, the only hyperparameter is the max sequence length, we empirically choose a number that can fit at least 99% of the samples. We respectively set it as 64, 64, 128, and 128 for intent classification, out-of-scope detection, utterance-level response selection and dialogue-level response selection. Hyperparameters for fine-tune evaluations as listed as follows:

Intent Classification We fine-tune all the models for 50 epochs with a batch size of 16 and learning rate of $3e$-05. We evaluate the model on the few-shot validation set after every 10 steps. Early stopping is applied based on the model's validation results. The max sequence length is set as 64 and the dropout at the classification layer is set as 0.1.

Utterance-level Response Selection In this task, we set the max sequence length as 128 and batch size as 100. Other hyperparameters are same as those in Intent Classification. We use the original SimCLR loss (Chen et al., 2020) to optimize the model.

Dialogue Action Prediction In this task, we fine-tune all the models for 100 epochs with a batch size of 32 and learning rate of $5e$-05. We evaluate the model on the few-shot validation set after every 30 steps. Early stopping is also applied. The max sequence length is set as 32 since we find shorter inputs leads to much better performance for all the models. We truncate sentences from the head to keep the most recent dialogue utterances as model input. We set the dropout at the classification layer as 0.2.

B.2 Datasets

Intent Classification We use 4 popular publicly available datasets: `Clinc150` (Larson et al., 2019) with 150 categories and 4500 test sample, `Bank77` (Casanueva et al., 2020) with 77 categories and 3080 test sample, `Snips` (Coucke et al., 2018) with 7 categories and 1447 test sample, and `Hwu64` (Liu et al., 2019a) with 64 categories and 3853 test sample. To apply the Clinc150 dataset in intent classification, we remove all the out-of-scope samples. We also use an internal dataset named `Appen`, whose texts are transcribed from customer recording. This dataset contains 30 categories and 310 test samples. There are two versions of each sentence. One is transcribed by Automatic Speech Recognition (ASR), which includes some ASR noise (e.g., transcribe errors). The other is transcribed by human annotator. We refer them respectively as `Appen-A` and `Appen-H`.

Out-of-scope Detection We use the entire `Clinc150` dataset, which contains 150 in-scope intents and one out-of-scope intent. There are 5500 test samples in total (4500 in-scope and 1000 out-of-scope).

Utterance-level Response Selection We use the `AmazonQA` dataset (Wan and McAuley, 2016), which contains 5334606 question-answer pairs about different products. Following Henderson et al. (2019a), we randomly select 300K pairs for model evaluation.

Dialogue-Level Response Selection We use the `DSTC7-Ubuntu` dataset (Lowe et al., 2017), which contains conversations about the Ubuntu system. Each query of this dataset comes together with one ground-truth response and 100 candidate responses. We combine the validation and test sets together for evaluation, which results in 6000 evaluation samples.

Dialogue Action Prediction We use the `DSTC2` (Henderson et al., 2014) and `GSIM` (Shah et al., 2018) dataset processed by Wu et al. (2020a). These two datasets respectively contains 13/19 actions and 1117/1039 test samples. The average number of samples in 10-shot and 20-shot training is 79 and 149 for DSTC2; 60 and 120 for GSIM.

C Results of BERT$_{\texttt{base}}$

In this section, we present other evaluation results on the BERT$_{\texttt{base}}$ model, including 1-shot and 5-shot fine-tune on intent classification (Table 7), 5-shot similarity-based out-of-scope detection (Table 8), and 500-shot and 1000-shot fine-tune on AmazonQA response selection (Table 9).

D Results of Other Backbone Models

In this section, we present similarity-based evaluation results on other four backbone models: BERT$_{\texttt{large}}$, RoBERTa$_{\texttt{base}}$, RoBERTa$_{\texttt{large}}$, and DistilBERT$_{\texttt{base}}$. Table 10 shows the results of similarity-based intent classification and Table 11 shows the results of similarity based response selection on both utterance-level and dialogue-level. As shown in the tables, DSE leads to consistent and significant performance boost on all the backbone models.

Abstract

Ethics is one of the longest standing intellectual endeavors of humanity. In recent years, the fields of AI and NLP have attempted to address ethical issues of harmful outcomes in machine learning systems that are made to interface with humans. One recent approach in this vein is the construction of NLP morality models that can take in arbitrary text and output a moral judgment about the situation described. In this work, we offer a critique of such NLP methods for automating ethical decision-making. Through an audit of recent work on computational approaches for predicting morality, we examine the broader issues that arise from such efforts. We conclude with a discussion of how machine ethics could usefully proceed in NLP, by focusing on current and near-future uses of technology, in a way that centers around transparency, democratic values, and allows for straightforward accountability.

1 Introduction

This paper offers a general critique of the nascent NLP task of computing moral and ethical decisions from text through reading a prominent system for moral prediction, Jiang et al. (Delphi, 2021), against the grain. We select Delphi for its prominence, and because it has received significant attention and criticism from the general public.[1] In contrast to that criticism, much of which has focused on details of the particular outputs of the model, our goal is to highlight broader, general issues with the task of automatically predicting the morality of judgments of text situations, and expound on why any such NLP model should be considered unsafe at any accuracy.

Work that uses NLP techniques to automate morality "aims to assess the ability of [NLP] models to make moral decisions in a broad set of everyday . . . situations" (Jiang et al., 2021). Delphi, is trained to emulate three conceptualizations of human moral and ethical judgments (see Figure 1): a free-form question answering (QA) task, a Yes/No QA task, and relative QA task, the latter judging how two statements rank in terms of morality.[2] The fact that the Delphi project includes multiple conceptualizations of human moral and ethical judgments makes it an ideal candidate for a case study for morality models in NLP, as we will argue that no currently existing conceptualization of the morality task resolves the issues we outline in this audit.

Through our discussion, we intend to highlight that "ethical inquiry in any domain is not a test to be passed or a culture to be interrogated, but a complex social and cultural achievement" (Ananny, 2016), and offer a critique of machine ethics from such a perspective. Our critique is divided into several points of rebuttal to the task. First, we discuss issues with the conceptualization of the task and the poor fit between the task and the learning paradigms employed for it. Then, we discuss issues with the training data available, as illustrated by COMMONSENSE NORM BANK—the corpus the authors develop to train Delphi—as a foundation for training a machine learning model that makes morality judgments. For example, it contains judgments of situations that are not morality judgments. We also consider the implication of COMMONSENSE NORM BANK, i.e. that ethical and moral judgments can be derived from short text snippets with little context.

Next, we argue that, despite the authors' assertion that Delphi is "the first unified model of descriptive ethics," any model developed for the task will necessarily be an inconsistent model of nor-

[2] Note that the relative QA task is no longer available in the Ask Delphi demo, but we include it in our discussion for completeness.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 769 - 779
July 10-15, 2022

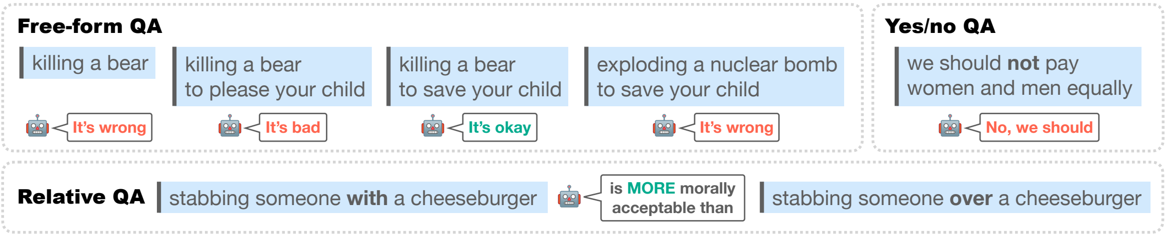

Figure 1: The three QA tasks Delphi computes (image source: Jiang et al. 2021). Note that the Relative QA fragment "stabbing someone with a cheeseburger" is structurally ambiguous: Either (i) someone with a cheeseburger was stabbed, or (ii) someone was stabbed using a cheeseburger. It is not clear whether (i) ought to be more morally acceptable than "stabbing someone over a cheeseburger."

mative ethics. Indeed, through generation, Delphi outputs a prescriptive moral judgment for any input situation. Given this, we also question (i) whether there ever could be sufficient diversity of moral judgment in a crowd-sourced dataset in practice, and (ii) whether aiming for a "diversity of moral perspective" is compatible with the desire for a morality model (especially one trained on an unconstrained crowd-sourced corpus).

We then turn to the inherent contradictions that arise when modeling ethics by averaging over individual morality judgments. Systems like Delphi are at best capable of approximating the morality judgments of the population they were trained on. However, the average human judgment is not a good substitute for a system of ethics, since ethical evaluation is an open-ended, debate-based, sociopolitical process. Ethics are not a static good that can be extracted from the public opinion of a given moment, but are instead continuously formed and negotiated through debate and dissent from previously accepted norms and values (see e.g., Wheeler et al. 2019). Thus, averaging over existing arguments cannot serve as a replacement for the processes of debate and negotiation.

Finally, we discuss some practical implications of the general prospect of utilizing Delphi-like models to automate moral decision-making. Systems for predicting morality like Delphi, lack agency and thus cannot be held responsible for their decisions. This raises a concern over who ought to bear the responsibility for any potential infraction such systems could make if deployed in an envisioned future. We therefore question an assumption implicit in NLP projects like Delphi that models ought to be ascribed the agency necessary to make moral prescriptions. We contend that, without an appropriate method of holding an agent to account, moral judgments are not of inherent utility, but dangerous: Through foreclosing the possibility of debate and contestation, such models undermine the essential social foundations of ethical decision making.

We conclude the paper by discussing how we believe NLP work at the intersection of ethics and machine learning could usefully proceed. We believe it is more crucial to address questions of morality or ethics in current and near-future use of technology, rather than considering hypothetical and distant-future uses (Birhane and van Dijk, 2020). Furthermore, we believe inquiries into the morality and ethics of current and near-future uses must keep actual human moral perspectives and their contradictions firmly at the forefront. We end with a word of caution: Researchers in NLP and AI more broadly should not base their work on the assumption of a particular future, as Delphi and others do, where the application technology *must* be made dependent on automated moral judgments, and humans (be they crowd-workers, researchers outside NLP, or other affected parties) have been cut out of the loop.

2 Background

In this section, we describe and discuss relevant previous work in ethical NLP and the assumptions behind the NLP task of generating moral judgments and the creation of models like Delphi. Incorporating ethics into NLP work explicitly is a relatively new development (Hovy and Spruit, 2016). For example, the TALN ETeRNAL, the first workshop on ethics in NLP, only took place seven years ago. Recent works have begun to supplement tasks like stance detection with additional morality annotations (Rezapour et al., 2019), or to use NLP tools to track changes in human morality over time (Ramezani et al., 2021). Other work seeks to characterize what language models already implicitly represent about morality by investigating their learned sentence representations (Jentzsch et al., 2019; Schramowski et al., 2020, 2021). Still other works like Prabhumoye et al. (2021) and Card and Smith (2020) focus on particular ethical theories and how they might be used in NLP to guide our modeling efforts, and Bender et al. (2020) foreground the importance of ethics training in NLP education. Works like Jiang et al. (2021) and Hendrycks et al. (2021) go beyond this in fine-tuning language models to output moral prescriptions for sentential descriptions of situations. As such, Hendrycks et al. (2021) and Jiang et al. (2021) each represent one further step along an evolving trajectory in research on the intersection of NLP and ethics: A shift from measurement and classification to generation, and thus from a murky mix of descriptive and prescriptive aspects, to models producing prescriptive outputs.

2.1 Underlying Ethical Assumptions

Here, we provide an overview of implicit and explicit assumptions made in the efforts to use machine learning to generate moral judgments, as exemplified by Jiang et al. As input, they provide linguistic descriptions of situations paired with human judgments about those situations to Delphi, in the hope that it will arrive at a generalizable notion of ethics. Given this operationalization, the authors clearly assume that a valid system of ethics can be approximated by a set of judgments communicated through snippets of text. Rather than simply surveying judgments of different populations to arrive at a descriptive picture, as would be standard in fields like psychology or sociology, this approach attempts to extract general ethical principles from individual judgments. As we will argue in §3.2.1, this means Delphi is not a model of descriptive ethics, as claimed, but rather one of normative ethics.

Similar to Delphi is the work by Hendrycks et al. (2021), which also trained machine learning models on sentences describing human ethical judgments. Hendrycks et al. additionally provide their model with explicit ethical perspectives to ground against; for example, one may ask their model to mimic a deontological or a utilitarian perspective. In this way, Hendrycks et al. (2021) seek to draw out salient norms from already normative schools of ethical thought. Jiang et al. attempt to further abstract away from the particularities of any particular ethical system and ethical thought through their set-up of the task. In this way, Delphi engages in concept drift (Malik, 2020), by modeling what is operationalizable (text) rather than the concept itself (situations and ethics). We discuss this design choice in §3.1.

2.2 The Learning Paradigm

The goal of Delphi and similar projects is to use a supervised learning paradigm (Vapnik, 2000) to learn ethics. A pre-requisite to train such models is a dataset labeled with ethical judgments for each document. We examine COMMONSENSE NORM BANK in §3.1, which Jiang et al. (2021) introduce in the hopes that it can serve a "moral textbook customized for machines." COMMONSENSE NORM BANK is an aggregation of previously published datasets that are labeled with ethical judgments, in addition to datasets which were labeled with other tasks in mind.

The corpus consists of a set of pairs $\{(s_n, j_n)\}_{n=1}^{N}$ where s_n is a textual description of a situation and j_n is a human annotator's written response to the situation (intended to be a moral judgment). If such resources are used in a fully supervised fashion, as Delphi is, developers are will presumably train a neural machine learning model that minimizes the cross-entropy loss $-\sum_{n=1}^{N} \log p(j_n \mid s_n)$ or a similar loss function. [3]

Even if we were to assume that $p(j \mid s)$ is a good model, i.e. it achieves low loss on the training data and generalizes well to held-out data, we should temper our expectations over its potential utility. For instance, we could at best expect that the distribution p yields a similar distribution over judgments for a given situation in the corpus as one would achieve if one polled the population that the corpus $\{(s_n, j_n)\}_{n=1}^{N}$ was collected from. However, one could not expect that p does *more* than mimic the specific population the data was collected from, at the specific time at which it was collected.

2.3 Choice of Training Data

The source text for COMMONSENSE NORM BANK comes from a variety of pre-existing sources. We enumerate all source datasets Delphi was trained with for completeness:

- ETHICS (Hendrycks et al., 2021), a partially crowd-sourced a dataset of "clear cut" ethical

---

[3] See Kloumann and Tygert (2020) for discussion of technical and conceptual limitations that suggest we should not rely solely on optimizing simple scalar objective values for ML applications that impact real people in society.

scenarios, labeled as either ethical or unethical, under 1 of 5 specified ethical schools of thought;

- SOCIAL BIAS INFERENCE CORPUS (Sap et al., 2020), a dataset of social media posts annotated for whether the posts are offensive, whether the posts' authors intended to cause offense, whether they contain sexual content, and who the target of the post was;

- SCRUPLES (Lourie et al., 2021), a dataset that contains anecdotes and dilemmas, where the dilemmas, used by Jiang et al., consists of natural language descriptions of two actions, from which annotators selected one as the *least* ethical;

- SOCIAL-CHEM-101 (Forbes et al., 2020), crowd-sourced dataset of rules of thumbs that are paired with an action and a judgment on the action;

- MORAL STORIES (Emelin et al., 2020), a dataset built on top of SOCIAL-CHEM-101, where annotators were asked to write 7-sentence stories that include "moral" and "immoral" actions taken, given a writing prompt.

The linguistic descriptions of situations in all original datasets were either partially or fully sourced from Reddit. Notably, "Am I The Asshole" either entirely or substantially makes up three of the underlying datasets: SCRUPLES (Lourie et al., 2021), SOCIAL-CHEM-101 (Forbes et al., 2020), and MORAL STORIES (Emelin et al., 2020). MORAL STORIES uses SOCIAL-CHEM-101 as their data source. The ETHICS dataset also, to a lesser degree, contains data collected from Reddit, that are subsequently annotated.

ETHICS is the only dataset that is annotated for specific schools of ethical thought. Using the ETHICS dataset, Hendrycks et al. (2021) proposed a "commonsense morality prediction" task, which mirrors Jiang et al. (2021) in its conceptualization and aims, i.e. to make a normative prediction on the morality of a given situation.

All data sources rely on crowd-workers on Amazon Mechanical Turk (AMT) for the judgments. Where annotator demographic information is provided along with the source datasets, the annotators overwhelmingly identify as white and American.

3 Points of Criticism

Our criticism falls into two parts that relate to the two stated contributions of Jiang et al. We first describe issues with COMMONSENSE NORM BANK, namely the contents of data and its interpretation. Second, we discuss general issues with the task formulation and training of models like Delphi.

3.1 COMMONSENSE NORM BANK

Recall that Delphi's learning paradigm relies on $p(j \mid s)$ being a good model (see §2.2). This requires that the set of sampled textual descriptions of situations $\{s_n\}_{n=1}^{N}$ is representative of the set of all possible situations that require or allow for moral judgments. It is unclear to us, however, how one could determine what the necessary properties for a good, representative sample of situations might be, let alone motivate that COMMONSENSE NORM BANK is such a sample.

3.1.1 Modeling Situations through Text

Delphi operates on free-form text snippets that serve as linguistic descriptions of situations. Since these textual descriptions are used as stand-ins for actual situations, the model crucially depends on natural language understanding. However, the input descriptions of situations are susceptible to the full range of linguistic complexities that arise in any NLP task, for example, textual ambiguities arising about pronominal reference and pragmatic considerations about who such pronouns actually refer to (Byron, 2002).

In general, linguistic phenomena that induce ambiguities are numerous and complicated, and it is not yet known whether any deep neural network model trained to perform any NLP task can handle them, let alone whether Delphi can. In the words of Jacob Eisenstein: "I don't think we even reach the question of how to handle ethical ambiguity [in natural language] until we show we can handle linguistic ambiguity first."

3.1.2 More Than Just Moral Judgments

The data used to train and/or test Delphi frequently contain judgments of other kinds. For example in Jiang et al.'s Table 4, Delphi states about "Drinking soy milk if I'm allergic to soy" that "It's bad". It's hard to picture this situation as requiring *moral* judgment. It is not unethical for a person with a soy allergy to drink soy milk—it may, however, be uncomfortable or unhealthy for them. Moreover, Delphi outputs "you shouldn't" both to "Drinking coffee if you're Mormon" and to "Drink[ing] coffee if you're pregnant" (Jiang et al.'s Table 13), presumably reflecting, in the former case, a historical religious prohibition against caffeine consumption by the Church of Jesus Christ of Latter-day Saints, and in the latter, and a health question. Similarly, Delphi returns "indefensible" to politicized situations like "Cleaning a toilet bowl with a national flag" (see Table 3 in Jiang et al., 2021).Grouping medical advice, religious prescriptions and political positions together as "descriptive morality" conflates several types of judgments, not all of which are obviously about morality.

Many of the examples provided in Jiang et al. begin with modal verbs such as "should". The interpretation of modal verbs is well-known to depend on the conversational backgrounds which is often not made explicit (Kratzer, 1981, 2012). Often, several conversational backgrounds are possible—for example, the answer to "should I do my homework?" can differ depending on whether you want the answer in relation to your desires (bouletic), your goals (teleological), or the rules (deontic), and only the last of these could be considered an ethical question.

3.1.3 Ethical Judgments in a Vacuum

Situations are provided to Delphi in a stripped down form, where the only provided context comes from the text snippet itself, i.e., the textual descriptions of events are generally not grounded. This is evidenced, for instance, by a lack of an explicit sentential subject or the presence of a second person pronoun—both of which are to be interpreted as pertaining to any arbitrary moral agent (e.g., "stealing a ball while playing baseball" or "stealing money if you are bored").

However, as Etienne (2021) points out in a related critique, embodied context may crucially influence and even alter people's moral stances: for instance, Francis et al. (2016) find that participants opt for different solutions to moral dilemmas when they are presented as text versus as actions in virtual reality simulations. Moreover, it is unclear, and possibly not a priori determinable which forms of contexts are relevant or required for a particular moral decision. Thus, the lack of context may introduce an empirical bias in sampling.

3.2 The Premise of Computational Approaches Morality

This section explores the underlying premise of computational approaches to morality, e.g. Delphi, which, we contend, is not well founded.

3.2.1 Predictive Models are Normative

Even if we were to grant the possibility that a corpus such as COMMONSENSE NORM BANK could be a representative sample of situations and moral judgments, this would merely suggest that it might be useful for *descriptive* ethics, i.e., as a tool for measuring and describing the ethical views of populations. In that case, it would constitute an attempt at a methodological innovation for describing human behavior (in which case, see also fn. 2) that should be justified in standard ways, namely by comparison with existing sociological and psychological methodologies, such as surveys, ethnographies, behavioral experiments, etc.[4]

However, we argue that a model that *generates* moral judgments cannot avoid creating and reinforcing norms, i.e., being *normative*. A moral judgment is inherently a prescription about how an action or a state of the world *ought* to be. Since it does, by its nature, rank possible states of the world according to some ethical (non-)desirability, a moral judgment is necessarily normative.

Throughout, the learning paradigm advocated for by Jiang et al. conflates descriptive and normative ethics. The authors claim that Delphi is "the first unified model of descriptive ethics," and assert that it is not a normative system, writing "rather than modeling moral 'truths' based on prescriptive notions of socio-normative standards, [Delphi takes] a bottom-up approach to capture moral implications of everyday actions in their immediate context, appropriate to our current social and ethical climate" (p.4). However, a problem emerges in that they subsequently use Delphi to make predictions/judgments. At various points, Jiang et al. foresee a normative use of their system, going so far as to suggest that Delphi may be used to "reason about equity and inclusion" (p. 3). Their "position is that enabling machine ethics requires a detailed moral

---

[4] If the goal of machine learning for morality is to better understand human behavior (descriptive ethics), such enterprises might require oversight from institutional review boards overseeing human subjects research (IRB) wherever they straddle the boundary between "annotation" and "research with human participants". According to the NYU IRB guidelines, "If you are asking a person's opinion, it could be human subjects research" (NYU Web Communications).

textbook customized to teaching machines" (ibid.), clearly styling machines as moral agents that can be taught to make decisions. Descriptive models do not require textbooks, and do not make decisions.

Whether or not the authors would advocate for any particular version of Delphi to be used in this way,[5] they have nevertheless built a system for the explicit purpose of computing ethical judgments. And the very act of providing ethical judgments—regardless of context—is normative.

The task in itself thus implies the induction of a normative ethical framework from a set of judgments. It is at this point that all of the aspects that the authors consider the virtues of the dataset are severely undermined. For example, Jiang et al. consider the fact that COMMONSENSE NORM BANK includes "diverse moral acceptability judgments gathered through crowdsourced annotations" to be a major advantage of their work (p.4). From a descriptive perspective, diverse (that is conflicting) ethical judgments are expected, but from a normative one, conflicting ethical judgments are simply incommensurable. To argue then that diversity is useful as a property of the set of moral judgments from which to induce a normative ethical framework is tantamount to arguing that an ideal ethical model ought to be self-contradictory.

3.2.2 The Tyranny of the Mean: Problems with Averaging Moral Judgments

In NLP, large-scale datasets are often collected through crowd-sourcing. It is clear that this approach has great utility for some NLP tasks (Snow et al., 2008). However, tasks for which crowd-sourcing is a useful method have a particular empirical character. For example, consider the historical observational study of a contest where individuals guessed the weight of an ox: Taking all the submissions in aggregate, the mean was found to fall very near the actual weight of the animal. Morality, on the other hand, is not an empirical question in the same way as the weight of an ox is. The latter has a single empirically verifiable answer, whereas the former does not. Indeed, we contend it is a category error to treat morality as though it were the same type of phenomenon as cow-weighing—in short, morality is not a test to be passed.

By inducing a normative framework from a descriptive dataset, as is the nature of the task devised by Jiang et al. and Hendrycks et al., the average view is implicitly identified with morally correctness. However, the average of moral judgments, which frequently reflects a status-quo perspective, does not necessarily reflect an immutable value, and may well be contested. For example, anti-Roma views and discrimination are present in much of Europe currently—in some areas held by the majority of the population (European Commission 2008; Kende et al. 2021). However, the authors of this work believe such discrimination to be unethical even though a machine learning model trained on crowd-sourced human judgments could inherit such views.

Ethical judgments are dynamic (Bicchieri, 2005). John Stuart Mill (1871) put it succinctly:

> *It often happens that the universal belief of one age of mankind [sic]—a belief from which no one was, nor without an extraordinary effort of genius and courage, could at that time be free—becomes to a subsequent age so palpable an absurdity, that the only difficulty then is to imagine how such a thing can ever have appeared credible.*

Notorious examples of views that are now widely considered unacceptable include the institutionalized justification of slavery in the 19th century and homophobia in 20th. It is unlikely that contemporaneous judgments will in principle be viewed any differently by future generations than we view past judgments—or, that contemporaneous ethical judgments by one human population will transfer readily to another. Historical changes like the abolition of slavery and the growing acceptance of LGBTQ+ communities show that disagreement is essential to the continual formation of a society's ethical perspectives. One democratic and participatory avenue for such disagreement is debate. Deriving a normative model from a set of existing judgments is tantamount to populism without democracy: It contains an implicit appeal to majorities, but insofar as it is *already normative*, it lacks any direct participation or recourse to debate.

If the continual (re-)formation of ethical perspectives requires debate and disagreement, then the *right to contestation* is essential to ethical reasoning at a socio-political level. Debate also requires transparency about the norms in question. Neither of these are afforded by a computational model for normative moral judgments.

---

[5] The current website demo for Jiang et al. (2021) has the following disclaimer "Model outputs should not be used for advice for humans."

3.2.3 Lack of Agency

In the last section, we argued that debate and contestation are essential to ethics. Naturally, the ability to partake in debate itself requires agency. However, recent critical scholarship on machine learning, and in particular on language models, argues that large-scale language models mimic without understanding (Bender et al., 2021), and don't have communicative intent (Bender and Koller, 2020)—in short, they lack what is required.

Some suspicion that these capacities are in fact requisite for ethical judgment is evident from the ways in which Jiang et al. (2021) describes computational models (emphasis ours):

> *"Delphi showcases a considerable level of* ***cultural awareness*** *of situations that are sensitive to different identity groups"*
>
> *"large-scale natural language models have revealed* ***implicit unethical considerations****, despite their exceptional performance over mainstream NLP applications"*
>
> *"Delphi* ***demonstrates strong moral reasoning capabilities****... Delphi* ***makes remarkably robust judgments*** *on previously unseen moral situations that are deliberately tricky. ... In addition, Delphi* ***can also reason about equity and inclusion****"*
>
> *"****encourage Delphi*** *to be more robust against different inflections of language"*
>
> *"To* ***empower Delphi with the ability to reason*** *about compositional and grounded scenarios"*
>
> *"Our position is that* ***enabling machine ethics requires a detailed moral textbook customized to teaching machines****"*

Such anthropomorphism applied to machine learning models presumes that machines reason in a manner comparable to (or better than) humans.[6] However, the learning paradigm adopted for Delphi and similar systems, assumes neither sentience nor agency: It presumes text–judgment pairs alone are sufficient for the task.

3.2.4 Agency and Accountability

Agency is also at the heart of accountability—we hold agents accountable for their deeds, not machines for their operations. In the case of a machine like Delphi, however, who is accountable is inherently obscured (Wagstaff, 2012). Crowd-workers clearly have the agency to make moral decisions and can, in principle, be held accountable for them. This is why Jiang et al. chose to rely on them as a source of moral judgments. On the other hand, a model trained on this data, although it cannot itself have agency, may appear to have agency, since it recombines and outputs texts generated by humans. By training Delphi, human agency has been transformed into something that the original agents, the crowd-workers, have no control over, or knowledge about. Yet, the trained model uses their past agency to pass novel judgments, based on some alleged—but uncontestable—moral common sense, which no one individual holds or is accountable for.

While Delphi is posed as the voice of the people, it is conveniently not a voice of any particular person, organization, or company. The responsibility for any position Delphi holds (or possible future action based on such positions) appears distributed, while in the end, the effect of such decisions, if employed in real-world scenarios, will eventually need to be accounted for. Under some legal systems, citizens have the right to challenge automated decision making which affects their rights or legitimate interests—for instance under the European Union's General Data Protection Regulation (GDPR) legislation (Rodrigues, 2020). Imagine that a technology for moral prediction were to be embedded within an autonomous system: The moral predictions occurring within the system would be obscured through layers of abstraction, thus leaving users little room to contest such decisions on principled grounds. The legal and ethical ramifications remain unclear.

In summary, crowd-sourcing ethics in this way at best obscures what is a set of problematic questions that should be addressed openly and directly and not inferred. Notably, Delphi represents one example of a wider trend in AI. As Ganesh (2017) argues: "In the development of machine intelligence towards [the goal of ethical self-driving cars], a series...of shifts can be discerned: from accounting for crashes after the fact, to pre-empting them; from ethics that is about values, or reasoning, to ethics as crowd-sourced, or based on statistics, and as

---

[6] Of course, it is common in the field to talk about neural models in ways that at least suggest animacy, such as *teaching/training a model* or talking about its *behavior*. Consider, however, that one would never say of a car that it "demonstrates strong acceleration capabilities" or of an elevator that "we empowered this elevator with the ability to ascend."

the outcome of software engineering. Thus ethics-as-accountability moves towards a more opaque, narrow project."

4 Future Directions for Machine Ethics

In this section, we discuss how accuracy improvements alone cannot mitigate the problems with work such as Delphi in §4.1 and encourage a shift towards multi-disciplinary work in §4.2.

4.1 Unsafe at Any Accuracy

The introduction of any new technology into society requires us to contemplate safety concerns in the context of its proposed application (Nader, 1965). Consider, for instance, the seatbelt. One can and indeed should acknowledge that seat belts are effective at preventing automobile-related injuries to occupants without needing to imbue them with an understanding of human ethics or morality at all. We can view concrete issues in AI safety through the same lens that we view a seat belt: We can introduce safety mechanisms directly without requiring that the technology be able to reason about human ethics; we can imagine machines that operate according to moral or ethical guidelines (i.e., cars that have safety features) as opposed to machines that perform actual moral reasoning (Cave et al., 2018).

Jiang et al. and Hendrycks et al. implicitly envision a future where machine learning models could be called upon to perform moral reasoning. At its core, this vision is one of artificial general intelligence (Goertzel and Pennachin, 2007), and similar in scope and intent to the Moral Machine experiment (Awad et al., 2018), which also sought to leverage the "wisdom of the crowd" in proposing frameworks for how a future self-driving car could make decisions in speculative automotive accident scenarios. Delphi and the Moral Machine thus consider a future where AI is given agency to make ethical decisions that ordinarily would be made by a human. However, this is just one possible future.

An alternative vision of the future is one where machine learning models primarily assist humans in making decisions (Dick, 2015), i.e. where machine learning models are viewed as non-moral agents as seat belts are. In such a future, we will not need to endow machine learning models with a sense of human ethics, just as we generally do not feel the need to endow a seat belt with a sense of human ethics. Furthermore, in this future, one might prefer general strategies for reducing and mitigating any harms machine learning may give rise to. For instance, as it stands now, many machine learning models trained on language encode harmful demographic biases that many works investigate through analysis of the models, their training regimes, and the data that they rely on (Hall Maudslay et al., 2019; Zhao et al., 2019; Dinan et al., 2020a,b; Vargas and Cotterell, 2020; Smith and Williams, 2021; Talat et al., 2021), rather than seeking to imbue models with a sense of ethics.

4.2 Machine Ethics is Multi-disciplinary

Jiang et al. (2021), like a large body of research from computer science that ventures into other fields, almost exclusively represents the perspectives of computer scientists. Another paper solely authored by computer scientists, Hendrycks et al. (2021) cautions against such a narrow perspective, stating that "computer scientists should draw on knowledge from [our] enduring intellectual inheritance, and they should not ignore it by trying to reinvent ethics from scratch" (p.3). Such disregard of expertise is apparent in several places in Jiang et al. (emphasis added):

> *"Fields like social science [sic], philosophy, and psychology have produced a variety of long-standing ethical theories. However,* ***attempting to apply such theoretically-inspired guidelines to make moral judgments of complex real-life situations is arbitrary and simplistic****."*

Through disciplinary siloing researchers often unwittingly make simplistic assumptions that are, at best, harmful to the research and, at worst, harmful to people. We therefore recommend that machine ethics and morality research should be performed by a multi-disciplinary team, with members including computer scientists, who can speak from diverse expertise about the object that is under study.

5 Conclusion

In this paper, we have offered a general critique of the NLP task of generating moral judgments through a targeted audit of Jiang et al. (2021). We have highlighted issues with the operationalization of the task, with the learning paradigm, and with currently available training datasets. We have argued that the general enterprise is rooted in multiple category errors: It belies a misunderstanding of the descriptive/normative distinction, and falsely treats morality as a mere test to be passed. Ultimately, automating ethical decisions forecloses possibilities for debate and contestation. Since these are themselves prerequisites for the socio-political process of ethical inquiry, such a task is inherently incompatible with the social project of ethics.

Abstract

The dominant paradigm for neural text generation is left-to-right decoding from autoregressive language models. Constrained or controllable generation under complex lexical constraints, however, requires foresight to plan ahead for feasible future paths.

Drawing inspiration from the A* search algorithm, we propose NeuroLogic A*esque,[1] a decoding algorithm that incorporates heuristic estimates of future cost. We develop *lookahead* heuristics that are efficient for large-scale language models, making our method a drop-in replacement for common techniques such as beam search and top-k sampling. To enable constrained generation, we build on NeuroLogic decoding (Lu et al., 2021), combining its flexibility in incorporating logical constraints with A*esque estimates of future constraint satisfaction.

Our approach outperforms competitive baselines on five generation tasks, and achieves new state-of-the-art performance on table-to-text generation, constrained machine translation, and keyword-constrained generation. The improvements are particularly notable on tasks that require complex constraint satisfaction or in few-shot or zero-shot settings. NeuroLogic A*esque illustrates the power of decoding for improving and enabling new capabilities of large-scale language models.

1 Introduction

The dominant paradigm for neural text generation is based on left-to-right decoding from autoregressive language models such as GPT-2/3 (Radford et al., 2019; Brown et al., 2020). Under this paradigm, common decoding techniques such as beam search or top-k/p sampling (Holtzman et al., 2020) determine which token to generate next based on what happened in the past, without explicitly looking ahead into the future. While this lack of foresight often suffices for open-ended text generation – where any coherent text can be acceptable – for constrained text generation, planning ahead is crucial for incorporating all desired content in the generated output (Hu et al., 2017; Dathathri et al., 2019).

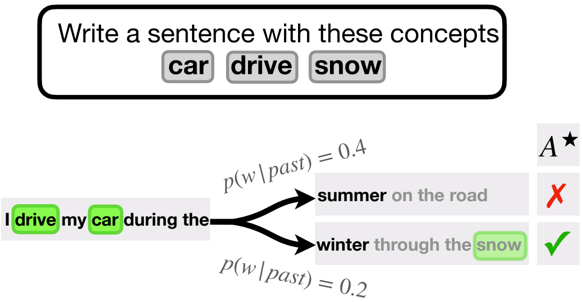

Figure 1: NeuroLogic* leverages *lookahead heuristics* to guide generations towards those that satisfy the given task-specific constraints. In this example from the CommonGen task, although **summer** is a *more likely* next word given the already-generated *past*, NeuroLogic* looks ahead to see that selecting **winter** results in a generation that incorporates unsatisfied constraint **snow** with a higher probability later on. Thus, **winter** is preferred despite being lower probability than **summer**.

Classical search algorithms such as A* search (Hart et al., 1968; Pearl, 1984; Korf, 1985) address the challenge of planning ahead by using *heuristic* estimation of future cost when making decisions. Drawing inspiration from A* search, we develop NeuroLogic A*esque (shortened to NeuroLogic*), which combines A*-like heuristic estimates of future cost (e.g., perplexity, constraint satisfaction) with common decoding algorithms for neural text generation (e.g., beam search, top-k sampling), while preserving the efficiency demanded by large-scale neural language models.

As selecting the next token to generate based on the *optimal* future cost is NP-complete (Chen et al., 2018), we develop *lookahead* heuristics, which approximate cost at each decoding step based on con-

tinuations of the sequence-so-far. Figure 1 shows an example, where NeuroLogic A$^\bigstar$esque guides generation towards a decision that would have been ignored based on the past alone, but is selected after looking ahead and incorporating the probability that constraints are satisfied in the future.

Our approach builds on NeuroLogic Decoding of Lu et al. (2021), a variation of beam-search for controlling generation through rich logic-based lexical constraints expressed in Conjunctive Normal Form (CNF). Our work generalizes Lu et al. (2021) by (1) incorporating novel lookahead heuristics to estimate future contraint satisfaction, and (2) developing additional *unconstrained* variants that can work with an empty set of constraints. These new algorithm variants support broad applications of NeuroLogic$^\bigstar$, including unconstrained generation, as demonstrated in our experiments.

Our experiments across five generation tasks demonstrate that our approach outperforms competitive baselines. We test NeuroLogic$^\bigstar$ in conjunction with both supervised and unsupervised models and find that the performance gain is pronounced especially in zero-shot or few-shot settings. On the CommonGen benchmark, using NeuroLogic$^\bigstar$ with an off-the-shelf language model outperforms a host of *supervised* baselines with conventional decoding algorithms, demonstrating that a strong inference-time algorithm such as NeuroLogic$^\bigstar$ can alleviate the need for costly annotated datasets. Moreover, NeuroLogic$^\bigstar$ achieves state-of-the-art performance in various settings, including WMT17 English-German machine translation with lexical constraints (Dinu et al., 2019) and few-shot E2ENLG table-to-text generation (Chen et al., 2020b).

In summary, we develop NeuroLogic A$^\bigstar$esque, a new decoding algorithm for effective and efficient text generation. To our knowledge this is the first A*-like algorithm for guided text generation via lookahead heuristics. Our algorithm is versatile, as it can be applied to a variety of tasks via inference-time constraints, reducing the need for costly labeled data. Extensive experiments show its effectiveness on several important generation benchmarks.

2 NeuroLogic A$^\bigstar$esque Decoding

We describe NeuroLogic A$^\bigstar$esque Decoding (shortened as NeuroLogic$^\bigstar$), our decoding algorithm motivated by A* search (Hart et al., 1968), a best-first search algorithm that finds high-scoring paths using a heuristic estimate of future return. We first introduce the decoding problem, and then describe our heuristics with a novel lookahead procedure for adapting NeuroLogic$^\bigstar$ search to unconstrained and constrained generation with large-scale autoregressive models.

2.1 Decoding With A$^\bigstar$esque Lookahead

Decoding. Sequence-to-sequence generation is the task of generating an output sequence $\mathbf{y}$ given an input sequence $\mathbf{x}$. We consider standard left-to-right, autoregressive models, $p_\theta(\mathbf{y} \mid \mathbf{x}) = \prod_{t=1}^{|\mathbf{y}|} p_\theta(y_t \mid \mathbf{y}_{<t}, \mathbf{x})$, and omit $\mathbf{x}$ to reduce clutter. Decoding consists of solving,

$$\mathbf{y}_* = \arg\max_{\mathbf{y}\in\mathcal{Y}} F(\mathbf{y}), \tag{1}$$

where $\mathcal{Y}$ is the set of all sequences. In our setting, the objective $F(\mathbf{y})$ takes the form $s(\mathbf{y}) + H(\mathbf{y})$, where $s(\mathbf{y})$ is $\log p_\theta(\mathbf{y})$, and $H(\mathbf{y})$ is either zero when no constraints are specified, or is a score for satisfying constraints on $\mathbf{y}$.

Our method takes the perspective of decoding as discrete search, in which *states* are partial prefixes, $\mathbf{y}_{<t}$, *actions* are tokens in vocabulary $\mathcal{V}$ (i.e., $y_t \in \mathcal{V}$), and *transitions* add a token to a prefix, $\mathbf{y}_{<t} \circ y_t$. Each step of decoding consists of (1) expanding a set of candidate next-states, (2) scoring each candidate, and (3) selecting the k best candidates:

$$\begin{aligned} Y'_t &= \{\mathbf{y}_{<t} \circ y_t \mid \mathbf{y}_{<t} \in Y_{t-1}, y_t \in \mathcal{V}\}, \\ Y_t &= \operatorname*{arg\,topk}_{(\mathbf{y}_{<t}, y_t)\in Y'_t} \left\{ f(\mathbf{y}_{<t}, y_t) \right\}, \end{aligned} \tag{2}$$

where $Y_0 = \{\langle bos \rangle\}$ and $f(\cdot)$ is a scoring function that approximates the objective F. Common decoding algorithms such as beam search score candidates without considering future tokens, e.g., $f(\mathbf{y}_{<t}, y_t) = \log p_\theta(\mathbf{y}_{\leq t})$.

Lookahead heuristics. Our method incorporates an estimate of the future into candidate selection. Ideally, we want to select candidates that are on optimal trajectories, replacing Equation 2 with:

$$Y_t = \operatorname*{arg\,topk}_{(\mathbf{y}_{<t}, y_t)\in Y'_t} \left\{ \max_{\mathbf{y}_{>t}} F(\mathbf{y}_{<t}, y_t, \mathbf{y}_{>t}) \right\}, \tag{3}$$

where $\mathbf{y}_{>t}$ represents future trajectories. However, computing Equation 3 presents two difficulties: 1) the objective $F(\mathbf{y})$ may be unknown or difficult to compute, and 2) the space of $\mathbf{y}_{>t}$ is prohibitively large.

Motivated by A* search (Hart et al., 1968), a best-first search algorithm that finds high-scoring paths by selecting actions that maximize:

$$f(a) = s(a) + h(a),$$

where $s(a)$ is the score-so-far and $h(a)$ is a heuristic estimate of the future score, we approximate the objective using a lightweight *heuristic* $h(\cdot)$:

$$Y_t = \operatorname*{arg\,topk}_{\mathbf{y}_{\le t}\in Y'_t} \left\{ s(\mathbf{y}_{\le t}) + \max_{\mathbf{y}_{>t}} h(\mathbf{y}_{<t}, y_t, \mathbf{y}_{>t}) \right\}, \tag{4}$$

where $s(\mathbf{y}_{\le t}) = \log p_\theta(\mathbf{y}_{\le t})$. To make the search tractable, we search over a set of *lookahead* continuations, approximating Equation 3 as,

$$Y_t = \operatorname*{arg\,topk}_{\mathbf{y}_{\le t}\in Y'_t} \left\{ s(\mathbf{y}_{\le t}) + \max_{\mathcal{L}_\ell(\mathbf{y}_{\le t})} h(\mathbf{y}_{\le t+\ell}) \right\}, \tag{5}$$

where each element $\mathbf{y}_{t+1:t+\ell}$ of $\mathcal{L}_\ell(\mathbf{y}_{\le t})$ is a length-ℓ continuation of $\mathbf{y}_{\le t}$. Beam search corresponds to setting ℓ and h to 0.

A★esque decoding. Beam search, A* search, and our method fall under a general class of algorithms that differ based on (1) which candidates are expanded, (2) which candidates are pruned, (3) how candidates are scored (Meister et al., 2020). We inherit the practical advantages of beam search-style expansion and pruning, while drawing on A*-like heuristics to incorporate estimates of the future, and refer to our method as **A★esque decoding**.

Generating lookaheads. We compare several methods for generating the lookaheads $\mathcal{L}_\ell(\mathbf{y}_{\le t})$.

The *greedy* lookahead produces a single sequence, $\mathcal{L}_\ell = \{\mathbf{y}_{t+1:t+\ell}\}$, starting from $\mathbf{y}_{\le t}$ and selecting each token according to $y_{t'} = \arg\max_{y\in\mathcal{V}} p_\theta(y \mid \mathbf{y}_{<t'})$.

We also consider a *soft* lookahead which interpolates between providing the greedy token and a uniform mixture of tokens as input at each step. Specifically, we adjust the model's probabilities with a temperature, $\tilde{p}_\theta(y_t \mid \mathbf{y}_{<t}) = \text{softmax}(s_t/\tau)$, where $s_t \in \mathbb{R}^{|\mathcal{V}|}$ is a vector of logits, and feed the expected token embedding as input at step t,

$$e_t = \mathbb{E}_{y_t\sim\tilde{p}(y_t|\mathbf{y}_{<t})}[E(y_t)], \tag{6}$$

where $E \in \mathbb{R}^{|\mathcal{V}|\times d}$ is the model's token embedding matrix. The soft lookahead moves from providing the greedy token as input ($\tau \to 0$) to a uniform mixture of tokens ($\tau \to \infty$) based on the value of temperature τ. When using the soft lookahead, we use $\tilde{p}$ in place of p when scoring tokens. The soft (and greedy) lookahead is efficient, but only explores a single trajectory.

The *beam* lookahead trades off efficiency for exploration, returning a set $\mathcal{L}_\ell$ containing the top-k candidates obtained by running beam search for ℓ steps starting from $\mathbf{y}_{<t}$.

Finally, the *sampling* lookahead explores beyond the highly-probable beam search continuations, generating each $\mathbf{y}_{t+1:t+\ell} \in \mathcal{L}_\ell$ using,

$$y_{t'} \sim p_\theta(y \mid \mathbf{y}_{<t'}),$$

for t' from t+1 to t+k.

Next, we move to our proposed lookahead heuristics, starting with the unconstrained setting.

2.2 Unconstrained Generation with NeuroLogic★

First we consider a standard decoding setting,

$$\arg\max_{\mathbf{y}\in\mathcal{Y}} \log p_\theta(\mathbf{y} \mid \mathbf{x}).$$

We score candidates based on a combination of the *history* and *estimated future*, by using the likelihood of the lookahead as a heuristic. That is, at the tth step of decoding, we use Equation 5 with:

$$h(\mathbf{y}_{\le t+\ell}) = \lambda \log p_\theta(\mathbf{y}_{t+1:t+\ell} \mid \mathbf{y}_{\le t}, \mathbf{x}), \tag{7}$$

where λ controls how much we rely on the estimated future versus the history, similar to weighted A* (Pohl, 1970).

2.3 NeuroLogic★ for Constrained Generation

Our lookahead heuristics lend themselves to decoding with lexical constraints in a way that standard beam search does not. For constrained generation, we build on and generalize NeuroLogic decoding algorithm of Lu et al. (2021)—a beam-based search algorithm that supports a wide class of logical constraints for lexically constrained generation—with estimates of future constraint satisfaction.

Background of NeuroLogic. NeuroLogic (Lu et al., 2021) accepts lexical constraints in CNF:

$$\underbrace{(D_1 \lor D_2 \cdots \lor D_i)}_{C_1} \land \cdots \land \underbrace{(D_{i'} \lor \cdots \lor D_N)}_{C_M}$$

where each D_i represents a single positive or negative constraint, $D(\mathbf{a}, \mathbf{y})$ or $\neg D(\mathbf{a}, \mathbf{y})$, enforcing the phrase $\mathbf{a}$ to be included in or omitted from $\mathbf{y}$. Lu et al. (2021) refer to each constraint D_i as a *literal*, and each disjunction C_j of literals as a *clause*.

NEUROLOGIC is a beam-based approximate search for an objective which seeks fluent sequences in which all clauses are satisfied:

$$\arg\max_{\mathbf{y}\in\mathcal{Y}} p_\theta(\mathbf{y} \mid \mathbf{x}) - \lambda' \sum_{j=1}^{M}(1 - C_j),$$

where $\lambda' \gg 0$ penalizes unsatisfied clauses. At each step of the search, NEUROLOGIC scores each of the $k\times|\mathcal{V}|$ candidates $(\mathbf{y}_{<t}, y_t)$ based on whether they (partially) satisfy new constraints,

$$f(\mathbf{y}_{\leq t}) = \log p_\theta(\mathbf{y}_{\leq t} \mid \mathbf{x}) + \lambda_1 \max_{D(\mathbf{a},\mathbf{y}_{\leq t})} \frac{|\hat{\mathbf{a}}|}{|\mathbf{a}|}, \quad (8)$$

where the maximization is over a set of unsatisfied multi-token constraints **a** tracked by NEUROLOGIC, and $\hat{\mathbf{a}}$ is the prefix of **a** in the ongoing generation. For example, for $\mathbf{y}_{\leq t}$ =“*The boy climbs an apple*” and constraint **a**=“*apple tree*”, $\hat{\mathbf{a}}$ is “*apple*”. Intuitively, this function rewards candidates that are in the process of satisfying a constraint.

In lieu of taking the top-k scoring candidates (Equation 5), NEUROLOGIC prunes candidates that contain clauses that violate constraints, groups the candidates to promote diversity, and selects high-scoring candidates from each group. We use the same pruning and grouping approach, and refer the reader to Lu et al. (2021) for further details.

NEUROLOGIC★ decoding. Our method improves upon the NEUROLOGIC scoring function with an estimate of future constraint satisfaction. Our key addition is a lookahead heuristic that adjusts a candidate $(\mathbf{y}_{<t}, y_t)$'s score proportional to the probability of satisfying additional *unsatisfied* constraints in the lookahead $\mathbf{y}_{t+1:t+\ell}$:

$$h_{\text{future}}(\mathbf{y}_{\leq t+\ell}) = \lambda_2 \max_{D(\mathbf{a},\mathbf{y}_{\leq t})} \log p_\theta(D(\mathbf{a}, \mathbf{y}_{t+1:t+\ell}) \mid \mathbf{x}, \mathbf{y}_{\leq t}), \quad (9)$$

where we define the probability that constraint **a** is satisfied using the most probable subsequence,

$$p_\theta(D(\mathbf{a}, \mathbf{y}_{t+1:t+\ell}) \mid \mathbf{x}, \mathbf{y}_{\leq t}) = \max_{t'\in[t,t+\ell]} p_\theta(\mathbf{y}_{t':t'+|\mathbf{a}|} = \mathbf{a} \mid \mathbf{x}, \mathbf{y}_{<t'}), \quad (10)$$

λ_2 is a scaling hyperparameter for the heuristic.

Intuitively, this lookahead heuristic brings two benefits. When y_t is a token that would satisfy a multi-token constraint, the lookahead incorporates the score of the *full* constraint. When y_t is a token that is not part of a constraint, the lookahead allows for incorporating the score of a future constraint that would be satisfied if y_t was selected.

We add our lookahead heuristic to the NEUROLOGIC scoring function (Equation 8), and call the resulting decoding procedure NEUROLOGIC A★esque (or, NEUROLOGIC★ in short).

3 Experiments

We first consider constrained generation benchmarks: COMMONGEN (§3.1), constrained machine translation (§3.2), table-to-text generation (§3.3), and constrained question generation (§3.4). NEUROLOGIC★ consistently outperforms previous approaches, especially in zero-shot and few-shot cases. These low-resource settings are particularly important, as many practical tasks face data scarcity. Finally, we find that A★esque lookahead is useful even without constraints, as shown in unconstrained story generation task (§3.5).

Metrics. As automatic metrics, we use: BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015), SPICE (Anderson et al., 2016) and NIST (Lin and Hovy, 2003).

3.1 Constrained Commonsense Generation

COMMONGEN (Lin et al., 2020) is a commonsense generation task with lexical constraints: given a set of concepts (e.g., {throw, run, javelin, track}), models need to generate a coherent sentence describing a plausible scenario using all given concepts (e.g., “a man runs on a track and throws a javelin.”).

Approach and Baselines. Following Lu et al. (2021), we enforce that each concept c_i appear in output **y** under some morphological inflection. We test in both supervised and zero-shot settings. In the supervised setting, we finetune GPT-2 (Radford et al., 2019) as a sequence-to-sequence model. In the zero-shot setting, we use GPT-2 off-the-shelf (no fine-tuning) and rely on constrained decoding to guide generation. We compare with previous constrained decoding algorithms CBS (Anderson et al., 2017), GBS (Hokamp and Liu, 2017), DBA (Post and Vilar, 2018a), NEUROLOGIC (Lu et al., 2021) and TSMH (Zhang et al., 2020).

Metrics. We report standard automatic metrics as well as *coverage*, the average percentage of concepts present in generations. Additionally, we conduct human evaluation on 100 test examples using Amazon Mechanical Turk (AMT), with 3 annotators per example (template in Appendix D). Workers rate each generation on *language quality*, *sce-*

Table 3: Results on constrained MT. The left section uses the same two-layer transformer as Dinu et al. (2019), while the right one uses a stronger Marian MT EN-DE model. The highlighted methods modify training data specifically for constrained generation, and thus cannot be applied to off-the-shelf models. The best numbers are **bold**, second best are underlined.

nario plausibility, *coverage of given concepts*, and an *overall score* on a 3-point Likert scale.[2]

Results. Table 1 compares different constrained decoding methods on top of the finetuned and off-the-shelf GPT-2, in supervised and zero-shot settings respectively. The key observations are:

1. NeuroLogic★ outperforms all previous constrained-decoding methods in both supervised and zero-shot settings. Surprisingly, *unsupervised* NeuroLogic★ outperforms all supervised methods based on human evaluation.
2. Compared to vanilla NeuroLogic, NeuroLogic★ improves generation quality while maintaining high constraint satisfaction. The difference is especially substantial in the zero-shot setting. Intuitively, this setting leaves more room for incorporating constraint-driven signals due to the lack of supervision.
3. NeuroLogic★ reaches similar performance using different lookahead strategies, among which beam lookahead slightly outperforms the others based on human evaluation, and greedy lookahead has the lowest runtime. We analyze lookahead strategies further in Appendix A.

3.2 Constrained Machine Translation

Next, we test on constrained machine translation (MT). It is often critical to have control over MT systems, such as to incorporate domain-specific terminology (Post and Vilar, 2018a; Dinu et al., 2019). To achieve this goal, recent work proposed constrained decoding algorithms (Chatterjee et al., 2017; Hokamp and Liu, 2017; Hasler et al., 2018; Hu et al., 2019, *inter alia*) or specialized training (Dinu et al., 2019). We demonstrate that

		NeuroLogic	26.2	95.2
		NeuroLogic★	**26.3**	**95.8**
2+	36	Beam search	28.1	85.0
		NeuroLogic	28.9	93.7
		NeuroLogic★	**29.3**	**96.5**

Table 4: Constrained MT performance broken down by the number of constraint terms (# T). All configurations use the two-layer tranformer from Dinu et al. (2019). The best numbers are **bolded** and the second best ones are underlined.

NeuroLogic★ can be readily applied to off-the-shelf MT systems for constrained machine translation. We follow Dinu et al. (2019) and evaluate on the WMT17 EN-DE test set (Bojar et al., 2017). The constraint here is to integrate given custom terminologies into the translation output; constraint terms are automatically created from the IATE EU terminology database for 414 test sentences.

Approach, Baselines, and Metrics. We experiment with two MT systems: Dinu et al. (two-layer transformer) and the off-the-shelf Marian MT (Junczys-Dowmunt et al., 2018). We compare with previous constrained decoding algorithms, including DBA (Post and Vilar, 2018a), NeuroLogic (Lu et al., 2021), and also specialized training proposed by Dinu et al. (2019). Following Dinu et al. (2019), we report BLEU and term use rates, i.e., percentage of times given constraint terms were generated out of total number of constraint terms.

Results. Table 3 presents experimental results with Dinu et al.'s model and Marian MT. In both cases, NeuroLogic★ outperforms prior methods in BLEU and term coverage. Besides higher quality and coverage, NeuroLogic★ is plug-and-play, working with any off-the-shelf MT system, unlike previous training-based methods. Table 4 breaks down the performance by the number of constraint terms. We see that the improvement brought by NeuroLogic★ is especially large when given complex constraints with multiple terms. (e.g., 96.5 vs. 93.7 from NeuroLogic in term of coverage).

3.3 Table-to-text Generation

Next we test on the table-to-text task, where models need to generate natural language for structured table data. Constrained generation ensures that the output text is factual and consistent with the input data. We follow the few-shot setup of Chen et al. (2020b) on the E2ENLG (Dušek et al., 2018) dataset, where randomly-sampled 0.1%, 0.5%, 1%, or 5% of training instances are used for finetuning.

Decode Method	NIST	BLEU	METEOR	CIDEr	ROUGE	Coverage
Beam Search	3.82	42.8	32.6	10.8	57.8	73.6
CBS	6.50	42.3	36.4	13.0	54.3	91.6
GBS	6.26	40.7	36.7	12.9	54.2	94.1
NeuroLogic	6.95	47.6	38.9	16.3	58.7	97.6
NeuroLogic★ (greedy)	**7.11**	49.2	40.0	**17.5**	**60.0**	**100.0**
NeuroLogic★ (beam)	7.01	48.9	40.0	17.2	59.8	99.9
NeuroLogic★ (sample)	**7.11**	**49.3**	**40.1**	**17.5**	**60.0**	**100.0**

Table 5: Performance of different decoding methods with few-shot GPT-2 finetuned on 0.1% E2ENLG data. The best numbers are **bold**, second best are underlined.

Method	0.1%	0.5%	1%	5%
TGen (Dušek and Jurčíček, 2016)	3.6	27.9	35.2	57.3
Template-GPT-2 (Chen et al., 2020a)	22.5	47.8	53.3	59.9
KGPT-Graph (Chen et al., 2020b)	39.8	53.3	55.1	61.5
KGPT-Seq (Chen et al., 2020b)	40.2	53.0	54.1	61.1
GPT-2	42.8	57.1	56.8	61.1
GPT-2 + NeuroLogic	47.6	56.9	58.0	62.9
GPT-2 + NeuroLogic★ (greedy)	**49.2**	**58.0**	**58.4**	**63.4**

Table 6: Few-shot results (BLEU-4) on E2ENLG test set with 0.1%, 0.5%, 1%, 5% of training instances. The best numbers are **bold**, second best are underlined.

Approach, Baselines, and Metrics. Following Shen et al. (2019), we linearize data tables into strings and finetune GPT-2 with few-shot examples. We compare NeuroLogic★ with three previous constrained decoding algorithms: CBS (Anderson et al., 2017), GBS (Hokamp and Liu, 2017), and NeuroLogic (Lu et al., 2021), based on few-shot GPT-2 finetuned with 0.1% data. Then we compare NeuroLogic★ on top of GPT-2, with previous table-to-text methods, including TGen (Dušek and Jurčíček, 2016), Template-GPT-2 (Chen et al., 2020a), KGPT (Chen et al., 2020b), in multiple few-shot settings with various numbers of training instances. We report standard automatic metrics, as well as information coverage, i.e., percentage of information present in the generation.

Results. Table 5 compares various decoding methods with few-shot GPT-2 finetuned on 0.1% of the data. NeuroLogic★ substantially outperforms previous methods on all metrics, consistently improving quality while achieving near-perfect constraint satisfaction. Previous work (CBS and GBS) improves constraint satisfaction, but negatively affects quality, indicated by drops in BLEU and ROUGE. Table 6 compares NeuroLogic★ on top of GPT-2 with previous table-to-text approaches. As before, NeuroLogic★ outperforms past approaches by a large margin, even if the latter ones leverage specialized model architectures or addi-

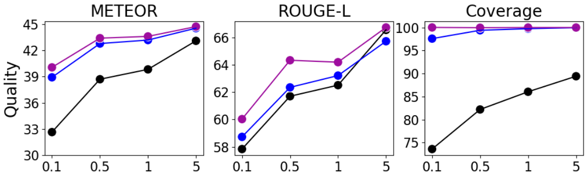

Figure 2: Performance (y-axis) of supervised GPT-2 on E2ENLG, with a varying percentage of training data for supervision (x-axis). The **purple**, **blue**, and **black** lines denote decoding with NeuroLogic★, NeuroLogic and conventional beam search, respectively.

tional pretraining on massive table-to-text corpora. Additionally, Figure 2 compares the performance (y-axis) of few-shot GPT-2 with NeuroLogic★ (**purple line**), NeuroLogic (**blue line**), and conventional beam search (**black line**) as a function of the varying percentage of training instances (x-axis). The benefit of NeuroLogic★ grows as data size is reduced. Indeed, constrained decoding enables impressive low-resource performance.

3.4 Constrained Question Generation

Next, we consider constrained question generation (Zhang et al., 2020), where models need to generate interrogative questions using given keywords. This task is zero-shot without any training data, further testing the capacity of NeuroLogic★ to guide off-the-shelf models without finetuning.

Approach, Baselines, and Metrics. We use GPT-2 off-the-shelf and compare NeuroLogic★ with previous constrained decoding methods, including CGMH (Miao et al., 2019), TSMH (Zhang et al., 2020) and NeuroLogic (Lu et al., 2021). We report standard generation metrics and keyword coverage as in §3.1. We conduct human evaluation following subsection 3.1, to measure grammar, fluency, meaningfulness, and overall quality of the generated questions, using a 3-point Likert scale[3] (template in Appendix D).

Results. Table 7 presents comparisons across different decoding methods based on off-the-shelf language models. NeuroLogic★ outperforms all previous methods with respect to both automatic and manual metrics; it enhances the generation quality while achieving perfect constraint satisfaction. The difference between NeuroLogic and NeuroLogic★ is particularly large compared to other tasks. We suspect that the search problem is much harder here, due to the lack of supervision and complex logical constraints involving both keywords and syntax. As a whole, the results demonstrate the effectiveness of NeuroLogic★ in tackling challenging constrained generation problems.

3.5 *Unconstrained* Story Generation

Finally, we demonstrate NeuroLogic★ can also improve *unconstrained* generation. We investigate whether A★esque decoding with our unconstrained lookahead heuristic (Equation 7) can (1) improve beam search, which typically struggles in open-ended settings (Holtzman et al., 2020; Welleck et al., 2019b), and (2) improve *sampling* algorithms that are commonly used in open-ended generation. We consider conditional story generation on the RocStories dataset (Mostafazadeh et al., 2016): given a first sentence $\mathbf{x}$, generate the full story $\mathbf{y}$.

Approach, Baselines and Metrics. We use GPT-2, fine-tuned on the RocStories training set. We apply A★esque decoding to (1) beam search, the setting used so far in the experiments, and (2) top-k sampling (Fan et al., 2018), a commonly used sampling algorithm in open-ended generation. For top-k sampling, we use the heuristic to adjust the probability scores, then renormalize. We use standard automatic metrics: perplexity and BLEU for fluency, and unique n-grams as a measure of diversity. We conduct human evaluation following subsection 3.1, for story flow and overall quality on a 3-point Likert scale[4] (template in Appendix D).

Results. Table 8 presents the results of beam search and top-k sampling with and without A★esque heuristics. A★esque heuristics result in more fluent, coherent and interesting stories for both beam search and top-k sampling. For beam search, A★esque not only enhances generation quality– e.g. improving human evaluation scores from 2.32 to 2.63–but also boosts generation diversity, reflected by number of unique n-grams. For top-k sampling, A★esque heuristics improve quality, while maintaining comparable diversity. We further analyze quality and diversity tradeoff in Appendix A. Moreover, we notice that beam lookahead works the best for beam search, and greedy lookahead works the best for top-k sampling. We suspect that beam lookahead gives the most accurate estimate of future beam path, while greedy

---

[3] Agreement by ordinal Krippendorff alpha ($0 \leq \alpha \leq 1$) (Krippendorff, 2007) is 0.27, 0.28, 0.25 and 0.30, indicating fair agreement.

[4] Agreement by ordinal Krippendorff alpha ($0 \leq \alpha \leq 1$) (Krippendorff, 2007) of 0.24 and 0.22 (respectively), indicating fair agreement.

Decode Method	Automatic Evaluation						Human Evaluation			
	ROUGE	BLEU	METEOR	CIDEr	SPICE	Coverage	Grammar	Fluency	Meaningfulness	Overall

lookahead provides an estimate which better resembles a continuation from top-k sampling.

4 Related Work

A* search in NLP. Many classical NLP problems (e.g., parsing, text alignment) can be seen as structured prediction subject to a set of task-specific constraints. For many such problems, A* search has been used effectively (Och et al., 2001; Haghighi et al., 2007; Hopkins and Langmead, 2009; Meister et al., 2020). For example, Klein and Manning (2003); Zhang and Gildea (2006); Auli and Lopez (2011); Lee et al. (2016) have used it in the context of parsing. Similar approaches are used for finding high-probability alignments (Naim et al., 2013). Despite these applications, applying informed heuristic search to text generation with autoregressive language models (this work's focus) has been underexplored.

Decoding strategies for text generation. The rise of autoregressive language models like GPT (Radford et al., 2018) has inspired work on decoding strategies (Post and Vilar, 2018a; Ippolito et al., 2019; Zheng et al., 2020; Leblond et al., 2021; West et al., 2021). These works often focus on incorporating factors like diversity (Ippolito et al., 2019), fluency (Holtzman et al., 2020), or constraints (Anderson et al., 2017; Hokamp and Liu, 2017; Post and Vilar, 2018b; Miao et al., 2019; Welleck et al., 2019a; Zhang et al., 2020; Qin et al., 2020; Lu et al., 2021). Constrained beam search (Anderson et al., 2017) and grid beam search (Hokamp and Liu, 2017) extend beam search to satisfy lexical constraints during generation. Lu et al. (2021) incorporate logic-based constraints into beam search, which we extend with lookahead heuristics.

Other work addresses the mismatch between monotonic decoding and satisfying constraints that can depend on a full generation, through MCMC sampling (Miao et al., 2019; Zhang et al., 2020), recursive non-monotonic generation (Welleck et al., 2019a), continuous optimization (Qin et al., 2020), or generated contexts (West et al., 2021). Unlike these past works, NeuroLogic A★esque explicitly decodes future text to estimate the viability of different paths for satisfying constraints.

5 Conclusion

Inspired by the A* search algorithm, we introduce NeuroLogic A★esque decoding, which brings A*-like heuristic estimates of the *future* to common *left-to-right* decoding algorithms for neural text generation. A★esque lookahead heuristics improve over existing decoding methods (*e.g.*, NeuroLogic, beam, greedy, sample decoding methods) in both *constrained* and *unconstrained* settings across a wide spectrum of tasks. Our work demonstrates the promise of moving beyond the current paradigm of unidirectional decoding for text generation, by taking bidirectional information from both the *past* and *future* into account to generate more globally coherent text.

Broader Impact and Ethical Implications

Our method deals with improving neural text generation, thus inheriting the potential impact and risks brought by text generation applications (e.g. dual use, see Pandya (2019); Brown et al. (2020)). Constraining generation through logical constraints offers the promise of improved control, consistency, and human-machine collaboration in high-impact applications such as translation, machine-aided writing, and education. On the other hand, constrained generation methods could foreseeably be used to generate text that contains biased, offensive, and/or hateful keywords (e.g., extremist texts; McGuffie and Newhouse, 2020). For a broader discussion of these risks, and of the risks of large pretrained language models in general, refer to discussions in Brown et al. (2020); Bender et al. (2021).

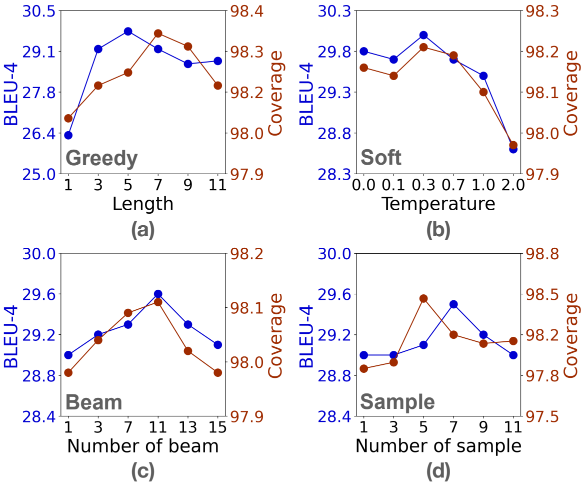

Figure 3: Effect of varying the primary hyperparameter for each lookahead strategy (§2.1) – (a) greedy (lookahead length), (b) soft (temperature), (c) beam (number of beams), and (d) sample (number of samples). Performance is measured on the CommonGen validation set, using **BLEU-4** and **Coverage**.

A Further Experiments

A.1 Constrained Commonsense Generation

Studying Lookahead Strategies. We further use CommonGen to study the lookahead strategies for NeuroLogic★ proposed in §2.1 (Figure 3). With infinite lookahead length ℓ and number of lookaheads $|\mathcal{L}_\ell|$, lookahead decoding exactly solves Equation 3, finding an optimal trajectory. In practice these are finite, meaning that the quality of the lookahead approximation can depend on the lookahead strategy and its hyperparameters. For practical choices of ℓ and $|\mathcal{L}_\ell|$, we empirically study how varying the lookahead strategy and hyperparameters affects performance. In Figure 3, we study the greedy, soft, beam, and sampling lookahead strategies.

Figure 3(a) shows the effect of increasing the lookahead length ℓ for the greedy lookahead strategy. Increasing the length improves up to one point – e.g., 5-7 steps – then decreases thereafter, likely due to the difficulty of long-horizon approximation.

Figure 3(b) studies the temperature in the soft lookahead, showing that greedy ($\tau = 0.0$) performs well, with slight gains if τ is carefully selected. The results suggest that one can safely bypass tuning τ using fast, greedy lookahead.

Next, Figure 3(c) shows that with beam lookahead, increasing the beam width improves performance up to a certain point (here, 11). Similarly, increasing the number of samples with sampling lookahead improves over a single sample, and then reaches an inflection point (Figure 3(d)).

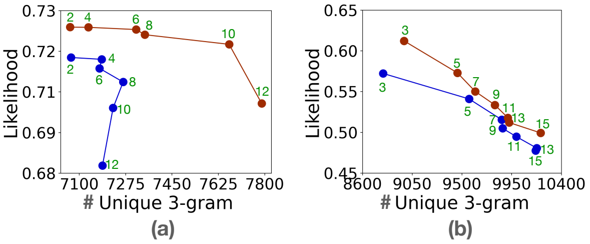

Figure 4: Likelihood (y-axis) vs. number of unique 3-grams (x-axis) using supervised GPT-2 on RocStories. Figure **(a)** denotes decoding with beam search, with a varying amount of beam size. Figure **(b)** denotes decoding with top-k sampling, with a varying amount of k value. The **brown** and **blue** lines denote with and without A★esque heuristics separately.

A.2 *Unconstrained* Story Generation

Fluency and Diversity Tradeoff We study the effect of A★esque decoding in unconstrained generation with different decoding hyperparameters: beam size in beam search and k value in top-k sampling. Figure 4 plots the fluency (measured by likelihood) versus diversity (measured by unique 3-grams) for generations with various beam sizes or top-k values. Ideally, we want generations to be both fluent and diverse (top right). However, we observe a fluency and diversity tradeoff in practice. A★esque decoding flattens this trend and results in larger area under the curve. The effect is especially strong with beam search. In summary, A★esque decoding yields a more favorable balance of fluency and diversity compared to conventional decoding methods, regardless of hyperparameters.

B Runtime

Decoding Method	Runtime
Beam Search	0.20
NeuroLogic	2.04
NeuroLogic A★esque	19.24

Table 9: Runtime (seconds per sentence) of different decoding algorithms with finetuned GPT2-L on the CommonGen dataset

C Experimental Details

C.1 Off-the-Shelf Models

We download off-the-shelf models, including pre-trained GPT-2 and Marian MT, from HuggingFace

Transformers (Wolf et al., 2020), which are implemented in the PyTorch deep learning framework.

C.2 Model Training Details

All training is performed on a single NVIDIA Quadro RTX 8000 GPU and costs about 100 GPU hours in total. Our method is implemented with PyTorch an the Huggingface Transformers library.

C.2.1 COMMONGEN

For supervised setting, we finetune GPT-2 for conditional generation. We follow Lu et al. (2021)'s setup and use their hyperparameters for finetuning, as shown in Table 10.

Hyperparameter	Assignment
model	GPT2-Large
number of parameters	774M
number of steps	15 epochs
batch size	64
learning rate optimizer	Adam
Adam epsilon	1e-8
Adam initial learning rate	1e-5
learning rate scheduler	linear with warmup
warmup steps	1.5 epoch
weight decay	0

Table 10: Hyperparameters for finetuning GPT-2 on COMMONGEN dataset.

C.2.2 Constrained Machine Translation

For fair comparison, we reproduced MT model (two-layer transformer) used by Dinu et al. (2019), using the same setup and hyperparameters reported in their original paper.

C.2.3 Table-to-text Generation

We finetune GPT-2 with random sampled few-shot training instances from E2ENLG dataset. We used the same hyperparameters for finetuning with Li and Liang (2021), as shown in Table 11.

Hyperparameter	Assignment
model	GPT2-Large
number of parameters	774M
number of steps	5 epochs
batch size	5
learning rate optimizer	Adam
Adam epsilon	1e-8
Adam initial learning rate	5e-5
learning rate scheduler	linear with warmup
warmup steps	100
weight decay	0

Table 11: Hyperparameters for finetuning GPT-2 on E2ENLG dataset.

C.2.4 Unconstrained Story Generation

We finetune GPT-2 for conditional story generation on the RocStories dataset: given a first sentence $\mathbf{x}$, generate the full story $\mathbf{y}$. Hyperparameters for finetuning are given in Table 12.

Hyperparameter	Assignment
model	GPT2-Large
number of parameters	774M
number of steps	10 epochs
batch size	64
learning rate optimizer	Adam
Adam epsilon	1e-8
Adam initial learning rate	1e-5
learning rate scheduler	linear with warmup
warmup steps	1 epoch
weight decay	0

Table 12: Hyperparameters for finetuning GPT-2 on the RocStories dataset.

C.3 Generation Details

All generation is performed on a single NVIDIA Quadro RTX 8000 GPU and costs about 100 GPU hours in total.

C.3.1 COMMONGEN

NEUROLOGIC★ hyperparameters for COMMONGEN in supervised and zero-shot setting are shown in Table 13 and Table 14 separately. We use the same NEUROLOGIC hyperparameters with Lu et al. (2021), including beam size, α, β and λ_1. We performed a hyperparameter grid search for the scaling factor λ_2 over the range $[0, 0.3]$, for the look ahead step over the the range $[1, 15]$, for the look ahead temperature over the the range $[0, 1.0]$, for the look ahead beam width over the the range $[1, 10]$, and for the look ahead number of sample over the the range $[1, 10]$, using a small subset of COMMONGEN development set.

Hyperparameter	Assignment
beam size	20
pruning threshold α	50
pruning threshold β	2
scaling factor λ_1	0
scaling factor λ_2	0.25
look ahead step	5
look ahead (greedy) temperature	0
look ahead (beam) beam width	5
look ahead (sample) number of sample	4

Table 13: NEUROLOGIC★ hyperparameters for COMMONGEN in supervised setting.

Hyperparameter	Assignment
beam size	20
pruning threshold α	500000
pruning threshold β	2
scaling factor λ_1	0
scaling factor λ_2	0.175
look ahead step	5
look ahead (greedy) temperature	0

Table 14: NEUROLOGIC★ hyperparameters for COMMONGEN in zero-shot setting.

C.3.2 Constrained Machine Translation

NEUROLOGIC★ hyperparameters for constrained machine translation are shown in Table 15. We use the same beam size with Dinu et al. (2019) for fair comparison. We performed a hyperparameter grid search for the pruning threshold α over the range $[50, 300]$, for the pruning threshold β over the range $[1, 3]$, for the scaling factor λ_1 over the range $[0, 1.0]$, for the scaling factor λ_2 over the range $[0, 0.3]$, for the look ahead step over the the range $[5, 40]$, using a subset of WMT2013 IATE development set. We use the same hyperparameters for look ahead temperature, look ahead beam width, and look ahead number of sample with supervised COMMONGEN and omit the hyperparameter search due to the computational cost.

Hyperparameter	Assignment
beam size	5
pruning threshold α	200
pruning threshold β	2
scaling factor λ_1	0.25
scaling factor λ_2	0.05
look ahead step	35
look ahead (greedy) temperature	0
look ahead (beam) beam width	5
look ahead (sample) number of sample	4

Table 15: NEUROLOGIC★ hyperparameters for constrained machine translation.

C.3.3 Table-to-text Generation

NEUROLOGIC★ hyperparameters for table-to-text generation are shown in Table 16. We performed a hyperparameter grid search for the scaling factor λ_2 over the range $[0, 0.3]$, for the look ahead step over the the range $[1, 15]$, using E2ENLG development set. For other hyperparameters, we use the same value with supervised COMMONGEN and omit the hyperparameter search due to the computational cost.

Hyperparameter	Assignment
beam size	20
pruning threshold α	50
pruning threshold β	2
scaling factor λ_1	0
scaling factor λ_2	0.05
look ahead step	7
look ahead (greedy) temperature	0
look ahead (beam) beam width	5
look ahead (sample) number of sample	4

Table 16: NEUROLOGIC★ hyperparameters for table-to-text generation.

C.3.4 Constrained Question Generation

NEUROLOGIC★ hyperparameters for constrained question generation are shown in Table 17. The task is zero-shot and doesn't provide train or development set, so we use the same decoding hyperparameters with zero-shot COMMONGEN.

Hyperparameter	Assignment
beam size	20
pruning threshold α	500000
pruning threshold β	2
scaling factor λ_1	0
scaling factor λ_2	0.175
look ahead step	5
look ahead (greedy) temperature	0
look ahead (beam) beam width	5
look ahead (sample) number of sample	4

Table 17: NEUROLOGIC★ hyperparameters for constrained question generation.

C.3.5 Unconstrained Story Generation

A★esque hyperparameters with beam search and top-k sampling for unconstrained story generation are shown in Table 18 and Table 19 separately. We performed a hyperparameter grid search for the scaling factor λ_2 over the range $[0, 1.0]$, for the look ahead step over the the range $[1, 15]$, for the look ahead temperature over the the range $[0, 1.0]$, for the look ahead beam width over the the range $[1, 15]$, and for the look ahead number of sample over the the range $[1, 15]$, using a small subset of RocStories development set.

C.4 Dataset Details

Details of datasets used for downstream tasks are provided in Table 22.

D Human Evaluation

We include screenshots of the human evaluation templates for CommonGen (Figure 5), Constrained

Hyperparameter	Assignment
beam size	4
scaling factor λ_2	0.6
look ahead step	4
look ahead (greedy) temperature	0
look ahead (beam) beam width	4
look ahead (sample) number of sample	15

Table 18: A$^\bigstar$esque hyperparameters with beam search for unconstrained story generation.

Hyperparameter	Assignment
k value	5
scaling factor λ_2	0.5
look ahead step	3
look ahead (greedy) temperature	0
look ahead (beam) beam width	4
look ahead (sample) number of sample	15

Table 19: A$^\bigstar$esque hyperparameters with top-k sampling for unconstrained story generation.

Question Generation (Figure 6), and RocStories (Figure 7) tasks. We ensure the annotators are paid adequately for at least $15 per hour and we inform annotators that their annotations are used for model evaluation purpose.

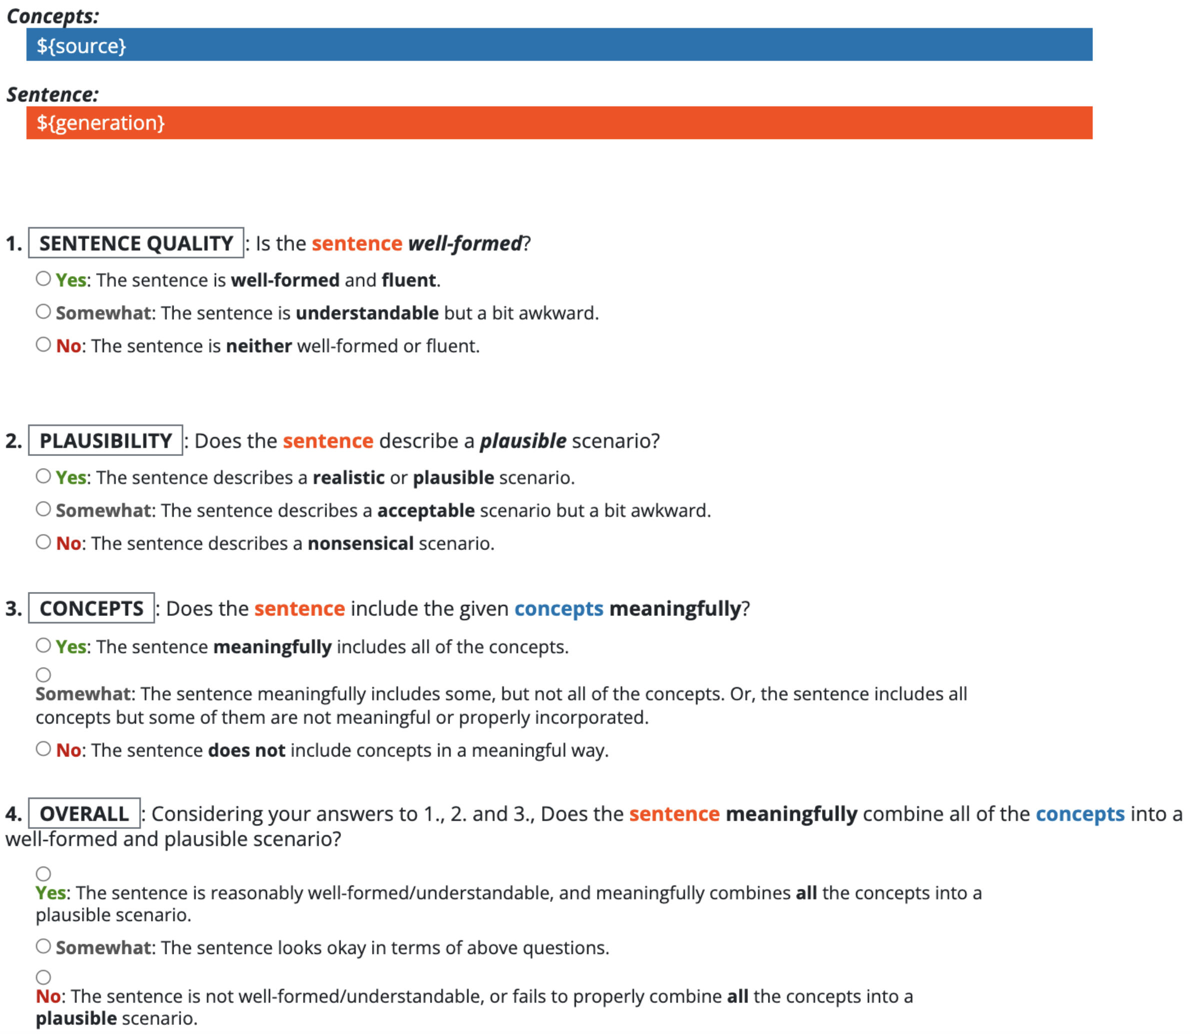
E Qualitative Generation Examples

Qualitative examples of the constrained question generation and unconstrained story generation are shown in Table 21 and 20.

F Limitations and Risks.

Limitations. For constrained generation, NEUROLOGIC A$^\bigstar$esque decoding can only take the constraints that can be formulated as logical expressions as described in the paper; we leave it to future work to expand the scope of such logical constraints.

Risks. Constrained generation methods could foreseeably be used to generate text that contains biased, offensive, and/or hateful keywords. (e.g., extremist texts; McGuffie and Newhouse, 2020). For a broader discussion of these risks, and of the risks of large pretrained language models in general, refer to discussions in Brown et al. (2020); Bender et al. (2021).



Concepts:

${source}

Sentence:

${generation}

1. **SENTENCE QUALITY**: Is the **sentence** ***well-formed***?

○ **Yes**: The sentence is **well-formed** and **fluent**.

○ **Somewhat**: The sentence is **understandable** but a bit awkward.

○ **No**: The sentence is **neither** well-formed or fluent.

2. **PLAUSIBILITY**: Does the **sentence** describe a ***plausible*** scenario?

○ **Yes**: The sentence describes a **realistic** or **plausible** scenario.

○ **Somewhat**: The sentence describes a **acceptable** scenario but a bit awkward.

○ **No**: The sentence describes a **nonsensical** scenario.

3. **CONCEPTS**: Does the **sentence** include the given **concepts** **meaningfully**?

○ **Yes**: The sentence **meaningfully** includes all of the concepts.

○ **Somewhat**: The sentence meaningfully includes some, but not all of the concepts. Or, the sentence includes all concepts but some of them are not meaningful or properly incorporated.

○ **No**: The sentence **does not** include concepts in a meaningful way.

4. **OVERALL**: Considering your answers to 1., 2. and 3., Does the **sentence** **meaningfully** combine all of the **concepts** into a well-formed and plausible scenario?

○ **Yes**: The sentence is reasonably well-formed/understandable, and meaningfully combines **all** the concepts into a plausible scenario.

○ **Somewhat**: The sentence looks okay in terms of above questions.

○ **No**: The sentence is not well-formed/understandable, or fails to properly combine **all** the concepts into a **plausible** scenario.

Question:

${generation}

Q1. **Grammar** Is the **question** written in a ***grammatically correct*** way?

○ **Yes** It is **entirely** or **mostly** grammatically correct, with **no** or **minimal** grammatical mistakes.
○ **Somewhat** It is **partially** grammatically correct, with **some** grammatical mistakes.
○ **No** It is **mostly not** grammatically correct, with **many** grammatical mistakes.

Q2. **Fluency** Is the **question** written in a ***fluent*** and ***understandable*** way?

○ **Yes** It is **entirely** or **mostly** fluent and understandable.
○ **Somewhat** It is **somewhat** fluent and understandable, but it reads **a bit awkward**.
○ **No** It is **mostly poorly written** and hard to understand.

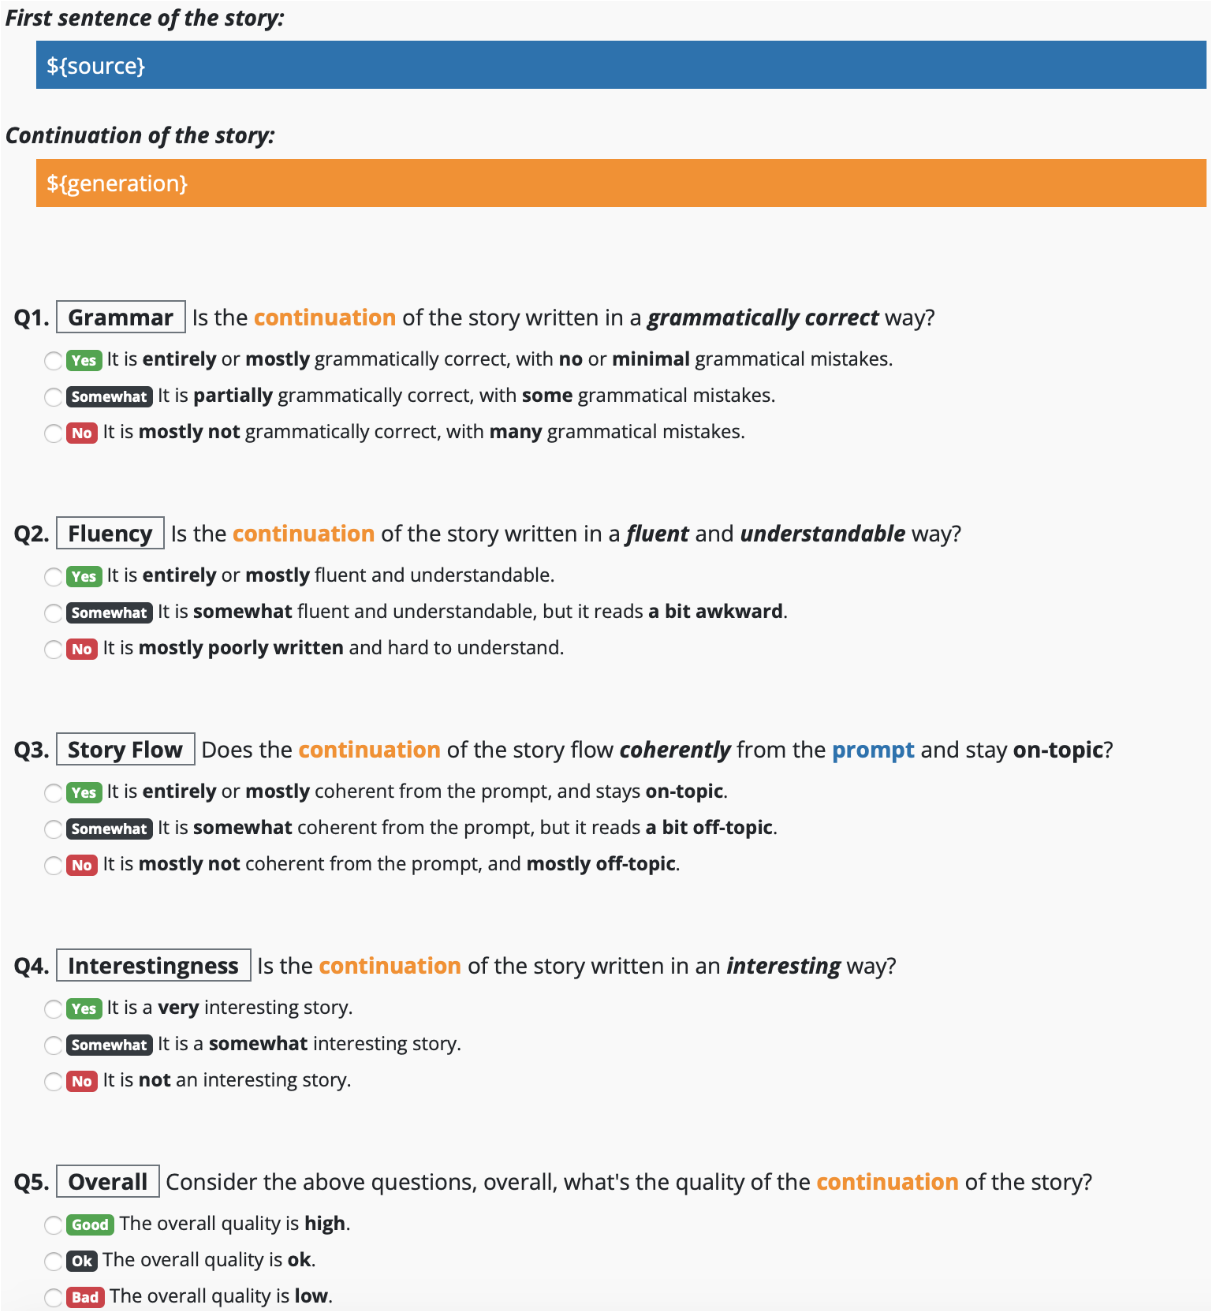
Q3. **Meaningfulness** Does the given **question** sentence ask a ***meaningful*** question?

○ **Yes** It is an **entirely** or **mostly** meaningful question.
○ **Somewhat** It is a **somewhat** meaningful question, but it might be **a bit unclear**.
○ **No** It is **mostly not** a meaningful question.

Q4. **Overall** Consider **grammar**, **fluency** and **meaningfulness**, overall, what's the quality of the **question**?

○ **Good** The overall quality is **high**.
○ **Ok** The overall quality is **ok**.
○ **Bad** The overall quality is **low**.

Figure 6: Human evaluation template for the Interrogative Sentence Generation task.



First sentence of the story:

${source}

Continuation of the story:

${generation}

Q1. **Grammar** Is the **continuation** of the story written in a ***grammatically correct*** way?

○ **Yes** It is **entirely** or **mostly** grammatically correct, with **no** or **minimal** grammatical mistakes.
○ **Somewhat** It is **partially** grammatically correct, with **some** grammatical mistakes.
○ **No** It is **mostly not** grammatically correct, with **many** grammatical mistakes.

Q2. **Fluency** Is the **continuation** of the story written in a ***fluent*** and ***understandable*** way?

○ **Yes** It is **entirely** or **mostly** fluent and understandable.
○ **Somewhat** It is **somewhat** fluent and understandable, but it reads **a bit awkward**.
○ **No** It is **mostly poorly written** and hard to understand.

Q3. **Story Flow** Does the **continuation** of the story flow ***coherently*** from the **prompt** and stay **on-topic**?

○ **Yes** It is **entirely** or **mostly** coherent from the prompt, and stays **on-topic**.
○ **Somewhat** It is **somewhat** coherent from the prompt, but it reads **a bit off-topic**.
○ **No** It is **mostly not** coherent from the prompt, and **mostly off-topic**.

Q4. **Interestingness** Is the **continuation** of the story written in an ***interesting*** way?

○ **Yes** It is a **very** interesting story.
○ **Somewhat** It is a **somewhat** interesting story.
○ **No** It is **not** an interesting story.

Q5. **Overall** Consider the above questions, overall, what's the quality of the **continuation** of the story?

○ **Good** The overall quality is **high**.
○ **Ok** The overall quality is **ok**.
○ **Bad** The overall quality is **low**.

PARADISE: Exploiting Parallel Data for Multilingual Sequence-to-Sequence Pretraining

Machel Reid
The University of Tokyo
`machelreid@weblab.t.u-tokyo.ac.jp`

Mikel Artetxe
Meta AI
`artetxe@fb.com`

Abstract

Despite the success of multilingual sequence-to-sequence pretraining, most existing approaches rely on monolingual corpora, and do not make use of the strong cross-lingual signal contained in parallel data. In this paper, we present PARADISE (**PARA**llel & **D**enoising **I**ntegration in **SE**quence-to-sequence models), which extends the conventional denoising objective used to train these models by (i) replacing words in the noised sequence according to a multilingual dictionary, and (ii) predicting the reference translation according to a parallel corpus instead of recovering the original sequence. Our experiments on machine translation and cross-lingual natural language inference show an average improvement of 2.0 BLEU points and 6.7 accuracy points from integrating parallel data into pretraining, respectively, obtaining results that are competitive with several popular models at a fraction of their computational cost.[1]

1 Introduction

Multilingual sequence-to-sequence pretraining has achieved strong results both in cross-lingual classification (Xue et al., 2021) and machine translation (Liu et al., 2020). These models are usually pretrained on combined monolingual corpora in multiple languages using some form of denoising objective. More concretely, they noise each sequence x with a noising function g_ϕ, and maximize the probability of recovering x given $g_\phi(x)$:

$$\ell_{\text{mono}}(x) = -\log P\big(x|g_\phi(x)\big) \quad (1)$$

Common noising functions include sentence-permutation and span masking (Lewis et al., 2020; Liu et al., 2020).

While these methods obtain strong cross-lingual performance without parallel data, they are usually trained at a scale that is prohibitive for most NLP practitioners. At the same time, it has been argued that the strict unsupervised scenario is not realistic (Artetxe et al., 2020), and parallel data could provide a stronger signal and make training more efficient.

Motivated by this, we propose PARADISE, a pretraining method for sequence-to-sequence models that exploits both word-level and sentence-level parallel data. The core idea of our approach is to augment the conventional denoising objective introduced above by (i) replacing words in the noised sequence according to a bilingual dictionary, and (ii) predicting the reference translation rather than the input sequence. Despite their simplicity, we find that both techniques bring substantial gains over conventional pretraining on monolingual data, as evaluated both in machine translation and zero-shot cross-lingual transfer. Our results are competitive with several popular models despite using only a fraction of the compute, providing strong support for the importance of the inclusion of parallel information in smaller-scale multilingual pretraining methods.

2 Proposed method

As illustrated in Figure 1, we propose two methods for introducing parallel data into pretraining: dictionary denoising and bitext denoising.

Dictionary denoising. Our first method encourages learning similar representations at the word-level by introducing anchor words through multilingual dictionaries (Conneau et al., 2020b). Let $D_l(w)$ denote the translation of word w into language $l \in L$ according to the dictionary D. Given the source sentence $x = (x_1, x_2, \ldots, x_n)$, we define its noised version $g_\psi(x) = (\tilde{x}_1, \tilde{x}_2, \ldots, \tilde{x}_n)$, where $\tilde{x}_i = D_l(x_i)$ with probability $\frac{p_r}{|L|}$ and $\tilde{x}_i = x_i$ otherwise (i.e. we replace each word with its translation into a random language with probability

(a) Dictionary Denoising

(b) Bitext Denoising

Figure 1: Our proposed techniques for integrating parallel data into sequence-to-sequence pretraining.

p_r). We set $p_r = 0.4$. Given the dictionary-noised sentence, we train our model using the denoising auto-encoding objective in Eq. 1:

$$\ell_{\text{dict}}(x) = -\log P\big(x | g_\phi(g_\psi(x))\big) \quad (2)$$

Bitext denoising. Our second approach encourages learning from both monolingual and parallel data sources, by including translation data in the pretraining process. Given a source-target bitext pair (x, y) in the parallel corpus, assumed to be semantically equivalent, we model the following:

$$\ell_{\text{bitext}}(x, y) = -\log P\big(y | g_\phi(x)\big) \quad (3)$$

in which we optimize the likelihood of generating the target sentence y conditioned on the noised version of the source sentence, $g_\phi(x)$.[2]

Combined objective. Our final objective combines ℓ_{mono}, ℓ_{dict} and ℓ_{bitext}.[3] Given that our corpus contains languages with varying data sizes, we sample sentences using the exponential sampling technique from Conneau and Lample (2019). We use $\alpha_{\text{mono}} = 0.5$ to sample from the monolingual corpus, and $\alpha_{\text{bitext}} = 0.3$ to sample from the parallel corpus. To prevent over-exposure to English on the decoder side when sampling from the parallel corpus, we halve the probability of to-English directions and renormalize the probabilities. In addition, given that we have fewer amounts of parallel data (used for ℓ_{bitext}) than monolingual data (used for ℓ_{mono} and ℓ_{dict}), we sample between each task using $\alpha_{\text{task}} = 0.3$.

3 Experimental settings

We pretrain our models on 20 languages (English, French, Spanish, German, Greek, Bulgarian, Russian, Turkish, Arabic, Vietnamese, Thai, Chinese, Hindi, Swahili, Urdu, Japanese, Basque, Romanian, Sinhala and Nepalese), and evaluate them on machine translation and cross-lingual classification.

3.1 Pretraining

Data. We use Wikipedia as our monolingual corpus, and complement it with OSCAR (Ortiz Suárez et al., 2020), and CC100 (Conneau et al., 2020a) for low-resource languages. For a fair comparison with monolingually pretrained baselines, we use the same parallel data as in our downstream machine translation experiments (detailed in §3.2). In addition, we train a separate variant (detailed below) using additional parallel data from ParaCrawl (Esplà et al., 2019), UNPC (Ziemski et al., 2016), CCAligned (El-Kishky et al., 2020), and OpenSubtitles (Lison and Tiedemann, 2016).[4] We tokenize all data using SentencePiece (Kudo and Richardson, 2018) with a joint vocabulary of 125k subwords. We use bilingual dictionaries from FLoRes[5] (Guzmán et al., 2019) for Nepalese and Sinhala, and MUSE[6] (Lample et al., 2018) for the rest of languages. Refer to Appendix A for more details.

Models. We use the same architecture as BART-base (Lewis et al., 2020), totaling ~196M parameters, and train for 100k steps with a batch size of ~520k tokens. This takes around a day on 32 NVIDIA V100 16GB GPUs. As discussed before, we train two variants of our full model: **PARADISE**, which uses the same parallel data as the machine translation experiments, and **PARADISE++**, which uses additional parallel data. To better understand the contribution of each objective, we train two additional models without dictionary denoising, which we name **PARADISE (w/o dict.)** and **PARADISE++ (w/o dict.)**, as well as a model without bitext denoising, which we name **PARADISE++ (only dict.)**. Finally, we train a baseline system using the monolingual objective alone,

---

[2] To make our pretraining sequence length consistent with ℓ_{mono} and ℓ_{dict}, we concatentate randomly sampled sentence pairs from the same language pair to fit the maximum length.

[3] We use the same noising function g_ϕ used by Lewis et al. (2020) and Liu et al. (2020).

[4] We cap the size of each language pair to 2GB.

which we refer to as **mBART (ours)**. This follows the original mBART work (Liu et al., 2020), but is directly comparable to the rest of our models in terms of data and hyperparameters.

3.2 Downstream settings

Machine translation. Following Liu et al. (2020), we evaluate our models on sentence-level machine translation from and to English using the following datasets: IWSLT (Cettolo et al., 2015, 2017) for Vietnamese, Japanese and Arabic, WMT (Callison-Burch et al., 2009a,b; Bojar et al., 2016, 2017) for Spanish, French, Romanian and Turkish, FLoRes (Guzmán et al., 2019) for Sinhala and Nepalese, and IITB (Kunchukuttan et al., 2018) for Hindi. We report performance in BLEU as detailed in Appendix C.

Cross-lingual classification. We evaluate our models on zero-shot cross-lingual transfer on XNLI (Conneau et al., 2018) and PAWS-X[7] (Yang et al., 2019), where we finetune on English data and test performance on other languages. We develop a new approach for applying sequence-to-sequence models for classification: feeding the sequence into both the encoder and decoder, and taking the concatenation of the encoder's `<s>` representation and the decoder's `</s>` representation as the input of the classification head. We provide an empirical rationale for this in Appendix E. We finetune all models with a batch size of 64 and a learning rate of 2×10^{-5} for a maximum of 100k iterations, performing early stopping on the validation set.

4 Results

4.1 Machine translation

As shown in Table 1, PARADISE consistently outperforms our mBART baseline across all language pairs. Note that these two models have seen the exact same corpora, but mBART uses the parallel data for finetuning only, whereas PARADISE also uses it at the pretraining stage. This suggests that incorporating parallel data into pretraining helps learn better representations, which results in better downstream performance.

Lang. pair (En-XX)	**Tr**	**Ro**	**Si**	**Hi**	**Es**	**Avg**$_\Delta$
mBART (ours)	15.8	34.9	2.7	19.0	30.4	20.6$_{\pm 0.0}$

Table 2: Ablation results on machine translation.

Table 2 reports additional ablation results on a subset of languages. As can be seen, removing dictionary denoising hurts, but is still better than our mBART baseline. This shows that both of our proposed approaches—dictionary denoising and bitext denoising—are helpful and complementary. Finally, PARADISE++ improves over PARADISE, indicating that a more balanced corpus with more parallel data is helpful.

4.2 Cross-lingual classification

We report XNLI results in Table 3 and PAWS-X results in Appendix F. Our proposed approach outperforms mBART in all languages by a large margin. To our surprise, we also observe big gains in English. We conjecture that this could be explained by bitext denoising providing a stronger training signal from all tokens akin to ELECTRA (Clark et al., 2020), whereas monolingual denoising only gets effective signal from predicting the masked portion. In addition, given that we are using parallel data between English and other languages, PARADISE ends up seeing much more English text compared to mBART—yet a similar amount in the rest of languages—which could also contribute to

---

[7] Following Hu et al. (2021), we use English, German, Spanish, French and Chinese for PAWS-X.

its better performance in this language. Finally, we observe that all of our different variants perform similarly in English, but incorporating dictionary denoising and using additional parallel data both reduce the cross-lingual transfer gap.

4.3 Comparison with prior work

So as to put our results into perspective, we compare our models with several popular systems from the literature. As shown in Table 4, our proposed approach obtains competitive results despite being trained at a much smaller scale. Just in line with our previous results, this suggests that incorporating parallel data makes pretraining more efficient given that we outperform XLM-R base, mT5, and mBART despite using less data/compute/model size. Interestingly, our method also outperforms XLM-15, MMTE, and mT6 which also use parallel data, as well as AMBER, showing evidence contrary to Hu et al. (2021)'s suggestion that using dictionaries may hurt performance. Detailed per-language results for each task can be found in Appendix F.

5 Related work

Most prior work on multilingual pretraining uses monolingual data only (Pires et al., 2019; Conneau et al., 2020a; Song et al., 2019; Liu et al., 2020; Xue et al., 2021). There have been several proposals to incorporate parallel data into encoder-only models (Lample and Conneau, 2019; Huang et al., 2019; Hu et al., 2021; Chi et al., 2021b), with some approaches replacing words according to a bilingual dictionary, similar to our dictionary denoising objective (Conneau et al., 2020b; Chaudhary et al., 2020; Dufter and Schütze, 2020). In contrast, we focus on sequence-to-sequence models, which we believe are more flexible and provide a more natural way of integrating parallel data. In that spirit, Siddhant et al. (2019) showed that vanilla machine translation models are already competitive in cross-lingual classification. Closer to our work, Chi et al. (2021a) incorporated parallel corpora into sequence-to-sequence pretraining by feeding concatenated parallel sentences to the encoder and using different masking strategies. In contrast, our approach feeds a noised sentence into the encoder, and tries to recover its translation in the decoder side, obtaining better results with a similar computational budget. Concurrent to our work, Kale et al. (2021) extended T5 to incorporate parallel corpora using a similar approach to our bitext denoising.

6 Conclusions

In this work, we proposed PARADISE, which introduces two new objectives to integrate parallel data into sequence-to-sequence pretraining. Experimental results on machine translation and cross-lingual classification show that PARADISE provides significant improvements over mBART-style pretraining on monolingual corpora, obtaining results that are competitive with several popular models at a much smaller scale. Given these findings, we encourage use of parallel data in smaller-scale multilingual pretraining work. In the future, we look to see if our improvements also hold at a larger scale.

A Data

We list data sources used for pretraining PARADISE++ in Table 5 (monolingual data) and Table 6 (parallel data).

B Pretraining hyperparameters

We use the Adam optimizer ($\epsilon = 10^{-6}, \beta = (0.9, 0.98)$), and warm up the learning rate to a peak of 7×10^{-4} after 10K iterations and then proceed to decay the learning rate with the polynomial decay schedule up until 100K iterations. All code and experiments are performed with `fairseq` (Ott et al., 2019). Following Liu et al. (2020), we add an additional layer-normalization layer on top of both the encoder and decoder to stabilize training with FP16 precision (Micikevicius et al., 2018). All models are trained on 32 V100 16GB GPUs and take 24 hours to finish training.

C Machine translation evaluation

Following Liu et al. (2020), we use detokenized SacreBLEU (Post, 2018) for all languages unless specified otherwise next. For Japanese we use KyTea[8], for Nepalese, Sinhala, and Hindi we use Indic-NLP[9], for Arabic we use the QCRI Arabic Normalizer[10,11], and for Romanian we use Moses tokenization and script normalization following Sennrich et al. (2016); Liu et al. (2020).

D Machine translation finetuning

We finetune our models using the same setup as mBART, warming up the learning rate to 3×10^{-5} over 2500 iterations and then decaying with a polynomial schedule. We use 0.3 dropout and label smoothing $\epsilon = 0.2$.

E Comparison of finetuning approaches

Table 7 compares our proposed finetuning approach, which combines the representations from both the encoder and the decoder (see §3), to using either of them alone.[12] While prior work either minimally used the decoder if at all (Siddhant et al., 2019; Xue et al., 2021), or only added a classification head on top of the decoder (Lewis et al., 2020), we find that combining them both works best.

[12] For *decoder-only*, we feed the input sequence to both the encoder and the decoder, but add a classification head on top of the decoder only, following Lewis et al. (2020).

F Additional results

We list detailed results by language in this section with results on XNLI in Table 8, PAWS-X in Table 9, and our machine translation ablation (with mBART (Liu et al., 2020) results included) in Table 10. We note that mBART underperforms XLM-R-large on XNLI, however that may be attributed to the fact that XLM-R was trained for much longer rather than the architectural design.

Abstract

Warning: This paper contains content that is offensive and may be upsetting.

Biased or toxic speech can be harmful to various demographic groups. Therefore, it is not only important for models to detect these speech, but to also output explanations of why a given text is toxic. Previous literature has mostly focused on classifying and detecting toxic speech, and existing efforts on explaining stereotypes in toxic speech mainly use standard text generation approaches, resulting in generic and repetitive explanations. Building on these prior works, we introduce a novel knowledge-informed encoder-decoder framework to utilize multiple knowledge sources to generate implications of biased text. Experiments show that our knowledge informed models outperform prior state-of-the-art models significantly, and can generate detailed explanations of stereotypes in toxic speech compared to baselines, both quantitatively and qualitatively.

1 Introduction

The toxic speech detection and classification problem has seen increasing interest in recent years. However, it is not only important for AI agents to recognize and classify toxic speech, but to also explain why it is toxic. For instance, debiasing methods that use information about toxic language may benefit from additional information given by detailed explanations of toxicity in text (Ma et al., 2020). Furthermore, detailed explanations of toxicity may facilitate human interaction with toxicity detection systems (Rosenfeld and Richardson, 2019). They can also help humans who work with toxicity classifiers use more information about the input when making decisions about toxic speech. To elucidate, consider the following offensive joke: "*What type of punch do you use against a kindergartener? A sandy-hook.*". While the literal text is not toxic, the implied meaning is offensive, particularly to those affected by school shootings. An AI agent capable of generating the implied meaning could thus provide additional information to downstream actors. Note that, we use the term *biased* and *toxic* interchangeably in this work.

Existing work largely addresses the problem of **detecting** and **classifying** toxic speech (Waseem and Hovy, 2016; Founta et al., 2018; Davidson et al., 2017). As mentioned earlier, explanations of toxicity can help with downstream tasks such as debiasing or decision making by humans, thus there has been increasing demand for explainable machine learning classifiers (Ribeiro et al., 2016; Došilović et al., 2018). Recent work around explainable toxicity classification introduced Social Bias Frames (Sap et al., 2020), a formal framework which combines explanations of toxicity along with toxicity classifications along multiple dimensions. However the explanations generated from the current state-of-the-art methods tend to be generic, without much detail. For instance, explanations may focus on certain toxic components of the input but ignore others, or include irrelevant stereotypes about the minority group affected.

To fill this gap, our work proposes to leverage different types of knowledge to provide rich context and background for toxicity explanation. Specifically, we introduce a novel framework to utilize three distinct knowledge sources. Prior work (Yu et al., 2022) divides knowledge broadly into internal and external knowledge, where internal knowledge is knowledge embedded in the input text, and external knowledge is derived from sources outside the input. Building upon these, we leverage **expert knowledge** that comes from high-quality expert annotations of the input, and **explicit knowledge** from knowledge graphs and bases, as such symbolic knowledge can provide relevant information to the output text (Yu et al., 2022; Mou et al., 2016). While knowledge graphs and bases deterministically retrieve and restructure knowledge from raw text sources, large pretrained generative models are

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 811 - 826
July 10-15, 2022 ©2022 Association for Computational Linguistics

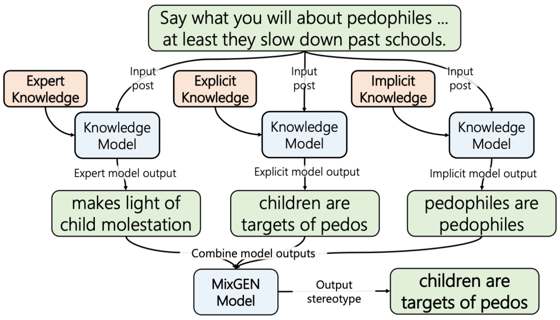

Figure 1: MixGEN takes 3 types of knowledge sources and outputs an implied explanation for the input post.

found to be effective in outputting useful knowledge in a probabilistic manner, complementing the expert and explicit knowledge (Razniewski et al., 2021). To this end, we also include **implicit knowledge** models which source knowledge from large pretrained text generation models. We further build a family of mixture models, MixGEN, to synthesize knowledge from all three sources, as shown in Figure 1. To sum up, our contributions are twofold: (1) We leverage three different sources of knowledge, and further combine them using simple yet effective mixture models to explain toxic text. (2) We show that our models outperform prior state-of-the-art baselines and generate more detailed explanations.

2 Related Work

Prior work on knowledge enhanced text generation (Yu et al., 2020) can be viewed across two different knowledge sources.

2.1 Internal Knowledge

Internal knowledge includes knowledge that is available within the input. For instance, Latent Dirichlet Allocation (LDA) (Blei et al., 2003) can learn topics from inputs, which can then be incorporated into text generation models (Cao et al., 2015; Guo et al., 2020). Keywords may also be extracted from input text using techniques like TF-IDF, PMI or independent classifiers. In one such work, Song et al. (2019) extract emotion oriented keywords using an independent emotion classifier to enhance dialogue generation. Similarly, Mou et al. (2016) use PMI to find relevant keywords for short text conversation. Forbes et al. (2020) develop conceptual formalisms that rely on annotations about the input to generate text. In this work, we denote the use of independent annotations on input to enhance text generation as **expert knowledge**, as such annotations often come from human experts.

2.2 External Knowledge

Knowledge graphs and bases are commonly used as a form of external knowledge. Zhang et al. (2019) use knowledge graph embeddings to model conversation flow, while Guan et al. (2020) use triples extracted from knowledge graphs to enhance story generation. Finally, Lian et al. (2019) develop probabilistic mechanisms to select knowledge from knowledge bases for response generation. Knowledge from conventional sources are determinstically created, in that they simply restructure raw text and store them in a knowledge base or graph. We refer to this type of external knowledge as **explicit knowledge**. On the other hand, there has been increasing interest in the use of large pretrained generative models as a source of knowledge. Heinzerling and Inui (2021) argue that large pretrained models can in fact serve as knowledge bases, while Davison et al. (2019) argue that pretrained models can accurately assess the validity of knowledge mined from raw text. While pretrained models are also trained on raw texts, similar to knowledge bases and graphs, they draw from this knowledge probabilistically and thus are a distinct approach. We denote this type of external knowledge as **implicit knowledge**.

2.3 Toxic Text Understanding

Prior work around toxicity understanding mainly focuses on detection (Schmidt and Wiegand, 2017). Early approaches include using n-grams (Waseem and Hovy, 2016; Sood et al., 2012; Perera and Fernando, 2021) as well as word clustering (Xiang et al., 2012; Zhong et al., 2016). Recently, knowledge enhanced approaches have also been used for toxicity *detection*. For instance, Dinakar et al. (2012) use ConceptNet to detect anti-LGBT bullying. The use of meta-information, such as information about the user (Dadvar et al., 2012), has proven to be useful, depending on the type of information used. Sap et al. (2020) use Social Bias Frames to produce both toxicity classifications and explanations of toxicity. Similarly, our approach attempts to explain toxicity by leveraging different sources of knowledge to provide more context and grounding for the models to generate explanations. Different from many prior works, we synthesize these diverse knowledge sources in a unified framework to utilize the unique contribution from each individual knowledge source.

3 Knowledge Enhanced MIXGEN

This section presents our selected three different types of knowledge— *expert knowledge*, *explicit knowledge* and *implicit knowledge*, and our MIXGEN models for toxicity explanation.

3.1 Expert Knowledge

Expert knowledge is sourced from annotations of the input. For instance, in the Social Bias Frames dataset (Sap et al., 2020), such expert knowledge include human judgements towards the lewdness, offensiveness, intent to offend, and group targeted categories. This type of expert knowledge provides useful insights and heuristics for the toxicity explanation task, if they are available.

We incorporate expert knowledge into the generation process using the join embedding technique (Pryzant et al., 2020) along with toxicity classification models. The join embedding architecture uses attention weights from the toxicity classifiers to inform the text generation model about parts of the input post relevant to toxicity classification, thus providing a heuristic for the related toxicity explanation task. Formal details of the architecture can be found in Appendix A.1.

We denote these models with the naming convention, “EXPERT [FEATURE]", where “[FEATURE]" is the categorical variable we use for the join embedding. We replace “[FEATURE]" with “ALL" when we train on all features.

3.2 Explicit Knowledge

Explicit knowledge is sourced from some knowledge base or graph. Common sources include ConceptNET, DBpedia, WikiData, etc. (Auer et al., 2007; Vrandečić and Krötzsch, 2014). We opt to use ConceptNet (Speer et al., 2017), since it contains commonsense knowledge (Liu and Singh, 2004). Commonsense knowledge incorporates everyday concepts, especially knowledge regarding social groups and situations.

Following Chang et al. (2020), given a BART model and an input, we extract ranked triples related to the input post and keep the top k triples per post where we vary the $k \in \{3, 5, 10, 15, 20, 25\}$. We experiment with both concatenation and attention based methods to incorporate the top k triples, but settle on a concatenation based approach due to its simplicity and the lack of performance gains from the attention based approach. Results and analysis for both the concatenation and attention based approaches are provided in Appendix 12. We denote these models with the naming convention, “EXPLICIT (K)", where K denotes the number of triples used.

3.3 Implicit Knowledge

Implicit knowledge is obtained from some text generator, such as a large pretrained generative model. Prior work such as Heinzerling and Inui (2021), argue that large pretrained models can in fact serve as knowledge bases. Implicit knowledge grants models a probabilistic view of external raw text sources related to a given scenario or input, since generative models tend to generate based on statistical correlations found in their training corpora (Razniewski et al., 2021).

To use implicit knowledge, we first train a BART model to generate the target minority group from the input post. Following Sheng et al. (2019), we use the predicted target minority corresponding to each input post and a set of prompts to induce biased prompt completions from GPT models. We may use multiple prompts per input post, where the number of prompt completions generated is governed by a hyperparameter, k. Then we train an independent BART model to generate these biased prompt completions, given the origin input post. This BART model is then retrained to produce the implied stereotype, given the input post. Again, we provide a formal description in Appendix A.3.

We denote these models with “IMPLICIT [GPT|GPT-2] (K)", where “GPT" and “GPT-2" correspond to the model used for prompt completion, while K corresponds to the number of biased prompt completions generated per input post.

3.4 MIXGEN Models

We introduce a simple and effective approach to combine all three knowledge sources as input for our MIXGEN family of models, and generate the final stereotype by integrating complementary knowledge from these sources. In our design, we take inspiration from Mixture of Experts models (Masoudnia and Ebrahimpour, 2012), which combine base expert model outputs into a final output using a gating mechanism. Here, we rely on attention mechanisms over the knowledge informed model outputs to serve as the gating mechanism.

We build two variants. The first variant is called MIXGEN CONCAT which uses concatenation to

Type	Description	Pros	Cons
Expert Knowledge	Expert judgements from annotations on the input.	• Easy-to-use. • High quality and accurate knowledge.	• Sparse and hard to obtain. • Difficult to get a lot of diverse knowledge.
Explicit Knowledge	External knowledge sourced from knowledge bases and graphs. Restructured, determinstic interpretations of raw text sources.	• Many knowledge bases and graphs exist. • Easy to query due to symbolic representation. • Explainable since knowledge source is known.	• Fixed knowledge, thus limited retrieval diversity. • Explicitly constructed, thus may not be complete.
Implicit Knowledge	External knowledge sourced from large pretrained models. Probabilistically generated from raw text sources	• Easy to retrieval. • Probabilistic, thus increasing diversity in retrieval.	• Low explainability. • Low quality, since the knowledge is implicitly learned.

Table 1: Some pros and cons about different types of knowledge used for toxicity explanation.

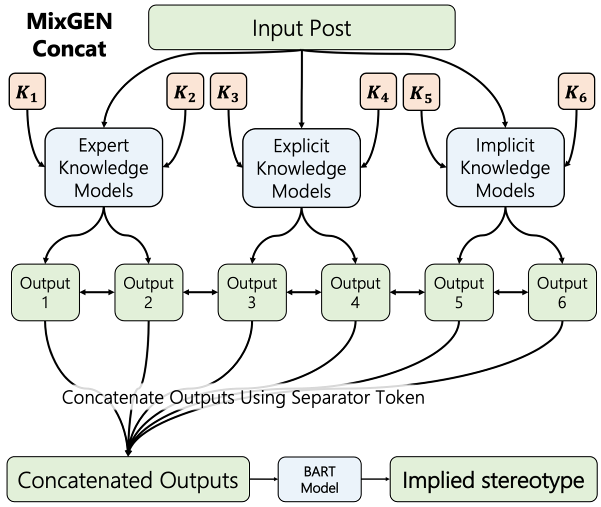

Figure 2: The MIXGEN model takes in the output of multiple trained knowledge models, concatenates them with separator tokens and uses the concatenation as input to a BART model to output the explanation. We test with six models, two from each knowledge source.

combine outputs from the knowledge informed models, as shown in Figure 2. The second variant is called MIXGEN MULTIVIEW which uses *views* to perform self attention over outputs of the knowledge informed models (Chen and Yang, 2020). Since the BART model already uses self attention over input tokens, we experiment with the MultiView architecture to see whether the additional self attention mechanisms of the MultiView model causes changes in performance.

For MIXGEN CONCAT, suppose we have k trained models, $M_1, \ldots, M_k$, each trained to produce the implied stereotype given the input post, and each informed by one of the aforementioned knowledge types. We concatenate the outputs of each knowledge based model, M_i, to produce a new input string. Thus if each model M_i outputs "$s_{[\text{OUT\_I}]}$", we get the following concatenated input string: "$s_{[\text{OUT\_1}]}[\text{SEP}]s_{[\text{OUT\_2}]} \cdots [\text{SEP}]s_{[\text{OUT\_K}]}$". Now, let M be a standard pretrained BART model. We train model M to produce the implied stereotype using "$s_{[\text{OUT\_1}]}[\text{SEP}]s_{[\text{OUT\_2}]} \cdots [\text{SEP}]s_{[\text{OUT\_K}]}$" as input. Note that the knowledge based models, $M_1, \ldots, M_k$ are fixed when training M. Model M serves as the final MIXGEN CONCAT model.

MIXGEN MULTIVIEW uses the MultiView architecture proposed by Chen and Yang (2020). In this case, the outputs of $M_1, \ldots, M_k$ are treated as separate views. If each model M_i outputs "$s_{[\text{OUT\_I}]}$" given the input post, then for each model M_i we configure the corresponding view as the string "$v_{1i}s_{[\text{OUT\_1}]}[\text{SEP}] \cdots v_{2i}s_{[\text{OUT\_I}]}v_{3i} \cdot [\text{SEP}]s_{[\text{OUT\_K}]}$", where v_{1i}, v_{2i}, and v_{3i} are view tokens. Here, v_{1i} is always the first token in the view string and v_{2i} and v_{3i} surround M_i's output. We configure k such views (one for each model) and pass each into the BART MultiView model as a set of views corresponding to the original input post. The BART MultiView model is then trained to produce the corresponding output stereotype. For details on the MultiView architecture, please see Chen and Yang (2020).

3.5 Training

We utilize the BART encoder decoder framework throughout (Lewis et al., 2020). We use batch gradient descent when training. For a batch B with padded input sequences X_i of length N_s and corresponding padded target sequences Y_i of length N_t, along with knowledge K_i from some knowledge

Dataset	# Posts	Annotations/Post

source, we minimize cross entropy loss:

$$\mathcal{L} = -\frac{1}{|B|N_t} \cdot \sum_{i=1}^{|B|} \sum_{j=1}^{N_t} \log p(Y_{ij}|Y_{i(1:j-1)}, X_i, K_i) \tag{1}$$

4 Experimental Setup

4.1 Dataset

We conduct our experiments on the SBIC dataset (Sap et al., 2020) and the Implicit Hate dataset (ElSherief et al., 2021). The SBIC dataset contains an input post, toxicity annotations and free text annotations of the implied stereotype. We work with the input post and the the implied stereotype. The Implicit Hate dataset (ElSherief et al., 2021) contains free text annotations of the implied stereotype. Dataset statistics are provided in Table 2.

4.2 Baselines

We compare our models with BART, and state of the art baselines from Sap et al. (2020):

- **GPT:** Following Sap et al. (2020), we train the GPT pretrained model from huggingface to generate the toxicity classifications, the Target Minority, and the Implied Stereotype as a string, when prompted with the input post.
- **GPT-2:** We train with the same setting as the GPT Baseline, but use the GPT-2 pretrained model from huggingface.
- **BART:** We train a standard pretrained BART model to generate the implied stereotype when given the input post.

4.3 Evaluation Metrics

We use BLEU (Papineni et al., 2002), ROUGE-L (Lin, 2004) and BERTScore (Zhang* et al., 2020) to evaluate our models and take the maximum score for each hypothesis over all of the corresponding references. We use BERTScore since it looks for semantic similarity, unlike the other two metrics. While we acknowledge it as a limitation, we ultimately do not use human evaluation for multiple reasons. First, the generated stereotypes are minimal in length compared to other text generation tasks. Moreover, we perform manual analyses of the results in Section 5. Second, we are following precedent set by prior work (Sap et al., 2020). Finally, we want to minimize annotator exposure to harmful content.

4.4 Results on SBIC

Our results on both dev and test are described in Table 3. Here we focus on dev since both sets of results track similar trends. We observe that the MIXGEN models outperform all other models. After MIXGEN, the model using Implicit Knowledge sources perform best. These are followed by the model using Explicit Knowledge, in turn followed by model using Expert Knowledge.

Both models with explicit and with implicit knowledge outperform expert language models. The models using implicit knowledge tend to perform best overall (BLEU: from 0.650 to 0.683, ROUGE-L: from 0.624 to 0.659, BERTScore: from 0.759 to 0.800). This is likely because implicit knowledge is less structured and hence easier to induce bias from (Petroni et al., 2019). On the other hand, while our source (ConceptNET) for explicit knowledge may be biased (Mehrabi et al., 2021), retrieved stereotypes are often mixed with general, unbiased facts.

The MIXGEN models outperform every other model. This makes intuitive sense since MIXGEN synthesizes multiple types of knowledge. Unexpectedly, MIXGEN MULTIVIEW model does not improve performance (the absolute difference is within 0.002 across all scores) over MIXGEN CONCAT. This is likely due to the fact that the MultiView model was intended to capture meta-sequences in text (Chen and Yang, 2020), whereas in our setting the input is not sequential. We also note that the MIXGEN models perform better than the source models, despite their input being sourced from the source models. Thus, despite differing performance, models from different knowledge sources are likely providing some distinct and complementary information.

4.5 Results on Implicit Hate Speech Corpus

Results on the implicit hate corpus (ElSherief et al., 2021) are given in Table 4. All models (including

Model	dev			test

MixGEN C	**0.467***	**0.340***	**0.912***
MixGEN MV	0.459	0.325*	0.910*

Table 4: This table shows the performance of our models on the implicit hate corpus (ElSherief et al., 2021). BERTS. stands for BERTScore. A superscript of * indicates statistically significant (p value < 0.05) improvements over the BART baseline.

baselines) generally perform worse than they do on the SBIC dataset. This is likely because the implicit hate corpus contains one reference per post, in contrast to the SBIC dataset (see Table 2). While the Expert knowledge model performs worse than the baseline, the other models perform slightly better. This is likely because the Expert model relies on toxicity classifications, which weren't available in the implicit hate corpus. We believe our models can be generalized to text generation tasks on other datasets, but they likely need multiple reference points where the implicit hate corpus only has one.

5 Error Analysis and Ablation Studies

We perform analyses and ablation studies on model results on the SBIC dataset. We do not perform these on the implicit hate dataset, since we have too few references per example. Examples of the error and challenge types below are given in Table 5. An additional full set of examples for each error and challenge type is given in Appendix 13.

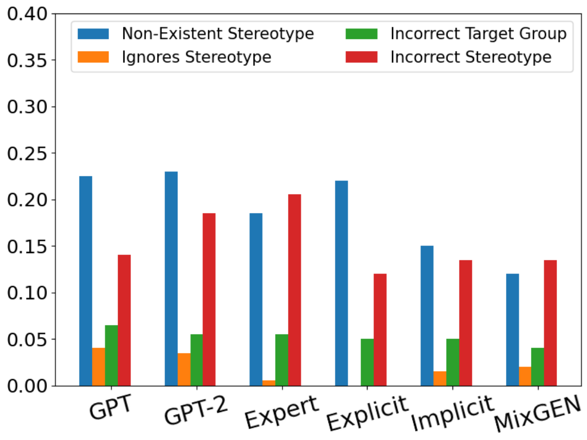

Figure 3: Distribution on the four error types across knowledge types and baselines.

5.1 Error Analysis

We categorize the types of errors made by models on a small sample of 200 examples from the dev set and provide the distributions in Figure 3. We provide the error categories below.

1. **Non-Existent Stereotype**: Model generates a stereotype when the reference stereotype is an empty string.

2. **Ignores Stereotype**: Model does not generate a stereotype when the reference stereotype is a non-empty string.

3. **Incorrect Target Minority**: Model uses the incorrect target minority.

4. **Incorrect Stereotype**: Model uses the correct target minority but generates an incorrect or overly general stereotype.

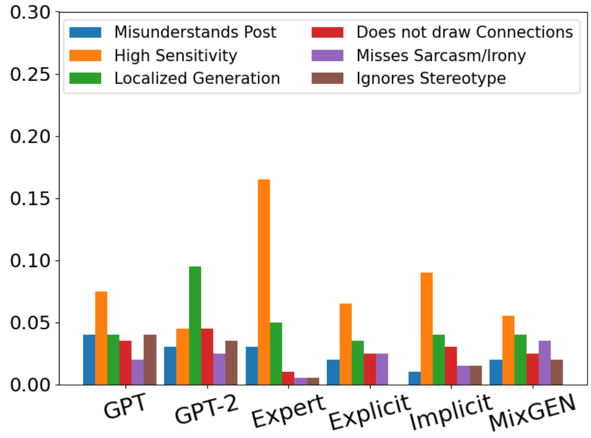

Figure 4: Distribution of challenges across knowledge types and baselines. We leave out cases of where models detect non existent stereotypes from challenge type 2.

The baseline GPT models tend to make more errors of every type, except that the expert model makes more errors of type 4. The expert model likely focuses on tokens that trigger toxicity classifications, which makes it less likely to focus on other relevant tokens. In the second example of Table 5, the token “black" may be triggering the Expert Model, causing an error of type 4.

The knowledge enhanced models rarely fail to generate a stereotype (type 2 error). On the other hand, they often detect non existent stereotypes (type 1 error), but less often than the baselines. In the third example of Table 5, “contraceptive" may be incorrectly triggering the implicit and explicit models, while the expert model is not triggered.

5.2 Challenges in Stereotype Generation

We categorize the various challenges faced by our text generation models and provide distributions in Figure 4 and counts in Appendix 15. We analyze the same sample of 200 examples from Section 5.1.

1. Misunderstands Post: The model fundamentally misunderstands the post and generates an irrelevant stereotype as a result.

2. High Sensitivity: The model is highly sensitive to trigger words, which causes it to detect non-existent stereotypes or generate stereotypes based on the triggers alone.

3. Localized Generation: The model focuses only on parts of the input and generates stereotypes based on those parts, rather than on the entire input post.

4. Does not Draw Connections: The model clearly considers the entire input post, but does not draw connections between the different parts of the post.

5. Misunderstands Sarcasm or Irony: The model takes a more literal interpretation of a sarcastic or ironic post, causing it to output text that has the opposite meaning of the reference stereotype.

6. Ignores Stereotype: The model does not generate a stereotype despite a non-empty reference stereotype.

Interestingly, the MIXGEN model tends to misunderstand sarcasm and irony at a slightly higher rate than the other knowledge model types. In the fourth example of 5, MIXGEN and the Implicit Model take literal interpretations of the input post. The Implicit Model type has difficulty with drawing connections over the input (challenge type 4). An example is given in the 6th row of Table 5, where the model does not draw a connection between the target minority and the stereotypes present.

5.3 How MIXGEN Synthesizes Knowledge

Table 5 provides examples of MIXGEN synthesizing knowledge across sources. In the third example, MIXGEN produces an empty string even though two of the more reliable sources (explicit and implicit knowledge) produce non empty strings. In the fifth example, MIXGEN clearly combines parts of all the knowledge sources, while in the sixth example MIXGEN produces a more accurate stereotype than any of the other models. Thus, it seems that MIXGEN does not simply attempt to copy the correct model, but actually possess a deeper understanding of the knowledge types it synthesizes.

5.4 Implicit Knowledge Ablation Study

Table 6 contains results of ablations on the Implicit Knowledge models. We vary the amount (k) and source (GPT and GPT-2) of implicit knowledge. The model which sources knowledge using GPT only outperforms the model sourcing knowledge using GPT-2 when $k = 3$. When $k = 15$, the latter model sourcing GPT-2 knowledge outperforms the model sourcing knowledge from GPT. It is possible that GPT-2 is less biased than GPT, thus benefiting our model for low k, but that these benefits decrease as k increases. With greater k, both models have a greater chance of exhibiting bias.

Input Post	Target Stereotype	Expert	Explicit	Implicit	MixGEN
what's the best part about being a midget pedophile? your dick can fit.	can fit inside a person sexually	mentally disabled folks are incompetent (3,1)	midgets are gross (4,2)	midgets have small penises (-,-)	midgets have small penises (-,-)
what's the most perfect thing? a rainbow, because it has no black on it.	black people are worth less	black people are criminals (4,2)	black people are inferior (-,-)	black people are inferior (-,-)	black people are inferior (-,-)
when we finally get the male contraceptive pill, it should be red.	“"	“" (-,-)	women are promiscuous (1,2)	women are promiscuous (1,2)	“" (-,-)
what do a dull blade and a lethargic emo have in common? they both don't cut like they used to	mentally ill people cut themselves	makes light of child molestation (3,1)	mentally disabled folks aren't smart (4,1)	emos don't cut (4,5)	physically disabled folks are useless (3,5)
what do you call two anorexic lesbians with yeast infections: double quarter pounder with cheese	lesbians are dirty	lesbians can't drive (4,2)	anorexics are gross (4,3)	anorexics are gross (4,3)	lesbians are gross (-,-)
what's can a white man say that a black man can't? “thanks officer!" and “hey dad!"	black folks are criminals,black fathers are not present in childrens lives	black people are criminals (-,-)	black people don't have fathers (-,-)	black people can't be trusted (4,4)	black men abandon their kids (-,-)

Table 5: Examples of generation from MixGen. The Error Type and the Challenge Type are given in parenthesis, “(error type number, challenge type number.)", with a “(-,-)" signifying no error.

Model	dev	test
GPT	0.712	0.713
GPT-2	0.733	0.741
BART Base	0.624	0.638
Implicit GPT (3)	0.787	0.796
Implicit GPT (15)	0.796	0.807
Implicit GPT-2 (3)	0.783	0.795
Implicit GPT-2 (15)	**0.800**	**0.811**

Table 6: BERTScores of baseline models and the implicit knowledge models.

5.5 MixGEN CONCAT Ablation Study

Model	dev	test
GPT	0.712	0.713
GPT-2	0.733	0.741
BART Base	0.624	0.638
MixGEN CONCAT (3)	0.803	0.814
MixGEN CONCAT (6)	0.807	0.817
MixGEN CONCAT (9)	0.799	0.804

Table 7: BERTScores of baselines and our MixGEN CONCAT models. The value in parentheses indicates the number of knowledge informed models used.

In Table 7, we look at ablations on the number of knowledge informed models, for the MixGEN CONCAT model. Let k be the number of knowledge informed models. The variant using $k = 6$ models performs best. Since the models variants within each knowledge type only vary by some hyperparameter, information gain probably saturates as the number of models increases; however performance decreases when $k = 9$. Since we tend to include models with lower performance for larger k, worse performing models are likely counter productive.

6 Limitations

We discuss limitations of our study here. Per the discussion in Subsection 4.3, we do not perform human evaluation of our results for multiple reasons. We do believe this is a limitation, and think future work may benefit from some form of human evaluation, while mitigating some of the concerns mentioned in Subsection 4.3.

The MixGEN model requires significant computational power. One needs to train models across knowledge sources, and then train the MixGEN model itself. Future work may alleviate this burden by considering end to end solutions, or more efficient knowledge retrieval techniques.

Future work could perform an “in the wild" analysis, produced by procuring random comments from the internet and running our proposed models on these comments, to determine how effective the models might be in a real world setting. Further ablations may also provide insight. For instance, with respect to our implicit knowledge models, it may be helpful to remove BART altogether and instead use GPT for predicting the target minority, pretraining on implicit knowledge and for generating the final stereotype. Finally, it may be helpful to standardize the incorporation of knowledge into the models, such that the models using different knowledge types may be directly compared.

7 Conclusion

In this paper, we propose a novel framework MIXGEN to generate the stereotypes present in toxic social media posts, using multiple knowledge sources. We categorized three different sources of knowledge and synthesize the sources of knowledge using the MIXGEN models. While the knowledge models perform as well as baselines, models built on different knowledge types vary in strengths and weaknesses. For instance, the expert model suffers from high sensitivity to trigger words, while the implicit models may not draw connections over complex inputs. The MIXGEN models takes this into account and minimizes the number of examples on which it has errors and/or faces challenges. We conclude that mixture and ensemble methods as simple as concatenation can leverage the complementary nature of distinct knowledge sources to produce high quality text generations.

Ethical Considerations

Models such as the one proposed in this paper, which output toxicity classifications of text or speech and reasoning behind such classifications should be used with care. Considerations of algorithmic fairness should be taken into account (Corbett-Davies et al., 2017), as well as cultural differences (Oliva et al., 2020) and racial biases (Xia et al., 2020) which can lead to misclassifications of offensiveness. Care should be taken to avoid political bias in training datasets, when training these models for deployment purposes (Wich et al., 2020). Finally, concerns about censorship should be taken seriously (Heins, 2014).

A Formal Details for Knowledge Incorporation

A.1 Expert Knowledge

A.1.1 Incorporating Expert Knowledge using the Join Embedding Technique

Given the BERT classifier with m attention heads, an input with length n, and a BART model with hidden dimension d, we pass the input to the BERT classifier to retrieve the attention head outputs of the last layer, namely $a_1, \ldots, a_m$, each in $\mathbb{R}^n$. We also pass the input to the BART model and retrieve the BART encoded input, namely $H \in \mathbb{R}^{n \times d}$. Let $v_1, \ldots, v_m$ in $\mathbb{R}^d$ be trainable weight vectors. For the j-th row vector, h_j of H, we compute an enriched hidden state h'_j as follows:

$$(h'_j)^T = h_j^T + \sum_{i=1}^{m} a_{ij} v_i \tag{2}$$

We then pass the enriched hidden state through the BART decoder to generate the output stereotype. To combine knowledge from multiple variables, we sum the enriched hidden state in Equation (2) over each variable.

A.2 Explicit Knowledge

A.2.1 Incorporating Explicit Knowledge using Concatenation

In this section, we provide formal details on how we incorporate explicit knowledge from ConceptNET using concatenation. In order to retrieve the top k triples (varying $k \in \{3, 5, 10, 15, 20, 25\}$), we first extract nouns, verbs, and adjectives from the input as our query tokens. We then query ConceptNet for triples associated with the query tokens and sort the triples by the product of the query's IDF weight and the triple's edge weight.

We then translate the triples into English (Robyn Speer, 2019). For example, if the entities "car" and "vehicle" are connected by the edge relation "IsA", the translation would be "Car is a vehicle". We concatenate the translations to the input post to form a new input. Formally, let the input be "s_{post}" and "$s_{\text{[trp\_i]}}$" be the sentence derived from the i-th triple. The modified input is then "s_{post}[SEP]$s_{\text{[trp\_1]}}$[SEP] $\cdots$ [SEP]$s_{\text{[trp\_k]}}$". We then pass the modified to the BART model which generates the implied stereotype.

The concatenation based approach allows the model to encode the external knowledge into its own embedding space.

A.2.2 Incorporating Explicit Knowledge using Attention

In this section, we provide formal details on how we incorporate explicit knowledge from ConceptNET using attention and the fusion layer described in Chang et al. (2020). This is an alternative method we tried in addition to the method described in Section A.2.1.

We first accumulate the top k triples (varying $k \in \{5, 10, 20\}$) associated with a post, using the method described in Appendix A.2.1. We then concatenate the numberbatch embeddings (each of dimension p) of the two entities in each of the k triples vertically to produce a vector in $\mathbb{R}^{2p}$. We then horizontally stack the concatenations to produce a matrix, $H_{KG} \in \mathbb{R}^{k \times 2p}$. The encoded input generated by the BART model can be represented by the matrix $H_B \in \mathbb{R}^{n \times d}$, where n is the input length and d is the hidden size of the BART model. We compute knowledge aware attention over the input as follows:

$$Q = H_B * W_1 + b_1^T \tag{3}$$

$$K = H_{KG} * W_2 + b_2^T \tag{4}$$

$$V = H_{KG} * W_3 + b_3^T \tag{5}$$

$$H_{KG}^B = \text{softmax}\Big(\frac{QK^T}{\sqrt{d}} V\Big) \tag{6}$$

where $W_1 \in \mathbb{R}^{d \times d}, W_2, W_3 \in \mathbb{R}^{2p \times d}$ and $b_1, b_2, b_3 \in \mathbb{R}^d$. The knowledge aware matrix is $H_{KG}^B \in \mathbb{R}^{n \times d}$. Finally, we concatenate the original encoded input and the knowledge aware matrix, H_{KG}^B and perform an affine transformation:

$$H' = (H_B \oplus H_{KG}^B) * W_4 + b_4^T \tag{7}$$

where $\oplus$ denotes column-wise concatenation, $W_4 \in \mathbb{R}^{2d \times d}$ and $b_4 \in \mathbb{R}^d$. $H' \in \mathbb{R}^{n \times d}$ is the new hidden state, which fuses the old hidden state and the new knowledge aware hidden state. H' is passed into the BART decoder.

A.3 Implicit Knowledge

A.3.1 Incorporating Implicit Knowledge using GPT

In this section, we provide formal details on incorporating implicit knowledge using a pretrained GPT models.

Let M_{tm} be a BART model trained to predict the target minority of a given input post. Let the target minority string predicted by $M_{\text{[tm]}}$ be "$s_{\text{[tm]}}$" and let "$s_{\text{[pr]}}$" be a prompt. We provide a list of prompts in Table 8 We then prompt the GPT models with the following string "The $s_{\text{[tm]}}$ $s_{\text{[pr]}}$". The GPT models complete the prompt with a generated string, "$s_{\text{[gpt]}}$", so that the final string is "The $s_{\text{[tm]}}$ $s_{\text{[pr]}}$ $s_{\text{[gpt]}}$". For GPT generations, we choose hyper-parameters based on methods in Patrick von Platen (2020). For each input, we randomly select various prompts to generate k sentences of the form "The $s_{\text{[tm]}}$ $s_{\text{[pr]}}$ $s_{\text{[gpt]}}$", varying $k \in \{3, 15\}$. Note that if there is no predicted

Table 8: Prompts for the GPT/GPT-2 biased sentence generators. The biased sentences are used to train the BART model, which is then retrained to produce the output stereotype. The predicted target minority of the input post is prepended to some of the prompts above, chosen at random. The GPT models then complete the prompt.

target minority, $s_{[\mathrm{tm}]}$ is the empty string and no sentence is generated using GPT. In this case, the input is paired with just the empty string.

We then pair the input with each of the k generated sentences (or the empty string if there is no predicted target minority) and train a BART model M to predict the generated sentences. Model M is then used as a pretrained model and is retrained to predict the implied stereotype given the same input. The retrained BART model is our final implied stereotype generator.

B Implementation Details

B.1 Implementation Details for BART Encoder Decoder Models

We train our BART models using a learning rate of $5e-6$ for 3 epochs with a batch size of 2 or 4, depending on the size of the input. This excludes the BERT classifier models, whose settings are given in Appendix B. The BART models have 406M parameters and all training is done on an Nvidia TITAN V GPU, with 12 GB memory, a boost clock speed of 1455 MHz, 640 Tensor cores and 5120 CUDA cores. Training under this regime takes approximately 90 - 120 minutes. We remove all URLs, “RT" strings, and “@" mentions from the input post. We train these models on just a single seed and results are reported on just that seed, as we had limited time to train and test our models. The baseline GPT-2 and GPT models are trained for 5 epochs, as in the original paper by Sap et al. (2020). Following the paper, we perform minimal preprocessing to the input text before training and testing and only remove all URLs. During inference, we pass batches of input from the dev and test sets to the generate method of the huggingface BART model class. We use beam search for generation, with a beam width of 10 and a length penalty of 5.0.

B.2 Implementation Details for BERT Classifier Models

We train base BERT models, which have 110M parameters. Training takes approximately 30 - 40 minutes on the GPUs described in B. We train these models on just a single seed, as results did not vary much as the seed varied and we had limited time to train and test our models.

Model	LR	Batch Size	Epochs
Offensiveness	5e-6	32	2
Intent to Offend	5e-7	32	1
Lewdness	5e-6	32	1
Group Targeted	5e-6	32	2

Table 9: Training Settings for BERT Classifier Models. LR stands for Learning Rate.

BERT Classifier Model training settings are given in Table 9 and Table 10.

C Further Ablation Studies

In this section, we look at ablation studies conducted on the Expert Knowledge models and the Explicit Knowledge models.

C.1 Expert Knowledge Ablation Study

Recall that we use the last attention layer of a BERT classifier with the join embedding architecture introduced in Pryzant et al. (2020) to enhance the hidden states of the BART model performing stereotype generation. We perform ablation studies by replacing the classifier over a few different annotated categories, namely Offensiveness, Intent to

Model	dev Offensive	dev Intent	dev Lewd	dev Group	test Offensive	test Intent	test Lewd	test Group
GPT	0.834	0.818	0.608	0.740	0.835	0.818	0.577	0.754
GPT-2	0.832	0.812	0.654	0.754	0.847	0.824	0.670	0.774
BERT	**0.863**	**0.832**	**0.726**	**0.810**	**0.867**	**0.828**	**0.708**	**0.826**

Table 10: GPT/GPT-2/BERT Classifier Performance on Dev and Test sets.

Models	dev BERTScore	test BERTScore
GPT	0.712	0.713
GPT-2	0.733	0.741
BART Base	0.624	0.638
EXPERT (OFFENSIVE)	0.759	0.767
EXPERT (INTENT)	0.761	0.764
EXPERT (LEWD)	0.757	0.764
EXPERT (GROUP)	**0.765**	**0.776**
EXPERT (ALL)	0.765	0.770

Table 11: We report BERTScores of baseline models (first three rows) and the expert knowledge models. The Expert Knowledge Models leverage annotations of categorical variables on the input to enhance stereotype generation. The **All** variant leverages all of the categorical variables.

Offend, Lewdness, and Group Targeted. We also train a model that uses all of the classifiers. The results for the ablations are in Table 11.

It is important to note the relative performance of the models. The Expert Knowledge model using the Group Targeted BERT classifiers performs better than the other single classifier models, and performs on par with the Expert Knowledge model leveraging all of the classifiers. It's likely that the tokens used by the BERT model to identify whether a minority group is targeted aligns closely with the portions of the encoded input used to generate the stereotypes. This makes intuitive sense, since the set of posts targeting some minority group likely has some stereotype mentioned in the post and vice versa. The same cannot be said for the other categories. This intuition is further strengthened by the fact that the Expert Knowledge model using all the classifiers does not perform much better than the Expert Knowledge model using just the Group Targeted classifier. Thus the other classifiers may be contributing little additional knowledge to the stereotype generation task.

C.2 Explicit Knowledge Ablation Study

In this section, we specifically discuss the number of knowledge triples we use when training explicit knowledge models and note trends in the BERTScore as k varies. The results are in Table 12. We discuss an additional attention based model not mentioned in the main paper. The detailed methodology for this model is given in Appendix A.2.2.

Model	dev	test
GPT	0.712	0.713
GPT-2	0.733	0.741
BART Base	0.624	0.638
EXPLICIT (INPUT) (3)	0.761	0.768
EXPLICIT (INPUT) (5)	0.748	0.757
EXPLICIT (INPUT) (10)	0.764	0.770
EXPLICIT (INPUT) (15)	0.769	0.772
EXPLICIT (INPUT) (20)	0.770	0.773
EXPLICIT (INPUT) (25)	0.752	0.763
EXPLICIT (ATTN) (5)	0.761	0.768
EXPLICIT (ATTN) (10)	0.759	0.765
EXPLICIT (ATTN) (20)	0.768	0.769

Table 12: We report BERTScores of baseline models (first three rows) and the explicit knowledge models.

We note that when concatenated directly to the input, performance increases as k increases up to a point and then starts to decrease. We believe that this occurs because the usefulness of knowledge initially increases then decreases as k increases. In particular, as k increases, many of the latter triples tend to be synonymous with earlier triples or unrelated to the original input. We also note that incorporating knowledge as attention tends to produce a better BERTScore, while not performing as well on other metrics. We suspect that this is due to the numberbatch embeddings capturing more semantic meaning than the BART embeddings. The numberbatch embeddings draw from a variety of sources, in addition to the graph structure itself and they perform well on benchmarks measuring word similarity.

D Analysis

We provide a few examples of stereotype generation, comparing and contrasting the different model types in Table 13.

Error/Challenge Type	Input Post	Generated Stereotype	Explanation
Error Type 1 (Non-Existent Stereotype)	what do you call it when you fuck an apple? an inside job	makes light of child abuse	The post does not refer or imply anything about children in any way.
Error Type 2 (Ignores Stereotype)	why do bitches hate so much tho? what's wrong with congratulating and giving people props sometimes?	“"	The post clearly refers to women in a derogatory manner.
Error Type 3 (Incorrect Target Minority)	if harvey and irma are god's fidget spinners, wouldn't god be autistic?	trivializes harm to victims	The post refers to autistic folks, but the generate stereotype doesn't capture it.
Error Type 4 (Incorrect Stereotype)	why don't black people go on cruises? because they already fell for that shit once.	black people deserve to die	The post refers to African American history (those arriving on slave ships), yet the generated stereotype does not mention this.
Challenge Type 1 (Misunderstands Post)	if the operation to remove your tonsils is called a tonsillectomy, then what is the name of the operation for a female do male sex change? addadictomy	women are only good for sex	The generate stereotype has nothing to do with the original post.
Challenge Type 2 (High Sensitivity)	why do jews have big noses? to smell the money.	jews were killed in the holocaust	The token “jew" triggers an irrelevant generation.
Challenge Type 3 (Localized Generation)	how do you know the asian food is undercooked? when it starts barking.	asians have no food	The post focuses on the first part of the sentence, but ignores the remainder.
Challenge Type 4 (Does not Draw Connections)	enjoy having multiculturalism shoved down your throat, fighting for israel and having a black or asian as your new best friend.	non-whites are inferior	The generated stereotype understands that the stereotype is about non-whites, but does not connect it to the broader stereotype of non-white cultures having a negative impact.
Challenge Type 5 (Misunderstands Sarcasm/Irony)	dating rules for women * don't be morbidly obese *	women shouldn't be skinny	The generated stereotype inverts the sarcasm of the original post and thus fails to capture the stereotype.
Challenge Type 6 (Ignores Stereotype)	fight anyone that tells you there's nothing wrong with being fat. and help your body and bones and lose weight, seriously.	“"	The input post targets those who are obese, yet the model does not generate a stereotype.

Table 13: Examples of generation from each of the error types described in Sections 5.1 and 5.2

D.1 Error Analysis

Table 14 provides the counts for the Error Analysis. Clearly, the MIXGEN models minimize the total number of errors made, although MIXGEN may not have the minimal number of errors in each category.

D.2 Challenges in Stereotype Generation

Table 15 provides the counts for the Challenges faced by each model. Clearly, the MIXGEN models minimize the total number of challenges face, although MIXGEN may not have faced the minimal number of challenges within each category.

Error Type	GPT	GPT-2	Expert	Explicit	Implicit	MIXGEN
1	45	46	37	44	30	24
2	8	7	1	0	3	4
3	13	11	11	10	10	8
4	28	37	41	24	27	27
5	106	99	110	122	130	137

Table 14: This table contains the counts for the error analysis. Though it is not quite an error and isn't mentioned in the main paper, Error Type 5 accounts for the examples in which the model outputs an accurate stereotype.

Challenge Type	GPT	GPT-2	Expert	Explicit	Implicit	MIXGEN
1	8	6	6	4	2	4
2 (Non-existent Stereotypes)	44	46	37	44	30	24
2 (Remainder)	15	9	33	13	18	11
3	8	19	10	7	8	8
4	7	9	2	5	6	5
5	4	5	1	5	3	7
6	8	7	1	0	3	4
7	106	99	110	122	130	137

Table 15: This table contains the counts for the error analysis. Though it is not quite a challenge and isn't mentioned in the main paper, Challenge Type 7 accounts for accurate generations by the model. Challenge Type 2 is partitioned into two sub-categories, one which includes only cases where the model detects non-existent stereotypes and another which does include such cases.

Teaching BERT to Wait: Balancing Accuracy and Latency for Streaming Disfluency Detection

Abstract

In modern interactive speech-based systems, speech is consumed and transcribed incrementally prior to having disfluencies removed. This post-processing step is crucial for producing clean transcripts and high performance on downstream tasks (e.g. machine translation). However, most current state-of-the-art NLP models such as the Transformer operate non-incrementally, potentially causing unacceptable delays. We propose a streaming BERT-based sequence tagging model that, combined with a novel training objective, is capable of detecting disfluencies in real-time while balancing accuracy and latency. This is accomplished by training the model to decide whether to immediately output a prediction for the current input or to wait for further context. Essentially, the model learns to dynamically size its lookahead window. Our results demonstrate that our model produces comparably accurate predictions and does so sooner than our baselines, with lower flicker. Furthermore, the model attains state-of-the-art latency and stability scores when compared with recent work on incremental disfluency detection.

1 Introduction

Many modern Natural Language Understanding (NLU) applications (e.g. transcribers, digital voice assistants, and chatbots) use streaming Automatic Speech Recognition (ASR) systems that incrementally consume speech, offering real-time transcription and predictions with minimal delay. However, these systems are often challenged by the presence of disfluencies, which are unintentional speech disruptions such as “um”, “no I meant”, and “I I I I think,” that occur naturally in spontaneous speech. Disfluencies not only hurt the readability of ASR transcripts, but also erode model performance on downstream tasks, such as machine translation (Hassan et al., 2014) and question answering (Gupta et al., 2021). Indeed, even state-of-the-art models such as BERT (Devlin et al., 2019) and T5 (Raffel et al., 2020) exhibit significant drops in performance (as much as 28 and 20 F1 points, respectively) on the SQuAD-v2 question-answering benchmark (Rajpurkar et al., 2018) when disfluencies are inserted into the questions (Gupta et al., 2021). Past work has shown that a prohibitively large amount of data is needed to train an end-to-end dialogue model that is robust to the presence of disfluencies (Shalyminov et al., 2017). As a result, modern ASR pipelines typically contain a separate post-processing step that detects and removes disfluencies from the transcript, which has been shown to perform better than end-to-end ASR models that generate fluent text from disfluent speech (Jamshid Lou and Johnson, 2020).

Shriberg et al. (1997) introduced the following disfluency schema components that are widely used in disfluency detection research: the *reparandum* (spoken segment intended to be removed), the *interruption point* (marked as “+”), the *repair* (spoken segment that comes as a replacement to the reparandum, of which the first word is known as the *repair onset*), and the *interregnum* (material that appears between the reparandum and repair). An example of this annotation schema is shown in Figure 1. Usually the disfluency detection task involves identifying and removing the reparandum portion of the disfluency. One of the most popular approaches that targets disfluency detection is the usage of sequence tagging models such as fine-tuned BERT (Bach and Huang, 2019; Rohanian and Hough, 2021) or LSTM (Zayats et al., 2016; Rohanian and Hough, 2020).

Another challenge in disfluency detection is the fact that most interactive speech- or text-based applications consume input incrementally, producing predictions one word at a time, rather than in entire sentences. However, recent state-of-the-art pretrained language models such as BERT have largely

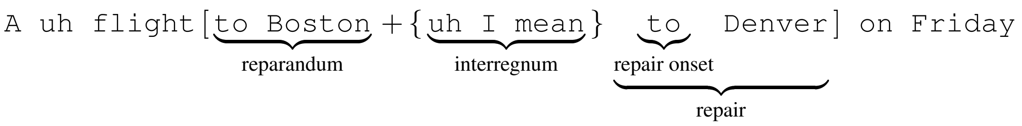

Figure 1: An example of disfluency annotation.

been designed for non-incremental processing and are trained only to output predictions on complete input utterances. Using a non-incremental model in an interactive setting produces undesirable delays, since downstream applications must wait for the user to finish their entire utterance before making any decisions.

To address the goal of streaming disfluency detection, recent work has focused on adapting non-incremental models for streaming settings. Madureira and Schlangen (2020) demonstrated that BERT-based models can adequately process incremental input for a variety of sequence tagging tasks when trained on partial sequences, although performance on full sequences suffers. Rohanian and Hough (2021) applied both the truncated training and prophecy generation strategies from (Madureira and Schlangen, 2020) to a BERT$_{\text{LARGE}}$ model, achieving state-of-the-art performance on streaming metrics among incremental systems. Notably, both these approaches employ the delay strategy of a fixed *lookahead window* - a short amount of right context that the model can "peek" at when making its prediction on the current token (Buß and Schlangen, 2011). Although a larger lookahead window can boost accuracy and stability, it also incurs extra delay (by definition).

In the task of incremental disfluency detection, a lookahead window is likely most useful for reparanda, since it is often nearly impossible to identify a reparandum without knowing whether it is followed by an interregnum or repair. However, this extra right context may be much less informative for fluent tokens. Guided by this insight, we extend the past research by training a BERT-based model to dynamically decide how much lookahead context to use. For each new input token that the model consumes, the model can choose to either immediately output a label for that token or to wait for further input before making its prediction. We also design a novel training objective that accounts for both the cross-entropy and latency costs incurred by delaying inference.

In our experiments we explore the trade-offs between accuracy, latency, and output stability for both partial and complete results. To our knowledge, this is the first work to adapt the BERT architecture and training objective to balance accuracy and latency in a streaming sequence tagging task.

The contributions of our paper are as follows: first, we propose a new model architecture and training objective for streaming sequence tagging tasks. This method involves fine-tuning a pretrained BERT model to decide when to immediately output predictions and when to wait for further input– temporarily abstaining from producing a prediction. Secondly, we show that this model achieves high accuracy in incremental settings with state-of-the-art latency and stability, all with a model architecture that is $\sim$ 35 times smaller than BERT$_{\text{BASE}}$ (Zhao et al., 2021). We demonstrate that the model continues to perform competitively in non-incremental settings when compared to its non-incremental counterparts. Finally, our analyses show that our streaming model learns to wait the most when it encounters an interregnum or reparandum, and the least for fluent or edit terms.

2 Related Work

Although disfluency detection itself is a well-studied task, only a handful of past work has explored disfluency detection in an online setting - that is, consuming the input a single token at a time and outputting predictions on the partial input as early as possible. Among the neural approaches, Hough and Schlangen (2015) were the first to demonstrate competitive performance of recurrent neural networks (RNNs) on incremental disfluency detection by applying an Elman RNN paired with a Markov decoder that jointly optimized the probability of the output tag over the past inputs and outputs. Hough and Schlangen (2017) built upon this by jointly training LSTMs on both utterance segmentation and disfluency detection, demonstrating that jointly training on the two tasks yielded higher accuracy and lower latency on both tasks than training on either task alone. This was followed by a number of other works that also suc-

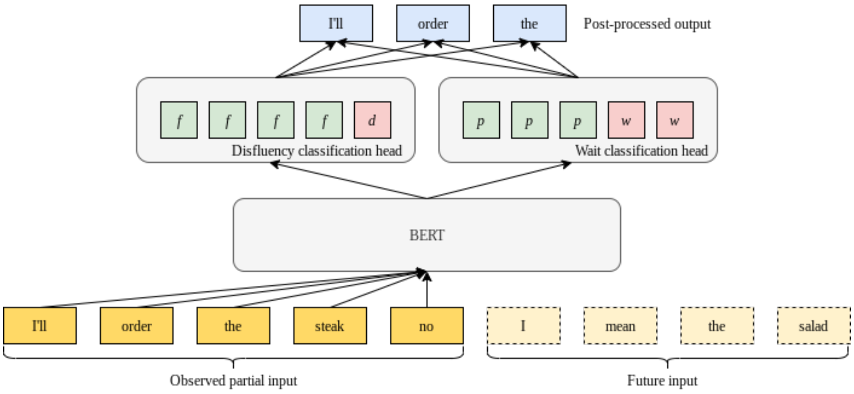

Figure 2: The architecture of our streaming BERT model. The disfluency classification head outputs predictions of *fluent* (f) or *disfluent* (d) for each token, whereas the wait classification head outputs predictions of *predict* (p) or *wait* (w) for each token. Given a partial input, we find the first token with a *wait* prediction and output only the tokens before it with *fluent* predictions.

cessfully paired incremental disfluency detection with other tasks, such as language modeling (Shalyminov et al., 2018) and POS tagging Rohanian and Hough (2020).

More recently, large pre-trained transformer architectures have demonstrated incredible success on sequence labeling tasks (Vaswani et al., 2017). Although the original transformer architecture was not designed for streaming input, Chen et al. (2020) proposed the controllable time-delay transformer instead, which combines a fast decoding strategy with a modified self-attention mechanism that attends only to future inputs in a fixed lookahead window.

The closest work to ours is that of Rohanian and Hough (2021), in which the authors fine-tuned a pre-trained $\text{BERT}_{\text{LARGE}}$ model via add-M training, which feeds the model successive prefixes of lengths $N + M, N + 2M, \cdots$ for each full-length training example. Their best-performing model also made use of a prophecy decoding strategy, in which a GPT-2 (Radford et al., 2019) model predicted the missing right context of each partial input. The BERT model then made its predictions based on the complete extrapolated sequence, POS tags, and word timings. Unlike their work, we aim to train a more lightweight small vocabulary 12×128 BERT model that is more suitable for on-device settings, does not require a separate prophecy generation model, and uses only disfluency-annotated training data. We also train our model on successive prefixes of the input (with $N = 1, M = 1$) but modify both the architecture and training objective in order to balance the competing objectives of accuracy and latency.

3 Training a Streaming BERT Model

In this section we describe the architectural changes, new training objective, and training scheme that we use to adapt a (non-incremental) BERT model for streaming sequence tagging tasks. Specifically, we modify the model to enable it to either immediately produce a prediction for a given token or to decide to wait for further input. These changes include a novel training objective that balances the cost between accuracy and latency – preventing the model from the extremes of either relying too much on waiting for further input or on speedily making predictions at the cost of accuracy. We train this model using a *restart-incremental* training procedure described in Section 3.2.

3.1 Model Design

Streaming settings force models to make trade-offs between accuracy and latency. More accurate predictions can be obtained by providing longer right context at the cost of incurring additional latency. However, since most tokens are not disfluent, a model may not require the right context in order to accurately classify fluent tokens. Rather than using a fixed lookahead window, we train a BERT model to jointly classify tokens and simultaneously choose the lookahead window size dynamically at each token.

Our proposed model architecture consists of a pre-trained BERT model with two separate token classification heads added on top, as shown in Figure 2. Each classification head consists of a linear layer applied to the hidden layer outputs of the BERT model. The first classification head, the disfluency classifier, is trained to classify whether each token is disfluent or not. The second classification head (the *wait classifier*) is trained to classify whether the model should wait for further input (temporarily abstain from predicting) or immediately output a prediction for the given token. In effect, the wait classifier decides how large of a lookahead window the model needs to make its prediction on the current input. At inference time, we only output tokens that lie to the left of the first token for which the model outputs a *wait* prediction and that are predicted to be fluent. This avoids potentially producing disjoint output in the case where the model produces predictions of *wait* followed by *predict*, making the output more clear for the user's display.

We also adapt the training objective such that it accounts for both the accuracy and latency of the model's outputs on each successive prefix. Let (x, y) be the pair of input sequence and target output sequence with prefixes $x_1, x_2, \cdots, x_{|x|}$ and $y_1, y_2, \cdots, y_{|x|}$, respectively where $|x|$ is the length of the full sentence. We also denote $f(x)$ as the output logits of the disfluency classifier, $g(x)$ as the output logits of the wait classifier, $\sigma(\cdot)$ as the softmax function, and $H(\cdot, \cdot)$ as the cross-entropy loss. Then the traditional cross-entropy loss on the full input and target sequences is

$$\ell_{\text{FULL}}(x, y) = H(\sigma(f(x)), y) \tag{1}$$

However, for each prefix we wish to only compute the cross-entropy loss on the tokens to the left of the first token for which the model outputs a *wait* prediction. To accomplish this, we devise a binary mask that zeros out the loss on the tokens to the right of and including the first *wait* prediction:

$$\mathbf{m}(\sigma(g(x_i)) = (m_1, \cdots, m_{|x_i|}) \tag{2}$$

where

$$m_j = \begin{cases} 1 & \text{if } j < k \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

$$k = \min\{j | \sigma(g(x_i)_j) > 0.5\} \tag{4}$$

where $g(x_i)_j$ is the j-th element of vector $g(x_i)$. We then apply this mask to the cross-entropy loss for each prefix of example x to obtain prefix loss:

$$\ell_{\text{PREFIX}}(x, y) = \sum_{i=1}^{|x|-1} \mathbf{m}(\sigma(g(x_i))) \circ H(\sigma(f(x_i)), y_i) \tag{5}$$

where we abuse notation here by denoting $H(\sigma(f(x_i)), y_i)$ as the vector for which the j-th element corresponds to the cross-entropy of $(\sigma(f(x_i)))_j, y_{i,j})$ and $\circ$ is element-wise multiplication. Lastly, we define a latency cost that scales with both the probability of abstaining from classifying the j-th token in the i-th prefix $(\sigma(g(x_i)_j))$ and with the expected wait time, as measured by number of tokens, incurred by abstaining starting from token j in prefix x_i:

$$\ell_{\text{LATENCY}}(x) = \sum_{i=1}^{|x|-1} \sum_{j=1}^{i} (i - j)\sigma(g(x_i)_j) \tag{6}$$

Putting these together, the total loss for a single example (x, y) is:

$$\begin{aligned} \ell(x, y) = \ell_{\text{FULL}}(x, y) + \gamma \ell_{\text{PREFIX}}(x, y) \\ + \lambda \ell_{\text{LATENCY}}(x) \end{aligned} \tag{7}$$

with hyperparameters γ and λ controlling the relative strengths of the prefix and latency costs, respectively. We also include the cross-entropy loss on the full sequences (ℓ_{FULL}) in addition to the prefix losses (ℓ_{PREFIX}) because we wish for the model to maintain its ability to make predictions on full sequences. Since $g(x)$ does not appear anywhere in ℓ_{FULL}, the model is effectively forced to make predictions once it receives the full utterance.

Similarly, the ℓ_{LATENCY} term is essential because without it, the model could achieve minimal loss by always waiting (e.g. $\sigma(g(x_i)_j) = 1$ for all prefixes i and time steps j), and only learning to classify disfluent tokens after receiving the full sequence. This is equivalent to the non-incremental classification loss. If we instead set $\sigma(g(x_i)_j) = 0$ for all i, j (the case where the model never waits), the resulting loss is equivalent to the learning objective for strongly incremental training (see Section 3.2). In essence, our training objective is a generalization of the strongly incremental objective.

3.2 Restart-Incremental Training

Although BERT models are typically fine-tuned using complete pre-segmented sequences, an incremental model must process partial inputs at inference time, resulting in a distributional shift between the complete utterances typically seen in training datasets and the partial utterances seen at inference time. A simple solution is to fine-tune BERT both on complete and partial inputs, a training scheme known as *restart incrementality* (Kahardipraja et al., 2021). By providing successively extended prefixes of a given utterance to the model and computing the loss on the model outputs for each prefix, we can mimic the streaming data that the model would encounter in real time. In all of our experiments, each successive prefix adds a single word to the previous prefix, a setting known as *strongly incremental* (Shalyminov et al., 2018). Although this approach requires re-computation of the model outputs for each successive prefix, this also enables the model to correct its previous predictions, or to switch between waiting and predicting when it receives helpful right context. Incorporating prefixes during training in incremental disfluency detection has been previously explored by Rohanian and Hough (2021). This serves as a strong baseline in our experiments.

4 Experimental Setup

We fine-tune all models on the Switchboard dataset (Godfrey et al., 1992), a transcribed English multi-speaker conversational corpus that is commonly used for ASR research. We specifically use the version from the Linguistic Data Corpus's Treebank-3 (Marcus et al., 1999) distribution, which additionally contains disfluency annotations and a standard train/dev/test split (Charniak and Johnson, 2001). We follow Rocholl et al. (2021), training our models to classify both the reparanda and interregna as disfluent for future removal in a final post-processed transcript.

4.1 Baselines

All of our experiments use small distilled BERT models, specifically a small vocabulary BERT model (Zhao et al., 2021) (BERT_{SV}) with 12 hidden layers of size 128 that is pre-trained on English Wikipedia and BookCorpus (Zhu et al., 2015). The details of our hyperparameter tuning can be found in the Appendix (Section A.2).

We use small models for two reasons: 1) fine-tuning a model on all given prefixes of each training example is resource intensive, and 2) many streaming natural language understanding applications run entirely on mobile devices which precludes the use of large models. Previous work on small non-incremental BERT-based models used for disfluency detection (Rocholl et al., 2021) showed significant improvement in memory and latency without compromising task performance. The core BERT_{SV} model is a distilled version of $\text{BERT}_{\text{BASE}}$ with smaller vocabulary and reduced hidden layer dimensions (Zhao et al., 2021). Due to its smaller vocabulary size (5K versus 30K tokens), the model has only about 3.1M parameters, as compared to $\text{BERT}_{\text{BASE}}$'s approximately 108.9M parameters, achieving around 80% latency reduction.

In order to isolate the effects of training with *restart incrementality* (Section 3.2) versus the improvements derived directly from incorporating our new training objective, we also evaluate two other models: 1) a non-incremental BERT_{SV} model trained in the usual way, on full sequences; and 2) a BERT_{SV} model trained with *restart incrementality* - i.e., on all prefixes of every training example (which we will refer to as "all prefixes" in following tables). Setup (1) is equivalent to ablating both ℓ_{PREFIX} and ℓ_{LATENCY} whereas setup (2) is equivalent to ablating only ℓ_{LATENCY}. We do not ablate ℓ_{PREFIX} in isolation since this leaves only the ℓ_{FULL} and ℓ_{LATENCY} terms, and there does not exist a meaningful measure of latency when the model never needs to wait for more input (since it is always given the full utterance as input). For each of these baseline models we also follow Rohanian and Hough (2021) and Kahardipraja et al. (2021) by evaluating with different fixed lookahead (LA) window sizes of $\text{LA} = 0, 1, 2$.

4.2 Incremental Evaluation

Accuracy alone is not a sufficient measure of success to robustly evaluate a streaming model. Since a streaming model is meant to operate in real time, it should return output as soon as possible after it receives new input. As such, we also need to evaluate it with respect to latency – i.e. the number of new tokens a model must consume before producing a prediction for the current token. Furthermore, streaming models are often designed to be capable of retroactively changing their predictions on previous tokens as new input arrives. This introduces the risk of output "jitter" or "flicker," where the output changes dramatically as new input is consumed, necessitating evaluation of stability. To capture all these important dimensions of streaming model performance, we evaluate the models using the following diachronic metrics (with formulas and further details in the Appendix):

- **Streaming** F_1: An accuracy metric scored in the same way as the typical F_1 score, albeit we score the predictions for a single token over the course of multiple time steps separately as if they were predictions for separate tokens.

Model	Training Scheme	Incremental						Final
		$F_1 \uparrow$	$P \uparrow$	$R \uparrow$	EO $\downarrow$	TTD $\downarrow$	AWT $\downarrow$	$F_1 \uparrow$
BERT_{SV}	Full sequences	0.76	0.74	**0.78**	0.31	1.46	**0.00**	**0.89**
BERT_{SV}	All prefixes	0.76	0.73	**0.78**	0.32	**1.37**	**0.00**	**0.89**
Streaming BERT_{SV}	All prefixes	**0.83**	**0.92**	0.75	**0.09**	2.32	0.21	0.88
Models with lookahead ≥ 1								
BERT_{SV} (LA = 1)	Full sequences	0.83	0.85	0.80	0.10	2.41	1.00	0.89
BERT_{SV} (LA = 2)	Full sequences	0.85	0.89	0.82	0.05	3.06	2.00	0.89
BERT_{SV} (LA = 1)	All prefixes	0.82	0.85	0.80	0.12	2.33	1.00	0.89
BERT_{SV} (LA = 2)	All prefixes	0.85	0.89	0.82	0.06	3.01	2.00	0.89

Table 1: Comparison of incremental performance on the Switchboard validation set of non-incremental small-vocab BERT models (BERT_{SV}) against that of a streaming small-vocab BERT model (streaming BERT_{SV}). In the lower half of the table we also list the evaluation results of non-incremental BERT_{SV} models with fixed lookahead (LA) window sizes of 1 and 2 tokens. Note that for the non-incremental models the lookahead window size is equivalent to the average waiting time (AWT). The arrows near each metric represent the desirable direction of the result: ↑ means the higher the performance the better and ↓ is the reverse.

- **Edit Overhead (EO)** (Buß and Schlangen, 2011): A stability metric that measures the average number of unnecessary edits, normalized by utterance length.
- **Time-to-detection (TTD)** (Hough and Schlangen, 2017): A latency metric that is only computed on disfluent tokens that are classified correctly. It is the average amount of time (in number of tokens consumed) that the model requires before first detecting a disfluency. As mentioned earlier, we include both reparanda and interregna as disfluencies.
- **Average waiting time (AWT)**: The average amount of time (in number of tokens consumed) that the model waits for further input before making a prediction on a given token. For models with a fixed lookahead window, this is equivalent to the lookahead window size. For the streaming model, this is equivalent to the average lookahead window size.
- **First time to detection (FTD)** (Zwarts et al., 2010; Rohanian and Hough, 2021): Similar to to the TDD metric described above with the main difference being that the latency (in number of words) is calculated starting from the onset of a gold standard repair.

5 Results

In this section we present a summary of both the non-incremental and incremental performance of our streaming model against that the baselines. We also present an analysis of the types of errors and average amount of waiting time the streaming model incurs.

5.1 Incremental Performance

Table 1 shows both the incremental and non-incremental evaluation metrics. Our proposed streaming BERT_{SV} model achieved a 9% increase[1] in streaming F_1 over both of the baselines (with lookahead = 0), as well as a 71% and 72% decrease in edit overhead compared to the non-streaming models trained on full sequences and all prefixes, respectively. Despite being trained with a different architecture and loss objective, the streaming model does not sacrifice its non-incremental performance, yielding a final output F_1 score that is only one point less than its non-streaming counterparts. Generally speaking, when the streaming model does output a prediction, it classifies tokens as disfluent less often than the non-streaming models with zero LA window, achieving much higher precision (P) and marginally lower recall (R), resulting in a model that "flickers" less frequently. However, this does contribute to a slightly higher time-to-detection score compared to the baselines with zero lookahead, since the streaming model is generally less aggressive but more precise with outputting disfluent predictions. When compared to the models with fixed lookahead (the lower half of Table 1), however, the streaming model always achieves lower TTD while achieving significantly lower waiting time and comparable accuracy and

[1] All percentages mentioned in this section are computed as a percentage of the original number, rather than as a difference in percentage points.

stability.

Type of disfluency	Average wait time
Repair	0.74
Fluent	0.15
Interregnum	1.06
Reparandum	0.76
Edit	0.14
Repair onset	0.46

Table 2: The streaming model's average waiting time (in number of tokens) for each type of token (as categorized in Marcus et al. (1999)) encountered in each prefix fed to the model for the Switchboard validation set. For a more fine-grained analysis, we separate the repair onset (the first word in the repair phrase) from the rest of the words in the repair. The category "Edit" consists of all edit terms that are not interregna (i.e. not inside of a repair structure).

Effect of lookahead window size We also evaluated the performance of the non-streaming baseline models with fixed lookahead window sizes of 1 and 2 tokens, as shown in the lower half of Table 1. In line with what has been reported in past work (Madureira and Schlangen, 2020; Buß and Schlangen, 2011), the size of the lookahead window scales directly with the accuracy and stability and inversely with the latency of the model. However, the streaming model has comparable streaming F_1 and edit overhead scores as the non-streaming models with $LA = 1$, even though the streaming model has 79% less average wait time. This indicates that the streaming model is able to correctly classify tokens sooner and with more stability than the baseline models that have $LA = 1$. Although the models with $LA = 2$ improve marginally on accuracy and stability over the models with $LA = 1$, the streaming model continues to have lower TTD and AWT but comparable F_1 and EO when compared to the models with $LA = 2$.

The utility of dynamic lookahead The results in Table 1 also reveal some insights into which parts of the model design and training scheme are more important for streaming performance and efficiency. Merely training a non-streaming model on prefixes of the training examples appears to have minimal effect on F_1, precision, and recall, but does somewhat improve the TTD score. We hypothesize that this is largely the result of training on a data distribution that more closely resembles the test distribution. Adding the extra wait classifier head and latency cost term in the training objective yields the greatest improvements in both precision and stability, as seen in the differences in F_1, P, and EO values between the BERT_{SV} model trained on all prefixes and the streaming BERT_{SV} model.

When to wait Since the streaming model can abstain from outputting predictions for arbitrarily long suffixes of the input, it incurs waiting time - an average of 0.21 tokens more than the non-streaming models with 0 lookahead. Table 2 shows that the streaming model abstains the most when encountering interregna and reparanda, waiting for approximately 1.06 and 0.76 more tokens, respectively. Given that it is easier to identify a disfluency once the entire reparandum and interregnum have been observed, it follows that the model's predictions may be more uncertain for reparanda and interregna upon first consumption, thus incurring the highest average waiting times. An example of the model's incremental outputs for a disfluency structure is shown in Table 4. For correctly classified disfluent tokens, the streaming model also has a higher TTD, likely because the non-incremental models are more aggressive in predicting disfluent labels (while making more errors) than the streaming model. Still, this TTD is lower than all the models with fixed lookahead windows.

5.2 Error Analysis

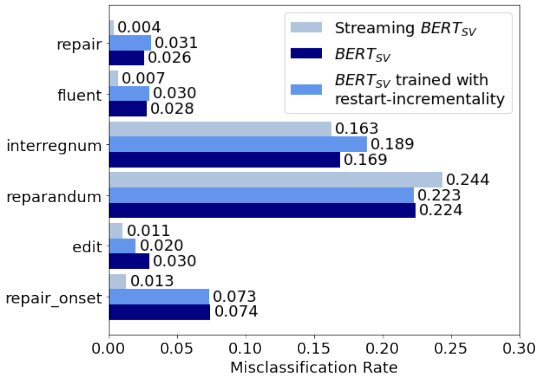

Figure 3: Token-wise misclassification rates for each type of disfluency annotation (as categorized in Marcus et al. (1999)) across all three evaluated models on the Switchboard validation set. If the model abstained from making a prediction on a particular token, we did not count this as an error.

Figure 3 shows an error analysis on the models' predictions. We computed the percentage of the

Model	**Training Scheme**	**Incremental metrics**	
		EO↓	**FTD↓**
$\text{BERT}_{\text{LARGE}}$ (Rohanian and Hough, 2021)	All prefixes	0.60	0.31
BERT_{SV}	Full sequences	0.30	0.79
BERT_{SV}	All prefixes	0.32	0.84
Streaming BERT_{SV}	All prefixes	**0.09**	**0.11**

Table 3: A comparison of the EO and FTD metrics of our baselines (BERT_{SV} trained on full sequences and all prefixes), our streaming BERT_{SV} model, and Rohanian and Hough (2021)'s incrementalized $\text{BERT}_{\text{LARGE}}$ model on the Switchboard test set. The arrows near each metric represent the desirable direction of the result – for both of the metrics, lower numbers are more desirable.

time that the streaming model misclassified a token, counting each incidence of the token across each time step separately. All models achieved the lowest misclassification rates on fluent and edit tokens, and the highest misclassification rates on reparanda tokens. For tokens that were fluent, edit terms, or part of a repair or repair onset, the streaming model achieved significantly lower misclassification rates than the baselines. However, all three models performed comparably on interregna and reparanda. Since we measure misclassification rate on every token at every time step, the high misclassification rates on reparanda are expected as it is often not feasible to detect a reparandum until an interregnum or repair onset has been seen.

Accuracy versus latency In comparison to the baseline models with 0 lookahead, the streaming model makes the largest tradeoffs in accuracy versus latency for repair onsets and repairs, as shown by Figure 3 and Table 2. While the streaming model incurs average additional wait times of 0.74 and 0.46 tokens for repairs and repair onsets respectively, its misclassification rates are also approximately 85% and 82% less than the baseline models on repairs and repair onsets respectively. In addition, Table 1 demonstrates that the streaming model still achieves comparable F_1 and greater stability (lower EO) in comparison to the non-streaming baselines with lookahead 1, despite having an average wait time that is 79% shorter.

5.3 Comparison with Competitor Baselines

As shown in Table 3, in comparison with the $\text{BERT}_{\text{LARGE}}$-based prophecy decoding model proposed in Rohanian and Hough (2021), our streaming model achieves state-of-the-art stability (85% decrease in EO) and latency (65% decrease in FTD)[2], despite having far fewer parameters.

6 Conclusion and Future Work

We have introduced a streaming BERT-based Transformer model that is capable of balancing accuracy with latency by simultaneously making token-level disfluency predictions and dynamically deciding how large of a lookahead window to use. Our approach improves both streaming accuracy and output stability on an incremental disfluency detection task. Furthermore, it incurs very low average latency in comparison with non-incremental BERT models of the same size. Lastly, our model requires minimal lookahead beyond disfluent regions and achieves state-of-the-art edit overhead and first-time-to-detection scores compared to past work (Rohanian and Hough, 2021).

While the main focus of this paper has been on developing a fast, accurate, and stable streaming model for disfluency detection, our approach is general enough to be used in other incremental tagging models of linguistic phenomena that benefit from the right context for optimal accuracy. In future work we are interested in applying this approach to tasks such as real-time punctuation prediction and incremental parsing.

Furthermore, the streaming model's efficiency is limited by its non-autoregressive nature and training via restart incrementality. Future work should also explore how to apply a dynamic lookahead window without re-computing the predictions on all the previous inputs and to rely on fewer prefixes during training.

---

[2] In addition to shorter word-level latency metrics presented in the results, the runtime latency of the BERT_{SV} model is 80% lower than that of $\text{BERT}_{\text{BASE}}$ (Rocholl et al., 2021).

7 Ethical Considerations

While our work does not introduce a new dataset, it does depend on a training dataset that was collected from fluent English-speaking, able-bodied human subjects. If deployed in a real-world application, this model would likely perform noticeably worse for users who speak with non-American accents or speech impediments. Transcripts for these users could be disproportionately noisy and the streaming model's average wait time would likely also be longer. Care should be taken to assess the sensitivity and robustness of such a model to non-fluent or non-American English prior to deployment. This model should also be used very cautiously in situations where mistakenly eliding fluent portions of speech from the captions or transcript could incur dire consequences, such as in an emergency call center.

8 Acknowledgments

We thank Johann Rocholl, Colin Cherry, Dan Liebling, Noah Murad, and members of the Google Research Speech Intelligence team for valuable feedback and discussion. We also thank the Google Student Researcher and research internship programs for supporting this work. Lastly, we also thank the anonymous reviewers for their thorough and helpful comments.

A Appendix

A.1 Evaluation Metrics

We provide more detailed formulas here for each of our evaluation metrics. For a given input utterance x, let $x[j]$ be the j-th token of x, $y[j]$ be the gold label (either 0 for fluent or 1 for disfluent) for $x[j]$, $x[: i]$ be the i-th prefix of x (i.e. the first i tokens of x), $f(x[: i])[j]$ be the predicted label for $x[j]$ after the model has consumed prefix i , D be the entire dataset that we are evaluating predictive performance for, and $|D|$ be the size of D.

Accuracy metrics Our definitions of the streaming true positives, true negatives, false positives, and false negatives are:

$$\begin{aligned} TP_{\text{streaming}} &= |\{(i,j)|y[j]=1, f(x[: i])[j]=1\}| \\ TN_{\text{streaming}} &= |\{(i,j)|y[j]=0, f(x[: i])[j]=0\}| \\ FP_{\text{streaming}} &= |\{(i,j)|y[j]=0, f(x[: i])[j]=1\}| \\ FN_{\text{streaming}} &= |\{(i,j)|y[j]=1, f(x[: i])[j]=0\}| \end{aligned}$$

Similar to the traditional definitions, streaming precision, recall, and F_1 are computed as:

$$\begin{aligned} P_{\text{streaming}} &= \frac{TP_{\text{streaming}}}{TP_{\text{streaming}} + FP_{\text{streaming}}} \\ R_{\text{streaming}} &= \frac{TP_{\text{streaming}}}{TP_{\text{streaming}} + FN_{\text{streaming}}} \\ F1_{\text{streaming}} &= 2 \times \frac{P_{\text{streaming}} \times R_{\text{streaming}}}{P_{\text{streaming}} + R_{\text{streaming}}} \end{aligned}$$

Stability metrics

- **Edit overhead (EO)** (Buß and Schlangen, 2011): To calculate edit overhead, we need to first identify, for each prefix $x[: i]$ of a given input x, which tokens $x[j]$ have predictions $f(x[: i])[j]$ that differ from the model's prediction in the previous prefix $f(x[: i-1])[j]$. Denoting the cardinality of this set as $E(x)$ (for the number of edits the model makes on x), we have:

  $$E(x) = |\{(i,j)|f(x[: i])[j] \neq f(x[: i{-}1])[j]\}|$$

  Then we can compute EO as follows:

  $$EO = \frac{1}{|D|} \sum_{x \in D} \frac{E(x)}{|x|}$$

  where $|x|$ is the number of tokens in x.

Latency metrics

- **Time-to-detection (TTD)** (Hough and Schlangen, 2017): Since time-to-detection (TTD) is measured only on disfluent tokens that are eventually predicted as such by the model, we need to first define the set of tokens in a given example x that are true positives at some point:

  $$TP(x) = \{x[k] \,|\, y[k] = 1, \exists i : f(x[: i])[k] = 1\}$$

  Then for a given token $x[k] \in x$, the detection time (DT) can be calculated as:

  $$DT(x[k]) = \min_i \{i | f(x[: i])[k] = 1\} - k$$

  It follows that the TTD for the entire dataset D is the average DT for all disfluent tokens that are eventually detected for all $x \in D$:

  $$TTD = \frac{1}{m} \sum_{x[k] \in TP(x), x \in D} DT(x[k])$$

  where

  $$m = |D| \sum_{x \in D} |TP(x)|,$$

  the total number of disfluent tokens in the dataset that are eventually detected by the model.

- **First time to detection (FTD)** (Zwarts et al., 2010; Rohanian and Hough, 2021): Similar to TTD, this metric is only measured on disfluent tokens that are eventually detected by the model. Then given some $x[k] \in TP(x)$, let $RI(x[k])$ represent the index of the first token in the repair that follows $x[k]$. Since we are measuring detection time from the start of a gold standard repair instead, the detection time becomes:

  $$DT(x[k]) = \min_i \{i | f(x[: i])[k] = 1\} - RI(x[k])$$

  The rest of the formula for the FTD is similar to that of the TTD:

  $$FTD = \frac{1}{m} \sum_{x[k] \in TP(x), x \in D} DT(x[k])$$

where

$$m = |D| \sum_{x \in D} |TP(x)|,$$

the total number of disfluent tokens in the dataset that are eventually detected by the model.

- **Average waiting time (AWT)**: Suppose that given an input token $x[k]$, the model can abstain from making a prediction (which occurs both with the streaming model and with the fixed lookahead models). We denote this outcome as $y[k] = \varnothing$. To compute AWT, we first calculate the first prediction time (FPT) for a given token $x[k]$,

$$FPT(x[k]) = \arg\min_i \{i | f(x[: i])[k] \neq \varnothing\},$$

i.e. the first time step i in which the model outputs a prediction for token $x[k]$. Then the AWT is

$$AWT = \frac{1}{m} \sum_{x[k] \in x, x \in D} FPT(x[k]) - k,$$

where

$$m = |D| \sum_{x \in D} |x|,$$

the total number of tokens in the dataset.

A.2 Model Training and Hyperparameter Tuning

We implemented our models using TensorFlow v2.7 (Abadi et al., 2015) and the Hugging Face `transformers` library (Wolf et al., 2020). We also fine-tuned all model hyperparameters using Vizier (Golovin et al., 2017), a black-box optimization system, using streaming F1 score on the Switchboard validation set as our objective. The searched ranges for each hyperparameter were learning rate $\in [1 \times 10^{-5}, 1 \times 10^{-1}]$, number of training epochs $\in [12, 20]$, $\lambda \in [1 \times 10^{-8}, 1 \times 10^{-6}]$, $\gamma \in [1, 10]$. For most experiments we ran 30 trials total, with 10 evaluations in parallel. Each individual trial (one set of hyper-parameters) ran on a single NVIDIA P100 GPU. Experimental run time varied from about 13 to 24 hours, depending mostly on the number of epochs. For each model variant we present only the results from the configuration with the highest streaming F_1 score on the Switchboard validation dataset. Our best performing streaming model used parameter values of $\lambda = 1.5 \times 10^{-7}$, learning rate 1.2×10^{-4}, $\gamma = 1.9$, training batch size 8, and 12 epochs.

Time step	**Model outputs**
3	**Input**: “I think [the real,” **Output**: “I think the real”
4	**Input**: “I think [the real, + the” **Output**: “I think the `<WAIT>`”
5	**Input**: “I think [the real, + the principal]” **Output**: “I think `<DIS>` `<DIS>` the principal”

Table 4: Example of the model’s outputs at each time step. (For brevity, we excerpt only a segment of the sentence that contains disfluencies.) A `<WAIT>` symbol indicates that the model decided to stop making predictions for the rest of the input sequence and to wait for further input instead. A `<DIS>` symbol indicates that the corresponding input token was given a classification of *disfluent* and therefore not included in the final edited output. For clarity we provide disfluency annotations in the form `[Reparandum, + Repair]`, but these are not actually provided to the model as input.

GRAM: Fast Fine-tuning of Pre-trained Language Models for Content-based Collaborative Filtering

Abstract

Content-based collaborative filtering (CCF) predicts user-item interactions based on both users' interaction history and items' content information. Recently, pre-trained language models (PLM) have been used to extract high-quality item encodings for CCF. However, it is resource-intensive to train a PLM-based CCF model in an end-to-end (E2E) manner, since optimization involves back-propagating through every content encoding within a given user interaction sequence. To tackle this issue, we propose **GRAM** (**GR**adient **A**ccumulation for **M**ulti-modality in CCF), which exploits the fact that a given item often appears multiple times within a batch of interaction histories. Specifically, **Single-step GRAM** aggregates each item encoding's gradients for back-propagation, with theoretic equivalence to the standard E2E training. As an extension of Single-step GRAM, we propose **Multi-step GRAM**, which increases the gradient update latency, achieving a further speedup with drastically less GPU memory. GRAM significantly improves training efficiency (up to 146×) on five datasets from two task domains of Knowledge Tracing and News Recommendation. Our code is available at https://github.com/yoonseok312/GRAM.

1 Introduction

Collaborative filtering (CF) is a popular technique used for mining relationships between items and users. Recently, CF has been successfully applied to various tasks including Knowledge Tracing and Recommender Systems (Smith and Linden, 2017; Bennett et al., 2007; Melville et al., 2002). However, conventional CF only considers item-user interactions, and disregards any item-/user-specific information. This leads to the so-called cold-start problem (Lam et al., 2008), where the CF model fails to make predictions for unseen users/items, even when they resemble observed users/items.

To remedy this issue, Content-based Collaborative Filtering (CCF) incorporates items' content information into the item encoding. This not only addresses the cold-start problem, but also leads to significant performance improvement (Wu et al., 2019, 2021a; Lu et al., 2018). Specifically, large pre-trained language models (PLM) (Devlin et al., 2019; Brown et al., 2020) have shown great potential for extracting items' content information. However, fine-tuning PLMs for CCF requires prohibitive computational resources in terms of (1) training time and (2) GPU memory footprint.

This issue arises due to CCF's multi-modal nature, where item representations are learned from both tabular user records and their textual information. As a given item appears multiple times within a batch of users' records, its textual encoding needs to be computed every time it appears within the batch. Moreover, the need to store intermediate activations for hundreds of millions of parameters in PLM requires high GPU memory footprint (Wang et al., 2020).

To that end, we propose **Single-step GRAM**, **GR**adient **A**ccumulation for **M**ulti-modality in CCF, which alternately trains the task specific module and content encoder module. Accumulating gradients for repeated items in a training step, Single-step GRAM provides 4 times faster training while being theoretically equivalent to standard E2E training.

As a natural extension of Single-step GRAM, we also propose **Multi-step GRAM** which accumulates gradients across *multiple training steps*. Multi-step GRAM (1) provides an even higher ratio of acceleration without significant performance loss and (2) consumes less than 40% GPU memory of E2E. Results show that the computational speed can increase up to 146× (45× on avg.) with less than 1% drop in AUC.

The contributions of our paper are as follows:

- We present GRAM (Single-step & Multi-step) which accelerate training of CCF by accumulating the gradients of redundant item encodings.
- We empirically show that GRAM, especially Multi-step GRAM, noticeably reduces GPU memory footprint compared to E2E training.
- We evaluate GRAM in a variety of settings on 5 real-world datasets in two task domains, News Recommendation and Knowledge Tracing.

2 Related Works

2.1 Collaborative Filtering and Content-based Filtering

Collaborative filtering (CF) (Su and Khoshgoftaar, 2009) attempts to predict user-item interaction based on past history. CF alone disregards any user-specific or item-specific information, leading to the inability to extract useful features from user information or item content. This especially leads to low performance on cold-start users and items. Various content-based filtering methods (Van Meteren and Van Someren, 2000; Basilico and Hofmann, 2004) have been proposed to mitigate these issues through labeled meta-data. It uses raw textual features of item, instead of requiring other users' data during a user's recommendation like CF. However, these approaches require manual labelling and lack the extensive usage of the content itself.

2.2 Content-based Collaborative Filtering

Content-based Collaborative Filtering (CCF) incorporates content into CF in order to unify the strengths of CF and content-based filtering. It consists of two major components: content-encoder (CE) and collaborative filter (CF) components connected in an end-to-end fashion. Major task domains where items' raw textual content may significantly aid CF include:

News Recommendation (NR), a task of predicting whether a user will click an article among others, provided with the user's past interactions.

Knowledge Tracing (KT), a task of predicting whether a user will correctly responds to a question or not based on the user's past responses.

In this section, we briefly review the widely-used approaches to utilize content information in CCF, with a focus on thse two domains.

2.2.1 Training Content-Encoder (CE) in CCF

Existing works mainly train or fine-tune CE module in an E2E fashion to obtain a useful content representations for the given CF task. In NR, NRMS (Wu et al., 2019) applied Glove (Pennington et al., 2014) word representation and Multi-head Self-attention (MHSA) (Vaswani et al., 2017) to encode the article's text to the item representation. Similarly in KT, EERNN (Su et al., 2018) used BiLSTM (Huang et al., 2015) to process Word2Vec (Mikolov et al., 2013) representations of question text into question representation. The representation is then fed into another LSTM layer to make final prediction on the user response.

While aforementioned methods directly use content-encoder's output as item vectors, there has also been work to use CE's output to regularize item vectors. Topical Attention Regularized Matrix Factorization (TARMF) (Lu et al., 2018) uses Matrix Factorization as CF and attention-based GRU network as CE to incorporate review data in predicting user-item ratings. Alternatively training CF and CE module, it uses the CE output to regularize the item representations in CF.

Most recently, researchers started to fine-tune large Pre-trained Language Models (PLMs) with generic language understanding as a CE module for better content representation. In NR, NRMS-PLM (Wu et al., 2021a) fine-tunes BERT (Devlin et al., 2019) in an E2E manner, achieving meaningful performance gain.

2.3 Efficient Fine-tuning of Large PLMs

While PLMs show powerful performance as a content-encoder in CCF, fine-tuning PLMs is known to be inefficient (Houlsby et al., 2019) as it includes updating billions of parameters. Although it is possible to use PLM's output as fixed features for downstream tasks, numerous studies (Devlin et al., 2019; Reimers et al., 2019) emphasize such feature-based approach cannot match the performance of E2E fine-tuning. Thus, researchers have considered fine-tuning a subset of the PLM architecture (Devlin et al., 2019) and adding task-specific parameters (Houlsby et al., 2019) to reduce cost and performance degradation.

However, the computational complexity deteriorates even more under multi-modal settings like CCF. In such cases, PLM is called numerous times for a single-user, adding a new dimension of computational load, making E2E training almost impossible. SpeedyFeed (Xiao et al., 2021) was proposed to accelerate the fine-tuning of PLM for news recommendation through combination of several methods. However, they are mainly engineering heavy implementations with domain dependencies. For a general training scheme in CCF, we propose a novel method that can be applied in an orthogonal manner to aforementioned techniques like (Houlsby et al., 2019) and (Xiao et al., 2021), while achieving remarkable speed boost in such multi-modal CCF settings.

3 Preliminaries

Notation	Description
I^u	Interaction sequence of user u
c_i	Content of item i
$I^u_n = (e^u_n, r^u_n)$	n-th interaction of user u
$e^u_n = CE(c^u_n)$	Embedding of content c^u_n from CE
$B^{(t)}$	Mini-batch B at update time-step t
$[B_I, B_u]$	Set of unique [items, users] in B
$[l_t, l_I]$	Length of [tokens, interactions] in [c, I]
d	Content embedding dimension
$\mathcal{L}$	CCF minimization objective

Table 1: Notations for Content-based CF(CCF)

In this section, we formally setup CCF framework and its notations for efficient discussion. CCF framework consists of two major components: content-encoder (CE) and collaborative filter (CF) components connected in an end-to-end fashion.

3.1 CF component

CF component predicts user u's response r to an arbitrary item based on the user's past interactions $I^u = (I^u_1, I^u_2, ..., I^u_{|I^u|})$ where each n-th interaction $I^u_n = (e^u_n, r^u_n)$ is represented as a tuple of item representation e^u_n and the user's response to the item r^u_n. In other words, the CF module aims to estimate the probability:

$$CF(I^u; e^u_{|I^u|+1}) = P(r^u_{|I^u|+1} | I^u_1, I^u_2, ..., I^u_{|I^u|}; e^u_{|I^u|+1})$$

3.2 CE component

CE component outputs the item representation e: $e^u_n = CE(c^u_n)$ where c^u_n is the token sequence of the corresponding item. The model parameters θ_{CE} and θ_{CF} of the CE-CF pipeline is then trained in an end-to-end fashion based on cross-entropy loss for response prediction. The summary of notation used for CCF is provided in Table 1. The existing approaches to tackle CCF are formatted and presented in Table 2, along with the pipeline we adopt for our later experiments.

Task	Model	CE	CF
NR	NRMS	Glove, MHSA	MHSA
	NRMS-PLM	BERT	MHSA
	Our Experiments	BERT	MHSA
KT	EERNN	W2V, BiLSTM	LSTM
	Our Experiments	BERT	LSTM

Table 2: CE-CF Pipeline Choice for CCF

3.3 Inefficiency of E2E in CCF

In CCF, end-to-end fine-tuning of the CE (PLM) suffers from cubic computational complexity in terms of sequence length, due to the data multi-modality. Let's assume average text token length of l_t and average interaction record length of l_I with each mini-batch B containing users B_u.

Attention-based CE module would be called l_I times, producing forward/backward-pass computational complexity of $O(|B_u| \cdot l_I(l_t^2 d + l_t d^2))$ where d represents embedding dimension.

Under similar average sequence length of per-item tokens and per-user interactions $l_t \approx l_I$, the resulting cubic complexity in terms of sequence length significantly increases space and time complexity of model training and becomes the limiting bottleneck factor.

4 Proposed Method

For efficient training, we propose **GR**adient **A**ccumulation for **M**ulti-modality in CCF (GRAM) with two variants: **Single-step GRAM** and **Multi-step GRAM**.

4.1 Single-step GRAM

Single-step GRAM trains CE module and CF module *separately*. To update the CE module, Single-step GRAM accumulates gradients of redundant items, effectively reducing the number of gradient computation for each step. As shown in Figure 1, Single-step GRAM can accelerate training by limiting the number of gradient calculation to the number of unique items in the batch. With this, Single-step GRAM can reduce the algorithmic complexity of CE to $O(|B_I| \cdot (l_t d^2 + l_t^2 d))$ per mini-batch update, from E2E's $O(|B_u| \cdot l_I(l_t^2 d + l_t d^2))$.

Proposition. *Given parameters* (θ_f, θ_g) *, suppose a neural network in separable form with* $y = g(h; \theta_g), h = f(x; \theta_f)$*, and loss* $L(\theta_f, \theta_g)$*. Define pseudo-target* $\tilde{h}$ *as*

$$\tilde{h} := f(x; \theta_f) - \left.\frac{\partial L}{\partial h}\right|_{h=f(x;\theta_f)}, \qquad (1)$$

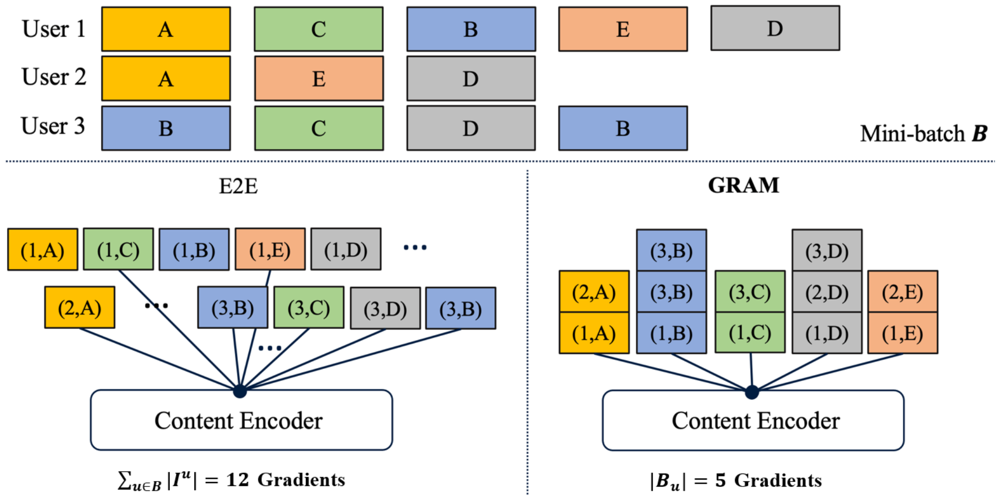

Figure 1: Comparison to E2E Training: Let's assume a mini-batch B of 12 interactions consisting of 3 users and 5 unique items. For the content encoder, E2E computes 12 gradients from each *interaction*, while GRAM computes 5 only, based on accumulated gradient signal in pseudo-target $\tilde{h}_i$ from each *item* i.

and pseudo-loss $\tilde{L}(\theta_f)$ *for another network* $f(x;\theta'_f)$ *as*

$$\tilde{L}(\theta_f) := \frac{1}{2}\left(\tilde{h} - f(x;\theta'_f)\right)^2. \qquad (2)$$

Then, the gradient of θ_f *w.r.t* L *is equivalent to the gradient of* θ'_f *w.r.t* $\tilde{L}$*,*

$$i.e. \quad \frac{\partial L}{\partial \theta_f} = \left.\frac{\partial \tilde{L}}{\partial \theta'_f}\right|_{\theta'_f=\theta_f}. \qquad (3)$$

While GRAM trains CF module and CE module separately, it guarantees a theoretically equivalent parameter update with E2E as shown in the Proposition (proof in Appendix A). Yielding identical outcome of E2E back-propagation with fewer gradient computation, Single-step GRAM enables efficient training under hierarchical multi-modal setting like CCF by accumulating gradient buffer in the pseudo-target for items that are updated multiple times in a mini-batch.

4.2 Multi-step GRAM

Instead of a single update, we can accumulate gradient buffers for *multiple* mini-batch updates, gaining additional speed boost. In other words, CF / CE modules may separately update multiple times across multiple mini-batches, further elaborated in the following section. However, this relaxation of GRAM's alternating period no longer guarantees equivalence with E2E back-propagation.

As the CE module can use multiple steps to update item representations, Multi-step GRAM can also reduce GPU memory footprint drastically compared to E2E.

4.3 Training Scheme of GRAM

Algorithm 1: GRAM

```
Input  : ${B_I^{(t)}}_{t=0}^{T-1}$: mini-batch,
         $\theta^{(0)}$: initial parameters
Output : $\theta^{(T)}$: resulting parameters

while $t = \{0, ..., T-1\}$ do
    (1. Produce content representations)
        $h_i^{(t)} \leftarrow CE(c_i;\theta_{CE}^{(t)}), \forall i \in B_I^{(t)}$   (4)
    (2. Update CF parameters)
        $\theta_{CF}^{(t+1)} \leftarrow \theta_{CF}^{(t)} - opt(\nabla\mathcal{L}(\theta_{CF}^{(t)}))$   (5)
    (3. Update content representations)
        $\tilde{h}_i^{(t)} \leftarrow h_i^{(t)} - \nabla\mathcal{L}(h_i^{(t)}), \forall i \in B_I^{(t)}$   (6)
    if $t \mod N = 0$ then
        (4. Update CE parameters)
            $\theta_{CE}^{(t+1)} \leftarrow \theta_{CE}^{(t)} - opt(\nabla\tilde{\mathcal{L}}(\theta_{CE}^{(t)}))$   (7)
    end
    $t \leftarrow t + 1$
end
```

See Algorithm 1 for the pseudo-code of GRAM. We denote gradient accumulation step as N. The algorithm becomes Single-step GRAM for $N = 1$ and it becomes Multi-step GRAM for $N > 1$.

First, CE produces content representation $h_i^{(t)}$ for CF module to complete the forward-pass for unique items i in the mini-batch $B^{(t)}$. Then, we update the CF module's parameters using standard back-propagation with a normal CF training objective $\mathcal{L}$ in Eq.(8), while simultaneously updating the content representation (output from CE module) by treating it as trainable embedding $\tilde{h}_i^{(t)}$.

$$\mathcal{L} := \sum_{u \in B_u^{(t)}} L(I^u, \{h_i^{(t)} | \forall i \in B_I^{(t)}\}; \theta_{CF}^{(t)}) \quad (8)$$

Lastly, for items of which embeddings are modified in Eq.(6), the CE module is trained to follow/regress towards the modification with respect to pseudo-target $\tilde{h}_i^{(t)}$ and pseudo-loss $\tilde{L}$ in Eq.(9).

$$\tilde{\mathcal{L}} := \frac{1}{2} \sum_{i \in B_I^{(t)}} (\tilde{h}_i^{(t)} - CE(c_i; \theta_{CE}^{(t)}))^2 \quad (9)$$

Based on updated content representations, we repeat the process with $t \leftarrow t + 1$. Note that for Eq.(6), Stochastic Gradient Descent with a learning rate of 1 should be used to guarantee the theoretical equivalence with E2E. For Eq.(5) and Eq.(7), choice of a optimizer (e.g. Adam) doesn't impact the equivalence with E2E.

4.4 GRAM's Speed Boost ratio $\mathcal{R}$

Given a mini-batch B of $|B_u|$ users' interaction sequences, the standard E2E back-propagation updates CE module for $\sum_{u \in B_u} |I^u|$ (i.e. number of total interactions), while Single-step GRAM updates CE module for $|B_I|$ (i.e. number of unique items) times only. Since PLM based CE modules are usually significantly larger than the head (CF module) attached for downstream task such as News Recommendation, the following ratio of speed boost for CE module applies in a close to directly proportionate manner for the entire training procedure.

$$\mathcal{R} := \frac{\sum_{u \in B_u} |I^u|}{|B_I|} = \frac{\#\text{interactions}(B)}{\#\text{items}(B)} \quad (10)$$

The ratio $\mathcal{R}$ monotonically increases as mini-batch size becomes larger. Thus, larger mini-batch size would yield larger efficiency boost via Single-step GRAM. This is why Multi-step GRAM can achieve even more speed boost compared to Single-step GRAM. If the gradient accumulation latency becomes 1 epoch for Multi-step GRAM, the speed boost ratio $\mathcal{R}$ becomes:

$$\mathcal{R} := \frac{\#\text{total interactions in dataset}}{\#\text{ total items in dataset}} \quad (11)$$

Considering there are significantly less number of items compared to the total number of interactions in real-world datasets, GRAM with high enough update latency can achieve remarkable speed boost. However, we can also expect that longer accumulation latency would hurt model performance and convergence. In the following section's experiments, (i) training efficiency boost and (ii) performance degradation from different alternating frequency are closely monitored on various GRAM alternating periods (Single-Step, 10-Step, Half-Epoch, Full-Epoch).

While GRAM utilizes gradient accumulation across duplicate item representations to boost training, the resulting speed boost is orthogonal with traditional gradient accumulation as it focuses on increasing effective batch size under limited computational resource.

5 Experimental Settings

We first define the scope of tasks and metrics used in the experiments. Detailed description of datasets and methods are provided in section 5.1 and section 5.2, respectively.

Tasks: Experiments are conducted on two major task domains of CCF: Knowledge Tracing(KT) and News Recommendation(NR), where models predict whether a student/reader will solve/click an question/article, as a classification task.

Metrics: Overall AUC and cold-start item AUC (CSAUC) are measured for KT. AUC, MRR, nDCG@5, nDCG@10 are measured for NR. As cold start problem is intrinsically abundant in news recommendation environment (Wu et al. (2019)), we did not measure CSAUC separately. Wall-clock training time until convergence is reported for all experiments. For fair comparison of training time, all models are run on equivalent device (NVIDIA A100 GPU) in an isolated manner.

Dataset	Users	Total Items	Total Interactions	CS Items	CS Interactions	Average l_t
Spanish	2,643	4,628	279,747	200	3,191	5.32
French	1,202	4,078	174,749	200	1,970	5.24
POJ	22,110	2,597	898,384	200	10,523	271.34
TOEIC	1,240,955	9,336	94,264,845	684	321,933	147.47
MIND	750,434	104,150	3,760,125			11.52(639.57)

Table 3: Dataset Information. For MIND, both average l_t of title alone and l_t of title + abstract + body are reported.

5.1 Experimental Details

To evaluate our model, we used five real-world datasets: four datasets in KT, and one dataset in NR, on which both textual content data and user interaction data are available. Experiments on Duolingo French and Spanish dataset are done with single NVIDIA A100 GPU, and those on POJ, TOEIC, and MIND are done with eight NVIDIA A100 GPUs, in distributed data parallel training. The results were shown to be statistically significant ($p < 0.05$).

Detailed per-dataset description is written below, and specification is in Table 3. [1] Dataset collection methods are mentioned in Appendix F.

5.1.1 Datasets

(KT) Duolingo (Spanish, French): Language Translation (Settles et al., 2018) contains questions and responses for Duolingo users. Following (Srivastava and Goodman, 2021), we collapsed the original token level mistakes to question level binary labels. We used Spanish and French dataset.

(KT) POJ: Computer Programming was collected from Peking online platform and consists of computer programming questions.

(KT) TOEIC: Language Comprehension from EdNet (Choi et al., 2020) is the largest publicly available benchmark dataset in education domain consisting of student interaction logs.

(NR) MIND: Microsoft News Dataset is one of the largest English dataset for monolingual news recommendation. MIND dataset provides news articles' title, abstract, and body text for news content modeling. For comparison with other models, we only utilized the news title, following Wu et al. (2019, 2021a). As Multi-step GRAM's significant speed boost allowed us to utilize more features, we also provide results on utilizing all textual features for Multi-step GRAM as well.

5.2 Baseline Methods

5.2.1 E2E & GRAM

To fairly compare GRAM's training methodology against the standard E2E, we apply GRAM/E2E on an identical model architecture, defined for KT and NR respectively. Model choices are shown in Table 2. To the best of our knowledge, this work is the first study to fine-tune BERT for KT. Detailed model architectures are described in Appendix D.

Based on this model architecture, we compare: **E2E** training, single-step **GRAM 1S**, 10-Step **GRAM 10S**, 0.5-Epoch **GRAM 0.5E**, and 1-Epoch **GRAM 1E** on the aforementioned metrics. We also provide benchmarks for other existing approaches, as elaborated in the following section 5.2.2. Note that E2E training in NR has the same structure as NRMS-PLM in (Wu et al., 2021a).

5.2.2 Other Baselines

In addition to the shared CCF model architecture defined above, we also include other approaches for extensive comparison.

NoFinetune approach directly adopts fixed item representation encoded from PLM without fine-tuning. Only the CF component is trained, receiving PLM's fixed output as the input.

NoContent approach does not incorporate any textual content at all. Each item representation is randomly initialized before being trained along with the standalone CF component. For KT, we used DKT (Piech et al., 2015).

(KT) Content Regularized CF (CRCF) is our implementation of the proposed regularization in TARMF with equivalent CF and CE modules of GRAM. As TARMF's content-encoder and user feature vector should go through additional iterations of optimization in sequential recommendation, we adopt hierarchical user encoder like E2E setting to eliminate the need of model retraining.

(KT) LM-KT formulates KT as auto-regressive modeling task to fine-tune pre-trained GPT-2. The method's major bottleneck to other sequential recommendation domains is that the model's sequence

---

[1] Train / Test set were randomly split in 8:2 ratio. 10% of train dataset were randomly chosen for validation set.

length has to increase in a multiplicative fashion: $O(l_t \times l_I)$ in Table 1.[2]

(KT) EERNN is a specific instance of CE-CF pipeline where Bi-directional LSTM (CE) encodes question text's W2V representation into question embedding. CF consists of another LSTM layer.

(NR) NRMS is another specific instance of CE-CF pipeline where CE uses Glove word embedding and Multi-Head Self-Attention layers. Its CF component is also based on MHSA layers.

(NR) SpeedyFeed used (i) auto-regressive modeling, (ii) BusLM, (iii) Dynamic Batching, and (iv) Cache mechanism to speedup PLM-based news recommendation. For fair comparison, we used equivalent CE module for both GRAM and SpeedyFeed.

Further experimental details are in Appendix D.

6 Results and Discussion

6.1 Knowledge Tracing

Performance Comparison: In general, E2E and GRAM in Table 4[3] shows best performance across datasets. Difference among GRAM variants highlights how Multi-step GRAM's performance gradually deviates from the E2E baseline as alternating period increases. As claimed in the previous section 4.1, GRAM(1S)'s performance most closely matches the E2E baseline. Confidence intervals of the two methods are reported in Appendix E.

NoFinetune and NoContent achieve significantly worse performances on both metrics on all datasets, as compared to the full CCF setting with both CE and CF fine-tuned properly. Also, NoContent does not show any inference power on cold-start items, reporting AUC values around 50. LM-KT and EERNN showed lower performance in AUC and CSAUC than E2E or GRAM(1S), respectively.

As shown in Figure 2, we empirically confirm that standard E2E training converged to better local minima than CRCF, at all regularization hyperparameter values used in (Lu et al., 2018). GRAM 1S even converges faster than all variants of CRCF while maintaining E2E performance. CRCF also showed larger degradation in CSAUC. We noticed that as the degree of regularization increases, time for convergence increases notably.

Speed Comparison: We first highlight the reduction in training time via GRAM. Across 4 datasets, GRAM 1S achieves **4.3**× speedup of the E2E baseline, while GRAM 1E achieves acceleration of **43**×. We observe GRAM 1E achieves most significant training time acceleration as expected, since the boost ratio $\mathcal{R}$ of Eq.(11) is the largest in epoch-wise alternation. The power of GRAM 1E multiplies as the size of dataset increases, achieving remarkable **146**× speed up for the largest dataset, TOEIC. Among all datasets, TOEIC has the largest boost ratio $\mathcal{R}$ based on Table 3 which explains the largest efficiency gain.

Dataset	Method	AUC	CSAUC	Speed-up
TOEIC	E2E	75.7	64.2	1(135hr)
	GRAM 1S	**76.0**	63.0	5.7
	GRAM 10S	75.8	**65.1**	1.7

GRAM 1E also out-speeds EERNN at all datasets despite the fact that EERNN uses W2V embeddings and a single LSTM layer for its CE. In terms of GRAM's alternating period, we note

---

[2] LM-KT baseline was only tested on Duolingo datasets as other datasets' large average token length prevents LM-KT from considering more than a few items per each user.

[3] For CRCF, best result is reported among hyper-parameter ablations in Figure 2.

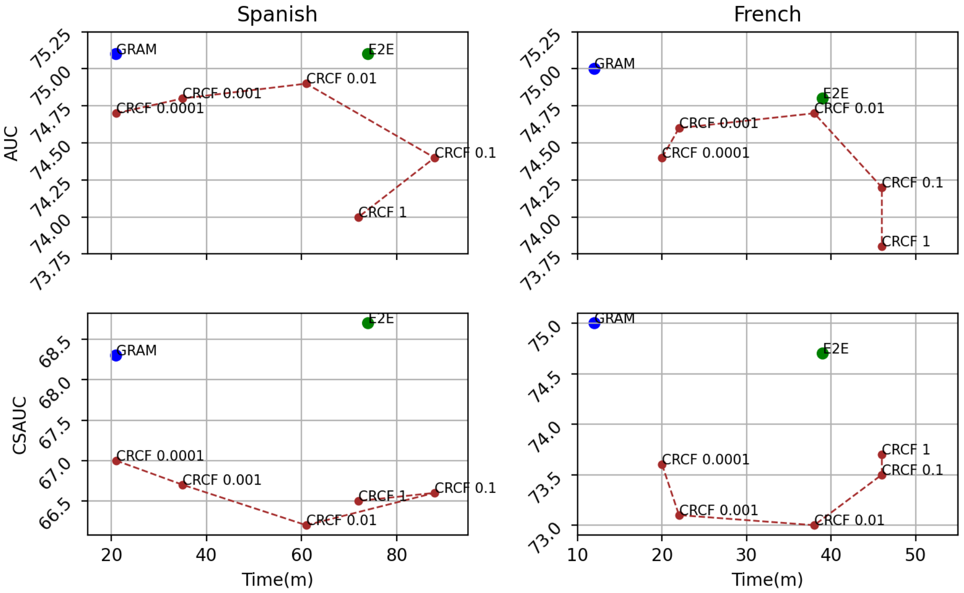

Figure 2: Comparison between GRAM, E2E, and CRCF. For CRCF, regularization parameter is marked as well.

that the impact on speed boost is not monotonic on some datasets, potentially due to increased variance of optimization switching between the CE component and the CF component.

Based on GCP GPU cost for ondemand A100 ($2.93/hr), training E2E model in TOEIC costs **$3,161**. GRAM 1E drastically reduces the training cost to **$21**.

Method	AUC	MRR	nDCG @5	nDCG @10	Speed-up
(Title-only)

Table 5: Prediction Performance and Training Speed on MIND Dataset. Training time is reported for E2E training. Overall best results among content finetuning methods are marked in bold, and best results utilizing title only are underlined.

6.2 News Recommendation

Performance Comparison: As shown in Table 5, Single-step GRAM matches performance of E2E training, and Multi-step GRAM shows less than 0.5% performance loss. Multi-step GRAM's capability to incorporate abstract and body of the news article (Title+Body) significantly improved the performance beyond all methods relying on title information alone.

SpeedyFeed (Xiao et al., 2021) shows worse performance than all GRAM methods. This may due to SpeedyFeed's cache mechanism, as it fails to optimize news representations that were generated in recent time steps, unlike GRAM. We also noticed that SpeedyFeed's performance is highly sensitive to its hyper-parameters on the method's cache policy. Increasing max cache step hyper-parameter for faster training easily caused the training loss to spike, deteriorating the model convergence.

An ensemble of Single-step GRAM and Multi-step GRAM is currently ranked 4th in the MIND official leaderboard provided by Microsoft.[4] Even without state-of-the-art CF module (Fastformer (Wu et al., 2021b)) and CE module (UniLM (Dong et al., 2019)), the ability to encode the body of the news article with GRAM shows a comparable performance with state-of-the-art News Recommendation models.

Speed Comparison: Multi-step GRAM shows consistent speed boost in MIND dataset, where

---

[4] https://msnews.github.io/

Title-only GRAM 1E is **17.3**× faster than E2E. SpeedyFeed's acceleration, on the other hand, was lower than that of GRAM 1S. Although SpeedyFeed's central batching collects unique items in the forward pass, it still requires gradient computations for PLM's weights on every interaction during backpropagation, having limited speed gain. Also, SpeedyFeed's auto-regressive formulation, the most significant factor of speed boost, was not applicable to MIND dataset, which does not provide negative samples (news impression list) per each positive interaction (news click) step.

While Wu et al. (2019) reported that using all textual information increases model performance significantly in a small version of MIND dataset, baseline results from Wu et al. (2019, 2021a) only utilize news title due to computational complexity. With eight A100 GPUs, E2E training with all textual features is estimated to require **202** hours [5] (**$4,735** of training cost) to converge. For this reason, we were unable to produce the result for E2E with all textual information. In contrast, GRAM 1E requires only **3.6** hrs (**$84**) to converge, requiring **56**× less training time compared with E2E.

Method	CE Batch Size	GPU Memory in %, (Gb) TOEIC	MIND
E2E	N/A	95.2, (38.6)	95.1, (38.4)
GRAM 1E	8	12.1, (4.8)	12.5, (5.1)
	32	16.0, (6.5)	34.9, (14.1)

Table 6: GPU Memory Consumption, with CF batch size of 4 in single NVIDIA A100. E2E doesn't have CE batch size as CE module naturally receives all items included in CF batch size as input.

6.3 GPU Memory Consumption

In E2E training, the entire computational graph as well as activations of all layers should be stored, resulting in a large GPU memory footprint (Wang et al., 2020). In this perspective, splitting CF module and CE module in GRAM brings down the required GPU memory during computation. As (1) the model size of the CF module is relatively small (single LSTM/MHSA) and (2) CE module of Single-step GRAM updates all item representations in a given batch in one step, the memory reduction is not significant in Single-step GRAM.

However, Multi-step GRAM can bring down the memory requirement significantly as its CE module uses multiple steps to update item representations. Table 6 compares the memory consumption between E2E and GRAM 1E with content encoder batch size of 8 and 32, respectively. Overall, GRAM 1E consumes less than 40% of memory compared to E2E. While only GRAM 1E is compared, Multi-step GRAM in general consumes similar memory given the same content encoder batch size.

7 Conclusion and Future Work

In this paper, we proposed GRAM as an efficient method to train content-based collaborative filtering models. Single-step GRAM splits the CE module and CF module during training, accumulating gradients for items appearing repeatedly in a batch. This effectively reduces the number of CE module's gradient computation and negates the need to store the intermediate activations for both of the modules at once. Extending Single-step GRAM, we increase the gradient accumulation latency for Multi-step GRAM, gaining additional training speed boost and memory footprint reduction.

GRAM was empirically evaluated on 5 different tasks to demonstrate its efficiency and comparable prediction power. Utilizing GRAM's efficiency, Knowledge Tracing model trained with GRAM 1E will be deployed in Santa[6], an AI-powered English learning platform with 4 million users.

A limitation of our method is that we introduce an additional hyperparameter of gradient accumulation latency for Multi-step GRAM. We expect a more sophisticated gradient accumulation scheme may adaptively choose the gradient accumulation latency. Another potential extension of our research is to scale up GRAM for CCF tasks involving higher-dimensional inputs, such as images and videos.

A Proposition

Proof.

$$\frac{\partial L}{\partial \theta_f} = \frac{\partial L}{\partial h}\frac{\partial h}{\partial \theta_f} = \frac{\partial L}{\partial y}\frac{\partial y}{\partial h}\frac{\partial h}{\partial \theta_f} \tag{12}$$

$$\left.\frac{\partial \tilde{L}}{\partial \theta'_f}\right|_{\theta'_f=\theta_f} = -\frac{\partial f}{\partial \theta'_f}\cdot\left(f(x;\theta_f) - \frac{\partial L}{\partial y}\frac{\partial y}{\partial h} - f(x;\theta'_f)\right) \tag{13}$$

$$= \frac{\partial L}{\partial y}\frac{\partial y}{\partial h}\frac{\partial h}{\partial \theta_f} \tag{14}$$

☐

B Hierarchical illustration of GRAM

Figure 3 is the hierarchical illustration of GRAM. Refer to Section 4.3 for more details.

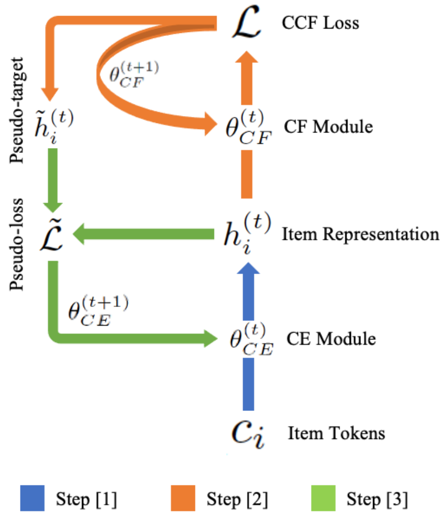

Figure 3: Gradient on item representations are accumulated on Pseudo-target to mimic E2E training.

C Validation Performance

Figure 4 shows the validation performance per training time for E2E and GRAM variants. As the graph includes 10 epochs for early stopping patience, some overfitting is witness at the end of the training curve, such as the sudden drop of GRAM 1S in Spanish dataset after marking best performance.

D Experiment Detail

All experiments are ran 3 times and averaged results are reported except TOEIC E2E and MIND E2E, due to high computational cost mentioned in the result section. Across all experiments, CE component uses TinyBERT(Jiao et al., 2020), a distilled BERT with on-par performance. The architecture contains 6 MHSA layers of dimension 768. CF component for KT uses 2-layer LSTM network, following Piech et al. (2015). In NR, we use a single MHSA layer, following Wu et al. (2019, 2021a).

In both domains, learning rate of 1e-4 was used for CF module and CE module after learning rate ablation in the scope of [1e-3, 1e-4, 1e-5]. Adam with Noam scheduler was used as the optimizer. Test metrics were measured by the best validation checkpoint after early stopping of patience 10 epochs. As E2E training consumes different amount of memory based on item token length, different batch sizes were used across datasets. Batch sizes per datasets are the following: 32 for Duolingo, POJ, and TOEIC, and 256 for MIND. As Multi-step GRAM requires much less memory compared with E2E, higher batch size was able to be used for large datasets such as TOEIC and MIND. Details are mentioned in Section C.

For NoFinetune experiment, pre-computed item representations from CE were initialized to CF's item embeddings to boost training speed.

Authors of EERNN also proposed EKT(Liu et al., 2019), which explicitly models the student's knowledge state for different knowledge concepts. As knowledge concept labels are not available in most datasets, we do not test EKT.

D.1 Knowledge Tracing

Mean-pooling was used to extract question representation from contextualized token embedding. For relatively small KT datasets (Duolingo and POJ), it was challenging to secure meaningful number of cold-start items (questions) in the test split. For these datasets, additional cold-start questions were randomly picked and interactions on those questions in the training split were removed to secure meaningful number of cold start interactions. Items with token length over max seq len (512) were truncated. For TOEIC dataset, passage, question, and choices were concatenated as content token sequence for CE component.

D.2 News Recommendation

For NR, we follow (Wu et al., 2021a) to use additive attention based pooling to extract news article representation. Title, abstract, body were concatenated for Setting B, with max len of 24 for title, 50 for abstract, and 400 for body. Items with token length over max seq len were truncated.

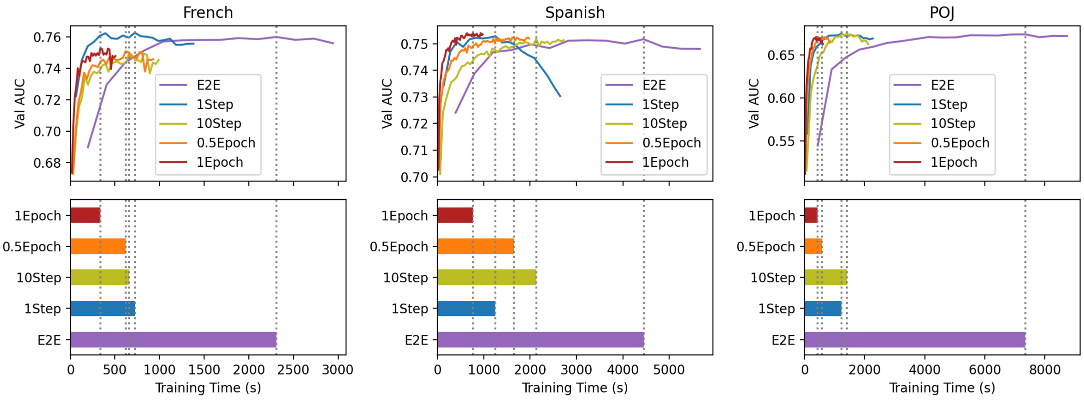

Figure 4: . Validation AUC convergence and training time until early-stopped checkpoint, across different GRAM alternation periods. Color schemes are synchronized across all subplots.

E Result Detail

E.1 E2E vs Single-step GRAM Confidence Interval

Metrics	E2E	GRAM (1S)
French Total AUC	0.748 (0.001)	0.750 (0.0006)
Spanish Total AUC	0.751(0.0005)	0.751(0.0006)
POJ Total AUC	0.654 (0.0009)	0.655 (0.0011)

Table 7

As TOEIC and MIND E2E result is from a single run due to high computational complexity, Test AUCs on remaining three datasets (Duolingo French, Spanish, POJ) are reported with 95% CIs in Table 7

F Dataset Collection Methods

Duolingo: gathered from 2018 Duolingo Shared Task on Second Language Acqui-sition Modeling.
POJ: publicly available question texts and interaction logs were scraped from their public website.
TOEIC: content materials for corresponding question IDs in the dataset were collected privately.
MIND: collected from website
Duolingo (French, Spanish), POJ, MIND datasets are free to download for research purposes under respective terms. Interaction data for TOEIC is avilable as well for research purposes.

Generating Repetitions with Appropriate Repeated Words

Toshiki Kawamoto, Hidetaka Kamigaito, Kotaro Funakoshi and Manabu Okumura
Tokyo Institute of technology
`{kawamoto,kamigaito,funakoshi,oku}@lr.pi.titech.ac.jp`

Abstract

A repetition is a response that repeats words in the previous speaker's utterance in a dialogue. Repetitions are essential in communication to build trust with others, as investigated in linguistic studies. In this work, we focus on repetition generation. To the best of our knowledge, this is the first neural approach to address repetition generation. We propose Weighted Label Smoothing, a smoothing method for explicitly learning which words to repeat during fine-tuning, and a repetition scoring method that can output more appropriate repetitions during decoding. We conducted automatic and human evaluations involving applying these methods to the pre-trained language model T5 for generating repetitions. The experimental results indicate that our methods outperformed baselines in both evaluations.

1 Introduction

Dialogues can build a trusting relationship with others, thus are essential in our daily lives (Schein, 1993; Searle and Vanderveken, 1985). There are several types of responses in dialogues, and the one we focus on is repetitions (Tannen, 1987). A repetition is a response that uses the previous speaker's words or phrases. Figure 1 shows an example. The phrases "a bear" and "came out" are repeated. Repetitions frequently appear in a conversation with diverse roles, e.g., to indicate attentive listening, confirm the previous utterance, and show agreement or sympathy (Machi, 2019; Shimojima et al., 2002). Many linguistic studies investigating repetitions have concluded that they are important for building and strengthening relationships between speakers (Tannen et al., 1989; Johnstone, 2002; Norrick, 1987; Brown, 1999). From the above linguistic point of view, we can say that repetitions are indispensable in dialogues.

Repetitions are similar to paraphrases and reflections, which are component skills of counseling (Theron, 2008), in terms of using the previous speaker's utterance. Paraphrases and reflections have been generated using a template-based method (Han et al., 2013).

Speaker: When I was driving, a bear suddenly came out .
Listener: Oh. A bear came out !?

Figure 1: Example repetition. Listener's response uses words from previous speaker's utterance. Yellow words indicate those that are repeated and green words indicate those in the repetition.

While many studies have tackled general response generation with neural network-based frameworks (Adiwardana et al., 2020; Zhang et al., 2020), less attention has been paid to repetitions. This might be because they are buried in a huge amount of response data. Therefore, we focus on automatically generating repetitions. To the best of our knowledge, this is the first study on generating repetitions with a neural approach. We used the pre-trained language model T5 (Raffel et al., 2019) for generating repetitions because it has performed well in language generation in past few years (e.g., Radford et al.; Raffel et al., 2019; Lewis et al., 2020).

In generating repetitions, it is important to take into account which words should be repeated from the previous utterance. The repeated words might represent objective facts, names of people and places, and the speaker's experiences and emotions, though they are different depending on the language (Machi, 2008). When we use a pre-trained language model, however, the model cannot explicitly learn the repeat likelihood among words during fine-tuning because it is difficult to directly teach which words are likely to be repeated at this step.

To solve this problem, we propose Weighted Label Smoothing (WLS), which is an improvement upon Label Smoothing (LS) (Szegedy et al., 2016). The method enables a language model-based re-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 852 - 859
July 10-15, 2022 ©2022 Association for Computational Linguistics

sponse generator to learn the words it should use for each input utterance during fine-tuning. We also propose the repetition scoring method (RSM) to expand the scoring method proposed in Wu et al. (2016) for selecting repetitions that contain appropriate repeated words during decoding.

We evaluated the proposed methods on a dataset we created in Japanese for automatic and human evaluations. Our methods outperformed baselines, i.e., fine-tuned pre-trained language models without our methods, in both evaluations. This indicates that our methods can generate repetitions that contain appropriate words to repeat.

Our contributions are as follows:

1. To the best of our knowledge, this is the first study to use a neural model for generating repetitions.
2. We will release our code and the dataset of repetitions we created.[1]
3. We propose WLS, that takes into account words that should be repeated during fine-tuning, for generating repetitions.
4. We propose RSM to select repetitions containing appropriate repeated words during decoding.

2 Proposed Methods

Repetitions do not necessarily mean we repeat any word. For the utterance "Today's dinner was pizza.", the repetition "Oh, you ate pizza." is more appropriate than "Oh, you ate today." However, a fine-tuned pre-trained language model alone may not be enough to generate repetitions with appropriate repeated words. Therefore, to generate a response that repeats more appropriate words, we introduce *repeat scores* (§2.1) to calculate how likely a word is repeated and incorporate the scores into WLS (§2.2) for fine-tuning and RSM (§2.3) for beam search in decoding.

2.1 Repeat Score

We should give high scores to words that tend to be used in repetitions and low scores to words that should not be. Since only content words (nouns, verbs, adjectives, or adverbs) are repeated in Japanese, we define a *repeat score* only for them. Since subwords are used as a unit in a pre-trained language model, all the subwords in the same content word receive the same *repeat score*.

We use BERT (Devlin et al., 2019) to construct a model for scoring the *repeat scores* in the range of [0, 1]. We pass the final hidden state of BERT through SpanExtractor (Lee et al., 2017) for each word and then convert the vector to a scalar value through a multi-layer perceptron, which has a sigmoid function as the last layer. In the training data, the label is set to 1 if the target content word was repeated, and 0 if it was not. The output is then normalized by applying min-max scaling.

2.2 Weighted Label Smoothing (WLS)

In this section, we explain how to learn words to repeat when fine-tuning a pre-trained language model for repetition generation. Neural response generation models try to optimize cross-entropy loss. Let X be a previous utterance and Y be a response, where Y is divided into subwords as $Y = y_1, \ldots, y_T$. Letting K be the total number of subwords and v_k be the k-th subword, the cross-entropy loss is defined as follows:

$$L(q, p) = -\sum_{k=1}^{K} q(v_k) \log\{p(v_k|y_{<t}, X)\},$$

where $p(v_k|y_{<t}, X)$ is the probability of v_k that the model outputs at time step t given X, and $q(v_k)$ is the probability of v_k in a target distribution that the model aims for. When a one-hot distribution is used, $q(v_k)$ is as follows with a function δ_{v_k, y_t}, which becomes 1 when $v_k = y_t$:

$$q(v_k) = \delta_{v_k, y_t}.$$

When LS is used, however, $q(v_k)$ is as follows with uniform distribution $u(v_k) = 1/K$:

$$q(v_k) = (1 - \epsilon)\delta_{v_k, y_t} + \epsilon u(v_k),$$

where ϵ is a hyperparameter.

A one-hot distribution and LS cannot learn a subword to repeat explicitly because there are labels other than the target, i.e., v_k when $v_k \neq y_t$, that have the same $q(v_k)$. Therefore, we propose WLS, which takes into account how likely a subword is repeated. We use *repeat scores*, explained in §2.1, instead of $u(v_k)$. The $q(v_k)$ of WLS is defined as follows:

$$q(v_k) = (1 - \epsilon)\delta_{v_k, y_t} + \epsilon \frac{r(v_k)^\gamma}{K},$$

---

Dialogue	運動やってました. (I played sports.) ヘーそしたら中学校高校はクラブは何か？ (Oh, did you participate in any clubs in junior high or high school?) 中学高校大学まで陸上部でした. (I was a member of a track and field club in junior high, high school, and college.)
Repetition1	陸上部ですか. (Track and field club?)
Repetition2	陸上部だったんですね. (You were in the track and field club.)
Repetition3	中学高校大学まで陸上とは, 長く続けられたんですね！ (You were in the track and field club for a long time, from junior high through high school and college.)

Table 1: Examples from repetition dataset. There are at most three repetitions for one dialogue.

where $r(v_k)$ is the *repeat score* for v_k, and γ is a hyperparameter. We use the $q(v_k)$ of WLS as the distribution in the cross-entropy loss function. Subwords in the previous speaker's utterance are weighted in accordance with their $r(v_k)$. Note that if we set $\gamma = 0$, WLS is the same as LS.

2.3 Repetition Scoring Method (RSM)

Pre-trained language models usually use beam search in decoding. We propose a scoring method, RSM, to select more appropriate repetitions in the beam search. RSM is an extension of a scoring method for machine translation in Wu et al. (2016). The original scoring method uses a length normalization procedure and coverage penalty (Tu et al., 2016). Length normalization treats sentences of different lengths equally. The coverage penalty gives a high score to a sentence that is most likely to cover all the words in the source sentence. Since the original scoring method cannot select a repetition with appropriate repeated words, we modify the method by adding *repeat scores*, which indicate words to repeat. Letting Y be a candidate response during beam search and X be the previous utterance, the generation probability is $P(Y|X)$. The scoring function $s(Y, X)$ of RSM is as follows:

$$
\begin{aligned}
s(Y,X) &= log\{P(Y|X)\}/lp(Y)+cp(X,Y)+rs(X,Y), \\
lp(Y) &= \frac{(5+|Y|)^{\alpha}}{(5+1)^{\alpha}}, \\
cp(Y,X) &= \beta * \sum_{i=1}^{|X|} log(\sum_{j=1}^{|Y|} p_{i,j}), \\
rs(Y,X) &= log \sum_{j=1}^{|Y|} r(v_j),
\end{aligned}
$$

where α and β are hyperparameters for length normalization and coverage penalty, respectively. We carry out two modifications to the original scoring method to yield RSM. First, we use the attention value of $p_{i,j}$ without suppression. In contrast to machine translation, in which an input and output have a one-to-one relationship, lengths of an input and output are not the same in repetition generation, and so it is not suitable to suppress the attention value under 1.0. Second, we add the term $rs(Y, X)$, which represents the sum of *repeat scores* for subwords in the response.

3 Dataset

We manually created pairs of a speaker's utterance and its repetition as our dataset using a crowdsourcing service.[2] Since repetitions often occur when a listener replies to a speaker, we used utterances in a corpus of listening dialogues (Yoshino et al., 2018) between an elderly person and caregiver or clinical psychologist as the speaker's utterances in our dataset.[3] In this corpus, the elderly person tends to be a speaker and the others are listeners. We extracted the elderly person's utterances containing content words for creating a repetition. The number of extracted utterances was 5,548. We asked three crowdsourcing workers to create repetitions for each utterance. Specifically, a worker was shown two utterances before each target utterance and asked to create a repetition, that supports the creation of context-aware repetitions. When the workers found it difficult to create a repetition for an utterance, they could discard it. The total number of workers was 333.

Examples from the dataset are given in Table 1. The size and statistics of our repetition dataset are shown in Tables 2 and 3. The word overlap rate is the percentage of words in an utterance that are

---

[2] `https://www.lancers.jp/`

[3] We attempted to extract repetitions from the corpus using a rule-based approach and found it is difficult to obtain a sufficient amount of such repetitions.

	Train.	Valid.	Test
Utterance (Dialogue)	4106	489	490
Repetition	10677	1305	1312

Table 2: Size of repetition dataset.

Total Dialogues	5085
Total Repetitions	13294
Average # of Repetitions per Utterance	2.61
Average # of Tokens per Utterance	26.25
Average # of Tokens per Repetition	11.74
Word Overlap Rate	36.48%
Content-word Overlap Rate	38.14%

Table 3: Statistics of repetition dataset.

repeated in a repetition. The content-word overlap rate is the percentage of content words of an utterance that are repeated. Comparing the average numbers of tokens, repetitions are much shorter than utterances. This may indicate that repetitions cannot be produced simply by copying the utterances, and we need to select information that is worth repeating from the utterances.

To understand what types of words overlap, Table 4 shows the percentage of all words' parts-of-speech and overlapped words' parts-of-speech in utterances. Since "postpositional particles" and "auxiliary verbs" tend to accompany content words in a Japanese unit called 'bunsetsu', it might be natural that they also appear in repetitions in high percentages.

While we can have at most three repetitions for an utterance in our dataset, we used only one randomly selected repetition for an utterance in the training data. We used all repetitions for an utterance for the evaluation on the validation and test data to consider the diversity of responses.

4 Experiments

4.1 General Setup

Repeat scores were calculated from the training data. SentencePiece (Kudo and Richardson, 2018) was used to segment the dataset into subwords. With WLS, the hyperparameter ϵ was set to 0.1 following a previous study (Szegedy et al., 2016), and γ was tuned to 4 with the validation data, as explained in Appendix A. With RSM, we used $\alpha = 0.2$ and $\beta = 0.2$, following a previous study (Wu et al., 2016), and a beam size of 5. We used MeCab[4] as a tokenizer to identify content words.

PoS	All(%)	Overlap(%)
Postpositional Particle	27.64	39.02
Noun	23.85	32.70
Auxiliary Verb	9.34	13.09
Verb	13.25	10.03
Adjective	1.86	2.52
Adverb	4.57	1.61
Filler	0.37	0.01

Table 4: The ratios of words and overlapped words of different parts-of-speech (PoS) in utterances.

Utterance	Rule-Based
それとやっぱり深さ, 魚のどの辺におるかとかが難しいんですわ. (It's hard to know where fish are and what depths they are at.)	難しいですか. (Hard, is it?)
先生の話をしっかり聞く言う事が大事. (It is important to listen carefully to what a teacher says.)	先生ですか. (The teacher, is it?)
色々ありましたからね, 国際的なニュースもね. (There's been a lot going on, and international news, too.)	ニュースですか. (News, is it?)

Table 5: Examples of utterance and rule-based response.

4.2 Compared Methods

The baseline methods were as follows:

Rule-Based is a rule-based method, with which a response is created with a content word in the speaker's utterance + *"desuka"* ("is it?"). The content word is randomly selected from the utterance. Examples of rule-based responses are given in Table 5. Responses made with Rule-Based always contain a repeated word and have few grammatical errors. However, *"desuka"* cannot cover all situations. *"desuka"* was chosen because 52% of repetitions in our dataset ends with *"desuka"*, and 6.1% of repetitions are a single word + *"desuka"*.

BertSumAbs (Liu and Lapata, 2019) is a model trained with BERT[5] as the encoder and randomly initialized Transformer as the decoder.

T5[6] (Raffel et al., 2019) is a model that was fine-tuned with the repetition dataset.[7]

LS is T5 fine-tuned with LS.

Copy is T5 fine-tuned with the copy mechanism (See et al., 2017). Since the copy mechanism can be considered similar to the repetition model in that it is used to generate the same words as in an input sentence, we used it for comparison.

[5] `https://huggingface.co/cl-tohoku/bert-base-japanese`

[6] `https://huggingface.co/sonoisa/t5-base-japanese`

[7] While another possible model for comparison is GPT-2 (Radford et al.), we did not use it since it was known that T5 is superior to GPT-2 in generation performance (Kale and Rastogi, 2020; Zhao et al., 2020).

	RG-1	RG-2	RG-L	%
Rule-Based	35.26	14.03	35.11	58.24
BertSumAbs	30.73	10.97	29.94	52.51
T5	45.34	22.34	44.59	81.67
LS	45.89	23.08	45.12	81.83
Copy	45.83	23.32	45.07	81.67
WLS	47.88†	24.56	47.14†	85.77†
RSM	46.96	24.66	46.13	84.38†
WLS + RSM	**49.16**†	**26.58**†	**48.28**†	**89.56**†

Table 6: Results of automatic evaluation. % is percentage of outputs containing correct repeated words. Results with † are significantly different from LS, best baseline, using Wilcoxon rank sum test ($p < 0.05$).

	RG-1	RG-2	RG-L	%
w/o lp	46.81	24.52	45.98	83.91
w/o cp	46.93	**24.66**	46.11	84.30
w/o rs	44.97	22.25	44.13	81.28
RSM	**46.96**	**24.66**	**46.13**	**84.38**

Table 7: Ablation study for RSM. lp, cp, and rs were explained in §2.3.

Note that the T5 and BERT were versions pre-trained in Japanese. Our methods are as follows:
WLS is T5 fine-tuned with WLS, as mentioned in §2.2.
RSM is T5 using RSM during beam search, as mentioned in §2.3.
WLS + RSM is T5 fine-tuned with WLS and using RSM during beam search.

4.3 Automatic Evaluation

The evaluation metrics were ROUGE (RG-1, RG-2, RG-L) (Lin, 2004) and the percentage of outputs containing correct repeated words. The correct repeated words are content words repeated in the gold response. The experimental results are listed in Table 6. WLS + RSM obtained the highest scores for all metrics, confirming the effectiveness of both WLS and RSM.

We conducted an ablation study to analyze the results of RSM. The results are listed in Table 7. Since w/o rs received the lowest scores, rs was considered the most effective.

Examples of an input and generated responses from the baseline and our model are shown in Table 8. The proposed model (WLS + RSM) successfully generated a response that was close to the correct response, focusing on "having friends who play Go".

Utterance	昨日は同じ僕らの仲間で囲碁する人いたからね. (Yesterday there were our friends who play Go.)
Gold	仲間で囲碁する人いたんですね. (There were friends who play Go.)
Rule-Based	囲碁ですか. (Go, is it?)
T5	囲碁をしてくれたんですね. (You played Go.)
Ours	仲間内で囲碁する人いたんですか. (There were friends who play Go.)

Table 8: Examples of generated responses from different models.

	Gram	Rel	Cohe	Rep
Rule-Based	2.63	2.49	2.37	2.64
T5	2.82	2.77	2.62	2.79
WLS + RSM	**2.85**†	**2.80**	**2.64**	**2.88**†

Table 9: Results of human evaluation. Results with † are significantly different from T5, the best baseline, using Wilcoxon rank sum test ($p < 0.05$).

4.4 Human Evaluation

We also conducted a human evaluation by comparing three types of response generation methods: Rule-Based, T5, and our model (WLS + RSM). The evaluation measures were grammaticality (Gram), relevance (Rel), coherence (Cohe), and whether repeated words are included (Rep). Two hundred pairs were randomly selected from the test data. The responses were shown to five workers and evaluated on a three-point Likert scale. The response was evaluated with the previous speaker's utterance and one turn before the speaker's utterance as context, meaning the context helps in determining whether the response is an appropriate repetition. The total number of evaluators was 110.

Average scores from the evaluation are listed in Table 9. WLS + RSM outperformed the other methods for all measures, confirming its effectiveness.

5 Conclusion

We focused on repetition generation. Although repetitions play an important role in dialogues, there has been no neural approach for this task to the best of our knowledge. We proposed WLS, which is an improvement upon LS, during fine-tuning and RSM, which is an extended scoring method, during decoding for repetition generation. Through automatic and human evaluations, we confirmed that our model can generate repetitions that contain more appropriate words to repeat than baseline models. For future work, we will take into account synonyms and multiple gold repetition instances to calculate *repeat scores* for improving the diversity of responses. We are also planning to incorporate our repetition model into a general response generation framework.

Acknowledgements

We thank Dr. Koichiro Yoshino of RIKEN for providing the listening dialogue data.

Ethical Statement

Neural generative models have the potential to generate unexpected responses such as violent remarks. As we focused on repetition generation, its model repeats a user's utterance, and so there is little chance of causing unintended responses compared with chit-chat dialogue systems. However, this does not mean that unintended responses will never appear, e.g., when a user's utterance is an unintended expression. Thus, the same consideration must be taken as with other dialogue systems.

Our dataset was created to repeat from utterances in a privacy-secured dataset, and so there is no privacy issue. Since the license of the original dataset is CC BY-NC 4.0, we could use it for this study. We define that the license of our dataset is also CC BY-NC 4.0.

γ	0.0	0.1	0.5	1.0	2.0	3.0	4.0	5.0	10.0
%	82.06	82.06	81.28	83.37	82.21	83.52	85.07	82.90	84.53

Table 10: Percentage of generated responses containing a correct repeated word in the development data when γ was changed. $\epsilon = 0.1$. $\gamma = 0$ indicates LS. The best score was obtained when $\gamma = 4.0$.

A Exploring Hyperparameter γ

We explored the effect of γ on the percentage of responses containing a correct repeated word. The model we used for experiments was the pre-trained model T5, fine-tuned with the training data in §3. We generated repetitions on the development data. The results are listed in Table 10. The best score was recorded when $\gamma = 4.0$. Therefore, we used this value.

B P-values

We now discuss the p-values in the experimental results. To obtain p-values, we conducted the Wilcoxon rank sum test to compare the effectiveness between baseline models and our proposed models. Table 11 shows the p-values for Table 6 from LS. Table 12 shows those for Table 9 from T5.

	RG-1	RG-2	RG-L	%
WLS	0.026	0.159	0.031	0.003
RSM	0.225	0.141	0.294	0.047
WLS + RSM	0.000	0.001	0.001	0.000

Table 11: P-values in Wilcoxon rank sum test between LS and our proposed models in Table 6.

Textless Speech-to-Speech Translation on Real Data

Abstract

We present a textless speech-to-speech translation (S2ST) system that can translate speech from one language into another language and can be built without the need of any text data. Different from existing work in the literature, we tackle the challenge in modeling multi-speaker target speech and train the systems with real-world S2ST data. The key to our approach is a self-supervised unit-based speech normalization technique, which finetunes a pre-trained speech encoder with paired audios from multiple speakers and a single reference speaker to reduce the variations due to accents, while preserving the lexical content. With only 10 minutes of paired data for speech normalization, we obtain on average 3.2 BLEU gain when training the S2ST model on the VoxPopuli S2ST dataset, compared to a baseline trained on unnormalized speech target. We also incorporate automatically mined S2ST data and show an additional 2.0 BLEU gain. To our knowledge, we are the first to establish a textless S2ST technique that can be trained with real-world data and works for multiple language pairs[1].

1 Introduction

Speech-to-speech translation (S2ST) technology can help bridge the communication gap between people speaking different languages. Conventional S2ST systems (Lavie et al., 1997; Nakamura et al., 2006) usually rely on a cascaded approach by first translating speech into text in the target language, either with automatic speech recognition (ASR) followed by machine tranlsation (MT), or an end-to-end speech-to-text translation (S2T) model (Bérard et al., 2016), and then applying text-to-speech (TTS) synthesis to generate speech output.

On the other hand, researchers have started exploring direct S2ST (Jia et al., 2019, 2021; Tjandra et al., 2019; Zhang et al., 2020; Kano et al., 2021; Lee et al., 2021), which aims at translating speech in the source language to speech in the target language without the need of text generation as an intermediate step. However, text transcriptions or phoneme annotations of the speech data is often still needed during model training for multitask learning (Jia et al., 2019; Lee et al., 2021) or for learning a decoder that generates intermediate representations (Jia et al., 2021; Kano et al., 2021) to facilitate the generation of speech output.

More than 40% of the languages in the world are without text writing systems[2], while very limited work exist to tackle the challenge of training direct S2ST systems without the use of any text data (Tjandra et al., 2019; Zhang et al., 2020). Moreover, due to the lack of S2ST training data, previous work on direct S2ST mainly rely on TTS to generate synthetic target speech for model training. The recent release of the large-scale S2ST data from VoxPopuli (Wang et al., 2021c) has opened up the possibility of conducting S2ST research on real data. In addition, Duquenne et al. (2021) have demonstrated the first proof of concept of direct S2S mining without using ASR or MT systems. The approach may potentially mitigate the data scarcity issue, but the authors had not evaluated the usefulness of such data for S2ST frameworks.

Most recently, Lee et al. (2021) have proposed to take advantage of self-supervised discrete representations (Lakhotia et al., 2021), or discrete units, learned from unlabeled speech data as the target for building a direct S2ST model. Experiments conducted with synthetic target speech data have shown significant improvement for translation between unwritten languages. In this work, we extend the *textless* S2ST setup in (Lee et al., 2021), i.e. training an S2ST system without the use of any text or phoneme data, and conduct experiments on real S2ST datasets, including VoxPop-

uli (Wang et al., 2021c) and automatically mined S2ST data (Duquenne et al., 2021). To tackle the challenge of modeling real target speech where there are multiple speakers with various accents, speaking styles and recording conditions, etc., we propose a speech normalization technique that finetunes a self-supervised pre-trained model for speech with a limited amount of parallel multiple-to-single speaker speech. Experiments on four language pairs show that when trained with the normalized target speech obtained from a speech normalizer trained with 10-min parallel data, the performance of a textless S2ST model can be improved by 3.2 BLEU points on average compared with a baseline with un-normalized target speech.

The main contributions of this work include:

- We propose a speech normalization technique based on self-supervised discrete units that can remove the variations in speech from multiple speakers without changing the lexical content. We apply the technique on the target speech of real S2ST data and verify its effectiveness in the context of textless S2ST.

- We empirically demonstrate that with the speech normalization technique, we can further improve a textless S2ST system's performance by augmenting supervised S2ST data with directly mined S2ST data, demonstrating the usefulness of the latter.

- To the best of our knowledge, we are the first to establish a textless S2ST technique that can be trained with real-world data, and the technique works for multiple language pairs.

2 Related work

Direct S2ST Jia et al. (2019, 2021) propose a sequence-to-sequence model with a speech encoder and a spectrogram decoder that directly translates speech from one language into another language without generating text translation first. The model can be trained end-to-end, while phoneme data is required in model training. On the other hand, Tjandra et al. (2019); Zhang et al. (2020) build direct S2ST systems for languages without text writing systems by adopting Vector-Quantized Variational Auto-Encoder (VQ-VAE) (van den Oord et al., 2017) to convert target speech into discrete codes and learn a speech-to-code translation model. Most recently, Lee et al. (2021) propose a direct S2ST system that predicts self-supervised discrete representations of the target speech. The system, when trained without text data, outperforms VQ-VAE-based approach in Zhang et al. (2020). As a result, in this work, we follow the design in Lee et al. (2021) and focus on training direct S2ST systems with real data.

S2ST data VoxPopuli (Wang et al., 2021c) provides 17.3k hours of S2ST data from European parliament plenary sessions and the simultaneous interpretations for more than 200 language directions, the largest to-date. There exists few S2ST corpora as the creation process requires transcribing multilingual speech (Tohyama et al., 2004; Bendazzoli et al., 2005; Zanon Boito et al., 2020) or high-quality ASR models (Wang et al., 2021c). On the other hand, Duquenne et al. (2021) extend distance-based bitext mining (Schwenk et al., 2021) to the audio domain by first learning a joint embedding space for text and audio, where sentences with similar meaning are close, independent of the modality or language. The technique was applied to mine for speech-to-speech alignment in LibriVox[3], creating 1.4k hours of mined S2ST data for six language pairs. The usefulness of the S2ST datasets is often showcased indirectly through a speech retrieval task (Zanon Boito et al., 2020) or human evaluation of the data quality (Duquenne et al., 2021), since existing direct S2ST systems are mostly trained with synthetic target speech (Jia et al., 2019; Tjandra et al., 2019; Zhang et al., 2020; Lee et al., 2021; Jia et al., 2021). In this work, we develop an S2ST system that can be trained on real target speech to mitigate the discrepancy between the S2ST system and corpus development process.

Speech normalization Speech normalization reduces the variation of factors not specified at the input when building TTS systems. One manual approach is to use clean data from a single speaker with minimal non-textual variation (Wang et al., 2017; Shen et al., 2018; Ren et al., 2019; Ito and Johnson, 2017). For automatic methods, silence removal with voice activity detection (VAD) is a fundamental approach (Gibiansky et al., 2017; Hayashi et al., 2020; Wang et al., 2021a). Speech enhancement can remove the acoustic condition variation when building TTS models with noisy data (Botinhao et al., 2016; Adiga et al., 2019). Speaker normalization through voice conversion,

Figure 1: Audio samples from one female ((a), (b)) and one male speaker ((c)) from VoxPopuli (Wang et al., 2021c) for the word "parliament" and the *reduced* units (consecutive duplicate units removed) encoded by the HuBERT model in Section 4.2. Differences in the units with respect to (a) are marked in gray.

which maps target speech into the same speaker as the source speech in the context of S2ST (Jia et al., 2021), can be considered as another speech normalization method. In this work, we propose a novel speech normalization technique based on self-supervised discrete units, which maps speech with diverse variation to units with little non-textual variation.

3 System

We follow Lee et al. (2021) to use HuBERT (Hsu et al., 2021) to discretize target speech and build a sequence-to-sequence speech-to-unit translation (S2UT) model. We describe the proposed speech normalization method and the S2UT system below.

3.1 Self-supervised Unit-based Speech Normalization

HuBERT and discrete units Hidden-unit BERT (HuBERT) (Hsu et al., 2021) takes an iterative process for self-supervised learning for speech. In each iteration, K-means clustering is applied on the model's intermediate representations (or the Mel-frequency cepstral coefficient features for the first iteration) to generate discrete labels for computing a BERT-like (Devlin et al., 2019) loss. After the last iteration, K-means clustering is performed again on the training data, and the learned K cluster centroids are used to transform audio into a sequence of cluster indices as $[z_1, z_2, ..., z_T]$, $z_i \in \{0, 1, ..., K-1\}, \forall 1 \leq i \leq T$, where T is the number of frames. We refer to these units as *orig-unit*.

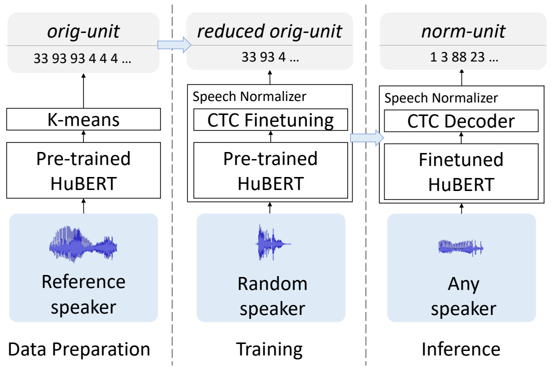

Figure 2: Illustration of the self-supervised unit-based speech normalization process. Left: *orig-unit* sequences extracted for audios from the reference speaker. Middle: CTC finetuning with *reduced orig-unit* from the reference speaker as the target and input audio from different speakers speaking the same content. Right: For inference, we apply the finetuned speech normalizer and obtain *norm-unit* from CTC decoding.

Unit-based speech normalization We observe that *orig-unit* from audios of different speakers speaking the same content can be quite different due to accent and other residual variations such as silence and recording conditions, while there is less variation in *orig-unit* from speech from the same speaker (Figure 1). Following the success of self-supervised pre-training and Connectionist Temporal Classification (CTC) finetuning for ASR (Graves et al., 2006; Baevski et al., 2019), we propose to build a speech normalizer by performing CTC finetuning with a pre-trained speech encoder using multi-speaker speech as input and discrete units from a reference speaker as target.

Figure 2 illustrates the process. First, a pair of audios from a random speaker and a reference speaker speaking the same content is required. Then, we convert the reference speaker speech into *orig-unit* with the pre-trained HuBERT model followed by K-means clustering. We further reduce the full *orig-unit* sequence by removing repeating units (Lakhotia et al., 2021; Lee et al., 2021; Kharitonov et al., 2021; Kreuk et al., 2021). The

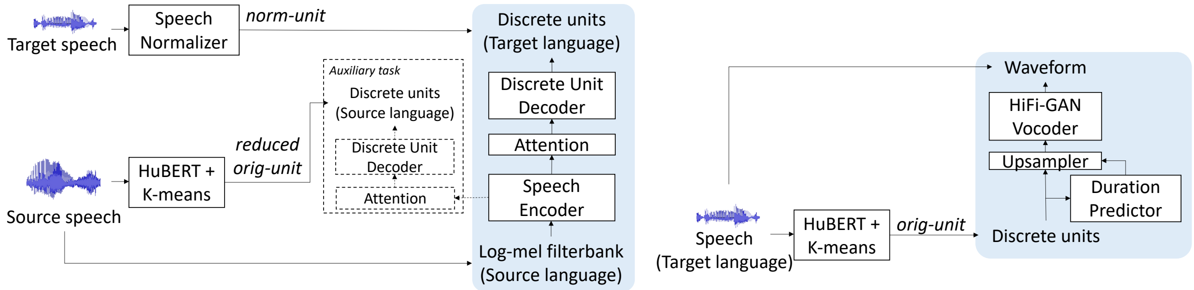

Figure 3: Illustration of the textless S2ST model. Left: The speech-to-unit translation (S2UT) model with an auxiliary task. Right: The unit-based HiFi-GAN vocoder for unit-to-speech conversion. We apply the speech normalizer (Fig. 2) to generate *norm-unit* as the target for S2UT training. The vocoder is trained with *orig-unit* obtained from HuBERT and K-means model. Only the shaded modules are used during inference.

resulting *reduced orig-unit* serves as the target in the CTC finetuning stage with the speech from the random speaker as the input.

The process can be viewed as training an ASR model with the "pseudo text", i.e. units from speech from a single reference speaker. The resulting speech normalizer is a discrete unit extractor that converts the input speech to units with CTC decoding. We refer to these units as *norm-unit*.

3.2 Textless S2ST

Figure 3 shows the main components of the system.

Speech encoder The speech encoder is built by pre-pending a speech downsampling module to a stack of Transformer blocks (Vaswani et al., 2017). The downsampling module consists of two 1D-convolutional layers, each with stride 2 and followed by a gated linear unit activation function, resulting in a downsampling factor of 4 (Synnaeve et al., 2019) for the log-mel filterbank input.

Discrete unit decoder We train the S2UT system with *norm-unit* as the target. The unit decoder is a stack of Transformer blocks as in MT (Vaswani et al., 2017) and is trained with cross-entropy loss with label smoothing. The setup can be viewed as the same as the "*reduced*" strategy in Lee et al. (2021), as the speech normalizer is trained on *reduced orig-unit* sequences.

Auxiliary task We follow the unwritten language setup in Lee et al. (2021) and incorporate an auto-encoding style auxiliary task to help the model converge during training. We add a cross-attention module and a Transformer decoder to an intermediate layer of the speech encoder and use *reduced orig-unit* of the source speech as the target.

Unit-based vocoder The unit-to-speech conversion is done with the discrete unit-based HiFi-GAN vocoder (Kong et al., 2020) proposed in Polyak et al. (2021), enhanced with a duration prediction module (Ren et al., 2020). The vocoder is trained separately from the S2UT model with the combination of the generator-discriminator loss from HiFi-GAN and the mean square error (MSE) of the predicted duration of each unit in logarithmic domain.

4 Experimental Setup

We examine four language pairs: Spanish-English (Es-En), French-English (Fr-En), English-Spanish (En-Es), and English-French (En-Fr). All experiments are conducted using `fairseq` (Ott et al., 2019; Wang et al., 2020a, 2021b)[4].

4.1 Data

Multilingual HuBERT (mHuBERT) As we focus on modeling target speech in En, Es or Fr, we train a single mHuBERT model (Section 4.2) by combining data from three languages. We use the 100k subset of VoxPopuli unlabeled speech (Wang et al., 2021c), which contains 4.5k hrs of data for En, Es and Fr, respectively, totaling 13.5k hours.

Speech normalization We use multi-speaker speech from the VoxPopuli ASR dataset (Wang et al., 2021c) and convert text transcriptions to reference units for training the speech normalizer. The text-to-unit (T2U) conversion is done with a Transformer MT model (Vaswani et al., 2017) trained

	duration	En	Es	Fr
train	10 mins	89	97	86
	1 hr	522	612 (61% CV)	510
	10 hrs	5.1k	6.7k (96% CV)	5.9k (56% CV)
dev	-	1.2k	1.5k	1.5k

Table 1: Number of samples of the data used in training speech normalizers. For Es and Fr, as there is no enough data from VoxPopuli ASR dataset after filtering out the overlap with the S2ST data, we include random samples from the Common Voice 7.0 (CV) (Ardila et al., 2020) dataset (denoted as X%).

on single-speaker TTS data (described later) with characters as input and *reduced orig-unit* as target.

We build training sets of three different sizes (10-min, 1-hr, 10-hr) for each language (Table 1). We remove the audios that exist in the VoxPopuli S2ST dataset (described later) and randomly sample from the Common Voice ASR dataset (Ardila et al., 2020) if there is no enough data. We also randomly sample 1000 audios from Common Voice dev sets and combine with the filtered VoxPopuli ASR dev sets for model development. Though the reference target is created synthetically, we believe that collecting a maximum of 10-hr speech from a single speaker is reasonable as in TTS data collection (Ito and Johnson, 2017; Park and Mulc, 2019).

S2UT We use the VoxPopuli S2ST dataset (Wang et al., 2021c) as the supervised S2ST data for model training. Take Es-En for example. We combine data from Es source speech to En interpretation with Es interpretation to En source speech for training. We evaluate on the dev set and test set from Europarl-ST (Iranzo-Sánchez et al., 2020), as it provides text translation for BLEU score computation and is of the same domain as VoxPopuli. In addition, we investigate incorporating S2ST data automatically mined from LibriVox (Duquenne et al., 2021).[5] Table 2 summarizes the statistics of the data for each language pair.

TTS data We train the unit-based HiFi-GAN vocoder using TTS data, pre-processed with VAD to remove silence at both ends of the audio. No text data is required during vocoder training. In addition, we use the same TTS dataset to train the T2U model for generating reference target units in speech normalizer training and to build the cascaded baselines described in Section 4.3.

4.2 Multilingual HuBERT (mHuBERT)

We build a single mHuBERT model for all three languages using the combination of 13.5k-hr data without applying any language-dependent weights or sampling, since the amount of data is similar between all three languages. A single codebook is used for all three languages, and no language information is required during pre-training. The mHuBERT model is pre-trained for three iterations following Hsu et al. (2021); Lakhotia et al. (2021). In each iteration, model weights are randomly initialized and optimized for 400k steps. We find that $K = 1000$ with features from the 11-th layer of the third-iteration mHuBERT model work the best for our experiments.

4.3 Baselines

S2UT with *reduced orig-unit* First, we consider a basic setup by training the S2UT system using *reduced orig-unit* extracted from the target multi-speaker speech with mHuBERT (Lee et al., 2021). For the second baseline, we concatenate a d-vector speaker embedding (Variani et al., 2014) to each frame of the speech encoder output to incorporate target speaker information. A linear layer is applied to map the concatenated feature vectors to the same dimension as the original encoder output. The 256-dimensional speaker embedding, which remains fixed during the S2UT model training, is extracted from a speaker verification model pre-trained on VoxCeleb2 (Chung et al., 2018). During inference, we use the speaker embedding averaged from all audios from the TTS dataset of the target language.

S2T+TTS We transcribe all the S2ST data with open-sourced ASR models (Section 4.4) and train a S2T+TTS system for each language pair. We build 2000 unigram subword units (Kudo, 2018) from the ASR decoded text as the target. For TTS, we explore two approaches: (1) Transformer TTS (Li et al., 2019), and (2) text-to-unit (T2U). The Transformer TTS model has a text encoder, a spectrogram decoder and a HiFi-GAN vocoder (Kong et al., 2020). The T2U model is the same model used in preparing reference units for speech normalizer training (Section 4.1), and we apply the same unit-based vocoder for the S2UT model for unit-to-speech conversion. Both Transformer TTS and T2U are trained with characters as input.

Table 3: Duration of the TTS datasets after VAD.

4.4 Evaluation

To evaluate translation quality, we first use open-sourced ASR models[6] to decode all systems' speech output. As the ASR output is in lowercase and without digits and punctuation except apostrophes, we normalize the reference text by mapping numbers to spoken forms and removing punctuation before computing BLEU using SACREBLEU (Post, 2018). To evaluate the naturalness of the speech output, we collect mean opinion scores (MOS) from human listening tests. We randomly sample 200 utterances for each system, and each sample is rated by 5 raters on a scale of 1 (the worst) to 5 (the best).

4.5 Textless S2ST training

Speech normalization We finetune the mHuBERT model for En, Es and Fr, respectively, resulting in three language-dependent speech normalizers. We perform CTC finetuning for 25k updates with the Transformer parameters fixed for the first 10k steps. We use Adam with $\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 10^{-8}$, and 8k warm-up steps and then exponentially decay the learning rate. We tune the learning rate and masking probabilities on the dev sets based on unit error rate (UER) between the model prediction and the reference target units.

S2UT We follow the same model architecture and training procedure in Lee et al. (2021), except having a larger speech encoder and unit decoder with embedding size 512 and 8 attention heads. We train the models for 600k steps for VoxPopuli S2ST data, and 800k steps for the combination of VoxPopuli and mined data, and use Adam with $\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 10^{-8}$, and inverse square root learning rate decay schedule with 10k warmup steps. We use label smoothing of 0.2 and tune the learning rate and dropout on the dev set. The model with the best BLEU on the dev set is used for evaluation. All S2UT systems including the baselines are trained with an auxiliary task weight of 8.0.

Unit-based vocoder We train one vocoder for each language, respectively. All vocoders are trained with *orig-unit* sequences as input, since they contain the duration information of natural speech for each unit. We follow the training procedure in Polyak et al. (2021) and train for 500k updates with the weight on the MSE loss set to 1.0. The vocoder is used for generating speech from either *orig-unit* or *norm-unit*, as they originate from the same K-means clustering process.

5 Results

5.1 Textless S2ST

S2ST with supervised data Table 4 summarizes the results from systems trained with VoxPopuli S2ST data. We also list the results from applying TTS on the ground truth reference text (8, 9) to demonstrate the impact from ASR errors and potentially low quality speech on the BLEU score.

First, compared with the basic setup, the baseline with target speaker embedding can give a 1.2-3 BLEU improvement on three language pairs (1 vs. 2), implying that there exists variations in *orig-unit* sequences which are hard to model without extra information from the target speech signals.

Table 5: BLEU scores (↑) from systems trained in a single run with the combination of VoxPopuli S2ST data (VP) (Wang et al., 2021c) and mined S2ST data (Duquenne et al., 2021) and evaluated on Europarl-ST (EP) (Iranzo-Sánchez et al., 2020) and CoVoST 2 (CVST) (Wang et al., 2020b) test sets. The S2T model in Wang et al. (2021c) is trained on more than 500 hrs of S2T data. The best results from S2UT with VP+mined data are highlighted in bold. (tgt spkemb: target speaker embedding, SN: speech normalization, gt: ground truth, tf: Transformer)

However, with only 10 minutes of paired multiple-to-single speaker speech data, we obtain *norm-unit* that improves S2UT model performance by 1.5 BLEU on average (2 vs. 3). The translation quality improves as we increase the amount of parallel data for training the speech normalizer. In the end, with 10 hours of finetuning data, we obtain an average 4.9 BLEU gain from the four language pairs compared to the basic setup (1 vs. 5).

On the other hand, compared with S2T+TTS systems that uses extra ASR models for converting speech to text for training the translation model (6, 7), our best textless S2ST systems (5) can perform similarly to text-based systems without the need of human annotations for building the ASR models.

We see that the MOS of S2UT systems trained with *orig-unit* is on average 0.85 lower than that of systems trained with *norm-unit* (1 vs. 5). We notice that the former often produces stuttering in the output speech, a potential cause to lower MOS. While worse audio quality may affect ASR-based evaluation and lead to lower BLEU, we verify that this was not the case as the ASR models could still capture the content. We also see that the proposed textless S2ST system can produce audios with similar naturalness as Transformer TTS models (5 vs. 6).

S2ST with supervised data and mined data Next, we add the mined S2ST data for model training, and the results are summarized in Table 5. We apply the speech normalizer trained with 1-hr data, as it provides similar translation performance as a speech normalizer trained with 10-hr data in VoxPopuli-only experiments (4 vs. 5 in Table 4).

On the Europarl-ST test set, we see consistent trend across the S2UT models trained with *norm-unit* and the two baselines with *orig-unit*, where the proposed approach gives on average 3.9 BLEU improvement compared to the basic setup (10 vs. 12), indicating that the speech normalizer trained on VoxPopuli and Common Voice data can also be applied to audios from different domains, e.g. LibriVox, where the mined data is collected. The addition of mined data with the proposed speech normalization technique achieves an average of 2.0 BLEU gain over four language directions (4 vs. 12).

We also examine model performance on the CoVoST 2 test set (Wang et al., 2020b) and see even larger improvements brought by mined data (10, 11, 12 vs. 4). One possible reason for this is that LibriVox is more similar to the domain of CoVoST 2 than that of Europarl-ST. With target speaker embedding, mined data improves S2ST by 7.1 BLEU on average (4 vs. 11). S2UT with *norm-unit* does not perform as well, and one explanation is that we select the best model based on the Europarl-ST dev set during model training.

Compared with S2T+TTS systems trained with text obtained from ASR, there is an average of 0.6 BLEU gap from our proposed system on Europarl-ST test sets (12 vs. 14). As the En ASR model was trained on Libripeech (Panayotov et al., 2015), it can decode high quality text output for the mined data. We also list results from the S2T systems from Wang et al. (2021c)[7] (15, 16), which shows the impact of having oracle text and in-domain training data and serves as an upper bound for the textless S2ST system performance.

5.2 Analysis on the speech normalizer

We analyze *norm-unit* to understand how the speech normalization process helps improve S2UT performance. First, to verify that the process preserves the lexical content, we perform a speech resynthesis study as in Polyak et al. (2021). We use the VoxPopuli ASR test sets, run the unit-based vocoder with different versions of discrete units extracted from the audio as input, and compute word error rate (WER) of the audio output. In addition to comparing between *norm-unit* and *reduced orig-unit*, we list the WER from the original audio to demonstrate the quality of the ASR models and the gap caused by the unit-based vocoder.

We see from Table 6 that *norm-unit* from a speech normalizer finetuned on 1-hr data achieves similar WER as *orig-unit*, indicating that the normalization process does not change the content of the speech. In addition, we observe that *norm-unit* sequences are on average 15% shorter than *reduced orig-unit* sequences. We find that this is mainly due to the fact that the speech normalizer does not output units for the long silence in the audio, while *reduced orig-unit* encodes non-speech segments such as silence and background noises. Therefore, *norm-unit* is a shorter and cleaner target for training S2UT models.

WER (↓)	En	Es	Fr
original audio	14.2	15.5	18.5
reduced orig-unit	22.4	22.7	24.1
norm-unit (10-min)	23.5	25.3	31.7
norm-unit (1-hr)	21.2	20.5	24.6
norm-unit (10-hr)	22.0	25.3	24.2

Table 6: Speech resynthesis results on the VoxPopuli ASR test set.

UER (↓)	En	Es	Fr
reduced orig-unit	74.4	70.6	73.5
norm-unit (1-hr)	48.2	31.6	46.4

Table 7: Unit error rate (UER) between units extracted from 400 pairs of audios from the Common Voice dataset.

Next, to examine that the speech normalizer reduces variations in speech across speakers, we sample 400 pairs of audios from Common Voice (Ardila et al., 2020) for En, Es and Fr, respectively. Each pair contains two speakers reading the same text prompt. Table 7 shows the unit error rate (UER) between the unit sequences extracted from the paired audios. We see that *norm-unit* has UER that is on average 58% of the UER of *reduced orig-unit*, showing that *norm-unit* has less variations across speakers.

5.3 Analysis of mined data

Each pair of aligned speech in the mined data has an associated semantic similarity score. In experiments above, we set the score threshold as 1.06, and use all mined data with scores above it. Given

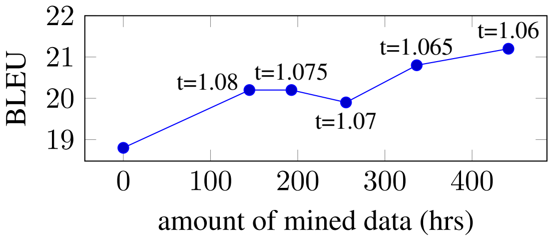

Figure 4: BLEU scores (↑) on Europarl-ST Es-En test set from models trained with VoxPopuli and mined data filtered at different thresholds (t) for the similarity score.

---

[7] Models downloaded from `https://github.com/facebookresearch/voxpopuli/`.

the trade-off between the quality and quantity of mined data, we analyze how the S2ST performance changes with the threshold set in mined data selection. Figure 4 demonstrates BLEU scores on Europarl-ST Es-En test set from S2UT systems trained with 1-hr *norm-unit*. The mined data is useful at different thresholds given its gains over the model trained without mined data. As we increase the threshold from 1.06 to 1.07, the performance drops due to less training data.

6 Conclusion

We present a textless S2ST system that can be trained with real target speech data. The key to the success is a self-supervised unit-based speech normalization process, which reduces variations in the multi-speaker target speech while retaining the lexical content. To achieve this, we take advantage of self-supervised discrete representations of a reference speaker speech and perform CTC finetuning with a pre-trained speech encoder. The speech normalizer can be trained with one hour of parallel speech data without the need of any human annotations and works for speech in different recording conditions and in different languages. We conduct experiments on the VoxPopuli S2ST dataset and the mined speech data to empirically demonstrate its usefulness in improving S2ST system translation quality for the first time. In the future, we plan to investigate more textless approaches to improve model performance such as self-supervised pretraining. All the experiments and ASR evaluation are conducted with public datasets or open-sourced models.

A mHuBERT Training details

Table 8 lists the details for the three iterations of mHuBERT training.

iteration	target features	K-means
1	MFCC	100
2	6-th layer from the first iteration	500
3	9-th layer from the second iteration	500

Table 8: Setup for the target labels used in mHuBERT training.

B Unit-based Vocoder

Table 9 shows the resynthesis performance of the unit-based vocoder of each language. The WER on the original audio indicates the quality of the open-sourced ASR model we use for evaluation. The WER difference between original audio and *orig-unit* shows the quality of the vocoder, and the difference between *orig-unit* and *reduced orig-unit* shows the further impact brought by the duration prediction module.

WER (↓)	En	Es	Fr
original audio	2.0	8.4	24.0
orig-unit	2.8	12.0	29.3
reduced orig-unit	3.4	11.9	31.3

Table 9: WER on the TTS dev sets (LJSpeech for En, and CSS10 for Es and Fr) of the audios resynthesized from units.

C Text-to-Unit (T2U)

Table 10 lists the WER of the audios generated by the T2U model, which is used in generating the reference target units for speech normalizer training. As the T2U model is trained with *reduced* unit sequences as the target, during synthesis, we apply the unit-based vocoder with duration prediction. We can see that T2U with a unit-based vocoder can produce high quality audio and can serve as another option of TTS.

WER (↓)	En	Es	Fr
original audio	2.0	8.4	24.0
T2U	4.2	9.1	24.4

Table 10: WER on the TTS dev sets (LJSpeech for En, and CSS10 for Es and Fr).

D Hyper-parameters

Table 11 lists the best hyper-parameters for training the speech normalizers for the three languages and three data setups, respectively. All models are trained on 8 GPUs with a batch size of 100-second (maximum total input audio length).

Table 12 lists the best learning rate tuned on the dev set for the S2UT experiments listed in Table 4 and Table 5. All models are trained on 8 GPUs with a total batch size of 160k tokens and dropout of 0.3, except for Es-En experiment ID 1 which uses 0.1.

language	duration	learning rate	mask prob	mask channel prob
En	10-min	0.00003	0.75	0.75
En	1-hr	0.00005	0.5	0.5
En	10-hr	0.0001	0.5	0.75
Es	10-min	0.00003	0.5	0.75
Es	1-hr	0.00003	0.5	0.25
Es	10-hr	0.00005	0.5	0.5
Fr	10-min	0.00003	0.5	0.5
Fr	1-hr	0.00005	0.5	0.25
Fr	10-hr	0.00005	0.5	0.25

Table 11: Hyper-parameters for training the speech normalizers.

ID	Es-En	Fr-En	En-Es	En-Fr
1	0.0005	0.0003	0.0003	0.0003
2	0.0003	0.0003	0.0003	0.0003

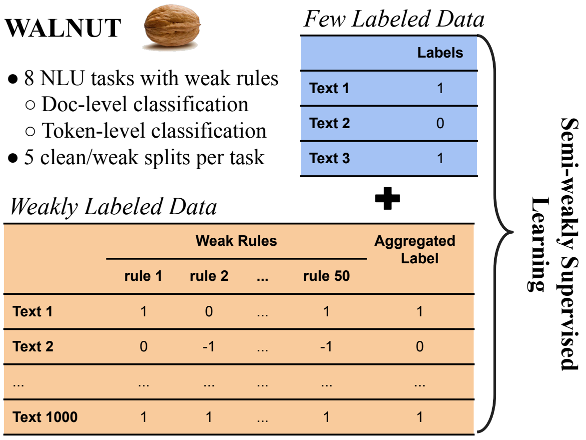
Abstract

Building machine learning models for natural language understanding (NLU) tasks relies heavily on labeled data. Weak supervision has been proven valuable when large amount of labeled data is unavailable or expensive to obtain. Existing works studying weak supervision for NLU either mostly focus on a specific task or simulate weak supervision signals from ground-truth labels. It is thus hard to compare different approaches and evaluate the benefit of weak supervision without access to a unified and systematic benchmark with diverse tasks and real-world weak labeling rules. In this paper, we propose such a benchmark, named WALNUT[1], to advocate and facilitate research on weak supervision for NLU. WALNUT consists of NLU tasks with different types, including document-level and token-level prediction tasks. WALNUT is the first semi-weakly supervised learning benchmark for NLU, where each task contains weak labels generated by multiple real-world weak sources, together with a small set of clean labels. We conduct baseline evaluations on WALNUT to systematically evaluate the effectiveness of various weak supervision methods and model architectures. Our results demonstrate the benefit of weak supervision for low-resource NLU tasks and highlight interesting patterns across tasks. We expect WALNUT to stimulate further research on methodologies to leverage weak supervision more effectively. The benchmark and code for baselines are available at `aka.ms/walnut_benchmark`.

1 Introduction

To tackle natural language understanding (NLU) tasks via supervised learning, high-quality labeled examples are crucial. Recent advances on large pre-trained language models (Peters et al., 2018; Devlin et al., 2018; Radford et al., 2019) lead to impressive gains on NLU benchmarks, including GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019), at the assumption that large amount of labeled examples are available. For many real-world applications, however, it is expensive and time-consuming to manually obtain large-scale high-quality labels, while it is relatively easier to obtain auxiliary supervision signals, or *weak supervision*, as a viable source to boost model performance without expensive data annotation process.



- 8 NLU tasks with weak rules
  - Doc-level classification
  - Token-level classification
- 5 clean/weak splits per task

Few Labeled Data

	Labels
Text 1	1

Text 1000	1	1	...	1	1

Figure 1: WALNUT, a benchmark with 8 NLU tasks with real-world weak labeling rules. Each task in WALNUT comes with few labeled data and weakly labeled data for semi-weakly supervised learning.

Learning from weak supervision for NLU tasks is attracting increasing attention. Various types of weak supervision have been considered, such as knowledge bases (Mintz et al., 2009; Xu et al., 2013), keywords (Karamanolakis et al., 2019; Ren et al., 2020), regular expression patterns (Augenstein et al., 2016), and other metadata such as user interactions in social media (Shu et al., 2017). Also, inspired by recent advances from semi-supervised learning, *semi-weakly supervised learning* methods which leverage both a small set of clean labels and a larger set of weak supervision (Papandreou et al., 2015; Hendrycks et al., 2018; Shu et al., 2019; Mazzetto et al., 2021; Karamanolakis

[1] WALNUT: Semi-**W**e**A**kly supervised **L**earning for **N**atural language **U**nderstanding **T**estbed

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 873 - 899
July 10-15, 2022 ©2022 Association for Computational Linguistics

et al., 2021; Maheshwari et al., 2021; Zheng et al., 2021) are emerging to further boost task performance. However, a unified and systematic evaluation benchmark supporting *both weakly and semi-weakly* supervised learning for NLU tasks is rather limited. On the one hand, many existing works only study specific NLU tasks with weak supervision, thus evaluations of proposed techniques leveraging weak supervision on a small set of tasks do not necessarily generalized onto other NLU tasks. On the other hand, some works rely on simulated weak supervision, such as weak labels corrupted from ground-truth labels (Hendrycks et al., 2018), while real-world weak supervision signals can be far more complex than simulated ones. Furthermore, existing weakly and semi-weakly supervised approaches are evaluated on different data with different metrics and weak supervision sources, making it difficult to understand and compare.

To better advocate and facilitate research on leveraging weak supervision for NLU, in this paper we propose WALNUT (Figure 1), a semi-weakly supervised learning benchmark of NLU tasks with real-world weak supervision signals. Following the tradition of existing benchmarks (e.g., GLUE), we propose to cover different types of NLU tasks and domains, including document-level classification tasks (e.g., sentiment analysis on online reviews, fake news detection on news articles), and token-level classification tasks (e.g., named entity recognition in news and biomedical documents). WALNUT provides few labeled and many weakly labeled examples (Figure 1) and encourages a consistent and robust evaluation of different techniques, as we will describe in Section 3.

In addition to the proposed benchmark, in Section 4.2 we shed light on the benefit of weak supervision for NLU tasks in a collective manner, by evaluating several representative weak and semi-weak supervision methods for and several base models of various sizes (e.g., BiLSTM, BERT, RoBERTa), leading to more than 2,000 groups of experiments. Our large-scale analysis demonstrates that weak supervision is valuable for low-resource NLU tasks and that there is large room for performance improvement, thus motivating future research. Also, by computing the average performance across tasks and model architectures, we show surprising new findings. First, simple techniques for aggregating multiple weak labels (such as unweighted majority voting) achieve better performance than more complex weak supervision paradigms. Second, weak supervision has smaller benefit in larger base models such as RoBERTa, because larger pre-trained models can already achieve impressively high performance using just a few clean labeled data and no weakly labeled data at all. We identify several more challenges on leveraging weak supervision for NLU tasks and shed light on possible future work based on WALNUT.

The main contributions of this paper are: (1) We propose a new benchmark on semi-weakly supervised learning for NLU, which covers eight established annotated datasets and various text genres, dataset sizes, and degrees of task difficulty; (2) We conduct an exploratory analysis from different perspectives to demonstrate and analyze the results for several major existing weak supervision approaches across tasks; and (3) We discuss the benefits and provide insights for potential weak supervision studies for representative NLU tasks.

2 Related Work

2.1 Weak Supervision for NLU

Document-level classification Existing works on weakly supervised learning for document-level classification attempt to correct the weak labels by incorporating a loss correction mechanism for text classification (Sukhbaatar et al., 2014; Patrini et al., 2017). Other works further assume access to a small set of clean labeled examples (Hendrycks et al., 2018; Ren et al., 2018; Varma and Ré, 2018; Shu et al., 2020b). Recent works also consider the scenario where weak signals are available from multiple sources (Ratner et al., 2017; Meng et al., 2018; Ren et al., 2020) to exploit the redundancy as well as the consistency in the labeling information. Despite the recent progress on weak supervision for text classification, there is no agreed upon benchmark that can guide future directions and development of NLU tasks in semi-weakly supervised setting.

Token-level classification Weak supervision has also been studied for token-level classification (sequence tagging) tasks, focusing on Named Entity Recognition (NER). One of the most common approaches is distant supervision (Mintz et al., 2009), which uses knowledge bases to heuristically annotate training data. Besides distant supervision, several weak supervision approaches have recently addressed NER by introducing various types of labeling rules, for example based on keywords, lexicons, and regular expressions (Fries et al., 2017; Ratner et al., 2017; Shang et al., 2018; Safranchik et al., 2020; Lison et al., 2020; Li et al., 2021). WALNUT integrates existing weak rules into a unified representation and evaluation format.

2.2 NLU Benchmarks

Accompanying the emerging of large pre-trained language models, NLU benchmarks has been a focus for NLP research, including GLUE (Wang et al., 2018) and SuperGLUE (Wang et al., 2019). On such benchmarks, the major focus is put on obtaining best possible performance (He et al., 2020) under the full training setting, which assumes that a large quantity of manually labeled examples are available for all tasks. Few-shot NLU benchmarks exist (Schick and Schütze, 2021; Xu et al., 2021; Ye et al., 2021; Mukherjee et al., 2021), however these do not contain weak supervision. Though research in weak supervision in NLU has gained significant interest (Hendrycks et al., 2018; Shu et al., 2019; Zheng et al., 2021), most of these work either focus on a small set of tasks or simulate weak supervision signals from ground-truth labels, hindering its generalization ability to real-world NLU tasks. The lack of a unified test bed covering different NLU task types and data domains motivates us to construct such a benchmark to better understand and leverage semi-weakly supervised learning for NLU in this paper.

Different from existing work based on crowdsourcing (Hovy et al., 2013; Gokhale et al., 2014) to obtain noisy labels, we focus specifically on the *semi-weakly supervised* learning setting, where we collect tasks with weak labels obtained from human-written labeling rules. (Zhang et al., 2021) is concurrent work that also features weak supervision for various (not necessarily text-based) tasks and assumes a purely weakly supervised setting, i.e., no clean labeled data is available. In contrast, WALNUT focuses on NLU tasks under a more-realistic semi-weakly supervised setting and, as we show in Section 3, a small amount of clean labeled data plays an important role in determining the benefit of weak supervision for a target task.

3 WALNUT

3.1 Benchmark Construction Principles

We first describe the design principles guiding the benchmark construction.

Task Selection Criterion We aim to create a testbed which covers a broad range of NLU tasks where *real-world weak supervision signals are available*. To this end, WALNUT includes eight English text understanding tasks from diverse domains, ranging from news articles, movie reviews, merchandise reviews, biomedical corpus, wikipedia documents, to tweets. The eight tasks are categorized evenly into two types, namely document classification and token classification (sequence labeling). It's worth noting that *we didn't create any labeling rules ourselves to avoid bias, but rather opted with labeling rules which already exist and are extensively studied by previous research.* Therefore, WALNUT does not include other NLU tasks, such as natural language inference and question answering, as we are not aware of previous research with human labeling rules for these tasks.

Semi-weakly Supervised Learning Setting While many previous works studied weak supervision in a purely weakly supervised setting, recent advances in few-shot and semi-supervised learning suggest that a small set of cleanly labeled examples together with unlabeled examples greatly helps boosting the task performance. Though large scale labeled examples for a task is difficult to collect, we acknowledge that it's rather practical to collect a small set of labeled examples. In addition, recent methods leveraging weak supervision also demonstrate greater gains of combining a small set of labeled examples with large weakly labeled examples (Hendrycks et al., 2018; Shu et al., 2019; Zheng et al., 2021). Therefore, WALNUT is designed to emphasize the semi-weakly supervised learning setting. Specifically, each dataset contains both a small number of clean labeled instances and a large number of weakly-labeled instances. Each weakly-labeled instance comes with multiple weak labels (assigned by multiple rules) and a single aggregated weak label derived from weak rules. *Note that this way WALNUT can be naturally used to support the conventional weakly supervised setting by ignoring the provided clean labels.*

Consistent and Robust Evaluation To address discrepancies in evaluation protocols from existing research on weak supervision and to better account for the small set of clean examples per task, WALNUT is constructed to promote systematic and robust evaluations across all eight tasks. Specif-

Table 1: Statistics of the eight document- and token-level tasks in WALNUT. See Section 3.2 for details.

Dataset	AGNews	IMDB	Yelp	GossipCop	CoNLL	NCBI	WikiGold	LaptopReview
Label granularity	doc.	doc.	doc.	doc.	token	token	token	token
Task	topic	sentiment	sentiment	fake	NER	NER	NER	NER

# Weak rules	9	8	8	3	50	12	16	12

ically, for each task, we first determine the number of clean examples to sample with pilot experiments (with the rest treated as weakly labeled examples by applying the corresponding weak labeling rules), such that the weakly supervised examples can be still helpful with the small clean examples present (typically 20-50 per class; see Sec. 3.3 for details); second, to consider sampling uncertainty, we repeat the sampling process for the desired number of clean examples 5 times and provide all 5 splits in WALNUT. Methods on WALNUT are expected to be using all 5 pre-computed splits and reporting the mean and variance of its performance.

To summarize, WALNUT can facilitate research on weakly- and semi-weakly supervised learning by offering the following:

- Eight NLU tasks from diverse domains;
- For each task, five pairs of clean and weakly labeled samples for robust evaluation;
- For each individual weakly labeled example, all weak labels from multiple rules and a single aggregated weak label.

3.2 Task Categories

Here, we describe the eight tasks in WALNUT (Table 1), grouped into four document-level classification tasks (Section 3.2.1) and four token-level classification tasks (Section 3.2.2).

3.2.1 Document-level Classification

The goal of document-level classification tasks is to classify a sequence of tokens $x_1, \ldots, x_N$ to a class $c \in C$, where C is a pre-defined set of classes. We consider binary and multi-class classification problems from different application domains such as sentiment classification (Zhang et al., 2015), fake news detection (Shu et al., 2020c), and topic classification (Zhang et al., 2015). Concretely, we include the following widely-used document-level text classification datasets: AGNews (Zhang et al., 2015), Yelp (Zhang et al., 2015), IMDB (Maas et al., 2011) and GossipCop (Shu et al., 2020a).

For Yelp, IMDB, and AGNews, the weak rules are derived from the text using keyword-based heuristics, third-party tools as detailed in (Ren et al., 2020). For GossipCop, the weak labeling rules are derived from social context information accompanying the news articles, including related users' social engagements on the news items (e.g., user comments in Twitter). For example, a weak labeling rule for fake news can be "If a news piece has a standard deviation of user sentiment scores greater than a threshold, then the news is weakly labeled as fake news. " (Shu et al., 2020c).

3.2.2 Token-level Classification

The goal of token-level classification tasks is to classify a sequence of tokens $x_1, \ldots, x_N$ to a sequence of tags $y_1, \ldots, y_N \in C'$, where C' is a pre-defined set of tag classes (e.g., person or organization). As one of the most common token-level classification tasks, Named Entity Recognition (NER) deals with recognizing categories of named entities (e.g., person, organization, location) and is important in several NLP pipelines, including information extraction and question answering.

We include in WALNUT the following four NER datasets from different domains, for which weak rules are available: CoNLL (Sang and De Meulder, 2003), the NCBI Disease corpus (Doğan et al., 2014), WikiGold (Balasuriya et al., 2009) and the LaptopReview corpus (Pontiki et al., 2016) from the SemEval 2014 Challenge. For the CoNLL and WikiGold dataset, we use weak rules provided by (Lison et al., 2020). For the NCBI and LaptopReview dataset, we use weak rules provided by (Safranchik et al., 2020).

(e) CoNLL (f) NCBI (g) WikiGold (h) LaptopReview

Figure 2: F1 score by varying (in the x-axis) the number of clean instances per class considered in the clean training set (D_C). The importance of weak supervision is more evident for settings with smaller numbers of instances, where the gap in performance between the "Clean" approach and "Clean+Weak" approach is larger. For a robust evaluation across tasks, WALNUT provides five clean/weak splits per task. See Section 3.3 for details.

3.3 Dataset Pre-Processing

To construct a semi-weakly supervised learning setting, we split the training dataset for each task into a small subset with clean labels (D_C) and a large subset with weak labels (D_W). For robust evaluation, we create five different clean/weak train splits as we noticed that the model performances may vary with different clean train instances. The validation/test sets are always the same across splits.

Because of different dataset characteristics (e.g., differences in number of classes, difficulty), we choose the size for D_C per dataset via pilot studies. (After having selected the instances for the D_C, we consider the remaining instances as part of the D_W split.) We defined the size of D_C such that we demonstrate the benefits of weak supervision and at the same time leave substantial room for improvement in future research. To this end, we compare the performances of the same base classification model (e.g., BiLSTM), trained using only D_C ("Clean" approach) v.s. using both D_C and D_W ("Clean+Weak" approach). As shown in Figure 2, for each dataset, we choose a small size of D_C, such that the "Clean+Weak" approach has a substantially higher F1 score than the "Clean" approach and at the same time the "Clean" approach has no trivial F1 score.

The statistics of the pre-processed datasets included in WALNUT are shown in Table 1.

4 Baseline Evaluation in WALNUT

In this section, we describe the baselines and evaluation procedure (Section 4.1), and discuss evaluation results in WALNUT (Section 4.2). Our results highlight the value of weak supervision, important differences across different baselines, and the potential utility of WALNUT for future research on weak supervision.

4.1 Baselines and Evaluation Procedure

We evaluate several baseline approaches in WALNUT by considering different base models (text encoders) and different (semi-)weakly supervised learning methods to train the base model.

Encoder Models To encode input text, we experiment with various text encoders, ranging from shallow LSTMs to large pre-trained transformer-based encoders (Vaswani et al., 2017). In particular, we consider a series of models with increasing model size: Bi-directional LSTM with Glove embeddings (Pennington et al., 2014), DistilBERT (Sanh et al., 2019), BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), BERT-large, and RoBERTa-large. For each text encoder, a classification head is placed on top of the encoder to perform the task. For more details on the base model configurations see Appendix A.1.

Learning Methods Given the semi-weakly supervised setting in WALNUT, we evaluate eight supervision approaches in the following categories:

- *Learning from clean labeled examples only.* The model is trained on only the small amount of available clean examples D_C, a naive baseline method leveraging no weak supervision, which we denote as **C**.

- *Learning from weakly labeled examples only.* The model is trained on all weakly labeled examples D_W. To produce a single weak label from the multiple labeling rules for training, we aggregate the rules via two methods: majority voting (denoted by **W**) and Snorkel (Ratner et al., 2017) (denoted by **Snorkel**).

- *Learning from both clean and weakly labeled examples.* The model is trained with both D_C and D_W in a weakly-supervised setting. The first two baselines in this category is simply concatenating D_C and the aggregated weak labels (from either **W** and **Snorkel**), and the model is trained on the combination. We denote these two as **C+W** and **C+Snorkel**, respectively. We also test three recent semi-weakly supervised learning methods which proposed better ways to leverage both D_C and D_W: **GLC** which is a loss correction approach (Hendrycks et al., 2018), **MetaWN** which is a meta-learning approach to learn the importance of weakly labeled examples (Shu et al., 2019; Ren et al., 2018) and **MLC**, a meta-learning approach to learn to correct the weak labels (Zheng et al., 2021).

To establish an estimate of the ceiling performance on WALNUT, for each task we also train with all clean training examples in the original dataset (denoted by **Full Clean**).

Experimental Procedure For a robust evaluation, we repeat each experiment five times on the five splits of D_C and D_W (clean and weak examples for each task; see Section 3.3), and report the average scores and the standard deviation across the five runs. In WALNUT, we report the average micro-average F1 score on the test set.[2] Datasets and code for WALNUT are publicly available at `aka.ms/walnut_benchmark`.

4.2 Experimental Results and Analysis

Table 2 shows the main evaluation results on WALNUT. Rows correspond to supervision methods for the base model, columns correspond to tasks, and each block corresponds to a different base model. Unless explicitly mentioned, in the rest of this section we will compare approaches based on their average performance across tasks (rightmost column in Table 2).

As expected, training with Full Clean achieves the highest F1 score, corresponding to the high-resource setting where all clean labeled data are available. Such method is not directly comparable to the rest of the methods but serves as an estimate of the ceiling performance for WALNUT. Training with only limited clean examples achieves the lowest overall F1 score: in the low-resource setting, which is the main focus in WALNUT, using just the available clean subset (D_C) is not effective.

Weak supervision is valuable for low-resource NLU. "W" and "Snorkel" achieve better F1 scores than "C" for many base models: even using only weakly-labeled data in D_W is more effective than using just D_C, thus demonstrating that simple weak supervision approaches can be useful in the low-resource setting. Approaches such as "C+W" and "C+Snorkel" lead to further improvements compared to "C" and "Snorkel", thus highlighting that even simple approaches for integrating clean and weak labeled data (here by concatenating D_C and D_W) are more effective than considering each separately.

There is no clear winner in WALNUT. Our results in Table 4.2 indicate that the performance of weak supervision techniques varies substantially across tasks. Therefore, it is important to evaluate such techniques in a diverse set of tasks to achieve a fair comparison and more complete picture of their performance. The performance of various techniques also varies across different splits (See Table 14 in Appendix for variances of all experiments). Interestingly, "C+W" and "C+Snorkel" sometimes perform better than more complicated approaches, such as GLC, MetaWN and MLC.

Larger base models achieve better overall performance. We further aggregate statistics across tasks, methods, and base models in Table 3. The bottom row reports the average performance across methods for each base model and leads to a consistent ranking in F1 score among base models: BiLSTM $\leq$ DistilBERT $\leq$ BERT-base $\leq$ RoBERTa-base. Observing higher scores for larger transformer models such as RoBERTa agrees with previous observations (Brown et al., 2020). Interestingly, switching from BERT-base to BERT-large (and from RoBERTa-base to RoBERTa-large) in base model architecture leads to marginal improvement, suggesting the need to explore more effective learning methods leveraging weak supervision.

---

[2] For token-level F1, we use the connleval implementation: `https://huggingface.co/metrics/seqeval`

Table 2: Main results on WALNUT with F1 score (in %) on all tasks. The rightmost column reports the average F1 score across all tasks. (MLC is not shown for BERT-large and RoBERTa-large due to OOM.)

Table 4: Overall performance gain and gap of all weak supervision methods (Weak Sup, by averaging performance of W, Snorkel, C+W, C+Snorkel, GLC, MetaWN and MLC) against no weak supervision (C) and full clean training. Note that RoBERTa-large in included here, as the standard deviation of its performance with different splits on tasks varies significantly (See Table 14 in Appendix) hence using its performance mean as an indicator is less conclusive.

	BiLSTM	DistilBERT	BERT	RoBERTa	BERT-large	AVG
Perf. gain: Weak Sup − C	3.90	4.21	2.98	-2.07	1.32	2.07
Perf. gap: Full Clean − Weak Sup	14.42	15.47	13.58	18.13	18.51	16.00

Weak supervision has smaller benefit in larger base models. Another question that we attempt to address in WALNUT is on whether weak supervision equally benefits each base model architecture. To quantify such benefit we compare the performance differences between models trained using semi-weak supervision and models trained using clean data only. The "Weak Sup" approach in Table 4 is computed as the average F1 score across all semi-weak supervision methods (C+W, C+Snorkel, GLC, and MetaWN). The performance gap between "Weak Sup" and "C" (training with few clean data only) is smaller for larger models. Additionally, the performance gap between "Full Clean" (full clean data training) and "Weak Sup" approach is larger for larger models. The two above observations highlight that weak supervision has smaller benefit in larger models. An important future research direction is to develop better learning algorithms and improving the effectiveness of weak supervision in larger models.

Analysis of weak rules. For now, we have focused on the evaluation of base models trained using weak labels generated by multiple weak labeling rules. It is interesting also to decouple the base model performance from the rule aggregation technique (e.g., majority voting, Snorkel) that was used to generate the training labels, which is an essential modeling component for weak supervision. The bottom row in Table 2 ("Rules") reports the test performance of rules computed by taking the majority voting of weak labels on the test instances. (For test instances that are not covered by any rules, a random class is predicted.) Such majority label is available in our pre-processed datasets. Interestingly, "Rules" sometimes outperforms base models trained using weak labels ("W", "Snorkel"). Note however that "Rules" assumes *access to all weak labels* on the test set, which might not always be available. On the other hand, the base model learns text features beyond the heuristic-based rules and does not require access to rules during test time and thus can be applied for any test instance.

For a more in-depth analysis of the rule quality, WALNUT also supports the analysis of individual rules and multi-source aggregation techniques, such as majority voting or Snorkel. Figure 3 shows a precision-recall scatter plot for each rule on each of the dataset in WALNUT. For instance, in the CoNLL dataset rules vary in characteristics, where most rules have a relatively low recall while there are a few rules that have substantially higher recall than the rest. Across datasets, we observe that rules

have higher precision than recall, as most rules are sparse, i.e., apply to a small number of instances in the dataset (e.g., instances containing a specific keyword). Similar trends are observed on other datasets as well. For detailed descriptions of all weak rules in all datasets, refer to Table 6 - 13 in the appendix.

5 Conclusions

Motivated by the lack of a unified evaluation platform for semi-weakly supervised learning for low-resource NLU, in this paper we propose a new benchmark WALNUT covering a broad range of data domains to advocate research on leveraging both weak supervision and few-shot clean supervision. We evaluate a series of different semi-weakly supervised learning methods with different model architecture on both document-level and token-level classification tasks, and demonstrate the utility of weak supervision in real-world NLU tasks. We find that no single semi-weakly supervised learning method wins on WALNUT and there is still gap between semi-weakly supervised learning and fully supervised training. We expect WALNUT to enable systematic evaluations of semi-weakly supervised learning methods and stimulate further research in directions such as more effective learning paradigms leveraging weak supervision.

Acknowledgements

We would like to thank Yichuan Li for helping adapt several weak supervision baselines for document-level classification tasks, and the reviewers for constructive feedback.

A Appendix

Limitations and Broader Impact

The proposed benchmark is likely to stimulate research on weakly supervised learning for NLU, and offer the research community on weakly supervised learning a unified testbed for evaluating new methodologies developed for low-resource NLU. For many practical NLU applications, large amount of manually labeled data is unavailable or expensive to obtain due to either cost or privacy concerns, resorting to proxy signals such as weak supervision is a viable solution to mitigate this annotation scarce problem. We hope WALNUT would provide such an evaluation environment to advocate progress in this direction.

Limitations. Due to the lack of existing real-world weak supervision for many NLU tasks, WALNUT does not include NLU tasks such as Natural Language Inference for which it is hard to construct weak supervision rules. Also, currently WALNUT only considers English data; a possible extension is to also include multi-lingual corpus with weak supervision available to boost the performance of multi-lingual language models with weakly supervised learning.

A.1 Implementation Details

We implement all baseline experiments with PyTorch and each experiment runs on a single NVIDIA GPU. Below are hyper-parameter specifications for all baseline methods (hyperparameters not mentioned below are given default values):

- Full Clean, C, C+W, Snorkel, C+Snorkel: Batch size is 32 for document-level classification datasets and 16 for the token-level classification datasets. The code for Snorkel is adapted from: `https://github.com/snorkel-team/snorkel`. Each training experiment is conducted for the 10 epochs with the checkpoint with the best validation performance saved for evaluation on the test set.

- GLC: Code is adapted from `https://github.com/mmazeika/glc`. Batch size is 16 for the 4 document-level classification datasets and 8 for the 4 token-level classification datasets. Each experiment trains for 10 epochs with the checkpoint with the best validation performance saved for evaluation on test set.

- MetaWN: Code is adapted from `https://github.com/xjtushujun/meta-weight-net`. Batch size is 8 for the 4 document-level classification datasets and 4 for the 4 token-level classification datasets. The meta-network is a three-layer feed-forward network with hidden dimension of 128. Each experiment trains for 10 epochs with the checkpoint with the best validation performance saved for evaluation on test set.

- MLC: Code is adapted from `https://github.com/microsoft/MLC`. Batch size is 8 for the 4 document-level classification datasets and 4 for the 4 token-level classification datasets. The meta-network is a three-layer feed-forward network with hidden dimension of 128; the label embedding dimension used in the meta-network is 64. Each experiment trains for 10 epochs with the checkpoint with the best validation performance saved for evaluation on test set.

To encode input text, we experiment with various text encoders, ranging from shallow LSTMs to large pre-trained transformerbased encoders (Vaswani et al., 2017):

- BiLSTM-based encoder: the BiLSTM implementations are all based on 50-dimensional pre-trained glove word embeddings (Pennington et al., 2014) and bi-directional LSTMs with hidden size 128. Note that our implementation is different than other BiLSTM implementations used by previous work, which are based on 100-dimensional word embeddings and LSTM hidden size 300. This renders our BiLSTM models roughly 3 times smaller than those used by previous work, thus the numbers are not directly comparable. We chose a smaller model capacity for BiLSTMs to contrast the performance with larger models including DistilBERT and others to show the importance of model capacity on WALNUT. During training, we use a learning rate of 0.005 for all BiLSTM-based models.

- Transformer-based encoders: we consider pre-trained DistilBERT (Sanh et al., 2019), BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), BERT-large, and RoBERTa-large.

We fine-tune these models (via the huggingface library) using task-specific classification heads on top of the encoder and a learning rate of 0.00001.

B Additional Benchmark Details

B.1 Document-level classification

- **AGNews:** and multi-class topic classification (world vs. sports vs. business vs. sci/tech) on news articles from the AGNews dataset (Zhang et al., 2015).
- **Yelp:** binary sentiment classification (negative vs. positive) of Yelp restaurant reviews (Zhang et al., 2015).
- **IMDB:** binary sentiment classification (negative vs. positive) of IMDB movie reviews (Maas et al., 2011).
- **GossipCop:** binary fake news detection (fake vs. not fake) on news articles from the GossipCop[3] fact-checking websites. The GossipCop dataset is part of the fake news detection benchmark FakeNewsNet (Shu et al., 2020a). (We only include the results of Gossipcop to represent fake news classification task as the results for Politifact are similar.)

B.2 Token-level classification

According to the BIO tagging scheme, “B,” “I,” and “O,” represent the beginning, inside, and outside, of a named entity span, respectively. (Not extracting any values corresponds to a sequence of “O”-only tags.) Consider, for example, named entity recognition in the CoNLL dataset:

Tokens:	Barack	Obama	lives	in	Washington
Tags:	B-PER	I-PER	O	O	B-LOC

- **CoNLL:** the CoNLL 2003 dataset (Sang and De Meulder, 2003) contains news articles from Reuters (split into sentences). In total, there are 35,089 entities from 4 types: organization (ORG), person (PER), location (LOC), and miscellaneous (MISC). Tag classes C': [’O’, ’B-PER’, ’I-PER’, ’B-ORG’, ’I-ORG’, ’B-LOC’, ’I-LOC’, ’B-MISC’, ’I-MISC’]
- **NCBI:** the NCBI Disease corpus (Doğan et al., 2014) contains PubMed abstracts with 6,866 disease mentions. Tag types: [’O’, ’B’, ’I’]
- **WikiGold:** the WikiGold dataset (Balasuriya et al., 2009) contains English Wikipedia articles that were randomly selected and manually annotated with the same entity types as CoNLL. Tag classes C': [’O’, ’B-PER’, ’I-PER’, ’B-ORG’, ’I-ORG’, ’B-LOC’, ’I-LOC’, ’B-MISC’, ’I-MISC’]
- **LaptopReview:** the Laptop Review corpus from the SemEval 2014 Challenge (Pontiki et al., 2016) contains 3,012 mentions to laptop features. Tag types C': [’O’, ’B’, ’I’]

Table 5 shows detailed statistics for token-level classification datasets. More dataset statistics are provided in Table 1. Tables 6-13 show detailed information for all rules. Figures 4-10 show examples of weak rules for various datasets.

---

[3] `https://www.gossipcop.com/`

Table 5: Extra token-level statistics for the token-level classification datasets.

	CoNLL	**NCBI**	**WikiGold**	**LaptopReview**
# train tokens	203,621	135,572	31,560	41,525
# dev tokens	51,362	23,789	3,683	9,970
# test tokens	46,435	24,219	3,762	11,884

Table 6: List of rules for the AGNews dataset. The rules are the same as the tagging rules in (Zhang et al., 2015). The Python implementations can be found in: `https://github.com/weakrules/Denoise-multi-weak-sources/blob/master/rules-noisy-labels/Agnews/angews_rule.py`

Rule name	**Description**
1. world1	Keyword-based detection of the WORLD topic
2. world2	Keyword-based detection of the WORLD topic
3. sports1	Keyword-based detection of the SPORTS topic
4. sports2	Keyword-based detection of the SPORTS topic
5. sports3	Keyword-based detection of the SPORTS topic
6. tech1	Keyword-based detection of the TECH topic
7. tech2	Keyword-based detection of the TECH topic
8. business1	Keyword-based detection of the BUSINESS topic
9. business2	Keyword-based detection of the BUSINESS topic

Table 7: List of rules for the IMDB dataset. The rules are the same as in (Zhang et al., 2015). The Python implementations can be found in: `https://github.com/weakrules/Denoise-multi-weak-sources/blob/master/rules-noisy-labels/IMDB/imdb_rule.py`

Rule name	**Description**
1. expression_nexttime	Regex-based detection of POSITIVE sentiment (re-watching expressions)
2. expression_recommend	Regex-based detection of POSITIVE sentiment (recommendation expressions)
3. expression_value	Regex-based detection of POSITIVE sentiment (value expressions)
4. keyword_compare	Keyword-based detection of NEGATIVE sentiment based on movie comparisons
5. keyword_general	Keyword-based detection of POSITIVE and NEGATIVE sentiment
6. keyword_actor	Keyword-based detection of POSITIVE sentiment regarding the actors
7. keyword_finish	Keyword-based detection of NEGATIVE sentiment
8. keyword_plot	Keyword-based detection of POSITIVE and NEGATIVE sentiment regarding the plot

Table 8: List of rules for the Yelp dataset. The rules are the same as in (Zhang et al., 2015). The Python implementations can be found in: `https://github.com/weakrules/Denoise-multi-weak-sources/blob/master/rules-noisy-labels/Yelp/yelp_rules.py`

Rule name	**Description**
1. textblob_lf	Model-based detection of POSITIVE and NEGATIVE sentiment (TextBlob model)
2. keyword_recommend	Regex-based detection of POSITIVE sentiment (recommendation expressions)
3. keyword_general	Regex-based detection of POSITIVE and POSITIVE sentiment (general expressions)
4. keyword_mood	Keyword-based detection of POSITIVE and NEGATIVE sentiment based on the user's mood
5. keyword_service	Keyword-based detection of POSITIVE and NEGATIVE sentiment relevant to the service
6. keyword_price	Keyword-based detection of POSITIVE and NEGATIVE sentiment regarding the prices
7. keyword_environment	Keyword-based detection of POSITIVE and NEGATIVE sentiment relevant to the ambience
8. keyword_food	Keyword-based detection of POSITIVE and NEGATIVE sentiment relevant to the food

Table 9: List of rules for the GossipCop dataset. The rules are the same as in (Shu et al., 2020a) (page 8 in `http://www.cs.iit.edu/~kshu/files/ecml_pkdd_mwss.pdf`).

Rule name	Description
1. mean_scores	User interaction-based detection of FAKE news: If a news piece has a standard deviation of user sentiment scores greater than a threshold τ_1, then the news is weakly labeled as FAKE news.
2. std_scores	User interaction-based detection of FAKE news: If the mean value of users' absolute bias scores - sharing a piece of news – is greater than a threshold τ_2, then the news piece is weakly-labeled as FAKE news.
3. credibility_score	User interaction-based detection of FAKE news: If a news piece has an average credibility score less than a threshold τ_3, then the news is weakly-labeled as FAKE news.

Table 10: List of rules for the CoNLL dataset. The Python implementation of CoNLL rules is provided in the "skweak" repo: `https://github.com/NorskRegnesentral/skweak/blob/670fcdec680930ce3e497886d06d61e6a1f2c195/examples/ner/conll2003_ner.py`

Rule name	Description
1. date_detector	Heuristic detection of entities of type DATE
2. time_detector	Heuristic detection of entities of type TIME
3. money_detector	Heuristic detection of entities of type MONEY
4. proper_detector	Heuristic detection of proper names based on casing
5. infrequent_proper_detector	Heuristic detection of proper names based on casing + including at least one infrequent token
6. proper2_detector	Heuristic detection of proper names based on casing
7. infrequent_proper2_detector	Heuristic detection of proper names based on casing + including at least one infrequent token
8. nnp_detector	Heuristic detection of sequences of tokens with NNP as POS-tag
9. infrequent_nnp_detector	Heuristic detection of sequences of tokens with NNP as POS-tag + including at least one infrequent token (rank > 15000 in vocabulary)
10. compound_detector	Heuristic detection of proper noun phrases with compound dependency relations
11. infrequent_compound_detector	Heuristic detection of proper noun phrases with compound dependency relations + including at least one infrequent token
12. misc_detector	Heuristic detection of entities of type NORP, LANGUAGE, FAC or EVENT
13. legal_detector	Heuristic detection of entities of type LAW
14. company_type_detector	Gazetteer using a large list of company names
15. full_name_detector	Heuristic function to detect full person names
16. number_detector	Heuristic detection of entities CARDINAL,ORDINAL, PERCENT and QUANTITY
17. snips	Probabilistic parser specialised in the recognition of dates, + times, money amounts, percents, and cardinal/ordinal values
18. core_web_md	NER model trained on Ontonotes 5.0
19. core_web_md+c	NER model trained on Ontonotes 5.0 + postprocessing
20. BTC	NER model trained on the Broad Twitter Corpus
21. BTC+c	NER model trained on the Broad Twitter Corpus + postprocessing
22. SEC	NER model trained on SEC-filings
23. SEC+c	NER model trained on SEC-filings + postprocessing
24. edited_core_web_md	NER model trained on Ontonotes 5.0 + alternative postprocessing
25. edited_core_web_md+c	NER model trained on Ontonotes 5.0 + alternative postprocessing
26. wiki_cased	Gazetteer (case-sensitive) using Wikipedia entries
27. wiki_uncased	Gazetteer (case-insensitive) using Wikipedia entries
28. multitoken_wiki_cased	Same as above, but restricted to multitoken entities
29. multitoken_wiki_uncased	Same as above, but restricted to multitoken entities
30. wiki_small_cased	Gazetteer (case-sensitive) using Wikipedia entries with non-empty description
31. wiki_small_uncased	Gazetteer (case-insensitive) using Wikipedia entries with non-empty description
32. multitoken_wiki_small_cased	Same as above, but restricted to multitoken entities
33. multitoken_wiki_small_uncased	Same as above, but restricted to multitoken entities
34. geo_cased	Gazetteer (case-sensitive) using the Geonames database
35. geo_uncased	Gazetteer (case-insensitive) using the Geonames database
36. multitoken_geo_cased	Same as above, but restricted to multitoken entities
37. multitoken_geo_uncased	Same as above, but restricted to multitoken entities
38. crunchbase_cased	Gazetteer (case-sensitive) using the Crunchbase Open Data Map
39. crunchbase_uncased	Gazetteer (case-insensitive) using the Crunchbase Open Data Map
40. multitoken_crunchbase_cased	Same as above, but restricted to multitoken entities
41. multitoken_crunchbase_uncased	Same as above, but restricted to multitoken entities
42. product_cased	Gazetteer (case-sensitive) using products extracted from DBPedia
43. product_uncased	Gazetteer (case-insensitive) using products extracted from DBPedia
44. multitoken_product_cased	Same as above, but restricted to multitoken entities
45. multitoken_product_uncased	Same as above, but restricted to multitoken entities
46. doclevel_voter	Considers all appearances of the same entity string in the document
47. doc_history_cased	Considers already introduced entities in the document (case-sensitive)
48. doc_history_uncased	Considers already introduced entities in the document (case-insensitive)
49. doc_majority_cased	Considers all entities in the document (case-sensitive)
50. doc_majority_uncased	Considers all majority labels in the document (case-insensitive)

Table 11: List of rules for the NCBI dataset. The rules are the same as the tagging rules in (Safranchik et al., 2020). Python implementations: `https://github.com/BatsResearch/safranchik-aaai20-code/blob/master/NCBI-Disease/train_generative_models.py`

Rule name	Description
1. CoreDictionaryUncased	AutoNER dictionary (biomedical entities)
2. CoreDictionaryExact	AutoNER dictionary (biomedical entities, exact match)
3. CancerLike	Heuristic detection of entities that are relevant to cancer
4. CommonSuffixes	Heuristic detection of entities that are relevant to common diseases
5. Deficiency	Heuristic detection of entities that are relevant to deficiencies
6. Disorder	Heuristic detection of entities that are relevant to disorders
7. Lesion	Heuristic detection of entities that are relevant to lesions
8. Syndrome	Heuristic detection of entities that are relevant to syndroms
9. BodyTerms	UMLS dictionary entries for terms that are relevant to body parts
10. OtherPOS	Heuristic detection of parts of speech that are not relevant to any disease
11. StopWords	Heuristic detection of stop words that are not relevant to any disease
12. Punctuation	Heuristic detection of punctiations that are not relevant to any disease

Table 12: List of rules for the WikiGold dataset. The Python implementation of WikiGold rules is provided in the "skweak" repo: `https://github.com/NorskRegnesentral/skweak/blob/670fcdec680930ce3e497886d06d61e6a1f2c195/examples/ner/conll2003_ner.py`

Rule name	Description
1. BTC	NER model trained on the Broad Twitter Corpus
2. core_web_md	NER model trained on Ontonotes 5.0
3. crunchbase_cased	Gazetteer (case-sensitive) using the Crunchbase Open Data Map
4. crunchbase_uncased	Gazetteer (case-insensitive) using the Crunchbase Open Data Map
5. full_name_detector	Heuristic function to detect full person names
6. geo_cased	Gazetteer (case-sensitive) using the Geonames database
7. geo_uncased	Gazetteer (case-insensitive) using the Geonames database
8. misc_detector	Heuristic detection of entities of type NORP, LANGUAGE, FAC or EVENT
9. wiki_cased	Gazetteer (case-sensitive) using Wikipedia entries
10. wiki_uncased	Gazetteer (case-insensitive) using Wikipedia entries
11. multitoken_crunchbase_cased	Same as above, but restricted to multitoken entities
12. multitoken_crunchbase_uncased	Same as above, but restricted to multitoken entities
13. multitoken_geo_cased	Same as above, but restricted to multitoken entities
14. multitoken_geo_uncased	Same as above, but restricted to multitoken entities
15. multitoken_wiki_cased	Same as above, but restricted to multitoken entities
16. multitoken_wiki_uncased	Same as above, but restricted to multitoken entities

Table 13: List of rules for the LaptopReview dataset. The rules are the same as the tagging rules in (Safranchik et al., 2020). Python implementations: `https://github.com/BatsResearch/safranchik-aaai20-code/blob/master/LaptopReview/train_generative_models.py`

Rule name	**Description**
1. CoreDictionary	AutoNER dict with entries of terms that are relevant to electronics
2. OtherTerms	Heuristic detection of laptop entities based on a pre-defined keyword list
3. ReplaceThe	Heuristic detection of laptop entities based on the “replace the” phrase
4. iStuff	Heuristic detection of laptop entities based on uppercase letters
5. Feelings	Heuristic detection of laptop entities based on common expressions
6. ProblemWithThe	Heuristic detection of laptop entities based on common expressions
7. External	Heuristic detection of laptop entities based on common hardware expression
8. StopWords	Heuristic detection of stop words that are not relevant to electronics
9. Punctuation	Heuristic detection of punctuation that are not relevant to electronics
10. Pronouns	Heuristic detection of pronouns that are not relevant to electronics
11. NotFeatures	Heuristic detection of terms that are not relevant to laptop features
12. Adv	Heuristic detection of adverbs that are not relevant to electronics

                    labels[i + 2] = 'I'

        return labels
```

Figure 10: Example of weak rule from the LaptopReview dataset (rule 5: Feelings from Table 13). This rule heuristically detects entities that are relevant to laptop features based on keywords that express the user's feelings.

C Additional Results

Table 14 shows standard deviation results for all datasets, methods, and base models. The rightmost column responds the average standard deviation (AVG std) across tasks, which we also reported in Table 3.

Analysis of individual weak rules. Tables 15-21 show performance results for each weak rule for the datasets in WALNUT. We evaluate two different strategies for majority voting in case of an instance that is not covered by any rules: (1) “Strict” counts the instance as misclassified and (2) “Loose” assigns a random label to the instance. Most rules have very low F1 score while there are a few rules with a relatively high F1 score.

Figure 3 shows the precision-recall scatter plots for each weak rule individually. (We skip the scatter plot for GossipCop as it has just 3 rules.) Several rules have relatively high precision but most rules have very low recall.

Table 14: Standard deviation results on WALNUT.

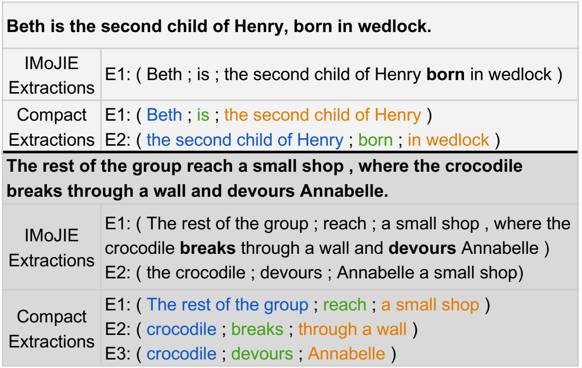
Abstract

A major drawback of modern neural OpenIE systems and benchmarks is that they prioritize high coverage of information in extractions over compactness of their constituents. This severely limits the usefulness of OpenIE extractions in many downstream tasks. The utility of extractions can be improved if extractions are compact and share constituents. To this end, we study the problem of identifying compact extractions with neural-based methods. We propose COMPACTIE, an OpenIE system that uses a novel pipelined approach to produce compact extractions with overlapping constituents. It first detects constituents of the extractions and then links them to build extractions. We train our system on compact extractions obtained by processing existing benchmarks. Our experiments on CaRB and Wire57 datasets indicate that COMPACTIE finds 1.5x-2x more compact extractions than previous systems, with high precision, establishing a new state-of-the-art performance in OpenIE.

1 Introduction

A popular domain-agnostic paradigm to structure the raw text is open information extraction (OpenIE) (Banko et al., 2007). Not relying on any predefined schema, OpenIE systems typically extract information as (subject; relation; object) triples. The extracted information is then used in several downstream applications, including answering questions (Khot et al., 2017), summarizing documents (Hao et al., 2018; Ji et al., 2013), and populating knowledge bases (Fan et al., 2019).

Despite much progress, state-of-the-art neural OpenIE systems focus on covering more information from the input sentence often at the cost of utility and compactness of the extracted triples. The extracted triples have long, over-specific *constituents* (i.e. the relation and its arguments). Figure 1 illustrates such example triples produced by a popular OpenIE system, IMoJIE (Kolluru et al., 2020b). As shown, the knowledge that *the second child of Henry* was born *in wedlock* is embedded in a long argument. This can be problematic for downstream applications, especially knowledge base population (Gashteovski et al., 2020; Stanovsky et al., 2015) that derive power from merging multiple pieces of information extracted about the same entity. In contrast, the compact extractions are more pliable for tasks such as identifying similar facts and merging facts that share constituents. For example, compact extractions in Figure 1 can be merged to derive that *Beth* is born *in wedlock*.



Beth is the second child of Henry, born in wedlock.	
IMoJIE Extractions	E1: (Beth ; is ; the second child of Henry **born** in wedlock)
Compact Extractions	E1: (Beth ; is ; the second child of Henry) E2: (the second child of Henry ; born ; in wedlock)
The rest of the group reach a small shop , where the crocodile breaks through a wall and devours Annabelle.	
IMoJIE Extractions	E1: (The rest of the group ; reach ; a small shop , where the crocodile **breaks** through a wall and **devours** Annabelle) E2: (the crocodile ; devours ; Annabelle a small shop)
Compact Extractions	E1: (The rest of the group ; reach ; a small shop) E2: (crocodile ; breaks ; through a wall) E3: (crocodile ; devours ; Annabelle)

Figure 1: Example sentences with non-compact triples from IMoJIE vs. compact triples from our benchmark. Compact triples can share constituents. Constituents for subjects, relations and objects are indicated in blue, green and orange, respectively.

Although some prior work (Corro and Gemulla, 2013; Gashteovski et al., 2017; Bhutani et al., 2016) has explored the compactness of OpenIE triples, these systems are rule-based and have been superseded by end-to-end neural OpenIE systems. In this work, we study the problem of identifying compact extractions with neural-based methods. Inspired by (Corro and Gemulla, 2013), we define an extracted triple to be *compact* if it does not contain information that can be independently represented in another triple. To further improve the suitability of

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 900 - 910
July 10-15, 2022 ©2022 Association for Computational Linguistics

compact triples for knowledge base population, we require compact triples extracted from a sentence to have overlapping constituents.

Existing neural systems adopt a sequence labeling (Kolluru et al., 2020a; Wang et al., 2021; Ro et al., 2020) or a sequence generation (Kolluru et al., 2020b) approach to identify triples and their constituents, typically all at once, or through a pipeline that first identifies the relations and then their corresponding arguments. None of these methods guarantee that the extracted triples will be compact and share constituents.

We propose a novel pipeline system for finding compact triples that share their constituents. We call our OpenIE system, COMPACTIE. To encourage the constituents to be shared across triples, COMPACTIE first extracts the constituents using a *Constituent Extraction* model and then links them using a *Constituent Linking* model to obtain triples.

We adapt a table filling method (Wang et al., 2021) with a new schema for identifying both constituent boundaries and their roles (i.e., subject or object). This allows the constituent extraction model to capture interactions among constituents and minimize ambiguities in boundary detection. For the task of constituent linking, we train a model that builds on contextual representations specific to a given pair of constituents and predicts their relation type. Such a two-step approach enables us to optimize the models for each sub-task with different objectives and also promote the constituent reuse across triples.

Existing neural OpenIE systems are trained on benchmarks that combine extractions from multiple OpenIE systems . However, no such large-scale benchmark exists for compact triples. We develop a new benchmark using a subset of sentences in the OpenIE2016 benchmark (Mausam, 2016). Specifically, we develop a data processing algorithm that targets extraction from individual clauses in a sentence. Given an input sentence, it identifies clauses and then uses OpenIE systems such as IMoJIE over the clauses to find compact triples. We train COMPACTIE on the new benchmark.

Our experiments on a fine-grained benchmark, Wire57, show that COMPACTIE outperforms existing non-neural and neural systems by 5.8 F1 pts and 7.1 F1 pts, respectively. Manual evaluation over a coarse-grained benchmark, CaRB, indicates that COMPACTIE produces 1.5x-2x more compact extractions than existing systems with comparable precision, establishing a new state-of-the-art for the OpenIE task[1].

2 Background and Preliminaries

Given a sentence $s = w_1 w_2 ... w_n$, an OpenIE system generates triples of the form *(subject; relation; object)*, where *subject*, *relation* and *object* are the constituents of a triple.

2.1 Extracting Compact Triples

A recent study (Gashteovski et al., 2020) shows that triples from modern neural OpenIE systems are difficult to align to knowledge bases such as DBpedia. Less than 77% of triples from neural OpenIE systems had the same arguments as DBpedia facts. In contrast, the corresponding alignment ratio for some of the non-neural OpenIE systems was as high as 98%. They attribute this behavior to the specificity of the triples. A compact triple, which does not contain complete clauses as part of a constituent or contain additional information, is easier to align to DBpedia. Our goal is to leverage neural-based methods to extract compact triples.

2.2 System Architecture

We focus on extraction from individual clauses within a sentence, where each clause includes a subject, a verb, optionally a direct object, and a compliment. Since extractions from different clauses share information, we split the OpenIE task into two sub-tasks: *constituent extraction* and *constituent linking*.

The task of constituent extraction is to find a set of constituents such that each constituent c is a contiguous span of words $c.span = \{(w_i, w_j)\}$ and has a pre-defined type $c.type \in Y_c$ where $Y_c = \{Argument, Predicate\}$. The constituent that takes the *relation* role in a triple has $c.type = Predicate$, and *subject* and *object* constituents have $c.type = Argument$. This schema simplifies the task and provides more information to the constituent linking model.

The task of constituent linking is to connect a given set of $Predicate$ constituents $\{p_1, \ldots p_m\}$ and $Argument$ constituents $\{a_1, \ldots a_n\}$ to obtain triples. We formulate this as a relation classification task where the set of relations is $Y_r = \{Subject, Object\}$. The model predicts relations r between each p_x and $\{a_1, \ldots a_n\}$ such that:

---

[1] Source code, benchmark dataset, and related resources are available at `https://github.com/FarimaFatahi/CompactIE`

$$\exists(i,j) : r(a_i, p_x) = Subject\,,\ r(p_x, a_j) = Object$$

to construct triple $(a_i; p_x; a_j)$.

Figure 2: Table filling based on the relation between each pair of words in the sentence. Argument (**A**) and Predicate (**P**) are constituent types. Subject (**S**) and Object (**O**) declare the relation between two constituents (**N** stands for no relation).

3 Approach

In this section we describe our pipeline system, COMPACTIE. We first detail the constituent extraction model, its training constraints, and the decoding algorithm in Section 3.1. Then, we describe the constituent linking model in Section 3.2. Figure 3 shows an overview of COMPACTIE architecture.

3.1 Constituent Extraction Model

The constituent extraction model aims to find constituent spans and their types in a sentence. Following recent progress in entity-relation extraction (Wang et al., 2021), we model this as a table filling problem. However, we design a new table schema for the constituent extraction task. Figure 2 shows an example schema. A sentence s with $|s|$ tokens corresponds to a table $T^{|s|\times|s|}$ such that each cell is labeled based on the relation between the pair of words. For each constituent, corresponding cells are labeled with $y_c \in \{Argument, Predicate\}$. For relations between different constituents, corresponding cells are labeled with $y_r \in \{Subject, Object\}$. The cells with no relations are labeled $None$. Graphically, constituents are squares on the diagonal, and relations are rectangles off the diagonal.

3.1.1 Table Filling Model

Given the tabular formulation, the constituent extractor performs two tasks: a) fill the table by predicting labels for each word pair, b) extract the constituents given the label probabilities. Following (Wang et al., 2021), we adopt a biaffine attention mechanism, described next, to learn interactions between word pairs when filling the table.
Given the input sentence s, we first obtain contextual representation $\mathbf{h_i}$ for each word using a pretrained language model (e.g. BERT (Devlin et al., 2018)). We then employ two MLPs to identify the head and tail role of the word given its vector representation h_i.

$$h_i^{head} = MLP_{head}(h_i), h_i^{tail} = MLP_{tail}(h_i)$$

Next, using the biaffine scoring function, we calculate the scoring vector of each pair of words (e.g. w_i, w_j) as follows:

$$t_{i,j} = (h_i^{head})^T U^{(1)} h_j^{tail} + (h_i^{head} \oplus h_j^{tail})^T U^{(2)} + b$$

where $U^{(1)}, U^{(2)}$ are weight parameters, b is the bias term and $\oplus$ denotes concatenation. Then, we feed the score vector t_i, j into a softmax function to calculate the probability distribution of the corresponding labels $l \in Y$, where $Y = Y_c \cup Y_r \cup None$.

$$P(y_{i,j}|s) = Softmax(t_{i,j})$$

Finally, we train the 2D table to minimize the following training objective:

$$L_{entry} = -\frac{1}{|s|^2} \sum_{i=1}^{|s|} \sum_{j=1}^{|s|} \log(P(y_{i,j} = Y_{i,j}|s))$$

where $Y_{i,j}$ is the gold label for cell (i,j) in the table.

3.1.2 Training Constraints

(Wang et al., 2021) shows that structural constraints imposed on the table during training can significantly enhance the model. We adopt their *symmetry* and *implication* constraints. However, we observed that these alone are not sufficient if certain labels are preferred over others. For example, all triples must have a subject, but some may not have an object. We propose a new *triple* constraint to further enhance our model. In this section, we describe the three constraints in detail. We also introduce $\mathcal{P} \in R^{|s|\times|s|\times|Y|}$ that denotes the stack of $P(y_{i,j}|s)$ for all word pairs in sentence s.

Symmetry: This constraint ensures that the table is symmetric i.e. the squares are symmetric about the diagonal. As shown in Figure 2, this ensures the label assigned to the (second, Henry) cell is the

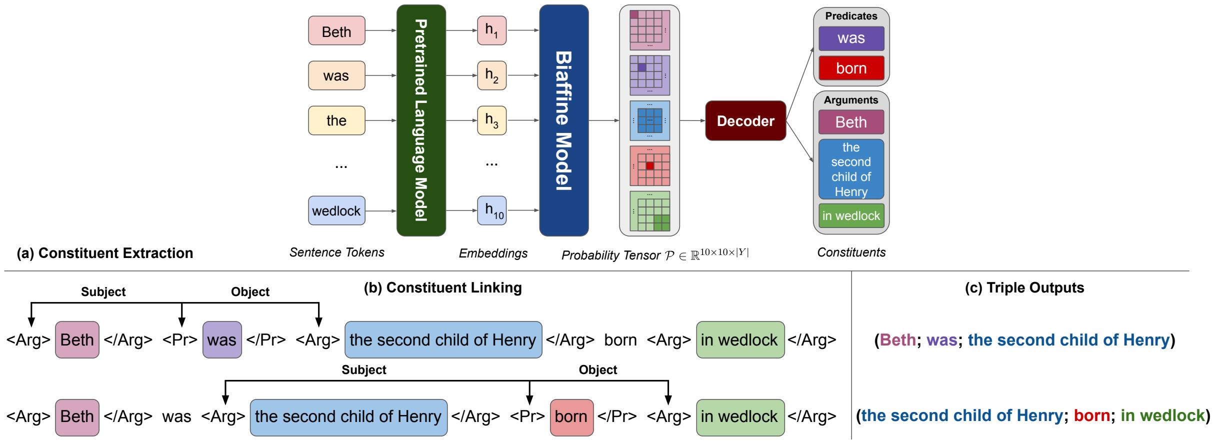

Figure 3: Overview of system architecture. Given the sentence: "Beth was the second child of Henry, born in wedlock.", the Constituent Extraction model identifies the span and type of constituents (top-right). Next, the Constituent Linking model (b) searches for $Arguments$ of each $Predicate$ constituent independently. Thus, for each of the two extracted $Predicates$, it modifies the input sentence by inserting typed constituent markers (<Arg>, </Arg> to specify the start and end of arguments and <Pr>, </Pr> for predicates). Finally, the modified sentence is fed into a classifier to find $Subject$ and $Object$ of each $Predicate$ and form triples (c).

same as the cell (Henry, second). Given matrix $\mathcal{P}$, We formulate this constraint as symmetrical loss:

$$L_{sym} = -\frac{1}{|s|^2}\sum_{i=1}^{|s|}\sum_{j=1}^{|s|}\sum_{t\in Y_r\cup Y_c}|\mathcal{P}_{i,j,t} - \mathcal{P}_{j,i,t}|$$

Implication: This constraint implies that no relation would appear unless its constituents are present in the table. This is imposed on $\mathcal{P}$: for each word in the diagonal, maximum possibility over the constituent type space $Y_c = \{Argument, Predicate\}$ is not lower than the maximum possibility for other words in the same row or column over the relation type space $Y_r = \{Subject, Object\}$.

$$L_{imp} = \frac{-1}{|s|}\sum_{i=1}^{|s|}\left[\max_{t\in Y_r}(\mathcal{P}_{i,:,t}, \mathcal{P}_{:,i,t}) - \max_{t\in Y_c}(\mathcal{P}_{i,i,t})\right]_*$$ [2]

Triple Constraint: This constraint enables the model to increase the likelihood of certain roles (e.g. ***Subject***) over the others (e.g. ***Object***) to ensure the triples are valid. We enforce this constraint on $\mathcal{P}$: For each column or row corresponding to a *Predicate* constituent, the maximum possibility of off-diagonal words over $Subject$ type is not lower than the maximum possibility of off-diagonal words over $Object$ type. We formulate this constraint as triple loss.

$$L_{triple} = \frac{-1}{2|ps|}\sum_{i\in ps}\Big[\{max(\mathcal{P}_{i,:,\boldsymbol{O}}) - max(\mathcal{P}_{i,:,\boldsymbol{S}}\} + \{max(\mathcal{P}_{:,i,\boldsymbol{O}}) - max(\mathcal{P}_{:,i,\boldsymbol{S}})\}\Big]$$

where ps is union of $Predicate$ spans in sentence.

Finally, we jointly optimize four objectives in training: $L_{entry} + L_{sym} + L_{imp} + L_{triple}$

3.1.3 Decoding

Given the label probability tensor $\mathcal{P}$, we need to decode the constituents in the testing phase. We follow a 2-step decoding procedure that finds spans of constituents first and then assigns a label to each span. The decoder first calculates the distance between adjacent rows and columns of the table to find constituents' boundaries. Next, it assigns a type to each span and filters out any $None$ constituents before passing the output to the linking model. The upper part of Figure 3 shows the output of the decoder, which extracts two constituents ("was", "born") of type $Predicate$ and three constituents ("Beth", "the second child of Henry", "in wedlock") of type $Argument$. We provide a detailed description of the decoding algorithm in Appendix A.2.

3.2 Constituent Linking Model

The constituent linking model aims to take a $Predicate$ constituent and a set of $Argument$ constituents as input and predict a relation label

---

[2] $[u]_* = max(u, 0)$ is the hinge loss.

$Y_r = \{Subject, Object, None\}$. This procedure is repeated for each predicate constituent in the sentence. We formulate this as a relation classification task where the model classifies relation labels of given constituent pairs based on context.

Following prior work (Zhang et al., 2019; Zhong and Chen, 2020), we modify the token sequence of input sentence by adding marker tokens <Pr>, </Pr>, <Arg>, </Arg> to highlight the constituent spans and their types. The markers help the linking model combine context information and constituent information for relation classification. As shown in Figure 3.a, two types of constituents are extracted from the input sentence. For each constituent of type $Predicate$, we modify the input sentence by highlighting the location of the $Predicate$ and all $Argument$ constituents. Then, we feed this processed sentence to a pre-trained encoder (BERT).

Next, we concatenate the output representation of the start position of predicate p with the output representation of the start position of argument a_i:

$$X_r(p, a_i) = h_{start(p)} \oplus h_{start(a_i)}$$

Finally, we feed the concatenated representation into a multi-layer perceptron (MLP) to predict the probability distribution of the relation type $r \in Y_r \cup None$:

$$P(r|p, a_i) = MLP(X_r)$$

4 Benchmark Creation

To train the constituent extraction and constituent linking models for extracting compact triples, we need a benchmark of compact triples. Existing OpenIE benchmark [3] is created by combining extractions from multiple existing OpenIE systems. Although widely adopted, we observed that it includes over-specific and sometimes incorrect extractions from previous systems. This encouraged us to design a data processing algorithm that can extract compact triples from scratch. Inspired by rule-based OpenIE system (Corro and Gemulla, 2013), we find compact triples by extracting the following clauses within a sentence:

Main Clauses are independent clauses that express a complete concept.

Complement Clauses are subordinate clauses that serve to complete the meaning of a verb or noun in the sentence.

	Our Benchmark			OIE2016
	Total	Train	Valid	
# Sentence	54.9k	54.5k	500	92.7k
# Triples	121.8k	120.6k	1155	190.6k
Avg. # triples per sent.	**3.165**	-	-	2.542
Avg. constituent length	**4.587**	-	-	7.893

Table 1: Statistics of our benchmark and OpenIE2016 benchmark.

Coordinate Clauses are independent clauses joined to the main clause using coordinating conjunctions such as *and*, *or*, *but*, etc.

We identify clauses within a sentence using its dependency graph. We first build a sentence tree such that the root is the head of the main clauses and the first-level children are clauses modifying the root word. We then perform a postfix traversal of the tree until we find a sub-tree with no clausal children. At this point, we run a standard OpenIE system, IMoJIE (Kolluru et al., 2020b), over the clause corresponding to the sub-tree to obtain triples. We then backtrack and extract triples for other clausal children and lastly the parent. We provide pseudo-code of algorithm in Appendix A.

We run our algorithm on each multi-clause sentence in the OpenIE2016 benchmark and obtain a new benchmark tailored for extracting compact triples. Figure 1 shows example sentences and compact triples from this benchmark.

5 Experimental Setup

Training Dataset: We train COMPACTIE using the benchmark described in Section 4. Table 1 compares the statistics of our new benchmark and bootstrapped OpenIE2016 benchmark. As shown, our benchmark has 1.25 times more extractions per sentence than OpenIE2016 and its constituents are more compact. We use about 1% of sentences for validation and the remaining for training.

Comparison Systems: We compare COMPACTIE against state-of-the-art sequence-labeling systems, OpenIE6 (Kolluru et al., 2020a) and Multi2OIE (Ro et al., 2020), and sequence-generation system, IMoJIE (Kolluru et al., 2020b)). We also compare it against traditional non-neural systems designed for extracting compact facts: NestIE (Bhutani et al., 2016) and MinIE (Gashteovski et al., 2017).

Evaluation Datasets and Metrics: We evaluate the OpenIE systems both automatically and manually on standardized benchmarks. For automatic

Table 2: Statistics of evaluation datasets, Wire57 and CaRB, before (Orig) and after processing (Proc).

evaluation, we first assess all systems with CaRB[4] test and Wire57 [5] datasets. Since these datasets are not targeted for compact triples, for a fair comparison we exclude triples that have at least one clause within a constituent. Table 2 shows the statistics of the original and processed datasets. Each dataset also provides its own scoring function. We report precision (P), recall (R), and F1 computed by these scoring functions. Wire57 contains more fine-grained extractions than the CaRB dataset and its scoring function is more rigorous for compact facts since it penalizes over-specific extractions. However, both CaRB and Wire57 scoring functions are based on token-level matching of system extractions against ground truth facts. Moreover, these benchmarks are incomplete, meaning that the gold extractions do not include all acceptable surface realizations of the same fact. These drawbacks encouraged us to additionally perform a fact-centered evaluation using the BenchIE (Gashteovski et al., 2021) benchmark and scoring paradigm. Finally, we carry out a manual evaluation on 100 sentences to avoid bias towards different scorers.

Implementation Details: Since the schema design of the table filling model does not support conjunctions inside constituents, we follow previous work (Kolluru et al., 2020a) and pre-process the sentences into smaller conjunction-free sentences before passing them to the system.

For a fair comparison to previous work, we use *bert-based-uncased* (Devlin et al., 2018) as the text encoder for both the constituent extraction model and constituent linking model. Each model contains nearly 110M parameters. For both models, we set the max sequence length to 512, initial learning rate to 5e-5, weight decay to 1e-5, and the batch size to 32. We use AdamW optimizer to fine-tune each model. The batch size is 300 for constituent extraction model and 20 for the constituent linking model, both equipped with early stopping. We use NVIDIA GeForce RTX 2080 Ti GPU to train both models for a cumulative time of 8 hours.

6 Experimental Results

6.1 Automatic Token-level Evaluation

Table 3 summarizes the performance of OpenIE systems across the CaRB and Wire57 datasets and scoring functions. On the fine-grained Wire57 dataset with a strict Wire57 scorer, COMPACTIE outperforms neural OpenIE systems (by 7.2 - 9 F1 pts) and non-neural systems (by 5.8 - 10.8 F1 pts).

On the more coarse-grained CaRB dataset, almost all OpenIE systems achieve comparable performance in terms of overall F1 using the CaRB scoring function. The neural systems still outperform non-neural systems in terms of F1, which is in line with previous studies. However, neural OpenIE systems are tuned based on the CaRB scoring function and thus tend to produce extractions that are biased towards this scoring method. Previous works (Kolluru et al., 2020a) also report issues with the scoring function not being able to handle conjunctions properly. Table 7 shows the limitations of the CaRB benchmark and scoring function through an example. As illustrated, the set of extractions produced by COMPACTIE is more exhaustive than IMoJIE and ground truth extractions. However, the CaRB scoring function assigns an F1 score of 62.0 to IMoJIE extractions, and 39.7 to COMPACTIE extractions. To resolve incompleteness of the CaRB benchmark and potential bias towards its scoring function, we undertake a fact-centered evaluation, detailed in Section 6.2, and a manual evaluation, described in Section 6.3.

6.2 Fact-centric Evaluation

(Gashteovski et al., 2021) claims that CaRB and Wire57 benchmarks and scoring functions overestimate a system's ability to extract correct facts. They propose an alternative benchmark and evaluation framework, BenchIE, that exhaustively lists all fact-equivalent extractions and clusters them into fact synsets. The scoring function considers an extraction as correct, if and only if it exactly matches any of the gold extractions from any of the fact synsets. They report Precision, Recall, and F1 based on exact triple matching.

Table 5 shows the performance of different OpenIE systems on BenchIE. As shown, COMPACTIE outperforms all other systems except MinIE. We found that MinIE aims to exhaustively produce different representations of the same fact. In contrast, COMPACTIE follows the setup of neural OpenIE systems and encourages at most one repre-

CompactIE	**40.3**	19.0	**26.2**

Table 5: Performances of OpenIE systems on the BenchIE dataset.

sentation per fact. As a result, MinIE produces 1.36x more extractions than CompactIE, achieving much higher recall than its neural counterparts.

6.3 Manual Evaluation

Limitations in the aforementioned benchmarks and evaluation frameworks encouraged us to perform human evaluation on triples generated by various systems. To this end, we randomly select 100 sentences from the CaRB validation set and feed them to all systems to investigate the generated triples. Next, we ask two graduate CS students, blind to the OpenIE systems, to mark each triple for correctness (0 or 1) based on whether it is asserted in the text and correctly captures the semantic information. They also label extractions for compactness (0 or 1). We consider an extraction compact if none of its constituents is longer than 10 words, includes conjunction or can be an independent extraction. We found an inter-annotator agreement of 0.68 on correctness and 0.83 on compactness using the Cohens Kappa metric. We report the results of the manual evaluation in Table 4. Neural systems target informativeness, which results in high precision at the cost of compactness. On the other hand, non-neural systems that aim for compact triples suffer from low precision. CompactIE offers a better trade-off between precision and compactness. It achieves comparable precision to neural models (-6 %) while providing substantially more compact extractions (+36 %). Compared to the MinIE, CompactIE produces triples with significantly higher precision (+22 %) while producing a comparable number of compact triples. NestIE achieves comparable compactness rate to CompactIE but suffers from low precision and total number of extractions.

7 Analysis

7.1 Compact and Overlapping Constituents

To understand the performance of CompactIE in generating compact triples that share constituents, we introduce the following metrics:

- Average Constituent Length (ACL): average length of constituents across all system-generated triples. This is a "syntactic" measure of compactness. The lower the ACL score, the higher the compactness of triples.
- Number of Constituent Clauses (NCC): average number of clauses per constituent that could be extracted as independent triples. The lower the NCC score, the better the compactness of triples.
- Repetitions Per Argument (RPA): number of total arguments divided by the number of unique arguments. The higher the RPA score, the higher fraction of total constituents produced per sen-

tence are shared.

Table 3 summarizes the performance on these metrics over CaRB and Wire57 benchmarks. We do not conduct a separate analysis over BenchIE since it uses a subset of CaRB sentences. As shown, the ACL scores of COMPACTIE are significantly lower than its neural counterparts and closely follows MinIE. The average constituent length (ACL) of NestIE triples is the lowest since it breaks sentences into small triples with verb, noun, preposition, and adjective mediated relations. For instance, the sentence: "2 million people died of AIDS." is broken down into T1: (2 million people; died), and T2: (T1; of; AIDS). However, its fine-grained strategy greatly sacrifices F1 for compactness. COMPACTIE achieves the lowest NCC score which indicates that the constituents in triples contain the fewest verbal clauses. As a result, these triples are more suitable for downstream applications such as text summarization and knowledge-base construction than other counterparts.

Finally, high RPA scores of COMPACTIE demonstrate the effectiveness of our approach as it enables the system to reuse the same constituent to generate multiple triples. MinIE achieves a slightly higher RPA score than COMPACTIE since it extracts multiple triples to represent the same fact leading to a higher repetition of unique constituents.

7.2 Effectiveness of Design Choices

Pipelined Approach vs. Unified Table Filling. To compare our pipelined approach with a unified extraction model, we follow UniRE (Wang et al., 2021), which decodes a single table to identify entities and relations jointly. We follow their 3-step decoding algorithm to obtain the constituents and links between them from the same table (with the schema shown in Figure 2). We refer to this model as COMPACTIE$_{\text{uni}}$. We report the performances in Table 6 and show that performance drops by jointly training the constituent and linking model. This aligns with the observations in recent entity-relation extraction work that pipelined approaches are more effective than joint models.

Effectiveness of Schema Design. Our table schema for constituent extraction includes both labels for constituents as well as labels to link them. We argued that this design captures the contextual dependency information between the constituents that boosts extraction performance. We compare the effectiveness of this schema design to another schema that uses only constituent labels $Y_c : \{Argument, Predicate\} \cup None$. Note that we use the same constituent linking model to obtain triples from the extracted constituents. We refer to this setting as COMPACTIE$_{\text{const table}}$. Table 6 illustrates the performance of this system on both CaRB and Wire57 datasets. We find that COMPACTIE achieves significantly higher F1 compared to COMPACTIE$_{\text{const table}}$ and conclude that incorporating additional context in the table schema improves the performance of the constituent extraction model.

Method	**Wire57**	**CaRB**
COMPACTIE	31.8	45.0
COMPACTIE$_{\text{uni}}$	17.6	35.8
COMPACTIE$_{\text{const table}}$	26.0	40.1

Table 6: Comparing F1 scores of CompactIE against joint extraction systems.

7.3 Error Analysis

We examine COMPACTIE triples produced for 50 randomly selected sentences of the CaRB validation dataset and 20 randomly selected sentences of the Wire57 dataset. Upon close analysis, we identify five major sources of error:

Constituent Not Found: (49.29%) We find that the constituent extraction model can fail to correctly label the constituents in the table. We found that the model gets biased towards producing $None$ labels due to the imbalanced distribution of labels.

Wrong Relation Type: (28.17%) These involve errors where the constituent linking model fails to correctly predict the link between the constituents. The current model encodes one sentence per predicate to find its arguments. Alternatively, we can encode one sentence per predicate-argument pair to focus more on each relation. Relation labels in the constituent extraction model can also assist the linking model in predicting the correct relations. We reserve this issue for future work.

Boundary Detection Error: (11.26%) These include errors where the decoder in constituent extraction fails to correctly identify the boundaries of the constituents. Boundary detection in constituent extraction model is highly dependant on the choice of distance threshold (α), as explained in A.2, which limits its robustness.

Inexpressive Table Error: (7.04%) These include errors where constituents have overlapping spans that participate in two roles within the same extrac-

System	Subject	Predicate	Object	F1

IMoJIE	Applications	use this service to record	activity for a system	62.0
	other OSIDs	use	the service to record data during ... analysis	
COMPACTIE	Applications	use	this service to record activity for a system	39.7
	other OSIDs	use	service to record data during development	
	other OSIDs	use	the service	
	the service	record	data during debugging	
	the service	record	data during analysis	

Table 7: Gold, IMoJIE and COMPACTIE extractions for the sentence: "*Applications use this service to record activity for a system while other OSIDs use the service to record data during development, debugging, or analysis.*" and their CaRB F1 score that evaluates extractors triples against gold triples.

tion or two different extractions.

Less than 4.22% of the errors were because of incorrect constituent type predictions. This indicates the effectiveness of our table filling method on constituent type detection.

8 Related Work

OpenIE has been studied extensively for over a decade with a history of statistical and rule-based systems (Banko et al., 2007; Fader et al., 2011; Corro and Gemulla, 2013; Mausam et al., 2012; Angeli et al., 2015) that extract triples from sentences without using any training data. Recently, neural models have been developed that are trained end-to-end on extractions bootstrapped from previous OpenIE systems. These can broadly be classified into *labeling-based* and *generation-based* systems.

Labeling-based systems (Stanovsky et al., 2018; Kolluru et al., 2020a; Ro et al., 2020) tag each word in the sentence and construct triples in an auto-regressive manner or by using a unique predicate for each triple. Generation-based systems (Kolluru et al., 2020b; Bhutani et al., 2019) use a sequence-to-sequence model to generate triples one word at a time. Labeling-based systems can handle redundancy in extracted triples and are faster than generation-based systems (Kolluru et al., 2020a).

Compactness in OpenIE: There has been prior work (Bhutani et al., 2016; Gashteovski et al., 2017; Stanovsky and Dagan, 2016; Angeli et al., 2015) that focuses on finding compact triples and shows that concise triples are useful in several semantic tasks. However, recent studies (Léchelle et al., 2018; Gashteovski et al., 2020) indicate that neural OpenIE systems produce more specific triples with additional information than conventional OpenIE systems and are harder to align with existing knowledge bases. Therefore, we focus on designing a neural OpenIE system that extracts compact triples.

Grid Labeling: Also known as table filling, grid labeling has been recently applied to entity relation extraction (Gupta et al., 2016; Wang et al., 2021) and open information extraction tasks (Kolluru et al., 2020b). However, these models map entities (constituents) and relations (subject, object) in a unified label space to capture the inter-dependency between them. (Zhong and Chen, 2020) shows that a pipelined approach for entity and relation extraction outperforms prior joint models that use the same encoder for the two sub-tasks. In this work, we validate this claim for the OpenIE task. Furthermore, we design a grid labeling schema that identifies constituents and their types, akin to entities in the entity relation extraction task.

9 Conclusion

In this work we extract compact triples from single sentences using an end-to-end pipelined approach, first extracting triple constituents using a novel table filling model and then determining relations between them with a classifier. Our method achieves excellent performance in producing exhaustive compact triples with high precision. We hope that COMPACTIE serves as a strong baseline and makes us re-think the value of all-at-once information extraction systems.

A Appendix

A.1 Benchmark Creation

The Algorithm 2 gives a high-level overview of our benchmark creation mechanism while a lot of details and difficulties have been omitted. The Benchmark Creation Algorithm extracts triples for each sentence using the Algorithm 1. The OpenIE system used to produce triples out of simple clauses is IMoJIE (Kolluru et al., 2020b).

The following example illustrates the benchmark creation algorithm. Given the sentence: *"The group reach a small shop, where the crocodile breaks through a wall"*, the algorithm first builds the sentence tree as shown in Figure 4. Then, starting from the root, *ExtractTriple* function traverses the tree until it reaches a child ("breaks") with no further clausal children. At this point, a clause for the subtree rooted at "breaks" is generated and fed into the IMoJIE system. IMoJIE extracts triple: (the crocodile; breaks; through a wall) out of this clause. Then, since both children of the root ("reach") are processed, the IMoJIE triple of the root's corresponding clause is extracted as (The rest of the group; reach; a small shop).

Algorithm 1: ExtractTriples

```
Data: Tree Node R
Result: Set of compact triples T
T = set() ;
for child in R.children do
    if child has no clausal child then
        T += IMoJIE(child.clause) ;
    end
    else
        T+= ExtractTriples(child) ;
    end
end
T += IMoJIE(R.clause) ;
return T
```

Algorithm 2: Benchmark Creation

```
Data: Sentence List S = [$s_1, s_2, .., s_n$]
Result: B benchmark of compact triples for
        sentences in S
B = set() ;
for sentence in S do
    root = build_sentence_tree(sentence) ;
    B += ExtractTriples(root) ;
end
return B
```

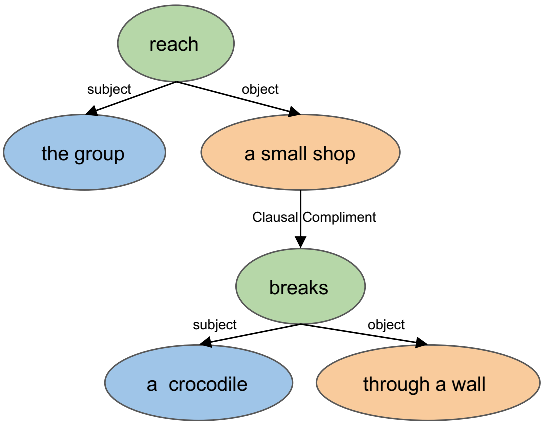

Figure 4: Sentence Tree for input sentence: *"The group reach a small shop, where the crocodile breaks through a wall"*.

A.2 Table Decoding

Following the (Wang et al., 2021) work, in the testing phase, we rely on the label probability tensor $\mathcal{P} \in \mathbb{R}^{|s|\times|s|\times|Y|}$ of the sentence s, to first extract constituent spans, and then predict the constituent type. Next, we describe the decoding procedure.

A.2.1 Constituent Span Detection

One important observation of the ground truth table is that a constituent's corresponding rows and columns are identical (e.g., row 2 and row 3 of Figure 2 are identical). Therefore, given the tensor $\mathcal{P}$, we compute the distance of adjacent rows (and columns). If the distance is larger than a predefined threshold α (which is set to 1.2), a split position is detected. This means that the two adjacent rows (columns) belong to different constituents or one belongs to a constituent while the other is not. Following the (Wang et al., 2021) work, we flatten the $\mathcal{P}$ tensor from both row and column perspectives and calculate the euclidean distance of adjacent rows and adjacent columns. Finally, we average these two distances as the final distance and compare the final distance to α to find the span of different constituents.

A.2.2 Constituent Type Detection

Given a constituent's span (i, j), we decode the constituent type $t^* \in Y$, where $Y = Y_c \cup Y_r \cup None$, according to its corresponding square symmetric about the diagonal:

$$t^* = argmax_{t\in\{Y_c \cup None\}} Avg(P_{i:j,i:j,t})$$

Spans with predicted type $t^* \in Y_c$ are regarded as constituents and passed to the constituent linking model.

CoSIm: Commonsense Reasoning for Counterfactual Scene Imagination

Hyounghun Kim[*] **Abhay Zala**[*] **Mohit Bansal**
UNC Chapel Hill
{hyounghk, aszala, mbansal}@cs.unc.edu

Abstract

As humans, we can modify our assumptions about a scene by imagining alternative objects or concepts in our minds. For example, we can easily anticipate the implications of the sun being overcast by rain clouds (e.g., the street will get wet) and accordingly prepare for that. In this paper, we introduce a new dataset called Commonsense Reasoning for **Co**unterfactual **S**cene **Im**agination (CoSIm) which is designed to evaluate the ability of AI systems to reason about scene change imagination. To be specific, in this multimodal task/dataset, models are given an image and an initial question-response pair about the image. Next, a counterfactual imagined scene change (in textual form) is applied, and the model has to predict the new response to the initial question based on this scene change. We collect 3.5K high-quality and challenging data instances, with each instance consisting of an image, a commonsense question with a response, a description of a counterfactual change, a new response to the question, and three distractor responses. Our dataset contains various complex scene change types (such as object addition/removal/state change, event description, environment change, etc.) that require models to imagine many different scenarios and reason about the changed scenes. We present a baseline model based on a vision-language Transformer (i.e., LXMERT) and ablation studies. Through human evaluation, we demonstrate a large human-model performance gap, suggesting room for promising future work on this challenging, counterfactual multimodal task.[1]

1 Introduction

Anticipating what would happen when there is a condition change in a situation is an important ability as it allows preparation for the implications of the change. For example, when swimming in the sea on a clear day, you might feel safe. However, if someone told you a storm warning has been issued and dark clouds are coming in soon, you would know that it is no longer safe to swim and return to land. It will be also very useful to have AI systems that could reason about the implications of such scenario changes and provide appropriate guidance/warnings; however, current AI systems will have a hard time performing such counterfactual commonsense reasoning.

Many efforts have been made to teach machines how to reason about images (Antol et al., 2015; Zhu et al., 2016; Johnson et al., 2017; Hudson and Manning, 2019) and videos (Tapaswi et al., 2016; Jang et al., 2017; Zhu et al., 2017; Lei et al., 2018). This area has been built upon further by efforts to teach machines to use commonsense knowledge when analyzing visual scenes (Pirsiavash et al., 2014; Wagner et al., 2018; Zellers et al., 2019; Park et al., 2020). Through these efforts, many AI systems have reached near human-level performance on scene understanding tasks. On the other hand, more complex reasoning on scene 'changes' has been less explored. Sampat et al. (2021) applies simple condition manipulations (e.g., *"Paint the small green ball with cyan color"*) on synthetic images in a visual question answering setup. However, this task is based on simple block objects that might not require complex implicit reasoning. Thus, complicated counterfactual commonsense reasoning on scene changes on real-world images and situations remains widely unexplored.

Therefore, in this paper, we introduce a new dataset called Commonsense Reasoning for **Co**unterfactual **S**cene **Im**agination (CoSIm) to evaluate the commonsense reasoning ability of agents about counterfactual visual scenes imagined via textual descriptions. To be specific, one data instance in our CoSIm dataset consists of an image, an initial question-response pair, an imagined

Question / Initial Response

Is the railway line safe?

Yes because there are safety lights and crosswalk signs

Change

add a train to the tracks.

Answer Choices

New Response: no. although there are safety lights and crossing gates, they don't appear to be working and there is a train coming.

Distractor #1: yes. there are safety lights and crossing gates, they appear to be working and there is a train coming and it will stop.

Distractor #2: yes. although there are safety lights and crossing gates, they don't appear to be working and there is no train coming.

Distractor #3: no. although there are safety lights and crossing gates, there is a power outage and there is a train coming.

Figure 1: Example from our CoSIm dataset. An image is associated with an initial commonsense question-response pair, a described counterfactual change to the image, and a new response to the question with three distractors.

visual scene change, and a new response with three distractors. The question is about commonsense which can be inferred from the image and the initial response includes a reasoning/justification for its answer. The imagined visual scene change is a textual description of what to modify in the scene to alter the conditions. The new response follows the same format as the initial response, but should be influenced by the imagined change (see Figure 1).

A model for this task needs to take this context information as input and try to predict the correct new response among other distractors. The distractors look similar to the correct new response but have subtle differences and are semantically different from the correct new response, thus a good model on this challenging new multimodal task cannot take shortcuts and needs to fully understand what each choice means based on the context. For example, as shown in Figure 1, given an image, the initial question-response pair (*"Is the railway line safe?"* - *"Yes because there are safety lights and crosswalk signs"*), and the scene change (*"add a train to the tracks."*), models should choose the correct new response (*"no. although there are safety lights and crossing gates, they don't appear to be working and there is a train coming."*) among other distractors (*"no. although there are safety lights and crossing gates, there is a power outage and there is a train coming."*, etc.). To solve this problem, models need to be able to understand the implications of an incoming train and how safety lights and gates operate at a railroad crossing.

We collect 3.5K high-quality and challenging data instances for this new multimodal reasoning task via a crowd-sourcing annotation platform. To collect each data instance and to help reduce individual crowd-worker load, we break the task up into three separate phases: the question collection phase, the scene change collection phase, and the distractor collection phase. During the distractor collection phase, to help avoid unexpected biases such as text-only, we implement a modified version of Human-And-Model-in-the-Loop Enabled Training (HAMLET) adversarial data collection (Nie et al., 2020) for the validation and test splits. We deploy the model trained on only the textual data and allow annotators to test their distractors against the model as they write (see Figure 2).

Our CoSIm dataset features several diverse types of imagined scene changes (object addition/removal, object state changes, etc.; see Sec. 5.2 for the full change type list and examples) which requires to deeply understand the contexts, making the task very challenging. For example, to understand the scene change of *"Add another person to the dock ..."*, the model should figure out what a dock is, where it is located in the image and be able to add one more person onto it via imagination.

As a baseline model for this new multimodal reasoning task, we employ a vision-language Transformer (based on LXMERT (Tan and Bansal, 2019)) which computes vision and language feature matching scores via multi-head self-attention layers followed by cross-modal attention layers, and we report ablation studies on input modality and scene change types. We also show a large human-model performance gap allowing more effective future work from the community on this new challenging multimodal task on commonsense reasoning for imagined counterfactual scene changes.

2 Related Work

Visual Question Answering. There have been many efforts to teach machines how to reason about images (Antol et al., 2015; Zhu et al., 2016; Johnson et al., 2017; Hudson and Manning, 2019) and videos (Tapaswi et al., 2016; Jang et al., 2017; Zhu et al., 2017; Lei et al., 2018), and in some of these tasks, machine performance is approaching human levels. Although these tasks require a complicated reasoning process, they provide very explicit context to solve the problems and might not be enough to evaluate the ability to reason about implicit aspects (i.e., commonsense).

Visual Commonsense Reasoning. Another actively explored line of study has been on visual commonsense reasoning (Pirsiavash et al., 2014; Wagner et al., 2018; Zellers et al., 2019; Park et al., 2020). In addition to using the provided clues in the context, these tasks require commonsense knowledge to reason about given problems, making these tasks more challenging since machines should be equipped with prior or external information. However, these tasks handle static scene understanding for which contexts and conditions are not changed during the reasoning process. On the other hand, our proposed CoSIm introduces an additional dimension of difficulty by integrating imagined scene changes in the context. Moreover, the changes in our CoSIm dataset are imagined (textually) and counterfactual, so imagination-based commonsense is required for the reasoning.

Textual Scene Change. Recent effort has been made on visual understanding by requiring mental simulation of changes to the scene (Sampat et al., 2021). These tasks require simulating change without any visible result, hence increasing the difficulty of VQA tasks. They, however, have been completed in the simpler context of basic shapes and objects and simple questions (E.g. *“How many blue objects will be present in this scene?”*). Our CoSIm dataset is based on complex real-world images/situations requiring commonsense reasoning about imagined counterfactual scene changes, allowing for evaluation of the ability to anticipate the implications of complex situation changes, thus, future events.

3 Task

Given a real-world image, models should predict a new response conditioned on the initial question-response pair and the imagined counterfactual scene change.

Initial Question and Response. The initial question-response pair is created only from a given image. The question and response themselves require quite an amount of commonsense reasoning to understand. For example, to understand the response to the question in Figure 1 (*“Is the railway line safe?”*), models should know that the *‘safety lights’* and *‘crosswalk signs’* are devised for keeping people safe around the railway (*“Yes because there are safety lights and crosswalk signs”*).

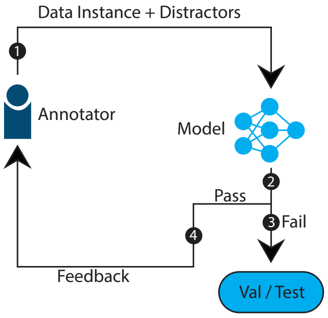

Figure 2: HAMLET cycle for distractor collection on validation and test splits.

Imagined Counterfactual Scene Change. The imagined counterfactual scene change is a textual description that modifies the scene in the image. The change affects the reasoning process of the initial question and response, and provides a new context for the new response (*“add a train to the tracks.”*).

Response on the Scene Change. Models should respond to the initial question with a proper reason based on the imagined counterfactual scene change.[2] The task is a multi-choice setup to pick the correct response among other distractors (*“no. although there are safety lights and crossing gates, they don’t appear to be working and there is a train coming.”*). To choose the correct response, models should understand what the implications and safety concerns of an incoming train are and that the safety lights should be turning on and the crossing gates should be closing when a train is in proximity.

4 Dataset

Our CoSIm dataset is composed of 3.5K[3] images paired with a commonsense question-response pair, a description of an imagined counterfactual change to the image, a new response to the question based on the effect of the described change, and then three distractor responses to the question (all text is in English).

---

[2] Models should derive scene knowledge from the image or clues embedded in the textual context like the initial response.

[3] Low resource setup of this middle-scale size dataset encourages employing effective external commonsense knowledge.

We employ annotators from the crowd-sourcing platform Amazon Mechanical Turk[4]. Our data collection is broken into three separate phases (question, change, and distractor) in order to reduce the workload for each worker. In the question phase, workers are asked to select an image (from three random images) to use, write a commonsense question and then respond to it. In the change phase, they are asked to describe a counterfactual scene change for the image and then write a new response to the initial question. Lastly, in the distractor phase, they are asked to write three distractor responses for the question.

Commonsense Question Collection. To collect the initial question and response, we present three images to the workers and then ask them to choose the one that they want to use (images are taken from Visual Genome (Krishna et al., 2017)). Then using that image, they should come up with a commonsense question about the image. We define a commonsense question as a question that requires logical thought and understanding of what is happening in the image to be able to answer. Then workers are asked to write a response to their question (the initial response). A response consists of two parts, an "answer" that is a direct answer to the question (e.g. *"Yes, ..."*) and then a "justification" that uses visual clues from the image to prove the answer is correct (e.g. *"..., because everyone is wearing shorts and short-sleeved shirts and a woman can be seen wearing sunglasses."*). See Appendix for the collection interface.

Counterfactual Scene Change Collection. In this phase, workers are given the image chosen from the previous commonsense question collection phase and the corresponding initial commonsense question-response pair. Then workers are asked to describe a counterfactual scene change for the image and write a new response to the question based on that scene change (the new response). To help ensure that workers describe a reasonable counterfactual scene change, we provide two guide templates for them to follow when they write. Workers are asked to select the guide template that they believe makes the most sense for them to use for each data instance (see Appendix for collection interface and guide template details).

Distractor Collection. Workers are given the image, the initial commonsense question-response pair, as well as the counterfactual scene change and new response. Then they are told to write three distractor responses that are similar to the new response but incorrect. To help ensure the distractors pose a challenge but are still distinct, we pre-fill the worker's textboxes with the new response. Then they are told to edit the text enough so the answers become false and distinct.

HAMLET Data Collection. To avoid having unexpected biases such as context+response bias in our textual data, when collecting distractors for the validation and test splits, we implement a HAMLET style collection (see Figure 2). We deploy the model trained only with textual data and allow workers to test their distractors directly against the model in real-time and check whether they are able to fool it. Workers are also permitted to edit the new response from the previous collection phase if it helps make distractor writing better (they must maintain the original meaning/intent of the new response if they choose to edit).

Data Verification. At each collection phase, we ask workers to verify the previous phase's work. If the previous set of work is not good, workers are given a place to flag and describe the reason for flagging. This reasoning is manually reviewed and if it is fair, then that data is removed and prevented from progressing to the next phase.

Worker Qualifications and Payment. For all 3 phases, workers are required to pass certain qualifications before they could begin. As all of the phases require reading and writing English, they were required to be from native English-speaking countries. Workers were also required to have at least 1,000 approvals from other tasks and a 95% or higher approval rating. Then for each phase, we require workers to pass a qualification test that tests their understanding of their task at each phase. See Appendix for worker totals and pay (+bonus) rates.

5 Data Analysis

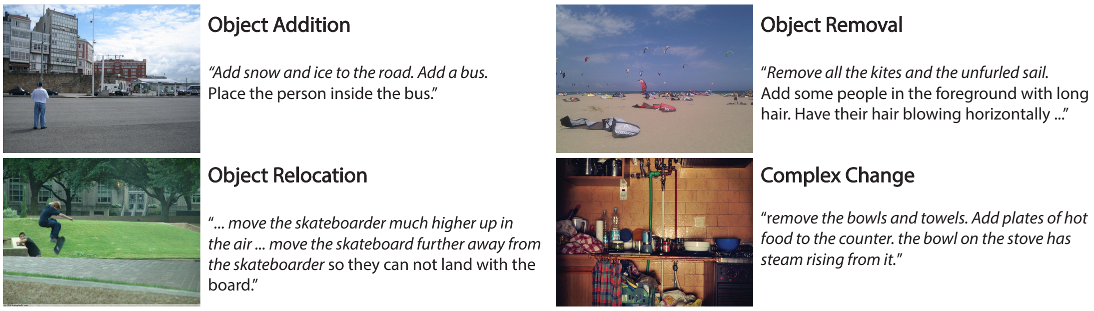
We collect 3.5K task instances (3.5K images, initial questions-response pairs, scene changes, new responses, and 10.5K distractors).

5.1 Statistics

Length. Lengths of each part of the data instances are shown in Table 1. While the lengths of questions are relatively short, the lengths of responses and the changes are long. This means that question

---

[4] https://www.mturk.com



Object Addition

"Add snow and ice to the road. Add a bus. Place the person inside the bus."

Object Removal

"Remove all the kites and the unfurled sail. Add some people in the foreground with long hair. Have their hair blowing horizontally ..."

Object Relocation

"... move the skateboarder much higher up in the air ... move the skateboard further away from the skateboarder so they can not land with the board."

Complex Change

"remove the bowls and towels. Add plates of hot food to the counter. the bowl on the stove has steam rising from it."

Figure 3: Scene change examples from our CoSIm dataset. The relevant portions of the change are in italics. Complex changes contain three or more changes within them (this example contains Object Removal, Object Addition, Object State Change).

Component	max.	min.	avg.	sd.
Question	22	3	7.6	3.03
Initial Response	59	4	18.62	8.06
Scene Change	127	3	16.08	13.01
New Response	109	5	23.38	12.40
Distractor	111	5	23.57	12.40

Table 1: In our CoSIm dataset, each part has a different length according to its role and contained information.

Number of changes present	Frequency
1	34.70%
2	35.82%
3	21.39%
Greater than 3	8.08%

Table 2: Frequency of number of change types present per instance (from the validation split).

itself does not contain detailed clues and models should figure out which information is needed to answer the question. On the other hand, the long responses contain reasons to justify their answers and require models to deeply understand the reasoning process to solve the problem. Furthermore, models should also carefully read the long textual scene change to capture all the condition modifications and apply them to images.

Vocabulary. Among all data instances in our CoSIm dataset, there are 9,946 total unique words. Within the commonsense questions, initial responses, scene changes, new responses, and the distractors, there are 3,261 / 4,397 / 4,637 / 5,318 / 6,404 unique words, respectively. The unique word count reflects what is shown by the lengths. Questions are on average the shortest part of each data instance and they have the fewest unique words. The new responses and distractors have long lengths and high unique word counts. The high unique word count for the distractors shows their diversity. Figure 4 shows the most commonly occurring keywords in our dataset. Many of the words are related to people and directional positioning.

5.2 Scene Change Type.

Different imagined scene change types are present in our CoSIm dataset. Imagined scenes changes describe a change (with counterfactual thought) to the image by applying various properties. Some of these scene change types include object addition/removal, object state changes, environment changes, etc. (see Figure 3 for some scene change types and their examples; see Appendix for a figure with a complete list of all the types with examples). These scene change types, while they are seemingly easy to visualize, require a complex understanding of the effect of the change on other elements in the scene. See Figure 5 for type frequencies.

Human/Object Addition. These two scene change types involve introducing new human(s)/object(s) into the image that was not there prior (*"A bunch of old men are standing next to the birds ..."* / *"There are tears in his eyes ..."*). The object addition scene change type is the most commonly appearing one.

Human/Object Removal. These two scene change types involve removing human(s)/object(s) that are visible in the image (*"... remove the workers ..."* / *"Remove the two people's coats"*).

Object Replacement. This scene change type involves removing object(s) from the image and replacing them with something else (*"... replace the plates of fruit by plates of dog biscuits ..."*).

Object Relocation. This scene change type involves re-positioning object(s). Rather than changing it directly, this type changes its relation to other objects (*"space the zebras out. move them a little*

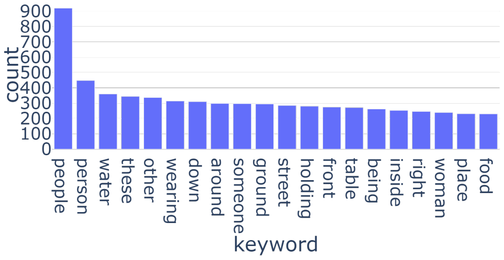


Figure 4: Most commonly occurring keywords in our CoSIm dataset. Many of them are related to people and directional positioning.

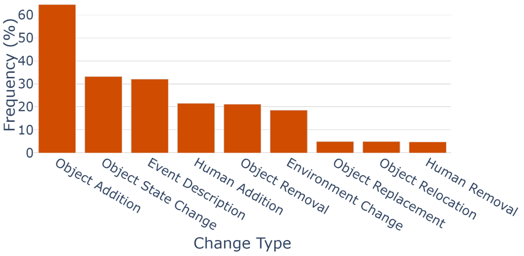

Figure 5: Frequencies of the change types in our CoSIm dataset (from the validation split).

further away”).

Object State Change. This scene change type involves altering the state of object(s) present in the image (*“... change her luggage to all have a Burberry pattern ...”*). The alteration of object(s) can occur in various forms such as changing color, size, shape, and orientation (e.g., opening a door).

Event Description. This scene change type involves the creation of an event or a description of motion or interaction between objects in the image. This type includes human actions and changes to human emotions (*“A pack of lions are approaching the sheep.”*).

Environment Change. This scene change type involves changes that cause large-scale changes to the entire environment either by drastically altering the current environment, creating a new environment, or causing changes in the weather (*“there is very thick dust everywhere”*).

Complex Changes. We define a complex change as a change that contains three or more different scene change types. For example, *“someone is throwing snow ball at her”* this change introduces a new human, a new object, and defines an interaction between all these and involves someone already present in the image. These complex changes require much thought to understand their full effect and implications. Complex changes make up about 30% of our dataset. See Table 2 for change types per instance statistics.

6 Models

We employ a vision-language Transformer as the base architecture of our baseline model for the CoSIm task. To be specific, we use LXMERT (Tan and Bansal, 2019) to compute the score of each context-response pair given an image feature, and select one with the highest score among them.

We employ Faster R-CNN (Ren et al., 2015) to extract object-level visual features $O = \{o_1, o_2, ..., o_{N_O}\}$ and bound boxes $B = \{b_1, b_2, ..., b_{N_O}\}$ from an image I, where N_O is the number of detected object features. For textual feature encoding we use BERT (Devlin et al., 2019) as it is used in LXMERT. We concatenate all the textual data, i.e., question $Q = \{q_1, ..., q_{N_Q}\}$, initial response $R_i = \{r_{i1}, ..., r_{iN_{R_i}}\}$, scene change $C = \{c_1, ..., c_{N_C}\}$, and new response $R_n = \{r_{n1}, ..., r_{nN_{R_n}}\}$ along with [CLS] and [SEP] tokens to create a sequence $W = \{[\text{CLS}], Q, [\text{SEP}], R_i, [\text{SEP}], C, [\text{SEP}], R_n, [\text{SEP}]\}$ where N_Q, N_{R_i}, N_C, and N_{R_n} are the lengths of question, initial response, scene change, and new response, respectively.

$$O, B = \text{FRCNN}(I) \tag{1}$$

$$\hat{O} = \text{Linear}_O([[\text{V-Tok}_O]; O]_{\text{dim=t}}) \tag{2}$$

$$\hat{B} = \text{Linear}_B([[\text{V-Tok}_B]; B]_{\text{dim=t}}) \tag{3}$$

$$\hat{V} = \text{Linear}_{OB}([\hat{O}; \hat{B}]_{\text{dim=f}}) \tag{4}$$

$$L = \text{Emb}(W), \quad \hat{L} = \text{TF}_L(L) \tag{5}$$

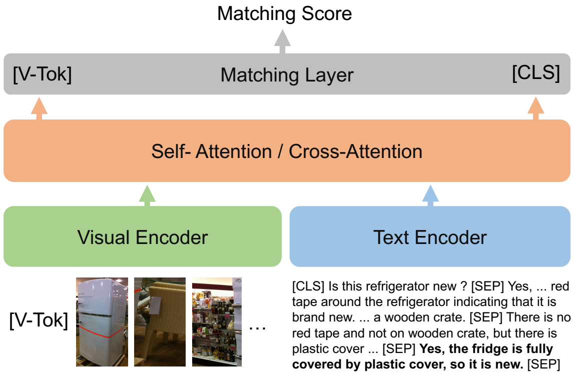
where Linear_O, Linear_B, and Linear_{OB} are linear layers. $[\text{V-Tok}_O]$ and $[\text{V-Tok}_B]$ are visual token attached to object and bounding box sequences (like [CLS] for a language sequence), respectively, and $[;]_{\text{dim=t}}$ is concatenation operation along the token-dimension and $[;]_{\text{dim=f}}$ is along feature-dimension. TF_L is a language Transformer (Vaswani et al., 2017) which consists of self-attention layers. The ith attention head in the lth layer $a_{i,l}$ is computed this way:

$$a_{i,l} = \text{Softmax}(\frac{QK^\top}{\sqrt{d_h}})V \tag{6}$$

$$Q = W_l^q H_{l-1},\ K = W_l^k H_{l-1},\ V = W_l^v H_{l-1} \tag{7}$$

$$H_l = [a_{0,l}; a_{1,l}; ...; a_{N_A,l}] \tag{8}$$

where W_l^q, W_l^k, and W_l^v are trainable parameters, N_A is the number of attention head, and d_h is the



[CLS] Is this refrigerator new ? [SEP] Yes, ... red tape around the refrigerator indicating that it is brand new. ... a wooden crate. [SEP] There is no red tape and not on wooden crate, but there is plastic cover ... [SEP] **Yes, the fridge is fully covered by plastic cover, so it is new.** [SEP]

Figure 6: The full model computes the matching scores between [V-Tok] token feature and each [CLS] token feature of the response candidates (a ground-truth response and three distractors), and selects the highest one as a final prediction.

dimension of each attention head. Then, $\hat{V}$ and $\hat{L}$ are fed to the cross-attention layers: $\bar{V}, \bar{L} = \text{TF}_X(\hat{V}, \hat{L})$, where TF_X is cross-attention layers of vision and language Transformer which consists of self-attention layers as well as cross-attention layers. Scores are computed between visual feature and each of the 4 language features (1 ground-truth and 3 distractors) pair: $s_k = \text{Linear}(\bar{V}_0 * \bar{L}_{k,0})$, where $*$ is the element-wise product, $\hat{V}_0$ is the visual token (i.e., [V-Tok]) that is attached in the input layer, and $\hat{L}_{k,0}$ is the first token (i.e., [CLS]) of k-th language feature. The model compares the 4 scores to select the pair with the highest score as the final answer. The loss is computed by cross-entropy: $\mathcal{L} = -\sum_j^N \log p(s_j^*)$, where s_j^* is a score for the ground-truth pair.

7 Experiments

Data Splits. We split the dataset into 1,924/800/800 (train/val/test).

Training Details. We use 768 as the hidden size and use Adam (Kingma and Ba, 2015) as the optimizer, setting the learning rate to 1×10^{-5}. See Appendix for more details.

Human Upper Bound Evaluation Setup. We conduct a human evaluation of our CoSIm task to estimate the upper bound that models can reach. We take 50 samples from the validation split and ask two experts to complete the task and average their scores.

Scene Change Types. We collect the type of the Scene Change for the validation set. Two experts are shown each change and then asked to label it into one or more types. See Figure 5 for the change types.

	Model	Accuracy (%)	
		Val	Test
1	Response-Only	38.37	-
2	TC-Response	44.62	-
3	Full (Image-TC-Response)	49.25	40.87
4	Human	98	-

Table 3: Model results. Human performance is quite high, showing large room for model improvement (TC: Textual Context). We only include the test performance for the full final model based on standard practice of not reporting ablations on test split.

	Scene Change Type	Accuracy (%)
1	Object Addition	46.41
2	Object Removal	37.87
3	Object Replacement	43.59
4	Object Relocation	48.72
5	Object State Change	51.70
6	Human Addition	56.40
7	Human Removal	42.10
8	Environment Change	52.70
9	Event Description	51.56

Table 4: Model performance on different change types. While the model generally shows balanced scores over all scene change types, the performance on removal types seems to be lower than addition types.

Multi-Task / Contrastive Learning. To exploit extra commonsense reasoning information, we explore multi-task learning (MTL) with a large-scaled visual commonsense reasoning dataset, VCR (Zellers et al., 2019) dataset through alternating mini-batch training. In one mini-batch, the model is trained on our CoSIm dataset, and in the next, the model is trained on the VCR dataset, and so on. Also, we try contrastive learning to explore potential improvement. Specifically, we compute matching scores between each visual token and [CLS] token of each ground truth text feature in a mini-batch, and compute contrastive loss.

8 Results

Modality Ablation. We build models with different input modalities and conduct an ablation study. As shown in Table 3, the Response-Only model (which only takes the new response/distractors as input) does not do well (row 1). The TC-Response model (which takes all text data as input) obtains a better score than the Response-Only model (row 1 and 2), but still performs poorly. The Full model (which takes the full image and text data as input) does best (row 3), meaning models need all the

Number of Scene Change Types	Accuracy (%)
1	52.35
2	46.34
3 or more	49.15

Table 5: Model performance on different numbers of change types, showing instances with single scene change type are relatively easier.

	Model	Accuracy (%)
1	MTL with VCR	47.37
2	Contrastive Learning	49.50

Table 6: Model performance on multi-task and contrastive learning approaches.

visual and textual input to perform reasonably.[5,6]

Human Evaluation. We conduct a human evaluation to check the upper performance bound for the CoSIm task. As shown in row 4 of Table 3, the score is quite high[7], indicating a large room for improvement from future work.

Scene Change Types. As shown Table 4, our model shows balanced scores over all scene change types in general, however, comparing the addition and removal types (row 1 and 2 for object, row 6 and 7 for human), the performance on removal types is lower than addition types. That is possibly because removing something from an image might be harder to imagine.

Number of Scene Change Types. As shown Table 5, instances with a single scene change type seem to be relatively easier to address than ones with multiple scene change types. This might imply that multiple scene changes make the reasoning process more complex and challenging.

Multi-Task / Contrastive Learning. As shown in row 1 of Table 6, multi-task training with VCR does not seem to help improve performance on our CoSIm dataset, implying our dataset is challenging to address and requires a more complex reasoning process. The performance of the contrastive learning (row 2) is also very close to the Full model's (row 3 in Table 3), meaning more advanced approaches might be needed to tackle our CoSIm dataset/task.

Q: Is it a good place for a beginner to learn to snowboard?

IR: No, because it is really crowded and there is not much space to practice.

CH: It is not crowded, but it has very steep slopes.

Model choice: no, because it has very precipitous slopes and it is not safe for new learners.

Q: Is it safe to swim here?

IR: No, it is a pier with lots of boats in and out, so it wouldn't be safe to swim.

CH: there are not a lot of boats, but there is a shark

Model choice: no, there is a shark in the boat.

Figure 7: Model output examples (Q: question, IR: initial response, CH: scene change).

Output Examples. As shown in the upper example of Figure 7, our model predicts the correct response by understanding the implication of *"steep slopes"* in the change. In the bottom example, our model fails to understand that *"there is a shark"* must mean the shark is in the water (as sharks live in the water), and choose a wrong response. We also split changes into sub-parts and compute scores for each part to see on which part the model focuses to answer questions. As shown in Figure 8, the model looks at *"Add labels to the spines of all the books"* to choose the answer.

9 Conclusion

We introduced a challenging counterfactual commonsense reasoning task/dataset called CoSIm which features imagined counterfactual scene changes requiring models to imagine the changed

---

[5] The standard deviation of the Full model's scores on validation split is 1.52

[6] The average length difference between the predicted responses and the rest is 0.0075 words, and the ground-truth response indices are randomly assigned, thus there is no bias based on the response length and index.

[7] Inter-annotator agreement (kappa) is 0.9461, which indicates nearly perfect agreement.

Q: Are the books for sale?

IR: Yes, as you can see the books are organized by names and authors on the shelves for the customers.

CH: Add a trolley in the foreground with many books replaced on it. Add labels to the spines of all the books.

Answer: It seems from the trolley that this is a library. the books on display are probable for reading and maybe to be borrowed but they are likely not for sale.

Figure 8: The model focuses on a crucial part in the scene change to properly select the answer.

situation to answer questions. We collected 3.5K high-quality instances that consist of an image, an initial question-response pair on the image, an imagined scene change, and a new response (with three distractors). The scene changes have different challenging types (such as object addition/removal/replacement, environment change, etc.). We presented a baseline model as a starting point with useful ablation studies and showed a large human-model performance gap allowing useful future works.

A Data Collection

We implement different interfaces for our data collection. The commonsense question collection interface allows for workers to choose which image they would like to use when making the question, as well as an object to focus on (Figure 9). The counterfactual scene change collection and the distractor collection interfaces (Figure 10 and Figure 11) feature a verification checkbox. Workers can check the box if the quality of the data from the previous phase is poor. If it is flagged, the reason is reviewed.[8] If the reasoning is valid, the instance is removed from the dataset/no longer progressed through the collection phases.

A.1 Counterfactual Change Collection templates

The first guide template is “Keep A, Flip B” and the second is “Flip A, Keep B” (where ‘A’ means answer and ‘B’ means justification). For “Keep A, Flip B”, workers are told to describe a change that results in the “answer” part of initial response to be the same, but with a different “justification” part (E.g. *“yes because people are wearing jackets and winter clothes.”* → *“yes because you can see some snow ...”*). In the change they write, they should negate/remove the “justification” part of initial response and add something that could be used for a new “justification”. For “Flip A, Keep B”, workers are told to describe a change that results in the opposite “answer”. The change should also modify the context so that the initial response “justification” part is true, but is no longer valid in proving the answer and a new “justification” part is needed. (e.g., *“no, as you can see the man is not soaking wet.”* → *“yes, the man isn’t wet and he is under a structure, however ...”*).[9]

A.2 Worker Totals and Payment

We had a total of 182, 97, 194 workers pass testing for question collection, change collection, distractor collection, respectively. For the question collection phase and the change collection phase, workers are paid 0.35 USD per instance they complete (each takes about 2 minutes). As the distractor collection phase is faster and easier, workers are paid 0.30 USD per instance (takes around 1.5 minutes). In all three phases, an additional bonus of 0.02 USD is given for each high-quality instance they completed, and then for every subsequent group of 25 high-quality instances completed, the bonus per instance is increased by 0.01 USD (0.02 USD bonus per instance for the first 25, 0.03 USD bonus

---

[8] Once the flag is checked, workers are provided with a textbox where they can explain their reasoning for flagging it.

[9] The proportions of “Keep A, Flip B” and “Flip A, Keep B” are 42.93% and 57.07%, respectively.

for the next 25, 0.04 USD bonus for the next 25, and so on). Since there is no limit on how much a worker can write, they can keep stacking the bonus as much as they want. All the payments are at a reasonable hourly rate of 11-12 USD.

B Scene Change Types

The scene change types, while they are seemingly easy to visualize, require a complex understanding of what effect the change has on other elements in the scene. The Object Addition scene change type (the most commonly occurring one) involves introducing new object(s) into the image that was not there prior. The Object State Change scene change type involves altering the state of object(s) present in the image. The alteration of object(s) can take place in various forms such as changing color, size, shape, and orientation (e.g., opening a door). The Event Description scene change type involves the creation of an event or a description of motion or interaction between objects in the image. Please see Figure 12 for the full list of the scene change types and examples.

C Training Details (Reproducibility)

All the model experiments are conducted on a Ubuntu 16.04 system using the NVIDIA GeForce GTX 1080 Ti GPU and Intel Xeon CPU E5-2630. We employ PyTorch1.4 (Paszke et al., 2017) to build our models. We run models up to 50 epochs (each epoch takes around 8 mins) and choose the best ones based on the validation split evaluation. We use 768 as the hidden size and use Adam (Kingma and Ba, 2015) as the optimizer, setting the learning rate to 1×10^{-5}. We initialize the language layer with the pretrained BERT weights and cross-attention layers with the pretrained LXMERT weights. We use 1234/2345/3456 as the random seed values. The number of trainable parameters of our full model is 173M. We employ accuracy as the evaluation metric. We use manual hyperparameter tuning (e.g, learning-rate=$\{1 \times 10^{-3}, ..., 1 \times 10^{-6}\}$, num-of-cross-layer=$\{1, 2, ..., 5\}$, batch-size=$\{2,4,6,8\}$, etc.) based on validation scores. We use the implementation of Yang et al. (2017) for the Faster R-CNN (Ren et al., 2015) model. The evaluation splits of our CoSIm dataset are not overlapped with the training split of the Faster R-CNN.

D Potential Risk

Potential models trained on our dataset may learn misleading information accidentally and create unsafe suggestions; therefore, careful use is required when deploying models in a real-world application.

Abstract

Article prediction is a task that has long defied accurate linguistic description. As such, this task is ideally suited to evaluate models on their ability to emulate native-speaker *intuition*. To this end, we compare the performance of native English speakers and pre-trained models on the task of article prediction set up as a three way choice (a/an, the, zero). Our experiments with BERT show that BERT outperforms humans on this task across all articles. In particular, BERT is far superior to humans at detecting the zero article, possibly because we insert them using rules that the deep neural model can easily pick up. More interestingly, we find that BERT tends to agree more with annotators than with the corpus when inter-annotator agreement is high but switches to agreeing more with the corpus as inter-annotator agreement drops. We contend that this alignment with annotators, despite being trained on the corpus, suggests that BERT is not memorising article use, but captures a high level generalisation of article use akin to human intuition.

1 Introduction and Motivation

Pre-trained models, such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019) and more recently T5 (Raffel et al., 2020), are the state of the art across several tasks in computational linguistics. In addition, transformer-based models are known to have access to information as varied as part of speech information (Chrupała and Alishahi, 2019; Tenney et al., 2019b), parse trees (Hewitt and Manning, 2019), the NLP pipeline (Tenney et al., 2019a), and constructional information (Tayyar Madabushi et al., 2020). These models tend to perform so well that, on certain tasks, they outperform human baselines (Zhang et al., 2020).

In this work, we investigate how well language models, specifically BERT Large, perform on the linguistically interesting task of article prediction. English article prediction, further discussed in Section 2, is a phenomenon that native speakers of English find almost trivial. At the same time, linguists find it particularly difficult to formulate the rules that would govern article usage: article use cannot be captured by local co-occurrence but is dependent on the wider context and often there is no one "right" article, but multiple options are possible, albeit with slight differences in the meaning conveyed. Grammar correction systems prior to BERT struggled to reach acceptable levels of performance on article selection (detailed in Section 2). As we will show, BERT shows performance on this task that is superior to that of humans. Given this, it is interesting to investigate how BERT attains this level of accuracy and what the implications are for the system: does BERT manage to go beyond the local vicinity into the larger context to track the referent?

The current study compares the performance of transformer-based pre-trained models and humans in an attempt to explore how language models handle an, in essence, *creative* task, with an emphasis on how model performance changes with inter-annotator agreement. We also explicitly incorporate the plural indefinite or zero (Ø) article (detailed in Section 2) as in the sentence *There are Ø merchant bankers who find it convenient to stir up Ø apprehension with a view to drumming up Ø business for themselves.*

The flexibility that is inherent in article usage requires us to explore methods of evaluation that do not rely solely on accuracy. While the shortcomings of relying too heavily on accuracy based metrics have been highlighted in prior work (see Section 3), these difficulties are accentuated by the presence of flexibility. Clearly, there is little need to require a model to output one specific class if people are comfortable with multiple options. As such, we evaluate performance based on the

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 924 - 931
July 10-15, 2022 ©2022 Association for Computational Linguistics

Matthews correlation coefficient between human annotators and model outputs *at each different level of inter-annotator agreement*.

To this end, this works aims to answer the following questions: a) How well do language models perform on a task that humans rely on intuition rather than deliberate reasoning, specifically article prediction, and b) how does this performance vary with increased flexibility in the article that can be used, as measured by inter-annotator agreement. So as to ensure reproducibility and to aid future research in this direction, we make our scripts freely available and our dataset, built from the British National Corpus (BNC) (BNC Consortium, 2007), available under the required licence[1]. Further details on the BNC are presented in Appendix A.

2 The English Article System

There are three articles in English: a) the definite article, *the*, b) the indefinite article, *a/an*, and c) the absence of an article or the *zero (Ø) article* (Swan and Walter, 1997).

There have been several sets of guidelines for the use of articles starting with the early works by Huebner (1983, 1985); Thomas (1989). The most general ones rely on a few parameters only, such as Hearer Knowledge (whether the interlocutor can be considered to be able to identify the referent) and Referent Specificity (whether a specific referent is identified), augmented with Number and Countability, while the more specific ones offer numerous semantic types and subtypes, bordering on the idiosyncratic; see work by Swan and Walter (1997) for an overview. Although none of these variables, individually or in conjunction, can accurately predict article usage, recent work on the classification of a large, manually annotated sample has found that a hierarchical ordering of these same parameters, with Hearer Knowledge at the top, predicts article usage correctly in 93 percent of all cases that allow variation (about 15% of all instances can be considered a set phrase in that only one article can be used, e.g., “one at a time” (Divjak et al., 2022).

However, deciding whether the interlocutor can be considered as able to identify the referent involves world knowledge, including cultural knowledge; although both Sheffield and Birmingham are home to many universities, when we refer to *the University of Sheffield/Birmingham* we have one particular one in mind, which our interlocutor only knows if they are familiar with the local landscape. In addition, article usage appears to be a matter of what cognitive linguists would call *construal*, or the freedom to present a situation linguistically in different ways. Analysing 3 alternative forced-choice data from 181 native speakers of English who were asked to insert articles that had been removed from longer (200-300 words) texts, (Romain et al., 2022) relied on Entropy to quantify the restrictiveness of the context and to identify types of contexts in which choice is allowed versus inhibited. They found that some contextual properties, such as Referent Specificity, are rather restrictive, leaving the speaker with little choice in terms of which article to use while other contextual properties, such as Hearer Knowledge, are such that several articles are possible, albeit with slightly different semantic implications In other words, only in situations where the referent is specific do native speakers tend to converge on the same article.

The English article system thus finds itself in the awkward position of its strongest predictor being open to interpretation. The freedom regarding the interpretation of the top predictor, and the semantic differences it entails, is possibly why second language learners whose first language does not include an article system find the article system notoriously difficult to master. The same can be expected to apply to computational systems who tend to struggle to capture fine-grained meaning nuances, even though they have acquired world knowledge.

3 Related Work

Automatic article prediction has been the focus of study for several decades starting with rule based systems, aimed at improving machine translation (Murata, 1993; Bond et al., 1994). Subsequent machine learning models for article prediction included work by Knight and Chander (1994), who use decision trees and Han et al. (2006), who use a maximum entropy classifier to select among a/an, the, or the zero article.

Article prediction was then clubbed with similar phenomena, such as prepositions and noun numbers, to be included as part of shared tasks on Grammatical Error Correction at CoNLL-2013 (Ng et al., 2013) and CoNLL-2014 (Ng et al., 2014). These shared tasks, and their associated datasets, signifi-

---

[1] https://github.com/H-TayyarMadabushi/Abstraction-not-Memory-BERT-and-the-English-Article-System-NAACL-2022

cantly increased interest in article prediction albeit as part of the broader problem of grammatical error correction. More recent methods, such as work by Lichtarge et al. (2020), make use of advances in neural machine translation for grammatical error correction. For an up-to-date and extensive handling of grammatical error correction, including article prediction, we direct readers to the tutorial by Grundkiewicz et al. (2020).

Of relevance to the second question we aim to answer, that of how annotator agreement affects model performance, is the work by Lee et al. (2009), who study the various factors that influence the level of human agreement. Additionally, Ribeiro et al. (2020) show that state-of-the-art models are better evaluated using a checklist as opposed to traditional metrics, a notion that we supplement in our experimental procedure (Section 4).

4 Methodology

As mentioned in Section 1, our goal is to understand how language models do on the task of article prediction and how their performance varies with inter-annotator agreement. Our overall methodology for answering these questions involved the following steps:

1. We start by explicitly adding the null article (Ø) to the British National Corpus (BNC).
2. We then set up the task of classifying articles as a token classification (sequence to sequence) task and train a (BERT Base) model. We use 150,000 examples as the training set.
3. Using the results of this model, we construct a set of around 2,500 examples, about 30% of which are selected to be incorrectly tagged by BERT Base. This is to ensure that the evaluation set contains examples from different levels of difficulty. These 2,500 examples are annotated by paid annotators, thus providing us with an evaluation set.
4. We compare the performance of human annotators to that of BERT Large, trained on the training set of 150,000 examples from the BNC.

These results are presented in Section 5 along with an analysis. The following sections detail the steps listed above.

4.1 Data Preparation and Zero article Tagging

Table 1 provides examples of when the zero article is used and we include the scripts used to add zero articles to sentences in the code released with this work.

Referent Specificity	**Noun Count**	**Example**
Not Specific, known to the hearer	Uncountable	Ø Pasta is an Italian commodity.
	Plural	Ø Tigers are magnificent animals.
Not specific, not known to the hearer	Uncountable	Can I order Ø rice?
	Plural	I would like Ø better shoes.
Specific, not known to the hearer	Uncountable	Ø Soup was served with the meal.
	Plural	Ø Engineers were called to the scene.

Table 1: Examples of some occurrences of the *zero article*, also known as the *plural indefinite article*.

All training and evaluation examples are created to consist of three sentences: the target sentence with one article blanked out and one preceding and one succeeding sentence with no words blanked out. We provide context to ensure that there is sufficient information available to correctly predict an article. Example 1, illustrates one element of the data used.

(1) It is a local landmark which received ø national and international recognition and helped turn the tide against the thoughtless demolition of the Sixties. Still with Booth Shaw, Denison produced _______ radical proposal for ø flats for ø single people in the heart of the city centre. The site was a rambling and derelict pub, the Royal Hotel, which was originally a Georgian coaching inn.

4.2 Model Selection and Training

Although masked language modelling, which involves "filling in the blanks" is most similar to the task at hand, the introduction of the zero article makes this impractical as pre-trained models are not trained on the zero article. Given these limitations we model this as a sequence to sequence task where, as is typical of, the output sequence is required to consist of the token 'A', 'The' or 'Zero' based on the corresponding article, or the token 'O' otherwise. As such, the model makes a prediction associated with *every* input token, not just the one that is masked.

Based on initial experimentation with different models and hyperparameters (i.e., manual tuning), we settled on the use of BERT fine-tuned on a training set consisting of 150,000 examples for one epoch, based on model performance on a development set (consisting of 30,000 examples). More epochs quickly lead to overfitting. RoBERTa (trained for 6 epochs), despite being considered a more optimised version of BERT, surprisingly does not perform as well as BERT.

We first use BERT Base, trained on 150,000 examples for 1 epoch, to predict all articles in the target (central) sentence. Based on this initial classification we pick 2,500 examples for manual tagging, such that approximately 30% of the examples were incorrectly tagged by BERT Base. We perform this additional step to ensure that we pick some examples that are 'difficult', as determined by BERT Base's inability to get them right. Finally, BERT Large trained on the same set of examples, is used to predict the articles presented to human annotators. In both cases, we use the models implemented by Wolf et al. (2020). These results and an analysis are presented in Section 5. Model and hyperparameters are presented in Appendix B.

4.3 Human Annotation

Manual annotation took the format of an online survey modelled after a cloze test. Participants were presented with individual examples consisting of three sentences each, wherein the central sentence had exactly one article omitted and replaced with a blank space, as illustrated in Example 1 above. Participants were required to select which article had been omitted from a multiple-choice list that was presented below the sentences.

A total of 2500 sentences were tagged, with each participant tagging 160 randomly selected items. The aim was for each sentence to be tagged by five different participants. Further details on the process including instructions, recruitment, payment and approvals are provided in Appendix C.

5 Empirical Evaluation and Discussion

The results presented in this section were obtained by evaluating BERT_L on the same gap filling exercise that was presented to humans. BERT_L was fine-tuned 5 times on 150,000 training examples and evaluated on a development set which, like the training set, was extracted from the corpus and not human annotated. The training data used consisted of 150,000 examples, of which about 135,000 were "the", 60,000 "a" and 146,000 "zero". The development set consisted of 30,000 examples, of which about 25,000 were "the", 12,000 were "'a" and 25,000 were "zero".

The best performing run on this development set was used for the human annotated test set. Of the 2,500 examples picked for manual annotation, 2,383 were annotated by the required five annotators and this subset was used for evaluation. This evaluation set consists of about 1200 sentences that were annotated by the majority of annotators with "the", 500 with "a", and about 550 with "zero". A further 108 sentences had multiple labels receiving the same number of votes and were thus tied. The complete evaluation set consists of about 150,000 tokens.

		The	**A/An**	**Zero (Ø)**
All Data (2384)	BERT_L vs 4 Human	0.580	0.659	0.589
	BERT_L vs Corpus	0.631	0.658	0.731
	4 Human vs Corpus	0.553	0.589	0.590
	BERT_L vs Control	0.488	0.573	0.514
	4 Human vs Control	0.490	0.578	0.515
	Corpus vs Control	0.440	0.519	0.501

Table 2: Phi coefficient (ϕ) of correlation between four human annotators (4 Human), BERT Large, a fifth annotator used as a human baseline (Control) and the corpus presented by each article. Number of examples in parenthesis.

Tables 2 and 3 present the Phi coefficients (Matthews Correlation Coefficient) between four human annotators (4 Human), different models, a fifth human used as a control (Control) and the corpus. Table 2 presents the Phi coefficients across all of the data. Each block in Table 3 presents Phi correlations between subsets of examples on which either the 4 annotators completely agree (4 agree), exactly three agree (3 agree), or on those examples on which two agreed. In instances other than where all data (Table 2) is presented, we exclude from our analysis those examples where there is a tie between different articles. Importantly, this results in a different number of examples at each level of agreement presented above (example counts listed in parenthesis). Finally, the last three rows in each block, which provide the correlations with the fifth annotator, provide a baseline or control for comparison.

Across all data, BERT_L has a higher correlation with the corpus (BERT_L vs Corpus) than do the four human annotators (Corpus vs 4 Human) across all articles. While this can be ascribed to the fact that BERT was fine-tuned on a fairly large training set of 150,000 examples, BERT Large also has a higher correlation with the four annotators ($\mathrm{BERT_L}$ vs 4 Human) than they do with the corpus (4 Human vs Corpus) across all but one of the articles on which it misses out by an insignificant margin.

		The	**A/An**	**Zero (Ø)**
4 Agree (984)	$\mathrm{BERT_L}$ vs 4 Human	0.810	0.869	0.792
	$\mathrm{BERT_L}$ vs Corpus	0.738	0.777	0.755
	4 Human vs Corpus	0.787	0.822	0.767

	Corpus vs Control	0.295	0.334	0.200

Table 3: Phi coefficients (ϕ) at different levels of inter-annotator agreement. See text for details.

Although BERT has a high correlation with the corpus across all data, a fine-grained analysis based on the possible level of flexibility in article use, as determined by inter-annotator agreement (Table 3), shows that this is not always the cast. Surprisingly, when there is least flexibility (i.e. when all four annotators agree) BERT agrees more with human annotators than with the corpus. In fact, in this case ('4 Agree' in Table 3) the agreement between BERT and the four annotators is higher than between any other pair. Also interesting is the fact that BERT switches back to being more highly correlated with the corpus when there is any possibility of flexibility (i.e. inter-annotator agreement is not perfect). This is contrary to what we expect as BERT is trained on the corpus and as such we expect to see a higher correlation between BERT and the corpus across all cases. *This behaviour suggest that BERT seems to have access to a high level generalised representation of article use that cannot be ascribed to memory.*

BERT also has a significantly higher correlation with the corpus on the null article than do either the four human annotators or the fifth control annotator except in the case where there is complete agreement between the four annotators (4 Agree). We believe that this is a result of the fact that we insert the null article using a fixed set of rules that deep neural models can easily pick up. Human annotators, on the other hand, seem to find it harder to identify this addition to the article system, except in the more obvious cases.

6 Conclusions and Future Work

In this work, we aimed to study the capabilities of pre-trained language models, specifically BERT, on the linguistically relevant task of article prediction that native speakers are intuitively good at but linguists have been unable to formalise adequately, while focusing on how these abilities change with the increased flexibility in article use. Our results show that BERT has a very high correlation with human annotators when there is least flexibility as measured by inter-annotator agreement, but switches to agreeing with the corpus when there is flexibility in article use. These results, we contend, point to BERT having access to a high level generalised representation of article use distinct from memorisation.

We intend to focus future work on better understanding the specifics of this high level representation of article use contained within BERT. Also, the current study is limited in the languages explored and we intend to address this limitation by studying similar intuitive phenomena that evade linguistic description on languages other than English; an example would be aspect in Slavonic languages. Finally, we intend to extend our analysis by comparing BERT's output 'confidence' with annotator agreement, similar to methods presented by (Divjak et al., 2016).

Acknowledgements

We would like to thank Christian Adam, who developed the script for null article tagging, and Daisy Collins for help with setting up and collecting annotations on Qualtrics.

The manual annotation presented in this work was made possible by the research grant awarded to Harish Tayyar Madabushi by the Paul and Yuanbi Ramsay Research Fund (School of Computer Science, The University of Birmingham).

This work was also partially supported by the UK EPSRC grant EP/T02450X/1

A The BNC

The dataset used in the experiments presented in this work is extracted from the British National Corpus (BNC) distributed by the University of Oxford on behalf of the BNC Consortium and is consistent with its intended use. We extract sentences from both the spoken (BNC 2014 release) and the written (BNC 1994 release) versions of the BNC. Examples cited within the paper have been extracted from the BNC and all rights in the texts cited are reserved. We make use of the BNC to ensure that we use a well balanced data source that does not uniquely identify individuals or include offensive content. Detailed statistics pertaining to the BNC are available on the BNC website[2].

The BNC is available under the BNC User Licence[3] and given that we build our dataset from the BNC, access to our dataset is subject to access to the BNC.

B Model, Training, Hyperparameter and Hardware Details

For our experiments, we make use of BERT Base, which consists of 110 million parameters and BERT Large consisting of 340 million parameters. We use the default hyperparameters for both models except in changing the number of epochs to 1 and the maximum input sequence length to 150. This was based on our initial experimentation wherein we found that more epochs quickly lead to overfitting. In particular, we run our experiments using the Hugging Face Transformers implementation available online[4].

Models were trained using a Tesla V 100 GPU, and the entire training and optimisation process took approximately forty hours.

Models were run multiple times, each with a different random seed so as to avoid local minimum. In each case, models were evaluated on the development set which, like the training set was extracted from the corpus and not manually annotated. The best performing model on the development set was used for subsequent experiments. The results over 10 different random seeds on the development set for BERT Base are presented in Table 4. .

Run No.	Dev F1
1	0.8940
2	0.8936
3	0.8953
4	0.8942
5	0.8957
6	0.8930
7	0.8941
8	0.8947
9	0.8936
10	0.8944

Table 4: Results over 10 different random seeds on the development set for BERT Base – used to pick the best run used in subsequent experiments. We note that the variation in results across radom seeds isn't significant due to the large training set used.

We calculate the Phi coefficients (ϕ) in R (version 4.0.3) using the psych package (version 2.0.9).

C Annotation Details

The annotation was done using Qualtrics and participants were recruited through Prolific. Each participant was compensated £3.75 for annotating approximately 160 examples, which took participants an average of 42 minutes, a little over the 30 minutes we estimated it would take. We recruited a total of 108 annotators of whom 68 were female and 40 were male. Most annotators had a Bachelor's degree or had attended some college, and close to 65% of them were between the ages of 20 and 40.

Participants, who were all native speakers of British English and residing in the UK or Ireland (due to the use of the BNC), were instructed to read all three sentences before choosing which article they would fill the gap with. Four quality control questions were included in order to make sure that participants were paying attention.

The exact quality control questions were chosen following a pilot study run on 15 participants - a manual analysis of these results by linguists indicated that those who failed to correctly answer any one of these quality control questions, considered to be relatively straightforward, seemed to do little better than chance overall. If any one of the quality control questions were answered incorrectly, participants were not allowed to continue with the survey.

The risks associated with annotation are two fold: The first is to do with the risk of annotators not being representative of the general population. As such, we placed no restrictions on the demographics of our annotators except as required by the study. That is, we recruited fluent English speakers from the UK and Ireland, to ensure that they speak British English, consistent with our use of the BNC. The second risk is to do with annotators not being treated fairly. To ensure that this was not the case, we paid annotators a sum of £3.75 for what we estimated, based on our internal trials, would constitute 30 minutes of work. In addition, data collection was run with the approval of the ethics committee at the University.

C.1 Instructions to Annotators

Thank you for agreeing to take part in this study. For participating in the study you will earn £3.75. This study is run with the approval of the ethics committee at the University.

If you have any questions about the survey please contact me, Dr Harish Tayyar Madabushi at: H.TayyarMadabushi.1@bham.ac.uk.

Instructions
Please read these instructions carefully before continuing to fill in this survey.

In this study you will be presented with three sentences on each trial. In the middle sentence, one word is missing and it is your task to provide it; it can be either a(n), the or ZERO. In the first and last sentence, all words are provided. Please read all three sentences before filling the gap.

Example
Consider the following example where the special character 'Ø' represents locations where an article could have occurred, but, in this particular case, does not:

But there is no escape for Ø non - runners , who are required to sign up for Ø light duties. That takes _______ care of Sunday . We cannot refuse, because we are in Ø awe of the formidable women running the PTA.

You are required to fill in the _______ with one of:

1. a/an
2. the
3. Zero (Ø)

In the example above, the correct answer is Zero (Ø).

Instructions
This survey consists of approximately 170 questions and should take you about 30 minutes to complete.

IMPORTANT: Some of these questions - the quality check questions - will be used to perform a quality check and will be presented at random points in this survey. If you get too many of the quality check questions incorrect, your submission may be rejected. Please pay attention to the answers you provide as rejected submissions are not eligible for payment.

Thank you very much for taking the time to participate in this study. You will first need to answer some questions about your background, followed by a few benchmark questions, before you start on the bulk of the survey.

OmniTab: Pretraining with Natural and Synthetic Data for Few-shot Table-based Question Answering

Abstract

The information in tables can be an important complement to text, making table-based question answering (QA) systems of great value. The intrinsic complexity of handling tables often adds an extra burden to both model design and data annotation. In this paper, we aim to develop a simple table-based QA model with minimal annotation effort. Motivated by the fact that table-based QA requires both alignment between questions and tables and the ability to perform complicated reasoning over multiple table elements, we propose an omnivorous pretraining approach that consumes both *natural* and *synthetic* data to endow models with these respective abilities. Specifically, given freely available tables, we leverage retrieval to pair them with relevant natural sentences for mask-based pretraining, and synthesize NL questions by converting SQL sampled from tables for pretraining with a QA loss. We perform extensive experiments in both few-shot and full settings, and the results clearly demonstrate the superiority of our model OmniTab, with the best multitasking approach achieving an absolute gain of 16.2% and 2.7% in 128-shot and full settings respectively, also establishing a new state-of-the-art on WikiTableQuestions. Detailed ablations and analyses reveal different characteristics of natural and synthetic data, shedding light on future directions in omnivorous pretraining.[1]

1 Introduction

Humans are voracious information omnivores, consuming information in a number of forms. Unstructured text is the form covered in most work in NLP, but another form widely used on the web, academic papers, and reports is the *table*, where elements are organized in rows and columns and presented in a structured and succinct way. Because of this, systems to aid information access over tables, such as table-based question answering (QA) (Pasupat and Liang, 2015; Iyyer et al., 2017; Zhong et al., 2017), hold significant promise. However, they also require understanding of the table structure and sophisticated reasoning across multiple elements to get the final answer. This intrinsic complexity not only often requires special-purpose model designs such as pipeline systems that generate structured queries as intermediate steps (Liang et al., 2018; Wang et al., 2019; Yin et al., 2020; Yu et al., 2021), but also adds an extra burden to the process of data annotation (Pasupat and Liang, 2015; Shi et al., 2020).

Given the challenges above, we ask the question: "can we create a *simple* model that is able to answer complex table-based questions with *minimal annotation effort*?" Both modeling simplicity and limited assumptions regarding data availability would make it easier to apply table-based QA systems in practical scenarios. To this end, we focus on developing a simple and generic end2end table-based QA model where only a limited number of annotated natural language (NL) questions are available; the first attempt to address this problem under few-shot settings. In order to answer table-related questions, an end2end model needs to understand both the NL question and the table, build connections between the two formats, then perform complex reasoning. Taking the manually annotated question in Fig. 1 as an example, models need to align entities ("Collateral Damage") and concepts ("film", "air") in the question to elements in the table (the "Collateral Damage" cell and the "Film" and "Date" columns) and perform comparative reasoning based on chronological order (indicated by "previous" and "before") to find the final answer. Motivated by this, we propose **OmniTab**, an omnivorous pretraining approach that consumes *natural* data to endow models with the ability to understand and align NL with tables, and *synthetic* data to train models to perform reasoning.

	Synthetic	SELECT film WHERE gross > (SELECT gross WHERE film = 'Star Wars') Which **film** has **grossed more than Star Wars**? [Table]	Spider-Man
Annotated Finetune		What was the **previous film** to **air before Collateral Damage**? [Table]	Black Hawk Down

Figure 1: Example of natural and synthetic pretraining data and a manually annotated finetuning question. Phrases aligned with table elements and reasoning operations are marked with violet and red respectively. [Table] denotes the linearized table.

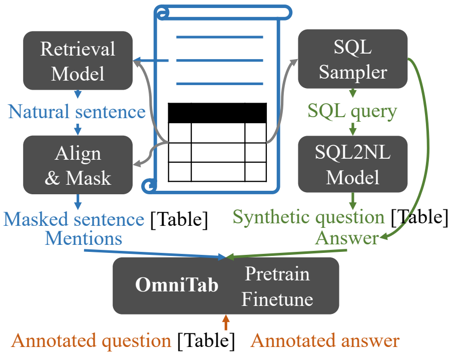

Figure 2: The overall framework of generating and pretraining with natural data (blue pipeline), synthetic data (green pipeline), and finetuning with limited annotated questions (orange pipeline) for our OmniTab model.

To obtain natural NL-table pairs, we propose a novel approach that leverages the multitude of tables freely available from the web, and uses *retrieval* to pair them with relevant NL sentences. Compared with manually defined heuristics used in previous work (Herzig et al., 2020; Yin et al., 2020), retrieval-based methods have the potential to discover better-aligned sentences. We explore different retrieval methods including string-based matching, sparse retrieval, and dense retrieval (Karpukhin et al., 2020; Khattab and Zaharia, 2020; Gao et al., 2021). Given these retrieved pairs, phrases in the sentence that align with table elements are then masked and the model takes both the masked sentence and the linearized table as input to predict masked mentions. For example, in Fig. 1 the retrieved sentence describes a particular row and contains two phrases matching cells in the table (i.e., "Spider-Man" and "$114.8 million") which are masked for prediction. To perform this sort of masked prediction, models need to understand that the sentence is about a record-breaking movie and refer to the table to extract the correct cells. Thus, training on this data endows models with better understanding and alignment across both formats.

For the synthetic data approach, we propose a method where structured queries such as SQL are first sampled and then converted into NL questions using an SQL2NL model, which allows for control of the reasoning operations covered by the SQL. Compared to existing work that trains directly on SQL (Liu et al., 2021), an approach hindered by the gap between structured and natural language, training on synthetic NL questions can close the gap, especially when limited annotated NL questions are available. We train the SQL2NL model with a small number of SQL-NL pairs and further boost its performance using verification-based self-training, which selects high-quality generated NL questions based on their likelihood to generate the gold answer. The converted NL question concatenated with the linearized table is fed into the model to directly generate the final answer, as shown in the synthetic example in Fig. 1 which involves comparative reasoning indicated by the phrase "more than". Although the fluency and naturalness of synthetic data is usually lower than natural data, learning on synthetic data provides a direct way to simulate different reasoning skills, which is relatively sparse in natural data.

Our overall framework is shown in Fig. 2. We use tables from Wikipedia and retrieve relevant sentences from the same page to generate natural text-table parallel data after masking mentions aligned to table elements (the blue pipeline on the left of Fig. 2). We use SQL queries sampled by Liu et al. (2021) and convert them to NL questions as synthetic text-table parallel data (the green pipeline on the right of Fig. 2). We use WikiTableQuestions (WTQ) (Pasupat and Liang, 2015), a widely used table-based QA dataset consisting of complex questions, as our major benchmark to evaluate our pretraining methods, and further use WikiSQL (Zhong et al., 2017) and topic-categorized WTQ (Chemmengath et al., 2021) to evaluate the robustness of our methods, all under few-shot setting with sizes ranging from 16 to 1,024. When using only 128 annotated questions, our model OmniTab improves over the best-performing baseline by an absolute gain of 13.2% and 12.3% with natural and synthetic pretraining separately and 16.2% when combined, demonstrating the effectiveness of the approach. We also achieve state-of-the-art performance on the full WTQ with an absolute gain of 2.7%. Extensive ablations and analyses reveal that natural and synthetic data indeed play the role of enhancing alignment and injecting reasoning, shedding light on future works on omnivorous pretraining.

2 End2End Table-based QA

In this section, we first explain the setting of table-based QA, then introduce the input format as well as our model architecture.

Table-based QA Each example in table-based QA consists of an NL question $\boldsymbol{q}$, a table T, and an answer $\boldsymbol{a}$. Both questions and answers are a sequence of tokens. Each table consists of N rows $\{r_i\}_{i=1}^{N}$ and M columns, where the token sequence in the cell located at the i-th row and j-th column is denoted as $\boldsymbol{c}_{i,j}$. The first row r_1 is the header row, indicating the meaning of each column. Table-based QA aims to generate the answer $\boldsymbol{a}$ given both the question $\boldsymbol{q}$ and the table T as the input.

Input Format We follow Liu et al. (2021) in concatenating the NL context with the linearized table as input. We flatten the table following a top-to-bottom and left-to-right order, where we prepend "col:" to the beginning of the header and "row i:" to the beginning of the i-th row to separate different rows: T = [col: r_1 row 1: r_2 ... row N: r_N]. Cells within each row are separated by a vertical bar "|" r_i = [$\boldsymbol{c}_{i,1}$ | $\boldsymbol{c}_{i,2}$ | ... | $\boldsymbol{c}_{i,M}$]. Finally, the question $\boldsymbol{q}$ is prepended to the linearized table: [$\boldsymbol{q}$ T].

Model Architecture We use the state-of-the-art table-based QA model TAPEX (Liu et al., 2021) as our base model, which is based on BART (Lewis et al., 2020b). It feeds questions and tables into the encoder and generates answers from the decoder: $P(\boldsymbol{a}|\boldsymbol{q}, T)$. Multiple answers are joined with commas into a single output sequence.

3 OmniTab: Pretraining with Natural and Synthetic Data

As mentioned in the introduction, table-based QA requires both (1) the ability to align NL phrases with table elements that could be expressed in different wording and (2) perform reasoning such as filtering, aggregation, superlatives, comparatives, and arithmetic. Compared to synthetic data, real NL sentences relevant to the table excel at enhancing the first capability since they are more natural and fluent, exhibiting various language variations. Learning on real sentences can endow models to grasp the nuances in language and align with structured tables. On the other hand, synthetic data is flexible, manipulable, and easy to obtain. It is costless to generate synthetic data via manipulating different aspects of the generated data to incorporate various desired properties. As a result, we can generate large amounts of complicated synthetic data covering various reasoning operations, which is lacking in the NL corpora. This motivates us to explore both types of data.

3.1 NL-Table Alignment Through Retrieval

Using the Wikipedia table corpus released by Herzig et al. (2020), we explore three retrieval methods to construct aligned NL-Table pairs and propose a new pretraining objective.

3.1.1 Retrieval Protocol

Since sentences relevant to a table are usually included in the same document, we restrict our retrieval models to only consider the document containing the table, with the purpose of reducing noise and increasing efficiency.

String-based Matching For each sentence, we enumerate over all cells in the table and find the longest common substring (LCS) between a cell $\boldsymbol{c}_{i,j}$ and a sentence $\boldsymbol{s}$. An LCS is considered as a mention to be masked if it (1) is not a stopword, (2) contains alphanumeric characters, (3) is a complete word, and (4) is longer than 70% of the length of the cell. We choose the sentence with the largest number of mentions to pair with the table.

Sparse Retrieval with BM25 Another method of string-based matching is BM25 with tables as queries and sentences as candidates. Different from the above method matching whole cells, BM25 treats tables as a bag of tokens. We linearize tables as queries and choose the most relevant sentence to compose the pair. Since BM25 retrieval does not return aligned phrases and cells, we resort to the above method detect mentions.

Dense Retrieval with Token Representations The above two methods can only consider exact

Figure 3: Applying max-sparsify on a relevance matrix of cells and phrases on two dimensions consecutively.

string matches, which is sub-optimal because different expressions might be used between sentences and tables such as "$114,844,116" and "$114.8 million" in Fig. 1. Tables tend to use full and formal expressions, while expressions in NL tend to be casual, often with abbreviations. To address this issue, we propose to use dense representations to perform soft matching. Many works use a single dense vector to represent the whole query/document for retrieval (Guu et al., 2020; Karpukhin et al., 2020). However, in our case, queries are tables usually consisting of many cells,[2] thus representing a whole table as a single vector might lead to information loss, which performs well below BM25 in our preliminary experiments. Additionally, retrieval based on a single vector only returns sentence-table pairs without revealing phrase-cell alignment, which is required for masking purposes. Thus, we propose to use token representation to directly match phrases and cells, similar to token-level dense retrieval (Khattab and Zaharia, 2020; Gao et al., 2021) in spirit.

Specifically, we use BART to obtain token representations for each sentence $\boldsymbol{s}$ and table T separately. We then use a named entity recognition (NER) model to detect candidate phrases $\{\boldsymbol{p}_l\}_{l=1}^{L}$ in the sentence. Each phrase and cell are represented as the average token representation, denoted as $\boldsymbol{e}_{\boldsymbol{p}_l}$ and $\boldsymbol{e}_{\boldsymbol{c}_{i,j}}$ respectively after normalized to a unit vector. We compute a similarity for each cell-phrase pair using dot product $\boldsymbol{e}_{\boldsymbol{c}_{i,j}} \cdot \boldsymbol{e}_{\boldsymbol{p}_l}$, resulting in a two-dimensional similarity matrix $A \in \mathbb{R}^{NM \times L}$, where each row and column correspond to a cell and a phrase respectively. We aggregate the relevance matrix A to derive relevance scores for ranking sentences and an assessment score for each phrase to choose salient mentions for masking. Given the fact that soft match based on dense vectors usually yields a non-zero relevance score even for irrelevant pairs, we apply the max-sparsify operator to emphasize relevant matches and eliminate noisy irrelevant matches, similarly to the max operator in Khattab and Zaharia (2020); Gao et al. (2021). The max-sp$(A, \text{dim} = i)$ keeps the max entry along dimension i of the matrix A and changes other entries to zero. As illustrated in Fig. 3, we first apply this operator over all phrases (dim $= 1$), assigning each cell the best-matching phrase, then apply it over all cells (dim $= 0$), assigning each remaining phrase to its best-matching cell. We use the sum of the sparsified matrix as the relevance score to choose the best-matching sentences, rank remaining phrases in that sentence ($\boldsymbol{p}_2 > \boldsymbol{p}_3 > \boldsymbol{p}_1$ in Fig. 3), and choose phrases with scores higher than a threshold τ as mentions to be masked.

$$\text{rel}(\boldsymbol{s}, T) = \text{sum}(\text{max-sp}(\text{max-sp}(A, 1), 0)). \quad (1)$$

3.1.2 Learning Objective

Given a retrieved sentence $\boldsymbol{s}$ associated with the table T, we apply two masking strategies: (1) randomly mask tokens in the sentence or cells in the table (2) salient mention masking where we first identify phrases in the sentence that align with table elements, then mask aligned phrases (denoted as mentions). Compared to random masking, salient masking specifically focuses on masking shared information, enabling the model to better learn the correspondence across formats, which we will verify in § 4.3. Since we use TAPEX as the base model, which is based on BART, we follow the pretraining format of BART to generate the original unmasked sequence given the input with masked tokens (in either NL or table). Instead of computing the negative log likelihood loss (NLL) over all tokens, we only compute at masked positions to emphasize the recovery of missing information:

$$\mathcal{L}_{\text{mask}} = -\log P_{\text{mask}}(\boldsymbol{s}, T | \boldsymbol{s}^*, T^*), \quad (2)$$

where $\boldsymbol{s}^*/T^*$ denote the masked sentence/table, and $P_{\text{mask}}(\cdot|\cdot)$ only computes loss at masked positions.

3.2 Synthetic Questions Converted from SQL

We use synthetic questions to simulate real table-based questions that involve various reasoning operations, such as the comparative operation in Fig. 1. While directly synthesizing complex NL questions is challenging, it is easier to generate complex structured queries such as SQL because they follow predefined syntax, and different reasoning operations can be implemented with different SQL templates. For example, the SQL query in Fig. 1 is based on

---

[2] Wiki tables have 26 cells on avg with extreme cases 500+.

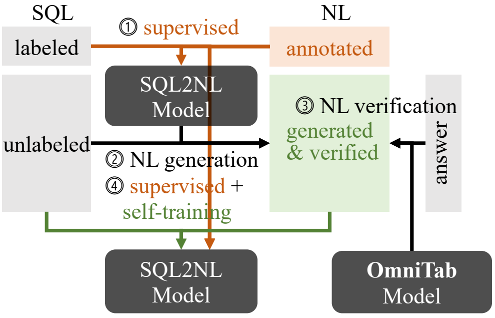

Figure 4: The procedure of learning a SQL2NL model with verification-based self-training. Annotated / generated NL questions are denoted as orange / green.

a template that compares entries w.r.t. a numerical property. This motivates us to first generate SQL ($\boldsymbol{o}$) then convert them to NL questions ($\boldsymbol{q}$).

Fortunately, Liu et al. (2021) already sampled a large corpus of SQL with associated answers based on tables from Wikipedia and used SQL plus tables as input to pretrain their model TAPEX. They achieved state-of-the-art performance on table-based QA, making TAPEX a strong base model. However, there is a large gap between SQL and NL questions, and training solely on SQL might hinder it from closing this gap. Instead, we use NL questions in the pretraining directly. Given synthesized NL questions, we pretrain with a standard generative QA loss that takes NL questions concatenated with tables as input and decode answers obtained by executing SQL queries over tables:

$$\mathcal{L}_{\text{QA}} = -\log P(\boldsymbol{a}|\boldsymbol{q}, T). \quad (3)$$

Sampling SQL Based on Templates Liu et al. (2021) leverage tables from WTQ and instantiate different templates over them to sample large amounts of SQL, where answers are obtained by execution. Templates are automatically extracted from SQUALL (Shi et al., 2020), which includes SQL corresponding to NL questions in WTQ.

Training SQL2NL Models We use BART as our base model and finetune it with limited SQL-NL pairs to strictly conform to the few-shot setting. We use SQUALL to simulate few-shot scenarios, by assuming that only a limited number of SQL queries have annotated NL questions, which we elaborate in § 4.1. The model takes SQL as input and generates NL questions autoregressively.[3]

Self-training with Verification-based Selection Even with a strong model like BART, the accuracy of SQL2NL is not perfect, especially in the face of limited data. To further improve performance, we devise a verification-based self-training approach that selects high-quality NL questions generated from unlabeled SQL by assessing how likely they elicit correct answers from the table-QA model.

As illustrated in Fig. 4, we first finetune BART model on supervised SQL-NL pairs to obtain the initial SQL2NL model (①), which is used to generate NL questions for unlabeled SQL (②) in the second step. We attempted two generation methods including beam search and top-k sampling (Fan et al., 2018) and found that beam search leads to more diverse results. Thus we use a beam size of 50 to generate candidate NL questions $\hat{\boldsymbol{q}}$. Third, we choose high-quality candidates for self-training based on various criteria. The most straightforward criterion is to choose questions with the highest generation probabilities for self-training $\text{score}_{\text{gen.}}(\hat{\boldsymbol{q}}) = P^{\text{SQL2NL}}(\hat{\boldsymbol{q}}|\boldsymbol{o})$, which does not lead to improvement as we will show in the ablations (§ 4.3). Motivated by the fact that OmniTab has a strong capacity to answer table-related questions after large-scale pretraining and finetuning, we rank generated sentences by verifying how likely they elicit the correct answer using OmniTab $\text{score}_{\text{ver.}}(\hat{\boldsymbol{q}}) = P(\boldsymbol{a}|\hat{\boldsymbol{q}}, T)$, which provides a simple and effective way to leverage the QA capacity of OmniTab to indirectly provide feedback to the SQL2NL model (③). Given the verification scores, we first pair each unlabeled SQL with the sentence with the highest score among 50 candidates, then keep the top-K SQL-NL ranked based on the score as our self-training data. At the last step, the small supervised data is combined with the enlarged self-training data to train the final SQL2NL model (④).

3.3 Combining Natural and Synthetic Data

We perform multitasking using the two previously defined objectives (Eq. 2, Eq. 3) to combine natural and synthetic data. In addition, since we use TAPEX as initialization and their SQL-based pretraining has demonstrated effective in endowing models with reasoning capability, we add SQL-based pretraining in the multitask setting. $\mathcal{L}_{\text{sql}} = -\log P(\boldsymbol{a}|\boldsymbol{o}, T)$, resulting a combination of three parts $\mathcal{L}_{\text{mask}} + \mathcal{L}_{\text{QA}} + \mathcal{L}_{\text{sql}}$ as the multitask loss.

---

[3] We tried adding the corresponding table as an additional input but found no gain despite increased computational cost.

4 Experiments

We first detail the experimental settings (§ 4.1). Then we report on extensive experiments, starting with the overall result including all design elements to achieve the best results (§ 4.2), then breaking down into each design choice to analyze their individual contribution (§ 4.3). Finally, we analyze concrete examples to provide insight on different characteristics of natural and synthetic data (§ 4.4).

4.1 Experimental Settings

Few-shot Settings We use WikiTableQuestions (Pasupat and Liang, 2015) as our major benchmark, as it is a widely used table-based QA dataset involving various complex reasoning operations, and report the answer accuracy given by the official evaluator. Following work on few-shot QA (Ram et al., 2021), we create few-shot settings of WTQ by sampling a subset from the original training containing 11K examples in total, with sizes changing on a logarithmic scale from 16 to 1024.

Another component that requires annotated NL questions is the SQL2NL model. We use SQUALL (Shi et al., 2020), which contains $\approx$10K annotations in total, to simulate few-shot scenarios by varying the number of SQL annotated with NL from 16 to 4,096. In the f-shot setting, we use SQUALL-f to train the SQL2NL model and WTQ-f to finetune QA models. Since SQUALL and WTQ share the same set of NL questions, we make sure that SQUALL-f also includes the same questions as WTQ-f, so in total only f annotated questions are used in the f-shot setting.

We also report on WikiSQL (Zhong et al., 2017), another table-based QA benchmark with relatively simple questions. To evaluate robustness under topical shift, we further use WikiTableQuestions-TS which split WTQ into five topics (Chemmengath et al., 2021) based on Wikipedia categories. We follow their creation procedure to reproduce the split, and evaluate our methods by finetuning on one topic and testing on the other four topics.

Pretraining Corpora We use the table corpus by Herzig et al. (2020) extracted from Wikipedia as our source of tables for retrieval. All tables are preprocessed into a two-dimensional structure with a single header and one or multiple data rows. We use a subset of this corpus and find the corresponding Wikipedia page through its URL, which is preprocessed into sentences using SLING. Since some tables are noisy and some Wikipedia pages do not contain meaningful sentences, eventually we pair approximately 0.5M tables with sentences using our three retrieval methods. To make the synthetic data of similar size, we also use 0.5M SQL sampled by Liu et al. (2021) to generate synthetic questions.

Baselines We consider two types of models as baselines (1) pipeline methods that execute generated SQL to get answers such as **TaBERT** (Yin et al., 2020) with **MAPO** (Liang et al., 2018) as the semantic parser and (2) end2end methods that directly generate answers, such as **BART** (Lewis et al., 2020b), **TAPAS** (Herzig et al., 2020), and **TAPEX** (Liu et al., 2021). More discussions about table-related models can be found in the related work section in § 5. Since we also incorporate the SQL data used by TAPEX in our final multitask setting, we report **TAPEX*** when comparing with our multitask setting, which continued to train TAPEX on SQL data for as many steps as OmniTab to make a fair and rigorous comparison. We use **OmniTab** to denote our full model trained in the multitask setting with both natural, synthetic, and SQL data (§ 3.3).

Implementation Details During pretraining, we use a batch size of 512 and train OmniTab for 5 epochs, which takes about 20 hours on 8 V100 GPUs for multitasking on both natural and synthetic data. During finetuning, we use a batch size of 96 and finetune OmniTab for 50 epochs, which takes about 30 minutes on 8 V100 GPUs. We use a learning rate of 2e-5 for both pretraining, finetuning. We use BART-large and TAPEX-large in all experiments. For dense retrieval, since we use the max operation, all phrases have scores $\in [-1, 1]$. We bucket phrases into bins with an interval of 0.1, manually inspect the quality of some randomly sampled phrases from each bin, and found that phrases with scores larger than $\tau = 0.6$ are of high quality. We use spaCy[4] to detect named entities for dense retrieval. For self-training of the SQL2NL model, we use the best-performing OmniTab model without self-training as the verification QA model, and make sure that it uses the same amount of annotations as the final model (i.e. if the final model is a f-shot model, we also use f annotations to train the verification model). In our final model, we added approximately 10K SQL-NL pairs for self-training.

4.2 Overall Results

The overall results comparing OmniTab with other baselines are listed in Tab. 1. Across three few-shot settings, simulating low, medium, and high resource scenarios, pretraining on natural or synthetic data individually both outperform baselines significantly, and multitasking further increases the performance by a large margin. OmniTab improves over the best baseline performance by 11.1%, 16.2%, and 6.4% across the three settings, clearly demonstrating that pretraining on natural sentences relevant to tables and synthetic questions provides OmniTab with a stronger capacity to align text and tables and perform reasoning. The two types of data are complementary to each other, which we will analyze in detail in § 4.4. Despite the fact that we focus on the few-shot setting, we also observe significant improvements of 2.7% on the full setting, establishing a new state-of-the-art on WTQ. The performance in all few-shot/full settings shown in Fig. 5 clearly indicates the superiority of OmniTab across the whole spectrum. The improvement is larger when annotations are fewer, indicating the value of pretraining especially when fewer annotations are available. We also observe improvements on WikiSQL as shown in Tab. 2, reinforcing the effectiveness of our methods.

Model *f*-shot:	**16**	**128**	**1024**	**full**

4.3 Ablation Study

Next, we study the contribution of individual components, including different retrieval methods, masking strategies, self-training methods, and varying the number of training pairs.

Comparison of Different Retrieval Methods Our first ablation concerns the influence of different retrieval methods on the final performance. We examined three retrieval methods to pair tables with a relevant sentence, including string-based matching, BM25, and dense retrieval (§ 3.1), as summarized in Tab. 3. We also add a baseline (title-based heuristic) that pairs a table with the caption, article title, and description used by Herzig et al. (2020) to validate the utility of retrieval. (1) Our three retrieval methods usually perform better than the title-based heuristic, indicating that retrieving sentences based on the table content is better than fixed heuristics that always pair a table with pre-specified content. (2) By comparing two string-based matching variants, we found that selecting the sentence with the maximal number of mentions is better than sentences with minimal overlap,[5] confirming our intuition that sentences more aligned with the table enable models to learn better alignment. (3) BM25 performs similarly to string-based matching, partially because we still rely on string-based matching to locate mentions after BM25 returns a similar sentence. (4) Dense retrieval with threshold $\tau = 0.6$ achieves the best overall performance, but it is relatively sensitive to the threshold. A high threshold only keeps highly relevant phrase-cell pairs, while a low threshold can discover more partial matches for masked pretraining, leading to a trade-off between quality and quantity. Given that this initial attempt to use dense retrieval for text-table alignment directly uses BART without further tuning, further advances in retriever could likely improve this trade-off.

Random Masking vs. Salient Masking We use both salient mention masking that only masks men-

---

[5] Average #mentions for max and min are 2.0 vs 1.2.

Model	***f*-shot:**	**16**	**128**	**1024**

string-based	(min)	23.3	35.5	47.5
	(max)	**24.2**	36.7	49.2
BM25		23.8	36.4	49.1
dense retrieval	($\tau = 0.5$)	22.7	35.9	48.4
	($\tau = 0.7$)	19.8	36.8	48.2
	($\tau = 0.6$)	22.8	**38.4**	**49.8**
dense retrieval ($\tau = 0.6$)	w/o salient mask	17.5	33.6	47.1
	w/o random mask	23.1	37.8	48.5

Table 3: WTQ test accuracy when pretraining on natural data obtained by different retrieval methods, and using two masking strategies separately. Design choices used in our final model are underlined.

tions of cells in the sentence and random masking in our final model. To examine the contribution of each masking strategy, we remove one masking strategy from the underlined model at the bottom of Tab. 3. It is clear that both maskings help, with salient masking being the major contributor, which indicates that masking tokens indicative of alignment is more effective than aimless masking.

Comparison of Different Self-training Methods To study which element is crucial in self-training, we perform ablations to study various aspects of self-training including (1) selection criterion for questions (generation- vs verification-based) and (2) models used for verification (BART vs OmniTab) by comparing all variants under the same setting of 128 annotated SQL-NL. As summarized in Tab. 4, self-training on selected questions with the highest generation probabilities given by the SQL2NL model does not improve over the baseline without self-training, which is mainly because the SQL2NL model is too weak to output reliable generation probabilities. However, our method that selects questions with the highest probabilities to elicit answers from OmniTab (last line) improve over no self-training by a large margin (4.3%, 2.5%, and 1.8%), validating the idea of leveraging the strong QA capacity of OmniTab to assess the quality of generated questions. To confirm the source of success, we perform a sanity check that selects sentences most *unlikely* to elicit answers (min), and the performance indeed becomes much lower. We also replace OmniTab with BART that is only finetuned with 128 annotations, and the performance is significantly lower, confirming that stronger QA models can provide a better assessment.

Model		**WTQ-**	**16**	**128**	**1024**

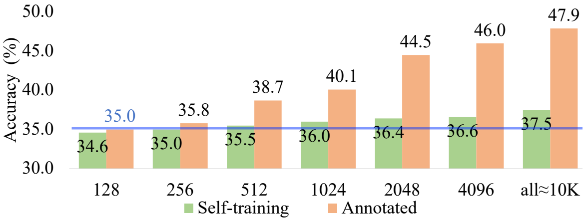

Figure 6: WTQ test accuracy (128-shot) using different numbers of annotated and self-training SQL-NL pairs.

Performance w.r.t. Number of Annotated and Self-training Pairs Here we study the influence of increasing either annotated or self-training SQL-NL pairs. We use the SQL2NL model trained with 128 annotated pairs as a starting point, and additionally using more annotated or self-training pairs. As shown in Fig. 6, using more annotated or self-training pairs both improves over the initial performance of 35.0%. However, the improvement due to self-training still falls far behind the supervised approach, demonstrating the challenge of learning a robust SQL2NL model with very few annotations. The increasing trend of self-training suggests that further improvements may be provided by using more pairs in self-training.

4.4 Analysis

Roles of Natural and Synthetic Data We quantitatively verified using the multitasking experiment that natural and synthetic are complementary to

Cases favoring:	**Natural**	**Synthetic**
Avg #tok in questions / SQL	10.6 / 11.4	10.8 / **12.9**
Avg #aligned question tok with tables	**1.8**	1.0

Table 5: Statistics of cases favoring natural vs synthetic data. Numbers indicating advantages are in **bold**.

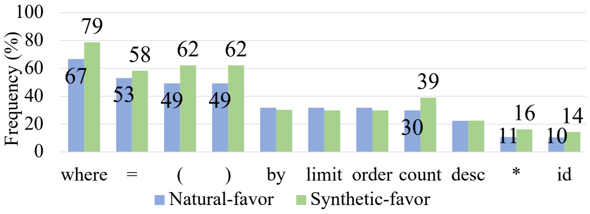

Figure 7: Frequent SQL keywords in cases favoring natural vs synthetic data. Keywords with a large frequency difference are annotated with frequencies.

Train/test	Sports	Culture	People	Politics	Misc
Sports	+16.3	+14.1	+15.8	+14.4	+18.8
Culture	+13.9	+12.7	+14.3	+13.0	+10.3
People	+21.5	+14.6	+20.6	+14.6	+17.5
Politics	+18.5	+14.3	+17.8	+16.0	+13.5
Misc	+18.3	+14.7	+17.2	+14.6	+14.9

Table 6: Accuracy gain (128-shot) of OmniTab over TAPEX when finetuned on one topic and tested on all.

each other, with the hypothetical reason that natural data excels at enhancing alignment while synthetic data is more targeted on endowing reasoning capabilities. Our analysis on cases where natural pretraining succeeds but synthetic fails and the opposite cases confirms that this is *indeed* the case. Enabled by the fine-grained annotation in SQUALL (Shi et al., 2020), we compare OmniTab trained on natural or synthetic data separately in the 128-shot setting, and study on the two groups of cases in the development set of WikiTableQuestions. Based on 309/315 cases favoring natural/synthetic pretraining, we witness a clear distinction on the average number of question tokens aligned with tables between the two groups in Tab. 5, indicating that natural data is indeed more targeted at addressing the alignment across formats. We also compute the frequency of each SQL keyword for the two contrasting groups of cases. As shown in Fig. 7, cases favoring synthetic data indeed involves reasoning-rich keywords more frequently, such as "where = ( )" which are often used in nested queries, and "count * id" which are often used in aggregation.

Performance under Topical Distributional Shift Last, we analyze the robustness of OmniTab under topical distributional shift on WTQ-TS, which splits WTQ into five topics. We finetune OmniTab on one topic (128-shot) and test the resulting model on all five topics. As indicated by Tab. 6, OmniTab outperforms TAPEX by a large margin across all topics, validating the robustness of our methods under topical shift.

5 Related Work

Table-based QA is a well-studied area from early systems using structured queries as intermediate steps (Krishnamurthy et al., 2017; Liang et al., 2018; Wang et al., 2019; Yin et al., 2020; Yu et al., 2021) to recent advances that generate answers in an end2end fashion (Herzig et al., 2020; Liu et al., 2021). Our methods follow the end2end approach because of its modeling simplicity and higher flexibility. Given large amounts of table and text on the web, table-based QA and other table-related tasks such as semantic parsing (Deng et al., 2021; Shi et al., 2021) and table understanding (Deng et al., 2020; Wang et al., 2021) start witnessing efforts invested in pretraining on both structured and unstructured information. Most works leveraging retrieval to find relevant information to assist pretraining are designed for text format only (Guu et al., 2020; Lewis et al., 2020a), while the majority of table-based pretraining still use alignment heuristics (Herzig et al., 2020; Yin et al., 2020). There are some initial attempts to perform retrieval over tables (Oğuz et al., 2020; Herzig et al., 2021; Ma et al., 2021), but they mainly use tables as an additional information source while we focus on pairing tables with text for pretraining.

6 Conclusion

We propose an omnivorous pretraining approach that consumes both natural and synthetic data to enhance the ability to understand and align text and tables and the ability to perform reasoning. Our extensive results demonstrate the effectiveness of both data and verify their complementary value. Our empirical results together with the case analysis indicate that omnivorous pretraining can indeed benefit from the merits of both data, encouraging future advances in retrieval and synthesis to obtain higher-quality data and better pretraining strategies to combine heterogeneous data.

Provably Confidential Language Modelling

Xuandong Zhao **Lei Li** **Yu-Xiang Wang**

Abstract

Large language models are shown to memorize privacy information such as social security numbers in training data. Given the sheer scale of the training corpus, it is challenging to screen and filter all privacy data, either manually or automatically. In this paper, we propose **C**onfidentially **R**edacted **T**raining (CRT), a method to train language generation models while protecting the confidential segments. We borrow ideas from differential privacy (which solves a related but distinct problem) and show that our method is able to *provably prevent* unintended memorization by randomizing parts of the training process. Moreover, we show that redaction with an approximately correct screening policy *amplifies* the confidentiality guarantee. We implement the method for both LSTM and GPT language models. Our experimental results show that the models trained by CRT obtain almost the same perplexity while preserving strong confidentiality[1].

1 Introduction

Language models (LM) have rich real-world applications in, among others, machine translation (Bahdanau et al., 2015), AI chatbots (Hosseini-Asl et al., 2020), question answering (Kwiatkowski et al., 2019), and information retrieval (Ganguly et al., 2015). The advent of transformers (Vaswani et al., 2017) has fostered a dramatic advancement in the capabilities of generative neural language models, yet they come at a cost to privacy, as the amount of excess parameters in the LM enables it to memorize certain training samples. Recent works show that sensitive user information from the training dataset, such as address and name, can be extracted verbatim from text generation models by querying the LM as an API (Carlini et al., 2019, 2021; Lee et al., 2022). How to train a high-performing language model without memorizing sensitive text has become a major research challenge.

Existing solutions to this problem primarily leverage differential privacy (DP) (Dwork et al., 2006).

Differentially private learning algorithms ensure that an attacker could not infer whether a data point is used for training, let alone extracting the sensitive information within that data point.

However, there are several mismatches between the problem of *privacy* that DP addresses, and our problem of preventing the memorization of sensitive text (henceforth referred to as *confidentiality*). First, confidential information in a natural language dataset is sparse (e.g., the bulk of an email might not carry confidential information). DP's undiscriminating protection for all sentences could be unnecessarily conservative which limits the utility of the trained model. Second, what needs to be protected is the content of the sensitive text, rather than the data context. For example, in the sentence "`My SSN is 123-45-6789.`", it is the actual SSN that we hope to conceal rather than the general information that someone entered her SSN in a chatbot dialogue. Thirdly, the same sensitive content could appear in many data points, which makes the protection of the content more challenging than protecting one data sample. These differences motivate us to treat the problem of confidentiality protection in LM separately with new definitions.

Besides DP, we also consider classical techniques of redaction and deduplication. *Redaction* refers to the process of removing sensitive or classified information from a document prior to its publication in governmental and legal contexts. *Deduplication* is the procedure of detecting and removing identical and nearly identical texts from a corpus. The main challenge of applying these techniques is that it is hard to manually redact a gigantic dataset and automated tools are far from being perfect.

USR: I have all I need.

SYS: Hello, I am the customer support bot. What do you need?
USR: Hello robot. Where is my package?
SYS: May I have your full name?
USR: Yes, James Bing.
SYS: We will need the shipping address as well.
USR: Ok, it is 81171 Nguyen Ford North Crystalbury, MO 52398.
SYS: The tracking number is VD98ID6CXJ. What else can I do?
USR: I have all I need.

Redaction with a policy with **recall 0.9 and high precision** compromises confidentiality.

SYS: Hello, I am the customer support bot. What do you need?
USR: Hello robot. Where is my package?
SYS: May I have your full name?
USR: Yes, James Bing.
SYS: We will need the shipping address as well.
USR: Ok, it is [redacted].
SYS: The tracking number is [redacted]. What else can I do?
USR: I have all I need.

Redaction with a policy with **recall 1.0 but poor precision** results in useless data.

SYS: Hello, I am the [redacted] need?
USR: Hello [redacted]. Where [redacted]?
SYS: May I have your full name?
USR: Yes, [redacted].
SYS: We will need [redacted] as well.
USR: Ok, it is [redacted].
SYS: The [redacted] is [redacted]. What else can I do?
USR: [redacted] I need.

Our results:
1. Provable confidentiality ensures that these two are indistinguishable!
2. Approximate redaction policy **amplifies** the confidentiality guarantee.

Figure 1: An example from simulated dialog dataset `CustomerSim`. The yellow highlights are confidential content (middle). Left shows the text after *Redaction* by a sequence labeling policy π. However, if the policy is not perfect, there exists false negative or false positive samples as shown on the right.

The contribution of this paper is fivefold.

1. We show that in the absence of a perfect screening policy, the risk of a language model memorizing sensitive content is real and can be efficiently exploited with only blackbox access to the model even if the learning algorithm satisfies the recently proposed notion of *selective differential privacy* (Shi et al., 2021).
2. Inspired by differential privacy, we introduce a new definition of *confidentiality* which precisely quantifies the risk of leaking sensitive text.
3. We propose CRT to train language generation models while protecting confidential text. The method with deduplication and redaction operations work even under imperfect confidential text labeling policies.
4. We theoretically prove that CRT, combined with differentially private stochastic gradient descent (DP-SGD), provides strong confidentiality guarantees.
5. Our experiments on both MultiWOZ 2.2 and CustomerSim datasets show that different models trained by CRT can achieve the same or better perplexity than existing solutions (against the attacks of Carlini et al. (2019, 2021)).

To the best of our knowledge, we are the first that rigorously establish the role of deduplication and redaction in achieving provably stronger confidentiality (or the related differential privacy) guarantees; and the first that achieve provably confidentiality in transformer models with only a mild utility loss.

2 Background & Related Work

Next, we briefly introduce the relevant background and discuss the related work to put our work in context.

Language modeling is a fundamental problem in natural language processing (Devlin et al., 2019; Howard and Ruder, 2018; Raffel et al., 2020). Consider a text sequence that consists of multiple tokens from a vocabulary $\mathcal{V}$, i.e., $\boldsymbol{w} = (w_1, w_2, \dots, w_n)$, where w_i is the i-th token. The goal of language modeling is to construct a generative model of the distribution $\Pr(\boldsymbol{w})$, by applying the chain rule $\Pr(\boldsymbol{w}) = \prod_{i=1}^{n} \Pr\left(w_i \mid \boldsymbol{w}_{<i}\right)$. We let $f_\theta(w_i|\boldsymbol{w}_{<i})$ denote the likelihood of token w_i when evaluating the neural network f with parameters θ. A language model is trained to maximize the probability of the data in a training set $\mathcal{W}$, by minimizing the negative log-likelihood over each training example with the loss function $\mathcal{L}(\theta) = -\log \prod_{i=1}^{n} f_\theta\left(w_i \mid \boldsymbol{w}_{<i}\right)$. Recurrent neural networks (RNNs) used to be a common choice for the neural network architecture to estimate the probability distribution $\Pr(\boldsymbol{w})$. (Hochreiter and Schmidhuber, 1997; Mikolov et al., 2010). More recently, large-scale Transformer-based language models have replaced RNNs in state-of-the-art

models for all sorts of NLP tasks (Vaswani et al., 2017; Radford et al., 2019). Nevertheless, common language models are vulnerable to privacy attacks and possibly expose information about their sensitive training data (Carlini et al., 2019, 2021).

Differentially private (DP) learning methods (see, e.g., Abadi et al., 2016) has been applied to language models as a blanket solution for a number of privacy and security risks. McMahan et al. (2018) trained an RNN language model with DP guarantees in a federated learning setup. Anil et al. (2021) pre-trained BERT under DP on datasets with hundreds of millions of examples. These paper also demonstrated that DP can effectively prevent data-extraction attacks in practice even for algorithms with DP guarantees that are considered too weak from a theoretical-perspective (e.g., $\epsilon = 8$ or 16). However, the strong protection of DP often results in a substantial drop in the utility of the trained model, which makes them less desirable in practice. In fact, it was recently shown that it is *necessary* for deep learning models to memorize certain training data to achieve high accuracy (Feldman, 2020), which suggests that DP or any other techniques that require the model to not memorize any training data will perform poorly in the high-dimensional, power-law distributed real datasets. This motivates us to consider weakened models that only prevent memorizing the sensitive part of the text.

Recent works (Lee et al., 2022; Kandpal et al., 2022) show that deduplication enables language models to emit memorized text less frequently with same or better accuracy. However, deduplicating training datasets can not prevent all unintended memorization. We combine deduplication and redaction and then apply both techniques to the training process of LM to achieve confidentiality with provable guarantee.

The closest to us is perhaps the work of Shi et al. (2021), who proposed *selective differential privacy* (S-DP), which requires indistinguishability between two datasets that differ only on a sensitive message. Correspondingly, they propose an algorithm (Selective DP-SGD) for training RNN that adds noise only to the part of computation that involves sensitive tokens. To define S-DP and to run Selective DP-SGD, one needs to have access to a policy function F which determines which token is sensitive. This requirement limits the applicability of their approach to those applications where such perfect F is known. We note that even for name-entity recognition the state-of-the-art model is far from being perfect, and which part of the text is considered sensitive is often ambiguous even for human annotators. We will see that naively running Selective DP-SGD with an approximate policy function does not provide a meaningful confidentiality guarantee and is vulnerable to practical data extraction attacks. Finally, we note that in the case when a perfect policy function is available, we can simply use it for redaction, which provides a perfect S-DP with $\epsilon = 0$. A big part of our contribution is to refine S-DP to a (slightly different) definition called "confidentiality" and to demonstrate that we use an approximate screening policy to amplify the confidentiality parameter.

3 The CRT Method and Theory

In this section, we develop our method with provable confidentiality.

3.1 Formally defining confidentiality

Let the dataset be a collection of n data points — each being a sequence of tokens. A "secret" x is a contiguous subsequence of tokens within a data point that is considered *sensitive* or *confidential*. The goal of our research is to allow us to train language models on such datasets that could contain secrets while provably prevent the model from remembering that these secrets were. We start by defining a formal definition of confidentiality, which uses the following idea of indistinguishability from the DP literature.

Definition 1 (Indistinguishability)**.** *We say that a pair of distributions P, Q defined on the same probability space are (ϵ, δ)-indistinguishable if for any measurable set S,*

$$\Pr_P[S] \le e^{\epsilon} \Pr_Q[S] + \delta.$$

Definition 2 (Confidentiality)**.** *We say that $\mathcal{A}$ ensures that a secret x is $(\epsilon(x), \delta)$-confidential, if for any dataset D that contains x in one of its data points, and an alternative dataset D' that replaces x in D with a generic* `<MASK>`*, it holds that $(\mathcal{A}(D), \mathcal{A}(D'))$ are $(\epsilon(x), \delta)$-indistinguishable. In addition, we simply say that $\mathcal{A}$ ensures (ϵ, δ)-confidentiality if $\epsilon(x) \le \epsilon$ for all secret x.*

This definition ensures that an attacker cannot distinguish from the output of $\mathcal{A}$ (the trained language model) whether it was x or `<MASK>` that was used for training, thus formalizing the idea of confidentiality. The protection should be viewed as relative, rather than absolute. The definition bounds the risk of any bad event by an multiplicative factor of e^ϵ and an additive factor of δ, which implies that anything that could happen when we run $\mathcal{A}$ on the sensitive data could've happened with with similar probability even if $\mathcal{A}$ runs on an alternative world where these sensitive information are perfectly masked.

Connections to differential privacy. Our definition of confidentiality is related to (and inspired by) (ϵ, δ)-differential privacy (DP) but is different in several ways. DP is stronger (and implies confidentiality!) requires $\mathcal{A}$ to ensure (ϵ, δ)-indistinguishability for all D, D' that can be modified from each other by adding or removing one individual person / data point (or tokens, depending on the desired granularity); but for $\mathcal{A}$ to ensure (ϵ, δ)-confidentiality, it only requires (ϵ, δ)-indistinguishability for specific D, D' where D' replaces x in D with `<MASK>`. Moreover, it is more informative to define ϵ as a function of each specific x, which is different from DP (it resembles personalized DP (Ghosh and Roth, 2015)).

The confidentiality definition makes sense for our problem because it protects the content of the sensitive text x rather than its existence. Specifically, a pre-processing algorithm that masks all sensitive text ensures $(0, 0)$-confidentiality but does not satisfy any non-trivial DP guarantees.

Sometimes, it is useful to consider the confidentiality of multiple secret texts. For example, a secret key x could appear multiple times in multiple data points. Also, there might be multiple secret texts that are correlated to each other such that the knowledge of one would reveal other secrets.

Definition 3 (Group Confidentiality)**.** *We say that $\mathcal{A}$ ensures that a **list** of sensitive texts $\mathcal{S} := [x_1, ..., x_k]$ is $(\epsilon(\mathcal{S}), \delta)$-(group) confidential, if for any dataset D that contains $[x_1, ..., x_k]$ in up to k data points, and D' being the version that replaces each element in $\mathcal{S}$ with `<MASK>`, it holds that $(\mathcal{A}(D), \mathcal{A}(D'))$ are $(\epsilon(\mathcal{S}), \delta)$-indistinguishable.*

A special case of such group confidentiality is when $\mathcal{S}$ collects the *all secret text* in D, which protects all secret texts uniformly. We call this *uniform-confidentiality*. Note that the standard definition of confidentiality also protect every secret x, except that it protects each secret x individually, rather than together.

Inspired by the recent development of Bayesian DP (Triastcyn and Faltings, 2020), we also define Bayesian confidentiality as follows.

Definition 4 (Bayesian Confidentiality)**.** *Let D be a dataset that is fixed except a random secret $x \sim \mu$ drawn from some distribution μ. Let D' be obtained by replacing x with `<MASK>`[2]. Then $\mathcal{A}$ ensures (ϵ, δ)-Bayesian Confidentiality if for any D', $(\mathcal{A}(D), \mathcal{A}(D'))$ is (ϵ, δ)-indistinguishable, where $\mathcal{A}(D)$ is jointly distributed over $x \sim \mu$ and $\mathcal{A}$.*

The Bayesian confidentiality measures how much information an attacker could gain if he/she's prior knowledge about this secret x is described by the distribution μ. This is a strict generalization because when μ is a single point mass at x, it recovers Definition 2. The additional generality allows us to quantify the stronger confidentiality guarantee against weaker adversaries without complete information.

3.2 Confidentially redacted training

In this section we describe the CRT method to train language models with provable confidentiality guarantee. It includes two pre-processing operations (deduplication and redaction) and a switching optimization procedure. The overall idea is to screen the corpus into two separate sets, one public set including sentences with no confidential information, and one private set including sentences containing confidential content. We then use normal optimization algorithms (e.g. SGD) on the public set and differential privacy optimizer (e.g. DP-SGD) on the private set.

Deduplication. The deduplication procedure Dedup detects all sentences that appear multiple times in the training data and replace them into a single `<MASK>` from the second occurrence onwards (`<MASK>` is for proving purpose).

Redaction. The redaction procedure Redact_π takes applies a sequence labelling policy π to screen confidential content in the training corpus D. $\pi(s, x) = 1$ if a token x in a sentence s should be confidential. The labeled span in each detected sentence is replaced with a special token `<MASK>`. Note that we do not assume the policy is perfect. It may label some non-sensitive tokens as sensitive (false positives) and label some sensitive text as non-sensitive (false negative, or $1-$recall).

---

[2] Notice that D' is fixed even though x is random.

Algorithm 1: CRT

```
Input: Dataset $D$ (after tokenization / splitting), labelling policies $\pi, \pi_c$, number of epochs $T$
$D' \leftarrow \mathrm{Dedup}(D)$
$D'' \leftarrow \mathrm{Redact}_\pi(D')$
$D^{pri} \leftarrow \{s \in D'' | \exists x \in s \text{ s.t. } \pi(s,x) = 1 \text{ or } \exists x \subset s \text{ s.t. } \pi_c(s,x) = 1\}$
$D^{pub} = \{s \in D'' | s \notin D^{pri}\}$.
for $e = 1, ..., T$ do
    Run one epoch of SGD with $D^{pub}$.
    Run one epoch[3] of DP-SGD with $D^{pri}$.
end
```

Redact and Dedup could be implemented manually, but with the large text corpus nowadays it is more common that these procedures are implemented using automated tools. For example, Dedup could be implemented efficiently with just one pass of data using a *bloom filter* (Bloom, 1970) (or other hashing tricks that also catches near-duplicates). Bloom filter in particular, enjoys the nice property that it could have false positives but never any false negatives. Redact_π could be realized by a named entity recognition (NER) model or a personal-identifiable information (PII) detector.

Finally, CRT combines the two pre-processing steps with normal optimizer and DP-SGD, the standard algorithm for deep learning with differential privacy. A pseudo-code of the algorithm is given in Algorithm 1.

Besides using a sequence labeling policy π with balanced precision/recall as part of the redaction process. The algorithm uses another, more conservative, policy π_c with nearly perfect recall to decide on the data points that do not contain sensitive text. In the situation when such π_c isn't available, we simply choose $\pi_c(s,x) = 1$ for all tokens x in a sentence s and the second part becomes the vanila DP-SGD. It is also important that every data point that contains a `<MASK>` requires protection.

3.3 Theoretical analysis

We analyze the theoretical properties of the above method and show that they result in provable improvements in the (regular, group and Bayesian) confidentiality parameters for any algorithms that are provably $(\epsilon(x), \delta)$-confidential as defined in Section 3.1.

The following theorem captures the benefit of redaction in improving confidentiality.

Proposition 5 (Confidentiality under redaction). *If $\mathcal{A}$ ensures $(\epsilon(x), \delta)$-Confidentiality for each token x of sentence $s \in \mathcal{S}$ ($\mathcal{S}$ is a corpus), then $\mathcal{A} \circ \mathrm{Redact}_\pi$ ensures $(\tilde{\epsilon}(x), \delta)$-confidentiality with*

$$\tilde{\epsilon}(x) = \begin{cases} \epsilon(x) & \text{if } \pi(s,x) = 0 \\ 0 & \text{otherwise.} \end{cases}$$

In addition, $\mathcal{A} \circ \mathrm{Redact}_\pi$ also satisfies $(\tilde{\epsilon}(S), \tilde{\delta}(S))$-group confidentiality with

$$\tilde{\epsilon}(S) = \sum_{x \in s \& s \in \mathcal{S}} \epsilon(x) \mathbf{1}(\pi(s,x) = 0),$$
$$\tilde{\delta}(S) = \tilde{k} e^{\tilde{\epsilon}(S)} \delta$$

where $\tilde{k} := \sum_{x \in S} \mathbf{1}(\pi(s,x) = 0)$.

As an application of the above, if $\mathcal{A}$ ensures (ϵ, δ)-confidentiality, and that the empirical recall rates of the redaction policy on D is $1 - \gamma$, then the above proposition suggests that $\mathcal{A} \circ \mathrm{Redact}_\pi$ improves the uniform-confidentiality over applying $\mathcal{A}$ without redaction by a factor of γ. The proof is in the appendix.

Redaction also improves Bayesian confidentiality in a way that mirrors the privacy amplification by sampling from the DP literature.

Proposition 6 (Bayesian Confidentiality under Redaction). *If $\mathcal{A}$ ensures (ϵ, δ)-Bayesian Confidentiality with respect to $\mu[x | \pi(s,x) = 0]$ for a token x in a sentence s, then $\mathcal{A} \circ \mathrm{Redact}_\pi$ ensures $(\log(1 + \gamma(e^\epsilon - 1)), \gamma\delta)$-Bayesian Confidentiality under μ if π has a false negative rate (i.e., $1-$"Recall") of γ under μ.*

The proposition says that if the redaction policy is accurate for secrets $x \sim \mu$, then we can have a stronger confidentiality parameter that scales roughly at $\tilde{\epsilon} = O(\gamma\epsilon)$. The idea behind the proof is that over the distribution of $x \sim \mu$, with probability $1 - \gamma$, $\mathrm{Redact}_\pi(D) = \mathrm{Redact}_\pi(D')$, thus $\mathcal{A} \circ \mathrm{Redact}_\pi(D) \equiv \mathcal{A} \circ \mathrm{Redact}_\pi(D')$. With probability γ, $\mathrm{Redact}_\pi(D), \mathrm{Redact}_\pi(D')$ are different and conditioning on the fact that Redact_π fails to detect x. Note that π is also applied to other text that are not sensitive, and could result in false positives, but they do not matter as the modification

---

[3] DP-SGD uses Poisson-sampled Gaussian mechanisms (with a random batchsize), thus cannot ensure all data points are seen and some data points might be seen many times. One epoch means the number of iterations that in expectation covers $|D^{pri}|$ data points.

of Redact_π to D and D' will be identical. A full proof is given in the appendix.

Next we turn to deduplication.

Proposition 7 (Group confidentiality under deduplication.)**.** *If* $\mathcal{A}$ *ensures* $(\epsilon(S), \delta(S))$*-Group Confidentiality, then* $\mathcal{A} \circ \mathrm{Dedup}$ *ensures* $(\epsilon(\mathrm{Unique}(S)), \delta(\mathrm{Unique}(S)))$*-Group Confidentiality.*

Deduplication provides a stronger protection for those cases where some secret x could appear multiple times in the dataset.

Theorem 8. *Let DP-SGD from Algorithm 1 satisfies* (ϵ, δ)*-differential privacy.*

1. *Assume* $\pi_c(s, x) = 1$ *for all secret tokens* x *in a sentence* s *such that* $\pi(s, x) = 0$*, then Algorithm 1 satisfies* $(\epsilon\mathbf{1}(\pi(s, x) = 0), \delta)$*-confidentiality.*

2. *Let* S *be a group containing* m *unique secrets such that* $\pi_c(s, x) = 1 \forall x \in s$ *and* $s \in \mathcal{S}$ *and that* π *detects* $\tilde{\gamma}$*-proportion of the unique secrets in* S*. Then Algorithm 1 satisfies* $(\tilde{\gamma} m\epsilon, \tilde{\gamma} m e^{\tilde{\gamma} m\epsilon}\delta)$*-group confidentiality for* S*.*

3. *Let* π, π_c *has a a recall of* $1 - \gamma$ *and* $1 - \delta_2$ *respectively on* μ*, then Algorithm 1 satisfies* $(\log(1 + \gamma(e^\epsilon - 1)), \gamma\delta + \delta_2)$*-Bayesian Confidentiality for* μ*.*

The theorem demonstrates that our CRT algorithm enjoys a full suite of confidentiality guarantees and they all benefit from the deduplication and redaction, particularly if π has high recall.

Note that the CRT algorithm achieves the worst-case confidentiality guarantee if we have a non-trivial conservative screening policy that outputs $\pi_c(x) = 1$ for *all* secret x that π misses, or we simply run vanilla DP-SGD after deduplication and redaction. On the other hand, CRT still satisfies Bayesian confidentiality for each μ depending on the recall rate of π_c under μ.

4 Experiments

We evaluate CRT by training two types of language model, LSTM and GPT-2, on two datasets: 1) MultiWOZ 2.2, a well-known human-written dialogue dataset and 2) CustomerSim, a simulated dialogue dataset for conversation generation.

MultiWOZ 2.2 is an already-public dialogue dataset written by crowd-workers, which collects over 10,000 annotated dialogues spanning 8 domains (Zang et al., 2020). We use this dataset to show how CRT works in real-world applications. Following US Department of Labor's guidance[4] on personal-identifiable information (PII), we treat all confidential information (e.g. email address, reference number, telephone number, etc.) as secrets. For the sequence labeling policy π and conservative policy π_c, we build upon an NER model to do redaction. See Appendix A.4 for more details.

CustomerSim. Following S-DP Shi et al. (2021), we simulate a dialog dataset called CustomerSim with synthetic user information. The dialog flow is simulated based on a fixed agenda and the language generation is template-based (Zhao and Eskénazi, 2018). CustomerSim consists of 10 thousand examples and over one million tokens. We treat user name, address, phone number, order, and tracking number as secrets, and use a regular expression tester (regex) to detect them for the redaction process.

Experiment details. For LSTM model, we follow the setting in S-DP to choose a one-layer LSTM. Because S-DP requires hidden states of the sensitive input to be protected, it doesn't support more layers nor Bidirectional LSTM. Since the advent of Transformers (Vaswani et al., 2017) significantly improves the capabilities of generative language models, we also test transformer-based language model GPT-2 (Radford et al., 2019) from HuggingFace (Wolf et al., 2019). As for deduplication, we use `SHA-1` (Jarvinen, 2004) hash function to encode sequences to `SHA-1` hash code and then remove identical sequences based on the same hash code. For Bayesian Confidentiality, we treat the uniform distribution over the secret sequences as the distribution μ. More experiment details can be found in Appendix A.3.

Baselines. For LSTM model, we compare four different training approaches: (1) vanilla SGD (denoted by "Non-private-LSTM"), (2) Selective DPSGD (denoted by "S-DP-LSTM") (3) DPSGD (denoted by "DPSGD-LSTM") and (4) confidentially redacted training (denoted by "CRT-LSTM"). While for GPT-2 model, we compare three different training approaches: (1) vanilla SGD (denoted by "Non-private-GPT"), (2) DPSGD (denoted by "DPSGD-GPT") and (3) CRT (denoted by "CRT-GPT"). Our implementation of S-DP-LSTM

---

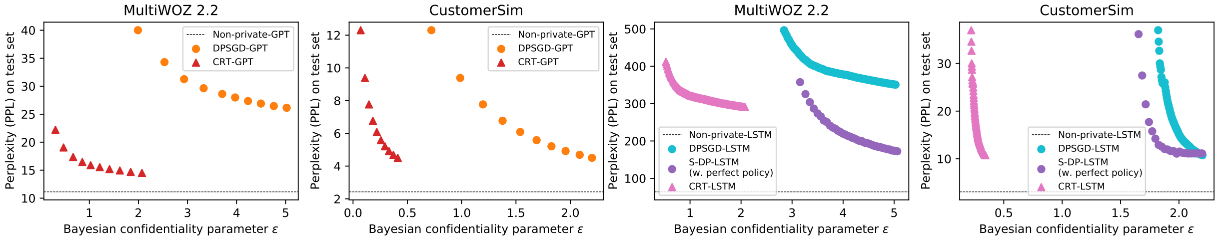

Figure 2: Model utility and confidentiality guarantee on MultiWOZ 2.2 and CustomerSim datasets with μ being a uniform distribution over the secret sequences in each dataset. PPL: Perplexity on the test set. ϵ: Privacy guarantee in Bayesian Confidentiality. We fix $\delta = 8e-5$ for all models. Since Selective DP-SGD with approximate policy gives $\epsilon = +\infty$, we show its result with a perfect screen policy. But when a perfect policy is available, `Redaction` only gives $\epsilon = 0$ and achieves the PPL of vanilla training with no noise added (Non-private-GPT/LSTM). For other models we set $\gamma = 0.1$ to show the result under approximate policy.

model is built upon Shi et al. (2021)[5]. We run the experiment for the GPT-2 model following Li et al. (2021)[6], in which they propose ghost clipping method to alleviate the computational challenge of running DP-SGD with large Transformers.

All the models are trained five times to reduce randomness, and the parameters are tuned based on the validation set performances.

5 Experimental Results

5.1 Evaluation procedure

We need to evaluate both model utilities and privacy guarantees of the language models. We measure predictive perplexity (PPL) for the quality of LM. We also analyze the theoretical privacy budget (ϵ, δ) and test whether language models are private under attacks detailed below.

Canary insertion attack. Canary insertion is proposed as a testing methodology for quantitatively assessing the risk of *unintended memorization* (Carlini et al., 2019). It inserts random sequences called canaries into the training dataset, then trains the model, and finally calculates the following exposure for the inserted canaries to measure a model's potential for privacy risks. In our experiment, we randomly generate 10 canaries in the form of "`My ID is: <random 6-digit number here>`". Each canary is inserted into the training dataset 20 times to generate more salient differences between models.

Definition 9 (Canary Exposure). *Given a canary $s[r]$, a model with parameters θ, and the randomness space $\mathcal{R}$, the exposure of $s[r]$ is*

$$\text{exposure}_\theta = \log_2 |\mathcal{R}| - \log_2 \text{rank}_\theta(s[r])$$

After training, we calculate empirical model perplexity for all possibly-instantiated canaries and list them in sorted order. Then we can get the canary exposure based on the rank of a specific canary sequence $\text{rank}_\theta(s[r])$ and the number of all possible candidates $|\mathcal{R}|$. In our setting, we show the highest canary exposure in 10 canaries. For example, if a canary ranks 1st among 1M candidates, the canary exposure is 19.93.

Membership inference attack. Membership Inference is a widely used privacy attack method. Given a non-privately trained model, an adversary can predict whether or not a particular example was used to train the model. We adopt the membership inference attack in Carlini et al. (2021). The general idea is to calculate the given samples' perplexities under the model, rank them and choose the ones with the lowest perplexities, i.e., highest likelihood by the model. We can think of this process as training a binary classifier based on the perplexity feature. We also implement the group membership inference attack to show the group confidentiality. More details about the implementation can be found in the Appendix A.5.

5.2 Overall performance

Figure 2 presents the results of model utilities and confidentiality guarantees across our models of interest on MultiWOZ 2.2 and CustomerSim datasets. Each point denotes a model for different epochs in a training process. Since the X-axis is ϵ in Bayesian Confidentiality (the lower the better) and the Y-axis is perplexity (the lower the better), a perfect model will lie in the bottom-left corner. CRT-GPT and DPSGD-GPT in general, perform better than S-DP-LSTM, CRT-LSTM and, DPSGD-LSTM on the test sets. Our model CRT-GPT's performance is

---

[5] https://github.com/wyshi/lm_privacy

[6] https://github.com/lxuechen/private-transformers

close to Non-private-GPT in terms of PPL while preserving strong confidentiality. Besides, CRT-GPT is better than DPSGD-GPT manifested by a much lower ϵ, which demonstrates that approximately correct screening policy amplifies the confidentiality guarantee.

Differences can be witnessed in the results from two different datasets: the models trained on CustomerSim achieve overall better performances than those trained on MultiWOZ. We think it's due to the fact that CustomerSim contains simple dialogs from template-based simulations.

5.3 Attack results

Figure 3, 4, and 5 present the results from canary insertion attack and individual/group membership inference attack on MultiWOZ 2.2 and CustomerSim datasets. The X-axis is the false negative rate γ of screening policy π, ranging from 0.0 to 0.5; the Y-axis is the canary exposure (in Figure 3) and membership inference accuracy (in Figure 4 and 5), which measures the effectiveness of the attacks. The lower the canary exposure or inference accuracy, the better protection the model provides against the attacks.

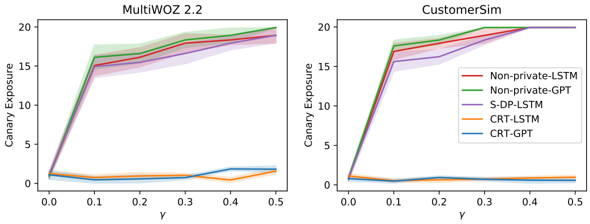

Figure 3: Canary insertion attack result. CRT achieves almost 0 canary exposure, which means it can prevent unintended memorization.

For canary insertion attack, it can be seen from Figure 3 that the canary exposures for CRT-LSTM and CRT-GPT are both close to 0 which thus guarantee excellent confidentiality. Non-private-LSTM and Non-private-GPT with mask can also attain great protection at perfect screening policy accuracy ($\gamma = 0$), nonetheless a rise in γ results in a sharp increase in the exposure. It should be noticed that S-DP-LSTM also has high exposure, similar to Non-private models, given any γ above 0. This is because that many sensitive data has been falsely identified as non-sensitive by the approximate policy, S-DPSGD does not protect these false negative samples and hence a privacy leakage.

For membership inference attack, we compare the inference accuracy with the benchmark value of 0.5, which equals the random guess performance. In Figure 4 and 5, we see that CRT-LSTM and CRT-GPT align well with the 0.5 horizontal line, suggesting that they are rather safe to the attack. The inference accuracy for Non-private-LSTM/Non-private-GPT/S-DP-LSTM, in contrast, surges above 0.5 as the false negative rate γ deviates from 0.0, indicating that these models become vulnerable to the attack under non-perfect screen policy. In addition, Non-private and S-DP models show even worse protection under the group attack than the individual one in view of a higher inference accuracy at certain γ.

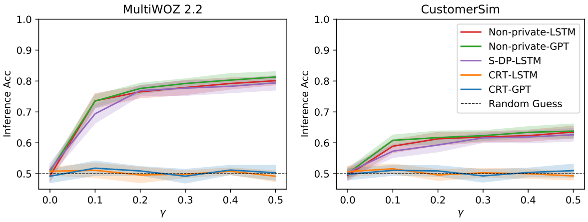

Figure 4: Membership inference attack result. CRT attains nearly 50% accuracy, indicating that the adversary could not infer whether a data point is used for training.

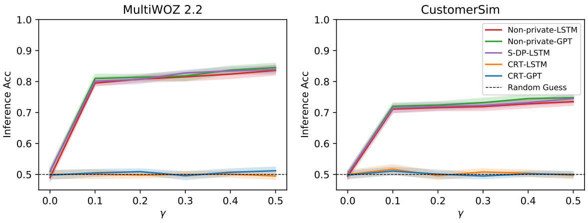

Figure 5: Group membership inference attack result.

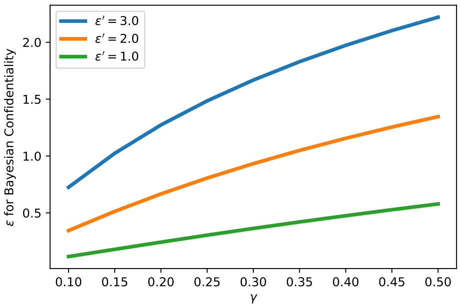

Figure 6: Bayesian Confidentiality amplification result. CRT helps to amplify the confidentiality guarantee.

5.4 CRT amplifies Bayesian Confidentiality guarantees

Figure 6 shows that confidentially redacted training can help to amplify the confidentiality guarantees. We set the ϵ' in DP-SGD fixed and show the corresponding ϵ in Bayesian Confidentiality with different screen policy π. Both ϵ' and ϵ are for $\delta = 8e-5$. If the approximately screening policy π has a high recall (γ is small), we will achieve much improvement in the Bayesian Confidentiality parameter ϵ by deduplication and redaction. For example, with $(\epsilon' = 1.0, \gamma = 0.1)$, we reduce the ϵ to 0.12.

6 Conclusion

In this paper, we propose confidentially redacted training (CRT), a method to train language models while protecting the secret texts. We introduce a new definition of confidentiality which quantifies the risk of leaking sensitive content. We prove the effectiveness of CRT both theoretically and empirically on multiple datasets and language models.

7 Broader Impact

This work will alleviate ethical concerns of large-scale pre-trained language models. This paper provides one promising solution to an important aspect of NLP: training high quality language models for text generation without compromising confidential information. The current use cases of language models involve pretraining on public web corpus and fine-tuning on individual application data. However, the private application specific data often contains user-generated sensitive information. The proposed method in this paper aims to use as much individual fine-tuning data as possible, while does not leak or memorize any confidential information with provable guarantees. Without the method, one has to either use the general pretraining LM without fine-tuning or manually filter sensitive information and fine-tuning on the remaining. It can be applied in broader applications that need language models or text generation models.

In our experiments, we use a simulation scheme to mimic confidential content in a real corpus. We did not compromise any real user's confidential information.

Selective noise-adding DP-SGD

Noise added to the gradients of all data points with a <MASK> And all data points selected by a policy with **nearly perfect recall**.

Figure 7: An illustration of our proposed algorithm on a dataset with two data points. The first data point is the example from Figure 1, and the second data point is modified to illustrate the various aspects of the pre-processing steps. The red-colored mask indicates the masks produced by deduplication just for illustration purposes. In the algorithm, both of them replace a sequence of tokens with the same special token `<MASK>`.

A.2 Proofs of technical results

Proof of Proposition 5. The first statement straigtforwardly follows from that $\text{Redact}_\pi(D) = \text{Redact}_\pi(D')$ if $\pi(s,x) = 1$ and that $\text{Redact}_\pi(D)$ and $\text{Redact}_\pi(D')$ remain a pair of neighbors differing by only x. The group confidentiality claims follows from the standard calculation of small group privacy from differential privacy, which applies the (single x) confidentiality iteratively. Let $\tilde{D} = \text{Redact}_\pi(D)$, $\tilde{D}' = \text{Redact}_\pi(D')$ and $\tilde{S} = [x_1, ..., x_{\tilde{k}}]$ be the list of S that are not masked by π. For any measurable event E

$$\begin{aligned}
\mathbb{P}[\mathcal{A} \circ \text{Redact}_\pi(D) \in E] = \mathbb{P}[\mathcal{A}(\tilde{D})] \leq e^{\epsilon x_1} \mathbb{P}[\mathcal{A}(\tilde{D}_{-x_1,+\texttt{<MASK>}}) \in E] + \delta \\
\leq & e^{\epsilon x_1 + \epsilon(x_2)} \mathbb{P}[\mathcal{A}(\tilde{D}_{-x_{1,2},+\texttt{<MASK>}^2}) \in E] + e^{\epsilon x_1}\delta + \delta \\
& \ldots \\
\leq & e^{\sum_{i=1}^{\tilde{k}} \epsilon x_i} \mathbb{P}[\mathcal{A}(\tilde{D}') \in E] + \delta(1 + e^{\epsilon x_1} + e^{\epsilon x_1 + \epsilon x_2} + \ldots + e^{\epsilon x_1 + \ldots + \epsilon x_{\tilde{k}-1}}) \\
\leq & e^{\tilde{\epsilon}(S)} \mathbb{P}[\mathcal{A} \circ \text{Redact}_\pi(D') \in E] + k e^{\tilde{\epsilon}(S)} \delta
\end{aligned}$$

□

Proof of Proposition 6. Consider a dataset D (in which one of the data point has $x \sim \mu$) and a fixed D'. Denote the probability distributions p, q, r as shorthands for

$$\begin{aligned}
p &\sim \mathcal{A} \circ \text{Redact}_\pi(D) | \pi(s,x) = 1 \\
q &\sim \mathcal{A} \circ \text{Redact}_\pi(D) | \pi(s,x) = 0 \\
r &\sim \mathcal{A} \circ \text{Redact}_\pi(D') | \pi(s,x) = 0
\end{aligned}$$

Moreover, we use $\alpha p + (1-\alpha) q$ to denote the mixture distribution that samples from p with probability α and q with probability $1 - \alpha$.

Recall that the Hockey-Stick-divergence characterization of (ϵ, δ)-indistinguishsability (Barthe and Olmedo, 2013), which says that (P, Q) are (ϵ, δ)-indistinguishsable if and only if

$$H_{e^\epsilon}(P \| Q) := \mathbb{E}_{y \sim Q}[(\frac{dP}{dQ}(y) - e^\epsilon)_+] \leq \delta.$$

It suffices for us to bound the following quantity:

$$\begin{aligned}&H_{1+\gamma(e^{\epsilon}-1)}(\mathcal{A}\circ\mathrm{Redact}_{\pi}(D)\|\mathcal{A}\circ\mathrm{Redact}_{\pi}(D')) = H_{e^{\epsilon}}((1-\gamma)p+\gamma q\|(1-\gamma)p+\gamma r)\\ =&\gamma H_{e^{\epsilon}}(q\|(1-\beta)p+\beta r)\leq\gamma\left((1-\beta)H_{e^{\epsilon}}(q\|p)+\beta H_{e^{\epsilon}}(q\|r)\right)\end{aligned}$$

where $\beta = \frac{1+\gamma(e^{\epsilon}-1)}{e^{\epsilon}}$. In the above, the second line follows from Theorem 2 of (Balle et al., 2018) (an identity called "Advanced Joint Convexity" by the authors) and the inequality is due to the (standard) joint convexity of the Hockey-Stick divergence. It remains to bound $H_{e^{\epsilon}}(q\|p)$ and $H_{e^{\epsilon}}(q\|r)$.

Check that $p, r, \mathcal{A}\circ\mathrm{Redact}_{\pi}(D')$ are identically distributed and that $H_{e^{\epsilon}}(q\|r)\leq\delta$ by our assumption on $\mathcal{A}$'s Bayesian confidentiality guarantee w.r.t. $\mu(x|\pi(s,x)=0)$. This completes the proof. ☐

Proof of Proposition 7. The proof is straightforward as $\mathrm{Dedup}(D)$ differs from $\mathrm{Dedup}(D')$ only by $\mathrm{Unique}(S)$. ☐

Proof of Theorem 8. The proof for the first statement follows from the fact that DP implies (ϵ,δ)-confidentiality and Proposition 5. Notably, if π_c catches all x that is missed by π, then we get that for all secret x, $\epsilon(x)\leq\epsilon$.

The proof of the second statement applies Proposition 7 and the second part of Proposition 5.

The proof of the third statement applies Proposition 6 but requires a separate treatment of the case when x is missed by both π and π_c. Let the event that a secret x is not selected by the conservative policy be E and let $\mathcal{A}$ be a generic algorithm satisfying (ϵ,δ_1) Bayesian confidentiality under μ,

$$\begin{aligned}\mathbb{P}[\mathcal{A}(D)\in S] &\leq \mathbb{P}[\mathcal{A}\circ\mathrm{Redact}_{\pi}(D)\in S\subset E^{c}]+\delta\\ &\leq e^{\epsilon}\mathbb{P}[\mathcal{A}(D')\in S\subset E^{c}]+\delta_1+\delta_2\\ &\leq e^{\epsilon}\mathbb{P}[\mathcal{A}(D')\in S]+\delta_1+\delta_2.\end{aligned}$$

This completes the proof. ☐

A.3 More details on experiments

We choose the one-layer LSTM with an embedding size of 200 and a hidden size of 200. We choose distill-gpt2[7] as the GPT-2 model, which has 6 layers, 768 dimension and 12 heads. Vocabulary size for GPT-2 is 50257. Our experiments are conducted on NVIDIA TITAN-Xp GPU. For LSTM models, we tune the hyperparameters of the learning rate (lr) among {20, 10, 5, 1, 0.1, 0.05, 0.01}, batch size (bs) and the epochs among {5, 10, 30, 50, 100}. We finally choose {lr=20, bs=256, epochs=50} for Non-private-LSTM, {lr=0.1, bs=5, epochs=50} for S-DPSGD-LSTM and {lr=0.05, bs=10, epochs=100} for CRT-LSTM. The same set of hyperparameters are tuned for GPT model as well. Our final choice for DPSGD-GPT/CRT-GPT model is {lr=5e-4, bs=256, epochs=10}. The actual run-time of algorithms depends on implementation details. Here, we outline estimates of the run-time for training. Running one epoch on CRT-LSTM takes 2 hours wheras the same task on CRT-GPT only takes 30 minutes since the implementation of Li et al. (2021) is highly efficient. We use autodp[8], an automating differential privacy computation for the privacy analysis. Noise scale σ is calculated numerically so that a DP budget of (ϵ,δ) is spent after T epochs.

A.4 Redaction policy details

We build the sequence labeling policy based on trimming one NER model[9] trained on OntoNotes-5.0 (Weischedel et al., 2013) dataset. We modify the last layer of the NER model and set the threshold for the output scores to enable abnormal/sensitive data detection. For the screen policy π, we set the threshold to be 0.3 for all predictions with OntoNotes tags. For the conservative policy π_c, we select all predictions with tags and all plain texts with scores smaller than 0.9 to be sensitive data. We manually label 200 data points and find that the conservative policy π_c can achieve 100% recall with lots of false positives and that π can achieve 90% recall with few false positives.

A.5 Membership inference attack details

In our experiments, we manually construct a dataset with 2000 sequences. We select 1000 sequences from the protected secrets used in the training data. And we randomly generate 1000 samples of similar format which are not used in the training data. In this way, a random guess generates an accuracy of 50%. For MultiWoz 2.2, we use sentences with reference numbers as the secrets. For CustomerSim, we choose customer addresses as the secrets.

In order to show group confidentiality guarantees, we also conduct group membership inference attack. In this setting, we construct a dataset with 2000 groups, each of which includes 20 sentences. One half of the groups are “sensitive groups" with all 20 sentences drawn from protected secrets and the other half are "insensitive groups" with all 20 sentences being random. We build the classifier based on the sum of the perplexities in one group.

A.6 “The devil is in the details” – how things could go wrong with seemingly inocuous changes to the algorithm.

In this section, we highlight various aspects of our algorithms and why certain choices in the pre-processing steps need to be done in the specific way we recommend for our results to hold for them.

1. It is important that the definition of confidentiality is defined with respect to a perfectly redacted version of the dataset. If we define it as in selective differential privacy, then there will *not* be an amplification effect from redaction. This is because if we replace a secret x that can be detected by π with another x' that cannot be detected by π, then even if x is replaced with `<MASK>`, x' will not be and the two datasets are still different after redaction. In addition, the S-DP definition will not be useful for us we do not know how to define a confidentiality parameter specific for each x or Bayesian confidentiality parameter for each μ

2. Tokenization and splitting into individual “sentences” (data points) should go before redaction / de-duplication. Otherwise redaction with an approximate screening policy and with an ideal screening policy, or deduplication may cause *misalignments*, resulting in almost all data points being different in the preprocessed version of D and D'.

3. Each data point should contain only “whole” natural sentences, otherwise the sensitive part of a natural sentence could split into two data points.

4. Deduplication steps should replace duplicate text with the same `<MASK>`, otherwise `<MASK_Dedup>` and `<MASK_Redact>` are not the same so even if all secrets are masked, there will be a difference between the pre-processed versions of D and its neighbor, while in our approach there are no differences and we achieve perfect confidentility (with $\epsilon = 0$).

5. Any data point containing `<MASK>` needs to be put in D^{pri}. This is because otherwise our algorithm that works on D' will be a deterministic algorithm that is perfectly distinguishable from the alternative world where the algorithm is random because the approximate policy π fails to redact certain secrets x.

6. In the DP-SGD algorithm, the sampled minibatches should contain the whole minibatch from D^{pri} or the whole minibatch from D^{pub}. Otherwise the noise always need to be added and the algorithm is identical to the vanilla DP-SGD, and there is no benefit of having a portion of the data being public comparing to all of the data are private.

KAT: A Knowledge Augmented Transformer for Vision-and-Language

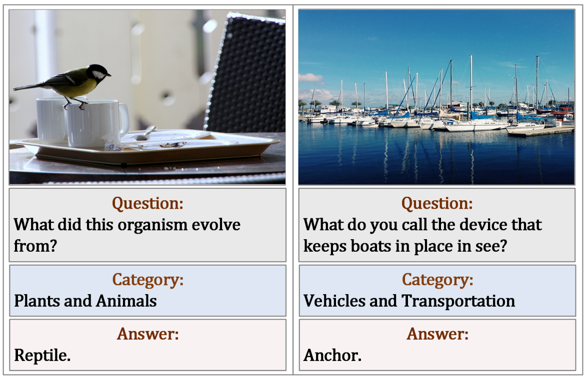
Abstract

The primary focus of recent work with large-scale transformers has been on optimizing the amount of information packed into the model's parameters. In this work, we ask a complementary question: Can multimodal transformers leverage explicit knowledge in their reasoning? Existing, primarily unimodal, methods have explored approaches under the paradigm of knowledge retrieval followed by answer prediction, but leave open questions about the quality and relevance of the retrieved knowledge used, and how the reasoning processes over implicit and explicit knowledge should be integrated. To address these challenges, we propose a - **K**nowledge **A**ugmented **T**ransformer (KAT) - which achieves a strong state-of-the-art result (+6% absolute) on the open-domain multimodal task of OK-VQA. Our approach integrates implicit and explicit knowledge in an encoder-decoder architecture, while still jointly reasoning over both knowledge sources during answer generation. Additionally, explicit knowledge integration improves interpretability of model predictions in our analysis. Code and pre-trained models are released at `https://github.com/guilk/KAT`.

1 Introduction

There has been a revival of interest in knowledge-intensive tasks which require an external knowledge source for humans to perform. Many applications in real-world scenarios, such as autonomous AI agents, need to seamlessly integrate implicit (*i.e.*, commonsense) and explicit knowledge (*e.g.*, Wikidata) to answer questions. In this work, we investigate how to effectively integrate implicit and explicit knowledge for reasoning. Tasks like Outside Knowledge Visual Question Answering (OK-VQA) (Marino et al., 2019) require that models use knowledge not present in the input to answer questions, making it an ideal test bed for investigating this implicit-explicit knowledge trade-off.



Question:	Question:
What did this organism evolve from?	What do you call the device that keeps boats in place in see?
Category:	Category:
Plants and Animals	Vehicles and Transportation
Answer:	Answer:
Reptile.	Anchor.

Figure 1: Examples of knowledge-based VQA that requires external knowledge. Success on this task requires not only visual recognition, but also logical reasoning to incorporate external knowledge about the world.

Consider the examples from OK-VQA shown in Figure 1. To answer the question in the left example, the system needs to both ground *organism* to bird through explicit knowledge and then apply the implicit knowledge *birds evolved from reptiles* to answer the question. Similarly for the question in the right example, the system needs to recognize boats and harbor and requires the implicit knowledge *anchors are used to stop boats from moving*. A key challenge here is to accurately link image content to abstract external knowledge. There have been a number of recent developments demonstrating the feasibility of incorporating external knowledge into Question Answering models (Wang et al., 2017b; Li et al., 2020b; Marino et al., 2021; Wu et al., 2022; Garderes et al., 2020). Existing methods first retrieve external knowledge from external knowledge resources, such as DBPedia (Auer et al., 2007) and ConceptNet (Liu and Singh, 2004) before jointly reasoning over the retrieved knowledge and image content to predict an answer.

However, most existing approaches have several drawbacks. First, explicit knowledge retrieved using keywords from questions or image tags may be

too generic, which leads noise or irrelevant knowledge during knowledge reasoning. Second, existing work mainly focuses on explicit knowledge which is often in the form of encyclopedia articles or knowledge graphs. While this type of knowledge can be useful, it is insufficient to answer many knowledge-based questions. As shown in Figure 1, questions require the system to jointly reason over explicit and implicit knowledge, which is analogous to the way humans do. To address these challenges, we propose an approach, **KAT**, to effectively integrate implicit and explicit knowledge during reasoning. The main contributions of our work are as follows:

i) Knowledge extraction. We adopt two novel methods for knowledge extraction that significantly improve the quality and relevance of extracted knowledge: for implicit knowledge, we design new prompts to extract both tentative answers and supporting evidence from a frozen GPT-3 model; for explicit knowledge, we design a contrastive-learning-based explicit knowledge retriever using the CLIP model, where all the retrieved knowledge are centered around visually-aligned entities.

ii) Reasoning in an encoder-decoder transformer. We design a novel reasoning module in *KAT* to perform jointly reasoning over explicit and implicit knowledge during answer generation, which is trained by using an end-to-end encoder-decoder transformer architecture.

iii) OK-VQA performance. *KAT* sets a new state of the art on the challenging OK-VQA (Marino et al., 2019) benchmark, and significantly outperforms existing approaches.

2 Related Work

Vision-Language Transformer. Multimodal transformers have made significant progress over the past few years, by pre-trained on large-scale image and text pairs, then finetuned on downstream tasks. VisualBERT (Li et al., 2019), Unicoder-VL (Li et al., 2020a), NICE (Chen et al., 2021b), and VL-BERT (Su et al., 2020) propose the single-stream architecture to work on both images and text. ViLBERT (Lu et al., 2019) and LXMERT (Tan and Bansal, 2019) propose a two-stream architecture to process images and text independently and fused by a third transformer in ta later stage. While these models have shown to store in-depth cross-modal knowledge and achieved impressive performance on knowledge-based VQA (Marino et al., 2021; Wu et al., 2022; Luo et al., 2021), this type of implicitly learned knowledge is not sufficient to answer many knowledge-based questions (Marino et al., 2021). Another line of work for multimodal transformers, such as CLIP (Radford et al., 2021) or ALIGN (Jia et al., 2021), aligns visual and language representations by contrastive learning. These models achieve state-of-the-art performance on image-text retrieval tasks. Different from existing work that uses multimodal transformers as implicit knowledge bases, we focus primarily on how to associate images with external knowledge. Importantly, our model only relies on multimodal transformers learned by contrastive learning which do not require any labeled images. This makes our model more flexible in real-world scenarios.

Knowledge-based VQA. Some Knowledge-based visual language tasks requires external knowledge beyond the image to answer a question. Early exploration, such as FVQA (Wang et al., 2017a), creates a fact-based VQA dataset by selecting a fact (*e.g., <Cat, CapableOf, ClimbingTrees>*) from a fixed knowledge base. A recent Outside Knowledge VQA (OK-VQA) dataset is a more challenging dataset, covering a wide range of knowledge categories. In our work, we focus on OK-VQA due to its large-scale knowledge-based questions as well as its open-ended nature.

Recent approaches have shown a great potential to incorporate external knowledge for knowledge-based VQA. Several methods explore aggregating the external knowledge either in the form of structured knowledge graphs (Garderes et al., 2020; Narasimhan et al., 2018; Li et al., 2020b; Wang et al., 2017a,b), unstructured knowledge bases (Marino et al., 2021; Wu et al., 2022; Luo et al., 2021), and neural-symbolic inference based knowledge (Chen et al., 2020; West et al., 2021). In these methods, object detectors (Ren et al., 2015) and scene classifiers (He et al., 2016) are used to associate images with external knowledge. Further, external APIs, such as Google (Wu et al., 2022; Luo et al., 2021), Microsoft (Chen et al., 2021a; Yang et al., 2022) and OCR (Luo et al., 2021; Wu et al., 2022) are used to enrich the associated knowledge. Finally, pre-trained transformer-based language models (Chen et al., 2021a; Yang et al., 2022), or multimodal models (Wu et al., 2022; Luo et al., 2021; Wu et al., 2022; Garderes et al., 2020; Marino et al., 2021) are leveraged as implicit knowledge bases for answer predictions.

Different from previous approaches, Our work aims to develop a single, unified architecture, by jointly reasoning over explicit and implicit knowledge to augment generative language models. While part of our approach is similar to PICa (Yang et al., 2022) which considers GPT-3 as implicit knowledge base, our model takes one step further by showing that how explicit and implicit knowledge can be integrated during knowledge reasoning. Another similar work Vis-DPR (Luo et al., 2021) collects a knowledge corpus from training set by Google Search which is specific to a certain dataset. Our proposed model is more generic by collecting entities from Wikidata and not limited to the training set.

Open-Domain Question Answering (ODQA). ODQA is the NLP task of answering general domain questions, in which the evidence is not given as input to the system. Several approaches (Chen et al., 2017; Karpukhin et al., 2020) propose to predict the answers by first retrieving support document from Wikipedia, before extracting answers from the retrieved document. Recent works (Izacard and Grave, 2020; Lewis et al., 2020b) combine text retrieval models with language generative models which achieve state-of-the-art performance on knowledge-intensive natural language processing tasks. Similar to these works as part of our method, we extend this framework to VQA domain and show the effectiveness of aggregating explicit and implicit knowledge for knowledge-based VQA.

3 Method

3.1 Overview

When humans reason about the world, they process multiple modalities and combine external and internal knowledge related to these inputs. Inspired by this idea, we introduce a new *KAT* approach. The overview of the proposed *KAT* model is shown in Figure 2. We define the knowledge from explicit knowledge bases as the explicit knowledge, and the knowledge stored in large-scale language models as the implicit knowledge (*i.e.*, implicit commonsense knowledge). We describe the retrieval method of our explicit knowledge (§3.2) and the retrieval method of our implicit knowledge (§3.3). Next, we introduce the details of our knowledge reasoning module which jointly reasons over both explicit and implicit knowledge (§3.4).

Problem Formulation. We apply our *KAT* on OK-VQA task in this paper. Formally, given a training dataset $\mathbb{D} = \{(v_i, q_i, a_i)\}_{i=1}^{s}$, where v_i denotes the i^{th} training image; s is the total number of the training images; q_i and a_i represent the i^{th} question and its corresponding answer, respectively. We use a sequence-to-sequence model that is composed of an encoder and a decoder, which is a comparison method of T5 (Raffel et al., 2020) or BART (Lewis et al., 2020a). Let θ be the parameters of the model p that needs to be trained. Unlike previous approaches that treat this task as a classification problem (Wu et al., 2022; Marino et al., 2021), our model is to take v_i and q_i as inputs and generate the answer a_i in an auto-regressive manner. It should be noted that our proposed model tackles a more challenging problem. As the generated answer may contain an arbitrary number of words from the entire vocabulary.

3.2 Explicit Knowledge Retrieval

3.2.1 Explicit Knowledge Extraction

Given an image v_i and corresponding question q_i, it is important to ground image regions with fine-grained descriptions, which is conducive to understanding both the image content and the question with the referred items. Existing approaches (Radford et al., 2021; Jia et al., 2021) on OK-VQA apply object detectors to generate image tags which are used for explicit knowledge retrieval. Such image tags can be generic and have a limited vocabulary size, leading noise or irrelevant knowledge. Motivated by the recent progress of visual-semantic matching approaches (Radford et al., 2021; Jia et al., 2021), we leverage a contrastive-learning-based model to associate image regions with external knowledge bases.

Similar to the previous work (Marino et al., 2021; Luo et al., 2021) which uses a subset of external knowledge, we construct an explicit knowledge base that covers the 8 categories of animals, vehicles and other common objects from Wikidata (Vrandecic and Krotzsch, 2014). The details can be found in Section 3.2.2. We denote the constructed knowledge base as $\mathcal{K}$. Each knowledge entry e from $\mathcal{K}$ is a concatenation of the entity and its corresponding description.

The goal of our explicit knowledge retriever is to index all knowledge entries in d_r-dimensional dense representations by a dense encoder $E_{ent}(\cdot)$, such that it can efficiently retrieve the top m knowl-

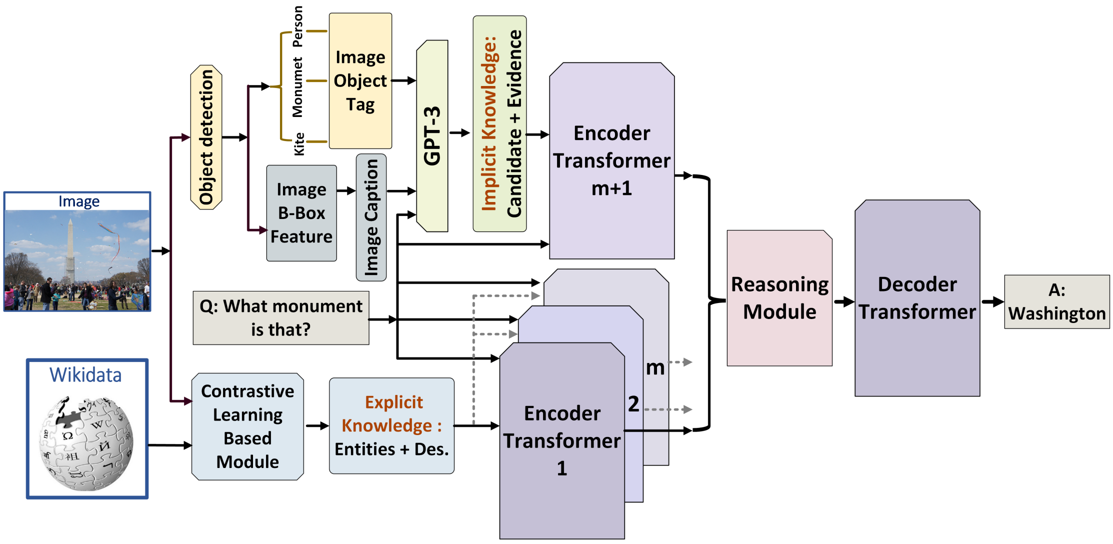

Figure 2: Our *KAT* model uses a contrastive-learning-based module to retrieve knowledge entries from an explicit knowledge base, and uses GPT-3 to retrieve implicit knowledge with supporting evidence. The integration of knowledge is processed by the respective encoder transformer, and jointly with reasoning module and the decoder transformer as an end-to-end training with the answer generation.

edge entries relevant to each input image. Given an image v_i, we use a sliding window with a stride to generate N image regions $\{v_i^1, ..., v_i^N\}$. Then an image encoder $E_{img}(\cdot)$ is applied to map each patch to a d_r-dimensional dense representation, and retrieves k knowledge entries from $\mathcal{K}$ whose representations are closest to the patch-level representation. To define the similarity score between the image region v_i^j and the entity e, we use the inner product of their normalized representations:

$$sim(v_i^j, e) = E_{ent}(e)^T E_{img}(v_i^j). \tag{1}$$

In total, we retrieve the top $N \times k$ knowledge entries relevant to image v_i. We keep top-m knowledge entries ranked by similarity scores as explicit knowledge source x^{exp}.

In principle, the image and knowledge entry encoders can be implemented by any multimodal transformer. We use the CLIP model (ViT-B/16 variant) (Radford et al., 2021) in our work and take the `[CLS]` as representations. We pre-extract representations of the knowledge entries in the knowledge base $\mathcal{K}$ using the entity encoder E_{ent} and index them using FAISS (Johnson et al., 2019). The qualitative example for the extracting explicit knowledge model is presented in Appendix A.

3.2.2 Knowledge Base Construction

We use the English Wikidata (Vrandecic and Krotzsch, 2014) dump from Sep. 20, 2021 as the explicit knowledge source base which contains 95,870,584 entities. Each data item is stored in a structured format constituted of property-value pairs. Properties are objects and have their own Wikidata pages with labels, aliases, and descriptions. We extract a subset that covers common objects in real-world scenarios. We remove all entities whose string labels or corresponding descriptions are empty or non-English. This results in a total of 423,520 entity triplets in the end (*e.g.*, <*Q2813, Coca-Cola, carbonated brown colored soft drink*>) (See Table 1).

Subclass		Number
Role	(Q214339)	162,027
Point of interest	(Q960648)	85,900
Tool	(Q39546)	78,621
Vehicle	(Q42889)	44,274
Animal	(Q729)	18,581
Clothing	(Q11460)	17,711
Company	(Q891723)	12,173
Sport	(Q349)	4,233
Total		423,520

Table 1: We collect a subset of Wikidata that covers common objects in real-life scenarios as our explicit knowledge base. Above are statistics of these subclasses.

3.3 Implicit Knowledge Retrieval

While our explicit knowledge retriever focuses on semantic matching between image regions and knowledge entries, it lacks implicit commonsense knowledge (*e.g.*, *Lemons are sour*) which is usually stored in large-scale language models (Brown et al., 2020). In this section, we retrieve implicit knowledge with supporting evidence by prompting from a large-scale pre-trained language model.

We design our implicit knowledge retriever with inspirations from the previous work (Yang et al., 2022). We leverage GPT-3 as an implicit language knowledge base and treat VQA as an open-ended text generation task. For each image-question pair, we first convert the image v_i into a textual description C via a state-of-the-art image captioning model (Li et al., 2020c), and then construct a carefully designed text prompt consisting of a general instruction sentence, the textual description C, the question, and a set of context-question-answer triplets taken from the training dataset that are semantically most similar to the current image-question pair (see Figure 7 in Appendix B for a concrete example). We then input this text prompt to the GPT-3 model in its frozen version and obtain the output from GPT-3 as the tentative answer candidate to the current image-question pair.

To gain deeper insights from the implicit knowledge coming out of GPT-3 and its rationale, we design another prompt to query GPT-3 for supporting evidence behind the tentative answer candidate that it generates. More specifically, for each image-question pair (v_i, q_i), and for a tentative answer a generated by GPT-3, we construct the prompt in the form of: "(question q_i)? (answer a). This is because" to query GPT-3 for supporting evidence (see Figure 6 in Appendix B for a concrete example). We finally compile both the tentative answers and the corresponding supporting evidence from GPT-3 as implicit knowledge source x^{imp}.

3.4 KAT Model

As showed in the Figure 2, the explicit knowledge entries are from an image, which are concerned with semantic matching of the image regions. These knowledge entries could be noisy or irrelevant to its corresponding question. Moreover, some of the supporting evidence prompted from GPT-3 is generic or not related to image content. Simple concatenation of different knowledge may introduce noise during model training. We design a knowledge reasoning module with inspirations from the previous work (Karpukhin et al., 2020). Our knowledge reasoning module encodes each question and knowledge pair separately, and jointly reason over both explicit and implicit knowledge when generating an answer.

Encoder. We concatenate question q_i with each knowledge as a question-knowledge pair. Firstly, we add sentinel tokens `question:`, `entity:` and `description:` before the question, the retrieved entity, and its description separately. Similarly, we add sentinel tokens `question:`, `candidate:` and `evidence:` before the question, the tentative answer, and its evidence. Secondly, we use an embedding layer followed by a sequence of encoder layers to encode the question-knowledge pairs separately. We average the token embeddings of each question-knowledge pair from the last encoder layer, which results in an embedding matrix of explicit knowledge $X^{exp} \in \mathbb{R}^{m \times d}$ and implicit knowledge $X^{imp} \in \mathbb{R}^{p \times d}$, where d, m and p are the embedding dimension, the number of explicit knowledge x^{exp}, and the number of implicit knowledge x^{imp}, respectively.

Reasoning Module. To jointly reason over implicit and explicit knowledge, we concatenate the embeddings of explicit and implicit knowledge form a global representation $X \in \mathbb{R}^{(m+p) \times d}$. The cross-attention module takes the global representation X of the encoder as the input. Let $H \in \mathbb{R}^d$ be the output of the previous self-attention layer of the decoder. By definition (Vaswani et al., 2017), the scaled dot-product attention can be expressed as:

$$Q_v = softmax(\frac{QK^T}{\sqrt{d}})V, \tag{2}$$

where queries Q, keys K, and values V are computed by applying linear transformations: $Q = W_Q H, K = W_K X, V = W_V X$. The attended representation Q_v is a weighted sum of the values, and implies that our model performs a joint reasoning over explicit and implicit knowledge when generating answers.

Decoder. We feed the embeddings of explicit and implicit knowledge to a sequence of decoder layers for answer generation. We train our model with a cross-entropy loss:

$$\mathcal{L}_{CE} = -\sum_{t=1}^{n} \log p_\theta(y_t | y_{<t}, x^{exp}; x^{imp}), \tag{3}$$

where y_t is predicted autoregressively.

	Method	Knowledge Resources	Acc (%)

	KAT (ensemble)	Wikidata+Frozen GPT-3 (175B)	**54.41**

Table 2: Results of OK-VQA comparing to standard baselines show that our KAT (large size) model achieves state-of-the-art performance on OK-VQA full testing set. It is important (see table sections) to compare methods based on their access to increasingly large implicit sources of knowledge and utilization of explicit knowledge sources. Our five KAT models variants make the relative importance of these decisions explicit. We train our model with 3 random seeds and the result is denoted as *ensemble*.

4 Experiment

4.1 Dataset

OK-VQA (Marino et al., 2019) is currently the largest knowledge-based VQA dataset, The questions are crowdsourced from Amazon Mechanical Turkers and require outside knowledge beyond the images in order to be answered correctly. The dataset contains $14,031$ images and $14,055$ questions covering a variety of knowledge categories. We follow the standard evaluation metric recommended by the VQA challenge (Antol et al., 2015).

4.2 Implementation Details

For the knowledge reasoning module, we initialize our model with the pre-trained T5 model (Raffel et al., 2020). We compare two model sizes, base and large, each containing $220M$ and $770M$ parameters respectively. We fine-tune the models on OK-VQA dataset, using AdamW (Loshchilov and Hutter, 2019). We use a learning rate of $3e-5$ to warm up for $2K$ iterations and train for $10K$ iterations. Limited by the computational resources, we set the number of retrieved entities to 40. The model is trained with a batch size of 32, using 16 V100 GPUs with 32Gb of memory each. Unless otherwise specified, all results reported in this paper as KAT use this model which we found to perform best. We evaluate our predictions with ground-truth after normalization. The normalization step consists of lowercasing, and removing articles, punctuation and duplicated whitespace (Chen et al., 2017; Lee et al., 2019). To be consistent with previous work (Marino et al., 2021), we train our model with 3 different random seeds and use the average results for the leaderboard submission.

4.3 Comparison with Existing Approaches

We compare our model against existing approaches on the OK-VQA dataset and the results are summarized in Table 2. Our model outperforms state-of-the-art methods by significant margins. We compare our model with existing approaches from two aspects. (1) If we only consider using explicit knowledge, our model achieves 44.25% which is 4.85% and 5.9% higher than MAVEx and KRISP, respectively. Our model uses contrastive-learning-based model to extract knowledge, leaving headroom by incorporating supervised pre-trained models, such as pre-trained object detectors. It should be noted that our proposed model is working on a more challenging problem. As the generated answer could contain an arbitrary number of words from the entire vocabulary. Our model is slightly better than PICa-Base which is a plain version of PICa-Full without example engineering. It implies that our single, unified architecture can effectively associate images with the explicit knowledge base. (2) If we take the implicit knowledge from GPT-3 as the additional input, our model outperforms PICa-Full by 6.41% which indicates it is important to integrate knowledge of different types when generating answers. The detailed comparison can be found in Table 3.

5 Ablation Study

To unpack the performance gain and understand the impact of different components, we ablate and compare different model architectures, types of knowledge and the number of explicit knowledge.

Model architecture		**Knowledge**		**Accuracy (%)**
Base	Large	Explicit	Implicit	
√				18.56
√		√		40.93
	√	√		44.25
√			√	47.60
	√		√	49.72
√		√	√	50.58
	√	√	√	54.41

Table 3: Ablation study on model architectures and types of knowledge. Our experiments show that larger model has more capacity for implicit knowledge reasoning and jointly reasoning over both knowledge sources has a consistent improvement with baselines.

Specifically, as shown in Table 3, our KAT-large shows a consistent improvement over using KAT-base. This larger model has more capacity for implicit knowledge reasoning. The integration of explicit and implicit knowledge achieves a performance gain of $\sim 4\%$, supporting the intuition that these two types of knowledge provide complementary pieces of knowledge.

5.1 Effectiveness of Knowledge Reasoning

To verify the effectiveness of our knowledge reasoning module, we use a KAT without the knowledge reasoning module which is denoted as KAT (w/o reasoning). This model concatenates explicit and implicit knowledge as a sentence and adopts a maximum length of 256 tokens. We train this variant with the same parameter settings. As shown in Table 4, simply concatenating knowledge sources is 2.43% lower than our proposed model. It indicates that KAT (w/o reasoning) may introduce noise to relevant knowledge during encoding. Our model adaptively attend different knowledge sources for answer generation that can reduce the influence of irrelevant knowledge.

Method	Accuracy (%)
KAT (w/o reasoning)	51.97
KAT	**54.41**

Table 4: Comparison with KAT (w/o reasoning) which uses the concatenated knowledge as inputs without the knowledge reasoning module.

5.2 Extracting Explicit Knowledge

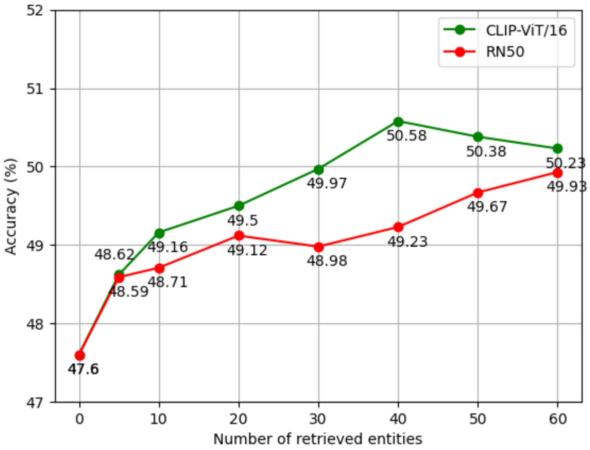

Figure 3: Our model achieves consistent improvement when aggregating more knowledge entries from an explicit knowledge base. However, as CLIP-ViT/16 and RN50 are very different explicit knowledge retrieval backbones we see the choice of backbone and number of sources to include are intimately related. Here we use KAT-base for demonstration.

From Figure 3 we can see, the performance of our model is directly affected by the size of retrieved explicit knowledge. When only considering the implicit knowledge (*i.e.*, the number of retrieved entities is 0), our model achieves 47.6% which is slightly worse than PICa-Full baseline. It indicates that solely increasing model complexity cannot improve the performance. This also demonstrates the importance of explicit knowledge. Our model shows a consistent improvement by incorporating more explicit knowledge. While a more

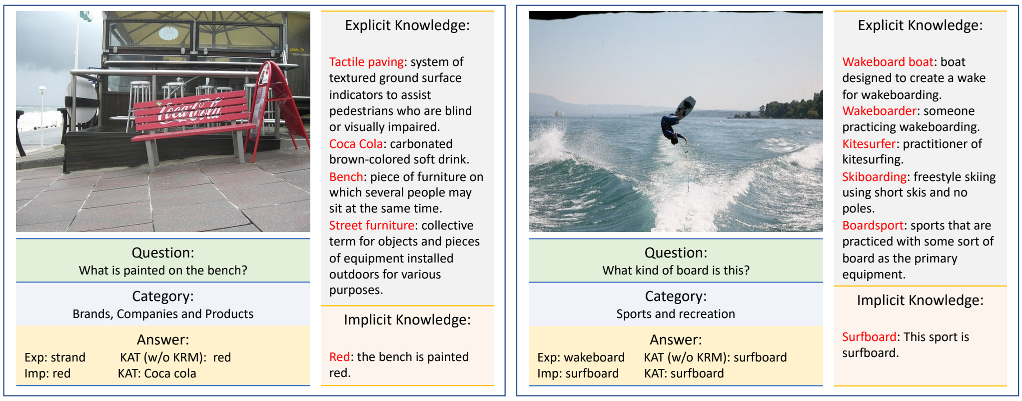

Figure 4: Two examples from OK-VQA dataset that our model generates correct answers by jointly reasoning over both implicit and explicit knowledge. (exp: predictions by using explicit knowledge only and imp: predictions by using implicit knowledge only). More examples and analysis can be found in Appendix C.

extensive knowledge set may include more distracting knowledge, retrieved knowledge entries can share either visually or semantically similar knowledge as the relevant ones. Thus this can massively reduce the search space and/or reduce spurious ambiguity.

We compare different explicit knowledge retrieval module. Though ViT/16 has a large classification improvement over ResNet-50 (*e.g.*, 6.9% on ImageNet) (Radford et al., 2021), there is a less gap between these two backbones. As the number of retrieved entities increases, our knowledge reasoning module can further migrate this gap by adaptively attending to different explicit knowledge.

5.3 Category Results on OK-VQA

Here we present quantitative analyses to illustrate how explicit and implicit knowledge influence the final predictions. Based on the types of knowledge required, questions in OK-VQA are categorized into 11 categories and the accuracy results of each category are reported in Table 5. We re-train our model under the same settings with only either explicit or implicit knowledge, denoted as “exp” and “imp” respectively.

For most categories, the model using only explicit knowledge performs worse than that using only implicit knowledge. As implicit knowledge comes from the results of state-of-the-art object detection, image captioning models and supporting evidence by prompting GPT-3. While explicit knowledge is retrieved based on semantic matching between images and entities from knowledge bases, it contains richer but more distracting knowledge. Note that using explicit knowledge performs better for category “Brands, Companies, and Products" and “Weather and Climate". It indicates that accurately recognizing objects with fine-grained descriptions in the images is important for these categories to answer corresponding questions.

Question Type	Exp	Imp	**Ours**	Δ
Plants and Animals	42.2	51.5	54.7	+3.2
Science and Technology	44.4	43.3	52.8	+8.3
Sports and Recreation	49.7	53.8	60.4	+6.7
Geo, History, Lang, and Culture	45.6	45.4	55.8	+10.2
Brands, Companies, and Products	41.7	38.2	48.5	+6.8
Vehicles and Transportation	41.5	42.9	51.3	+8.4
Cooking and Food	47.9	47.7	52.7	+4.8
Weather and Climate	51.7	46.3	54.8	+3.1
People and Everyday	43.1	44.4	51.5	+7.1
Objects, Material and Clothing	42.9	45.4	49.3	+3.9
Other	41.5	50.2	51.2	+1.0

Table 5: Accuracy (%) of question types in OK-VQA full testing set. Our models outperforms exp and imp models by a large margin on all categories. (exp: explicit-only model and imp: implicit-only model)

5.4 Qualitative Analysis

Analyzed in previous sections, jointly reasoning over both knowledge sources during answer generation improves the explicit-only and implicit-only models by large margins. Figure 4 shows two examples comparing answers generated by different models along with retrieved knowledge. The left example shows that while explicit knowledge retrieved from the knowledge base contains the necessary knowledge entries for reasoning, it fails to generate the answer which requires the relation between bench and Coca Cola logos. On the other side, implicit knowledge retrieved from GPT-3 can only infer the bench is painted red, failing to recognize its logo. By jointly considering both knowledge sources, our model can associate the color of

Coca Cola logo with the painted color of the bench which derives the correct answer. The right example shows that though explicit knowledge does not contain the right knowledge entries, it provides visually similar descriptions of this sport which further constrains the search space of our model and verifies the correctness of the implicit knowledge.

6 Conclusion

This paper takes a step towards understanding the complementary role of implicit knowledge gained from continuing to scale models and explicit knowledge from structured knowledge bases. Importantly, it appears that there is headroom in both directions (i.g. improving retrieval and reasoning). Our conceptually simple yet effective approach for knowledge-based VQA makes these relationships explicit while still achieving a significant improvement against state-of-the-art results. Additional challenges remain, for example how best to align image regions with meaningful external semantics deserves and how to efficiently and accurately integrate multiple knowledge bases.

Acknowledgement

We are especially grateful to Jianwei Yang, Daniel McDuff, Dragomir Radev, Harkirat Behl, Hao Chen, Chunyuan Li, Baolin Peng, Kezhen Chen, Tejas Srinivasan for their for the early insightful discussions, suggestion, and their pointers to the modeling generation and literature. We thank Zhe Gan, Zhengyuan Yang, Lijuan Wang from cognition service team of Microsoft for their work and their generous helps and feedback for the project. We appreciate Subhojit Som from Turing team of Microsoft for his enormous support and encouragement. The authors gratefully acknowledge Kenneth Marino from DeepMind, and Roozbeh Mottaghi from the AllenAI for their comments, supporting and helps of the work. This research was supported in part by the Defense Advanced Research Projects Agency (DARPA) under contract number D17PC00340 and also supported by the US DARPA KAIROS Program No. FA8750-19-2-1004.

Appendix

A Figure of Explicit Knowledge

In this section, we show one example Figure 5 to extract explicit knowledge from an image, which use the CLIP model to conduct the explicit knowledge retrieval with the image and a wiki knowledge base.

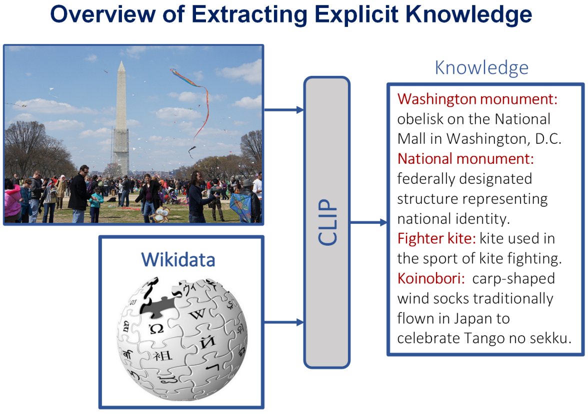

Figure 5: Overview of the explicit knowledge extraction. We use a sliding window to crop image regions and retrieve knowledge entries from an explicit knowledge base by CLIP.

B Examples of Prompts of Implicit Knowledge

In this Section B of the Appendix, we show two concrete examples (Figure 6 and Figure 7) for the prompts that constructed to query GPT-3 for implicit knowledge in our experiments:

```
Query Prompt:
What is the shape? circle. This is because

Response from GPT−3:
'the circle is the only shape that has no corners.'
```

Figure 6: An example of the evidence of rationale that we obtain from GPT-3 by using a combination of question and answer candidate to query it.

C Analysis on More Examples

In this section, we showcase more predictions from variants of our model. As shown in Figure 8, we analyze the predictions based on different type of knowledge from several aspects:

Effectiveness of explicit knowledge retriever. Our explicit knowledge retriever can retrieve fine-grained knowledge entries from the explicit knowledge base, such as *golden retriever* (a fine-grained breed of dogs), *cucumber sandwich* (a specific type of sandwich) and *Macbook Pro* (a specific model of Apple products). These fine-grained entities are hardly obtained from existing object detection models, which can constraint the search space of our model and are beneficial to our answer generation process.

```
Please answer the question according to the above context and the provided knowledge if given.

Knowledge:
A Benelli Adiva is a motor scooter model.
A Yamaha TMAX is a scooter.
A mofa is a moped with a maximum speed of 20 to 25 km/h.
A motorcycle based vehicle is a motor vehicle with two or more wheels, based on cycle technology.
A sport bike is a motorcycle designed for sporty riding regardless of other characteristics.
A motorcycle development rider is a person who for their profession participates in tests to develop a motorcycle.
A Bravo is a Piaggio moped.
A Suzuki X-90 is a motor vehicle.
A Polaris Industries is a Designs, engineers and manufactures powersports vehicles.
A Monark is a Bicycle, moped and motorcycle manufacturer.
===
Q: What sport can you use this for?
A:
```

Figure 7: An example of the prompts that we use to query GPT-3 in our knowledge-aumented GPT-3 query system.

Effectiveness of implicit knowledge retriever. Our implicit knowledge retriever can retrieve supporting evidence from GPT-3, such as *Thomas: the train is named after the man who designed it.* and *Refrigerator: the refrigerator is used to keep food cold.* These kinds of knowledge are highly related to commonsense knowledge which needs further inference based on entities and provide complementary explanation to explicit knowledge.

Answer generation & classification. As most previous work on OK-VQA task, such as KRISP or MAVEx method, implement OK-VQA as a classification task. The prediction vocabulary is dataset-specific and assumes the training and test set are sharing a similar vocabulary. The limitation of these methods is the generalization ability. Our proposed KAT model treats OK-VQA as an open-end generation task. From these examples we found, our model can generate answers like *Iphone* or *Hercules* that are visually and semantically reasonable. Our proposed novel KAT model using the explicit

Question:
Can you guess the material used to make the bag shown in this picture?

Category:
Objects, Material and Clothing

Answer:
Exp: canvas
Imp: leather
KAT (w/o KRM): leather
KAT: canvas

Explicit Knowledge:
(entity:description)
Acer Aspire one: line of notebooks by Acer Inc.
Drawing instrument: tool used for drawing or drafting.
Writing implement: tool used for writing
Book bag: a bag, usually a backpack, used by students to carry their textbooks.

Implicit Knowledge:
(candidate:evidence)
leather: the bag is made of leather.

Question:
What breed are the dogs?

Category:
Other

Answer:
Exp: golden retriever
Imp: husky
KAT (w/o KRM): husky
KAT: golden retriever

Explicit Knowledge:
(entity:description)
Snow pillow: measuring device for snowpack.
Search and rescue dog : dog trained to locate or retrieve a missing or trapped person.
Golden retriever: dog breed.
Mushing: Sport or dog powered transport method.

Implicit Knowledge:
(candidate:evidence)
Husky: The husky is a very intelligent dog. They are independent and will do what they want to do.

Question:
What type of sandwich is being served?

Category:
Cooking and Food

Answer:
Exp: cucumber
Imp: sub
KAT (w/o KRM): sub
KAT: cucumber

Explicit Knowledge:
(entity:description)
Salad: dish consisting of a mixture of small pieces of food, usually vegetables or fruit.
Cucumber sandwich: the traditional cucumber sandwich is composed of thin slices of cucumber placed between two thin slices of crustless, lightly butterd white bread.
Vegetable chip: cooked chip prepared using vegetables.

Implicit Knowledge:
(candidate:evidence)
Sub: the sub is a type of sandwich.

Question:
What sort of phone would you associate with this computer?

Category:
Brands, Companies and Products

Answer:
Exp: Iphone
Imp: smartphone
KAT (w/o KRM): cell
KAT: Iphone

Explicit Knowledge:
(entity:description)
Floor lamp: lamp standing on the floor, often with a hight reaching up to the vertical middle of the room.
Macbook Pro: laptop made by Apple.
MacOS: operating system for Apple computers, launched in 2001 as Mac OS X.
Smart mattress: Mattress monitoring sleep patterns.

Implicit Knowledge:
(candidate:evidence)
Smartphone: the computer is not a smartphone.

Question:
What is the name of the famous train pictured?

Category:
Vehicles and Transportation

Answer:
Exp: Smoot
Imp: Thomas
KAT (w/o KRM): Thomas
KAT: Thomas

Explicit Knowledge:
(entity:description)
Fog machine: device that emits a dense vapor that appears similar to fog.
Draisine: small powered rail vehicle used by track maintenance workers.
Oast house: buildings designed for kilning (drying) hops as part of the brewing process.
Clouding agent: type of emulsifier used to make beverage such as fruit juice to look more cloudy.

Implicit Knowledge:
(candidate:evidence)
Thomas: the train is named after the man who designed it.

Question:
What is this dog running after?

Category:
Plants and Animals

Answer:
Exp: person
Imp: ball
KAT (w/o KRM): ball
KAT: ball

Explicit Knowledge:
(entity:description)
Sighthound: dog breed.
American Staffordshire Terrier: dog breed.
Greyhound racing: canine racing sport involving the Greyhound dog breed.
Whipper racing: dog sport.

Implicit Knowledge:
(candidate:evidence)
Ball: the dog is chasing after the ball.

Question:
How often should someone use this?

Category:
Objects, Material and Clothing

Answer:
Exp: twice day
Imp: daily
KAT (w/o KRM): daily
KAT: daily

Explicit Knowledge:
(entity:description)
Bathroom linen: household linen used specifically for the bathroom.
Toothbrush: oral hygiene instrument used to clean the clean the teeth, gums, and tongue.
Toothbrush holder: container or rack for toothbrushes.
Laubwerk: delicate foliage ornament with interlacing straps.

Implicit Knowledge:
(candidate:evidence)
Daily: the product is made with natural ingredients. This is why it is safe to use daily.

Question:
What hobby might this depict?

Category:
Objects, Material and Clothing

Answer:
Exp: paper craft
Imp: scrapbook
KAT (w/o KRM): painting
KAT: scrapbook

Explicit Knowledge:
(entity:description)
Embroidery workshop: workshop where embroidery is created.
Scissors: hand-operated cutting instrument.
Paper knife: an implement used for cutting open sealed envelopes.
Leather cutter: craftman.

Implicit Knowledge:
(candidate:evidence)
Scrapbooking: the bobby is a form of art.

Question:
What type of plane is this?

Category:
Vehicles and Transportation

Answer:
Exp: Hercules
Imp: jet
KAT (w/o KRM): jet
KAT: jet

Explicit Knowledge:
(entity:description)
Avro Shackleton: maritime patrol aircraft family by Avro.
MC-130 Hercules: airlifter series by Lockheed.
P-3B Orion: anti-submarine maritime patrol aircraft.
C-130B Hercules: airlifter series by Lockheed.

Implicit Knowledge:
(candidate:evidence)
Jet: the plane is flying at a high speed.

Question:
What is this machine used for?

Category:
Brands, Companies and Products

Answer:
Exp: refrigerate food
Imp: freezer
KAT (w/o KRM): freeze
KAT: keep food cold

Explicit Knowledge:
(entity:description)
Shelf-stable food: food of a type that can be safely stored at room temperature in a sealed container.
Free box: box or location used to allow for people to rid themselves of excess items.
Icebox: non-mechanical household applicance for cooling foodstuffs.
Refrigenration: process of moving heat from one location to another in controlled conditions.

Implicit Knowledge:
(candidate:evidence)
Refrigerator: the refrigerator is used to keep food cold.

Figure 8: More examples from OK-VQA dataset that our model generates answers by jointly reasoning over both implicit and explicit knowledge.

and implicit knowledge is designed to enhance semantic alignment and generate representations with stronger knowledge-awareness.

When a sentence does not introduce a discourse entity, Transformer-based models still sometimes refer to it

linzen@nyu.edu

Abstract

Understanding longer narratives or participating in conversations requires tracking of discourse entities that have been mentioned. Indefinite noun phrases (NPs), such as *a dog*, frequently introduce discourse entities but this behavior is modulated by sentential operators such as negation. For example, *a dog* in *Arthur doesn't own a dog* does not introduce a discourse entity due to the presence of negation. In this work, we adapt the psycholinguistic assessment of language models paradigm to higher-level linguistic phenomena and introduce an English evaluation suite that targets the knowledge of the interactions between sentential operators and indefinite NPs. We use this evaluation suite for a fine-grained investigation of the entity tracking abilities of the Transformer-based models GPT-2 and GPT-3. We find that while the models are to a certain extent sensitive to the interactions we investigate, they are all challenged by the presence of multiple NPs and their behavior is not systematic, which suggests that even models at the scale of GPT-3 do not fully acquire basic entity tracking abilities.

1 Introduction

In order to understand longer narratives or to participate in conversations, humans and natural language understanding systems have to keep track of the entities that have been mentioned in the discourse. For example, when someone tells you that *Arthur owns a dog*, they have introduced the entity of a person named *Arthur* and the entity of a dog owned by Arthur into the discourse. Once entities have been introduced to the discourse, it is natural to refer back to them with noun phrases or pronouns to elaborate further, e.g., by saying *It has a red collar* to elaborate on the dog.

While no fully-specified account exists of how humans achieve this feat, many existing theories are based on the idea that humans maintain mental files (e.g., Heim, 1982; Murez and Recanati, 2016), i.e., explicit memory representations for each entity that encode all properties of an entity and its relation to other entities. When engaging in a conversation or reading a longer narrative, humans then update these representations as they encounter new entities or new information about existing entities.

Large pre-trained language models (LMs) such as GPT-2 (Radford et al., 2019) and GPT-3 (Brown et al., 2020), which in recent years have become the dominant foundation for natural language understanding and generation tasks, lack explicit representations of discourse entities. It remains largely an open question to what extent LMs can match human behavior in tracking discourse entities.

The most extensive investigation of this phenomenon has been through evaluations with the LAMBADA dataset (Paperno et al., 2016). LAMBADA consists of a cloze task for which an LM has to predict the last word of naturalistic passages extracted from a corpus. Solving this task requires keeping track of longer contexts, and making a correct guess frequently requires keeping track of the entities mentioned in the passage.
