How many? 0. Captions do not normally contain mentions of '*zero*' object counts. Hence, marking spans in a caption does not generate questions with the answer '*0*'. Therefore, we randomly sample a generated "*How many?*" question (with a non-zero answer) from a different caption and add it with the answer changed to '*zero*' to the candidate set of the target caption. This procedure is potentially noisy because the answer for the sampled question could be non-zero also for the target image. From a manual inspection of 200 such questions, we found this to happen infrequently – about 4.5%.

Our extraction method covers various answer candidates such as compound nouns, noun phrases,

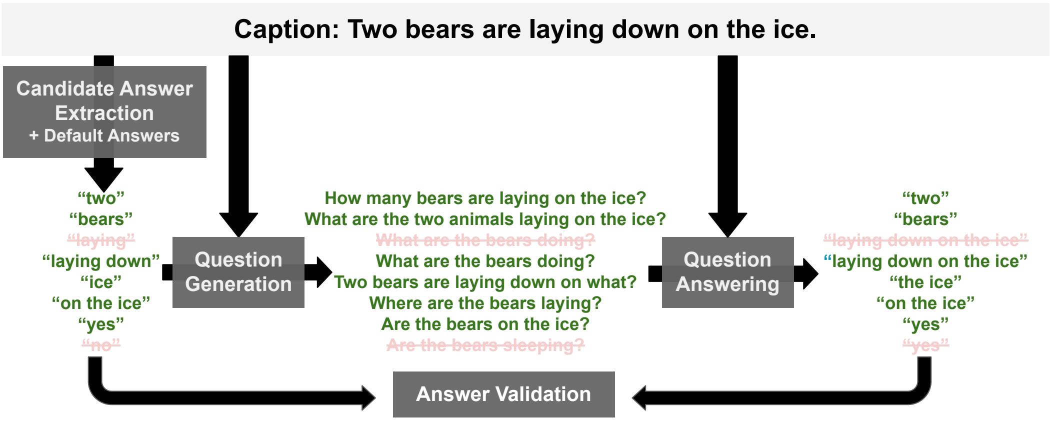

Figure 2: **V**isual **Q**uestion Generation with **Q**uestion **A**nswering validation (VQ^{2}A) has three main stages: Candidate Answer Extraction (Section 3.1), Question Generation (Section 3.2), and Question-Answering Filtering (Question Answering + Answer Validation, Section 3.3).

Candidate Answer	Noun Phrase	POS	Parse Tree	Boolean
'*two*'	V	V		
'*bears*'		V		
'*two bears*'	V		V	
'*laying*'		V		
'*laying down*'		V		
'*ice*'		V		
'*the ice*'	V			
'*on the ice*'			V	
'*no*'				V
'*yes*'				V

Table 1: Answer candidates extracted from the sentence "*two bears are laying down on the ice*" and the mechanism used to extract them.

named entities, boolean answers, cardinal and ordinal numbers, verbs and their compounds, (multi-word) adjectives and prepositional phrases. Table 1 provides an example of candidate answers of various types and the mechanism used to extract them.

3.2 Question Generation

Our question generation model, $\mathrm{q} = QG(\mathrm{a}, \mathrm{cap})$, takes as input a caption, cap, and a candidate answer span within it, a, and generates a question q, whose answer given the input caption is the input answer span. Importantly, the answer a does not need to appear verbatim in the caption, enabling the generation of questions for answer types like boolean and zero counts (see Section 3.1).

Given the advances in neural text generation, including models like T5 (Raffel et al., 2020), we choose to use a neural generation model as QG. Concretely, we use a T5-XXL model and further fine-tune it on SQuAD1.1 (Rajpurkar et al., 2016) for question generation. We take the top-scoring generated question for each caption-answer input. We note that our QG model is trained on a question answering dataset that is not caption-specific, and therefore is not optimized for caption inputs. From manual inspection of hundreds of generated questions, our QG model copes well with captions as input; see examples in Table 2 and Section 3.5.

3.3 Question-Answer Filtering

Generative models may hallucinate, that is, generate content that is inconsistent with its input source (Alberti et al., 2019; Honovich et al., 2021). To mitigate this, we follow (Alberti et al., 2019) and apply round-trip consistency by answering the generated question on the caption text with a question answering model. If the answer does not match the answer candidate offered as input to the question generation model, the generated question is discarded.

We use the token-level F1 score (Wang et al., 2020) to determine if the candidate answer and the QA model's answer is a match; If the score is above a threshold (manually set to 0.54, exemplified in Table 2), the pair is a match. For question answering, we use a T5-XXL model and further fine-tune it on SQuAD2.0 (Rajpurkar et al., 2018) and Natural Questions (Kwiatkowski et al., 2019).

3.4 Sources of Image/Caption Data

To gain insights on VQ^{2}A potential performance, we generate VQA triplets with VQ^{2}A from two sources of image captions: MSCOCO Captions (COCO-CAP) (Chen et al., 2015) and Conceptual Captions (CC3M) (Sharma et al., 2018). COCO-CAP captions contains 123,287 images from the COCO dataset (Lin et al., 2014), each with 5 *gold* captions manually created by raters with careful guidelines. CC3M contains 3.32M images

Candidate Answer	Generated Question	Validated Answer	Match Score & Result
'*two*'	'*How many bears are laying on the ice?*'	'*two*'	1.0 (Pass)
'*bears*'	'*What are the two animals laying on the ice?*'	'*bears*'	1.0 (Pass)
'*two bears*'	'*How many bears are laying on the ice?*'	'*two*'	1.0 (Pass)
'*laying*'	'*What are the bears doing?*'	'*laying down on the ice*'	0.4 (Fail)
'*laying down*'	'*What are the bears doing?*'	'*laying down on the ice*'	0.7 (Pass)
'*ice*'	'*Two bears are laying down on what?*'	'*the ice*'	1.0 (Pass)
'*the ice*'	'*Where are the bears laying?*'	'*on the ice*'	0.7 (Pass)
'*on the ice*'	'*Where are the bears laying?*'	'*on the ice*'	1.0 (Pass)
'*no*'	'*Are the bears sleeping?*'	'*yes*'	0.0 (Fail)
'*yes*'	'*Are the bears on the ice?*'	'*yes*'	1.0 (Pass)
'*zero*'	'*How many people are sitting down?*'	-	Pass by definition

Table 2: Question/answer pairs generated from the sentence "*two bears are laying down on the ice*" and the filtering decision. For answer candidate '*zero*', no validation is performed .

Dataset	Image		VQA examples	
	train	dev	train	dev
VQ^{2}A COCO	114.9K	8.4K	3.50M	257.5K
VQ^{2}A CC3M	3.32M	15.8K	13.29M	61.2K
COCOQA	64.5K	4.7K	108.7K	38.6K
VQA2.0	114.9K	8.4K	582K	65.1K
GQA	82.4K	0.4K	1.08M	12.6K
OKVQA	9K	5K	8.3K	4.7K

Table 3: **Sizes** of our generated VQ^{2}A data (top two rows) and VQA datasets used in our experiments.

automatically-collected from the web, each with one associated alt-text which we treat as a *silver* caption.

These datasets are quite different. Both the amount and the domain of CC3M images are larger and its captions look more plausible for capturing a larger set of object/attribute/action annotations. On the other hand, COCO-CAP's captions are cleaner and represent image content more adequately (see also Section 3.5). Thus, using COCO-CAP would show the potential of training a VQA model using VQ^{2}A in a "cleaner" zero-shot setup, where captions are human-curated. Using CC3M would indicate the potential of training on noisy web image–alt-text pairs, where scaling up to billions of examples is possible.

To quantify the impact of our method, we focus on VQA classification for the VQA2.0 (Goyal et al., 2017), GQA (Hudson and Manning, 2019), and OKVQA (Marino et al., 2019) benchmarks (see Section 4.2). We thus restrict our classifier to top 5,971 answers that are part of a unified answer vocabulary from these benchmarks (Appendix B.1). To this end, we remove triplets whose answers are not in the target answer vocabulary, and leave the study of using all generated triplets to future work. We then split our datasets into train/dev sets. In particular, since the images in VQA2.0 are taken from COCO, we split the COCO dataset based on the standard VQA2.0 train/dev splits of *train2014 and minival2014 (Jiang et al., 2018)[2]. For the CC3M dataset, we use the default CC3M train/dev splits (Sharma et al., 2018). For each unique image-question pair in the dev split, we construct an answer target of size 10, following VQA2.0, by reducing or expanding the set of seed answers that occur for this image-question pair. Additional details are in Appendix B.1.

Table 3 depicts the size of the induced datasets, named VQ^{2}A-COCO and VQ^{2}A-CC3M, as well as the VQA datasets used in our experiments.

3.5 Quality Analysis

To measure the quality of the generated datasets, we sampled 800 examples from each of the VQ^{2}A-COCO and VQ^{2}A-CC3M datasets. The sample was split between four authors, who assessed whether the answer to the question in an example is justified based on the example's image. For each dataset, 50 examples were rated by all raters, resulting in a free-margin Kappa (Randolph, 2005) of 0.71 for VQ^{2}A-COCO and 0.59 for VQ^{2}A-CC3M, corresponding to high inter-rater agreement. The measured percentage of valid triplets is 87.3% for VQ^{2}A-COCO and 66.0% for VQ^{2}A-CC3M. This shows the difference between the high-quality captions of COCO-CAP and the noisier web-based ones of CC3M.

Fig. 3 demonstrates the diversity of questions generates in the VQ^{2}A datasets. One can see that a significant amount of questions generated by VQ^{2}A for the shared VQA2.0/COCO image do not appear in VQA2.0. Additional analysis and examples are in Appendix A.

4 Visual Question Answering (VQA)

To assess the effectiveness of our automatic generation of VQA annotations, we perform extrinsic

Question	Answers
How many pieces of fruit are in the bowl	“0”
Is there a refrigerator in the kitchen	“yes”
What color are the cabinets in the kitchen	“white”
Is the kitchen lit or dark	“lit”
Is there a stove in the kitchen	“no”
What color is the formica in the kitchen	“white”
What is on the door of the refrigerator	“papers”, “several papers”
Where are the papers on the refrigerator	“door”
What kind of kitchen does the house have	“small white formica kitchen”

Question	Answers
What is flying over the ocean	“eagle”, “brown eagle”
What color is the bird's head	“white”
What color is the bird	“brown”
Is the brown eagle flying over land	“no”
Is the brown eagle flying over the ocean	“yes”
What does the bird do over the water	“glides”
Which part of the bird is white	“head”
What color are the bird's wings	“brown”, “brown wings”
What color is the eagle in the picture	“brown”
Why is the bird flying down to the water	“to catch food”

Question	Answers
Is the tumbler dishwasher safe	“no”
Is the tumbler insulated	“yes”
What color is the tumbler	“blue”, “shiny blue”
What kind of blue is on the tumbler	“shiny”
What is the name of the blue drinkware item	“tumbler”
What is ceramic used for in the tumbler	“lining”
Which part of the tumbler is made of stainless steel	“exterior”
Which part of the tumbler is ceramic	“inner”
What is the purpose of the stainless steel exterior of the tumbler	“insulating”
What kind of steel is on the outside of the tumbler	“stainless”
What material is the inside of the tumbler made of	“ceramic”
What material is the outside of the tumbler made of	“steel”, “stainless steel”

Question	Answers
What type of art is this	“vector”
Aside from watches what else is included in the illustration	“clocks”
What is the illustration of	“clocks and watches”
Is this a hand drawn clock and watch set	“yes”
How were the clocks and watches drawn	“hand”
In addition to gold what color is used for the clocks and watches in this illustration	“gray”
What colors are the clocks and watches in the illustration	“gray and gold”
What kind of illustration is this	“vector art”

Figure 3: **Examples** from VQ^{2}A COCO (top) and VQ^{2}A CC3M (bottom). Questions with the green background are also present in VQA2.0.

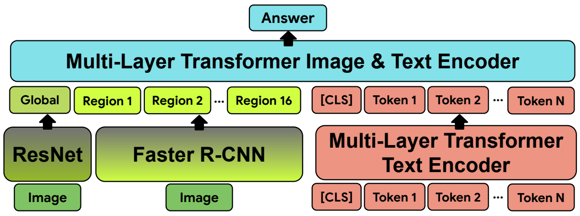

Figure 4: **VQA model** used in our experiments. The text encoder is initialized from a T5-base checkpoint, while the image-text encoder is initialized from scratch. The parameters of ResNet and Faster R-CNN are frozen during VQA training.

evaluations of the generated data by measuring its impact on a variety of established VQA benchmarks. We first describe the model, followed by the experimental setup and the results.

4.1 VQA Formulation and Model

Following the literature, we treat VQA as a classification task, i.e., vocab-based VQA. In particular, we treat our target answers as labels, where a label could be multi-token (e.g., "Christmas tree", "black and white", "play tennis"). We define our set of labels based on top answers in the training set of downstream VQA datasets, which allows for a fair comparison with most work in the VQA literature since Antol et al. (2015).

Since our work explores the impact of automatically-generated training data, we fix the VQA model architecture across all experimental conditions. Our model fuses the input image and question (Fig. 4). On the image side, we take global image features from ResNet-152 (He et al., 2016) pre-trained on ImageNet (Russakovsky et al., 2015) plus 16 region-of-interest image features from Faster R-CNN (Ren et al., 2015b) pre-trained on Visual Genome (Krishna et al., 2017), following the bottom-up-features paradigm (Anderson et al., 2018). On the question side, we use the encoder of a pre-trained T5-base checkpoint (Raffel et al., 2020). Given the image features and the output token embeddings of the question encoder, a Transformer (Vaswani et al., 2017) fuses the multi-modal intermediate representation and classifies it into the predefined answer space. We train the (randomly-initialized) fusing encoder and the text encoder end-to-end using standard cross-entropy loss. The parameters of both ResNet and Faster R-CNN are frozen during training. Additional details are given in Appendix B.2.

4.2 Experimental Setup

We consider three VQA benchmarks: VQA2.0 (Goyal et al., 2017), GQA (Hudson and Manning, 2019), and OKVQA (Marino et al., 2019). These datasets have their own characteristics and thus test different capability of VQA models. For instance, GQA puts emphasis on reasoning and OKVQA on external knowledge, whereas VQA2.0 is more general; VQA2.0 and GQA are order-of-magnitude larger than OKVQA; GQA is generated using a question engine while VQA2.0 and OKVQA are human-annotated.

For training and evaluating on VQA2.0, we use the standard train/dev splits *train2014 and minival2014 (Jiang et al., 2018). For GQA, we use the balanced v1.2 and combine the train and val splits for training and use the testdev split for evaluation, following the official guideline[3] and (Tan and Bansal, 2019). For OKVQA, we use the train/val splits for training/evaluation. Table 3 summarizes the sizes of the different datasets.

Evaluation Settings and Baselines. The main

---

[3] `https://cs.stanford.edu/people/dorarad/gqa/evaluate.html`

goal of our experiments is to explore the utility of our VQ^{2}A data for transfer learning, as training or evaluation data.

Our main focus in this paper is on zero-shot evaluation. Still, fine-tuning would provide additional insight on using our induced data for pre-training. Therefore, following (Banerjee et al., 2021), we train VQA models on the generated VQ^{2}A data and then evaluate them in two settings: (i) **zero-shot** evaluation, in which we evaluate our models as-is on the dev split of VQA2.0, GQA, or OKVQA; and (ii) **fully-supervised** fine-tuning evaluation, in which we further fine-tune our models on the training split of VQ^{2}A, GQA, or OKVQA before evaluating them. When training on VQ^{2}A data, we explore training on VQ^{2}A-COCO only, VQ^{2}A-CC3M only, and a two-stage training VQ^{2}A-CC3M followed by VQ^{2}A-COCO (VQ^{2}A CC3M → COCO).

Our baselines, which do not use VQ^{2}A data, include (i) our VQA model trained on template-based question generation data COCOQA[4] (Ren et al., 2015a), (ii) state-of-the-art zero-shot WeaQA (Banerjee et al., 2021) and its fully-supervised variants, and (iii) our VQA model trained supervisely on each of the target benchmarks' training data.

Metrics. To be compatible with prior work, on VQA2.0 and OKVQA we measure the standard *VQA Accuracy*. It is the average score over 9 subsets of the ground-truth 10 answers[5], where each score is: $min(\frac{\#answer\ occurrences}{3}, 1)$. On GQA, we measure *Top-1 Accuracy* against the single ground-truth answer.

5 Results

We report several sets of experimental results that shed light both on the accuracy and on the robustness of VQA models trained on VQ^{2}A data in this section, with additional results, analysis and ablation studies in Appendix C.

5.1 Zero-Shot Setting

Table 4 summarizes the outcomes of our VQA experiments on various benchmarks. Our main result is that the VQ^{2}A models achieve new state-of-the-art results in the zero-shot transfer learning setting. The improvement in performance is large: to the best of our knowledge, previous state-of-the-art zero-shot accuracy was 46.8% on VQA2.0 and 33.7% on GQA by WeaQA (Banerjee et al., 2021), which also induces their training VQA data from COCO Captions. Our VQ^{2}A-COCO model reaches 60.0% on VQA2.0 and 51.3% on GQA, an absolute improvement of +13.2% and +17.6%, respectively. Even higher accuracy for the zero-shot setting – 61.1% (VQA2.0) and 52.1% (GQA) – is reached with the VQ^{2}A CC3M → COCO model (trained first on the CC3M-derived data and then fine-tuned on the COCO-derived data), establishing new state-of-the-art results.

Approach	Evaluation Benchmark		
	VQA2.0	GQA	OKVQA
Zero-shot			
VQ^{2}A COCO, nouns only	10.5	-	-
COCOQA	11.7	4.4	6.3
WeaQA ZSL	46.8	33.7	-
VQ^{2}A COCO	60.0	51.3	18.0
VQ^{2}A CC3M	56.5	49.9	19.1
VQ^{2}A CC3M → COCO	61.1	52.1	19.7
VQ^{2}A CC3M +D	57.9	50.0	19.8
Fully-supervised			
WeaQA FSL	65.3	55.2	-
w/o VQ^{2}A data	68.8	61.8	22.1
w. VQ^{2}A COCO	71.6	63.3	36.0
w. VQ^{2}A CC3M	71.3	63.4	39.0
w. VQ^{2}A CC3M → COCO	71.4	64.0	39.3
Human performance	82.4†	89.3‡	82.8†

† from the inter-annotator agreement of ground-truth answers.
‡ from (Hudson and Manning, 2019).

Table 4: VQ^{2}A **as training data.** Accuracy in zero-shot and fully-supervised settings. All results use our architecture, except *WeaQA ZSL* and *WeaQA FSL*, which are the zero-shot (ZSL + Patches + Encoder) and fully-supervised (FSL + Patches + Encoder) models in (Banerjee et al., 2021), respectively. +D stands for recovered raw CC3M alt-texts with digits.

Training the same model architecture on the manually-constructed VQA2.0 and GQA training sets in a fully-supervised manner achieves 68.8% and 61.8% accuracy, respectively. Hence, our results significantly close the performance gap between automatically-generated and manually-constructed training sources, indicating that the VQ^{2}A method may reduce the need for human curated VQA training examples.

The captions for COCO images are carefully annotated to be of high-quality (Chen et al., 2015). Additionally, the VQA2.0 images are taken from COCO. To test the robustness of VQ^{2}A, we also evaluate a VQ^{2}A-CC3M model. While CC3M contains more image–alt-text pairs than COCO (see Table 3), the images are from a different distribution and the text annotations are noisier and may represent a larger spectrum of discourse intents

---

[4] Train/dev based on the standard VQA2.0 train/dev splits.

[5] 5 targets in OKVQA, replicated twice (Marino et al., 2019).

(Alikhani et al., 2020). In spite of these differences, the gap between COCO-based and CC3M-based VQ^{2}A models is not large, 60.0% vs 56.5% on VQA2.0 and 51.3% vs. 49.9% on GQA. This result strengthens our previous observation, in that it does not seem to be crucial that the starting captions are manually-annotated; it appears that "silver" annotations such as the ones provided by CC3M are competitive in zero-shot VQA performance.

To cover the types of answers present in VQA benchmarks, there is a need for thorough extraction of various answer/question types (Section 3). The QACE model (Lee et al., 2021), for example, focuses only on noun-phrases as answer types. By analyzing the VQA2 devset, we find that only 32% of its answers are nouns. As such, it makes sense that, when limiting to only this answer type, the *VQA Accuracy* of VQ^{2}A-COCO is 10.5%, compared to the 60% achieved with a full coverage. As another example, our model trained COCOQA (Ren et al., 2015a), which focuses on a few answer types and one-word answers, barely surpasses the accuracy of our *COCO, nouns only* baseline. For similar reasons, we want to be able to generate '*how many*' questions from the CC3M data, even though the published annotations have been stripped of digits and numerals. To solve this problem, we recover the original captions from the CC3M URLs, generate questions of the type '*how many*', and train an additional VQ^{2}A-CC3M +D model. The results in Table 4 show a small but consistent improvement over vanilla VQ^{2}A-CC3M, further closing the gap between VQ^{2}A models using curated "gold" captions and noisier "silver" captions.

To gain further insights, we provide a breakdown of *VQA Accuracy* per VQA2.0 question types in Table 5. Boolean questions are the easiest and all models perform well on them. More challenging question types are '*How many?*' and '*What is*'. One reason could be the validity of various answers, like "*several*" for counts. '*What time?*' is the most difficult, probably due to lack of such information in captions.

Finally, we provide zero-shot results on the more difficult OKVQA benchmark. In this setting, a supervised model reaches 22.1% accuracy, while VQ^{2}A models in zero-shot setting achieve close to that – 18.0% with COCO and 19.1% with CC3M, while their combination reaches 19.7%, -2.4% shy of the supervised level. This result also supports the conclusion that creating training data with the VQ^{2}A method is a good replacement for small-scale supervised training data.

Question Prefix	VQA2.0 Supervised	VQ^{2}A-COCO Zero-shot	VQ^{2}A-CC3M Zero-shot
Boolean	96.3	93.2	94.2
'*What color*'	69.2	64.8	56.8
'*What kind/is*'	52.6	36.9	32.1
'*How many*'	49.3	29.4	19.5
'*Where are/is*'	38.0	30.0	25.3
'*What does*'	33.0	24.1	20.3
'*What time*'	23.6	11.9	12.7

Table 5: Aggregated average Accuracy on VQA2.0 for the most common question types.

5.2 Fully-Supervised Setting

Another aspect of the VQ^{2}A method that we want to evaluate is whether it produces training data that is similar with the human-annotated data, or it complements it. To this end, we perform experiments in which we first train a model using the VQ^{2}A data, and then fine-tune it in a supervised manner using the human-annotated training data.

The results, in the *Fully-supervised* part of Table 4, tell two stories. For VQA2.0 and GQA, there is a small yet consistent improvement of the fine-tuned models on top of a model trained directly on the supervised data in each benchmark (labeled *w/o* VQ^{2}A). This indicates that, at least for these two benchmarks, there is a high overlap in the nature of the signal between the human-annotated data and the VQ^{2}A data.

The results on OKVQA show a different trend. Here, training first with VQ^{2}A boosts performance by +17.2% compared to supervised training without VQ^{2}A (22.1% → 39.3%). The small scale of the OKVQA training set (Table 3) certainly contributes to this effect, but it also points to another aspect: question-answer pairs that subsume world knowledge can only be made available at-scale to models by means that are not bottlenecked by human-annotation processes.

5.3 Robustness of Existing VQA Training Sets

So far we have assessed the capability of models trained on VQ^{2}A data. As a complementary study, we use 500 manually-validated random samples (see Section 3.5) from the dev part of each VQ^{2}A dataset to assess VQA robustness for various training setups. We use the *VQA Accuracy* metric for the VQ^{2}A datasets (10 target answers, see Section 3.4), and *Top-1 Accuracy* on COCOQA (one target answer).

Table 6 shows the results. The fully-supervised

Training data	Evaluation Benchmark (Acc %)			
	COCO-QA	VQA2.0	VQ^{2}A COCO	VQ^{2}A CC3M
COCOQA	70.3	11.7	13.2	5.8
VQA2.0	35.9	68.8	44.4	41.6
VQ^{2}A COCO	**55.9**	**60.0**	72.6	**56.8**
VQ^{2}A CC3M	42.1	56.5	**65.6**	76.4

Table 6: **Manually-validated** VQ^{2}A **data for robustness evaluation**: Accuracy of training on "row" and tested on "column"; diagonal (gray) numbers denote supervised setting, non-diagonal numbers denote zero-shot cross-dataset setting. Best zero-shot is in **bold**.

models (diagonal, similar training and test distributions) achieve in-domain Accuracy around 70%, with VQ^{2}A CC3M achieving slightly higher 76.4% Accuracy. When tested on out-of-domain (non-diagonal), however, each model poses performance degradation at different degrees. First, the model based on template-generated COCOQA does not generalize at all. Second, the VQA2.0 model sees significant accuracy drops, even on the COCO (44.4%) and COCOQA (35.9%), which share a similar image domain with VQA2.0. This result provides another evidence that progress made on the VQA2.0 benchmark may not reflect progress on the VQA task in full (Chao et al., 2018a; Bras et al., 2020).

In contrast, both VQ^{2}A COCO and VQ^{2}A CC3M perform robustly with more modest performance drops. For instance, on COCOQA, VQ^{2}A CC3M achieves even better performance than VQA2.0 (42.1% vs. 35.9%) despite being tested on out-of-domain images. This suggests that the VQ^{2}A training data possesses a higher degree of question variations, provides better answer coverage, and exhibits less biases than the manually-curated VQA2.0 training data, at least enough to address these different benchmarks.

6 Considerations and Limitations

Automatic data generation is prone to erroneous outputs. In VQ^{2}A these may include hallucinations of the generative model, incorrect negative sampling, and bad answer span extraction. In addition, the image captions may contain details not in the image, e.g. additional details only aware to the photo taker or personal opinions, or information that is inconsistent with the image due to human mistakes and biases. We address some of these issues automatically, filtering bad generations via question answering round-trip validation. In addition, the classification task itself curbs the effects of such errors through the use of a fixed answer vocabulary. Yet, for automatic generation to be more robust, additional methods to narrow down mistakes or mismatches need to be developed.

The resulting VQA model incorporates and may reinforce some of the biases and stereotypes present in the data. For instance, it may learn that answering questions such as “What is the gender of this person?” is a binary choice dictated by shallow cues, or that the answer to “For whom is this room decorated?” depends on stereotypical features present (or not) in the room depicted in the image. Mitigation strategies for such issues go beyond the scope of this paper, but we encourage the research community to consider addressing these issues as central for the successful deployment of this technology.

7 Conclusions

In this paper, we show that high-quality VQA training data can be automatically induced at scale from existing image-caption datasets. Our method, VQ^{2}A, annotates candidate answers using syntactic parsing of the captions and then derives questions for them using neural models for question generation and question answering verification. We demonstrate that VQA models trained only on such data exhibit high zero-shot performance with new state-of-the-art results on VQA2.0 and GQA. Additionally, we provide evidence for the brittleness of VQA systems built with human-annotated examples compared to the ones built with automatically-induced image-question-answer triplets using VQ^{2}A.

For future work, we plan to explore even larger automatically-curated image-text datasets, consisting of billions of examples. In addition, we want to test the applicability of VQ^{2}A to languages other than English, for which human-annotated VQA data is scarce.

Acknowledgments. We would like to thank Or Honovich, Hagai Taitelbaum and Roee Aharoni for their help with question generation, Sebastian Goodman for his help with the VQA infrastructure, Piyush Sharma for his help with the Conceptual Captions, Nassim Oufattole for his early exploration of question generation, Gal Elidan, Sasha Goldshtein, and Avinatan Hassidim for their useful feedback.

A Additional Examples and Analysis of Generated Data

Fig. 5 provides additional examples of VQ^{2}A COCO and CC3M generated VQA triplets, showing the diversity compared to what can be found in VQA2.0.

Table 7 presents the top question prefixes and their distribution in the VQA2.0 and VQ^{2}A-based dev sets, showing significant differences between datasets. Many questions in VQA2.0 are of boolean answer type, e.g. '*is the*', '*is there*' and '*does the*', summing to 29.2%. In addition, ('*how many*') questions are frequent, 11%. Finally, questions for the color attribute are standing out with 9%. On the other hand, COCO and CC3M questions are more explanatory in nature, with the majority of questions (45.5% in COCO, 43.9% in CC3M) of the form '*what is/are/do/does/type*'. Another type that is more prominent in COCO and CC3M are '*where is/are*' questions, which are more than twice frequent compared to VQA2.0.

Another difference between the manually curated VQA2.0 dataset and the VQ^{2}A automatically generated datasets is question and answer word length distribution (Fig. 6 and 7). The questions in VQ^{2}A-CC3M and VQ^{2}A-COCO have an average word length of 8.3 and 7.8 respectively, while the average VQA2.0 is 6.3. Inspecting the generated questions, we noticed that QG model tends to quote parts of the caption, extending the question length. The average answer word length in VQ^{2}A-CC3M and VQ^{2}A-COCO is 1.76 and 1.85 words respectively, while in VQA2.0 it is 1.1. While all answers tend to be short, the VQ^{2}A-induced datasets have more "detailed" answers of length 2-3 words.

Fig. 8 offers a more visual view of the differences between question type distribution presented in Table 7.

Table 8 depicts the percentage of questions of each type (prefix) that were retained (not filtered out) when applying the question answer validation phase of VQ^{2}A (Section 3.3).

B Implementation Details

B.1 Details on Data Processing

Our default question and answer preprocessor is based on (Jiang et al., 2018; Singh et al., 2020)[6], with the exception of GQA which we use [7]. The unified answer vocabulary used in our experiments is the union of top answers from existing COCO-based VQA benchmarks: VQA2.0 (3,128, minimum answer frequency=9), GQA (1,843, all), OKVQA (2,000, top), and Visual7W (3,140, minimum answer frequency=3) of total size 5,971

For each image-unique question pair generated by our VQ^{2}A approach, we reduce or expand a list of possibly different candidate answers based on the list length, such that we eventually have a target list of answers of size 10. In particular, we first sort the answers based on their lengths ("dog" before "black dog"), and select up to top-10 answers. If the list legnth is less than 10, we replicate each of the top answers one-by-one until we have the list of size 10, similar to the process in OKVQA(Marino et al., 2019). This is to ensure that we can adopt *VQA Accuracy* to make the performance comparison.

B.2 Details on Training and Evaluating Visual Question Answering

Our code for the VQA model is based on the Flaxformer framework[8]. Both the text encoder and the multi-modal encoder have 6 blocks of Transformers, each of which consists of self-attention and a feed-forward network. We use 12 heads of inner dimension of 64, the embedding dimension of 768, and the MLP dimension of 2048. During training, we use Adafactor (Shazeer and Stern, 2018), with an initial learning rate of 0.0025, a linear warm-up step of 5K for (pre-)training and 1K for fine-tuning, and an "inverse square root" learning rate schedule $\frac{1}{\sqrt{\max(n,k)}}$, where n is the current training iteration and k is the number of warm-up steps. We use a dropout rate of 0.0. We train each of the models with data parallelism using 16 Cloud TPU Pods[9], each with a batch size of 256, unless otherwise stated.

The default numbers of training steps during training and fine-tuning are 100K and 30K, respectively. The exceptions are OKVQA (30K/15K) and VQ^{2}A CC3M (150K/NA). In addition, in the two-stage training where we fine-tune a VQ^{2}A-CC3M model with VQ^{2}A COCO, we also use 100K steps. Each single training run on average took fewer than 10 hours, including the time used to evaluate

Question	Answers
What is in the middle of the photo	“coffee”
Where is the coffee in the three frame photo combination	“middle”, “in middle”
How many frames are in the photo	“3”, “3 frame”
How many plates have desserts on them	“2”
How much of the pastry had been eaten	“partially”
Is there a cup of juice in the puzzle	“no”
Is there a pie in the middle of the photo	“no”
Are the desserts on the two plates the same or different	“different”
A beverage is displayed in what type of glassware	“cup”
What is the medium of the images of the desserts	“photos”

Question	Answers
How many people are in the picture	“0”
Is there a stoplight at the intersection of S Lane St. and 12th Ave S.	“no”
Is there a street sign in the picture	“yes”
On what is a street sign pictured	“hill”
What color is the street sign next to the dirt field by the playground	“green”
What is in front of the street sign	“gravel”
Which avenue meets S Lane St	“12th”
Which street does 12th Ave S intersect with	“lane st”
What does a street sign do at the intersection of S Lane St. and 12th Ave S.	“marks”

Question	Answers
Where is the woman in the photo	“car”
Is the woman in the picture doing her makeup	“yes”
What adjective would you use to describe the woman in the car	“pretty”
Who is in the car doing makeup	“pretty young woman”
What is the woman in the car doing	“makeup” “doing makeup”

Question	Answers
Pink shoes are for whom	“women”
What are the pink shoes for	“for women”
What item for women is all pink	“shoes”
What are all pink	“shoes for women”

Figure 5: Additional examples from VQ^{2}A COCO (top) and VQ^{2}A CC3M (bottom). Questions with the green background are present in VQA2.0.

Question Prefix	VQA2.0 %	VQ^{2}A-COCO %	VQ^{2}A-CC3M %	Question Example from VQ^{2}A-COCO
‘What is’	0.140	0.288	0.217	*‘What is the man swinging?’*
‘How many’	0.110	0.022	0.005	*‘How many people are standing in front of a tv?’*
‘Is the’	0.098	0.084	0.053	*‘Is the baby wearing a Santa hat?’*
‘What color’	0.090	0.022	0.018	*‘What color is the man’s hair?’*
‘Is this’	0.082	0.008	0.015	*‘Is this a safe way to fly?’*
‘Is there’	0.037	0.011	0.022	*‘Is there a pool in the backyard?’*
‘What kind’	0.025	0.049	0.078	*‘What kind of truck is the yellow one?’*
‘What are’	0.024	0.049	0.022	*‘What are the sheep and other animals roaming?’*
‘Are the’	0.024	0.022	0.007	*‘Are the apples on the cutting board green?’*
‘Are there’	0.020	0.002	0.004	*‘Are there any exceptions to this rule?’*
‘Where is’	0.019	0.071	0.034	*‘Where is the tennis player pictured?’*
‘What type’	0.018	0.006	0.022	*‘What type of picture is this?’*
‘Is it’	0.017	0.001	0.005	*‘Is it possible to eat a whole pizza?’*
‘Does the’	0.014	0.007	0.007	*‘Does the adult giraffe have any young?’*
‘What does’	0.011	0.015	0.038	*‘What does a giraffe do with its long neck?’*
‘Where are’	0.006	0.032	0.014	*‘Where are the skateboarders in the photo?’*
‘Who is’	0.005	0.054	0.020	*‘Who is in the photo?’*
‘What do’	0.002	0.003	0.018	*‘What do the father and son ride?’*
‘What was’	0.000	0.009	0.023	*‘What was the woman looking at?’*
‘What did’	0.000	0.001	0.021	*‘What did the cat lay inside of?’*

Table 7: Most popular question prefix distribution on valid questions whose answers are in the 6k target vocabulary.

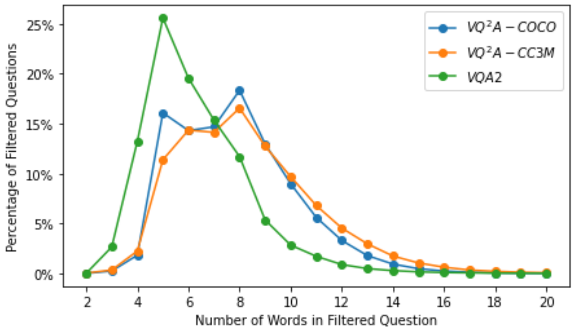

Figure 6: Question length distributions per dataset.

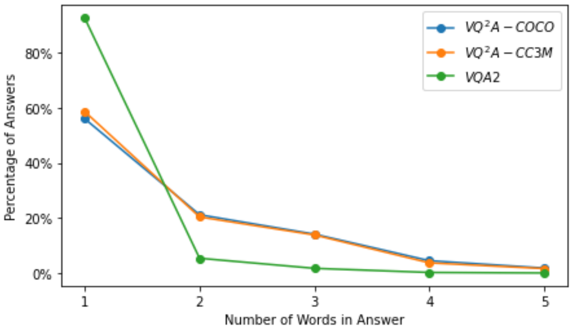

Figure 7: Answer length distributions per dataset.

a checkpoint — every 1K iterations. For instance, training on VQA2.0 took approximately 7 hours, VQ^{2}A COCO 13 hours, VQ^{2}A CC3M 10 hours. Note that VQ^{2}A COCO has larger evaluation set than other datasets, hence taking longer time to to train then VQ^{2}A CC3M.

The hyperparameters for Transformers are selected to be consistent with a T5-base checkpoint, which has 220 million parameters (Raffel et al., 2020) (except that now we have 2 encoders rather

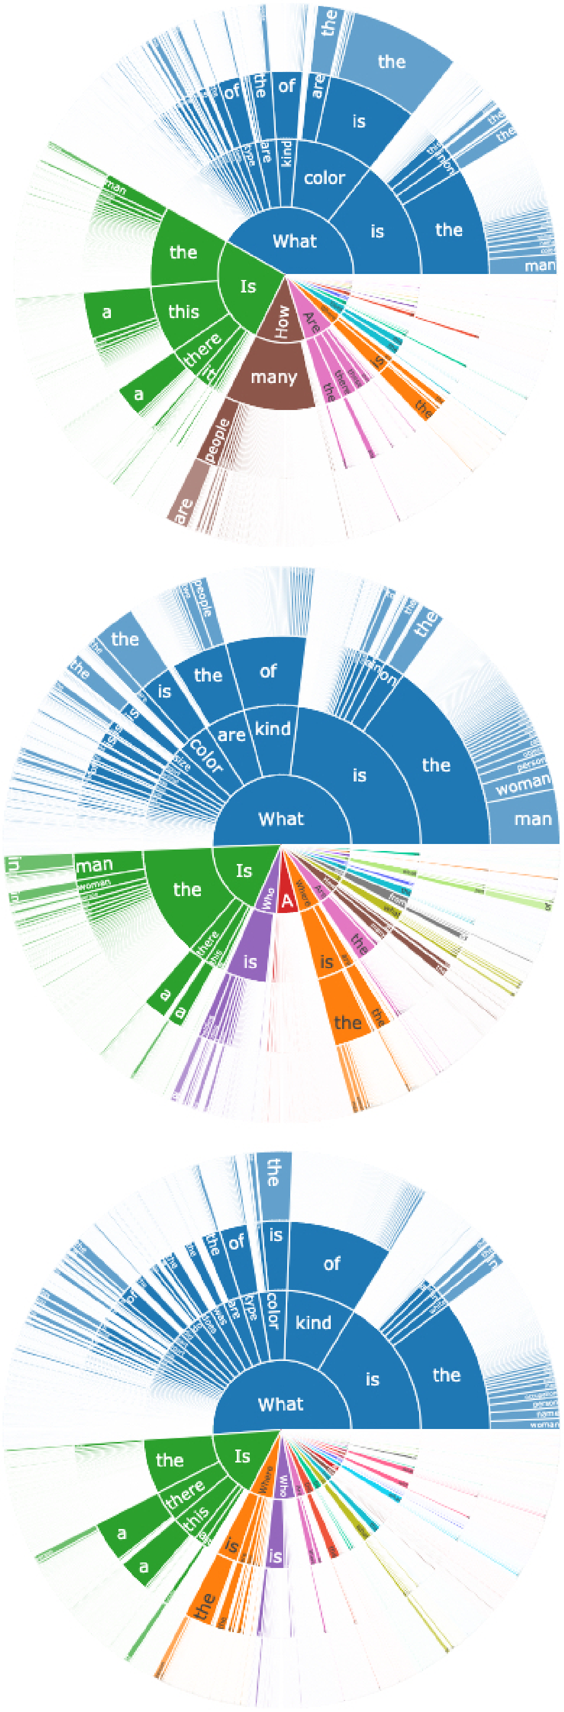

Figure 8: VQA2.0 (top), VQ^{2}A-COCO (middle), VQ^{2}A-CC3M (bottom) sunburst plots of question prefixes.

Question Prefix	VQ^{2}A-COCO Filter Pass Ratio	VQ^{2}A-CC3M Filter Pass Ratio
'What is'	0.73	0.65
'Is the'	0.64	0.39
'What kind'	0.84	0.80
'How many'	0.83	0.51
'What color'	0.92	0.90

than an encoder and a decoder). We initially tuned the initial learning rate (0.0125, 0.075, 0025, 0.00125, 0.00075) and the dropout rate (0.0, 0.1, 0.2) on a fully-supervised model on VQA2.0 baseline using *VQA Accuracy* and observed that 0.0025 and 0.0 work robustly across our experiments but we did not extensively tuned them in all of our experiments.

We implement *VQA Accuracy* ourselves based on the official challenge page for VQA2.0[10].

C Additional Results

Table 9 offers the Accuracy of the supervised VQA2.0 model, as well as of the zero-shot VQ^{2}A models, on the VQA2.0 devset, split by most common question prefixes. The Table is sorted by the supervised model's Accuracy. It shows a several performance differences, first between all types of boolean questions, which all have high precision on all models, vs. other types, which show not only lower performance for all models, but also more significant performance drop between the supervised and zreo-shot models.

Table 10 shows the zero-shot performance of models when using all of the VQ^{2}A dev sets, not only the manually validated sample, for which Table 6 reports results. What we see is that the difference in performance on the whole VQ^{2}A dev sets (Table 10) is similar in magnitude to that of the manually validated dev samples (Table 6), and most

Table 9: Average accuracy (%) on VQA2.0 for the most common question prefixes.

Training data	Evaluation Benchmark			
	COCO-QA	VQA2.0	VQ^{2}A COCO	VQ^{2}A CC3M
COCOQA	70.3	11.7	11.5	3.7
VQA2.0	35.9	68.8	41.1	33.3
VQ^{2}A COCO	**55.9**	**60.0**	71.2	**49.3**
VQ^{2}A CC3M	42.1	56.5	**60.3**	69.5

Table 10: VQ^{2}A **as evaluation data** for measuring robustness: VQA Accuracy when training on "row" and tested on "column"; diagonal (gray) numbers denote the supervised setting, non-diagonal numbers denote zero-shot cross-dataset setting. Best zero-shot is **bold**.

importantly, it keeps the order of models in terms of capabilities/performance. We therefore suggests that the utility of the VQ^{2}A approach could go beyond training; it can be used as an automatic test-bed for VQA robustness, if not for absolute figures, for ranking models for robustness zero-shot capabilities.

Table 11 shows the effect of candidate answer types on the VQA2.0 performance. We train our model on VQ^{2}A COCO or VQ^{2}A CC3M subsets with questions with (i) noun answers, (ii) yes/no answers, (iii) answers containing color-related tokens based on a list of common colors from Wikipedia, and (iv) answers containing digits from 0 to 100. We then evaluate models trained on these subsets on VQA2.0 using *VQA Accuracy* and the normalized version (by the percentage of evaluation questions with corresponding answer types. This highlights the importance of incorporating diverse answer candidates in our datasets. We also observe that VQ^{2}A CC3M is on par with VQ^{2}A COCO on yes/no-answer questions but are behind on nouns, color, and number, which we attribute to their lower degree image-text relevance, less mentioning of colors (due to the style of alt-texts vs. captions), and digit substitution.

Training data	*VQA Accuracy* on VQA2.0	
	Standard	Normalized
VQ^{2}A COCO	60.0	60.0
VQ^{2}A COCO nouns	10.5	32.5
VQ^{2}A COCO yes/no	38.4	94.3
VQ^{2}A COCO color	6.7	55.6
VQ^{2}A COCO number	3.9	25.4
VQ^{2}A CC3M	56.5	56.5
VQ^{2}A CC3M nouns	8.8	27.2
VQ^{2}A CC3M yes/no	38.4	94.4
VQ^{2}A CC3M color	6.0	49.5
VQ^{2}A CC3M number	3.4	22.1

Table 11: **Effect of candidate answer types** on the VQA2.0 performance.

Training data	*VQA Accuracy* on VQA2.0
VQ^{2}A COCO (100%)	60.0
VQ^{2}A COCO (50%)	58.5
VQ^{2}A COCO (20%)	56.7
VQ^{2}A COCO (10%)	55.4
VQ^{2}A CC3M (100%)	56.5
VQ^{2}A CC3M (50%)	55.8
VQ^{2}A CC3M (20%)	54.8
VQ^{2}A CC3M (10%)	53.8

Table 12: **Effect of dataset sizes** on the VQA2.0 performance.

Table 12 shows the effect of scale on the VQA2.0 performance. We randomly sampled 10%, 20%, and 50% of VQ^{2}A COCO or VQ^{2}A CC3M training data. We observe that the bigger the data, the higher the accuracy. However, the gain is diminishing. We identify improving the data generation process to achieve higher degree of diversity in the output as interesting future work.

Table 13 provides question-only baselines (no image features as input). Interestingly, the models trained on our generated VQ^{2}A data has similar answer distributions to those of existing VQA benchmarks. At the same time, this reveals the exploitation of the language bias, suggesting that additional research on bias mitigation is needed, both in terms of model and data (existing benchmarks and our datasets).

D Further Considerations

Information that names or uniquely identifies individual people or offensive content. COCO

Approach	Evaluation Benchmark		
	VQA2.0	GQA	OKVQA
Zero-shot			
questions VQ^{2}A COCO	48.9	44.4	11.4
questions VQ^{2}A CC3M	47.8	44.6	11.9
VQ^{2}A COCO	60.0	51.3	18.0
VQ^{2}A CC3M	56.5	49.9	19.1

Table 13: **Zero-shot question-only baselines** using VQ^{2}A as training data.

Captions are human-curated and cleaned while the approach to collection of CC3M upholds rigorous privacy and ethics standards such as the removal of offensive content and hypernymization. This significantly mitigates the risks that our VQ^{2}A datasets would contain such information.

Intended uses. Due to considerations and limitations as we mention in Section 6, COCO Captions, CC3M, and our induced VQ^{2}A are intended to be used for research-only purposes.

Frustratingly Easy System Combination for Grammatical Error Correction

Abstract

In this paper, we formulate system combination for grammatical error correction (GEC) as a simple machine learning task: binary classification. We demonstrate that with the right problem formulation, a simple logistic regression algorithm can be highly effective for combining GEC models. Our method successfully increases the $F_{0.5}$ score from the highest base GEC system by 4.2 points on the CoNLL-2014 test set and 7.2 points on the BEA-2019 test set. Furthermore, our method outperforms the state of the art by 4.0 points on the BEA-2019 test set, 1.2 points on the CoNLL-2014 test set with original annotation, and 3.4 points on the CoNLL-2014 test set with alternative annotation. We also show that our system combination generates better corrections with higher $F_{0.5}$ scores than the conventional ensemble.[1]

1 Introduction

Grammatical error correction (GEC) is the task of detecting and correcting grammatical errors present in a text (Ng et al., 2013). Grammatical error correction has achieved remarkable progress since the late 2000s, and has flourished more along with the development of sequence-to-sequence architecture. Grammatical error correction shared tasks such as CoNLL-2013 (Ng et al., 2013), CoNLL-2014 (Ng et al., 2014), and BEA-2019 (Bryant et al., 2019) also contribute to popularizing the task.

With the success of Transformer (Vaswani et al., 2017) architecture in sequence-to-sequence tasks, most recent state-of-the-art grammatical error correction systems use Transformer-based architecture. Even though they all use a Transformer-based architecture, there are still some variations to the models, especially in the task formulation and pre-training data.

Generally, we can divide the recent state-of-the-art systems into a sequence tagging approach (Awasthi et al., 2019; Omelianchuk et al., 2020) that usually uses a large pre-trained masked language model, and a sequence-to-sequence approach (Rothe et al., 2021; Stahlberg and Kumar, 2021; Kaneko et al., 2020) that usually pre-trains a Transformer architecture with synthetic data. The differences in the synthetic data generation methods and seed corpora used also contribute to more diverse GEC systems.

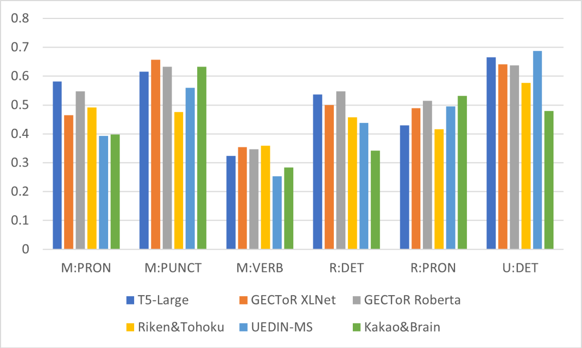

Figure 1: The $F_{0.5}$ scores of the base GEC systems that we use in our experiments on selected error types in the BEA-2019 development set.

With these differences, each model has its own strengths and weaknesses (Figure 1). Susanto et al. (2014) has demonstrated that the differences in the strengths of the GEC models can be utilized to generate better grammatical error corrections by combining them through a system combination method. In this paper, we present our simple yet effective system combination method for grammatical error correction that outperforms all prior state-of-the-art systems on both CoNLL-2014 and BEA-2019 shared tasks.

The contributions of this paper are as follows:

- We propose a novel method for combining grammatical error correction systems, by formulating the task as binary classification that predicts each edit independently. To the best of our knowledge, this is the first time that

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1964 - 1974
July 10-15, 2022

system combination for grammatical error correction is formulated this way.

- Our proposed method only relies on the outputs of the base systems, making our method compatible with any base GEC systems.
- We demonstrate that the combined GEC system using our method outperforms all state-of-the-art systems on both CoNLL-2014 and BEA-2019 shared tasks.
- We demonstrate that our system combination method outperforms other prior system combination methods, and it is also a better alternative than the conventional ensemble.

2 Related Work

In this section, we discuss some prior work on GEC system combination. One approach (MEMT) only uses the output sentences without relying on any edit type, while the other two approaches (IBM, GEC-IP) only use the edit type and which hypotheses (output sentences of component systems) propose an edit type while not using the output sentences at all. In this section, we also discuss another system combination method (DDC) that introduces diversity to the base systems, which is complementary to our system combination method.

2.1 MEMT

MEMT is a system combination method that is originally designed to combine machine translation hypotheses from multiple base systems. Susanto et al. (2014) have demonstrated that the method works well for GEC system combination also. MEMT combines the hypotheses by first aligning them and generates all possible paths of the candidate tokens from the hypotheses. MEMT has some constraints in searching the possible candidate tokens, such as no repetition, weak monotonicity, and completeness. MEMT then learns to score the candidate tokens based on the n-gram language model score, n-gram similarity to the hypotheses, and the number of tokens in the candidate.

2.2 IBM

The IBM system combination method (Kantor et al., 2019) works by separating the edits from two hypotheses into three groups: edits that appear exclusively in the first hypothesis, edits that appear in both hypotheses, and edits that appear exclusively in the second hypothesis. This grouping is done for each edit type. Then, the model learns the decision of which group to include for each edit type. The IBM method can only combine two systems at a time. Hence, combining more than two systems requires applying this method iteratively.

2.3 GEC-IP

GEC-IP (Lin and Ng, 2021) is similar to the IBM method, but is simpler and directly optimizes the parameters using non-linear integer programming, instead of optimizing real-valued parameters and rounding them later as used in the IBM method. Another key difference between GEC-IP and IBM is that GEC-IP can combine many base systems at once, instead of combining only two systems at a time. In GEC-IP, for each edit type, the system chooses the edits from only one base system to be applied as the final correction, and ignores the edits from the other base systems.

2.4 DDC

Diversity-driven combination (DDC) (Han and Ng, 2021) is a method that aims to increase the diversity among the base systems in a system combination scenario, so as to improve the performance of the combined system. Macherey and Och (2007) show that the base systems should be diverse (almost uncorrelated) and have similar quality to be useful for system combination. DDC is not entirely a black-box method as it requires a base system to act as the backbone system to be fine-tuned. DDC uses reinforcement learning to induce diversity to the base systems, then uses an off-the-shelf system combination method to combine the base systems. As DDC is orthogonal to this research and is not a black-box system combination method, this paper does not compare to DDC.

3 Method

In this section, we describe how we formulate the task and present our method, which gathers all possible edits from the hypotheses (i.e., output sentences of individual base systems) and for each edit, predicts whether it should be kept or discarded to generate the final output sentence of the combined system. Our method is named ESC (Edit-based System Combination).

3.1 Task Formulation

We formulate GEC system combination as a binary classification task. We regard the base GEC models as black boxes and combine the models based on their proposed edits. From the hypotheses generated by the base GEC models, we extract the edits in the form of (start index, end index, correction string) tuples. In addition, each edit also has an edit type that is acquired from an automatic error annotation tool, and the edit type is used as part of the features of an edit. We follow the edit type convention of Bryant et al. (2017). Each edit can be one of three operations: insertion (prefixed with 'M:' for 'missing'), deletion (prefixed with 'U:' for 'unnecessary'), and substitution (prefixed with 'R:' for 'replacement'). An example of extracted edits and edit types is shown in Table 1.

We take the union of edits from all hypotheses and gather them into a unified set E. Our method evaluates each edit independently, without the information of surrounding edits or context words. Similar to (Kantor et al., 2019) and (Lin and Ng, 2021), our method also entirely relies on the edit type and does not use the textual information of the edit. We use a generalized linear model to predict whether each edit from E should be kept or discarded to create the output sentence of the combined system, according to the features of the edit to be defined in the next subsection.

3.2 Features

Suppose there are k hypotheses from k base (component) systems to be combined. Each edit e in E is represented by a feature vector $\boldsymbol{x}$, which is formed by concatenating the feature vectors $\boldsymbol{x}_i$, $i = 1 \dots k$:

$$\boldsymbol{x} = [\boldsymbol{x}_1; \boldsymbol{x}_2; \dots ; \boldsymbol{x}_k]$$

$\boldsymbol{x}_i$ is the one-hot representation of the edit type of e in hypothesis i (e.g., M:ADJ -> [1, 0, 0, ..], M:ADV -> [0, 1, 0, $\dots$]) if the edit type exists in hypothesis i, and a zero vector if it does not. This way, the model learns to determine whether or not to keep an edit purely based on the edit type and which hypotheses propose this edit. The supplied information to the model is the same as the IBM method (Kantor et al., 2019) and GEC-IP method (Lin and Ng, 2021), but the task formulation and optimization method differ. For set of edit types T, $\boldsymbol{x}_i \in \mathbb{R}^{|T|}$ and $\boldsymbol{x} \in \mathbb{R}^{k|T|}$. In our work, $|T| = 54$.

3.3 Model

We use logistic regression as the classification model. Using logistic regression as the classifier makes the model trainable with only a modest amount of training data and makes the results interpretable. Moreover, we found that it works very well in combining different kinds of base GEC systems. For each edit, we obtain the probability of the edit being a correct edit to be used to generate the output sentence as follows:

$$p = \sigma(\boldsymbol{w} \times \boldsymbol{x} + b) \quad (1)$$

where σ is the sigmoid function.

3.4 Post-processing

Since we combine the edits from multiple hypotheses, we may have overlapping edits, either due to multiple insertions at the same location or overlapping substitutions.

- **Multiple insertions** Multiple conflicting insertion edits at the same location are not to be applied together when proposed by different base GEC systems. If there are multiple insertion edits at the same position (e.g., (3, 3, on) and (3, 3, in)), we consider this as a multiple insertion conflict.

- **Overlapping substitutions** If an edit's start or end index is in between another edits' start and end indices (e.g., (2, 4, eaten) and (2, 3, ate)), we consider this as an overlapping substitution conflict.

We use a greedy strategy to select the edits after we obtain the probabilities from the model. First, we only consider edits that have probabilities above a certain threshold. Then, we sort the edits based on their probabilities from the highest to the lowest and check the edits one-by-one to only select the edits that do not have any conflict with previously selected edits.

4 Experiments

4.1 Implementation

We extract the edits from the base GEC models' output using ERRANT (Bryant et al., 2017) and implement our model using the Linear module of PyTorch (Paszke et al., 2019). We optimize the model using stochastic gradient descent (SGD) with binary cross entropy, and use the threshold of 0.5 to select the edits. Our model's hyper-parameters are given in Table 2.

Source	In this case , the families played important roles in daily lives .
Correction	In this case , family members play important roles in our daily lives .
Edits	(4, 5, ‘’), (5, 6, family members), (6, 7, play), (10, 10, our)
Edit types	U:DET, R:NOUN, R:VERB:TENSE, M:DET

Table 1: Extracted edits from a sample pair of source and corrected sentences.

Momentum	0
Dampening	0
Weight decay	0
Criterion	Binary Cross Entropy
Criterion reduction	Mean
Learning rate	0.1
Batch size	16
Shuffle train	True

Table 2: Hyper-parameters for all experiments.

4.2 Dataset

Following Kantor et al. (2019) and Lin and Ng (2021), we train the model on the base systems' outputs on BEA-2019 shared task development data (Bryant et al., 2019). All base systems that we combine in our experiments are publicly available. Except for T5-large, the outputs of the models can be downloaded directly. For T5-large, their results can be readily reproduced following the instructions in the T5 repository, fine-tuning[2] it with the dataset that is published by (Rothe et al., 2021). The URLs of these base systems are listed in the Appendix.

Our method only requires one hyper-parameter that needs to be set in each experimental setting, which is the number of epochs to train the model. Its value is determined by first training our model on 80% of the BEA-2019 development data. The epoch number that results in the highest $F_{0.5}$ score on the remaining 20% of the BEA-2019 development data is chosen. We then train on the complete BEA-2019 development data for the same number of epochs to obtain the final model.

4.3 Evaluation

We evaluate our model on CoNLL-2014 (Ng et al., 2014) and BEA-2019 test data. We use the MaxMatch (M2) scorer (Dahlmeier and Ng, 2012) to obtain the CoNLL-2014 results and ERRANT scorer (Bryant et al., 2017) to obtain the BEA-2019 results. To reduce randomness in our experiments, we report the average and standard deviation of 5 runs. For MEMT and ESC, we set a different random seed in each run. For IBM, we randomize the way of combining the base systems. Since the IBM method combines two systems in each step, the order of combining the base systems affects the combination results. For GEC-IP, its optimization is deterministic. There is only slight variation due to conflict resolution if there are overlapping edits, but it does not happen in our experiments. Thus, our repeated experiments of GEC-IP have the exact same output in both the BEA-2019 and the CoNLL-2014 experiments. We measure the statistical significance of our experiments with bootstrap resampling on 100 samples.

5 Results

We combine up to six strong GEC base systems, namely T5-Large (Rothe et al., 2021), GECToR XLNet (Omelianchuk et al., 2020), GECToR Roberta (Omelianchuk et al., 2020), Riken&Tohoku (Kiyono et al., 2019), UEDIN-MS (Grundkiewicz et al., 2019), and Kakao&Brain (Choe et al., 2019). For the CoNLL-2014 combination, we do not include the Kakao&Brain system as a base system since its CoNLL-2014 score (61.15) is significantly lower than the other systems ($\geq$ 64.00). For the BEA-2019 combination, our main results combine all 6 aforementioned base GEC systems.

We compare the scores of our model (ESC) with other system combination methods that have been shown to work well on the grammatical error correction task, such as MEMT (Heafield and Lavie, 2010), IBM (Kantor et al., 2019), and GEC-IP (Lin and Ng, 2021). With almost no hyper-parameter tuning, our model works very well and outperforms

ESC (ours)	**86.6**	60.9	**79.9**

Table 5: Comparison of our BEA-2019 test scores with state-of-the-art systems.

all the other system combination methods.

Our ESC method increases the $F_{0.5}$ score by 4.17 points from the highest base GEC system on CoNLL-2014 (Table 3) and 7.24 points on BEA-2019 (Table 6). The high performance on both CoNLL-2014 and BEA-2019 shows that our model does not overfit to the dataset even though the model is trained with BEA-2019 development set. We confirm that the $F_{0.5}$ scores on both CoNLL-2014 and BEA-2019 are significantly higher than the $F_{0.5}$ score of each of the other combination methods ($p < 0.001$).

In addition, our BEA-2019 $F_{0.5}$ score outperforms the state of the art by 4.0 points (Table 5), and our CoNLL-2014 $F_{0.5}$ score outperforms the state of the art by 1.21 points on the original annotation and 3.41 points on the alternative annotation (Table 4). For the CoNLL-2014 score comparison, we report both the $F_{0.5}$ scores on the original annotation and the alternative annotation (alt) that includes moderated participants' alternative annotations. This is because one of the current top systems for CoNLL-2014 reported its score on the alternative annotation[3]. From the experiments on CoNLL-2014 (Table 3) and BEA-2019 (Table 6), we can see that the strength of ESC lies in its high precision compared to other system combination methods.

6 Analysis

In this section, we analyze the capability of our ESC method in comparison with other GEC system combination methods. Our method, which is a simple logistic regression, chooses whether to include an edit based on its appearance and the edit type in each component system. With edit type set T and k hypotheses, the model is a function of $k|T|+1$ weight parameters: $\boldsymbol{w} \in \mathbb{R}^{k|T|}$ and the bias parameter b. If we assume the edit type for the same edit span and correction between the hypotheses to always be the same, we can decompose the model into $|T|$ independent functions that accept k inputs, one function for each edit type $t \in T$, as

ESC (ours)	**73.63**	40.12	**63.09**	**86.65**	60.91	**79.90**	79.86 ± 0.07

Table 6: BEA-2019 combination results. The first group of rows shows the base GEC systems and the second group of rows shows the combination results. The rightmost column shows the mean and standard deviation of the BEA-2019 test set $F_{0.5}$ scores from 5 experiments. The rest come from a single experiment that has the highest $F_{0.5}$ score on BEA-2019 dev set.

follows:

$$f_t(x_1, x_2, \ldots, x_k) = \begin{cases} 1 & \text{if} x_1 w_1^e + x_2 w_2^e + \ldots + x_k w_k^e + b > 0 \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

where x_j denotes whether the edit appears in hypothesis j. The edit is selected only if f_t results in 1. In this analysis, we also assume that there are no conflicting edits and we use the probability threshold of 0.5. We use this function formulation throughout our analysis.

6.1 Comparison with MEMT

Compared to ESC, IBM, and GEC-IP, MEMT has a significantly different approach to combine the hypotheses. MEMT does not utilize edit types at all. Instead of learning the weight for each edit type from each component system, MEMT learns the weight of n-gram matching to the output of each component system. Moreover, MEMT also scores the candidate sentence with an n-gram language model, so candidate selection is affected by the domain of the language model's training data and the language model's limited context.

In Table 7, MEMT chooses to keep the edit of changing the word "practise" to the word "do". Since there is only one hypothesis proposing this edit, the n-gram match of this edit will have a lower score than not keeping the edit. Thus, MEMT keeps this edit due to the higher language model score. It is likely that the phrase "they can do it" appears more often in the language model training data than "they can practise it".

Source	However , the adults they can practise it as well and they will get the same .
S1	However , the adults ~~they~~ can **do** it as well and they will get the same .
S2	However , the adults ~~they~~ can practise it as well and they will get the same .

Table 7: An example of MEMT's weakness.

6.2 Comparison with IBM

Proposition 1. *In the combination of 4 or more base systems, ESC has more expressive power than any of IBM's combination settings.*

The IBM method separates the edits from 2 hypotheses (e.g., $S1$ and $S2$) into three groups: edits that appear exclusively in S1 ($S1 \cap \neg S2$), edits that appear in S1 and S2 ($S1 \cap S2$), and edits that appear exclusively in S2 ($\neg S1 \cap S2$). In the combination of more than 2 hypotheses, we apply the IBM method iteratively in some order.

In each iteration, for each edit type $t \in T$, we can formalize the IBM method as the following logic function:

n	**IBM's upper-bound**	**ESC's lower-bound**
2	8	7
3	64	52
4	512	941
5	4096	47286
6	32768	7514067
7	262144	4.189035e+9
8	2097152	8.7807698e+12
9	1.1677722e+7	7.2065266e+16

Table 8: IBM's upper bound of expressive power and ESC's lower bound of expressive power, both in terms of possible logic function expressions. n denotes the number of base systems.

$$g_t(x_i, x_j) = (s_1 \cap (x_i \cap \neg x_j)) \cup (s_2 \cap (x_i \cap x_j)) \cup (s_3 \cap (\neg x_i \cap x_j)) \tag{3}$$

where x_i denotes whether the edit appears in hypothesis i, and s_1, s_2, and s_3 denote parameters to select/ignore the edit group.

Note that $g_t(x_i, x_j)$ is a commutative function, i.e., $g_t(x_i, x_j) = g_t(x_j, x_i)$. We can just swap the values of s_1 and s_3 from the above equation. Thus, the number of expressions that g can express is not more than all possible combinations of s_1, s_2, and s_3 values, which is $2^3 = 8$.

In combining k systems, the maximum number of iterations is $k - 1$ steps. Thus, the number of logic functions the IBM method can express with k base systems, no matter in which order the component models are combined (combination setting)[4], is at most 8^{k-1}. On the other hand, ESC can express all linearly separable Boolean functions with k variables. Since we do not consider edits that do not exist in any of the hypotheses, the number of unique functions that ESC can express is at least half of the possible linearly separable Boolean functions. We show the rationale behind this in the Appendix.

Currently, the number of linearly separable Boolean functions is known only up to 9 variables (Gruzling, 2007). However, in comparison with IBM's expressivity (Table 8), we know that ESC has more expressive power until at least the combination of 19 base systems, since $8^{18} < 7.2 \times 10^{16}$.

	BEA-2019

+ Kakao&Brain	86.65	**60.91**	**79.90**

Table 9: The performance of GEC system combination with different number of base systems on the BEA-2019 test set.

6.3 Comparison with GEC-IP

Proposition 2. *ESC is a generalized form of GEC-IP.*

GEC-IP works by selecting one hypothesis for each edit type. We can model GEC-IP's final decision with ESC Equation 2 by setting one of the weights to one, and the others to zero, i.e., $w_{\bar{s}} = 1, w_{j \neq \bar{s}} = 0 \ \forall j \in \{1, \ldots, k\}$, where $\bar{s}$ denotes the optimal hypothesis from GEC-IP training, for each edit type. Thus, this shows that GEC-IP is a special case of ESC.

7 Discussions

7.1 Effect of the Number of Base Systems

In this section, we discuss the effect of using different number of GEC base systems in our combination. We conduct an experiment of GEC system combination with increasing number of base systems from 2 to 6 (Table 9). In this experiment, we always pick the best-performing base systems first, i.e., we combine T5-Large with GECToR XLNet in the 2-system combination, then add GECToR Roberta in the 3-system combination, and so on.

We find that even with combining only three systems, our method already outperforms the state of the art (75.9). We also find that adding more base systems, even though an additional system is weaker than the already combined base systems, is still beneficial to improve the $F_{0.5}$ score. We find that adding more base systems allows the model to have more information in picking the correct edits, hence improving the precision.

7.2 Ensemble Alternative

We run system combination experiments with base systems that are very similar to each other to evaluate whether our system combination can be an alternative to the conventional ensemble. We run this experiment on two sets of models, a set of sequence-

Table 11: Comparison of ESC with conventional ensemble on sequence tagging models.

to-sequence models and a set of sequence-tagging models. By conventional ensemble, we mean the method of averaging the output probabilities from multiple models during the prediction step, i.e., when predicting the tag for each token in sequence tagging models and when predicting the next token during beam search in sequence-to-sequence models.

The sequence-to-sequence experiment combines 4 transformer-big models we train ourselves. The four models only differ in the random seeds, pre-training data, and batch sizes during fine-tuning. 2 of them are pre-trained with 50M sentences of synthetic data, and the other 2 are pre-trained with 100M sentences of synthetic data before being fine-tuned with BEA-2019 training data. For the sequence tagging experiment, we use GECToR's (Omelianchuk et al., 2020) models[5], which differ in the pre-trained masked language model, and then fine-tune with GEC parallel data.

We find that even though the base systems are relatively similar, our system combination can still improve the $F_{0.5}$ score by at least 1.7 points. Furthermore, our model yields higher $F_{0.5}$ scores than the conventional ensemble (Tables 10 and 11). This suggests that using ESC instead of the conventional ensemble is better when combining multiple models.

8 Conclusion and Future Work

In this work, we present a novel GEC system combination method using logistic regression by formulating the task as binary classification. Our method increases the $F_{0.5}$ score by 4.17 points from the highest base GEC system on CoNLL-2014 and 7.24 points on BEA-2019. This shows that our method does not overfit to the dataset even though it is trained on the BEA-2019 development data. In addition, our combined system outperforms the best published GEC system by 4.0 points on the BEA-2019 test set, 1.21 points on the CoNLL-2014 test set with original annotation, and 3.41 points on the CoNLL-2014 test set with alternative annotation.

We also compare our system combination method to the other GEC system combination methods, including MEMT (Heafield and Lavie, 2010), IBM (Kantor et al., 2019), and GEC-IP (Lin and Ng, 2021), and show that our method has better expressive power compared to IBM and GEC-IP. We also show that our method produces a higher $F_{0.5}$ score than the conventional ensemble.

This work highlights the importance of edit type information in system combination for grammatical error correction. In recent GEC research, most systems just employ end-to-end learning without making use of any syntactic knowledge. We show that syntactic information, such as edit type, can also be useful to improve neural grammatical error correction models. Even though we only evaluate this method on English GEC, we believe our method can also be applied to other languages when a similar error type annotation toolkit is available.

C Complete Experimental Results

The complete 5-run experiments can be seen in Table 13 for our CoNLL-2014 results and Table 14 for our BEA-2019 results. The experiment with the highest BEA-2019 dev set $F_{0.5}$ score for the CoNLL-2014 experiments is from the one with random seed 8888, and the experiment with the highest BEA-2019 dev set $F_{0.5}$ score for the BEA-2019 experiments is from the one with random seed 999.

D Expressive Power of ESC

D.1 Definition

Suppose $f_\theta(x_1, \ldots, x_n)$ is a combination function which takes $x_1, \ldots, x_n$ as input and returns a binary value using the parameter value $\theta \in \Omega$ where Ω is the parameter space. Let $\mathcal{EP}(f)$ be the expressive power of f, which is defined as the number of unique functions of f, obtained from all possible parameter values, formally given as follows:

$$\mathcal{EP}(f) \quad = \quad |\{f_\theta | \theta \in \Omega\}|$$

D.2 Calculating the Number of Possible Functions[6]

With n Boolean variables, there are 2^n possible combinations of the variable values. For example, for $n = 2$, there are 2^2 possible values:

- $a = 0, b = 0$
- $a = 0, b = 1$
- $a = 1, b = 0$
- $a = 1, b = 1$

From these 4 possible values, we can generate 2^4 functions, based on the combination of the returned values for each input combination. The possible functions are shown in Table 15. If we set the output of $a = 1, b = 1$ to a fixed value such as in Table 16, the number of semantically different functions is reduced by half, as F0 becomes the same function as F1, F2 becomes the same function as F3, and so on. This reduces the expressive power of the function to half from 16 to 8.

6	2^{2^6}	15028134	7514067
7	2^{2^7}	8.3780708e+9	4.189035e+9
8	2^{2^8}	1.7561539e+13	8.7807698e+12
9	2^{2^9}	1.4413053e+17	7.2065266e+16

Table 17: The number of possible Boolean functions. n denotes the number of parameters, which is the same as the number of hypotheses.

ESC is a generalized linear function, so it can only express linearly separable functions. Furthermore, we do not consider any edits that do not appear in any of the hypotheses, making the output of the function with the input of ($x_1 = 0, x_2 = 0, \ldots, x_k = 0$) always resulting in 0. Thus, the number of semantically different logic functions that can be expressed is at least half of linearly separable Boolean functions. With the list of number of linearly separable Boolean functions from (Gruzling, 2007), we can get the lower bound of ESC's expressive power in Table 17.

Simple Local Attentions Remain Competitive for Long-Context Tasks

Abstract

Many NLP tasks require processing long contexts beyond the length limit of existing pretrained models. To scale these models to longer text sequences, many efficient long-range attention variants have been recently proposed. Despite the abundance of research in this direction, it is difficult to gauge the relative effectiveness of these models in practical use cases, *e.g.*, if we apply these models following the pretrain-and-finetune paradigm. In this work, we aim to conduct a thorough analysis of these emerging models with large-scale and controlled experiments. For each attention variant, we pretrain large-size models using the same long-doc corpus and then finetune these models for real-world long-context tasks. Our findings reveal pitfalls of a widely-used long-range benchmark and show that the other efficient attentions fail to outperform the simple local-window attention after standard pretraining. Further analysis of local-attention variants suggests that even the commonly used attention-window overlap is not necessary to achieve good downstream results — using disjoint local attentions, we are able to build a simpler and more efficient long-doc QA model that matches the performance of Longformer (Beltagy et al., 2020) with half of its pretraining compute.[1]

1 Introduction

The quadratic complexity of Transformer architectures makes it prohibitive to apply large state-of-the-art pretrained models to full-length documents. To efficiently handle longer text while still maintaining the capacity of attention-based models, a long list of efficient attention variants have been proposed and many claim to effectively capture long-range dependencies. Typical paradigms of these architecture innovations involve *learnable sparse attention patterns* (Kitaev et al., 2020; Tay et al., 2020; Roy et al., 2021), *fixed local patterns* (Beltagy et al., 2020; Ainslie et al., 2020; Zaheer et al., 2020) and *attention matrix approximation methods* (Wang et al., 2020; Choromanski et al., 2021; Xiong et al., 2021). While most of these studies have reported numbers on long sequence inputs, they tend to adopt quite different benchmarks. For instance, Reformer (Kitaev et al., 2020) is tested on the 64k-chunk enwik8 dataset for unidirectional language modeling; Performer (Choromanski et al., 2021) reports masked language modeling (MLM) perplexity on the PG-19 book corpus and protein sequences; Linformer (Wang et al., 2020) reports MLP perplexity with various input length, while most of the documents in their pretrain corpus are short documents.[2] The divergence of evaluation protocols makes it hard to compare the relative performance of each attention variant and it is also unknown how they perform well in more practical use cases, which typically involve large-scale pretraining and downstream finetuning.

Other lines of work such as Longformer (Beltagy et al., 2020) and ETC (Ainslie et al., 2020) conduct experiments on real-world long-context tasks such as long document QA and summarization. These methods only test fixed local attention patterns, *i.e.*, each token can only attend to a small set of nearby tokens. To reduce the pretraining cost, these models are all initialized from the RoBERTa (Liu et al., 2019) checkpoint[3] before further long-doc pretraining. While this paradigm is useful to achieve strong downstream performance, it is not ideal for a fair comparison of all available attention mechanisms, since some of the models use different parametrization that is incompatible

with the vanilla transformer attention.

A recently proposed benchmark (Tay et al., 2021), named long-range arena (LRA), aims to address the lack of unified evaluation with a bundle of long-sequence tasks. However, the text-related tasks in this benchmark are either automatically generated or artificially lengthened by enforcing byte-level inputs, making them rather synthetic. With a fixed byte-level vocabulary and pre-specified model size, all models are trained from scratch with the same epoch limit on each dataset. While the evaluation protocol is consistent across architectures, this setup still deviates from the common paradigm of applying Transformer models, *i.e.*, standard tokenization like BPE or wordpiece, large-scale pretraining followed and task-specific finetuning (Devlin et al., 2019). Thus, an important question yet to be addressed is whether the results on these artificial datasets are indicative of real-world long-context tasks.

In this work, our goal is to better understand the effectiveness of various attention mechanisms through a systematic study on practical long-context tasks. Instead of only relying on language modeling or synthetic tasks, we test each model under the standard pretraining-and-finetuning paradigm. For a fair comparison, we implement these attentions under a unified framework and test them using the same Transformer architecture[4] used by RoBERTa-large. We pretrain all models using a large corpus that contains mostly long documents and then finetune them on tasks like long-document question answering, full document retrieval, and text classification. Our experiments show the discrepancies between the commonly used LRA benchmark and downstream results (after pretraining). Additionally, our analysis on the best local attention models allows us to further simplify these models and results in a more efficient long-context encoder. More specifically, the key findings of this paper include:

- With proper tuning, we find that all the tested models can achieve similar level of performance on the LRA benchmark while their performance diverges significantly on large-scale pretraining and downstream tasks;

- In our experiments, the other attention paradigms barely outperform the class of simple local attentions on downstream tasks when using similar pretraining compute;

- As a result of our further analysis of the best performing attention variants, we are able to build a long-doc QA model that is on-par with Longformer while being 2x more efficient.

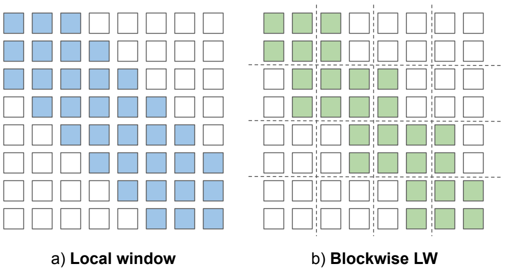

Figure 1: Attention pattern visualization of two types of local attentions: **Left**: Local window attention as in Longformer, with window size 2; **Right**: Blockwise local window attention with block size 2. The rows represent the tokens in the sequence and the columns represent the tokens being attended to.

2 Preliminaries of Tested Attention Variants

We study three classes of efficient attentions:

Fixed local patterns. These methods restrict each token to only attend a local window of tokens. The long-range interactions are achieved by the depth of the model. We consider two variants of these models, the token-wise local window attention (**Local Window**) proposed in Beltagy et al. (2020) where each token attends to the same number of tokens on each side, and a simplified and easy-to-implement blockwise version (**Blockwise LW**) (Zaheer et al., 2020) where each token attends to tokens in the same block and half of the tokens in the left/right blocks. A visualization comparing these two models is shown in Figure 1.

Learnable sparse attention patterns. Instead of relying on the inductive bias of locality, methods like **Reformer** (Kitaev et al., 2020) and **Sinkhorn** Attention (Tay et al., 2020) allow the model to adaptively select tokens to attend to. Briefly, Reformer uses a learnable hashing function to bucket the sequence and each token only attends to tokens in the same bucket; Sinkhorn uses a learnable sorting function to learn a permutation of the segments and each token will attend to tokens in its segment, and the corresponding segment after permutation.

---

[4] We only modify the attention calculation within the multi-head attention blocks

Kernel-based/Low-rank methods. This class of methods use matrix approximation methods to approximate the full attention function. For sequence length L and the hidden dimension d, **Linformer** (Wang et al., 2020) simply uses a projection matrix ($L \times k$) to reduce the length of key and value feature matrix, i.e., from $L \times d$ to $k \times d$ ($k \ll L$). **Nyström** (Xiong et al., 2021) attention adopts a classic matrix approximation method which reconstructs the full attention matrix using a sampled sub-matrix. **Performer** (Choromanski et al., 2021) eliminates the need of explicitly calculating the $L \times L$ attention matrix by using a random feature method that can approximate the softmax kernel with only dot-product operations.

Hybrid attention. In addition to these representative methods in each class, our study also includes the more recent **Long-Short** attention (Zhu et al., 2021) which has a similar compression component as in Linformer and combines it with local attentions. Unlike Linformer's compression component which is simply implemented as a standalone projection matrix, **Long-Short** proposes an input-dependent compression layer, which can adaptively reduce the sequence length.

A note on global tokens. For many practical NLP tasks, *e.g.*, classification or entailment, the final layer of the model usually requires a single sequence-level representation as input. For local attention models, it is common practice (Beltagy et al., 2020; Zaheer et al., 2020) to mark a single or a small number of tokens as global tokens and allow these tokens to attend to and be attended by all other tokens. Without incurring much computational cost, these global tokens are important to get better sequence representations and achieve good downstream results. While the mechanism of global tokens has not been used in models with learnable attention patterns, it is straightforward to augment **Reformer** and **Sinkhorn** with global tokens using *gather* operations in standard neural network packages, as their attention scores are still calculated by dot product and softmax operations. Thus, in our experiments, except for the kernel-based/low-rank methods, we augment all other models with global tokens to offset the potential performance gap resulting from this trick.

3 Experiment Setup

We restrict our studies to encoder-only models and leave the analysis of generative models to future work. We begin by implementing a collection of efficient attentions with a unified framework (Lefaudeux et al., 2021), which allows us to plug these models into our pretraining-and-finetuning pipeline in a consistent fashion.

3.1 LRA Experiments

Following recent work on efficient long-range attentions, we take the LRA benchmark as our first set of experiments. As our focus here is on NLP tasks, we consider a subset of LRA tasks with text inputs, *i.e.*, the ListOps, IMDB sentiment analysis, and text matching tasks. All tasks are formulated as classification problems: ListOps requires the model to predict the correct output of an expression (10-way classification), sentiment analysis is to predict the positive/negative labels of IMDB reviews and text matching aims to predict citation links between papers. We follow the hyperparameter settings of recent work (Xiong et al., 2021; Zhu et al., 2021). Two-layer Transformer encoders are used across all tasks and enough training updates are allowed to ensure convergence[5]. Note that this is different from the setup proposed in the original LRA benchmark, where different tasks adopt different model sizes. It is observed from recent work that two-layer models with smaller dimensions are sufficient to achieve similar or better results than previously reported results. The final classification layer is added on top of the representations of `[CLS]` tokens which are prepended to each sequence.

3.2 Pretraining and Downstream Tasks

For practical NLP application, large-scale self-supervised training has become an indispensable ingredient to fully unlock the power of Transformer models. In terms of the experiment scale and testing settings, there is a clear gap between LRA's setup and how we apply state-of-the-art Transformer models in practice. For the second set of experiments, we aim to test these models at scale and investigate whether the results on the LRA benchmark are accurate indicators for real-world long-context tasks after standard large-scale pretraining and finetuning.

---

[5] The limit of training updates is arbitrarily set in LRA and various work have reported hugely improved results on the text matching task, simply by running more training steps.

Pretraining Resource. Following Beltagy et al. (2020), we compile a corpus that contains mostly long documents, including Stories (Trinh and Le, 2018), RealNews (Zellers et al., 2019), Books corpus (Zhu et al., 2015) and English Wikipedia. To make the experiments manageable and relevant for standard GPU hardware, we restrict each model's memory usage close to the 16GB threshold when taking 4,096 tokens in each training batch. We control the batch size and training update across all models: we use a batch size of 256 sequences (2^{20} tokens) and pretrain each model using the standard masked language modeling objective for 100k updates. We find that all models' training curves almost stabilize after this amount of training steps. We use 32 A100 GPUs for pretraining and all model runs are finished within around 2 days.

Pretraining Architecture In contrast to Longformer (Beltagy et al., 2020) and Bigbird (Zaheer et al., 2020) where the models are initialized from RoBERTa before pretraining on long documents, we pretrain these models from scratch, as our goal here is to ensure fair comparison and not all architectures can reuse weights from a standard transformer model. In particular, Nyström and Performer do not use the standard dot-product and softmax to compute attention probabilities, making their parameters not compatible with common models like RoBERTa or BERT. Furthermore, other models like Linformer or LongShort introduce additional parameters inside the attention module. In our initial experiments, we observe initializing from the RoBERTa put these models at a significant disadvantage compared to other models (e.g., local window attention) that are more compatible with vanilla transformers. Apart from the expanded position embedding matrix and the attention blocks, the architecture hyperparameters are consistent with RoBERTa-large. For both LRA and the large-scale experiments, we adopt the pre layer-normalization trick (Xiong et al., 2020) for feedforward and attention blocks. This usually results in better performance in LRA and turns out to be essential for several models in the pretraining experiments.[6] See additional model-specific architecture settings and models' average memory usage in the Appendix.

Downstream Datasets and Metrics. We consider practical tasks that naturally involve long documents. We test extractive QA over long documents, long document classification, and document retrieval. For the first two tasks, we use TriviaQA and Hyperpartisan classification respectively, both of which have been used in existing long Transformer work (Beltagy et al., 2020). For full document retrieval, we construct the dataset based on recent open-domain QA work (Lee et al., 2019) that uses passage-level retrievers. We take an existing passage corpus from Karpukhin et al. (2020) and reconstruct the document-level corpus. We consider a document to be positive if it includes the answer passage. We reported token-level answer exact match and F1 for extractive QA and the classification accuracy for Hyperpartisan. For the retrieval task, for the ease of experiments, we reported the mean reciprocal rank on the dev set[7], which has been shown to correlate well with final retrieval metric like answer recall (Oguz et al., 2021). We conduct grid search for all tasks and report the best dev results. Given the small size of the Hyperpartisan dataset, we reported averaged results from 4 random seeds.

Task-specific Architectures for Finetuning. We use standard architectures for the finetuning tasks: for extractive QA, a single-layer MLP span predictor is added on top of the output token representations; the classification task uses a binary MLP classifier that takes the `[CLS]` vector as input. For retrieval, we share the query and document encoder using our pretrained models and use dot-product of the `[CLS]` vectors as the similarity score. For models that are compatible with global tokens, we use all the question tokens as global tokens in the QA task and use a single global token at the start of the sequences for both classification and retrieval. Except for the Hyperpartisan dataset, the document lengths of the other two datasets usually exceed 4,096 tokens after tokenization. In these cases, we drop the tokens outside the models' position range. We put further implementation details and each task's length statistics in the Appendix.

4 Results and Analysis

4.1 Models Perform Similarly in LRA

We report our reimplemented LRA results in Table 1. While previous work (Tay et al., 2021) has

---

[6] Linformer and Performer cannot reach reasonable perplexity without pre-layer normalization.

[7] For each question, the ground-truth document will be ranked with all documents (both positive and negative) corresponding to the dev-set questions.

Model	ListOps	Text	Matching	Avg Acc	GFlops
Learnable attention pattern					
Sinkhorn	37.6	63.8	80.4	60.6	0.289
LSH	37.9	62.5	80.5	60.3	0.273

Local Window	37.4	65.7	81.6	61.6	0.153
Blockwise LW	37.4	65.6	81.3	61.4	0.146

Table 1: LRA (the text-input subsets) results with our reimplementations. We did not observe significant performance gaps between different attention variants and simple local attentions remain strong compared to the best Nyström attention.

shown a clear performance gap between different models, we find that with proper tuning, the results of several models could be significantly improved, (*e.g.*, Sinkhorn, Linformer, Reformer, Performer) and *there is no significant performance gap between any of the models* when using a similar level of compute (measure by FLOPS). It is worth noting that these improved results are not obtained by increasing the complexity of models (*e.g.*, by using larger bucket size in Sinkhorn), as our implementation either uses similar or smaller size models compared to existing work. Also note that while the single global token we added to Sinkhorn and LSH might be essential for some performance gains, it only brings trivial computation overhead.

4.2 Pretraining and Downstream Tasks

We now evaluate these models on practical benchmarks that involve real-world long documents. As shown in Table 2, after we scale up the experiments and control the memory consumption of each model, we see more clear differences between these models than what we observe in LRA. Clearly, fixed local attentions remain to be strong baselines. However, in contrast to LRA, we observe local attentions are significantly better than the other attention variants, for both pretraining perplexity and downstream task results. The only exception in terms of the pretraining perplexity is the hybrid Long-Short attention, which already integrates a local attention component: it achieves better perplexity than fixed local attentions, but the downstream results are at most on par with much simpler models like Blockwise LW. It is worth noting that while we only control the training updates and memory usage in Table 2, the conclusion still holds if we control the training time of each model: We compare the training perplexity of Blockwise LW attention and other faster models with fixed training time in Table 3.

Even though our LRA experiments also study tasks with text inputs, we see clear discrepancies between the two sets of experiments. Apart from models with fixed local attention patterns, improvements on these text LRA tasks often do not transfer to the standard scaled pretraining-finetuning experiments. For instance, while Performer can outperform most of the non-local attention methods on LRA, it performs poorly on both large-scale MLM and downstream long-context tasks. Similarly, while Nyström is significantly better than LSH in LRA on average, we observe the opposite trend in Table 2. Among the three tasks, only ListOps is loosely aligned with the MLM perplexity. However, the gaps between each model on this task are still too narrow to be indicative.

Given that large-scale pretraining has become the gold-standard paradigm to build state-of-the-art NLP models. Our findings here call for a more careful and reliable evaluation of lots of existing and emerging long-range attentions. On the other hand, our results also reveal that the local context

Blockwise LW	4.04

Table 3: Training perplexity of our best fixed local attention and other faster attention variants. Each model uses similar GPU memory **and** training time.

might still be highly essential even in long context tasks. In the following section, we conduct further analysis on local attention models and attempt to identify the key ingredients of building strong NLP models for downstream long-context tasks.

4.3 Analysis on Local Attentions

As we have seen in §4.2, models that compute exact attention for local contexts around each token achieve better results. Moreover, the Blockwise LW variant performs the best even it does not guarantee a balanced left and right context window for each token. Given these intriguing findings, we aim to investigate the following questions: *How effective are the long-range mechanism in local attention models?* and *Whether the studied long-context tasks still mostly rely on locality bias?*

Ablation Study. In the Blockwise LW model, there are two mechanisms that enable long-range connections: the global tokens and the attention window overlap, *i.e.*, each token will additionally attend to half the tokens in the neighboring blocks, and the receptive field increases with model depth. While both are adopted as common practice in existing work (Zaheer et al., 2020; Beltagy et al., 2020), we study the isolated effect of each component in both pretraining and finetuning experiments. For the non-overlap variant, we increase the block size by a factor of 2 such that the amount of tokens each token attends to remains the same. We show the results in Table 4. Surprisingly, we see different stories in terms of MLM pretraining and downstream tasks. While both mechanisms are useful for achieving lower MLM perplexity, only the global-token mechanism seems important for downstream tasks. Note that in the document retrieval tasks, removing both mechanisms results in slightly better performance. Now the model is only able to use the first block of the whole document for retrieval. While this seems to suggest that this task is highly local and involves strong positional bias[8], the gap might be too trivial to be conclusive. Additionally, we only use a single global token for this task, it is likely that assigning more global tokens, *e.g.*, at passage boundaries, could bring additional improvements. Investigating the particular task further is beyond scope of this work. In terms of the effect of attention-window overlap, it is expected that this scheme is crucial for lower perplexity: it not only enables more distant dependencies but also reduces the number of "boundary tokens" which can only attend to one side of the context. However, it is counter-intuitive that the

---

[8] The answer context appears at the beginning of the Wikipedia page.

Model	MLM PPL	TriviaQA	NQ Doc Retrieval	Hyperpartisan
Blockwise LW	**3.39**	68.1/72.9	85.0	95.0
- w/o overlap	3.52	**68.4/73.2**	**86.3**	**96.5**
- w/o overlap & global tokens	3.54	56.5/61.0	85.4	94.6

Table 4: Ablation of the Blockwise LW Model.

overlapping attention links between neighboring blocks, which adds more long-range information, result in worse downstream performance. Also, note that this observation is consistent for all the tasks we studied. There are two possible implications of this finding: 1) the tested tasks still highly depend on locality bias, *i.e.*, most of the important information can be captured solely from the local bias, or 2) the overlapping scheme is not effective at capturing the long-range dependency in downstream tasks. To confirm either hypothesis, we conduct another set of experiments with models that have access to different sizes of context.

On Locality Bias. We take the non-overlapping variant and experiment with various block sizes to see whether longer context is important to studied tasks. We show the results in Table 5 and the pretraining curves in Figure 2. While the long-range connections brought by the attention overlap is not helpful for downstream results, we see that increasing the local block sizes does consistently improve both pretraining and downstream performance although the improvement becomes modest beyond block size 256. It is also interesting that the models with smaller block sizes converge faster at the early stage of pretraining. This suggests a staged pretraining process might be more efficient than directly training from long sequences, which aligns with Press et al. (2021)'s finding on unidirectional LMs. Overall, this set of experiments suggests that increasing model's capabilities to capture a longer context is generally helpful for both pretraining and downstream tasks. However, using overlapping attention windows is not an effective way to make use of more context. Thus, we hypothesize the MLM perplexity improvements of overlapping local attentions might mainly come from the reduction of the "boundary" tokens instead of the ability to capture long-range dependencies. For downstream tasks, the issue of "boundary" tokens is not that essential and the introduction of the overlapping attention windows might disrupt the effective modeling of local context, as the attention module needs to extract both local and distant information from the same set of tokens.[9]

Blocksize	Val PPL	TriviaQA Ans F1
64	4.16	68.9
128	3.74	70.7
256	3.52	73.2
512	3.39	73.5

Table 5: Pretraining and long-doc QA results of the non-overlapping blockwise attention.

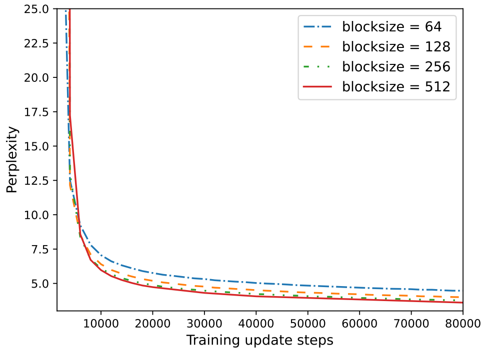

Figure 2: Pretraining curves of the non-overlapping block attentions with various context windows.

Initializing from Existing Short Models. While we train all models from scratch for the sake of fair comparison, existing state-of-the-art long context models like Longformer (Beltagy et al., 2020) or BigBird (Zaheer et al., 2020) usually initialize their longer models from an extensively pretrained short model like RoBERTa (Liu et al., 2019). With simple techniques like positional embedding copying, a strong long-context encoder can be initialized without the need of pretraining from scratch. To test our findings from the above analysis in this setting, we follow the same scheme

Blocksize	Speed ↑	Ans EM/F1
Longformer (64k)	6.6k	73.1/77.8
Blockwise LW w/o overlap (64k)	14.8k	**73.2/77.9**

Table 6: Comparing with Longformer with TriviaQA when initializing the models from RoBERTa. Speed is measure by thousand word per second at pretraining.

---

[9] As the depth of the model increase, the tokens' representation will be added information of more distant tokens.

but use the non-overlapping block attention as discussed in §4.3. We compare this model with Longformer (based on Sliding Window attention) as it uses the same long-doc corpus and pretrain-and-finetune pipeline (*e.g.,* packages and downstream data processing) as our experiments.[10] Same as our setting in §4.2, here we control the batch size and number of training updates: we use a batch size of 64 and train the model for 64k steps. Note that as we drop the attention window overlaps, the model is 2x more efficient than Longformer: Given the same window/block size B and sequence length L, the complexity of the non-overlapping block attention is $L \times B$ compared to Longformer's $2L \times B$. We show the TriviaQA results in Table 6, where the speed is measured by words per second during pretraining. With only half of the pretraining compute, our model with disjoint attention blocks achieves slightly better performance than Longformer. This confirms that our findings of the attention overlap from the above section are still valid when the models are not trained from scratch.

5 Related Work

Long-Range Context in Language Models. Various studies have investigated the effective usage of distant context in unidirectional language models. Khandelwal et al. (2018) look into the context usage of LSTM LMs and find that these models are only capable to make full use of the nearby 50 tokens and the longer range context is only roughly captured, *i.e.*, excluding detailed information such as word orders. Similarly, O'Connor and Andreas (2021) studies the mid- and long-range context usage in transformer LMs, by manipulating the ordering and lexical information in the text. Their experiments show that while long-range context is usually helpful, most of the usable information is carried by local ordering statistics and non-function words instead of detailed content like sentence orders. These observations provide a possible explanation of our ablation experiments in §4.3 that adding overlaps to attention windows does not yield better downstream results, despite allowing the capture of more long-range interaction. Press et al. (2021) observe diminishing returns as they increase the context length when using sliding windows at inference time. They propose a staged training paradigm that train LMs from smaller context to longer ones. This paradigm can more efficiently use the training compute and achieves lower perplexity compared to directly training with long sequences. Given that models with smaller attention windows converge faster at early training steps (Figure 2), the staged training might also benefit MLM pretraining but further investigation is required to validate whether it can also bring downstream improvements.

Other Long-Range Architectures. Instead of modifying the attention calculation, other work proposes to augment transformers with parametric long-term memories. Transformer-XL (Dai et al., 2019) maintains frozen activations of previous tokens in memory and uses them as additional inputs. To handle the shift of positional information of these activations, it also requires a relative position encoding mechanism which brings additional computation cost. The Compressive Transformer (Rae et al., 2020) takes a similar scheme but proposes to use compression modules to account for even further memories. Both methods cannot be directly applied to long-context understanding tasks. Under the scheme of kernel-based methods, Katharopoulos et al. (2020); Peng et al. (2021); Schlag et al. (2021) also attempt to linearize the softmax with kernel methods. The core ideas of these methods are similar to Performer and they only differ in the choice of kernel functions. Outside of the transformer families, a recent work (Lei, 2021) proposes to augment recurrent LMs with minimal attention blocks. It is more efficient while achieving stronger LM perplexity compared to Transformer-XL. However, it is still unknown whether this model scales as well as transformer architectures.

6 Conclusion

We present a systematic study of recent proposed efficient attention variants on real-world long-context NLP tasks. In contrast to existing work, we are the first to test these models with a set of unified and large-scale experiments. Our results reveal the gap between a widely used benchmark and practical downstream tasks after conducting large-scale pretraining. Among all the studied attention methods, we find that the simplest local attentions outperform other complex attention paradigms on downstream tasks. We also show that existing local-attention models can be further simplified by removing the attention-window overlap, resulting in

---

[10] Note that while BigBird has a similar overlapping local attention and outperforms Longformer, it uses a larger corpus, more pretraining compute and different finetune pipelines, making a direct comparison difficult.

a faster model that achieves similar or better results. Importantly, our work calls for more careful and practical evaluation protocols while developing long-context NLP models.

Table 8: Document length statistics in the tested downstream datasets.

Downstream Task Details. On TriviaQA, there are usually multiple matched spans in the document, we train the model to maximize the marginalized probability of all matched spans. The prediction head in the classification task is defined as a 2-layer MLP with *tanh* activations. For the retrieval task, we follow existing passage retrieval methods and use in-batch documents as negative retrieval targets. The loss is simply a cross-entropy loss defined over the scores of all documents in the batch. All the models are finetuned using the Adam optimizer with linear decays. We conduct grid search for all the tested models. The hyperparameters for all the three tasks are shown in Table 7. In Table 8, we show the average and the 95% percentile of the document lengths in each dataset. As mentioned in the main text, we drop the tokens exceeding 4,096 tokens.

Pretraining Details. Our pretraining pipeline is implemented with fairseq[11]. We control the memory usage of each model by adjusting model-specifc hyperparameters. The details in shown in Table 9. Due to different model designs, we are not able to exactly control the memory consumption. However, the tested local attentions typical requires less GPU memory than all the other models.

Abstract

The power and the potential of deep learning models attract many researchers to design advanced and sophisticated architectures. Nevertheless, the progress is sometimes unreal due to various possible reasons. In this work, through an astonishing example we argue that more efforts should be paid to ensure the progress in developing a new deep learning method. For a highly influential multi-label text classification method XML-CNN, we show that the superior performance claimed in the original paper was mainly due to some unbelievable coincidences. We re-examine XML-CNN and make a re-implementation which reveals some contradictory findings to the claims in the original paper. Our study suggests suitable baselines for multi-label text classification tasks and confirms that the progress on a new architecture cannot be confidently justified without a cautious investigation.

1 Introduction

Deep learning has been a popular research topic in NLP due to its superior performance. The intrinsic structure of deep learning allows researchers to enhance the model performance by introducing more complex network architectures. Nevertheless, the increasing complexity brings difficulties to ensure the true architectural progress. For example, Adhikari et al. (2019) have shown that LSTM architectures with appropriate regularization are either competitive or superior to more recent models. As another example, Liu et al. (2021) report that the lack of hyperparameter tuning in an influential work (Mullenbach et al., 2018) makes the progress of subsequent network developments questionable. Complex architectures are more difficult to train, involve more hyperparameters, and are riskier to unintentional implementation. Because new architectures are usually modified from previous ones, a questionable work may make the research progress unclear. Therefore, re-examining or reproducing influential architectures are now considered important in the community.

In this work, we re-examine XML-CNN (Liu et al., 2017), an influential work in extreme multi-label text classification (XMTC), as a case study to demonstrate the demands of inspecting existing architectures. XML-CNN has been viewed as an essential baseline in subsequent works (Peng et al., 2018; Prabhu et al., 2018; You et al., 2019; Chang et al., 2020; Adhikari et al., 2019) with more than hundreds of citations. XML-CNN roots from Kim-CNN (Kim, 2014), a classical architecture for multi-class text classification. The authors of XML-CNN proposed several modifications from Kim-CNN to accommodate the XMTC task and empirically claim that all modifications bring significant improvements.

Despite XML-CNN's popularity, we identified two serious implementation issues that make the original claims uncertain. First, the authors introduced dynamic max-pooling into XML-CNN, but the implementation is actually far from the intended formulation. Second, a bug in the experiment code caused the dimensions of convolution operations accidentally swapped. The two issues coincidentally make XML-CNN competitive, leading the authors to illusively claim superiority over Kim-CNN and usefulness of dynamic max-pooling in the original paper (Liu et al., 2017).

Our contribution can be summarized as follows.

- We point out, analyze, and correct the issues in the authors' XML-CNN implementation. Our implementation is made public to help the community build future works on top of the correct implementation
- We re-examine the claims about XML-CNN. Our results demonstrate that the progress from Kim-CNN to XML-CNN may not be as significant as claimed in Liu et al. (2017), and again confirm that careful attention is needed on ensuring true architectural progress.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 1987 - 2000
July 10-15, 2022

- Our investigation suggests that instead of XML-CNN, Kim-CNN or a simpler variant of XML-CNN should be considered as a baseline in XMTC tasks.

The paper is organized as follows: in Section 2, we introduce Kim-CNN, XML-CNN, and their differences. We conduct an investigation on XML-CNN in Section 3. The investigation includes inspection of the authors' code and our analysis on why it coincidentally works. We then conduct a fair and thorough comparison between Kim-CNN and XML-CNN in Section 4. Finally, we conclude this work in Section 5. Supplementary materials and programs used for experiments are available at `https://www.csie.ntu.edu.tw/~cjlin/papers/xmlcnn/`.

2 XML-CNN: CNN for Multi-Label Text Classification

For multi-label text classification, each instance is an n-word document that is associated with a subset of L possible categories. The relationship between the document and the categories can be modeled by a convolutional neural network (CNN), as pioneered for multi-class text classification by Kim-CNN (Kim, 2014). The architecture was later extended to XML-CNN (Liu et al., 2017) for multi-label text classification. Here we introduce the two architectures along with a focus on the key modifications.

2.1 CNN for Text Classification

Kim-CNN (Kim, 2014) is the first work that applies convolutional neural networks in text classification. The architecture is illustrated in Fig. 1a. Kim-CNN preprocesses a document by first encoding the i-th word to a k-dimensional embedding vector $\boldsymbol{x}_i \in \mathbb{R}^k$ (Pennington et al., 2014). We denote an n-word document by $\boldsymbol{x}_{1:n}$, where $\boldsymbol{x}_{i:j} = [\boldsymbol{x}_i, \dots, \boldsymbol{x}_j]^\top \in \mathbb{R}^{(j-i+1)\times k}$ represents a sub-sequence from the i-th to the j-th word in the document.

A convolutional operation applies a filter $\boldsymbol{w}_i \in \mathbb{R}^{m\times k}$ to a sub-sequence of m words to produce a new feature:

$$c_i = f(\boldsymbol{w}_i \cdot \boldsymbol{x}_{i:i+m-1} + b_i), \tag{1}$$

where f is an activation function such as ReLU, $b_i \in \mathbb{R}$ is a bias term and the "$\cdot$" operator means the sum after component-wise products between two matrices. The filter is applied to all m-word sub-sequences in the document to form a feature map $\boldsymbol{c} = [c_1, \dots, c_{n-m+1}] \in \mathbb{R}^{n-m+1}$. Suppose Kim-CNN uses t filters and let $\boldsymbol{c}^{(1)}, \dots, \boldsymbol{c}^{(t)}$ be the corresponding feature maps. A max-pooling layer is then applied to summarize the features as $\boldsymbol{z} = \left[\max(\boldsymbol{c}^{(1)}), \dots, \max(\boldsymbol{c}^{(t)})\right] \in \mathbb{R}^t$. Lastly, a dropout layer and a fully-connected layer is used to predict a score vector

$$\boldsymbol{s} = \tilde{\boldsymbol{W}}(\boldsymbol{z} \odot \boldsymbol{r}) + \tilde{\boldsymbol{b}} \in \mathbb{R}^L, \tag{2}$$

where $\odot$ is the element-wise multiplication operator, $\tilde{\boldsymbol{W}} \in \mathbb{R}^{L\times t}, \tilde{\boldsymbol{b}} \in \mathbb{R}^L$ are learnable parameters and each r_i of $\boldsymbol{r} \in \mathbb{R}^t$ is a dropout random variable that follows a Bernoulli distribution.

Kim-CNN was originally proposed for multi-class classification based on the cross-entropy loss

$$-\sum_{i=1}^{L} y_i \log p_i, \quad \text{where } p_i = \frac{e^{s_i}}{\sum_{j=1}^{L} e^{s_j}} \tag{3}$$

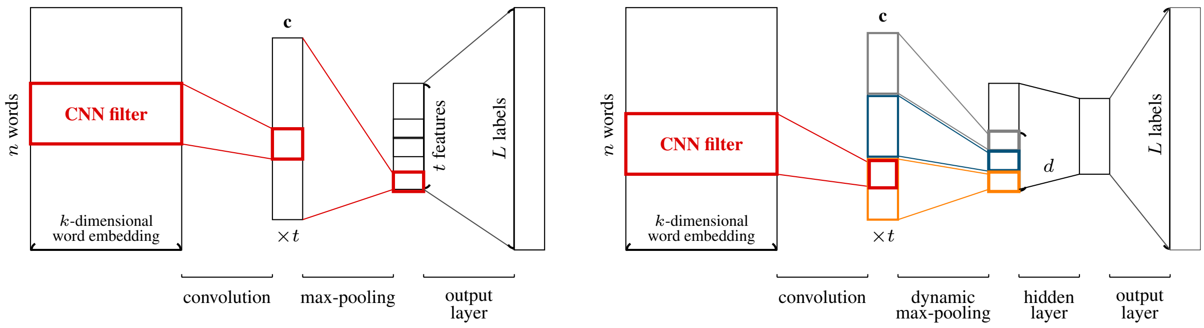
is the estimated probability of the i-th class, s_i is the i-th element of $\boldsymbol{s}$ that denotes the score of the i-th class, and $\boldsymbol{y} \in \{0,1\}^L$ denotes the ground truth of the instance. If the i-th label is associated with the document, then $y_i = 1$; otherwise, $y_i = 0$. By the construction of p_i in Eq. (3), $\sum_i p_i$ is forced to be 1, which is natural for multi-class classification. For multi-label classification, however, it is not clear whether requiring all p_i's to sum to one would be too restrictive, given that there can be multiple y_i's with $y_i = 1$. Nevertheless, the loss has been considered for some multi-label works (Gong et al., 2014; Ghosh et al., 2015).

2.2 From CNN to XML-CNN

XML-CNN is a pioneering work that extends Kim-CNN from multi-class text classification to XMTC. The architecture of XML-CNN is illustrated in Fig. 1b. It extends Kim-CNN with three modifications:

- using a label-wise binary cross-entropy loss instead of the cross-entropy loss in Eq. (3),
- adding an additional linear hidden layer with dropout,
- introducing dynamic max-pooling (Chen et al., 2015) to extract multiple features from each CNN filter.

For the first modification, the authors noticed the issue of the cross-entropy loss discussed in Section 2.1. They then allow the model to flexibly



(a) Kim-CNN (b) XML-CNN

Figure 1: Architectures of Kim-CNN and XML-CNN.

predict multiple positive labels by taking the independent binary cross-entropy loss instead:

$$-\sum_{i=1}^{L}\left[y_i\log(\sigma(s_i))+(1-y_i)\log(1-\sigma(s_i))\right], \tag{4}$$

where $\sigma(s)=\frac{1}{1+e^{-s}}$ is the sigmoid function.

For the second modification, the additional linear layer may help to reduce the number of parameters, allowing the model to be stored in common GPU devices when L is extremely large. Let h be the number of elements in the added hidden layer. XML-CNN reduces the number of parameters after the CNN layer from $t \times L$ in the original Kim-CNN to

$$t \times h + h \times L \tag{5}$$

when h is sufficiently small.

For the third modification, the authors applied dynamic max-pooling (Chen et al., 2015) in XML-CNN to capture multiple features from different parts of the document. In contrast to the traditional max-pooling, which calculates the maximum along the whole sequence, dynamic max-pooling divides the sequence into multiple pools and then collects the maximum values within each pool to get some fine-grained features. Given a filter map $\boldsymbol{c} \in \mathbb{R}^n$,[1] the formulation with d pools is:

$$D(\boldsymbol{c})=\left[\max\{\boldsymbol{c}_{1:\frac{n}{d}}\},\ldots,\max\{\boldsymbol{c}_{n-\frac{n}{d}+1:n}\}\right]\in\mathbb{R}^d. \tag{6}$$

The output becomes

$$\boldsymbol{z}=\left[D(\boldsymbol{c}^{(1)}),\ldots,D(\boldsymbol{c}^{(t)})\right]\in\mathbb{R}^{dt}$$

instead of $\left[\max(\boldsymbol{c}^{(1)}),\ldots,\max(\boldsymbol{c}^{(t)})\right]\in\mathbb{R}^t$ in Kim-CNN.

2.3 Claims about XML-CNN

Liu et al. (2017) compared their proposed XML-CNN with Kim-CNN by reporting P@K on six datasets,[2] as shown in Table 1. P@K calculates for each document the percentage of correct predictions (i.e., precision) among the top K predicted labels and reports the average over all test documents. Table 1 clearly indicates significant improvements from Kim-CNN to XML-CNN on all datasets. To examine the impact of each new component in XML-CNN, the authors further conducted ablation studies to make the following claims.

- Eq. (4) is more suitable than Eq. (3) for multi-label classification problems.
- The additional linear layer improves both the performance and the scalability.
- Dynamic max-pooling further improves the performance significantly.

The impressive progress of XML-CNN makes it a standard benchmark for XMTC (e.g., Peng et al., 2018; Prabhu et al., 2018; You et al., 2019; Chang et al., 2020; Adhikari et al., 2019). However, we will show in this study that the progress may not be as significant as the authors claimed. While the first modification is included in our evaluation in Section 4.2, our focus is on the other two modifications, which correspond to the differences between XML-CNN and Kim-CNN-Eq.(4), the multi-label version equipped with the binary cross-entropy loss in Eq. (4). Subsequently, Kim-CNN-Eq.(4) will be shorthanded Kim-CNN for simplicity.

---

[1] Though we use $\boldsymbol{c} \in \mathbb{R}^{n-m+1}$ earlier, we let $\boldsymbol{c} \in \mathbb{R}^n$ here for easier explanation.

[2] Due to the space limit, we leave their and our NDCG@K results in the supplementary materials.

3 Investigation into XML-CNN

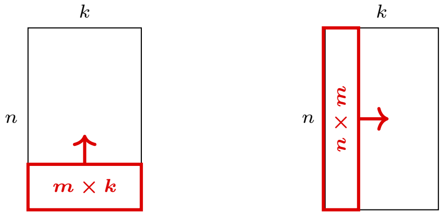
In this section, we point out a significant gap between the formulations in the XML-CNN paper and the authors' implementations. We first reproduce the results in Liu et al. (2017) to ensure what the authors have done. We then confirm the reported superiority of XML-CNN over Kim-CNN is actually due to some coincidences.

3.1 The Challenges of Reproducing Liu et al. (2017)

The authors have released their implementation of XML-CNN on GitHub.[3] They wrote the code in Lasagne (Dieleman et al., 2015), an outdated deep learning framework. To facilitate a thorough comparison, we implement a PyTorch-based program[4] that is as close to the released Lasagne code as possible. Though their implementation is available, to our surprise, reproducing XML-CNN results on the same datasets is more challenging than expected. We leave details of solving various challenges in Appendix A. In particular, we find that some data sets used in Liu et al. (2017) are no longer available, so similar ones are considered; see data statistics in Table 2.

We choose EUR-Lex for checking the reproducibility due to the following reasons.

- The dataset is publicly available and from Tabel 2 it has the same statistics as in Liu et al. (2017).
- The improvement of XML-CNN is significant as shown in Table 1.
- The size is relatively small but adequate.



(a) Normal CNN that follows Eq. (1) to go along the words.

(b) CNN in the public code of Liu et al. (2017) that goes along the embedding dimension.

Figure 2: Two implementations of CNN.

The results of the authors and our implementations are respectively shown in the second and the third rows in Table 3. The difference between the two implementation is even smaller than the difference between XML-CNN's paper numbers to its public implementation. This justifies that our results are close enough for reproducing the numbers. We conclude that the author's result on EUR-Lex can be reproduced, though many issues must be addressed in the entire process.

3.2 Problematic Gap Between Implementations and Formulations

Though we can reproduce the results reported in Liu et al. (2017), in checking their programs, we surprisingly found some significant gaps between the implementation and the formulations in their paper. The first one is that their implementation of the convolutional operation is completely different from Eq. (1). We illustrate the two CNNs in Fig. 2. In the authors' implementation, the convolution operation sweeps along the embeddings rather than the words, as shown in Fig. 2b. That is, it seems the authors did not implement what they intended to do.

Another problem is about the dynamic max-

Our code mimicking the above	PyTorch	75.50	60.47	49.38

Table 3: Reproducing results reported in Liu et al. (2017) on EUR-Lex by using the authors' and our implementations.

pooling. The authors set the default pool size to 2 and stride to 1 in their public implementation:

$$[\max\{\boldsymbol{c}_{1:2}\}, \max\{\boldsymbol{c}_{2:3}\}, \ldots \max\{\boldsymbol{c}_{n-1:n}\}], \quad (7)$$

which differs from Eq. (6) in that overlapped pools are used. Further, given that the aim of max-pooling is to extract information from each pool, a size-two pool is unusually small. We do not know why the authors implemented dynamic max-pooling in this form, but we will show that this odd implementation, together with the wrong convolution mentioned earlier, surprisingly works well.

To compare with these unusual settings, we generate another implementation of XML-CNN by following Eq. (1) and Eq. (6). The details of our implementation can be found in Appendix B. According to Liu et al. (2017), this version should be what its authors intend to have. Table 4 shows the results on EUR-Lex by various ways to implement Kim-CNN and XML-CNN. Other settings (e.g., hyperparameters) are kept to be the same as those in the authors' implementation; see also Section 3.1 and supplementary materials.[5] From Table 4, we have the following observations.

- For each category (Kim-CNN or XML-CNN), the last row indicates the setting described in the original papers. If the CNN input is changed to the wrong one, the results of both Kim-CNN and XML-CNN become dramatically worse (rows 1 and 5). On the other hand, if the implementation of dynamic max-pooling follows Eq. (7) rather than Eq. (6), the result of XML-CNN also significantly deteriorates (row 4).
- However, if both inappropriate settings for CNN and dynamic max-pooling are applied, the resulting procedure corresponds to the actual implementation by Liu et al. and works surprisingly well (row 3). In contrast, without the help of Eq. (7), Kim-CNN by the inappropriate CNN implementation performs poorly. In such a situation, Kim-CNN's scores are quite similar to the results of Kim-CNN reported in Liu et al. (2017), as shown in Table 1. So we presume that in Liu et al. (2017), Kim-CNN was implemented with the inappropriate CNN setting.

In sum, the implementation seems not what Liu et al. intended to do in their paper. Thus, their conclusions based on the unintentional implementations may be questionable. In particular, in Table 4 Kim-CNN is competitive if an implementation following its original paper (Kim, 2014) is considered.

For better distinction in subsequent discussions, we name the two XML-CNN implementations respectively corresponding to Liu et al.'s paper and public code as follows.

- **XML-CNN-paper**: XML-CNN following Eq. (1) and Eq. (6).
- **XML-CNN-impl**: XML-CNN using CNNs sweeping along embeddings and Eq. (7).

3.3 The Two Implementations of XML-CNN: Analysis

We try to explain why XML-CNN-impl can achieve competitive results. For the analysis, we first argue that conceptually, the unusual dynamic max-pooling Eq. (7) is similar to not doing pooling. The reason is because the small pool size = 2 implies that at least half of $\boldsymbol{c}$ elements are retained. Then we design an experiment to compare the combina-

---

[5] As mentioned in Section 2.3, we note again that Kim-CNN in all our experiments, unless specified, optimizes the same loss in Eq. (4) as XML-CNN.

Method	CNN sweeping direction	Dynamic Max-pooling	P@1	P@3	P@5	Note
Kim-CNN	embeddings	N/A	45.38	34.02	27.72	Actual implementation of Liu et al. (2017)
Kim-CNN	words	N/A	75.83	61.08	50.19	Procedure described in Kim (2014)
XML-CNN	embeddings	Eq. (7)	75.96	60.56	49.23	XML-CNN-impl: actual implementation of Liu et al. (2017)

XML-CNN	embeddings	Eq. (6)	63.03	48.31	39.32	
XML-CNN	words	Eq. (6)	75.73	61.82	50.82	XML-CNN-paper: procedure described in Liu et al. (2017)

Table 4: Results of different implementations of the convolutional layer and dynamic max-pooling for Kim-CNN and XML-CNN. The standard CNN input should be $k \times n$. Other settings are the same as those for the last two rows of Table 3.

tions of the following settings.

- CNN sweeping direction: embeddings or words
- Pooling implementation: standard max-pooing or no pooling

Table 5 shows the P@1 scores on predicting the test set of EUR-Lex. We have the following observations.

- Results of the (embeddings, no pooling) setting are similar to those of the (embeddings, Eq. (7)) setting in Table 4. This confirms our earlier argument that Eq. (7) is close to no pooling.
- If CNN sweeps along the words, the standard max-pooling is significantly better than no pooling. A possible explanation is that when CNN sweeps along the words, some sub-sequence of words are shown to be more important than others. Then the standard max-pooling is helpful to identify them. This situation is similar to that in image classification, where max-pooling is effective to extract "sharp" features (Springenberg et al., 2015).
- If CNN sweeps along the embeddings, an opposite situation occurs. No pooling is much better than standard max-pooling. Because all the embeddings can be considered equally useful, the resulting features after convolutional operation have similar importance. For such "smooth" features, it is known in image classification that average pooling or no pooling are recommend (Springenberg et al., 2015). In other words, standard max-pooling can extract little information in such a case and may lead to worse performance.

In Section 3.4, we will present results to further support the above analysis.

	$\max\{\boldsymbol{c}\}$	No pooling
words	74.67	53.61
embeddings	58.14	76.48

Table 5: P@1 of combinations of CNN sweeping directions and pooling methods for implementing XML-CNN. Note that the first column differs from the first two rows in Table 4 because we now have a hidden layer.

3.4 The Two Implementations of XML-CNN: Performance Comparison

Table 6 shows a comprehensive comparison between XML-CNN-impl and XML-CNN-paper on more datasets. In contrast to Table 4 where we follow the hyperparameters used in Liu et al. (2017), we tune the hyperparameters for both methods in Table 6.[6] We observe that XML-CNN-paper outperforms XML-CNN-impl on EUR-Lex and Wiki10-31K. Following the discussion in Section 3.3, the reason may be that XML-CNN-impl lacks the ability to learn position-agnostic features when documents are long. Note that for EUR-Lex and Wiki10-31K, the documents are truncated to 500 words because of the long document length. On the other hand, XML-CNN-impl works competitively on AmazonCat-13K and Amazon-670K. Though the documents are also truncated to 500 words when needed, the average document lengths of these two sets are less than 250.

In sum, XML-CNN-paper should be preferable

---

[6] Details of experimental settings and hyperparameter search are in Section 4.1 and Appendix C.

because of the more reasonable architecture and better performance on long documents. Moreover, XML-CNN can deal with variable sentence lengths, while XML-CNN-impl cannot because the network architecture depends on the sentence length. We consider XML-CNN-paper as the setting for XML-CNN in subsequent experiments.

4 The True Performance of XML-CNN

After showing the gap between the implementation and the formulation in Liu et al. (2017), the true performance of XML-CNN should be re-examined. In this section, we conduct a comprehensive ablation study for XML-CNN to investigate the claims in the original paper. We then investigate more deeply on dynamic max-pooling to determine its usefulness for XMTC tasks. The results bring us a similarly competitive but simpler baseline for XMTC tasks.

4.1 Experimental Setup

We consider a random 80/20 split of the training data to generate a training subset and a validation subset for hyperparameter selection. We follow Liu et al. (2017) to truncate the documents to 500 words, represent each word as a 300-dimensional GloVe word embedding (Pennington et al., 2014) and pad the sequences in each batch when needed. The word embeddings are considered as trainable parameters during training. We have carefully conducted hyperparameter selection. The procedure and other details are in Appendix C.

We follow Liu et al. (2017) to train the models with 50 epochs on the whole training set after hyperparameter tuning and then evaluate the test set. We evaluate each method on three datasets: EUR-Lex, Wiki10-31K, and AmazonCat-13K. In Section 4.2, we conduct the ablation study by including one larger dataset: Amazon-670K. All of them are in English. The datasets are obtained from the repository of You et al. (2019) and we follow Liu et al. (2017) to reduce the vocabulary set.[7]

4.2 Ablation Studies of XML-CNN

To understand how each component introduced in Liu et al. (2017) really works, we conduct an ablation study as what the authors have done. Specifically, the effects of using Eq. (4) as the loss, adding a linear hidden layer, and introducing dynamic max-pooling are checked. By the results shown in Table 7, we can re-examine what the authors have claimed in Liu et al. (2017). To begin, from the first and the second rows, the loss function Eq. (4) indeed improves the scores 2%-6% on each dataset. The results validate the claim that Eq. (4) is more suitable for multi-label tasks than Eq. (3).

Next, while adding a hidden layer is claimed to be beneficial in Liu et al. (2017), our results show that the hidden layer is slightly harmful on EUR-Lex and Wiki10-31K when the standard max-pooling is applied; see rows 2 and 4 in Table 7. It works when dynamic max-pooling is employed, but the improvements are not significant. The authors also claimed that the hidden layer could reduce the number of parameters; see Eq. (5). This claim is true when h is relatively small compared with the number of convolutional features. However, we noticed that larger h's such as 512 and $1,024$ are always preferable after hyperparameter tuning. In these cases, the number of parameters may not be reduced.

Lastly, we discuss the effect of dynamic max-pooling. In the situation of not adding a hidden layer, dynamic max-pooling slightly improves upon the standard max-pooling on most but not all datasets. If a hidden layer is included in the architecture, dynamic max-pooling also gives moderate improvements. However, dynamic max-pooling may require more network parameters due to multiple pools. To check its usefulness, we investigate more in Section 4.3.

4.3 Further Investigation on Dynamic Max-Pooling

We conduct two experiments to understand whether dynamic max-pooling always benefits XML-CNN. The first experiment is a comparison between different numbers of pools. The second experiment compares dynamic max-pooling with standard max-pooling by using a similar total number of parameters.[8] The experiment results and more discussions are in Appendix D.1 and Appendix D.2. The investigations tell us:

- Using too many pools may deteriorate the performance.
- Under similar total numbers of parameters, standard max pooling is more preferable than dynamic max-pooling.

---

[7] See details in Appendix A.4.

[8] For dynamic max-pooling, the output size $t \times d$ is proportional to the pool size d. For standard max-pooling ($d = 1$), we can enlarge the number of filters t to have a similar number of parameters; see details in Appendix D.2.

Table 7: An ablation study of XML-CNN. For max-pooling, “standard” means the standard way of using the single maximal value, while “dynamic” means to use Eq. (6).

4.4 What We May Claim about XML-CNN

We conclude our findings in this section as follows:

- Eq. (4) is indeed more suitable for multi-label tasks than Eq. (3).
- For the hidden layer, there is a minor tradeoff between the number of parameters and the performance. A negative way to interpret this is that introducing the hidden layer does not always improve the performance. However, a positive interpretation is that with a slight performance loss, a hidden layer can effective reduce the number of parameters when the output size of the pooling operation is large.
- Dynamic max-pooling is not as beneficial as increasing the number of convolutional filters.

After our careful re-investigation, our suggestion to future studies of XMTC is that instead of using XML-CNN as a baseline, the following simpler settings can be considered.

- If there is no memory concern, Kim-CNN is suitable for its similar performance to XML-CNN.
- Otherwise, a simplified version of XML-CNN without dynamic max-pooling, namely Kim-CNN with an additional hidden layer, is sufficiently strong and space-efficient as the baseline.

5 Conclusion

This work aims to highlight the importance of validating existing works. From the investigation of XML-CNN, we learned that there are many pitfalls when developing new architectures. We correct the issues in the authors’ implementation, carefully re-examine the claims about XML-CNN and recommend suitable baselines for future studies. Though not proposing a new method, we hope this work encourages the community to reproduce and re-examine influential works. This may help the community build future works on top of correct materials.

A The Challenges of Reproducing Liu et al. (2017)

A.1 Dataset

The authors evaluated XML-CNN on six datasets from the Extreme Multi-Label Repository.[9] Unfortunately, some of the datasets have been changed on the repository to different number of data/labels (with a similar name). Furthermore, for some of them, the repository does not provide the raw-text documents, making it hard to preprocess the documents to the embedding needed for XML-CNN. Fortunately, we find the repository of AttentionXML.[10] (You et al., 2019) where two datasets (EUR-Lex and Amazon-670K) of raw text match the statistics of the datasets in the XML-CNN work. We then choose the smaller EUR-Lex as the first attempt to reproduce XML-CNN faithfully.

A.2 Evaluation

The released code includes only the training but not the validation/evaluation procedure. In the original paper (Liu et al., 2017), it is mentioned that 25% of training data is reserved as the validation set for hyperparameter selection. However, the details such as how to generate the validation set, which metric was considered in validation, and whether they re-trained the model with the whole training set are not specified in the paper. Therefore, we cannot exactly replicate the results in Table 1. We ran the released code and observed that with only 75% of training data, the results are always worse than ones reported in Liu et al. (2017). Thus, we presume that in Liu et al. (2017), the authors reported the results of models trained on the whole training set by using the selected hyperparameters.

A.3 Lasagne vs PyTorch

As mentioned in Sec 3.1, we implement a PyTorch-based program that is as close to the released Lasagne code as possible. We fix the common hyperparameters such as the number of filters and the dropout rate as ones provided in the authors' implementation. Then we train the whole training set and follow their setting to report the test scores at the 50-th epoch. The results of their and our implementations are respectively shown in the second and the third rows in Table 8. The minor differences between the scores are possible because ensuring everything to be the same from the beginning to the end is tremendously difficult. For example, optimizers implemented in Lasagne and PyTorch are not entirely the same. What we have confirmed is that for the network part, under the same input, the two implementations generate exactly the same output and loss values. Therefore, we conclude that our implementation can be used together with theirs in checking the reproducibility. However, both are still worse than the results of Liu et al. (2017) in the first row of Table 8. This fact encouraged us to investigate more on the data processing step done in Liu et al. (2017).

A.4 Vocabulary Set

In Liu et al. (2017), the authors compared XML-CNN with some linear-based algorithms, which use bag-of-word (BOW) features to deal with document inputs. The BOW features usually only consider vocabularies with higher frequency to reduce the dimensionality. To fairly compare XML-CNN with linear models, the authors removed vocabularies which are not used in the BOW features. While the Extreme Multi-Label Repository provides BOW features of EUR-Lex and we assume that they were used in Liu et al. (2017), the vocabulary set of the BOW features is not accessible now. Fortunately, we obtained from the repository owner the vocabulary set used in generating their BOW features. The results of XML-CNN with the reduced vocabulary set are shown in the fourth and the fifth rows in Table 8. By using the reduced vocabulary set, the results of both Lasagne and PyTorch implementations are improved to be closer to the ones in Table 1. As a result, we conclude that the authors' result on EUR-Lex can be reproduced, though many issues must be addressed in the entire process.

B Implementation Details of Section 3.2

To implement Eq. (6), we follow Adhikari et al. (2019) to use AdaptiveMaxPool1d[11] and consider 4 pools, i.e., $d = 4$. Notice that Eq. (6) does not handle the situation where the sequence length is not divisible by d. Adaptive max-pooling solve the problem by allowing some overlapping between

pools. Therefore, it generates exactly d outputs from documents with varying lengths.

C Details of Experimental Setup

From the hyperparameter ranges listed in Table 9, we apply Optuna (Akiba et al., 2019) to select the best hyperparameters from 48 random trials. In the validation procedure, we optimize P@1 for EUR-Lex, AmazonCat-13K, and Amazon-670K, and P@3 for Wiki10-31K. We do not optimize P@1 for Wiki10-31K because there is a dominant class that is associated with about 80% of data. Each trial is stopped if the validation metric does not improve for 10 epochs or when it reaches 50 epochs.

In the original papers of Kim-CNN and XML-CNN, both described the use of filters with different window sizes in the convolutional layer. In Kim (2014) and Liu et al. (2017), filter sizes 3, 4, 5 and 2, 4, 8 are respectively used. However, as shown in Table 10, using multiple filter sizes does not have a significant benefit compared with using a fixed filter size 8. Furthermore, among single filter-size settings, the filter size 8 is generally competitive, so we use it in our ensuing investigation.

The experiments are conducted on Azure with an Nvidia Tesla V100 GPU, taking <1, <1, 6, 20 GPU hours for one trial on EUR-Lex, Wiki10-31K, AmazonCat-13K, and Amazon-670K respectively.

D Further Investigation on Dynamic MaxPooling

D.1 Effect of the Number of Pools

In dynamic max-pooling, a crucial hyperparameter is the number of pools d. Nevertheless, in the public code of the XML-CNN work (Liu et al., 2017), due to the unusual setting in Eq. (7), d is not a fixed number but depends on the document length. Consequently, discussion about the number of pools is lacking in the original work.

In Table 11, we conduct a comparison by using $d \in \{1, 2, 8, 32, 64\}$. On all datasets, $d = 2$ and $d = 8$ have the best performance. Increasing the number of pools to more than 8 not only leads to worse results on some problems, but also costs more memory and training time. Our results indicate that while the goal of dynamic max-pooling is to extract multiple features from each CNN filter, using too many pools may deteriorate the performance instead.

D.2 Investigation on Dynamic Max-Pooling by Fixing the Number of Parameters

As discussed in Sec 4.2, we noticed that the number of parameters in XML-CNN increases along with the number of pools in dynamic max-pooling. Assume the number of filters is t and the number of pools is d. In XML-CNN, the total number of filters after the pooling layer is $t \times d$, while Kim-CNN still only has t filters. It is unclear whether the improvement of dynamic max-pooling is caused by the richer information from multiple pools or simply the larger number of parameters. We investigate this issue by comparing XML-CNN with different numbers of pools but ensuring the similar number of parameters. From Table 12, we observe that XML-CNN with 1 pool (i.e., without dynamic max-pooling) outperforms XML-CNN with 2 or 8 pools. The result reveals that the architectural modification of dynamic max-pooling may not be that useful.

Though increasing the number of filter also introduced more parameters in CNN, the number is negligible compared to the number of parameters in

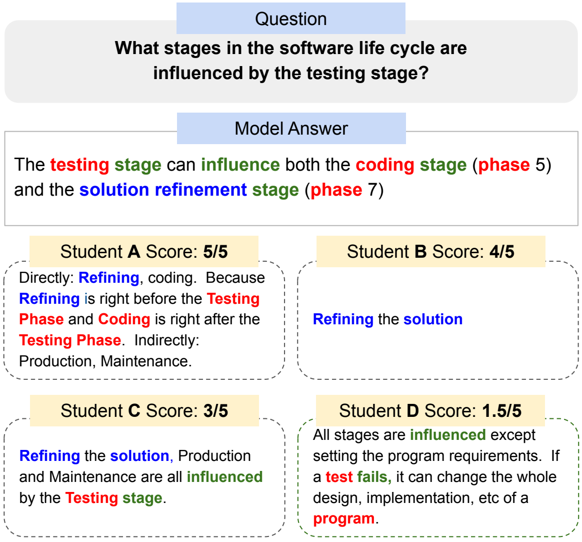
Abstract

The recent transition to the online educational domain has increased the need for Automatic Short Answer Grading (ASAG). ASAG automatically evaluates a student's response against a (given) correct response and thus has been a prevalent semantic matching task. Most existing methods utilize sequential context to compare two sentences and ignore the structural context of the sentence; therefore, these methods may not result in the desired performance. In this paper, we overcome this problem by proposing a Multi-Relational Graph Transformer, **MitiGaTe**, to prepare token representations considering the structural context. Abstract Meaning Representation (AMR) graph is created by parsing the text response and then segregated into multiple subgraphs, each corresponding to a particular relationship in AMR. A Graph Transformer is used to prepare relation-specific token embeddings within each subgraph, then aggregated to obtain a subgraph representation. Finally, we compare the correct answer and the student response subgraph representations to yield a final score. Experimental results on Mohler's dataset show that our system outperforms the existing state-of-the-art methods. We have released our implementation[1], as we believe that our model can be useful for many future applications.

1 Introduction



Question

What stages in the software life cycle are influenced by the testing stage?

Model Answer

The **testing stage** can **influence** both the **coding stage** (**phase** 5) and the **solution refinement stage** (**phase** 7)

Student **A** Score: **5/5**

Directly: **Refining**, coding. Because **Refining** is right before the **Testing Phase** and **Coding** is right after the **Testing Phase**. Indirectly: Production, Maintenance.

Student **B** Score: **4/5**

Refining the **solution**

Student **C** Score: **3/5**

Refining the **solution**, Production and Maintenance are all **influenced** by the **Testing stage**.

Student **D** Score: **1.5/5**

All stages are **influenced** except setting the program requirements. If a **test fails**, it can change the whole design, implementation, etc of a **program**.

Figure 1: A motivating example for using multiple relations in automatic short answer grading.

Grading student work is critical for assessing their course understanding. However, answer grading can become monotonous and tedious for teachers. *Automatic Short Answer Grading* (ASAG) task is to assign ordinal scores to student answers, given some 'model' answer by an academician or instructor. Figure 1 presents a sample question, model answer, and student answers from an undergraduate computer science course (Mohler et al., 2011). One of the early approaches for solving the ASAG task has been to build models based on human-designed features (Mohler et al., 2011; Sultan et al., 2016). Recent works utilize deep learning methods such as convolutional neural networks (CNNs), long short-term memory networks (LSTMs), Transformer (Vaswani et al., 2017) to learn the representation of student responses and to avoid designing features manually (Alikaniotis et al., 2016; Hassan et al., 2018; Kumar et al., 2017; Riordan et al., 2017; Yang et al., 2018). Due to semantic heterogeneity, the main problem in assessing student responses given instructor-provided model answers is a complex natural language understanding task (the same answer could be articulated in different ways)(Gomaa et al., 2013).

We hypothesise that a student's answer will be considered correct if the keywords in the answer are in the right relationship with the corresponding

words from the model answer. As can be seen from Figure 1, Student A is awarded full marks because the words like *Testing Phase* and *Coding* are adequately associated with words in the model answer like *testing stage* and *coding phase*. However, other students are awarded partial marks because not a lot of words in those correspond to some relation in the model answer, i.e. the decreasing score corresponds to the decreasing number of relations in the model answer being captured in the student response. This motivates us to incorporate structural relationship context information for effective comparison. We discuss the various types of relations captured in detail in the further sections.

This paper applies the principle of short text matching to solve the problem of grading short subjective student's response. The key steps for textual matching are efficient textual representation, followed by semantic matching. In literature, we see that short text matching is broadly based on two approaches: sequence-based and structure-based. Sequence-based models fully exploit semantic information of sentences without incorporating syntactic information (Mueller and Thyagarajan, 2016), (He et al., 2015; Cer et al., 2018; Conneau et al., 2017; Agirre et al., 2014). Recent works by (Vashishth et al., 2019; Croce et al., 2011; Severyn et al., 2013) have found that the structural information of sentences is beneficial for sentence representation. Therefore, structure-based neural networks (Le et al., 2018; Yao et al., 2019; Huang et al., 2019), (Defferrard et al., 2016; Liu et al., 2020) exhibit better performance than sequence-based models. *Graph Convolutional Network* (GCN) (Kipf and Welling, 2016) can extract semantic and syntactic information of sentences simultaneously from the graph. GCN first propagates information among nodes and their neighbors and then provides node representation by aggregating the received information. However, GCNs are designed for homogeneous graphs and cannot handle different types of nodes and relationships in the graph. Recently there have been attempts to explore relationships in the graphs. Schlichtkrull et al. (2018) introduces RGCN to handle relationships in knowledge graphs by using specific matrices for each relationship. Nevertheless, it focuses only on characteristics of the relations and does not study different types of features associated with a node.

This paper introduces a Multi-Relational Graph Transformer (MitiGaTe) for ASAG to incorporate the structural context. We first transform a sentence into an Abstract Meaning Representation (AMR) graph (Banarescu et al., 2013). AMR parses a sentence into a rooted directed graph. Then subgraphs are prepared corresponding to the relationships (types of edges) in the original AMR graph. For each subgraph, MitiGaTe prepares relation-specific token representations and aggregates them to obtain a subgraph representation. Finally, these relation-enriched subgraph representations of the student and the model answer are matched using multi-perspective matching (Wang et al., 2017) and the matching result yields the student score. We evaluate our model on the benchmark Mohler's dataset (Mohler et al., 2011) and it outperforms the *current state of the art models*.

Our main contributions can be summarized as follows:

1. We propose a Graph Transformer-based technique to incorporate relation-enriched structural information for ASAG.
2. We also demonstrate that including the semantic representation of a relationship in the preparation of token embeddings improves the model's overall performance.
3. We perform a case study to show that MitiGaTe can provide reasonable feedback to students explaining the (in)correct parts of the student answer.
4. MitiGaTe is evaluated through extensive experiments on a benchmarking dataset. The experimental results verify our proposed model's performance.

2 Related Work

ASAG: Traditional methods utilize handcrafted features, such as lexical similarity features (Dzikovska et al., 2013), graph alignment features (Mohler et al., 2011), n-gram features (Heilman and Madnani, 2013), soft cardinality text overlap features (Jimenez et al., 2013), averaged word vector text similarity features (Sultan et al., 2016) and other shallow lexical features (Ott et al., 2013). More recently, deep learning approaches have been utilized for the automatic short answer scoring task. Mueller and Thyagarajan (2016) proposed a siamese adaptation of the LSTM network for labelled data comprised of pairs of variable-length sequences. Zhao et al. (2017) proposed an efficient memory networks-powered automated scoring model. Riordan et al. (2017) explored simple LSTM and CNN-based architectures for short answer scoring. Kumar et al. (2017) proposed a method involving Siamese biLSTMs, a novel pooling layer based on the Sinkhorn distance between LSTM state sequences, and a support vector ordinal output layer. However, the approaches mentioned above do not incorporate the structural information, and as a result, the matching performed is partly inadequate (Croce et al., 2011; Severyn et al., 2013).

Application of GCN on NLP: GCN is a simplified graph neural network (GNN) introduced by (Kipf and Welling, 2016) to perform semi-supervised classification. In NLP, GCN is mainly explored in tasks such as semantic role labeling (Marcheggiani and Titov, 2017), machine translation (Bastings et al., 2017). Yao et al. (2019) first model a whole corpus as a graph where documents and words are regarded as nodes. However, most GNNs were designed for homogeneous graphs and could not handle different nodes and relations in heterogeneous graphs.

Unlike the existing methods, we consider the role of relations to improve the learning of more fine-grained node representation.

3 Methodology

We formally define the ASAG short text matching problem as follows: Given two sentences $\mathcal{A}^M = \{w_1^M, w_2^M, \dots\}$ and $\mathcal{A}^S = \{w_1^S, w_2^S, \dots\}$, where $\mathcal{A}^M$ and $\mathcal{A}^S$ refers to Model and Student answer respectively with w as words in the sentence, the goal of a text-matching model $\mathbf{f}(\mathcal{A}^M, \mathcal{A}^S)$ is to compute the semantic similarity of $\mathcal{A}^M$ and $\mathcal{A}^S$.

In this section, we discuss a graph-based matching model. To create graphs from the input sentences, we first parse each sentence into an AMR graph (Section 3.1). Further, we prepare subgraphs G_{sub} from AMR graphs corresponding to each relation (Section 3.2). The intuition behind subgraph splitting is to get relation-enriched structural information which can improve matching performance and interestingly can be used to provide a reasonable feedback to students (Section 5.5). We then create relation-specific token representation $\mathbf{h}_{w,r}$ from each subgraph and aggregate them to a final subgraph representation denoted as $g^{\phi}_{r,M}$ for model and $g^{\phi}_{r,S}$ for student answer (Section 3.3). Lastly, we compare them in Section 3.4 to predict the grading score in Section 3.5.

As shown in Figure 3, our model consists of five layers namely, Text to AMR conversion, Subgraph preparation layer, Graph Transformer Encoder layer, Subgraph matching layer and lastly, score prediction layer. We discuss each layer below.

3.1 AMR Parsing

The meaning of a sentence is represented by AMR as a rooted directed graph. Here, nodes represent the concepts or predicates and are not always directly related to words. Edges in AMR represent the relations between concepts such as subject/object. AMR provides a high-level abstraction by capturing meaningful content but ignores functional and inflectional words in a sentence (Xu et al., 2021).

We choose AMR over dependency parser for sentence parsing because unlike the dependency structure of a sentence where each word token is a node in the dependency tree, AMR concepts and relations abstract away from actual word tokens. Content words generally become concepts while function words either become relations or get omitted if they do not contribute to the meaning of a sentence, which is more intuitive and suitable for the ASAG task, unlike dependency parser that merely extracts grammatical relations between entities. Further, the AMR parser parses semantically similar but syntactically dissimilar answers into nearly similar graphs, which ensures that students who answer differently are not penalised.

We use the AMR Model API[2] from amrlib library to create AMR graphs $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ of a given input sentence $\mathcal{S}$. Each node $v \in V$ in the AMR graph represents a concept or predicate. Edge $e_{i,j}$ denotes the specific relation type between nodes v_i and v_j. The details are dicussed in Section 4.2. AMR Graphs for student answers in Figure 1 are shown in Appendix A.

3.2 Subgraph Preparation Layer

We transform the original AMR graph into subgraphs based on the number of relations or types of edges in the graph. All the subgraphs have the same number of nodes as the original graph. However, only a particular type of edge is enabled, and

---

[2] `https://bit.ly/amrlibrary`

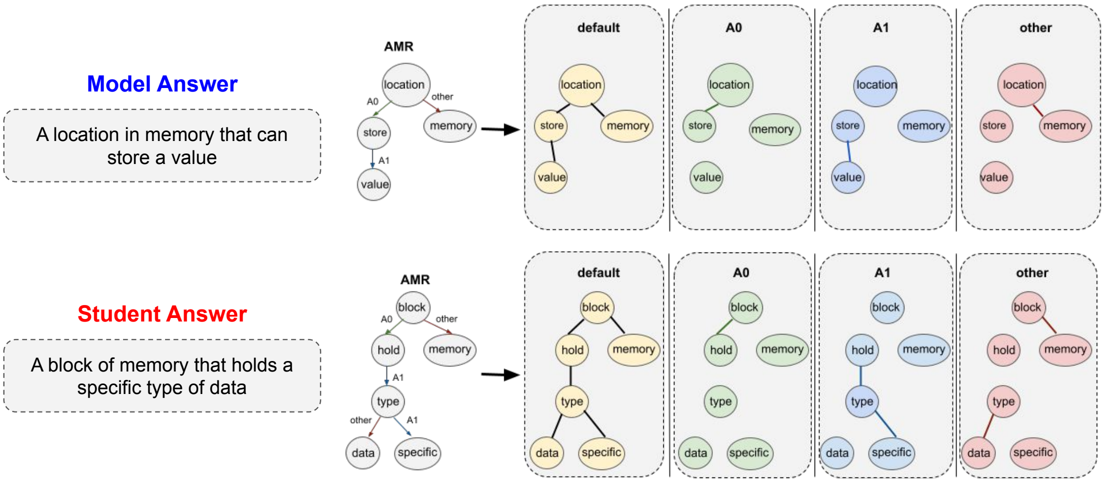

Figure 2: Example to show subgraph splitting and intuition behind using AMR for ASAG task. Similar relations in model and student answers have similar structures. Example, *location* and *store* in model answer are connected as A_0 and similarly *block* and *hold* in student answer are connected with A_0. This applies to other relations as well.

all other types of edges are disabled in the subgraph corresponding to relation r.

We first group all edge types into one to get a homogeneous subgraph referred to as the default subgraph $default$. The default subgraph is an undirected graph that contains the complete connected information in the original graph. Then we split the input graph into multiple subgraphs according to the edge types. Figure 2 demonstrates the subgraph preparation by an example.

AMR uses approximately 100 different relations to capture the semantics. Thus, it would be inefficient to capture all these relations in separate subgraphs as many of these occur rarely. In this work, we have used `ARG1` and `ARG0` relations to capture primary information, and all remaining relations are grouped as an `other` relation. We will be denoting `ARG1` and `ARG0` relations as A_1 and A_0 for the scope of this paper.

With reference to the PropBank[3] guidelines, the A_0 label is assigned to arguments which are understood as agents, causers or experiencers. The A_1 label is usually assigned to the patient argument, i.e. the argument which undergoes the change of state or is being affected by the action. The `other` category could include relations for quantities like `:unit`, date-entities like `:time`, and semantic relations like `:consist-of`. More information about the various types of relations captured by AMR can be found in the original paper (Banarescu et al., 2013).

Hence, we can denote the collection of these subgraphs as G_{sub}, where,

$$G_{sub} = \{default, A_0, A_1, other\} \tag{1}$$

3.3 Preparing Node and Subgraph Representation

In this layer, we prepare a relation-specific subgraph representation that reflects the characteristics of tokens in a particular relation. We perform two steps: firstly, we prepare relation-specific node representation using Graph Transformer and secondly, all relation-specific node representations are aggregated into a relation-specific subgraph representation. Below we discuss the process for tokens in $\mathcal{A}^M$ and the same process is applied to $\mathcal{A}^S$.

3.3.1 Relation-Specific Node Representation

Our model is adapted from the Transformer model introduced by (Vaswani et al., 2017). It is a sequence-to-sequence neural architecture originally used for neural machine translation. It uses encoder-decoder architecture. The encoder consists of two sublayers: a self-attention mechanism and a position-wise feed-forward network. The self-attention mechanism employs H attention heads, and each of them learns a distinct attention function. Finally, the outputs of all attention heads are concatenated, followed by feed-forward layers, residual connections and normalization. The encoder computes the token representations iteratively using the output of the previous layer as input.

---

[3] https://verbs.colorado.edu/~mpalmer/projects/ace/PBguidelines.pdf

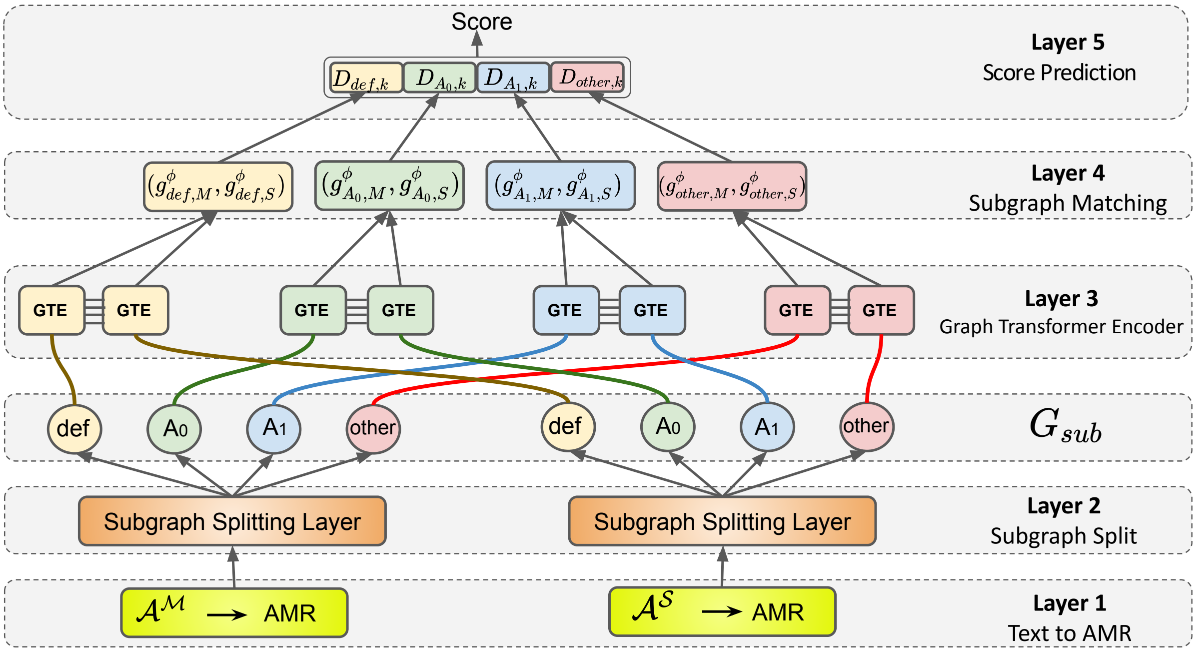

Figure 3: The framework of the proposed model **MitiGaTe** employs Graph Transformer for learning the structural context of a sentence. Please refer to Section 3 for more details.

Transformer (Vaswani et al., 2017) treats the sentence as a fully-connected graph. In MitiGaTe, we mask the non-neighbor nodes' attention while updating each node's representation. Specifically, we mask the attention w_{ij} for node $j \notin \mathcal{N}_i^+$, where $\mathcal{N}_i^+$ is the set of neighbors of node i in the graph including self-loop.

So given the input sequence $x = (x_1, \ldots, x_n)$, the output representation of node i, denoted as h_i^{l+1} for $l + 1$th layer is computed as follows:

$$h_i^{l+1} = O_h^l ||_{k=1}^H \Big(\sum_{j \in \mathcal{N}_i^+} w_{ij}^{k,l} V^{k,l} h_j^l \Big) \tag{2}$$

$$e_{ij}^{l+1} = O_e^l ||_{k=1}^H (\hat{w}_{ij}^{k,l}) \tag{3}$$

$$w_{ij}^{k,l} = \mathrm{softmax}_j(\hat{w}_{ij}^{k,l}) \tag{4}$$

$$\hat{w}_{ij}^{k,l} = \Big(\frac{Q^{k,l} h_i^l \cdot K^{k,l} h_j^l}{\sqrt{d_k}} \Big) \cdot E^{k,l} e_{ij}^l \tag{5}$$

where $Q^{k,l}$, $K^{k,l}$, $V^{k,l}$, $E^{k,l} \in \mathbb{R}^{d_k \times d}$, O_h^l, $O_e^l \in \mathbb{R}^{d \times d}$ are trainable parameter matrices, $k = 1$ to H denotes the number of attention heads and $||$ denotes concatenation. Following (Dwivedi and Bresson, 2020) we explicitly incorporate edge representation e_{ij}^l to improve attention weights $w_{ij}^{k,l}$. This above mentioned process of Graph Transformer is applied for each relation $r \in G_{sub}$. For brevity, we denote node representation of the last layer as $h_{w,r}$ where w represents a word and r denotes a specific relation.

A side point to note is that a subgraph has a single type of edge (a homogeneous graph), and therefore e_{ij}^l is the same within a Graph Transformer corresponding to relation r. However, e_{ij}^l gets updated over the layers similar to node representation h_i^l. We think that it stores a semantic representation of a relation which helps in improving the predictions as described in Section 5.3.

3.3.2 Relation-Specific Subgraph Representation

In particular, this component takes $h_{w,r}, r \in G_{sub}$ and computes relation-specific subgraph representation g_r^{ϕ} as a mean of $h_{w,r}$ using following equation:

$$g^{\phi}_{r,M} = \frac{\sum_{w \in \mathcal{A}_M} h_{w,r}}{||\mathcal{A}_M||}, \forall r \in G_{sub} \tag{6}$$

where $||\mathcal{A}_M||$ denotes the length of the sentence or the number of nodes in a subgraph. Similarly, we create $g^{\phi}_{r,S}$ for the subgraphs associated with student textual sentence.

3.4 Graph Matching Layer

After obtaining all the subgraph representations which have syntactically and semantically rich information, we utilize the multi-perspective cosine distance (Wang et al., 2017) to compare $g^{\phi}_{r,M}$ and $g^{\phi}_{r,S}$

$$\mathcal{D}_{r,k} = cosine(w^{cos}_k \odot g^{\phi}_{r,M}, w^{cos}_k \odot g^{\phi}_{r,S}) \quad (7)$$

$$\mathcal{D} = [\mathcal{D}, \mathcal{D}_{r,k}] \quad (8)$$

Where $k \in \{1, 2, \ldots, P\}$ (P is number of perspectives). w^{cos}_k is a parameter vector, which assigns different weights to different perspectives. With P perspectives $d_1, d_2, \ldots, d_P$, the $\mathcal{D}_{r,k}$ is updated to P size. The concatenation of two vectors is denoted using $[., .]$, where $\mathcal{D}$ is initialized with a $Null$ value and later it stores the concatenated value of all $\mathcal{D}_{r,k}$. $\mathcal{D}$ stores the matching score for all relation-specific subgraphs.

3.5 Score Prediction Layer

Student score $Score$ is calculated by using a fully connected layer FFN which takes $\mathcal{D}$ as input and has an output layer of a single dimension.

$$Score = FFN(\mathcal{D}) \quad (9)$$

During training phase we have used RMSE loss, where y_i and $\hat{y}_i$ represents the ground truth and predicted values respectively.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{N}(y_i - \hat{y}_i)^2} \quad (10)$$

4 Experimental Setup

4.1 Dataset

In our experiments, we use the Mohler's dataset (Mohler et al., 2011). It consists of 80 questions of an undergraduate Data Structures course. 2273 student responses are recorded in the dataset, which is evaluated independently by two academicians. We have considered the average scores as model scores. The score lies within a range of 0 to 5. We have considered it as a regression problem.

4.2 Data Processing

As described in section 3.1, we use the Model API from the amrlib library to create Abstract Meaning Representation graphs $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ of a given input sentence $\mathcal{S}$.

It is crucial to note that we consider the AMR representation as undirected while constructing the adjacency list. This can be intuitively justified as if there exists a relation (say A_0) between w_a and w_b ($w_a \rightarrow w_b$) the same relation justifies $w_b \rightarrow w_a$, and could thus be helpful in the final score prediction.

When we parse an original sentence $\mathcal{S} = \{w_1, w_2, \ldots w_n\}$, we get a directed AMR graph. Our next step is to convert the AMR to a NetworkX[4] graph. While creating the NetworkX graphs, the GloVe[5] embeddings for all the words i.e. the nodes in the AMR graph, are embedded as features in the NetworkX graph. We apply Principal Component Analysis (PCA) (Abdi and Williams, 2010) on the original 300D Glove embeddings to reduce it to a lower dimension. Before feeding into the graph transformer, we convert all the NetworkX graphs to DGL format[6]. A similar procedure is repeated for all subgraphs.

It is noteworthy that in some cases, AMR representation contains certain phrases like $have-degree$, which is actually a combination of two or more words ($have$ and $degree$). Such phrases/words don't have a GloVe representation and are thus treated as out-of-vocabulary.

4.3 Parameter Settings

The graph transformer has 2 layers since it gives the best results as observed in preliminary experiments. We use 4 attention heads as we observed that the model performance deteriorates if more/fewer heads are used as described in Section 5.4. We have also added self-loops to include each graph node while updating its representation. The subgraph representation is the mean of node representations. We use $P = 16$ in the graph matching layer, where P is the number of perspectives defined in Section 3.4.

We employ the RMSProp optimizer to minimize RMSE loss. The batch size is set to 128 and the initial learning rate to 0.0007. The 'ReduceLROnPlateau' scheduler is used to reduce the learning rate by a factor of 0.5 when the loss stagnates, with a patience level of 15 epochs. Our implementation uses PyTorch [7], a popular deep learning framework in Python. All experiments are run on Intel Xenon CPU with 1 Nvidia Quadro P5000 GPU.

4.4 Baselines and Metrics

For evaluating MitiGaTe on (Mohler et al., 2011) dataset, we compare against the following base-

[6] `https://www.dgl.ai/`

[7] `https://pytorch.org/`

lines. **BOW** (Mohler et al., 2011) is a simple model based on Bag Of Words. **Tf-idf** (Mohler et al., 2011) is a simple tf-idf similarity between $\mathcal{A}^M$ and $\mathcal{A}^S$. **Sultan et al.** (Sultan et al., 2016), a fast, simple and high performance system which uses Random Forest classifier. **Kumar et al.** (Kumar et al., 2017) uses a Siamese LSTM network. **Word2Vec**, **GloVe** and **FastText** (Gaddipati et al., 2020) are context independent token embedding models. **ELMO**, **GPT**, **BERT** and **GPT-2** (Gaddipati et al., 2020) are deep learning based context based token embedding models. **GCN** (Kipf and Welling, 2016) performs homogeneous graph convolutions. **GAT** (Hamilton et al., 2017) performs the attentive weighted sum to update node representation. **GraphSAGE** (Hamilton et al., 2017) is a framework for inductive representation learning. All GNN baselines use the $default$ subgraph as input, and have 2 layers. **RGCN** (Schlichtkrull et al., 2018) employs relation specific transformation matrix to incorporate relations in the graph.

We use Root mean square error (RMSE) for performance evaluation, which gives a fair assessment of students' responses. A lower metric value corresponds to better model.

5 Results and Analysis

In this section, we attempt to answer following questions: **RQ1**. How does each subgraph influence the final results? (Section 5.2) **RQ2**. Does incorporating edge representation while computing node representation improve the final results? (Section 5.3) **RQ3**. Can MitiGaTe provide feedback to students i.e. Why did a student lose marks? (Section 5.5)

5.1 Results on Mohler's Data

Table 1 presents the results of our model on the Mohler's dataset. We can see that our model outperforms all of the previous models by a significant margin. It demonstrates the importance of incorporating relation-enriched structural context in the tokens for effective text comparison. The existing baseline models can be categorized as (i) Handcrafted features (ii) Deep Learning-based models (iii) Word Embeddings based on sequential context information (iv) Graph-based, which store the structural information and relationship information.

ELMo outperforms the other transfer learning models. It is fundamentally a direct result of the capacity of the model to assign context-dependent word-vectors. RGCN performs better than other graph-based baselines because it incorporates the relation-specific information in the form of a heterogeneous graph. Nevertheless, it focuses only on the characteristics of the relations and does not study different types of features associated with a node. Our results establish that incorporating the relation-enriched structural information (MitiGaTe) contributes to significant performance improvement in the downstream task. This observation is generic and can be applied to different applications beyond ASAG.

Model	Features	RMSE
BOW	SVM Rank	1.042
	SVR	0.999
tf-idf	SVR	1.022
Sultan	LR + SIM	0.887
Kumar	Siamese	0.830
Word2Vec	SOWE	1.025
	SIM+Verb	1.016
GloVe	SOWE	1.036
	SIM+Verb	1.002
FastText	SOWE	1.023
	SIM+Verb	0.956
ELMO	SOWE	0.978
GPT	SOWE	1.082
BERT	SOWE	1.057
GPT-2	SOWE	1.065
GCN	HG	0.991
GAT	AWG	0.974
GraphSAGE	HG	0.986
RGCN	HtG	0.892
MitiGaTe	MRGT	**0.762**

Table 1: MitiGaTe Evaluation on Mohler Dataset (Mohler et al., 2011). SVM = Support Vector Machine, SVR = Support Vector Regression; LR = Length Ratio between desired answer and student answer; SIM = Similarity score; SOWE = Sum Of Word Embeddings; HG = Homogeneous Graph; AWG = Attention Weighted Graph, HtG = Heterogeneous Graph, MRGT = Multi-relational Graph Transformer.

5.2 Influence of Subgraphs

In this section, we investigate how each subgraph influences the final results of our best model MitiGaTe. Table 2 shows the effect of using different combinations of relation-specific subgraphs on the result. Using only the $default$ subgraph implies that the model does not consider the relational

Model	RMSE
MitiGaTe	**0.762**
Only $default$	0.968
Only A_0	1.017
Only A_1	1.020
Only $other$	1.144
Only $default + other$	1.178
Only $default + A_1$	0.949
Only $default + A_0$	0.872
MitiGaTe - A_0	0.925
MitiGaTe - $default$	0.888
MitiGaTe - A_1	0.816
MitiGaTe - $other$	0.794

Table 2: Influence of relation-specific subgraphs on performance. MitiGaTe uses $default$ + A_0 + A_1 + $other$ subgraphs.

information in inputs, i.e., considers a simple homogeneous graph. We see that it performs better than GCN (mentioned in Table 1) because it uses a Graph Transformer encoder. On using A_0, A_1 and $other$ subgraphs separately, the model performance degrades as they capture a subset of the relations captured by $default$.

Using the $default$ subgraph along with the primary relations A_0 and A_1 improves the performance because incorporating multiple relations supplements the syntactic and semantic information. We think that the reason for performance degradation to 1.178 RMSE on using the $other$ subgraph along with $default$, is that we have stored all remaining relations available in the AMR under the $other$ class.

Furthermore we can observe that on removing the individual subgraphs one-by-one from MitiGaTe, the performance deteriorates in all cases. These results corroborate the hypothesis that utilizing multi-relational information helps in improving the overall outcomes. The relation A_0 stores the information related to $agents$ or $causers$, and therefore it influences the results the most.

5.3 Influence of Edge Representations

Table 5.3 demonstrates that incorporating the edge representations in the graph transformer certainly helps in improving the attention weights, and therefore the overall results have improved significantly. The edge embeddings are initialized with random values, but they get updated in the layers of the graph transformer. As stated earlier, we expect that the edge embeddings store a relation's semantic representation. From the results, we can infer that a relation's semantic representation plays an essential role in the overall process.

Model	RMSE
MitiGaTe w/o edge representation	0.864
MitiGaTe w/ edge representation	**0.762**

5.4 Analysis of Parameters

We study the impact of the number of transformer layers and attention heads on MitiGaTe. The results are summarized in Figure 4. We vary the number of layers keeping the number of heads fixed as 4. The performance first improves with increasing layers as a deeper model receives better information from multi-hop neighbors. However, too many layers lead to performance degradation, and we see that this is due to the over-smoothing problem discussed by (Li et al., 2018). Next, the number of attention heads is varied keeping the number of layers fixed as 2. We observe that more attention heads improve the performance during training but are redundant during the testing. This is consistent with the observation of (Michel et al., 2019).

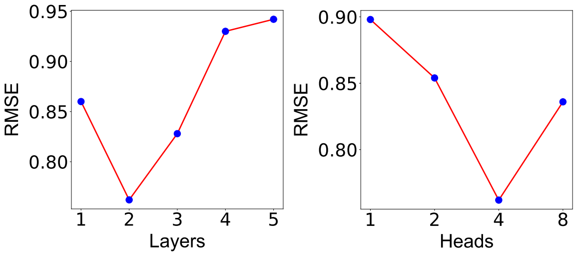

Figure 4: Effect of parameters on RMSE (Layers, Heads).

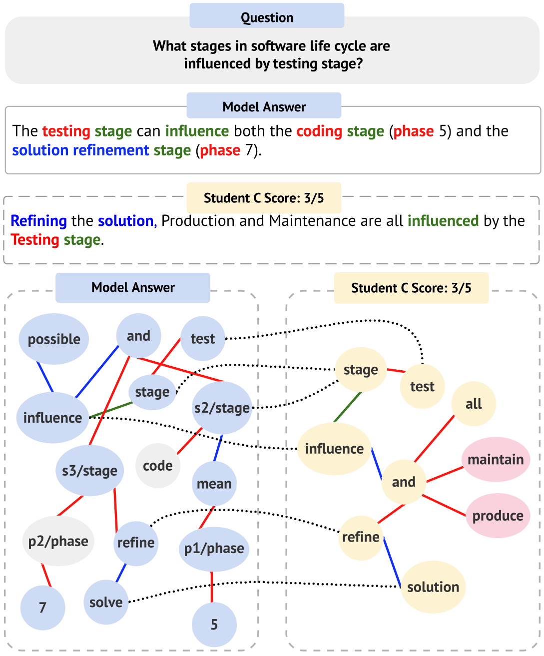
5.5 Case Study: Feedback to Students

In addition to scoring a student response, a significant focus of the human evaluation is giving feedback on why a student lost marks. MitiGaTe matches tokens at the relation-level as illustrated in Figure 5. Student C scored 3/5 because of the corresponding matching of words belonging to the same relation in student and model answers. There exists the same relation A_1 between words *refine* and *solve*, in model answer and words *refine* and *solution* in student answer. Similarly the $other$ and A_0 relations have been highlighted in the Figure 5. However, the student loses marks because there are a few relationships between words like *code* and



Question

What stages in software life cycle are influenced by testing stage?

Model Answer

The testing stage can influence both the coding stage (phase 5) and the solution refinement stage (phase 7).

Student C Score: 3/5

Refining the solution, Production and Maintenance are all influenced by the Testing stage.

Figure 5: Example from Figure 1, demonstrating how the model performs matching at the relation-level. The green, red and blue color edges indicate A_0, A_1, *other* relations respectively. Dotted lines denote the relation-specific token matching. Grey nodes indicate the **missing content**, and pink nodes denote the **extra information** provided in student answer.

phase in the model answer, which are not present in the student response. These relations can be used to highlight the (in)correct parts of the student answer. We see that the relational matching information intuitively acts as feedback to explain the final scores.

6 Conclusion

In this paper, we have proposed MitiGaTe for ASAG. It prepares token embeddings considering the structural context of a sentence and thus provides a more efficient matching method by considering multiple relations at a granular level. Experimental results show that MitiGaTe outperforms the existing ASAG systems by a significant margin, and can be extended to give an intuitive feedback to explain the provided score.

In the future, we would like to investigate how to deal with long and multi-lingual answers. Our approach uses an AMR graph, and thus such tasks will need a compatible AMR parser. We also aim to incorporate the explainability of the final scoring to generate more comprehensive evaluator feedback.

Event Schema Induction with Double Graph Autoencoders

Xiaomeng Jin, Manling Li, Heng Ji
University of Illinois Urbana-Champaign
`{xjin17, manling2, hengji}@illinois.edu`

Abstract

Event schema depicts the typical structure of complex events, serving as a scaffolding to effectively analyze, predict, and possibly intervene in the ongoing events. To induce event schemas from historical events, previous work uses an event-by-event scheme, ignoring the global structure of the entire schema graph. We propose a new event schema induction framework using double graph autoencoders, which captures the global dependencies among nodes in event graphs. Specifically, we first extract the event skeleton from an event graph and design a variational directed acyclic graph (DAG) autoencoder to learn its global structure. Then we further fill in the event arguments for the skeleton, and use another Graph Convolutional Network (GCN) based autoencoder to reconstruct entity-entity relations as well as to detect coreferential entities. By performing this two-stage induction decomposition, the model can avoid reconstructing the entire graph in one step, allowing it to focus on learning global structures between events. Experimental results on three event graph datasets demonstrate that our method achieves state-of-the-art performance and induces high-quality event schemas with global consistency. [1]

1 Introduction

Event Schema (Chambers and Jurafsky, 2008, 2009; Balasubramanian et al., 2013; Nguyen et al., 2015; Modi et al., 2016; Li et al., 2021) is induced from historical events to describe the common or stereotypical evolution pattern of complex events. Figure 1b shows an example schema of complex event "IED-bombing" (Improvised Explosive Device), where multiple events are inter-connected via temporal links (e.g., TRANSPORT happens after ASSEMBLE) and arguments (e.g., the transporting ENTITY is the weapon that is being assembled; the transporting DESTINATION is controlled by the assembler, i.e., the AGENT). It enables a descriptive analysis of inter-event structures, as well as the prediction of future events over temporal-based and argument-based structures.

A number of methods have been proposed for learning event schemas from instance event graphs, called *event schema induction*, which fall into three categories. The *set-based* (Chambers, 2013; Sha et al., 2016; Huang et al., 2016) and *sequence-based* (Granroth-Wilding and Clark, 2016; Rudinger et al., 2015) methods treat a complex event as a set or a linear sequence of atomic events, respectively. However, they fail to capture the multi-dimensional evolution of real-world complex events, i.e., multiple events may precede or follow one event. *Graph-based* methods (Li et al., 2020, 2021), instead, adopt graphs to formulate event schemas. A graph model is usually learned from instance event graphs through generating the schema event by event. Although graph-based methods are theoretically superior to the first two categories, existing graph-based methods are limited to modeling only the *local* structure of event graphs, i.e., the first-order dependency of an event node with respect to its neighbors, while ignoring the *high-order* and *global* dependencies among atomic events in the entire graph.

However, modeling the global structure of event graphs is crucial to event schema induction. The global structure enables the model to be aware of the position of each event node in the entire graph. It allows the model to better comprehend the role of a specific event in the complex event. For example, in Figure 1b, there are three TRANSPORT events in the schema, but they differ regarding the item being transported, i.e., bombs, the injured, or suspects. The global structure context enables the model to differentiate the position of the three TRANSPORT events and predict their neighbor events precisely. Moreover, when the model only has access to local

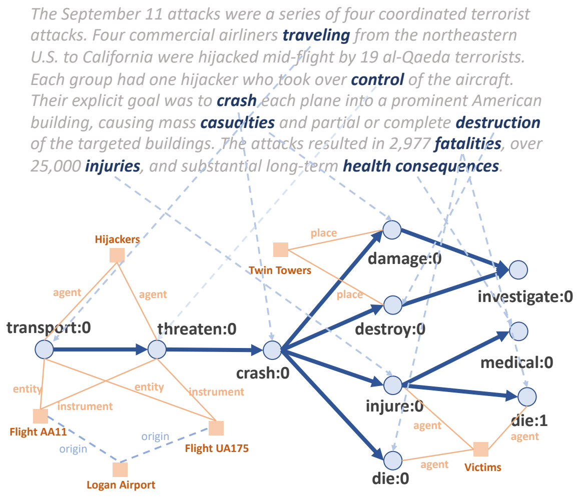
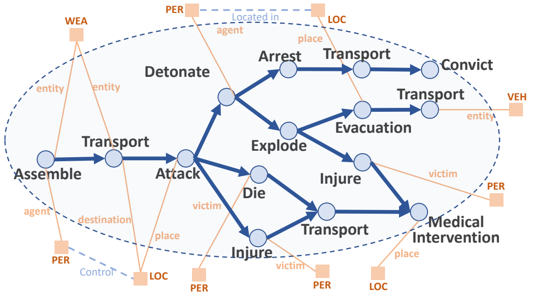
July 10-15, 2022



The September 11 attacks were a series of four coordinated terrorist attacks. Four commercial airliners **traveling** from the northeastern U.S. to California were hijacked mid-flight by 19 al-Qaeda terrorists. Each group had one hijacker who took over **control** of the aircraft. Their explicit goal was to **crash** each plane into a prominent American building, causing mass **casualties** and partial or complete **destruction** of the targeted buildings. The attacks resulted in 2,977 **fatalities**, over 25,000 **injuries**, and substantial long-term **health consequences**.

(a) Event instance graph



(b) Event schema graph

Figure 1: An illustrative example of (a) an instance event graph of 9/11 Attacks extracted from a news article and (b) graph-based event schema of IED bombings. We use circles to denote events and squares to represent event arguments (entities). The solid blue arrows represent temporal links between events (i.e., event skeleton), the solid yellow lines represent argument roles between events and entities, and the dashed blue lines represent entity-entity relations.

structure information during the generation process, the schema generated may only be consistent at the local level, but not at the global level. For example, the schema may keep repeating the sequence of ASSEMBLE - TRANSPORT - ATTACK. From this perspective, the global structure information can be viewed as the supervision that guides the entire generation process to be globally consistent.

To capture the global structure information of complex events, in this paper, we propose a new event schema induction approach using double graph autoencoders. *Graph Autoencoder* (Salha et al., 2019; Zhang and Chen, 2018) is known to be able to preserve the structural information of an entire graph in the embedding space. Therefore, our key idea is to use graph autoencoders to capture the global dependency among nodes in event graphs.

Specifically, our model contains two graph autoencoders that are organized in a hierarchical manner: (1) To model the skeleton of an event graph, we design a high-level variational graph autoencoder for directed acyclic graphs (DAGs). *Event skeleton* is a subgraph of an event graph, which consists of salient events and their temporal orders, representing the fundamental structure of event evolution. (2) With the event skeleton as the global context, we decorate entity nodes in the skeleton by introducing a low-level graph autoencoder based on Graph Convolutional Network (GCN). It takes as input an expanded event skeleton and reconstructs the original event graph by adding coreferential entities and entity-entity relations.

These two graph autoencoders decompose the process of event schema induction into two steps, thereby avoiding the need to reconstruct the entire graph directly, and improving the schema learning efficiently at both the high level (event schema skeleton) and the lower level (entity-entity relations).

We conduct extensive experiments on three event graph datasets. The experimental results demonstrate that our proposed method achieves state-of-the-art performance on event schema induction. Additionally, we show in a case study that the event schema generated by our method is more reasonable and globally consistent.

We make the following novel contributions:

- We propose a two-stage global structure aware schema induction framework, providing a global context of event skeleton to determine inter-event interactions via arguments.
- We introduce a double graph autoencoder that preserves the global structural information, allowing the model to capture high-order dependencies between nodes.
- We propose a comprehensive set of metrics for structure-aware comparison between schema graphs and instance graphs.
- Our method significantly outperforms baselines, demonstrating the effectiveness of considering global structure context in event schema induction.

2 Problem Formulation

Our data resources come from news and Wikipedia articles that describe a series of complex events.

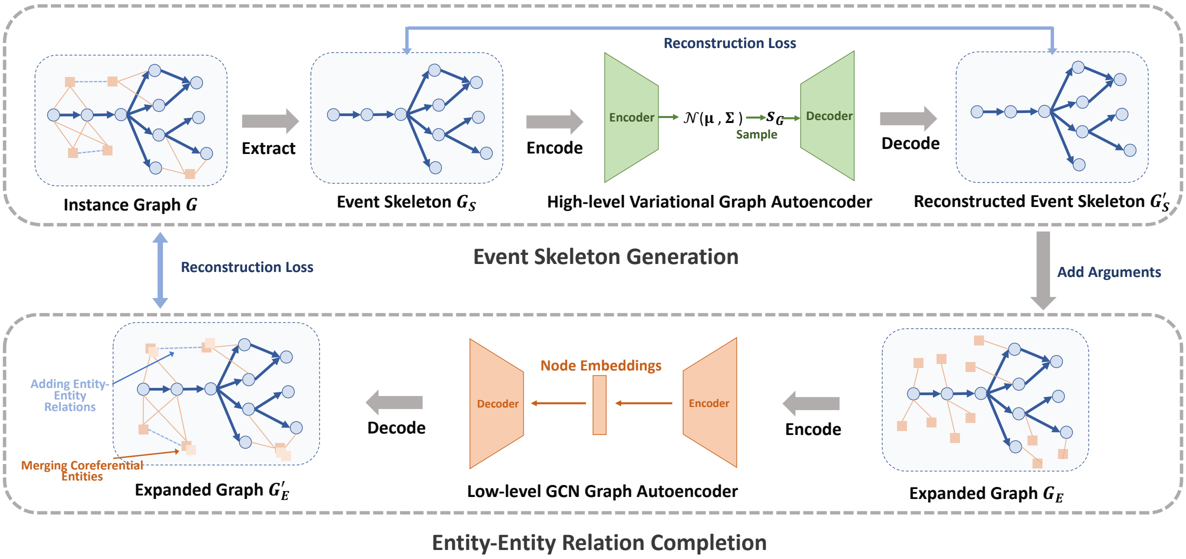


Figure 2: The architecture of our model.

We extract events, entities, as well as their relations using Information Extraction (IE) tools (Wu et al., 2008; Li et al., 2011; Hogenboom et al., 2013; Lin et al., 2020), then construct instance event graphs. An instance event graph consists of two types of nodes: event nodes and entity nodes, and we use t_i to represent the type of node i. Similarly, we use t_{ij} to denote the edge type between node i and node j. Accordingly, there are three types of edges in an instance graph: (1) the event-event temporal link (i, j), which represents a temporal order that event j happens after event i, with t_i and t_j indicating their event types, such as TRANSPORT; (2) the event-entity argument link (i, a, m), which represents that event i has an argument entity m, which plays the argument role $t_{im} = a$, such as AGENT; (3) the entity-entity relation (m, r, n), which represents that there is a relation $t_{mn} = r$ between entity m and entity n, such as AFFILIATION.

Given a set of instance graphs $\{G_1, G_2, \cdots\}$ that belong to the same topic, our goal is to learn a schema S that summarizes the instance graphs and represents their underlying common evolution pattern. Note that different from instance graphs, nodes (events and entities) in the schema S are not instantiated but represented by their types.

3 Our Approach

3.1 Overview

We design two graph autoencoders, where the first autoencoder deals with the high-level skeleton of an event graph and the second autoencoder focuses on the low-level arguments of an event graph.

As shown in the upper side of Figure 2, the high-level autoencoder, which is specially designed for directed acyclic graphs (DAGs), takes an instance event skeleton as input, and encodes the event skeleton as a probability distribution in the embedding space. Then it reconstructs the input skeleton by feeding a vector sampled from the distribution into the decoder.

After the event skeleton is reconstructed, we decorate the entity nodes according to the pre-defined argument roles of each event (as shown on the right side of Figure 2). However, the entity-entity relations and coreference links among arguments are still missing in the expanded event skeleton. Therefore we introduce a low-level graph autoencoder to take as input an expanded event skeleton and reconstruct the original event graph (as shown in the lower part of Figure 2). The low-level graph autoencoder employs Graph Convolutional Network (GCN) to encode each node into an embedding vector, then predicts the type of an entity-entity relation based on the learned entity embeddings.

3.2 Event Skeleton Generation

An instance event graph can contain up to hundreds of nodes, but the majority are entity nodes that are associated with event nodes. Therefore, as shown in the upper left of Figure 2, our first step is to extract the event skeleton G_S from the instance graph G, which serves as the backbone of G.

For a given instance event graph G, we use a graph neural network (GNN) based variational autoencoder to process its event skeleton $G_S \subseteq G$. Traditional GNNs learn the node representations by aggregating information from their neighbors iteratively, then apply a readout function to all node representations and output the representation of the entire graph (Xu et al., 2019). However, off-the-shelf GNNs are not suitable for modeling event skeleton, because event skeleton is a DAG whose nodes follow an intrinsic partial order, whereas existing GNN models focus more on capturing the local structure of a graph.

Encoding. To capture the global structure of event skeleton G_S, inspired by Zhang et al. (2019), we design a new GNN architecture for the encoder, in which messages can only pass forward following event-event temporal orders. Specifically, for a given event node i in the event skeleton G_S, its representation $\mathbf{s}_i$ is computed by:

$$\mathbf{s}_i = \mathrm{AGG}\big(\{\mathbf{s}_j \mid (j,i) \in G_S\} \cup \mathbf{t}_i\big), \qquad (1)$$

where $\mathbf{t}_i$ is the one-hot event type vector of an event node i, and we use it as the initial feature for the event. $\mathrm{AGG}(\cdot)$ is the aggregate function. In Eq. (1), we only consider predecessors as neighbors, allowing the model to capture the temporal flow of the event graph. Considering that predecessors contribute differently to predicting the current event node, we utilize a self-attention function as the aggregate function to characterize the importance of different predecessors:

$$\mathbf{s}_i = \sigma\Bigg(\mathbf{W}_1 \sum_{j:(j,i)\in G_E} \mathrm{SoftMax}\big(\alpha_{ij}\big)\mathbf{s}_j + \mathbf{W}_2\mathbf{t}_i\Bigg), \qquad (2)$$

where $\alpha_{ij} = \mathrm{LeakyReLU}\Big(\mathbf{w}^\top\big[\mathbf{W}_1\mathbf{s}_j, \mathbf{W}_2\mathbf{t}_i\big]\Big)$ is (unnormalized) attention weight, $\mathbf{w}$ is a learnable vector, $\mathbf{W}_1$ and $\mathbf{W}_2$ are learnable matrices, $[\cdot,\cdot]$ denotes concatenate operation, and $\sigma(\cdot)$ is a nonlinear activation function.

It is worth noting that according to Eq. (1), $\mathbf{s}_i$ can only be computed after its predecessors' representations have been computed, which implies that the encoder computation sequence naturally follows the topological order of the event skeleton. Specifically, we first create a dummy event node START that has an outgoing link to each event node that has no predecessor, and a dummy event node END with an incoming link from each event node that has no successor. Then we compute the representations of all event nodes according to their topological order. Finally, the representation of END, i.e., $\mathbf{s}_{\mathrm{END}}$, is taken as the output of the encoder.

Algorithm 1: Event Skeleton Generation

```
   Input: Graph embedding $\mathbf{s}_{\mathrm{END}}$ for $G_S$ output by the
          encoder
   Output: Reconstructed event skeleton $G'_S$
1  $G'_S \leftarrow \varnothing$;
2  $\boldsymbol{\mu} \leftarrow \mathrm{MLP}_\mu(\mathbf{s}_{\mathrm{END}}), \boldsymbol{\Sigma} \leftarrow \mathrm{MLP}_\sigma(\mathbf{s}_{\mathrm{END}})$;
3  Sample the global graph representation:
     $\mathbf{s}_G \sim \mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$;
4  Initialize the state of the generated graph as zero:
     $\mathbf{g} \leftarrow \mathbf{0}$;
5  while True do
       // Generate a new event $i$
6      Sample the type for the generated new event $i$:
         $t_i \sim \mathrm{MLP}_{node\_type}([\mathbf{s}_G, \mathbf{g}])$;
7      Add event node $i$ with type $t_i$ into $G'_S$;
8      if $t_i = $ END then
9          Add edge $(j,i)$ to $G'_S$ for every $j \in G'_S \backslash i$ if
             $j$ has no successor;
10         break;
11     else
12         for $j \in G'_S \backslash i$ do
13             $p_{ij} \leftarrow \mathrm{MLP}_{edge\_prob}([\mathbf{t}_i, \mathbf{s}_j])$;
14             if $p_{ij} > 0.5$ then
15                 Add edge $(j,i)$ into $G'_S$;
16         Compute $\mathbf{s}_i$ according to Eq. (2);
17         Update the state of the generated graph:
             $\mathbf{g} \leftarrow \mathbf{s}_i$;
18 return $G'_S$
```

Decoding. The decoder follows a GNN architecture similar to the encoder, as presented in Algorithm 1. The input is the encoder output $\mathbf{s}_{\mathrm{END}}$ for G_S, and our goal is to reconstruct the skeleton graph G'_S. Specifically, we first obtain the posterior approximation $p(\cdot|G_S)$ by calculating the mean vector $\boldsymbol{\mu}$ and the diagonal covariance matrix $\boldsymbol{\Sigma}$ via two Multi-Layer Perceptrons (MLPs) (line 2). Then we sample a vector $\mathbf{s}_G$ from the Gaussian distribution $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ as the global representation of the skeleton graph, which will be used throughout the following generation process (line 3). The representation of the generated graph $\mathbf{g}$ is initialized as an all-zero vector (line 4).

Next, the decoder generates a DAG node by node (line 5-17). When generating a new event node i, the decoder computes the event type distribution for node i to obtain a sampled type t_i (line 6). The distribution is learned based on the concatenation of $\mathbf{s}_G$ and $\mathbf{g}$, summarizing the input skeleton graph and the generated graph. Based on the value of t_i, the decoder performs one of the following two steps:

- If the generated event node i is END, then the decoder will stop the generation procedure, and connect all nodes that do not have any predecessor to the END node (line 8-10).
- Otherwise, the decoder uses another MLP to predict the edge probability of node i with existing nodes, and add the generated edges into the graph (line 12-15). After the generation step for node i is completed, the decoder then computes the representation $\mathbf{s}_i$ for node i according to Eq. (2) (line 16), and updates the generated graph representation $\mathbf{g}$ by $\mathbf{s}_i$ (line 17). The updated $\mathbf{g}$ will be further used to generate a new node for the next iteration.

Different from existing event schema induction methods that are only able to model the local structural information of event graphs, our method encodes the global information of an event graph as the global graph representation $\mathbf{s}_G$, and further applies this global state to guide the entire generation process. This enables our model to fully capture the structural information of event graphs, which has been shown to be extremely important for event schema induction.

3.3 Entity-Entity Relation Completion

After generating the event skeleton, we aim to complete the generated event schema graph by adding back entities as well as edges associated with these entities. We take advantage of the event ontology, where each event has a predefined set of argument roles. For example, an ATTACK event has an ATTACKER argument role whose type can be PERSON (PER), as well as a TARGET argument role whose type can be LOCATION (LOC). Therefore, we first expand the event skeleton by adding the predefined event arguments back to each event, as shown in the right of Figure 2. Yet, such an expanded event skeleton G_E is not the final event schema, because: (1) entity-entity relations are missing, e.g., the LOCATED_IN relation between a PER entity and a LOC entity in Figure 1b; (2) entities in G_E can be coreferential, which require to be merged. For example, in Figure 1b, the DESTINATION of the TRANSPORT event is also the PLACE where the ATTACK event happens.

We formulate the above two cases as a unified entity-entity edge missing problem, by treating coreference as a special type of entity-entity relation between unmerged nodes. To predict missing entity-entity relations, we design a low-level graph autoencoder. It reads the expanded event skeleton G_E as input, and then reconstructs the original event graph G by adding entity-entity relations back, as shown in the lower part of Figure 2. During the inference stage, the learned graph autoencoder can therefore take a generated event skeleton as input, and output a comprehensive event schema graph.

Encoding. Different from the high-level autoencoder whose purpose is to generate event skeleton, the low-level autoencoder is to reconstruct the relations between entities, therefore, the low-level graph autoencoder is expected to be non-probabilistic, and therefore we adopt Graph Convolutional Networks (GCN) (Kipf and Welling, 2017) as our encoder. Let $\mathbf{s}_i^k$ denote the representation at iteration k for the node $i \in G_E$, which can be either an event or an entity. The encoder updates node representations iteratively for $k = 1, \cdots, K$, where K is the layer number of the GCN encoder:

$$\mathbf{s}_i^k = \sigma\Big(\mathbf{W}^k \sum\nolimits_{j \in \mathcal{N}(i) \cup \{i\}} \alpha_{ij} \mathbf{s}_j^{k-1}\Big). \quad (3)$$

Here $\mathcal{N}(\cdot)$ denotes the set of neighbors of node i, $\alpha_{ij} = 1/\sqrt{|\mathcal{N}(i)| \cdot |\mathcal{N}(j)|}$, $\mathbf{W}^k$ is a learnable matrix, and σ is an activation function. $\mathbf{s}_i^0$ is initialized as the one-hot type vector of node i, i.e., $\mathbf{s}_i^0 = \mathbf{t}_i$. All edges in G_E, including event-event temporal links and event-entity argument links, are treated as undirected when counting neighbors, due to our focus on the local graph structure. The encoder output is the final representation $\mathbf{s}_i^K$ of node $i \in G_E$.

Decoding. The decoder takes as input the final node representations $\mathbf{s}_i^K$ from the encoder, and reconstructs entity-entity relations in the original event graph G. The entity-entity relation can be one of the following three cases: no relation, coreference, or predefined entity-entity relation types in the ontology. Therefore, we create two new relation types NO-RELATION and CO-REFERENCE, and add them into the original set of entity-entity relations as the prediction target. Specifically, the decoder predicts the relation type t_{ij} of two given entities i and j by a MLP:

$$\hat{t}_{ij} = \mathrm{MLP}_{entity\_rel}\big([\mathbf{s}_i^K, \mathbf{s}_j^K]\big), \quad (4)$$

where $\hat{t}_{ij}$ denotes the predicted relation type. It is noteworthy that NO-RELATION dominates the prediction targets, making the classification problem highly unbalanced. To address this issue, we divide the task into two steps: predicting the existence of edges and then predicting the type of a known edge, to optimize the learning effectiveness.

3.4 Training and Generation

Training. The training objective for the high-level variational graph autoencoder consists of a reconstruction loss and a regularization loss:

$$L_{high} = \mathrm{Dist}(G_S, G'_S) + \mathrm{KL}\big(\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma}), \mathcal{N}(\mathbf{0}, \mathbf{1})\big), \tag{5}$$

where the first term $\mathrm{Dist}(G_S, G'_S)$ measures the distance between the input event skeleton G_S and the reconstructed event skeleton G'_S. We sum up the negative log-likelihood of each decoding step by forcing them to generate the ground truth event type or edge at each step. The second term $\mathrm{KL}\big(\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma}), \mathcal{N}(\mathbf{0}, \mathbf{1})\big)$ forces the distribution output by the encoder to be close to the standard Gaussian distribution, to ensure a smooth embedding space.

The loss function for the low-level GCN graph autoencoder is the cross-entropy loss between predicted and ground-truth entity-entity relations:

$$L_{low} = \sum_{\text{event } i,j} \mathrm{CELoss}(\hat{t}_{ij}, t_{ij}). \tag{6}$$

Schema Generation. We are able to generate the event schema by decoding the trained model. We first sample a global graph representation from $\mathcal{N}(\mathbf{0}, \mathbf{1})$ in the embedding space of the high-level variational graph autoencoder. It is then fed into the decoder to generate a schema skeleton with event nodes only. Afterwards, the skeleton is further fed into the low-level graph autoencoder to predict coreferential entities and entity-entity relations.

4 Experiments

4.1 Datasets

We conduct experiments in the scenario of IED bombings following the state-of-the-art graph-based schema induction literature (Li et al., 2021). Specifically, three subtypes of complex events for IED are considered, including *General IED*, *Car bombing IED*, and *Suicide IED*. To construct the dataset, we select a set of Wikipedia articles related to IED bombings and identify the references in each Wikipedia article, then collect news articles from those references [2]. We use RESIN (Wen et al., 2021; Du et al., 2022), a state-of-the-art IE system, to extract event mentions, relations, and entity mentions from these news articles, and perform entity coreference resolution. We also do human curation to correct obviously erroneous event-event links (e.g., a temporal link indicating that an INJURE event happens after a DIE event for one person). The statistics of these three datasets are summarized in Table 1.

4.2 Baselines

We compare our proposed method with graph schema induction baselines:

(1) *Temporal Event Graph Model* (TEGM) (Li et al., 2021). It is the state-of-the-art graph schema induction model, which generates the entire event graph using an auto-regressive graph generation model. We compare with it to explore the effectiveness of the two-stage framework that generates event skeleton first and provides a global context for argument generation.

(2) *Frequency-Based Sampling* (FBS). To examine the effectiveness of our graph autoencoder to generate event skeleton, we compare with a frequency-based baseline. It constructs the event schema based on the frequency of event-event temporal links in the training data. Specifically, for each possible pair of event types (t, t'), we compute the number of edges in training graphs whose two associated events exactly have type t and t'. After that, we construct a schema graph in which each node corresponds to one event type, and there is no edge in the schema graph initially. Then at each timestamp, we sample one pair of event types according to their frequency, and add this sampled edge into the schema graph. The procedure is repeated until we detect a cycle in the schema graph after adding a new edge.

4.3 Experimental Setup

Evaluation Metrics. For a given dataset, we first train our model on the training instance graphs, then generate the event schema according to the steps presented in Section 3.4. To evaluate the quality of the generated schema, we compare the schema with test instance graphs in terms of the following metrics, to see how the schema captures the structure information of test instance graphs:

(1) *Event type match*. We compute the set of event types in the generated schema graph, as well as the set of event types in one test instance graph,

---

[2] We select news articles that are rich in events from the IED article collections (Li et al., 2021) with further curation. The curated dataset is included in our released code base.

Datasets	General-IED	Car-IED	Suicide-IED
# train/val/test instance graphs	88 / 11 / 12	75 / 9 / 10	176 / 22 / 22
Avg # e/v nodes per graph	90.8 / 251.5	146.5 / 421.3	117.4 / 381.7
Avg # ee/ev/vv links per graph	212.6 / 278.5 / 230.5	345.7 / 457.7 / 397.0	246.2 / 403.5 / 373.7

Table 1: Statistics of the three datasets. “e” and “v” are short for “event” and “entity”, respectively.

Datasets	**Methods**	**Event type match (F1)**	**Event seq match (F1)**		**KL divergence**		**MCS**	
			$l = 2$	$l = 3$	Node type	Edge type	# nodes	# edges
General-IED	TEGM	0.638	0.181	0.065	1.72	6.11	6.40	5.40
	FBS	0.617	0.149	0.064	1.88	**4.32**	1.65	0.67
	DoubleGAE	**0.697**	**0.273**	**0.128**	**1.66**	4.96	**16.37**	**15.63**
Car-IED	TEGM	0.588	0.162	0.044	2.92	6.60	5.67	4.78
	FBS	0.542	0.126	0.038	4.12	6.37	1.74	0.72
	DoubleGAE	**0.674**	**0.259**	**0.081**	**2.14**	**5.42**	**10.98**	**10.33**
Suicide-IED	TEGM	0.609	0.174	0.048	2.39	6.36	5.92	5.00
	FBS	0.642	0.164	0.036	2.75	**5.16**	1.67	0.75
	DoubleGAE	**0.709**	**0.290**	**0.095**	**1.76**	5.91	**6.19**	**5.28**

Table 2: The result of similarity measurement between the generated schema and test instance graphs. The best results for each dataset are highlighted in bold.

then we compute how similar these two sets are by calculating the F1 score between the two sets.

(2) *Event sequence match*. We collect all event sequences with a length of 2 or 3 from the generated schema graph and one test instance graph, respectively, and compute the F1 score between these two multi-sets.

(3) *Node/edge type distribution*. We compute the node type distribution and edge type distribution of the generated schema and one test instance graph, respectively, then compute the KL divergence between the node/edge type distributions of the schema and each test instance graph.

(4) *Maximum common subgraph* (MCS). A maximum common subgraph of two graphs is an induced subgraph of both graphs, and that has as many nodes as possible. The size of the maximum common subgraph can reflect the global structure similarity between two graphs. Therefore, we compute the number of nodes and edges of the maximum common subgraph between the schema and each test instance graph.

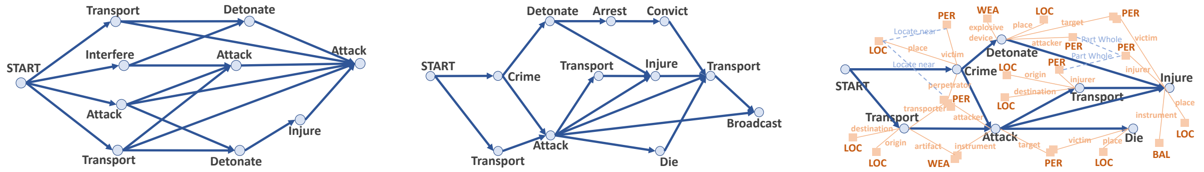
Note that the last two metrics, i.e., node/edge type distribution and maximum common subgraph, are new metrics proposed by us. We compute the above metrics between the schema and each test instance graph, then report the average values on all test instance graphs.

Hyperparameter Settings. For the high-level variational autoencoder, the dimension size of node hidden state is 256, and the dimension size of the Gaussian distribution is 56. The learning rate is 10^{-5}, and the number of training epochs is 700. For the low-level GCN autoencoder, we use a two-layer GCN as the encoder, whose dimension sizes of hidden layers are 256 and 64, respectively. The learning rate is 10^{-5}, and the number of training epochs is 500. We investigate how the size of training instance graphs and the dimension of hidden node state influence the model performance, with results shown in Appendix A.

4.4 Results

Comparison with baselines. All methods are evaluated on the same test set. Our method achieves the best performance on both original and revised datasets. We only show results on the revised dataset since it is cleaner and the induced schema is more reasonable. In Table 2, our method DoubleGAE achieves significant gains compared with baselines on event type, event sequence matching, and maximum common subgraph matching. It demonstrates that capturing the global node dependency in event graphs is essential to event schema induction. In contrast, Temporal Event Graph Model (TEGM) does not consider global graph structure, thus has a large performance gap compared to our model. It is worth noticing that Frequency-Based Sampling (FBS) is a competitive baseline according to the experimental result, especially when measured by KL divergence of edge type distribution. This is because FBS constructs an event schema exactly based on the frequency of edges in the training instance graphs.

Case study. We plot the schema skeleton generated by Temporal Event Graph Model (TEGM)



(a) A snippet of schema skeleton generated by TEGM

(b) A snippet of schema skeleton generated by DoubleGAE

(c) A snippet of complete event schema output by DoubleGAE

Figure 3: Case study on the generated event schema skeleton and full event schema.

and our model (DoubleGAE) in Figure 3. In Figure 3a, there is a recurrence of certain local structures of events within the schema. e.g., TRANSPORT-ATTACK and ATTACK-ATTACK. This demonstrates that TEGM is able to successfully capture and memorize the local structure information of event graphs. However, such learned local structures may not always be reasonable, since an ATTACK event is not likely to repeat immediately after another ATTACK multiple times. In addition, TEGM may not be able to learn the correct position of an event in the entire schema, for example, the INTERFERE event happens at the very beginning of the schema. The result indicates that TEGM fails to maintain global consistency when generating schemas. In contrast, there are no consecutively repeated events in the schema induced by our model, and the entire schema is more logically meaningful in both local and global levels.

We also present the complete schema output of our model after filling in event arguments and entity-entity relations in Figure 3c. As we can see, our model successfully identifies coreferential entities, e.g., the transporter of TRANSPORT, the perpetrator of CRIME, and the attacker of ATTACK belong to one entity. Our model is also able to add entity-entity relations between event arguments, for example, the victim of a CRIME event is "located near" the place where this CRIME event happens.

5 Related Work

Existing event schema induction methods can be classified into three categories: set-based schema, sequence-based schema, and graph-based schema.

The set-based methods represent event triggers by a set without modeling their inter-relations (Chambers, 2013; Cheung et al., 2013; Nguyen et al., 2015; Sha et al., 2016; Huang et al., 2016; Yuan et al., 2018; Huang and Ji, 2020; Shen et al., 2021; Zeng et al., 2021), which can be regarded as atomic schema induction. In contrast, we aim to induce schemas for complex events involving multiple events.

Another line of work focuses on the sequence-based methods, which takes event-event relations into account, and orders event structures into sequences (Chambers and Jurafsky, 2008, 2009; Rudinger et al., 2015; Granroth-Wilding and Clark, 2016; Pichotta and Mooney, 2016; Modi, 2016; Weber et al., 2018, 2020a). Instead of representing events as structures, some work treats events as natural language steps and induces schema knowledge through story ending prediction (Mostafazadeh et al., 2016; Weber et al., 2020b; Kwon et al., 2020), machine reading comprehension (Ostermann et al., 2018, 2019), and schema goal-step prediction (Zhang et al., 2020; Yang et al., 2021). Instead of ignoring event structures or organizing events as simple sequences, we aim to capture the multi-dimensional evolution of events, as well as the structured connections.

As a further step, researchers propose to use graphs to represent schemas (Wanzare et al., 2016; Modi et al., 2016; Li et al., 2020, 2021), where each event can be followed by multiple alternative outcomes. Li et al. (2021) introduce the concept of "complex event schema", a comprehensive graph schema consisting of both temporal orders and multi-hop argument relations, allowing time-, location-, and argument-based tracking of events. However, it adopts an auto-regressive graph generation model, which only models the first-order dependency of an event node with respect to its neighbors. In contrast, we propose to encode a global graph context via event skeleton generation using double auto-encoders.

6 Conclusion and Future Work

In this work, we propose a novel event schema induction framework using double graph autoencoders, i.e., a high-level variational graph autoencoder to learn the event skeleton, followed by a low-level GCN graph autoencoder to reconstruct entity-entity relations. Our autoencoders are able to preserve the global structural information of event graphs, thus capturing the multi-dimensional evolution of complex events, and providing global context to consolidate argument relations. Experiments demonstrate that our method significantly outperforms baselines by generating high-quality and globally consistent event schemas.

In the future, we aim to effectively induce schemas from graphs of different sizes, especially extremely large graphs. We also plan to make use of event hierarchies and induce hierarchical schemas with optimal event type granularity.

A Additional Discussions

Impact of training graph size. It is shown in Table 1 that instance event graphs consist of hundreds of nodes on average. To see if the size of training instance graphs can affect the model performance, we set a threshold for the size of training instance graphs, and only train our method on those graphs whose size is less than the given threshold. The result is presented in Figure 4a, which shows that our model achieves the best performance when the threshold is relatively small. The result demonstrates that including large training instance graphs will not help improve the model performance, because larger instance graphs may have more noisy events nodes with repeated types.

Impact of dimension of node hidden state. We also investigate the impact of dimension of node hidden state in the high-level variational graph autoencoder to model performance. The result is presented in Figure 4b, which demonstrates that our model performs best when $dim = 256$ in all three datasets, since a too large or a too small dimension will lead to performance drop due to over-fitting or under-fitting.

(b) Dimension of node hidden state

Figure 4: Impact of (a) the threshold of training instance graph size and (b) the dimension of node hidden state on DoubleGAE.

B Implementation Details

B.1 Details of Dataset Cleaning Strategy

For each complex event, we construct an instance graph, where coreferential events or entites are merged. Among the events we include those that are connected through entity coreference links, or that have temporal relationships. The graph can then be extended using related events that share arguments or that are linked by a relation. We consider isolated events to be irrelevant nodes in schema induction, therefore they are excluded from the instance graphs during graph construction. In schema graphs, type labels and node indices are used to represent each node, with mention level information ignored. Although RESIN is a state-of-the-art IE system, there still remains some errors in event temporal links. Therefore, we do human curation to remove obviously erroneous links. Below are some event-event link examples that we delete from the instance graphs: (Die, Injure), (ArrestJailDetain, Attack), (EndPosition, StartPosition), (Die, Die), (Defeat, ExchangeBuySell), (Sentence, Die), (EndPosition, Sentence), (ThreatenCoerce, ReleaseParole).

C Scientific Artifacts

C.1 RESIN Information Extraction System

Data License and Usage We obtain the code from the open-source information extraction system RESIN (Wen et al., 2021). We run the code at `https://github.com/RESIN-KAIROS/RESIN-pipeline-public`. The system is released for research purpose and is licensed under the GNU General Public License v3 or later. The system covers the general news domain and supports three languages, i.e., English, Spanish and Russian. It does not contain offensive content.

Discussions about IE Quality The performance of each component is shown in Table 3 (Wen et al., 2021). Although IE graphs are noisy, schema induction can still benefit from it. It is because that the schema induction task aims to find the recurring patterns, which will still be preserved even in the noisy data.

C.2 IED Schema Induction Corpus

Data License and Usage We obtain the dataset from the state-of-the-art graph schema induction literature (Li et al., 2021). The dataset is released for research purpose and is licensed under the GNU General Public License v3 or later. The system covers the general news domain and is an English corpus.

Data Collection We utilize the news articles in the state-of-the-art graph schema induction literature (Li et al., 2021) in `https://github.com/limanling/temporal-graph-schema`. We collect associated news articles concerning each complex event type, such as *Car-bombing IED*, using Wikipedia as a source. As a first step, we search candidate Wikipedia categories based on the name of the complex event type, and then dig deeper into each page to identify complex

events that belong to that category. Afterwards, we collect the reference news articles for each complex event, use these articles as the cluster of documents relating to the complex event, and perform IE to construct the instance graph. Using this Wikipedia-based data collection approach, we have been able to cover a wide range of scenarios, including most complex events that occur in human society, such as *Disease outbreak* and *Disaster*. Therefore, our schema induction method does not depend on manual work and is not limited to a specific complex event scenario.

CS1QA: A Dataset for Assisting Code-based Question Answering in an Introductory Programming Course

Changyoon Lee, Yeon Seonwoo, Alice Oh
School of Computing, KAIST
`changyoon.lee@kaist.ac.kr, yeon.seonwoo@kaist.ac.kr`
`alice.oh@kaist.edu`

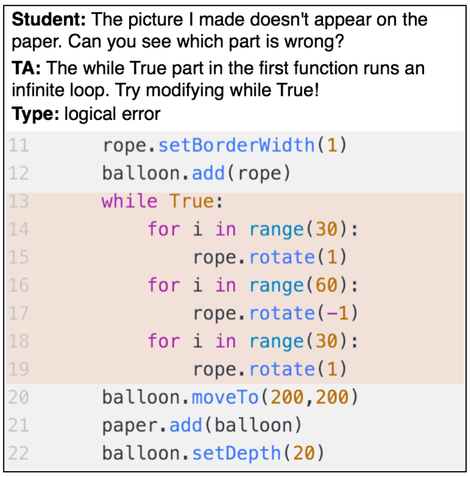
Abstract

We introduce CS1QA, a dataset for code-based question answering in the programming education domain. CS1QA consists of 9,237 question-answer pairs gathered from chat logs in an introductory programming class using Python, and 17,698 unannotated chat data with code[1]. Each question is accompanied with the student's code, and the portion of the code relevant to answering the question. We carefully design the annotation process to construct CS1QA, and analyze the collected dataset in detail. The tasks for CS1QA are to predict the question type, the relevant code snippet given the question and the code and retrieving an answer from the annotated corpus. Results for the experiments on several baseline models are reported and thoroughly analyzed. The tasks for CS1QA challenge models to understand both the code and natural language. This unique dataset can be used as a benchmark for source code comprehension and question answering in the educational setting.

1 Introduction

Question answering (QA) studies systems that understand questions and the relevant context to provide answers. Question forms include single document QA (Rajpurkar et al., 2016), multi-hop QA (Yang et al., 2018), conversational QA (Reddy et al., 2019), and open domain QA (Kwiatkowski et al., 2019). Questions about specific domains are asked in NewsQA (Trischler et al., 2016) and TechQA (Castelli et al., 2020), and images are provided with the question in visual QA (Antol et al., 2015). Another interesting field of QA asks questions about source code (Liu and Wan, 2021).

A useful application of QA is in the educational domain. Asking questions and getting the answer is an essential and efficient means of learning. In this paper, we focus on QA for programming education, where both the input modes and the domain pose interesting challenges. Answering these questions requires reading and understanding both source code and natural language questions. In addition, students' questions are often complex, demanding thorough understanding of the context such as the intention and the educational goal to answer them.



Student: The picture I made doesn't appear on the paper. Can you see which part is wrong?

TA: The while True part in the first function runs an infinite loop. Try modifying while True!

Type: logical error

```
        rope.setBorderWidth(1)
        balloon.add(rope)
        while True:
            for i in range(30):
                rope.rotate(1)
            for i in range(60):
                rope.rotate(-1)
            for i in range(30):
                rope.rotate(1)
        balloon.moveTo(200,200)
        paper.add(balloon)
        balloon.setDepth(20)
```

Figure 1: An example of our data tuple. Each data tuple consists of {question, answer, question type, code, relevant code lines}. We annotate the type of each question and the code lines (orange) relevant to the question.

Recently, models that understand programming languages (PL) have been studied, and show promising results in diverse code comprehension tasks (Alon et al., 2018; Feng et al., 2020; Guo et al., 2021). However, these models have limitations to support question answering. They are not trained on datasets containing questions about the code and are not designed for QA tasks. Also, many assume fully functional code as input, while students' code contains diverse syntax and logical errors and is often incomplete.

To address this issue, we introduce CS1QA, a new dataset with tasks for code-based question answering in programming education. Questions and answers about programming are collected from the

---

[1] The code and the data used in this paper can be found at `https://github.com/cyoon47/CS1QA`.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2026 - 2040
July 10-15, 2022 ©2022 Association for Computational Linguistics

naturally occurring chat messages between students and TAs. The question type and the code snippet relevant to answering the question are also collected. The final CS1QA dataset consists of question, question type, answer, and code annotated with relevant lines. The data is collected mostly in Korean and then machine-translated into English and quality-checked for easy application on models pretrained in English. Figure 1 shows an example of our data. We also include two-semesters' worth of TA-student chat log data consisting of 17,698 chat sessions and the corresponding code.

We design three tasks for the CS1QA dataset. Type classification task asks the model to predict the question type. Code line selection task asks the model to select lines of code that are relevant to answering the given question. Answer retrieval task finds a similar question already answered, and uses its answer as the answer to the given question. The outputs for these tasks can help the students debug their code and the TAs spend less time and effort when answering the students' questions.

Finally, we implement and test baseline models, RoBERTa (Liu et al., 2019), CodeBERT (Feng et al., 2020) and XLM-RoBERTa (Conneau et al., 2020), on the type classification and code line selection tasks. The finetuned models achieve accuracies up to 76.65% for the type classification task. The relatively low F1 scores of 57.57% for the line selection task suggest that the task is challenging for current language models. We use DPR (Karpukhin et al., 2020) to retrieve the most similar question and its answer. We compare the retrieved answer with the gold label answer, and achieve a BLEU-1 score of 13.07, which shows incompetent performance of answer retrieval on CS1QA dataset. We show with a qualitative evaluation the model behavior with different inputs for the first two tasks. Our contributions are as follows:

- We present CS1QA, a dataset containing 9,237 question-answer-code triples from a programming course, annotated with question types and relevant code lines. The dataset's contribution includes student-TA chat logs in a live classroom.
- We introduce three tasks, question type classification, code line selection and answer retrieval, that require models to comprehend the text and provide useful output for TAs and students when answering questions.
- We present the results of baseline models on the tasks. Models find the tasks in CS1QA challenging, and have much room for improvement in performance.

2 Related Work

Code-based Datasets Recently, research dealing with large amounts of source code data has gained attention. Often, the source code data is collected ad hoc for the purpose of the research (Allamanis et al., 2018; Brockschmidt et al., 2018; Clement et al., 2020). Several datasets have been released to aid research in source code comprehension, and avoid repeated crawling and processing of source code data. These datasets serve as benchmarks for different tasks that test the ability to understand code. Such datasets include: ETH Py150 corpus (Raychev et al., 2016), CodeNN (Iyer et al., 2016), CodeSearchNet (Husain et al., 2020) and CodeQA (Liu and Wan, 2021). We compare these datasets with CS1QA in Table 1.

In an educational setting, students' code presents different chracteristics from code in these datasets: 1) students' code is often incomplete, 2) there are many errors in the code, 3) students' code is generally longer than code used in existing datasets, and 4) questions and answers from students and TAs provide important additional information. In CS1QA, we present a dataset more suited for the programming education context.

Source Code Comprehension In the domain of machine learning and software engineering, understanding and representing source code using neural networks has become an important approach. Different approaches make use of different characteristics present in programming languages. One such characteristic is the rich syntactic information found in the source code's abstract syntax tree (AST). Code2seq (Alon et al., 2018) passes paths in the AST through an encoder-decoder network to represent code. The graph structure of AST has been exploited in other research for source code representation on downstream tasks such as variable misuse detection, code generation, natural language code search and program repair (Allamanis et al., 2018; Brockschmidt et al., 2018; Guo et al., 2021; Yasunaga and Liang, 2020). Source code text itself is used in models such as CodeBERT (Feng et al., 2020), CuBERT (Kanade et al., 2020) and DeepFix (Gupta et al., 2017) for use in tasks such

Dataset	Programming Language	Data Format	Dataset Size	Data Source
ETH Py150	Python	Parsed AST	7.4M files	GitHub
CodeNN	C#, SQL	Title, question, answer	∼187,000 pairs	StackOverflow
CodeSearchNet	Go, Java, JavaScript, PHP, Python, Ruby	Comment, code	∼2M pairs	GitHub
CodeQA	Java, Python	Question, answer, code	∼190,000 pairs	GitHub
CS1QA	Python	Chat log, question, answer, type, code	9,237 pairs	Real-world classroom

Table 1: Comparison between different code-based datasets and CS1QA.

as natural language code search, finding function-docstring mismatch and program repair.

The tasks that these methods are trained on target expert software engineers and programmers who can gain significant benefit with support by the model. On the other hand, students learning programming have different objectives and require fitting support by the models. Rather than getting an answer quickly, students seek to Students ask lots of questions while learning, and thus question answering for code is needed. CS1QA focuses on code-based question answering and can be used as training data and a benchmark for neural models in an education setting. The CS1QA data can also be used for other tasks than QA, such as program repair and code search.

3 CS1QA Dataset

3.1 Data Source

The data for CS1QA is collected from an introductory programming course conducted online. Students complete lab sessions consisting of several programming tasks and students and TAs ask questions to each other using a synchronous chat feature. We make use of the chat logs as the source for the natural question and the corresponding answer. These chat logs are either in Korean or in English. The student's code history is also stored for each programming task for every keystroke the student makes. This allows us to extract the code status at the exact time the question is asked, which provides valuable context for the question. We take this code as the context for the given question. The thorough code history and the student-TA chat logs are a unique and important contribution of CS1QA. CS1QA also contributes with data from multiple students working on the same set of problems.

3.2 Question Type Categorization

Answering different types of questions requires understanding the different intentions and information - answering questions about errors requires identifying the erroneous code and answering questions about algorithms requires understanding the overall program flow. As the different question types affect the answering approach and location of code to look at, knowing them in advance can be beneficial in the QA and code selection tasks.

Allamanis and Sutton (2013) have categorized questions asking for help in coding on Stack Overflow into five types. We adapt these types to students' questions. In addition, we define the "Task" type that asks about the requirements of the task. TAs' question types are derived from the official instructions by the course instructors given in the beginning of the semester. TAs were instructed to ask questions that gauge students' understanding of their implementation, for example by asking the meaning of the code and reasoning behind the implementation. TAs' probing questions are categorized into five types: *Comparison*, *Reasoning*, *Explanation*, *Meaning*, and *Guiding*. Examples for the question types can be found in Table 2. We present intentions of the question types in Table 3.

3.3 Collecting Question-Answer Pairs with Question Types

We collected a total of 5,565 chat logs over the course of one semester from 474 students and 47 TAs. After removing the logs where the TA did not participate in the chat, 4,883 chat logs remained.

We employed crowdworkers with self-reported skill in Python of three or higher on a 5-point Likert Scale to collect the questions. Each worker first selected messages in the chat log corresponding to the question and the answer, then selected the question type. Workers were provided with descriptions of the question types with examples before working on the task. Workers were asked to divide the message into individual questions when there were multiple questions or answers in the message. They were instructed to only choose programming related questions, for which the answer is obvious in the chat from the question alone. This ensures that the questions and answers are independent from the

Question Type	Allamanis' Type	Question	Answer
Code Understanding	How/why something works	Why is the print cards function at the bottom of the check function? Can I not have it?	This is because if two cards match through a check, you have to show them two cards.
Logical Error	Do not work	Now, the file is created, but when I go inside and look at the value, it seems to be a little different from the one requested in the problem.	You seem to have forgotten the line break in the middle I think you can add \n
Error	Do not work	I don't know where the task 2 error came from....	When creating image There is a negative number in the image size Please do something like absolute value
Function/Syntax Usage	Way of using	And I forgot how to make a blank image	Blank images can be created with new_img= create_picture(width,height)!
Algorithm	How to implement	So, what if there is any other way to count the number including the number not included in the randomly created list?	Parameter: a list which is returned from drawing_integers Count integers function is supposed to take that as input
Task	-	Isn't it a task in which the number of iteration steps changes according to the input value?	Yes, but the value of x must also change according to the input value!
Comparison	-	How was the method of reading and writing different in task1?	There was a difference between read mode and write mode, open(file name, r) and open (file name, w)
Reasoning	-	I've read the task1 code. What is the intention of using continue on line 55?	This is to go back to the beginning without executing the next print function.
Explanation	-	How do you create new_img when 'horizontal' is input as Direction in Task2?	I did it like I did with vertical, but since the y value is changing, when I change the y value and run the loop, I did x first among x and y.
Meaning	-	Can you explain the role of the global keyword in Task 1?	If you use a variable specified only within a function, it cannot be used in other functions, so I used it for global variable processing!
Guiding	-	Is there a simpler way to change average_integers using a function already defined in the python list??	In average_integers, it would be more convenient to use the len function when counting the total number of elements.

Table 2: Examples of translated and untranslated question and answer texts for each question type in CS1QA. First column shows our type classification, and second column shows the classification by Allamanis and Sutton (2013). The first six rows in the top part are student question types, the last five rows in the bottom part are TA's probing question types.

chat history. Every chat log was annotated by two workers to ensure the quality of annotation. A total of 20,403 question-answer pairs were collected.

The question and answer texts are machine-translated using Google's Neural Machine Translation model (Wu et al., 2016) from Korean to English to form the dataset in two languages. The translation allows for easy integration of CS1QA data to models pretrained in English, which make up a huge portion of NLP models.

3.4 Selecting Code Lines

Providing relevant code snippets allows the answerer to identify the problem more quickly and easily. We annotate the lines of code that provide information necessary to answer the question for use in the code line selection task.

We collected code for all questions asked by students. For the TA probing questions, we collected code for all *Reasoning* and *Meaning* types, and 472 randomly selected *Explanation* questions, for a total of 4677 questions. This keeps a balance in the number of questions for each type. *Comparison* questions were left out as they require comparison of code across different tasks, making the annotation and the tasks too complicated. We exclude *Guiding* questions as answering them requires more than just understanding code; the answer is often new algorithms not based on the current code.

We employed crowdworkers who have worked as TAs for the programming course to select the code that the questions refer to. We provided the workers with the collected questions, answers, and the student's code for each task at the time the question was asked. The workers selected the code file for the question and the relevant code lines to answer the question. When reading the code was not necessary to answer the question, the workers were asked to choose *Not Applicable (NA)* for the code selection. For every question, two workers made code annotations.

A total of 9,359 code selections were made by the workers. Some of the selections with empty code or incorrectly extracted code were removed from the dataset. The remaining 9,237 questions annotated with type, lab and task numbers, code, code lines and answer make up the final CS1QA dataset. Every code selection made by the workers is used as gold labels even if the two workers choose different lines. Thus, every question can have up to two correct code selections in different parts of code. An example of the data is found in Appendix A.

	Q Type	Intention	# Q	# Code	NA (%)	Span (%)
S	Code Understanding	Understanding the functionality of the code	105	209	33.9	11.0
	Logical Error	Investigating the cause of the unexpected outputs of the code	541	1060	16.7	21.6
	Error	Resolving syntax errors and exceptions	488	959	10.1	13.0
	Function/ Syntax Usage	Learning correct usage of a function or syntax	411	811	55.4	11.8
	Algorithm	Learning the underlying algorithm for the task	603	1194	50.0	19.3
	Task	Confirming the goal and requirement of the task	677	1322	82.3	15.3
T	Reasoning	Understanding the reasoning behind student's implementation	402	799	5.6	21.8
	Explanation	Checking the validity of student's explanation of their code	472	940	2.6	42.8
	Meaning	Checking the meaning of a function or a variable in the code	978	1943	2.1	24.2

Table 3: Types of questions asked by students (S) and TAs (T) in a programming class. Questions are categorized by different intention and information required to answer them. The number of questions and code snippets collected from the annotators, percentage of *Not applicable* code selections and selected code lines are reported.

3.5 Quality Control and Validation

As the workers worked independently, there were some differences in the annotated data even when they correspond to the same question. There were some questions that were selected by only one worker as well. These questions are further reviewed to ensure the quality of the collected dataset.

Out of 20,403 collected questions, 3,556 questions were selected by only one worker, and 4,787 pairs of questions had some differences between the workers' selections. The remaining questions had perfect agreement between the workers. The authors reviewed questions selected by only one worker, and those without perfect agreement. Unnecessary words present in only one text were removed and crucial words missing in the question were added to the text while preserving the meaning to make the two texts equal. The conflicts in question types were resolved with the authors' additional vote that made a clear majority in the type selection.

We calculate the inter-rater reliability score with Cohen's Kappa (Cohen, 1960) for the question type selection. The Kappa value is calculated between every pair of workers who selected the same question-answer pairs. The mean of the Kappa values is 0.657, which suggests substantial agreement for type classification between the annotators.

Out of 9,237 questions with code line selection, 2,197 pairs had perfect agreement (100% overlap), while 1,225 pairs had 0% overlap. We compute the mean line F1 as the measure for agreement of spans, considering one annotator's span selection as the ground truth and the other annotator's selection as prediction. The resulting F1 score is 0.6482. The disagreements are largely due to selecting different but relevant code and selecting different amounts of surrounding context in the code.

4 Task Definition

We design three tasks for the CS1QA dataset that identify important information that leads to the answer.

The type classification task is to predict the question's type. We use nine types of questions that we categorized as the candidates for classification, each question belonging to a single type. We use the accuracy and macro F1 score as the measure of performance. The code line selection task is to select lines of code that give relevant information to answer the question. The code is a strong supporting context to answering the given question, and this task tests the model's ability to retrieve this critical information.

For the code line selection task, we use the Exact Match (EM) and line F1 score as the measure of performance, same as the metrics used for supporting fact selection task in HotpotQA (Yang et al., 2018). The EM score measures the proportion of selections that exactly match the ground truth. The line F1 score measures the average overlap between the selected lines and the ground truth selections. The score is computed by treating the selections as bags of lines and calculating their F1 with the annotated lines. These two tasks take as inputs the lab and task numbers of the question, the questioner (student or TA), question and the code texts.

The answer retrieval task retrieves a similar question given an unseen question, and uses the retrieved question's answer as the answer to the unseen question. BLEU score is calculated between the retrieved answer and the gold label answer.

Answer generation task given the question and the code context is possible with CS1QA dataset. However, meaningfully generating the answer demands a model that understands long and erroneous code, and the natural language question. This poses a significant challenge, and we leave the generation task as future work.

5 Dataset Analysis

644 out of 9,237 questions are originally asked in English, while the rest are asked in Korean. The CS1QA dataset is split into train, development and test sets in the ratio of 0.6, 0.2 and 0.2 respectively, keeping the ratio of question types in each set the same to ensure equal distribution in all three sets.

5.1 Text Lengths

Table 4 shows the statistics of question and answer token lengths, for data translated to English (EN) and the original (ORIG) data, and the number of lines of code.

	Data	Min	Max	Mean	Median
Question	EN	1	119	15.7	13
	ORIG	1	79	10.9	9
Answer	EN	1	272	27.2	22
	ORIG	1	166	17.6	14
Code	-	1	655	76.0	52

Table 4: Statistics of question, answer lengths in tokens and code length in number of lines in CS1QA.

The lengths of questions and answers lie mostly between 10 to 30 tokens. The distributions show long tails for both questions and answers, but answers are more evenly distributed. The distribution of token lengths for questions and answers can be found in Appendix B.

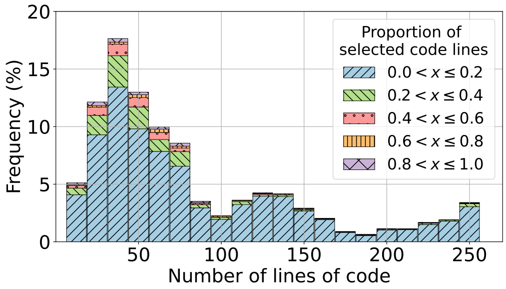


Figure 2: The total number of lines in code and the proportion of selected code lines in code (color coded). The last bin contains all code longer than 250 lines.

The number of lines of code shows a peak between 12.5 and 50, as shown in Figure 2. Code snippets have a wider distribution in length. This can be the result of varying difficulties of tasks, with more difficult tasks requiring longer code snippets to solve. The number of lines of code in CS1QA is larger than those in other code-based datasets, which can present interesting challenges.

5.2 Question Type Distribution

We present the distribution of question types in Table 3 in number of questions collected and number of code snippets collected.

The CS1QA dataset contains similar number of questions for each student type of questions, except for *Code Understanding* type, which contains significantly fewer questions. One plausible reason for this is that most of the tasks require writing the program from scratch, thus students ask fewer questions about the skeleton code.

There are more *Meaning* questions than other types of TAs' probing questions. This can be because TAs often ask the students about the meanings of functions and variables to make sure that the students understand the code they wrote for each task.

5.3 Code Line Distribution

The average number of selected code lines is 13.0. A majority of the questions can be answered by looking at fewer than 20 lines of code. The number of selected code lines can be a gauge of the difficulty of answering the questions; a longer selection means that one has to read and understand a larger amount of code. The detailed distribution of code lines and code lengths can be found in Appendix B. Figure 2 shows the percentage of selected code lines. The graph shows that majority of the selected code lines are less than 20% of the total number of lines of code.

The proportion of *Not applicable* code selections differ by question types, as shown in Table 3. As TAs ask questions about the implementation details, answering most of them requires looking at the code. On the other hand, students often ask about the approach to the problems and implementation. These questions have less basis on the code and often refer to shorter spans where an error occurs or a function is used. Thus finding the relevant code takes more effort, although answering them requires looking at less code on average.

5.4 Machine Translation Quality

We have employed 16 workers who are fluent in both Korean and English to check the quality of the machine translation of sampled questions and answers. Each worker checked the quality of 8 question-answer pairs per question type. Each pair was checked by at least two workers. Workers compared the original and the translated texts, and gave scores to four statements on a 5-point Likert scale, with 1 being disagree/bad and 5 being agree/good. The statements were: 1) I can understand the translation, 2) The translation has similar meaning to the original text, 3) The translation contains grammatical and lexical errors, and 4) Overall translation quality. The mean scores between workers for each statement were 4.37, 4.11, 2.06 and 3.92 respectively. The results suggest that the translation was overall in good quality, with high understandability and similar meaning to the original text. The translation contains grammatical or lexical errors, but not to a significant extent.

6 Experimental Setup

We select three baseline models, CodeBERT, RoBERTa and XLM-RoBERTa, and test their performance on the type classification and code line selection tasks. CodeBERT model is selected to test the effectiveness of pretraining on NL-PL paired data. Other models based on syntactic structures of code cannot take students' erroneous code as input. RoBERTa and XLM-RoBERTa models are selected to test the performance of NL-based models, for translated and untranslated data respectively. Questions translated to English are provided to the two models pretrained in English, CodeBERT and RoBERTa. XLM-RoBERTa model receives the untranslated questions as input to compare the performance when using the untranslated data. We used the default hyperparameters used in CodeBERT for training. The tokenizers encode newline token to maintain the code's structure in the tokenized text. For the code line task, we also test the performance of the naive baseline, which selects the middle 60 lines of code, which showed the best performance among different numbers of lines, as the output.

Since the token lengths for code in CS1QA are greater than the limit of the transformer-based models, we preprocess the input to fit within the token length limit. We split the code into smaller segments so that the combined length of the split segment and the question is within the limit. For type classification, the type with the most number of votes is selected as the final selection. For code line selection, the model chooses a start and end token position from each segment. The lines between the start and end tokens are given as the output for the segment, and the union of segment outputs is given as the final selection for the question. N/A is given as the output when 1) the end position is before the start position, 2) either the start or the end position is 0 ([CLS] token), or 3) either the start or the end position is out of range.

For the answer retrieval task, we train the DPR by taking the questions as the passages. We use the question with the highest BM25 score in the corpus set as the gold label for the questions in the training set. For testing, the most similar question in the corpus is retrieved using the trained DPR with the new question as the query. The retrieved answer is used as the answer to the new question verbatim.

7 Results

We report the mean score from three runs with different seeds for all experiments. The test score is reported on the best-performing epoch out of 10 on the development set.

7.1 Type Classification

The results of our baseline models on type classification are shown in Table 5. The models learn to predict the question types with relatively high accuracy, but there is still a room for improvement.

Model	Dev		Test		Q only	
	Acc	F1	Acc	F1	Acc	F1
RoBERTa	**77.57**	**72.31**	**76.65**	**71.10**	75.74	**69.40**
CodeBERT	76.20	69.09	75.65	70.13	74.75	67.07
XLM-R	72.60	67.88	72.62	66.19	**76.18**	68.68

Table 5: Type classification task scores for the three baseline models. Q only column shows the test scores with only the question text as the input.

The class-wise classification F1 scores in Table 6 shows a significant drop for 'understanding' type when code is not provided. The low number of

		Understanding	Logical	Error	Usage	Algorithm	Task	Reasoning	Explanation	Meaning
RoBERTa	w/ code	29.26	70.53	77.14	53.23	60.22	66.95	96.41	91.59	95.26
	w/o code	21.99	70.76	76.39	50.87	67.96	68.64	95.32	88.35	94.38
CodeBERT	w/ code	28.80	68.35	74.46	54.29	61.77	66.26	95.94	87.87	93.80
	w/o code	13.63	67.91	74.77	44.07	59.93	65.49	95.96	87.91	93.98
XLM-R	w/ code	15.12	68.13	72.26	46.87	59.22	61.88	93.83	86.32	92.12
	w/o code	9.70	71.40	75.20	53.04	61.42	67.05	97.44	88.77	94.12

Table 6: Class-wise F1 scores on test set for type classification for baseline models

		Understanding	Logical	Error	Usage	Algorithm	Task	Reasoning	Explanation	Meaning
RoBERTa	w/ code	30.89	72.64	77.09	53.18	59.95	68.06	96.96	90.62	95.00
	w/o code	33.16	72.67	77.45	53.37	59.46	66.40	96.15	90.05	94.44
CodeBERT	w/ code	28.93	68.82	76.87	54.53	60.02	64.35	95.94	87.42	94.81
	w/o code	30.33	65.67	72.85	54.65	60.97	67.60	96.19	88.48	94.96
XLM-R	w/ code	25.02	73.44	76.80	52.77	62.13	67.21	95.90	87.92	94.21
	w/o code	28.77	69.68	77.39	54.83	59.23	67.29	96.70	88.17	93.91

Table 7: Class-wise F1 scores on test set for type classification for baseline models trained with augmented data.

questions for the understanding type might be the reason, thus we augment the dataset with generated understanding type questions. The common question templates for understanding type questions are extracted, and keywords in the question are randomly replaced with keywords in a randomly chosen code in the dataset. The generated question and the chosen code are given as the input to the models. The question templates are provided in Appendix C. The class-wise classification F1 scores are reported in Table 7. The difference in scores depending on the presence of code is reduced, and overall performance increases. The results suggest that presence of code does not significantly affect the type classification performance. This is expected, as the question type annotation was conducted without providing the code.

Model	Dev		Test		Valid Line	
	EM	F1	EM	F1	EM	F1
Naive	1.08	23.97	0.65	21.84	0.90	30.42
RoBERTa	**46.62**	**62.61**	**41.80**	**57.57**	**22.02**	43.50
CodeBERT	42.00	57.74	38.95	54.06	16.42	37.12
XLM-R	42.57	58.63	39.14	55.40	21.85	**43.90**

Table 8: The naive and three baseline models' scores on line selection task.

7.2 Code Line Selection

The results of our baseline models on line selection are shown in Table 8. We also conduct another set of experiments with questions with N/A line selection removed (Valid Line column). The drop in scores on the code with valid line selections shows that large portion of the scores come from the model correctly identifying N/A selections.

The naive baseline performance is much worse than the models' performance, which suggests that line selection task is not trivially solved. The relatively low scores on the tasks for CS1QA suggest that they are challenging for models built for natural language understanding. CodeBERT's performance is not superior for the span selection task even though the model was pretrained on code and natural language together. This suggests that CodeBERT's pretraining objective is not appropriate for the CS1QA tasks.

7.3 Answer Retrieval

The mean BLEU-1 score that compare the answers for the questions in the test set is 13.07. This shows that a simple retrieval based answering system is not sufficient for answering students' questions. The code provides important context to generate accurate answers, and the answer likely differs even for the same question, depending on the code.

The mean BLEU score for TA's probing questions is 18.48, while that for student-asked questions is 8.91. This suggests that the TAs tend to ask similar questions that have similar answers, while students' questions vary more with largely different answers.

7.4 Qualitative Analysis

In order to better understand the baseline models' behavior, we analyze the output type classifications and line selections for 180 questions, 20 per question type.

For type classification, most of the 'why' questions from students are classified as 'logical error' or 'error' types. These questions are often phrased as "I don't know why…" or "why something doesn't work". This leads to relatively high scores for the two error types. 84% of the 'why' questions were classified into the two types. 15 questions were correctly classified.

Keyword matching for line selection task accounts for approximately 54% of line selections. When a function name or variable name is mentioned in the question, the selected code lines often include the mentioned name. However, this tactic sometimes fools the model into selecting more lines than necessary. This was more frequently observed for *Meaning* and *Function/Syntax Usage* tasks, where 94% and 75% of the line selections included the keyword.

8 Conclusion

In this paper, we present CS1QA, a dataset for code-based question answering in introductory programming course. CS1QA's crowdsourced data from a programming course provide rich information that code understanding models need to consider to correctly answer the given questions. We introduce three tasks for CS1QA, whose output can help students debug and reduce workloads for the teaching staff. Results from the baseline models indicate that tasks for CS1QA are challenging for current language understanding models. CS1QA promotes further research to better represent and understand source code for code-based question answering.

As CS1QA data deliver the full context of the questions, the answer texts in CS1QA can be used as training and testing data for an answer generation task in the future. Although the generation task is difficult and demands new code representation and processing methods, models that show good performance on it will allow a new level of automation in code-based QA. We hope that CS1QA will bring research interest in the domain of code understanding for question answering.

9 Ethical Consideration

All students and TAs, whose chat logs and code are used to build the dataset, have given permission to use these data for research purposes prior to this research. No disadvantage was given to any student or TAs for not providing their data for this research. The IRB at our university approved the annotation experiments conducted in this research.

The annotators were compensated appropriately for their participation in the experiments. Compensation was determined to meet the minimum wage requirements. For the experiment collecting question-answer pairs with question types, the workers were paid $9 for the first 50 chat logs marked and $13.50 for every 50 chat logs marked afterwards. It took less than an hour to complete annotations for 50 chat logs on average. For the experiment collecting the code lines, the workers were paid $0.45 for every code annotation made. Workers were able to complete approximately 30 selections in an hour on average. For the experiment testing the effectiveness of providing relevant code lines on answering the questions, the participants were paid $13.50 to answer 48 questions by the students. It took approximately an hour for each participant to finish answering all 48 questions.

The authors made their best efforts to anonymize the dataset and remove all personal information such as student ID and phone number from the dataset.

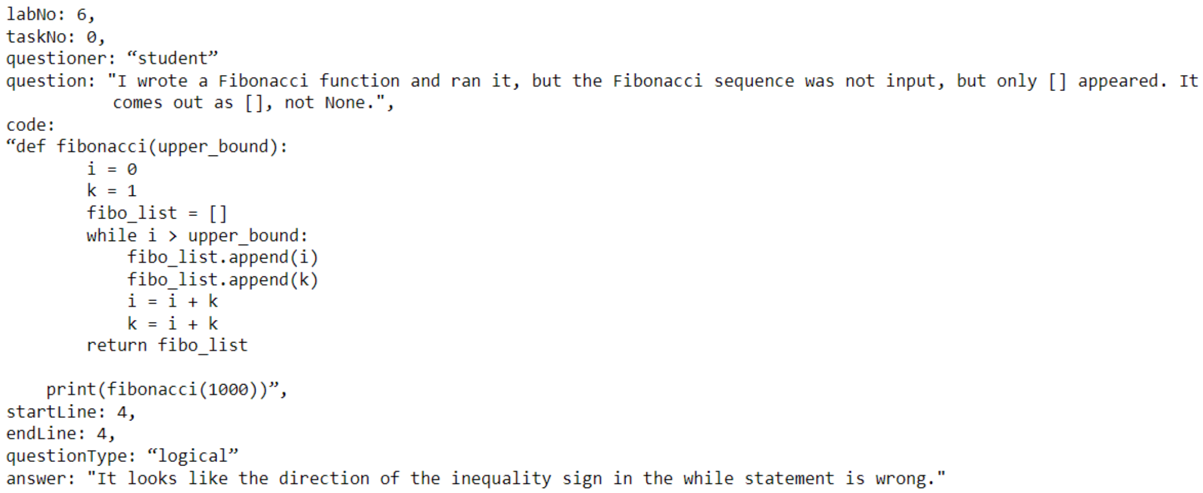
Appendix

A Example data in CS1QA

We present an example of a question in the CS1QA dataset in Figure 3.



```
labNo: 6,
taskNo: 0,
questioner: “student”
question: "I wrote a Fibonacci function and ran it, but the Fibonacci sequence was not input, but only [] appeared. It
          comes out as [], not None.",
code:
“def fibonacci(upper_bound):
        i = 0
        k = 1
        fibo_list = []
        while i > upper_bound:
            fibo_list.append(i)
            fibo_list.append(k)
            i = i + k
            k = i + k
        return fibo_list

    print(fibonacci(1000))”,
startLine: 4,
endLine: 4,
questionType: “logical”
answer: "It looks like the direction of the inequality sign in the while statement is wrong."
```

Figure 3: An example of the data in CS1QA. Note that taskNo, startLine and endLine variables count from 0. The code is prettified for readability.

B Distribution of Question, Answer and Code Lengths

Figures 4 and 5 show the distribution of question lengths for questions translated to English and original questions respectively.

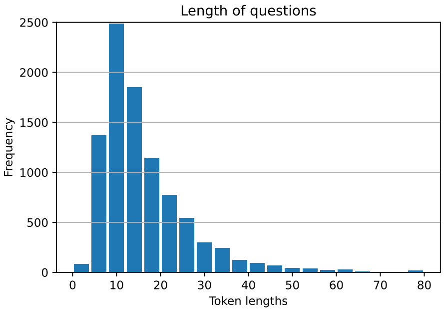


Figure 4: The distribution of question lengths translated to English in number of white space separated tokens. The last bin contains all questions longer than 80 tokens.

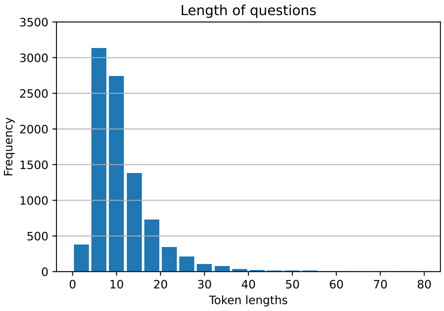

Figure 5: The distribution of original question lengths in number of white space separated tokens. The last bin contains all questions longer than 80 tokens.

Figures 6 and 7 show the distribution of answer lengths for answers translated to English and original answers respectively.

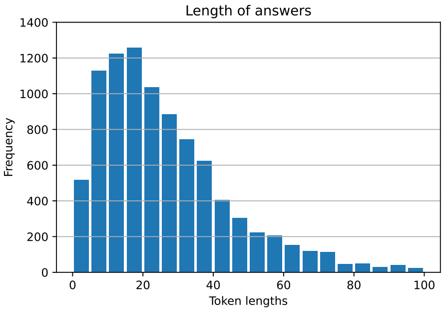

Figure 6: The distribution of answer lengths in number of white space separated tokens. The last bin contains all answers longer than 100 tokens.

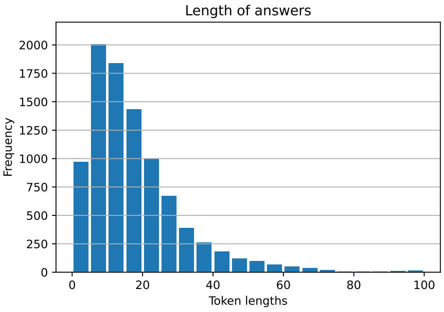

Figure 7: The distribution of original answer lengths in number of white space separated tokens. The last bin contains all answers longer than 100 tokens.

Figure 8 shows the distribution of number of lines in the selected code spans. Figure 9 shows the distribution of proportions of the code lines that is included in the selected code span.

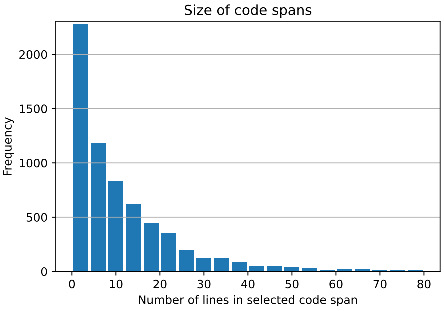

Figure 8: The distribution of number of lines selected in code spans. The last bin contains all selections with more than 80 lines of code.

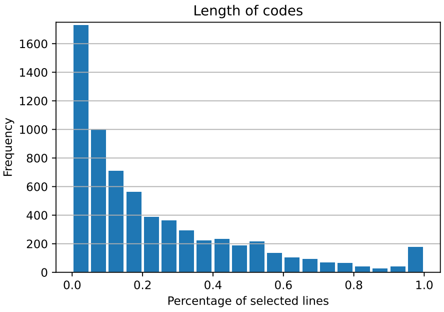

Figure 9: The distribution of the percentage of selected code lines in code.

C Question Templates for Understanding Type Questions

The templates used for augmenting CS1QA dataset with understanding type questions are presented in Table 9. The keywords variable, function, and snippet are extracted from the randomly chosen code in the dataset. Variable is a random token, function is a random function name, and snippet is a random line of code. In the last template, one of the words list, dictionary, variable, function is chosen randomly to complete the template.

Template format
What does [variable, function] mean?
What does [variable, function] refer to?
What's the meaning of [variable, function]
What does [function] do?
Can you explain what [function] does?
Can you describe what [function] is doing?
How do I use [function]?
How to use [function]?
I don't understand [snippet].
What is [function]?
Should I use [function, snippet]?
Why do you do [snippet]?
Is [variable, function] a {list, dictionary, variable, function}?

Table 9: Templates used for the question augmentation for Understanding type questions. The keywords in square brackets are chosen from a randomly chosen code in the dataset. The words in curly brackets are randomly chosen.

D Experiment Details

We ran the experiments for RoBERTa-base, CodeBERT-base and XLM-RoBERTa model on 4 Quadro RTX 8000 GPUs. We ran 10 epochs for fine-tuning the models. All of these models were released with MIT License, and our use is consistent with the license.

For all models, we used the batch size of 32 for training, evaluating and testing.

The average runtime for each epoch for RoBERTa-base and CodeBERT-base models is approximately 1 hour for training, and 1 minute for evaluating and testing. For XLM-RoBERTa-base model, the average runtime for each epoch is approximately 3.3 minutes hour for training and 0.5 minute for evaluating and testing.

The number of parameters for RoBERTa-base, CodeBERT-base and XLM-RoBERTa models are 125M, 125M and 270M respectively.

E Annotation Interface

We present the annotation interface used to collect the question, answer, and question type in Figure 10. Annotators can choose the messages corresponding to the question or answer text, and modify the texts in the interface. Annotators also select a question type for every question.

이부분을 참고해서 생각해보면 어떨까요!

Task 2 질문입니다.
randint(a, b) 함수의 출력(return 값)은 무엇인지 입력값과 연관지어 설명해 주세요.
답변은 잘 생각해 보시고 천천히 해 주시면 됩니다.

네

task2 먼저 답변해도 될까요

네넹

randint(a,b)를 하게되면 a<= x <=b 사이의 정수를

랜덤해서 하나를 뽑아 출력하게됩니다

Task 3에서는 게임을 약간 매운맛으로

틀렸을때 다시 보여주지 않게 바꿔볼수있을까요

!!

오...

악랄하군요

프린트 카드를 삭제하면 될거 같긴한데

조금 더 고려를 해봐야될 것 같습니다

그거 고쳐보시면 될 거 같아용

사실 1번은

f[i]+f[i+1] 대신

Abstract

Providing technologies to communities or domains where training data is scarce or protected e.g., for privacy reasons, is becoming increasingly important. To that end, we generalise methods for unsupervised transfer from multiple input models for structured prediction. We show that the means of aggregating over the input models is critical, and that multiplying marginal probabilities of substructures to obtain high-probability structures for distant supervision is substantially better than taking the union of such structures over the input models, as done in prior work. Testing on 18 languages, we demonstrate that the method works in a cross-lingual setting, considering both dependency parsing and part-of-speech structured prediction problems. Our analyses show that the proposed method produces less noisy labels for the distant supervision.[1]

1 Introduction

Recent successes of NLP systems have been enabled by supervised learning algorithms requiring a large amount of labelled data. Creating such data can be costly for structured prediction tasks such as dependency parsing (Böhmová et al., 2003; Brants et al., 2003). Transfer learning (Pan and Yang, 2010) is a promising solution to this problem. In this work, we focus on a case of transfer learning, namely cross-lingual learning. We consider the setup where the target language is low-resource having only unlabelled data, commonly referred to as unsupervised cross-lingual transfer. This is an important problem because most world's languages are low-resource (Joshi et al., 2020). Successful transfer from high-resource languages enables language technologies development for these low-resource languages.

One recent method for unsupervised cross-lingual transfer is PPTX (Kurniawan et al., 2021). Developed for dependency parsing, it transfers from multiple source languages, which has been shown to be superior to transferring from just a single language (McDonald et al., 2011; Duong et al., 2015; Rahimi et al., 2019, *inter alia*). PPTX computes the union of high-probability trees from all source parsers and uses the result as supervision to train the target language parser. One advantage is that, in addition to not requiring labelled data in the target language, it does not require any data in the source languages either, which is useful if such data is private. All it needs is access to multiple, trained source parsers. Despite its benefits, PPTX has only been applied to dependency parsing, although in principle it should be extensible to other structured prediction problems. More concerningly, we show in this work that PPTX generally underperforms compared to a majority voting baseline.

In this paper, we generalise and improve PPTX for structured prediction problems. As with PPTX, this generalisation casts the unsupervised transfer problem as a supervised learning task with distant supervision, where the label of each sample in the target language is based on the structures predicted by an ensemble of source models. Moreover, we propose the use of logarithmic opinion pooling (Heskes, 1998) to improve performance (see Fig. 1). Unlike PPTX that performs simple union, the pooling considers the output probabilities in aggregating the source model outputs to obtain the structures used for distant supervision. We test our method on 18 languages from 5 language families and on two structured prediction tasks in NLP: dependency parsing and POS tagging. We find that our method generally outperforms both PPTX and the majority voting baseline, with absolute accuracy gains of up to 7 % on parsing and 20 % on tagging. Our analysis shows that the use of logarithmic opinion pooling results in fewer predicted

structures that are also more concentrated on the correct ones.

In summary, our contributions in this paper are:

1. developing a generic unsupervised multi-source transfer method for structured prediction problems;
2. leveraging logarithmic opinion pooling to take into account source model probabilities in the aggregation to produce the labels for distant supervision; and
3. outperforming previous work in dependency parsing and part-of-speech tagging, especially in the context of a stronger, multi-source transfer baseline.

2 Unsupervised Transfer as Supervised Learning

Suppose we want to create a model for a low-resource language that has only unlabelled data, but we only have access to a set of models trained on other languages. This is an instance of cross-lingual transfer learning. We cast this problem as a (distantly) supervised learning task with the training objective

$$\ell(\boldsymbol{\theta}) = -\sum_{\boldsymbol{x} \in \mathcal{D}} \log \sum_{\boldsymbol{y} \in \tilde{\mathcal{Y}}(\boldsymbol{x})} p(\boldsymbol{y} \mid \boldsymbol{x}; \boldsymbol{\theta}) \qquad (1)$$

where $\boldsymbol{\theta}$ is the target model parameters, $\mathcal{D}$ is the unlabelled target data, and $\tilde{\mathcal{Y}}(\boldsymbol{x})$ is a set of distant supervision labels for an unlabelled input $\boldsymbol{x} = x_1 x_2 \cdots x_n$. Thus, $\tilde{\mathcal{Y}}(\boldsymbol{x})$ contains supervision in the form of one or more potentially ambiguous/uncertain labels. In single-source transfer, $\tilde{\mathcal{Y}}(\boldsymbol{x})$ can be as simple as a singleton containing the predicted label for $\boldsymbol{x}$ by the source model, in which case this is related to self-training (McClosky et al., 2006). In our case, however, this supervision is assumed to arise from an ensemble of models, each is based on transfer from a different source language (Section 2.1). Optionally, the parameters $\boldsymbol{\theta}$ can be initialised to the source model parameters (or the parameters of one of the source models in the multi-source case) and regularised to this initialiser during training, in order to both speed up training and encourage the parameters to stay near known good parameter values. Overall, the objective becomes $\ell'(\boldsymbol{\theta}) = \ell(\boldsymbol{\theta}) + \lambda \|\boldsymbol{\theta} - \boldsymbol{\theta}_0\|_2^2$ where $\boldsymbol{\theta}_0$ is the source model parameters and λ is a hyperparameter controlling the regularisation strength.

2.1 Supervision via Ensemble

In multi-source transfer, the set $\tilde{\mathcal{Y}}(\boldsymbol{x})$ can be obtained by an ensemble method applied to the source models. PPTX (Kurniawan et al., 2021) is one such method designed for arc-factored dependency parsers. We generalise PPTX, making it applicable to any set of source models that predict structured outputs that decompose into substructures (of which a set of arc-factored dependency parsers is a special case). For the rest of this paper, we assume that the source models are graphical models over these structured outputs. Let $C(\boldsymbol{x}, j)$ denote the set of substructures associated with x_j whose marginal probabilities form a probability distribution:

$$\sum_{c \in C(\boldsymbol{x}, j)} p^{(k)}(c \mid \boldsymbol{x}) = 1$$

for any source model k. For example, for dependency parsing, $C(\boldsymbol{x}, j)$ is the set of arcs whose dependent is x_j (see Fig. 1 part ②). The chart $\tilde{\mathcal{Y}}(\boldsymbol{x})$ can then be obtained as follows. Define $\tilde{A}_k(\boldsymbol{x}, j)$ to be the set of substructures associated with x_j having high marginal probability under source model k. This set is obtained by adding substructures $c \in C(\boldsymbol{x}, j)$ in descending order of their marginal probability until their cumulative probability exceeds a threshold σ:

$$\sum_{c \in C(\boldsymbol{x}, j)} p^{(k)}(c \mid \boldsymbol{x}) \geq \sigma \qquad (2)$$

where $0 \le \sigma \le 1$. Therefore, $\tilde{A}_k(\boldsymbol{x}, j)$ contains the substructures that cover at least σ probability mass of the output space under source model k. Next, define

$$\tilde{A}(\boldsymbol{x}) = \bigcup_{k,j} \tilde{A}_k(\boldsymbol{x}, j) \tag{3}$$

as the set of high probability substructures for $\boldsymbol{x}$ given by the source models. The chart $\tilde{\mathcal{Y}}(\boldsymbol{x})$ is then defined as the set of structures whose substructures are all in $\tilde{A}(\boldsymbol{x})$. Formally,

$$\tilde{\mathcal{Y}}(\boldsymbol{x}) = \{\boldsymbol{y} \mid \boldsymbol{y} \in \mathcal{Y}(\boldsymbol{x}) \wedge A(\boldsymbol{y}) \subseteq \tilde{A}(\boldsymbol{x})\}$$

where $\mathcal{Y}(\boldsymbol{x})$ is the output space of $\boldsymbol{x}$ and $A(\boldsymbol{y})$ is the set of substructures in $\boldsymbol{y}$. To prevent $\tilde{\mathcal{Y}}(\boldsymbol{x})$ from being empty, the 1-best structure $\hat{\boldsymbol{y}} = \arg\max_{\boldsymbol{y}} p^{(k)}(\boldsymbol{y} \mid \boldsymbol{x})$ from each source model k is also included in the chart, but they don't count toward the probability threshold.

2.2 Proposed Method

Multilinguality is the key factor contributing to the success of PPTX (Kurniawan et al., 2021). Therefore, optimising the method to leverage this multilinguality provided by the source models is important. One potential limitation of PPTX is the inclusion of substructures having relatively low marginal probability under some source model because of the union in Eq. (3). As an extreme illustration, consider a poor source model k assigning uniform marginal probability to substructures in $C(\boldsymbol{x}, j)$. Most of these substructures will be included in $\tilde{A}_k(\boldsymbol{x}, j)$ and, subsequently, $\tilde{A}(\boldsymbol{x})$. As a result, noisy structures may be included in $\tilde{\mathcal{Y}}(\boldsymbol{x})$ which makes learning the correct structure difficult.

Instead of computing the set of high-probability substructures from each source model separately, a potentially better alternative is to aggregate the marginal probabilities given by the source models and then compute the chart from the resulting distribution. We propose to use logarithmic opinion pooling (Heskes, 1998) as the aggregation method. To obtain the chart $\tilde{\mathcal{Y}}(\boldsymbol{x})$, first we compute the logarithmic opinion pool of the source models' marginal probabilities. That is, for all $j \in \{1, \ldots, n\}$, define

$$\bar{p}_j(c \mid \boldsymbol{x}) \propto \prod_k \left[p^{(k)}(c \mid \boldsymbol{x})\right]^{\alpha_k} \tag{4}$$

where we normalise over the substructures $c \in C(\boldsymbol{x}, j)$, and α_k is a non-negative scalar weighting the contribution of source model k satisfying $\sum_k \alpha_k = 1$. Thus, $\bar{p}_j$ gives the new probability distribution over substructures in $C(\boldsymbol{x}, j)$. Then, we compute the set $\tilde{A}(\boldsymbol{x}, j)$ using $\bar{p}_j$ in a similar fashion as before: adding substructures $c \in C(\boldsymbol{x}, j)$ in descending order by their marginal probability given by $\bar{p}_j$ until their cumulative probability exceeds σ. Lastly, we define $\tilde{A}(\boldsymbol{x}) = \bigcup_j \tilde{A}(\boldsymbol{x}, j)$, and keep the definition of $\tilde{\mathcal{Y}}(\boldsymbol{x})$ unchanged: the set of structures induced by $\tilde{A}(\boldsymbol{x})$ plus the 1-best structures,[2] which is used as labels for training with the objective in Eq. (1). Fig. 1 illustrates the process using dependency parsing as an example.

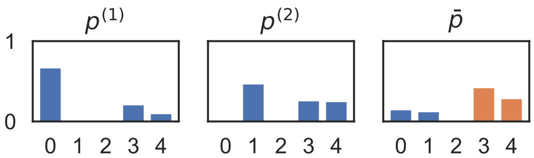

Figure 2: Logarithmic opinion pool with uniform weighting ($\bar{p}$) for two distributions $p^{(1)}$ and $p^{(2)}$. The opinion pool $\bar{p}$ assigns lower probabilities to substructures indexed by 0 and 1 than those indexed by 3 and 4 because $p^{(1)}$ and $p^{(2)}$ assign very low probability to either 0 or 1. Selected substructures in the context of Eq. (2) with $\sigma = 0.7$ are in orange.

Setting the Weight Factors Finding an optimal value for α_k is possible if there is labelled data (Heskes, 1998). However, we do not have labelled data in the target language in our cross-lingual setup. There is some method to find similar weighting scalars for cross-lingual transfer that may work in our setup (Wu et al., 2020), but they require unlabelled source language data and only marginally outperform uniform weighting. Therefore, unless stated otherwise, we set α_k uniformly, reducing Eq. (4) to the normalised geometric mean of the marginal distributions.

Motivation The motivation behind the proposed method is the observation that PPTX obtains the high-probability substructures by applying the threshold in Eq. (2) for each source model separately *before* they are aggregated into a single set in Eq. (3). This means PPTX considers the uncertainty of the source models in isolation to create the chart. In contrast, our method considers the uncertainty of the ensemble by applying the threshold *after* aggregating the probabilities in the logarith-

---

[2] Concrete (sub)structures in set C, $\tilde{A}$, and $\tilde{\mathcal{Y}}$ depend on the task. For parsing, they are arcs and trees. For tagging, tag pairs and sequences. See Section 2.3 for more details.

mic opinion pool in Eq. (4). The opinion pool assigns more probability mass to substructures to which all the source models assign a high probability (see Fig. 2), and we hypothesise that such substructures are more likely to be correct.

2.3 Application to Structured Prediction

The above method can be applied to structured prediction problems. Crucial to the application is the definition of $C(\boldsymbol{x}, j)$. Below, we present two applications: arc-factored dependency parsing and sequence tagging.

Arc-Factored Dependency Parsing For dependency parsing, we can define $C(\boldsymbol{x}, j)$ as the set of dependency arcs having x_j as dependent:

$$C(\boldsymbol{x}, j) = \{(i, j, l) \mid i \in \{0, \ldots, n\} \wedge i \neq j \wedge l \in L\}$$

where (i, j, l) denotes an arc from head x_i to dependent x_j with dependency label l, L denotes the set of dependency labels, and x_0 is a special token whose dependent is the root of the sentence.[3] Since exactly one arc in $C(\boldsymbol{x}, j)$ exists in any possible dependency tree of $\boldsymbol{x}$, the marginal probabilities of arcs in $C(\boldsymbol{x}, j)$ form a probability distribution. The rest follows accordingly.

Sequence Tagging In sequence tagging, the structured output is a sequence of tags, which decomposes into consecutive tag pairs. Given a sequence of tags $\boldsymbol{y} = y_1 y_2 \cdots y_n$ corresponding to the input $\boldsymbol{x}$, its consecutive tag pairs are $A(\boldsymbol{y}) = \{(j, y_j, y_{j+1})\}_{j=1}^{n-1}$. We define $C(\boldsymbol{x}, j)$ as the set of possible tag pairs for x_j and x_{j+1}:

$$C(\boldsymbol{x}, j) = \{(j, t, t') \mid (t, t') \in T \times T\}$$

where T is the set of tags. Note that any sequence of tags for $\boldsymbol{x}$ has exactly one tag pair in $C(\boldsymbol{x}, j)$ and thus, the marginal probabilities of these tag pairs in $C(\boldsymbol{x}, j)$ form a probability distribution.

3 Experimental Setup

Data and Evaluation We evaluate on dependency parsing and part-of-speech (POS) tagging. We use Universal Dependencies v2.2 (Nivre et al., 2018) and test on 18 languages spanning 5 language families (see Appendix A). We divide the languages into distant and nearby groups based on their distance to English (He et al., 2019). We use the universal POS tags (UPOS) as labels for tagging. We exclude punctuation from parsing evaluation following the standard practice and report average performance across five random seeds unless stated otherwise. We also include a PPTX baseline applied to tagging. Our evaluation metric is accuracy for both tasks, which is equivalent to LAS for parsing.

Model Architecture For parsing, we use the same architecture as was used by Kurniawan et al. (2021), consisting of embedding layers, a Transformer encoder layer, and a biaffine output layer (Dozat and Manning, 2017). At test time, we run the MST algorithm (Chu and Liu, 1965; Edmonds, 1967) to find the highest scoring tree. For tagging, we replace the output layer with a linear CRF layer. At test time, the Viterbi algorithm is used to obtain the tag sequence with the highest score.

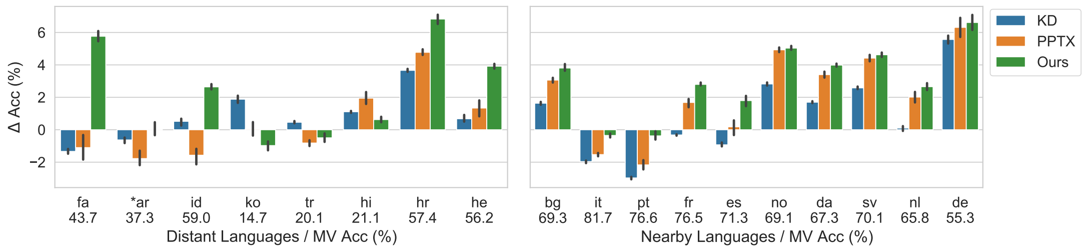
Source Selection We adopt a "pragmatic" approach where we include 5 high-resource languages as sources: English, Arabic, Spanish, French, and German (Kurniawan et al., 2021),[4] which have been categorised as "quintessential rich-resource languages" due to the availability of massive language datasets (Joshi et al., 2020). When a source language is also the target language, we exclude the language from the sources. For example, if Arabic is the target language, then we use only the other 4 languages as sources, thus the target language is always unseen. See Appendix B for more details.

Baselines Our main baseline for both tasks is a majority voting ensemble (MV). For parsing, we score each possible arc by the number of source parsers that have the arc in the predicted tree and then run the MST algorithm. For tagging, we use the most commonly predicted tag for each input token. This baseline is not only more appropriate for multi-source transfer but also stronger than the direct transfer baseline used by Kurniawan et al. (2021) which uses only a single source language (English), with accuracy gains of up to 15 points on both tasks. We also include knowledge distillation (KD) which has been used for parsing as a baseline (Hu et al., 2021). For tagging, we include BEA (Rahimi et al., 2019) which explicitly

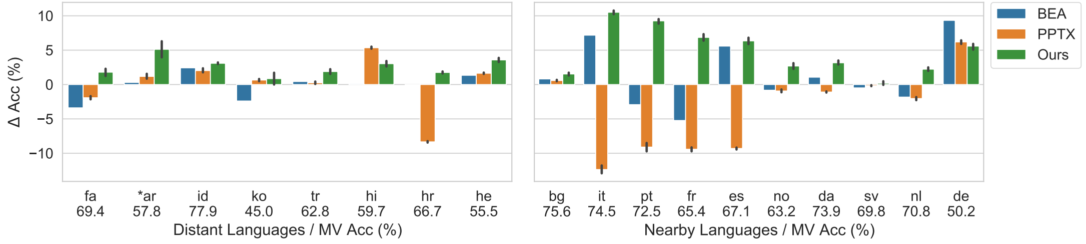
---

[3] This formulation is widely used in graph-based dependency parsing, which dates back to the work of McDonald et al. (2005).

[4] This setup is called PPTX-PRAG by Kurniawan et al. (2021), which is reported in their Figure 3.



(a) Dependency parsing



(b) POS tagging

Figure 3: Performance difference of PPTX and our method against majority voting (MV) on parsing and tagging. Numbers on the x-axis are the MV performance corresponding to the zero value on the y-axis. BEA is run only once as it always gives the same result. Table 11 reports the full results. *: hyperparameters are tuned on this language.

models the label confusion of source taggers and has been used successfully for multi-source cross-lingual NER. More details on these two baselines are reported in Appendix C.

Training We use the same setup as Kurniawan et al. (2021) for parsing. We include the gold universal POS tags as input to the parsers. We discard sentences longer than 30 tokens to avoid memory issues and train for 5 epochs using Adam (Kingma and Ba, 2015). Note that we discard long sentences only at training time. In other words, we evaluate on all lengths at test time. We tune the learning rate and λ on the development set of Arabic, select the values that give the highest accuracy, and use them for training on all languages. For tagging, we set the length cut-off to 60 tokens (again, only at training time) and train for 10 epochs. Again, we tune the hyperparameters on Arabic and use the best values for training on all languages. For both tasks, we obtain cross-lingual word embeddings using an offline transformation method (Smith et al., 2017) applied to fastText pre-trained word vectors (Bojanowski et al., 2017). We set the threshold $\sigma = 0.95$ (Kurniawan et al., 2021). We initialise the parameters of the target language model with the parameters of the English source model and regularise the former towards the latter during training. In other words, we set the parameters of the English source model as $\boldsymbol{\theta}_0$ as described in Section 2.1. See Appendix D for further details.

4 Results and Analysis

Fig. 3a shows the accuracy difference of KD, PPTX, and our method against MV on parsing. We see that PPTX does not consistently outperform MV, substantially underperforming on 6 languages.[5] On the other hand, our method outperforms not only PPTX but also both KD and MV on most languages. Fig. 3b shows the corresponding results on POS tagging which is particularly convincing. We see that PPTX often underperforms, with up to 10 % drop in accuracy compared to MV. In contrast, our method consistently outperforms MV with up to 10 % accuracy improvement. These results suggest that PPTX may not improve over a

---

Method	Distant	Nearby
PPTX	-1.2 ± 5.0	0.5 ± 2.4
Ours	2.1 ± 2.7	2.8 ± 2.0

Table 2: LAS difference against majority voting using predicted POS tags, averaged over all nearby and distant languages (± std). Average LAS for the majority voting on distant and nearby languages are 38.4 ± 18.3 and 68.1 ± 7.3 respectively.

simple majority voting ensemble, and our method is the superior alternative. In addition, our method shows higher improvement against MV on nearby than distant languages, which is unsurprising because our pragmatic selection of source languages is dominated by languages in the nearby group.

From the figure, we also see that on Portuguese and Italian, our method slightly underperforms compared to MV on parsing, but outperforms MV considerably on tagging. We hypothesise that this disparity is caused by the variability of the source models quality. On tagging, the direct transfer performance of 3 out of 5 source taggers is relatively poor on Portuguese and Italian, making it more likely for MV to predict wrongly as the good taggers are outvoted. In contrast, on parsing, Arabic is the only source parser that has very poor transfer. The other source parsers achieve comparably good direct transfer performance so MV already performs well.

Parsing results using predicted POS tags Since low-resource languages often don't have gold POS tags, we also evaluate our method for parsing using predicted POS tags. We use Stanza (Qi et al., 2020) to predict the POS tags of all target languages, and replace the gold UPOS with the predicted tags as the input. Table 2 shows that our method still outperforms PPTX in this setup, although there is a large variance across languages.

4.1 Chart Size Analysis

To understand the differences between PPTX and our method better, we compare the size of the chart $\tilde{\mathcal{Y}}(\boldsymbol{x})$ produced by PPTX and our method, in terms of the number of structures in it. We take the median of this size over all unlabelled sentences in the training set of each target language and compare the results. Table 1 reports the median chart size of PPTX, and the median chart size of our method relative to PPTX for both parsing and tagging on 6 representative languages (the trend for other languages is similar). We find that for parsing, the size of our method's chart is much smaller than $1\,\%$ of the size of PPTX chart for all target languages.[6] This finding shows that our method's charts are much more compact than those of PPTX. Thus, it may explain the improvement of our method over PPTX because smaller charts may be more likely to concentrate on trees that have many correct arcs, making it easier for the model to learn correctly (we explore this further in Section 4.2). For POS tagging, we observe the same trend where our method's charts are smaller, but to a lesser extent, presumably because the typical output space of tagging is several orders of magnitude smaller than that of parsing. Occasionally, our method's chart is larger than that of PPTX, although our method outperforms PPTX substantially (French and Spanish). We speculate that this is because most of the source taggers are very confident but on different substructures, so only a handful of substructures are selected by PPTX after applying the threshold in Eq. (2), making the chart small. Meanwhile, the logarithmic opinion pool is less confident as it corresponds to the (geometric) mean of the distributions, so more substructures are selected, making the chart larger.

4.2 Chart Quality Analysis

Continuing the previous analysis, we check if the smaller charts of our method indeed concentrate more on the correct structures than those of PPTX. To measure this, we define the notion of precision and recall of the chart $\tilde{\mathcal{Y}}(\boldsymbol{x})$. We define precision as the fraction of correct substructures in $\tilde{\mathcal{Y}}(\boldsymbol{x})$ and recall as the fraction of gold substructures that occur in any structure in $\tilde{\mathcal{Y}}(\boldsymbol{x})$. Formally,

$$\mathrm{P}(\tilde{\mathcal{Y}}(\boldsymbol{x})) = \frac{\sum_{(\boldsymbol{x},\boldsymbol{y}^*)} \sum_{\boldsymbol{y}\in\tilde{\mathcal{Y}}(\boldsymbol{x})} |A(\boldsymbol{y}) \cap A(\boldsymbol{y}^*)|}{\sum_{\boldsymbol{x}} \sum_{\boldsymbol{y}\in\tilde{\mathcal{Y}}(\boldsymbol{x})} |A(\boldsymbol{y})|}$$

and

$$\mathrm{R}(\tilde{\mathcal{Y}}(\boldsymbol{x})) = \frac{\sum_{(\boldsymbol{x},\boldsymbol{y}^*)} \sum_{a\in A(\boldsymbol{y}^*)} \mathrm{I}(a, \tilde{\mathcal{Y}}(\boldsymbol{x}))}{\sum_{\boldsymbol{y}^*} |A(\boldsymbol{y}^*)|}$$

where

$$\mathrm{I}(a, \tilde{\mathcal{Y}}(\boldsymbol{x})) = \begin{cases} 1 & \text{if } \boldsymbol{y} \in \tilde{\mathcal{Y}}(\boldsymbol{x}) \text{ s.t. } a \in A(\boldsymbol{y}) \\ 0 & \text{otherwise} \end{cases}$$

---

[6] Except for Turkish, where this number is $3\,\%$, which is still very small.

Δ over the accuracy results for both tasks are included for completeness, and correspond to the bar height difference of the two methods in Fig. 3.

and $\boldsymbol{y}^*$ denotes the gold structure for input $\boldsymbol{x}$. A good chart must have high precision and recall. In particular, if $\tilde{\mathcal{Y}}(\boldsymbol{x})$ is a singleton containing the gold structure, then both precision and recall will be $100\,\%$.

Table 3 reports the precision and recall of the charts produced by PPTX and our method for both tasks, as well as the performance differences, for the same 6 languages as before (the trend for other languages is similar). We observe that with our method in parsing, both precision and recall consistently improve over PPTX, suggesting that the charts indeed contain more correct arcs. However, higher precision and recall do not guarantee performance improvement, as shown by Korean where both precision and recall improve with our method but its performance is lower than PPTX.[7] We suspect that this is caused by the unusually low precision even with our method, indicating that the chart is very noisy. For POS tagging, the result is less obvious, but we find that generally our method improves chart precision, but often sacrificing chart recall. For Spanish, precision decreases with our method, and only recall improves.[8] An interesting case is again Korean where both precision and recall worsen, probably because of very poor source taggers performance on the language. Overall, our method generally improves the chart quality in terms of either precision or recall, but to a lesser extent, which again may be attributed to the smaller output space compared with parsing.

4.3 Effect of Opinion Pool Distance to True Distribution

We explore whether there is a relationship between (a) how distant the opinion pool is to the true distribution over substructures and (b) the performance improvement of our method against majority voting. Intuitively, the closer the opinion pool is to the true distribution, the higher its absolute performance would be. However, it is unclear whether this translates into an advantage over majority voting. This is important because if such relationship exists, then it may be worthwhile spending some effort on optimising the opinion pool. To this end, we measure the distance between the true distribution and the opinion pool by computing the Kullback-Leibler divergence (KL)

$$\mathrm{KL}(\hat{p} \mid \bar{p}) = \frac{1}{n(\mathcal{D})} \sum_{\boldsymbol{x} \in \mathcal{D}} \sum_{j=1}^{|\boldsymbol{x}|} \mathrm{KL}(\hat{p}_j \mid \bar{p}_j) \qquad (5)$$

where $n(\mathcal{D})$ is the total number of tokens of all input sentences in $\mathcal{D}$, $\hat{p}_j(c \mid \boldsymbol{x})$ is the (empirical) true distribution of substructures in $C(\boldsymbol{x}, j)$, and $\bar{p}_j(c \mid \boldsymbol{x})$ is the logarithmic opinion pool distribution defined in Eq. (4). Note that $\hat{p}_j(c \mid \boldsymbol{x})$ is a one-hot distribution so $\mathrm{KL}(\hat{p}_j \mid \bar{p}_j)$ reduces to the negative log likelihood of the labelled data under the opinion pool. We compute the KL divergence on the training set of both parsing and tagging and display the regression plots in Fig. 4. We see a medium correlation between opinion pool distance and performance gain against majority voting, with $r = -0.45$ for both parsing and tagging (p-value is 0.06 for both). However, there is substantial variance, especially in the right half figure of parsing, caused by the lack of languages in that region of the plot. Nonetheless, the plots suggest that there

(a) Dependency parsing (b) POS tagging

Figure 4: Relationship between $\mathrm{KL}(\hat{p} \mid \bar{p})$ and the accuracy difference of our method and MV, where $\hat{p}$ and $\bar{p}$ denote the empirical true distribution and the opinion pool distribution respectively. Shaded area is 95 % confidence interval computed via bootstrapping.

is indeed a positive relationship between how close the opinion pool is to the true distribution and the performance gain of our method compared with majority voting.

There are ways to obtain an opinion pool that is closer to the true distribution. One way is to leverage a small amount of labelled data in the target language to estimate the weight factors α_k, which can be done by optimising Eq. (5). This option is suitable if such labelled data is available or can be obtained cheaply. If we have the freedom to choose the source languages, another method is to select them carefully so they are both reasonably close to the target language and also diverse. This is because Eq. (5) can be expressed as $E - D$, where E denotes how distant the source models' output distributions are to the target's true distribution (*error*) and D denotes how distant the output distributions are to each other (*diversity*) (Heskes, 1998). Having the source languages reasonably close to the target language and also diverse means reducing E and increasing D respectively, moving the opinion pool closer to the true distribution. That said, when the source languages are close to the target language, the source models may already be good for direct transfer so our method may not give meaningful improvement over majority voting.

4.4 Learning the Opinion Pool Weight Factors

Motivated by the previous findings, we deviate from our unsupervised setup by learning the weight factors α_k using a tiny amount of labelled target data. Concretely, we randomly sample 50 sentences from the training set of each target language and learn α_k that minimises Eq. (5) for all source model k. We then use the learned weights to obtain the opinion pool as defined in Eq. (4) (see Appendix F for further details). Table 4 shows the results on parsing and tagging, averaged over the target languages. We observe that by using the learned weight factors, our method slightly improves over the version using uniform weights, suggesting that our method can readily leverage labelled target data if it is available. On the other hand, the fact that the improvement is only modest also reaffirms that uniform weighting is a strong baseline.

	Parsing	Tagging
MV	56.3	65.4
Uniform α_k	59.0	69.3
Learned α_k	59.4	70.0

Table 4: Parsing and tagging performance of MV and our method with uniform and learned weight factors α_k for the logarithmic opinion pool, averaged over 18 languages. Full results are reported in Table 11.

5 Related Work

A straightforward method of multi-source transfer is training a model on the concatenation of datasets from the source languages. This approach was used by McDonald et al. (2011) for dependency parsing and yields a substantial gain compared with single-source transfer. More recent work by Guo et al. (2016) proposed to learn multilingual representations from the concatenation of source language data and use them to train a neural dependency parser. Another method is language adversarial training, used by Chen et al. (2019) for various NLP tasks including named-entity recognition, which is often cast as structured prediction. Despite their success, multi-source unsupervised cross-lingual transfer methods typically require the source language data, which is not always feasible.

There are recent methods suitable in this source-free setup. Rahimi et al. (2019) proposed a method based on truth inference to model label confusion in multi-source transfer of named-entity recognisers. Wu et al. (2020) used teacher-student learning for named-entity recognition. A closely related work is by Hu et al. (2021) who argued that a small amount of labelled data in the target language is cheap to obtain and proposed an attention-based method to weight the source models leveraging 50 labelled target sentences. Our work is different as we do not require any labelled data and evaluate on 3 times more languages than they did. In addition, their model is based on mBERT (Devlin et al., 2019), which benefits from larger data from multiple languages during pretraining. In many application scenarios, BERT-based models are too costly, especially when criteria other than accuracy matter (Nityasya et al., 2020).

Our work builds upon the work of Kurniawan et al. (2021) who proposed a method based on self-training for unsupervised cross-lingual dependency parsing. In this work, we generalise their method to structured prediction problems and propose a modification to improve the quality of the distant supervision.

6 Conclusions

In this paper, we (1) generalise previous methods for cross-lingual unsupervised transfer without source data to structured prediction problems and (2) propose a new aggregation technique which can better handle mixed-quality input distributions. Experiments across two structured prediction tasks and 18 languages show that, unlike previous work, our method generally outperforms a strong multi-source transfer baseline. Our analyses suggest that our method produces distant supervision of better quality than that of the previous methods. Our work potentially generalises beyond language transfer to (a) structured prediction tasks beyond NLP and (b) transfer across other types of domains (e.g., genres), a direction we aim to explore in future work. We are also interested in investigating in future work whether our method helps transfer with recent multilingual pretrained models.

Table 5: List of languages in our evaluation, grouped into distant and nearby languages based on their distance to English (He et al., 2019). IE stands for Indo-European. †: licence is the United States version.

B Source Models Performance

To train the source models, we tune the hyperparameters on English and use the values for training on the other source languages. Table 6 reports the performance of our source parsers and taggers. We also report the performance numbers of previous work, copied from their respective papers, to serve as reference. Generally, the source models achieve in-language performance comparable to previous work (e.g., Ahmad et al., 2019) with the exception of the Arabic parser whose accuracy is noticeably lower, possibly caused by the model architecture optimised for transfer rather than in-language evaluation. However, we argue that the lower performance reflects a realistic application scenario where some of the source models are expected to be poor.

	en	ar	es	fr	de
Parsing	86.9	76.9	90.0	89.1	82.1
Tagging	94.5	95.4	96.5	96.5	92.1
			Previous work (reference only)		
LSTM parser	88.3	81.8	90.8	89.1	83.7
Stanza tagger*	95.4	94.9	96.7	97.3	94.1

Table 6: Parsing and tagging accuracy of the source models. We copy numbers of the LSTM parser (Ahmad et al., 2019) and Stanza tagger (Qi et al., 2018) from their respective papers to serve as reference only. * indicates that the numbers are not directly comparable to ours because of the difference in the evaluation setup.

C Additional Baseline Details

Knowledge Distillation We use a similar method to the soft-KD baseline used by Hu et al. (2021), which was based on the teacher-student learning method of Wu et al. (2020). Let $p^{(k)}_{\text{head}}(h_j = i \mid \boldsymbol{x})$ denote the probability of x_j having x_i as head under source parser k. Similarly, let $p^{(k)}_{\text{label}}(l_{ij} = r \mid \boldsymbol{x})$ denote the probability of the arc between head x_i and dependent x_j having label r under source parser k. These distributions are obtained from the output of the corresponding biaffine layer that is then passed through a softmax layer. We average these distributions over the source parsers to give

$$\bar{p}_{\text{head}}(h_j = i \mid \boldsymbol{x}) = \frac{1}{K}\sum_k p^{(k)}_{\text{head}}(h_j = i \mid \boldsymbol{x}),$$
$$\bar{p}_{\text{label}}(l_{ij} = r \mid \boldsymbol{x}) = \frac{1}{K}\sum_k p^{(k)}_{\text{label}}(l_{ij} = r \mid \boldsymbol{x})$$

where K is the number of source parsers. The training objective of this KD baseline is then

$$\begin{aligned}\ell(\boldsymbol{\theta}) &= \text{MSE}(p_{\text{head}}(\cdot \mid \boldsymbol{x}; \boldsymbol{\theta}), \bar{p}_{\text{head}}(\cdot \mid \boldsymbol{x})) \\ &\quad + \tau\text{MSE}(p_{\text{label}}(\cdot \mid \boldsymbol{x}; \boldsymbol{\theta}), \bar{p}_{\text{label}}(\cdot \mid \boldsymbol{x})) \\ &\quad + \lambda\|\boldsymbol{\theta} - \boldsymbol{\theta}_0\|_2^2\end{aligned}$$

where MSE denotes the mean squared error function. We include τ as a tunable hyperparameter. Table 9 reports the full list of hyperparameter values.

Table 7: Number of parameters of the parsers and taggers with our method, rounded to the nearest million.

BEA We use the implementation of BEA (Rahimi et al., 2019) provided by the authors.[9] We run BEA on the unlabelled test data of each language (transductive setup). This potentially gives the BEA baseline more advantage, so it is not directly comparable to PPTX and our method. We find that our hyperparameter tuning protocol (i.e. tuning the parameters of the Dirichlet priors on Arabic and using the best values for all languages) underperforms compared to using uninformative priors, so we report the BEA results without any tuning.

D Additional Experiment Details

	en	ar	es	fr	de
Parser	14	14	27	20	23
Tagger	12	12	25	18	21

Table 8: Number of parameters of the source parsers and taggers, rounded to the nearest million.

We implement our method using Python v3.7, PyTorch v1.4 (Paszke et al., 2019), and PyTorch-Struct (Rush, 2020). We run our experiments with Sacred v0.8.2 (Greff et al., 2017), which also sets the random seeds. Experiments are run on NVIDIA GeForce GTX TITAN X with CUDA 10.1 and GPU memory of 11 MiB. CPU model is Intel(R) Xeon(R) CPU E5-2687W v3 @ 3.10GHz with Ubuntu 16.04 as the operating system. Table 8 and Table 7 show the number of parameters of the source parsers and taggers, and the target parsers and taggers using our method respectively. A single run takes not much longer than 1 GPU hour for both parsing and tagging.

E Hyperparameters

We tune learning rate η and λ (and also τ for KD) using random search. Table 9 shows the distributions of each hyperparameter we use, and the best values we find. We sample 20 values from the distribution and pick the values that yield the best accuracy on the Arabic development set. We follow Kurniawan et al. (2021) for other hyperparameters, whose values are reported in Table 10.

Task	Method	Hyperparameter Dist.	Best Value
Parsing	KD	$\log\eta \sim U(-6,-3)$ $\log\tau \sim U(-2,2)$ $\log\lambda \sim U(-4,1)$	$\eta = 3.3\times10^{-5}$ $\tau = 0.66$ $\lambda = 10^{-3}$
	PPTX	$\log\eta \sim U(-6,-3)$ $\log\lambda \sim U(-4,1)$	$\eta = 8.5\times10^{-5}$ $\lambda = 2.8\times10^{-5}$
	Ours	$\log\eta \sim U(-6.5,-3.5)$ $\log\lambda \sim U(-4,1)$	$\eta = 9.4\times10^{-5}$ $\lambda = 1.6\times10^{-4}$
Tagging	PPTX	$\log\eta \sim U(-6,-4)$ $\log\lambda \sim U(-4,1)$	$\eta = 5.9\times10^{-5}$ $\lambda = 0.1$
	Ours	$\log\eta \sim U(-6.5,-3.5)$ $\log\lambda \sim U(-4,1)$	$\eta = 2.6\times10^{-4}$ $\lambda = 4.7\times10^{-3}$

Table 9: Distributions of hyperparameters we use for tuning on Arabic with random search and the best values found. All logarithms are of base 10.

Hyperparameter	Value
Word embedding size	300
Word dropout	0.2
$d_{\text{key}}, d_{\text{value}}$	64
d_{ff}	512
n_{head}	8
n_{layer}	6
Batch size	80
Parsing-only	
POS tag embedding size	50
Output embedding dropout	0.2
d_{arc}	512
d_{deptype}	128

Table 10: List of hyperparameter values used in our parsers and taggers. $d_{\text{key}}, d_{\text{value}}$: size of key and value vector in the Transformer encoder. d_{ff}: size of feedforward network hidden layer in the Transformer encoder. n_{head}: number of heads in the Transformer encoder. n_{layer}: number of layers in the Transformer encoder. $d_{\text{arc}}, d_{\text{deptype}}$: size of feedforward network output layer corresponding to arcs and dependency types in the biaffine output layer of parsers.

F Learning the Opinion Pool Weight Factors

We learn the factors α_k weighting the contribution of source model k in the logarithmic opinion pool by minimising Eq. (5) with respect to α_k. The minimisation is done on 50 randomly sampled sentences from the target language's training set using gradient descent. We set the initial learning rate to 0.1 and reduce it at every epoch by a factor of 0.9. We initialise the weight factors uniformly at the start and run the training until convergence. After the weight factors are learned, we use and fix them for all subsequent experiments. We proceed with hyperparameter tuning on Arabic using the same procedure as the version with uniform weights. For both tasks, we tune η and λ with random search (20 runs), drawing from $\log_{10} \eta \sim U(-6, -3)$ and $\log_{10} \lambda \sim U(-4, 1)$ respectively. For parsing, the best values are $\eta = 9.1 \times 10^{-5}$ and $\lambda = 5.1 \times 10^{-4}$. For tagging, they are $\eta = 4.7 \times 10^{-4}$ and $\lambda = 0.062$. These values are then used for the other languages. Lastly, we report the average accuracy over the languages in Table 4.

G Full Experiment Results

We report in Table 11 the full results of MV, PPTX, and our method (with both uniform and learned weight factors α_k) on both dependency parsing and POS tagging, averaged over 5 runs.

(b) Test set

Table 11: Full performance results. Except for MV and BEA, numbers are averages (± std) over 5 runs with different random seeds. For parsing, the numbers correspond to labelled attachment score (LAS) whereas for tagging, they correspond to accuracy. Both metrics are better if higher. Hyperparameters are tuned on Arabic, hence the asterisk. In columns "Ours, learned α_k", α_k is learned in a supervised manner on tiny labelled sentences (Section 4.4).

Don't Take It Literally:
An Edit-Invariant Sequence Loss for Text Generation

Abstract

Neural text generation models are typically trained by maximizing log-likelihood with the sequence cross entropy (CE) loss, which encourages an *exact* token-by-token match between a target sequence with a generated sequence. Such training objective is sub-optimal when the target sequence is not perfect, e.g., when the target sequence is corrupted with noises, or when only weak sequence supervision is available. To address the challenge, we propose a novel Edit-Invariant Sequence Loss (EISL), which computes the matching loss of a target n-gram with all n-grams in the generated sequence. EISL is designed to be robust to various noises and edits in the target sequences. Moreover, the EISL computation is essentially an approximate convolution operation with target n-grams as kernels, which is easy to implement and efficient to compute with existing libraries. To demonstrate the effectiveness of EISL, we conduct experiments on a wide range of tasks, including machine translation with noisy target sequences, unsupervised text style transfer with only weak training signals, and non-autoregressive generation with non-predefined generation order. Experimental results show our method significantly outperforms the common CE loss and other strong baselines on all the tasks. EISL has a simple API that can be used as a drop-in replacement of the CE loss.[1]

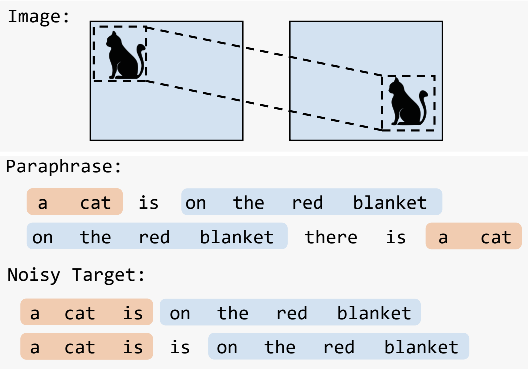

Figure 1: Invariance exists in both image and text, e.g., image is invariant to translation (top), and text is robust to many forms of edits (bottom).

1 Introduction

Neural text generation models have ubiquitous applications in natural language processing, including machine translation (Bahdanau et al., 2015, Sutskever et al., 2014, Wu et al., 2016, Vaswani et al., 2017), summarizations (Nallapati et al., 2016, See et al., 2017), dialogue systems (Li et al., 2016), etc. They are typically trained by maximizing the log-likelihood of the output sequence conditioning on the inputs with the cross entropy (CE) loss. The CE loss can be easily factorized into individual loss terms and can be optimized efficiently with stochastic gradient descent. Due to its computational efficiency and ease to implement, the training paradigm has played an important role in building successful large text generation models (Lewis et al., 2020, Radford et al., 2019). However, the CE loss minimizes the negative log-likelihood of only the reference output sequence, while all other sequences are equally penalized through normalization. This is over-restrictive since for a given reference target sentence, many possible paraphrases are semantically close, hence should not completely be treated as negative samples. For example, as shown in Figure 1, `a cat is on the red blanket` should be treated equally with `on the red blanket there is a cat`. A model trained with CE loss falls short of modeling such type of invariance for text.

The problem is even exaggerated when the supervision from a target sequence is not perfect (Pinnis, 2018). On one hand, there could be *noises* in the reference sequence which makes itself not a valid sentence. As in the last example shown in Figure 1, there is a repetition error in the target sequence, which is common in human generated text. With

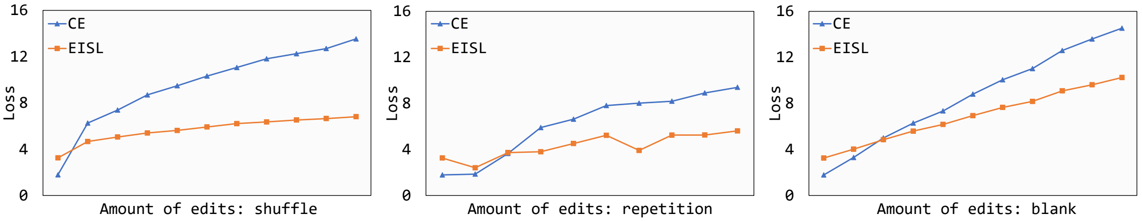

Figure 2: Sensitivity of CE and EISL loss w.r.t different types of text edits as the amount of edits increases (x-axis). We use a fixed machine translation model, synthesize different types of edits on target text, and measure the CE and EISL losses, respectively. The edit types include shuffle (changing the word order), repetition (words being selected are repeated), and word blank (words being replaced with a blank token). CE loss tends to increase drastically once a small amount of edits is applied. In contrast, EISL loss increases much more slowly, showing its robustness.

the CE loss, the model is forced to copy all tokens including the error, and assign a high loss for the grammatically correct sequence. The exact tokens matching renders the CE loss sensitive to noises in the target, as shown in Figure 2. On the other hand, there are many problems with only *weak* supervision for target sequences (Tan et al., 2020, Wang et al., 2021, Lin et al., 2020). For example, in tasks of unsupervised text style transfer (Jin et al., 2022) aiming to rewrite a sentence from one style to another, the original sentence offers weak supervision for the content (rather than the style). Yet using a CE loss here is problematic since it encourages the model to copy every original token.

Prior works have tried to address this problem using reinforcement learning (RL) (Guo et al., 2021, O'Neill and Bollegala, 2019, Wieting et al., 2019). For example, policy gradient was used to optimize sequence rewards such as BLEU metric (Ranzato et al., 2016, Liu et al., 2017). Such algorithms assign high rewards to sentences that are close to the target sentence. Though it is a valid objective to optimize, policy optimization faces significant challenges in practice. The high variance of gradient estimate makes the training extremely difficult, and almost all previous attempts rely on fine-tuning from models trained with CE loss, often with unclear improvement (Wu et al., 2018).

In this paper, we propose an alternative loss to overcome the above weakness of CE loss, but reserve all nice properties such as being end-to-end differentiable, easy to implement, and efficient to compute, which hence can be used as a drop-in replacement or combined with CE. The loss is based on the observation that a viable candidate sequence shares many sub-sequences with the target. Our loss, called *edit-invariant sequence loss* (EISL), models the matching of each reference n-gram across all n-grams in a candidate sequence. The design is motivated by the translation invariance properties of ConvNets on images (see Figure 3), and captures the edit invariance properties of text n-grams in calculating the loss. Figure 2 shows the invariance property of EISL in comparison with CE. Appealingly, we show the conventional CE loss is a special case of EISL—when n equals to the sequence length, EISL calculates the exact sequence matching loss and reduces to CE. Moreover, the computations of EISL is essentially a convolution operation of candidate sequence using target n-grams as kernels, which is very easy to implement with existing deep learning libraries.

To demonstrate the effectiveness of EISL loss, we conduct experiments on three representative tasks: machine translation with *noisy* training target, unsupervised text style transfer (only *weak* references are available), and non-autoregressive generation with *flexible generation order*. Experiments demonstrate EISL loss can be easily incorporated with a series of sequence models and outperforms CE and other popular baselines across the board.

2 Related Work

Deep neural sequence models such as recurrent neural networks (Sutskever et al., 2014, Mikolov et al., 2010) and transformers (Vaswani et al., 2017) have achieved great progress in many text generation tasks like machine translation (Bahdanau et al., 2015, Vaswani et al., 2017). These models are typically trained with the maximum-likelihood objective, which can lead to sub-optimal performance due to CE's exact sequence matching assumption. There are lots of works trying to overcome this weakness. For examples, some works (Ranzato et al., 2016, Rennie et al., 2017, Liu et al., 2017, Shen et al., 2016, Smith and Eisner, 2006) proposed to use policy gradient or minimum risk training to optimize the expected BLEU metric (Papineni et al., 2002a). Due to the high variance and unstableness in RL training, a variety of training tricks are used in practice. Wieting et al. (2019) developed a new reward function based on semantic similarity for translation. Guo et al. (2021) introduced soft Q-learning for more efficient RL training. On the other hand, Zhukov and Kretov (2017), Casas et al. (2018) made the initial attempts to develop differentiable BLEU objectives, making soft approximations to the count of n-gram matching in the original BLEU formulation. Shao et al. (2018, 2021, 2020) minimized the n-gram difference between the model outputs and targets in non-autoregressive generation.

Another line of research that is relevant to our work is learning with noisy labels in classification (Zhang and Sabuncu, 2018, Xu et al., 2019, Wang et al., 2019b, Hu et al., 2019). For text generation, Nicolai and Silfverberg (2020) proposed student forcing to substitute teacher forcing, which can alleviate the influence of noise in the target sequence during decoding. Kang and Hashimoto (2020) proposed loss truncation, which adaptively removes high-loss examples considered as invalid data. Our empirical study shows substantial improvement of our approach over the previous ones.

3 Edit-Invariant Sequence Loss

In this section, we first review the conventional cross-entropy (CE) loss for sequence learning, and point out its weakness, especially when the target sequence is edited. We then introduce the EISL loss which gives a model the flexibility to learn from sub-sequences in a target sequence.

We first establish notations for the sequence generation setting. Let $(\boldsymbol{x}, \boldsymbol{y}^*)$ be a paired data sample where $\boldsymbol{x}$ is the input and $\boldsymbol{y}^* = (y_1^*, ..., y_{T^*}^*)$ is the reference target sequence. Define $\boldsymbol{y} = (y_1, ..., y_T)$ as a candidate sentence. Our goal is to build a model $p_{\boldsymbol{\theta}}(\boldsymbol{y}|\boldsymbol{x})$ that scores a candidate sequence $\boldsymbol{y}$ with parameter $\boldsymbol{\theta}$. In the sequel, we omit the condition $\boldsymbol{x}$ and the subscript $\boldsymbol{\theta}$ for simplicity.

3.1 The Difficulty of Cross Entropy Loss

The standard approach to learn the sequence model is to minimize the negative log-likelihood (NLL) of the target sequence, i.e., minimizing the CE loss $\mathcal{L}^{\text{CE}}(\boldsymbol{\theta}) = -\log p(\boldsymbol{y}^*)$. The CE loss assumes *exact* matching of a candidate sequence $\boldsymbol{y}$ with the target sequence $\boldsymbol{y}^*$. In other words, it maximizes the probability of only the target sequence $\boldsymbol{y}^*$ while penalizing all other possible sequence outputs that might be close but different with $\boldsymbol{y}^*$.

The assumption can be problematic in many practical scenarios: **(1)** For a given target sentence, there could be many ways of paraphrasing the sentence such as word reordering, synonyms replacement, active to passive rewriting, etc. Many of the paraphrases are viable candidate sequences, and/or share many sub-sequences with the reference sentence, and thus should not be treated completely as negative samples. Similar to the translation invariance which is shown to be effective in image modeling, a sequence loss that is *robust* to the shift and edits of sub-sequences in the reference sequence is preferred in order to model the rich variations of sequences; **(2)** The edit-invariance property is particularly desirable when the reference target sequence is corrupted with noise or is only weak sequence supervision. For instance, in Figure 3, the word `is` is repeated twice, which is one of the common errors in typing. Using CE loss in the noisy target setting forces the model to learn the data errors as well. In contrast, a sequence loss robust or invariant to the shift of sub-sequences assigns a high probability to the correct sentence even though it does not match the noisy target exactly. The loss thus offers flexibility for the model to select right information for learning.

3.2 EISL: Edit-Invariant Sequence Loss

Motivated by the above discussion, in this section, we draw inspirations from the convolution operation that enables translation invariance in image modeling (Figure 3, left), and propose an edit-invariant sequence loss (EISL) as illustrated in Figure 3 (right). Intuitively, for instance, given a 4-gram `on the red blanket`, because there is no extra knowledge to determine the position of the 4-gram in the noisy target sequence, we compute the losses across all positions in the noisy target sequence and aggregate. This is essentially a convolution over the target noisy sequence with the given n-gram as a convolution kernel.

We now derive the EISL loss in more details. Let $\boldsymbol{y}_{a:b} = (y_a, ..., y_{b-1})$ denote a sub-sequence of $\boldsymbol{y}$ that starts from index a and ends at index $b-1$, which is of length $b-a$. Thus $\boldsymbol{y}^*_{i:i+n}$ denotes the i-th n-gram in the reference $\boldsymbol{y}^*$. Denote $C(\boldsymbol{y}^*_{i:i+n}, \boldsymbol{y})$ as the number of times this n-gram occurs in $\boldsymbol{y}$:

$$C(\boldsymbol{y}^*_{i:i+n}, \boldsymbol{y}) = \sum_{i'=1}^{T-n+1} \mathbb{1}(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}), \qquad (1)$$

where $\mathbb{1}(\cdot)$ is the indicator function that takes value

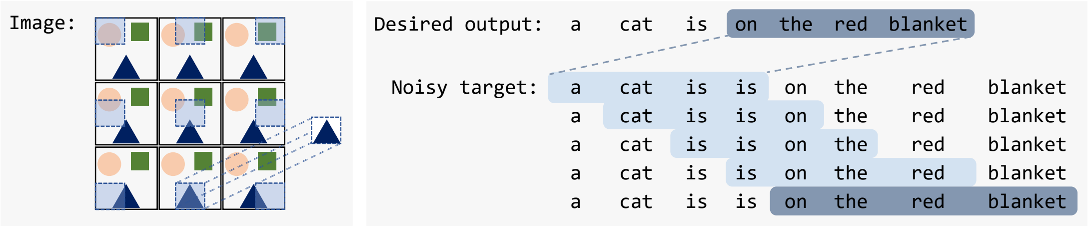

Figure 3: Inspired by the ConvNet convolution which applies a convolution kernel to different positions in an image and aggregate (**left**), we devise similar n-gram matching and convolution, which is robust to sequence edits (noises, shuffle, repetition, etc) (**right**).

1 if the n-grams match, and 0 otherwise. Intuitively, for a text generation model, we would like to maximize the occurrence of an n-gram from the reference in the target sequence. For a given probabilistic model $p_{\boldsymbol{\theta}}(\boldsymbol{y})$ (we omit the parameter $\boldsymbol{\theta}$ wherever the meaning is clear), the expected value of $C(\boldsymbol{y}^*_{i:i+n}, \boldsymbol{y})$ can be computed as follow:

$$\begin{aligned}&\mathbb{E}_{\boldsymbol{y}\sim p(\boldsymbol{y})}[C(\boldsymbol{y}^*_{i:i+n}, \boldsymbol{y})]\\ &= \sum_{i'=1}^{T-n+1} \mathbb{E}_{p(\boldsymbol{y}_{i':i'+n})}[\mathbb{1}(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n})]\\ &= \sum_{i'=1}^{T-n+1} p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}).\end{aligned} \tag{2}$$

Thus, for each i-th n-gram in the reference, a straightforward way to define the learning objective is to minimize the negative log value of its expected occurrence, i.e., $-\log \mathbb{E}_{\boldsymbol{y}\sim p(\boldsymbol{y})}[C(\boldsymbol{y}^*_{i:i+n}, \boldsymbol{y})]$.

The above loss requires computation of the marginal probability $p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n})$ of an n-gram, which is intractable in practice. We therefore derive an upper bound of the loss and use it as the surrogate to minimize in training. We denote the upper bound surrogate as our EISL loss. Specifically, since for a given i', $p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}) = \sum_{\boldsymbol{y}} p(\boldsymbol{y}_{<i'})p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}|\boldsymbol{y}_{<i'})$, then:

$$\begin{aligned}&-\log \mathbb{E}_{\boldsymbol{y}\sim p(\boldsymbol{y})}[C(\boldsymbol{y}^*_{i:i+n}, \boldsymbol{y})]\\ &= -\log \sum_{i'=1}^{T-n+1} p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}),\\ &\leq \frac{-\mathbb{E}_{\boldsymbol{y}\sim p(\boldsymbol{y})} \sum_{i'=1}^{T-n+1} \log p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}|\boldsymbol{y}_{<i'})}{T-n+1}\\ &:= \mathcal{L}^{\text{EISL}}_{n,i}(\boldsymbol{\theta}).\end{aligned} \tag{3}$$

The detailed derivation is attached in Appendix A.1. Notice that the EISL loss involves only the conditional distribution $p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}|\boldsymbol{y}_{<i'})$ which is convenient to compute—we first sample tokens from the model up to the i' position, then compute NLL of the reference n-gram $\boldsymbol{y}^*_{i:i+n}$ occurring at position i' under the model distribution. The full n-gram EISL loss is then defined by averaging across all n-gram positions in the reference:

$$\mathcal{L}^{\text{EISL}}_{n}(\boldsymbol{\theta}) = \frac{1}{T^*-n+1} \sum_{i=1}^{T^*-n+1} \mathcal{L}^{\text{EISL}}_{n,i}(\boldsymbol{\theta}). \tag{4}$$

In practice, inspired by the standard BLEU metric (more in section 3.3), we could also straightforwardly combine different n-gram losses depending on tasks:

$$\mathcal{L}^{\text{EISL}}(\boldsymbol{\theta}) = \sum\nolimits_{n} w_n \cdot \mathcal{L}^{\text{EISL}}_{n}(\boldsymbol{\theta}), \tag{5}$$

where w_n is the weight of the n-gram loss. The rule of thumb is that a n-gram EISL loss with lower n is more robust to noises, as shown in our experiments. Following BLEU, we found that simply using equal weights for different n-grams up to $n = 4$ often produces good performance.

As discussed shortly, it is appealing that the n-gram EISL loss is indeed a direct generalization of the CE loss on the n-gram level: we sum the CE loss of an n-gram over all candidate sequence positions by conditioning on samples from the model. Besides, the derivation of the upper bound makes no assumption on the probability function $p(\boldsymbol{y})$, hence holds for both autogressive and non-autoregressive sequence models as demonstrated in our experiments.

Position Selection Minimizing the gram matching loss over all positions can make the model assign equal probabilities at all positions, which causes the training to collapse. We further adapt the loss to enable the model to automatically learn the positions of reference n-grams. For notation simplicity, let $g^n_{i,i'}$ denote the conditional probability $p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}|\boldsymbol{y}_{<i'})$ involved above (Eq.3). We can vectorize the probability to get $\boldsymbol{g}^n_i = [g^n_{i,1}, ..., g^n_{i,T-n+1}]^T$, spanning all potential positions in the candidate sequence. We then normalize the probability vector $\boldsymbol{g}^n_i$ by Gumbel

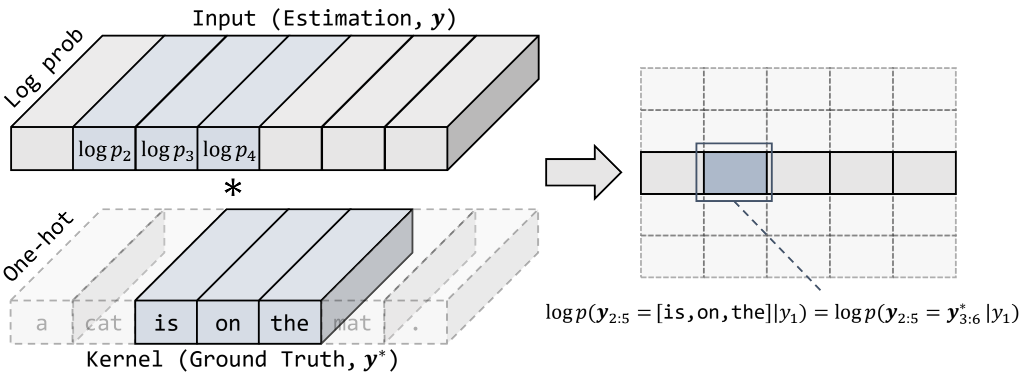

Figure 4: As convolution is a common operation for translation invariance in image, we adopt a convolution to achieve the translation invariance in text. The input is the distribution from the model output in log domain, kernel represents the convolution kernel and $*$ is the convolution operation. In this 3-gram example, there are 5 kernels, which correspond to the 5 rows on the right.

softmax (Jang et al., 2017), denoted as $\boldsymbol{q}^n_i = \texttt{Gumbel\_softmax}(\boldsymbol{g}^n_i)$, which we use as the weight for every n-gram positions. We multiply the weight with the original log probability to get the new adjusted loss:

$$\mathcal{L}^{\text{EISL}}_{n,i}(\boldsymbol{\theta}) \approx -\boldsymbol{q}^n_i \cdot \log \boldsymbol{g}^n_i. \tag{6}$$

The loss can roughly be viewed as the “entropy” of the unnormalized probabilities $\boldsymbol{g}^n_i$, which has minimal value if the mass of the probability is assigned to one location only. Intuitively, if an $g^n_{i,i'}$ is large, then it is likely i' is the correct position for the reference n-gram, hence the weight for this position should also be large. This is like the greedy exploitation in reinforcement learning (Mnih et al., 2015). On the other hand, to overcome over-exploitation, the Gumbel softmax introduces randomness in the weight assignment, which helps balance the exploitation-exploration trade-off in position selection for the model.

Efficient Approximate Computation: EISL as Convolution We show the EISL loss can be computed efficiently using the common convolution operator, with very little additional cost compared with the CE loss. The computation involves moderate approximation if the generation model is an autoregressive model, and is exact in the case of a non-autoregressive model (e.g., as in section 4.3). We first discuss the easy case when the model is a non-autoregressive model, where we have $g^n_{i,i'} = p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}|\boldsymbol{y}_{<i'}) = \prod_{j=1}^n p(y_{i'+j-1} = y^*_{i+j-1})$. Denote V as the vocabulary size. Let $\boldsymbol{P} = [\boldsymbol{p}_1, \boldsymbol{p}_2, ...\boldsymbol{p}_T]$ be the probability output by the model across positions, where $\boldsymbol{p}_{i'} \in \mathbb{R}^V$ is the probability output after softmax at i'-th position, and each $\boldsymbol{p}_{i'}$ is independent with each other. On this basis, we compute the key quantity $\log \boldsymbol{g}^n_i$ in Eq. 6 as the direct output of the convolution operator. As shown in Figure 4, we can get $\log \boldsymbol{g}^n_i$ by applying convolution on $\log \boldsymbol{P}$, with $\boldsymbol{y}_{i:i+n}$ as the kernels:

$$\log \boldsymbol{g}^n_i = \texttt{Conv}(\log \boldsymbol{P}, \texttt{Onehot}(\boldsymbol{y}^*_{i:i+n})), \tag{7}$$

where $\texttt{Onehot}(\cdot)$ maps each token to its corresponding one-hot representation and $\texttt{Conv}(\cdot,\cdot)$ is the convolution operation with the first argument as input and the second as the kernel. We transform $\boldsymbol{P}$ into log domain to turn the probability multiplication into log probability summations, where $\texttt{Conv}$ can be directly applied. As shown in Figure 4, $\log \boldsymbol{P}$ is of shape $V \times T$ and $\texttt{Onehot}(\boldsymbol{y}^*_{i:i+n})$ is of shape $V \times n$, so $\texttt{Conv}(\log \boldsymbol{P}, \texttt{Onehot}(\boldsymbol{y}^*_{i:i+n}))$ is an one-dimensional convolution on the sequence axis. Formally, the i'-th convolutional output is:

$$\begin{aligned} \log g^n_{i,i'} &= \sum_{j=1}^{n} \log \boldsymbol{p}_{i'+j-1} \cdot \texttt{Onehot}(y^*_{i+j-1}) \\ &= \sum_{j=1}^{n} \log p(y_{i'+j-1} = y^*_{i+j-1}|\boldsymbol{y}_{<i'+j-1}) \end{aligned} \tag{8}$$

After obtaining $\boldsymbol{g}^n_i$ by convolution, the EISL loss in Eq. 6 can be easily calculated. We now discuss the case of autoregressive model, where by definition we have $g^n_{i,i'} = \prod_{j=1}^n p(y_{i'+j-1} = y^*_{i+j-1}|\boldsymbol{y}_{<i'}, \boldsymbol{y}^*_{i:i+j-1})$. The dependence on both $\boldsymbol{y}_{<i'}$ and $\boldsymbol{y}^*_{i:i+j-1}$ in each conditional makes exact estimation of $\log \boldsymbol{g}^n_i$ very complicated and costly. We thus introduce the approximation where we approximate $g^n_{i,i'}$ as $\widetilde{g}^n_{i,i'} = \prod_{j=1}^n p(y_{i'+j-1} = y^*_{i+j-1}|\boldsymbol{y}_{<i'+j-1})$. That is, instead of conditioning on $\boldsymbol{y}^*_{i:i+j-1}$, we use the model-generated tokens $\boldsymbol{y}_{i':i'+j-1}$ as the condition. This simple approximation enables us to define the probability output

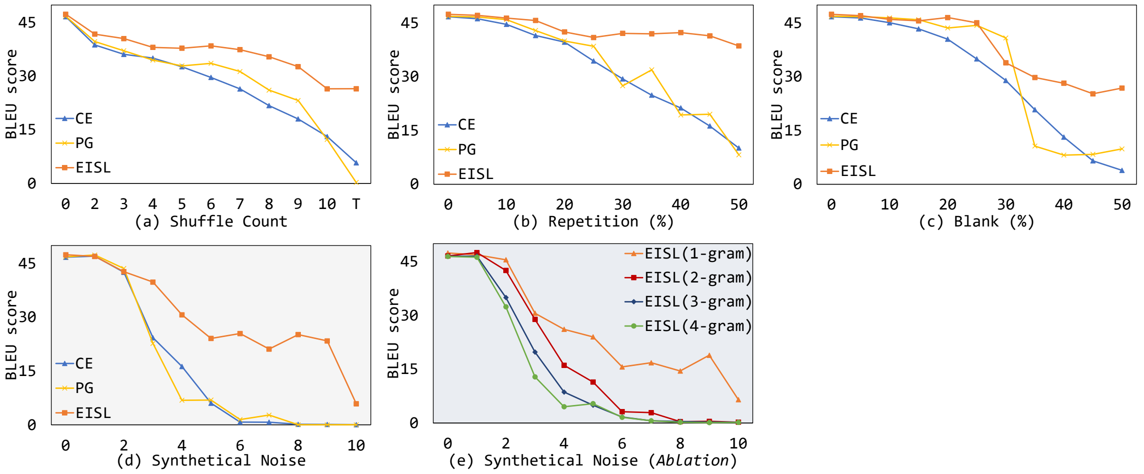

Figure 5: Results of Translation with Noisy Target on German-to-English(de-en) from Multi30k. BLEU scores are computed against clean test data. The x-axis of all figures denotes the level of noise we injected to target sequences in training. (a) Shuffle: selected tokens are shuffled; (b) Repetition: selected tokens are repeated; (c) Blank: selected tokens are substituted with a special blank token; (d) Synthetical noise: the combination of all three noises ($x = x_0$ stands for the combination of $5x_0\%$ of all kinds of noises); (e) Ablation study of n-grams for EISL on synthetical noise. BLEURT results are shown in Appendix A.3.

$\boldsymbol{P}$ as in the non-autoregressive case, by just performing a forward pass of the model (i.e., sampling a token $\boldsymbol{y}'_i$ for each position i' and feeding it to the next step to get $\boldsymbol{p}_{i'+1}$). We can then apply the same convolution operator to approximately obtain $\log \boldsymbol{g}_i^n$ as in Eq. 7. Besides the great gain of computational efficiency, we note that the approximation is also effective, especially due to the *position selection* discussed above. Specifically, for each reference n-gram $\boldsymbol{y}^*_{i:i+n}$, the position selection in effect (softly) picks those large-value $g^n_{i,i'}$ (while dropping other low-value ones) to evaluate the loss. A large $g^n_{i,i'}$ value indicates the candidate $\boldsymbol{y}_{i':i'+n}$ is highly likely to match the reference $\boldsymbol{y}^*_{i:i+n}$, meaning that using $\boldsymbol{y}_{i':i'+n}$ in replacement of $\boldsymbol{y}^*_{i:i+n}$ is a reasonable approximation for evaluating the above conditionals. We provide empirical analysis of the approximation in Appendix A.8, where we show the efficient approximate EISL loss values are very close to the exact EISL values.

3.3 Connections with Common Techniques

CE is a special case of EISL A nice property of EISL is that it subsumes the standard CE loss as a special case. To see this, set $n = T^*$ (the target sequence length), and we have:

$$\mathcal{L}^{\text{EISL}}_{T^*} = \mathcal{L}^{\text{EISL}}_{T^*,1} = -\log \boldsymbol{g}_1^{T^*} = -\log p(\boldsymbol{y} = \boldsymbol{y}^*) = \mathcal{L}^{\text{CE}}.$$

The connection shows the generality of EISL. As a generalization of CE, it enables learning at arbitrary n-gram granularity.

Connections between BLEU and EISL Both our method and the popular BLEU (Papineni et al., 2002b) metric use n-grams as the basis in formulation. Here we articulate the connections and difference between the two. Let us first take a review of the BLEU metric. Specifically, BLEU is defined as a weighted geometric mean of n-gram precisions:

$$\text{BLEU} = \text{BP} \cdot \exp\left(\sum_{n=1}^{N} w_n \log \text{prec}_n\right)$$
$$\text{prec}_n = \frac{\sum_{s \in \text{gram}_n(\boldsymbol{y})} \min(C(\boldsymbol{s}, \boldsymbol{y}), C(\boldsymbol{s}, \boldsymbol{y}^*))}{\sum_{s \in \text{gram}_n(\boldsymbol{y})} C(\boldsymbol{s}, \boldsymbol{y})},$$

where BP is a brevity penalty depending on the lengths of $\boldsymbol{y}$ and $\boldsymbol{y}^*$; N is the maximum n-gram order (typically $N = 4$); $\{w_n\}$ are the weights which usually take $1/N$; prec_n is the n-gram precision, $\text{gram}_n(\boldsymbol{y})$ is the set of unique n-gram subsequences of $\boldsymbol{y}$; and $C(\boldsymbol{s}, \boldsymbol{y})$ is the number of times a gram s occurs in $\boldsymbol{y}$ as defined in Eq. 1. The conventional formulation above enumerates over unique n-grams in $\boldsymbol{y}$. In contrast, we enumerate over token indexes in calculating the n-gram matching loss. BLEU considers the n-gram precisions and has a penalty term while EISL simply maximizes the log probability of n-gram matchings.

The non-differentiability of BLEU makes it hard to optimize directly, hence most prior attempts resort to reinforcement learning algorithms and use BLEU as the reward (Ranzato et al., 2016, Liu et al., 2017). There are also some works trying to introduce differentiable BLEU metric using approximation like (Zhukov and Kretov, 2017). However, such losses are often too complicated and have not yet demonstrated to perform well in practice.

4 Experiments

In this section, we present the experimental results on three text generation settings to test EISL's effectiveness, including learning from noisy text, learning from weak sequence supervision, and non-autoregressive generation models that require flexibility in generation orders. More details of the experimental setting are provided in Appendix A.2.

4.1 Learning from Noisy Text

To test the robustness to noise, we evaluate on the task of machine translation with noisy training target, in which we train the models with noisy sequence targets and evaluate with clean test data.

Setup We test EISL loss on Multi30k and WMT18 raw corpus. We use German-to-English (de-en) dataset from Multi30k (Elliott et al., 2016), which contains 29k training instances. As inspired by Shen et al. (2019), to simulate various noises in the real data, we introduce four types of noises: shuffle, repetition, blank, and the synthetical noise, i.e., the combination of the aforementioned three types of noise. The noises are only added to the training target sequences. To verify the validity of EISL on real noisy data, we also use German-to-English (de-en) dataset from WMT18 raw corpus, which is a very noisy de-en corpus crawled from the web. We randomly select different number of training samples to test the influence of the data scale. We use a Transformer-based pretrained model BART-base (Lewis et al., 2020) and adopt greedy decoding in training and beam search (beam size = 5) in evaluation. We compare EISL loss with CE loss, Policy Gradient (PG), and Loss Truncation (LT). We also conduct ablation experiments to explore the effect of different n-grams in EISL loss. We use both BLEU (Papineni et al., 2002b) and BLEURT, an advanced model-based metric (Sellam et al., 2020), as the automatic metrics for evaluation. Due to space limit, we report BLEU results in the main paper, and defer BLEURT results in the appendix, where we can see BLEURT leads to the same conclusion as BLEU.

Results The results on noisy Multi30k are presented in Figure 5. The proposed EISL loss provides significantly better performance than CE loss and PG on all the noise types, especially on the high-level noise end. For synthetical noise as shown in Figure 5(d), it's interesting to see that CE and PG completely fail when the noise level is beyond 6, but model trained with EISL has high BLEU score, demonstrating EISL can select useful information to learn despite high noise. This validates that the proposed EISL is much less sensitive to the noise than the traditional CE loss and policy gradient training method. The results of different n-gram are shown in Figure 5(e). As the noise increases, the importance of lower grams, e.g., 1-gram, is more obvious. The results on real noisy data, WMT18 raw data, are shown in Figure 6. EISL loss achieves better performance than CE loss and PG, and the difference is getting larger when the training data scale increases. This again demonstrates EISL could learn more valid information in rather noisy data, while CE loss which only

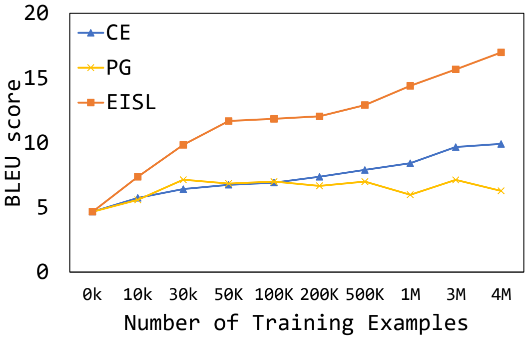

Figure 6: Results of German-to-English(de-en) Translation on WMT18 raw corpus. BLEU scores are computed against clean parallel test data. On x-axis, 0k denotes the performance of the pretrained model. BLEURT results are similar as shown in Appendix A.3.

Model	Acc (%)	BLEU	BLEU (Human)	PPL	POS Distance

22.0	30.7	47.3

Table 1: **Top:** automatic evaluations on the Yelp review dataset. The BLEU (human) is calculated using the 1000 human annotated sentences as ground truth from Li et al. (2018). The first four results are from the original papers. **Bottom:** human evaluation statistics of base model vs. *with* EISL. The results denotes the percentages of inputs for which the model has better transferred sentences than other model.

considers whole-sentence matching could struggle on noisy data. In Appendix A.3, we provide more results (e.g., comparison with loss truncation (Kang and Hashimoto, 2020)) and case studies.

4.2 Learning from Weak Supervisions: Style Transfer

We experiment on transferring two types of text styles (Jin et al., 2022), namely sentiment and political slant, to verify EISL can learn from weak sequence supervisions.

Setup We use the Yelp review dataset and political dataset. Yelp contains almost 250k negative sentences and 380K positive sentences, of which the ratio of training, valid and test is $7 : 1 : 2$. Li et al. (2018) annotated 1000 sentences as ground truth for better evaluation. The political dataset is comprised of top-level comments on Facebook posts from all 412 members of the United States Senate and House who have public Facebook pages (Voigt et al., 2018). The data set contains 270K democratic sentences and 270K republican sentences. And there exists no ground truth for evaluation. The data preprocessing follows Tian et al. (2018). The structured content preserving model (Tian et al., 2018) is adopted as the base model.

Following previous work, we compute automatic evaluation metrics: accuracy, BLEU score, perplexity (PPL) and POS distance. We also perform human evaluations on Yelp data to further test the transfer quality.

Results As sentiment results are shown in Table 1, the BLEU gets improved from 65.71 to 68.51 with EISL loss. On the premise of the correctness of sentiment transfer, EISL loss plays a critical role to guarantee lexical preservation. In the meanwhile, all of BLEU(human), PPL, and POS distance get improved. It is not surprising that EISL loss helps generate sentences more fluently and select the more appropriate words conditions on the content information. As the human evaluation results are shown in Table 1, the model with EISL loss performs better, in accord with the automatic metrics. After analyzing the generated samples, we found EISL loss could drive the model to adopt the words which fit the scene better and could understand more semantics but not just replace some keywords. See some examples in the Appendix A.4.1.

We report the results of political data in Appendix A.4.2. Our method outperforms all models on BLEU, PPL, and POS distance with comparable accuracy. For a more fair comparison with the base model, our EISL loss improves the base model on all four metrics, including the accuracy.

The results demonstrate the effectiveness of EISL for weak supervision task, improving both transfer accuracy fluency and content preservation.

4.3 Learning Non-Autoregressive Generation

Non-autoregressive neural machine translation (NAT, (Gu et al., 2018)) is proposed to predict tokens simultaneously in a single decoding step, which aims at reducing the inference latency. The non-autoregressive nature makes it extremely hard for models to keep the order of words in the sentences, hence CE often struggles with NAT problems. In experiments, we show EISL is superior to CE in NAT which requires modeling flexible generation order of the text.

Setup We use English-to-German dataset from WMT14 (Luong et al., 2015), which contains 4.5M training instances. We apply our proposed EISL loss on both fully NAT models (Gu et al., 2018, Sun et al., 2019) and iterative NAT models (Lee et al., 2018, Gu et al., 2019, Ghazvininejad et al., 2019), showing its general applicability and superiority, and we also compare with a wide range of recent methods (Shao et al., 2020, Wang et al., 2019a, Li et al., 2019, Ghazvininejad et al., 2020). We evaluate with both BLEU and BLEURT metrics.

Results We first summarize the comparison of BLEU between EISL loss and CE loss in Table 2 (comparison of BLEURT is in Appendix A.5.2). The proposed EISL improves the model performance on both the KD and original datasets. More specifically, for fully NAT models (Vanilla-NAT and NAT-CRF), EISL gives strong improvement. For iterative NAT models (iNAT, LevT, and CMLM), EISL also significantly outperforms the baselines when the iteration step is restricted to a small level as suggested by Kasai et al. (2020). (We show in Appendix A.5.1 that, with increasing iteration steps, the difference fades away. However, as studied in Kasai et al. (2020), iterative NAT models with many iteration steps do not hold the intrinsic advantage of speed since Transformer baselines with a shallow decoder can achieve comparable speedup and only at the sacrifice of minor performance drop.) Table 3 provides more comparison of with recent strong baselines. Specifically, we apply our EISL on the CMLM base model (Ghazvininejad et al., 2019) which shows strong superiority. We

Decoding method	Model	WMT14 en-de KD		WMT14 en-de	
		CE	EISL	CE	EISL
Autoregressive	Transformer base (Vaswani et al., 2017)	27.48			
Non-Autoregressive	Vanilla-NAT (Gu et al., 2018)	17.9	**22.2**	9.12	**15.46**
	NAT-CRF (Sun et al., 2019)	21.88	**22.43**	-	-
	iNAT (Lee et al., 2018)	16.67	**22.59**	-	-
	LevT (Gu et al., 2019)	17.84	**23.61**	9.91	**18.47**
	CMLM (Ghazvininejad et al., 2019)	17.12	**23.05**	-	-

Table 2: The test-set BLEU of EISL loss and CE loss applied to non-autoregressive models. “KD” refers to the standard “knowledge distillation” setting in NAT (Gu et al., 2018). iNAT, LevT and CMLM are iterative non-autoregressive models, that could run in multiple decoding iterations. However, the first decoding iteration of these models is fully non-autoregressive, which is what we use as our baselines.

Fully Non-Autoregressive model	WMT14 en-de KD
CMLM *with* CE (Ghazvininejad et al., 2019)	17.12
Auxiliary Regularization (Wang et al., 2019a)	20.65
Bag-of-ngrams Loss (Shao et al., 2020)	20.90
Hint-based Training (Li et al., 2019)	21.11
CMLM *with* AXE (Ghazvininejad et al., 2020)	23.53
CMLM *with* EISL (**Ours**)	**24.17**

Table 3: The test-set BLEU of CMLM trained with our EISL, compared to other recent fully non-autoregressive methods. The baseline results are from (Ghazvininejad et al., 2020), where CMLM-with-AXE generates 5 candidates and ranks with loss. Our method follows the same generation configuration as CMLM-with-AXE.

provide qualitative analysis in Appendix A.5.3.

5 Conclusions

We have developed Edit-Invariant Sequence Loss (EISL) for end-to-end training of neural text generation models. The proposed method is insensitive to the shift of n-grams in target sequences, hence suitable for training with noisy data and weak supervisions, where CE loss fails easily. We show CE loss is a special case of EISL and build the connection of EISL with BLEU metric and convolution operation, which both have the invariant property. Experiments on translation with noisy target, text style transfer, and non-autoregressive neural machine translation demonstrate the superiority of our method. The more general applications and superiority of EISL on other diverse text generation problems as well as fundamental challenges, such as compositional generalization (Andreas et al., 2019) and causal invariance (Hu and Li, 2021) in language, remain to be explored further, which we are excited to study in the future.

A Appendix

A.1 Additional Derivation

For a given i',

$$p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n}) = \sum_{\boldsymbol{y}} p(\boldsymbol{y}_{<i'}) p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^*_{i:i+n} | \boldsymbol{y}_{<i'}),$$

then we derive the detail of Eq. 3 in Eq. 9, where the first inequality holds since $T - n + 1 \geq 0$; and the second inequality holds by Jensen's inequality.

A.2 Detailed Experimental Setup

A.2.1 Learning from Noisy Text

We use a Transformer-based pretrained model BART-base (Lewis et al., 2020), containing 6 layers in the encoder and decoder. We train the model using the Adam optimizer with learning rate 3×10^{-5} with polynomial decay and the maximum number of tokens is 6000 in one step. The models are trained on one Tesla V100 DGXS with 32GB memory. We start with CE training using teacher forcing for fast initialization. We then switch to combined 1- and 2-gram EISL with weight $0.8 : 0.2$, which we select using the validation set. We adopt greedy decoding in training and beam search (beam size $=$ 5) in evaluation. We use fairseq[2] (Ott et al., 2019) to conduct the experiments. We compare EISL loss with CE loss and Policy Gradient (PG), where PG is used to finetune the best CE model. Teacher forcing is employed in CE training.

A.2.2 Learning from Weak Supervisions: Style Transfer

We use the Adam optimizer with learning rate 5×10^{-4}, the batch size is 128 and the model is trained on one Tesla V100 DGXS 32GB. We compare the results between the base model and the model with EISL. Specifically, on top of the base model, we add the EISL loss (a combination of 2, 3 and 4-gram with the same weights $1/3$) to reduce the discrepancy between the transferred sentence generated by language model and the original sentence. We assign EISL loss with weight 0.5.

Following previous work, we compute automatic evaluation metrics: accuracy, BLEU score, perplexity (PPL) and POS distance. For accuracy, we adopt a CNN-based classifier, trained on the same training data, to evaluate whether the generated sentence possesses the target style. Then we measure BLEU score and BLEU(human) score of transferred sentences against the original sentences and ground truth, respectively. PPL metric is evaluated by GPT-2 (Radford et al., 2019) base model after finetuning on the corresponding dataset, with the goal to assess the fluency of the generated sentence. POS distance is used to measure the model's semantics preserving ability (Tian et al., 2018).

We also perform human evaluations on Yelp data to further test the transfer quality. We first randomly select 100 sentences from the test set, use these sentences as input and generate sentences from the base model (Tian et al., 2018) and our model. Then for each original sentence, we present the outputs of the base model and ours in random order. The three annotators are asked to evaluate which sentence is preferred as the transferred sentence of the original sentence, in terms of content preservation and sentiment transfer. They can choose either output or select the same quality. We measure the percentage of times each model outperforms the other.

A.2.3 Learning Non-Autoregressive Generation

We use the Adam optimizer with learning rate 5×10^{-4} with inverse square root scheduler. We apply sequence-level knowledge distillation to the dataset, which can reduce the complexity of the dataset, making it easier for the model to learn and improving the performance. The models are first trained by CE loss for fast initialization, then focus on 2-gram, 3-gram, and 4-gram with the same weights. Fairseq (Ott et al., 2019) is adopted to conduct the experiments. We average the last 5 checkpoints as the final model.

A.3 Additional Results of Learning from Noisy Text

A.3.1 Results of BLEURT Metric

In this section, we evaluate the results of CE, PG and EISL on BLEURT (Sellam et al., 2020) metric. We use the recommended BLEURT-20 checkpoint. It gives a score for every sentence pair, and we averaged the scores to get the final score. The results are shown in Figure 7. Both BLEU metric and BLEURT metric show the superiority of our proposed EISL loss.

A.3.2 Comparison with Loss Truncation

The Loss Truncation (LT (Kang and Hashimoto, 2020)), method adaptively removes high log loss

---

[2] Fairseq(-py) is MIT-licensed.

$$\begin{aligned}
l_{n,i}^{\mathrm{EISL}}(\boldsymbol{\theta}) &= -\log \sum_{i'=1}^{T-n+1} p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^{*}_{i:i+n}), \\
&= -\log \frac{1}{T-n+1} \sum_{i'=1}^{T-n+1} \sum_{\boldsymbol{y}} p(\boldsymbol{y}_{<i'}) p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^{*}_{i:i+n} | \boldsymbol{y}_{<i'}) - \log(T-n+1), \\
&\leq -\log \frac{1}{T-n+1} \sum_{i'=1}^{T-n+1} \sum_{\boldsymbol{y}} p(\boldsymbol{y}_{<i'}) p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^{*}_{i:i+n} | \boldsymbol{y}_{<i'}), \\
&\leq -\frac{1}{T-n+1} \sum_{i'=1}^{T-n+1} \sum_{\boldsymbol{y}} p(\boldsymbol{y}_{<i'}) \log p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^{*}_{i:i+n} | \boldsymbol{y}_{<i'}), \\
&= -\frac{1}{T-n+1} \mathbb{E}_{\boldsymbol{y} \sim p(\boldsymbol{y})} \sum_{i'=1}^{T-n+1} \log p(\boldsymbol{y}_{i':i'+n} = \boldsymbol{y}^{*}_{i:i+n} | \boldsymbol{y}_{<i'}), \\
&= \mathcal{L}_{n,i}^{\mathrm{EISL}}(\boldsymbol{\theta}),
\end{aligned} \tag{9}$$

examples as a way to optimize for distinguishability. In this section, We'd like to show the comparisons with Loss Truncation. We evaluated two variants of LT: (1) LT_Pre which first trains the model with CE loss and then adds LT for further training, and (2) LT which directly trains the model with CE loss and LT together. Hyperparameters were selected on the validation set. For simplicity, we remove the PG curves (Figure 5), and the comparison results with LT are shown in Figure 8.

We can see Loss Truncation can sometimes slightly improve over CE, especially when the data is clean or with low/moderate noise. However, by simply ignoring high-loss data, LT is not good at handling data with high noise (which often leads to high loss). In comparison, our proposed EISL achieves a substantial improvement in the presence of high noise.

A.3.3 Reasons of Better Performance with Lower-gram EISL

In this section, we discuss the reason of why the performance of using lower grams is better than higher-gram EISL in Figure 5(e).

Lower-gram EISL is less sensitive to noise. For example, 1-gram EISL focuses mostly on matching individual tokens without caring much about the order of tokens; while a high-gram EISL (e.g., consider the extreme case of T^*-gram where T^* is the target length) reduces to CE (as discussed in Sec 3.3) and is highly sensitive to noise. Thus, in the presence of high data noise, lower-gram EISL would be more robust and perform better.

Besides, on low-noise data (e.g., noise-level = 0 or 1), lower-gram EISL performs comparably with higher-gram EISL, both close to the CE performance. This is because we pretrained the model with CE (as mentioned in the experimental setup), and finetuning with EISL (either with lower- or higher-grams) would not change the performance a lot given the low-noise data.

A.3.4 Cases Study

As shown in Table 8, 9, 10, 11 and 12, we randomly sample some examples from generated sentences of the models trained with different types of noise on Multi30k dataset. For the sake of convenience, we use abbreviations in the tables, i.e., SC, RR, BR and NL are short for Shuffle Count, Repetition Ratio, Blank Ratio and Noise Level (for Synthetical Noise), respectively.

Shuffle Noise When there exist a few shuffle noises, e.g., SC = 3, CE loss may lead word reduplicated (Example 1 and Example 2) and slightly wrong word order (Example 4 and Example 5), and there are some information mistranslated (*beautiful* in Example 4) or extra irrelevant information added (*black* in Example 5). As shuffle count increases, the aforementioned problems are increasingly severe, resulting the generated sentences meaningless. Especially, there are some words untranslated in PG examples (*eingezäunten* in Example 1, *irgendwo* in Example 2, *haben* in Example 5,). But EISL loss could keep the content consistency and grammatical correctness as far as possible.

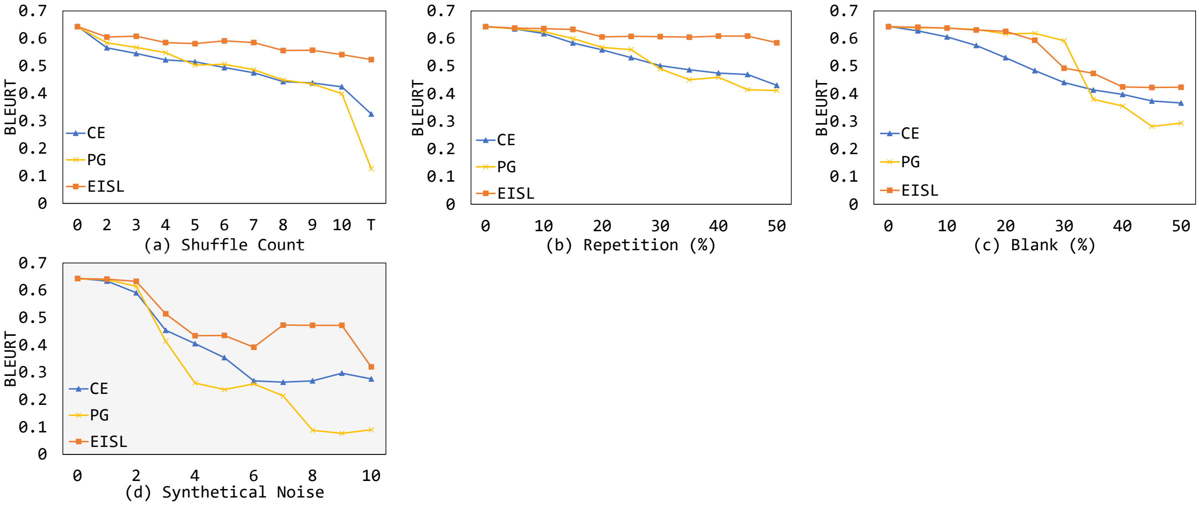

Figure 7: Results of Translation with Noisy Target on German-to-English(de-en) from Multi30k. BLEURT scores are computed against clean test data.

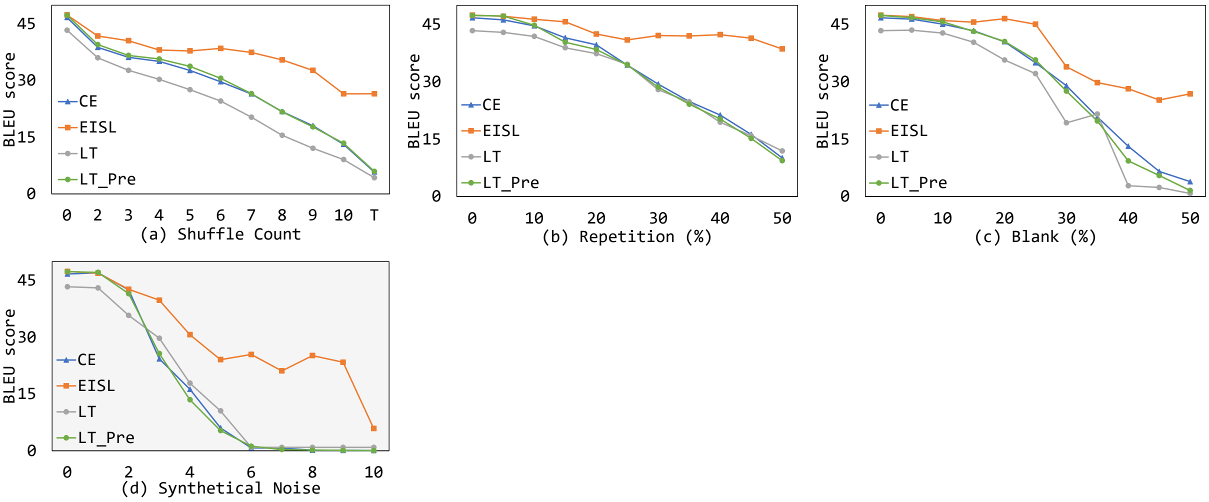

Figure 8: Comparison results with Loss Truncation(LT) of Translation with Noisy Target on German-to-English(de-en) from Multi30k. BLEU scores are computed against clean test data.

Repetition Noise The main problem of the models trained by CE and PG with repetition noises is that the models can't filter the repetition noise out in training samples, and try to learn the wrong distribution, leading to generate reduplicated words frequently (Example 1-5). Specifically, the examples of CE and PG in RR $= 50\%$ are very representative. However, it's amazing that EISL can almost avoid such a problem even the repetition ratio achieves 50%. Meanwhile, the main semantics is preserved and the grammar is correct.

Blank Noise When adding blank noise, some tokens in targets will be substituted as *unk* so the targets will lose some information. We could measure from two aspects: one is the term frequency of meaningless token *unk* in generated sentences, and the other is the meaningful contents preserved by the models. Obviously, EISL loss handles better than CE loss on both aspects. Especially, when BR $= 20\%$, unlike models with CE, models with PG and EISL barely generate the *unk* token, and could translate the core content (Example 1-5). As BR increases, EISL could preserve more key information and produce less *unk* than CE and PG. Moreover, PG performs rather poor when BR is high (like BR $= 45\%$), and it almost loses all information (Example 1-5) and generates some confusing words (*teil* in Example 1, *afroamerikanischer* and *irgendwo* in Example 3, *beachaufsichtgebäude* in Example 4, and *holzstück* in Example 5).

Synthetical Noise We then evaluate the results of models trained by synthetical noise. Such a

Source	my “ hot ” sub was *cold* and the meat was *watery* .
Base Model	my “ hot ” sub was *excellent* and the meat was *excellent* .
with EISL	my “ hot ” sub was *delicious* and the meat was *delicious* .
Source	the man did *not stop* her .
Base Model	the man did *definitely right* her .
with EISL	the man did *definitely stop* her .

Table 4: Examples of the generated sentences.

Model	Accuracy(%)	BLEU	PPL	POS distance
Prabhumoye et al. (2018)	86.5	7.38	-	7.298
Hu et al. (2017)	**90.7**	47.50	-	3.524
Tian et al. (2018)	88.0	59.63	28.46	2.348
with EISL	89.2	**60.26**	**27.85**	**2.191**

Table 5: The results on the political dataset. The first two results are reported by (Tian et al., 2018).

situation combines aforementioned three types of noises. One most highlighted advantage of EISL is that the generated sentences are almost grammatically correct and include main content as far as possible. However, CE can only stiffly joint some words, and can't guarantee the grammatical correctness (word order, word repetition and so on). PG performs worst, involving all the problems in CE cases and the meaningless word generation problem (Example 1-5).

A.4 Additional Results of Text Style Transfer

A.4.1 Examples on Yelp dataset

Some examples of generated sentences are given in Table 4. The model with EISL can select more appropriate adjective and improve the quality of the sentences. In the first example, the model should transfer the negative adjectives *cold* and *watery* to some positive adjectives that describe food. Obviously, the *delicious* is more appropriate than *excellent*. In the second example, the base model reverses both *not* and *stop*, leading to wrong sentiment and inconsistent content. While the model with EISL could avoid such a situation and generate more suitable sentence.

A.4.2 Results on Political dataset

Since the instances from democratic data and republican data are quite different, names of politicians have high correlation with the political slant. Therefore the BLEU score and POS distance have a big gap with the sentiment results. The results are shown in Table 5.

A.5 Additional Results of Non-Autoregressive Generation

A.5.1 Results of Iterative NAT Models

As shown in Figure 9, with the increasing of iteration steps, the difference fades away.

A.5.2 Results of BLEURT Metric

To show the superiority of our method, We also evaluate on recent text generation metric, BLEURT (Sellam et al., 2020). BLEURT is an evaluation metric for Natural Language Generation. It takes a pair of sentences as input, a reference and a candidate, and it returns a score that indicates to what extent the candidate is fluent and conveys the mearning of the reference. We use the recommended BLEURT-20 checkpoint. It gives a score for every sentence pair, and we averaged the scores to get the final score. The results are shown in Table 6.

A.5.3 Qualitative Analysis on NAT Experiments

Given the non-autoregressive nature (i.e., all tokens are generated simultaneously), the one-to-one matching of CE loss can lead to severe mismatching. We consider the example: the predicted sentence is `a cat is on the red blanket` and the target sentence is `a cat is sitting on the red blanket`. The "on the red blanket" part of the prediction will be corrected to match the target positions, and this may lead to overcorrection (e.g., "on the red red blanket ."). Repetition is often a sign of overcorrection. However, with EISL, this situation will not happen because the phrase will be matched to appropriate

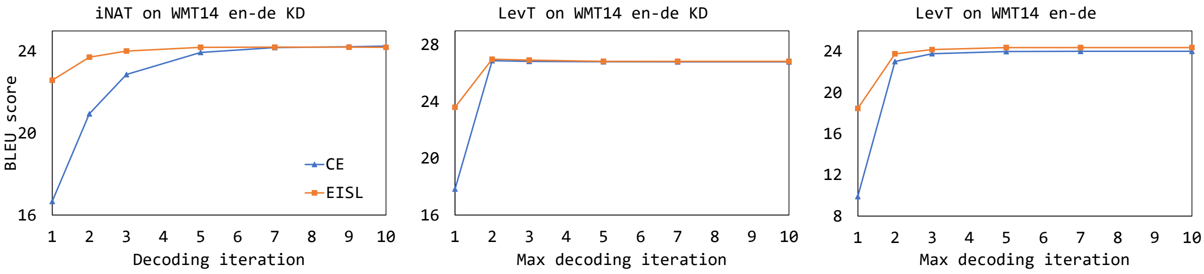

Figure 9: Results of iterative NAT on different decoding iterations.

Model	**WMT14 en-de KD**		**WMT14 en-de**	
	CE	EISL	CE	EISL
Vanilla-NAT (Gu et al., 2018)	0.346	**0.416**	0.194	**0.277**
NAT-CRF (Sun et al., 2019)	0.441	**0.464**	-	-
iNAT (Lee et al., 2018)	0.332	**0.437**	-	-
LevT (Gu et al., 2019)	0.355	**0.458**	0.214	**0.333**
CMLM (Ghazvininejad et al., 2019)	0.345	**0.450**	-	-

Table 6: The results (test set BLEURT) of EISL loss and CE loss applied to non-autoregressive models.

target tokens. Let's have a look at a real example in Figure 10.

Source	Anja Schlichter managed the tournament
Target	Anja Schlichter leitet das Turnier
CE	Anja Schlichter leitdas Turnier Turnier
EISL	Anja Schlichter leitete das Turnier geleitet

Figure 10: Examples of the generated sentences.

Take the non-autoregressive model CMLM (Ghazvininejad et al., 2019) for example, we evaluate the translation of CMLM models trained by CE and EISL. As shown in Figure 11, our proposed EISL can reduce repetition to a large extent.

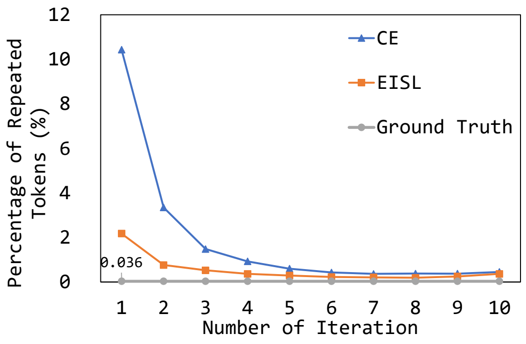

Figure 11: The percentage of repeated tokens under different iteration steps.

A.6 Efficiency Analysis

Complexity analysis Given T^* tokens, the time complexity of CE loss is $\mathbf{O}(T^*)$, while the complexity of n-gram EISL loss is $\mathbf{O}(n(T^* - n + 1)^2) \approx \mathbf{O}(T^{*2})$, assuming small n is used in practice (e.g., $n \in \{1, 2, 3, 4\}$). However, in practice, the computation cost of the loss (either CE or EISL) is **negligible** compared to the cost of model forward and backward during training. Thus, the extra cost introduced by the EISL loss is rather minor.

Empirical comparison of time cost To quantify the computational cost of different methods, we adopt CE and EISL on top of the same model and setting, and evaluate the consumed time for 1 training epoch. For comparison on both small and large dataset, we evaluate on Multi30k (29k training data, 1k test data) and 1M scale WMT-18 raw corpus (1M training data, 3k test data). The models are tested on one Tesla V100 DGXS with 32 GB memory, the batch size is 128, max number of tokens is 6000 and update frequency is 4. For each method, we test 6 times and average the results as final time. The results are shown in Figure 12.

Empirical total time cost of EISL training As discussed in the experiments in the paper, we first pretrain the model with the CE loss until convergence, and then finetune with the EISL loss. Here we report the total time cost of each stage, based on the WMT-18 translation setting as described in Section 4.1. The results are shown in Table 7. As

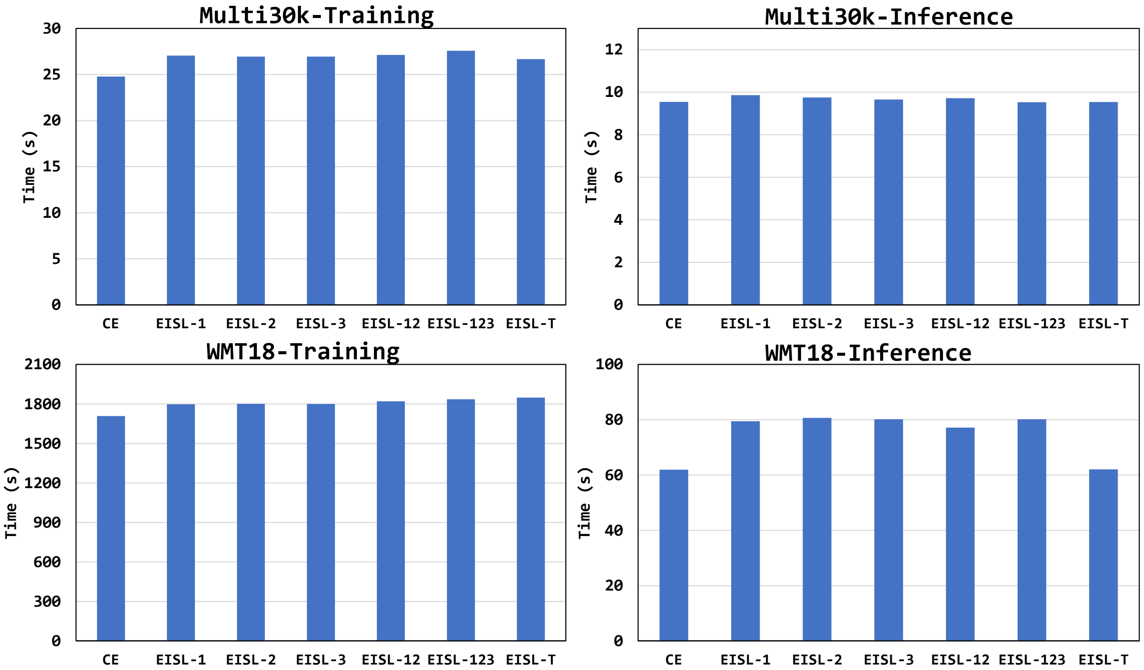

Figure 12: Results of training and inference time. EISL-n represents n-gram EISL loss and EISL-12 represents the combination of 1-gram and 2-gram EISL loss.

the data size increases, the convergence time of both pretraining and finetuning grows. The time cost of the finetuning stage is less than half of that of the pretraining stage.

A.7 Hyperparameters

Regarding which n-grams to use and their weights w_n in the EISL loss, we found in our experiments that the default values *largely* following the standard BLEU metric (i.e., maximum $n = 4$ with equal weights) work well. Specifically, we use $n \in \{2, 3, 4\}$ and equal weights $w_n = 1/3$ as our default values. Most of our experiments adopt the default values which achieve consistent substantial improvement over CE and other rich baselines as shown in our experiments. (except for the synthetic experiment where we show the effect of different n-grams including those selected using the validation set).

Besides, in our experiments, we first pretrain the model with the CE loss (i.e., EISL with $n = T^*$ and teacher forcing, see Section 3.3) and then finetune with the EISL loss. We simply do the CE pretraining *until convergence* before switching to the EISL finetuning. Therefore, there is no need of tuning for the training iterations of pretraining.

A.8 Analysis of Efficient Implementation

In order to validate the efficiency and accuracy of our approximation (for autoregressive models) discussed in Section 3.2, we conduct the analysis experiments, showing that the approximate (and efficient) EISL loss values are very close to exact (but expensive) EISL value. We use the same setting as section 4.1, and finetune the model with our efficient approximate EISL loss on Multi30k. Throughout the course of training, we record the loss values of both the exact implementation and our approximate implementation. As shown in Figure 13(a) and (b), the tendency of two losses is very close to each other. We also plot the absolute difference of the two losses as shown in Figure 13(c). We can see the difference decreases as training proceeds. The observations validate the effectiveness of our approximate implementation.

We note that training the model with the exact loss is costly, which necessitates our approximation. Specifically, for n-gram loss, we need to run the forward pass of the decoder $(T - n)^2$ times, and keep the whole computation graph for backpropagation, which will consume much more time and memory. Even for only loss evaluation (without the backward pass), we found the runtime of the exact loss is about 15 times longer than that of the efficient approximate implementation based on convolution operator.

Data Size	PreTraining Time (CE)	Finetuning Time (EISL)
1M	1h 40min 57s	49min 33s
2M	5h 56min 57s	1h 35min 10s
4M	8h 55min 18s	3h 57min 44s

Table 7: Convergence time of pretraining and finetuning stages.

Modeling Exemplification in Long-form Question Answering via Retrieval

Abstract

Exemplification is a process by which writers explain or clarify a concept by providing an example. While common in all forms of writing, exemplification is particularly useful in the task of long-form question answering (LFQA), where a complicated answer can be made more understandable through simple examples. In this paper, we provide the first computational study of exemplification in QA, performing a fine-grained annotation of different types of examples (e.g., hypotheticals, anecdotes) in three corpora. We show that not only do state-of-the-art LFQA models struggle to generate relevant examples, but also that standard evaluation metrics such as ROUGE are insufficient to judge exemplification quality. We propose to treat exemplification as a *retrieval* problem in which a partially-written answer is used to query a large set of human-written examples extracted from a corpus. Our approach allows a reliable ranking-type automatic metrics that correlates well with human evaluation. A human evaluation shows that our model's retrieved examples are more relevant than examples generated from a state-of-the-art LFQA model.

1 Introduction

When an author introduces a complicated concept, they commonly follow it up with a concrete example to help clarify their intended meaning. This process, known as *exemplification*, occurs in diverse forms, including hypothetical examples, personal anecdotes, and analogies (Clouse, 2013). Exemplification is particularly common within the NLP task of *long-form question answering* (LFQA), where an author wants to communicate a concept unknown to the question asker. Consider the following QA pair from the `r/explainlikeimfive` subreddit (Fan et al., 2019):

> **Q:** How does the ground not cave in while being under the heavy weight of cities?
> **A:** It's all about what they're building on, and occasionally they get it wrong... For example, San Francisco's Millennium Tower, built on mud and sand, has already sunk 18 inches into the ground.

Here, the answerer uses a specific example to emphasize the importance of building on a solid foundation. In general, explaining via exemplification is a fundamental technique in these kinds of pedagogical scenarios (Hyland, 2007), and it warrants separate study due to its importance in LFQA and the challenges in evaluating it. However, existing work on building LFQA models (Fan et al., 2019) does not give special treatment to exemplification or any other discourse phenomena, choosing instead to evaluate model outputs against reference answers using metrics such as ROUGE (Lin, 2004) that are not meaningful for this task (Krishna et al., 2021). In the above QA pair, any other structurally-unstable building (e.g., the Leaning Tower of Pisa) could serve as a valid example, but an LFQA model would be unfairly penalized for generating one of these acceptable alternatives.

In this paper, we first conduct a detailed study of exemplification across three different domains: Wikipedia, web articles, and community answers to questions from the ELI5 LFQA dataset. We extract sentences and clauses associated with exemplification by matching on explicit markers such as *"for example"* and *"(e.g., ...)"* and annotate 300 examples from this dataset. Our analysis reveals significant variation in occurrence frequencies of different forms of exemplification (e.g., hypothetical vs. specific examples) across the three domains.

Next, we focus on improving the modeling and evaluation of the subtask of exemplification within LFQA. We propose to treat it as a *retrieval* problem rather than a generation problem: given a question and a prefix of a reference answer (in the above QA pair, all of the text before *"For example"*), a model must retrieve the ground-truth example that follows the prefix (the sentence about the Millenium Tower) from the set of all exemplifying sentences

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2079 - 2092
July 10-15, 2022

and clauses in the dataset. We can use retrieval metrics such as recall@k to evaluate a model's ability to select the ground-truth example, which are more informative than metrics such as ROUGE.

We demonstrate that pretraining our retriever on a large-scale dataset of exemplifying units extracted from the Books3 corpus (Gao et al., 2020) and then fine-tuning it on ELI5 examples results in substantial improvements on these ranking metrics. Finally, we crowdsource human evaluation comparing our retriever's outputs with those generated by the state-of-the-art ELI5 model of Krishna et al. (2021) and find that workers prefer the retriever's outputs far more frequently than those of the generation model. We hope that our work spurs more research into the evaluation and modeling of exemplification and other complex discourse phenomena present in LFQA. To facilitate future research, we publicly release the code and trained models from our work.[1]

2 Exploring Exemplification

In this section, we first describe our data extraction process, which we use to mine instances of exemplification from three datasets (and domains): ELI5 (Fan et al., 2019), Natural Questions (Kwiatkowski et al., 2019) and Books3 (Gao et al., 2020). This process involves matching on a set of "exemplification markers" and collecting both the text of the matching example (a sentence or clause) as well as the surrounding context on both sides. We then conduct a fine-grained human annotation study on the extracted data, breaking exemplification down into different types and exploring how they are used across the different domains.

2.1 Extracting a Dataset of Exemplification

Exemplification markers: Hyland (2007) annotated a diverse collection of articles from multiple disciplines with a variety of rhetorical practices[2] and found that more than 75% of "examples" are signalled parenthetically or lexically with the use of the three most frequent "exemplification markers": *"such as"*, *"for example"*, *"e.g."*. Empirically, we find that the *"such as"* marker is noisy at signalling exemplification and often leads to ambiguous cases where it is hard to automatically detect the example boundary. Hence, we take the other two most frequent exemplification markers, namely *"for example"* and *"e.g."*, and extract the parentheses-enclosed clauses and sentences that contain these exemplification markers as examples.

	ELI5	NQ	Books3
# training examples	65,157	1,209	2,848,171
# validation examples	1,185	52	712,043
avg. # context words	123.7	74.0	155.7
avg. # example words	23.3	33.1	27.1
avg. # right words tokens	135.3	54.8	107.5

Table 1: Statistics of extracted example-in-context data.

Examples from Diverse Domains Using these two exemplification markers, we extract a dataset of examples in context from two popular LFQA datasets that come from different domains, ELI5 (Fan et al., 2019, Reddit answers) and Natural Questions (Kwiatkowski et al., 2019, Wikipedia passages).[3] To study the exemplification phenomenon from a more diverse perspective, we also extract examples along with their surrounding context from the Books3 Corpus (Gao et al., 2020), a large-scale 100GB collection of books spanning a variety of topics and genres. Table 1 contains detailed statistics for the extracted example-in-context datasets.

2.2 Fine-grained Annotation Study

With the extracted dataset of examples, we conduct an in-depth analysis to understand different uses of exemplification in various domains. We (the authors) annotate a total of 300 examples extracted using exemplification markers from Natural Questions, ELI5 and Books3 as below. Fifty examples are annotated by two annotators (for purposes of computing agreement, reported in Section 2.3) and the rest are annotated by one annotator.

Given an extracted example and its left and right context, we first filter out around 7% of the extracted examples, either because they are extraction artifacts or because the marker is used for functions other than exemplification (e.g., referring to a figure or table). After this basic check, we annotate both structural information about the example (e.g., discourse units such as the anchor of the example) and semantic information about how it is used

---

[1] https://github.com/north125ptlm/lfqa-retrieval

[2] The annotation included texts from physics, biology, mechanical & electric engineering, philosophy, sociology, applied linguistics, and marketing.

[3] We consider questions with *only* a long answer span (i.e. paragraph answer) since they cannot be addressed solely by entity names or a boolean, and are suitable for studying LFQA.

Dataset	Valid	Extracted	% Valid
ELI5	87	93	94%
NQ	89	95	94%
Books3	85	94	90%
Total	261	282	93%

Table 2: Statistics of annotated examples.

in the context. Table 2 contains statistics of the annotated subset.[4]

2.2.1 Discourse units

Exemplification is usually expressed through three discourse units (Meyer, 1992; Triki, 2021): the anchor (also known as "exemplified unit"), the exemplification marker, and the example text itself ("exemplifying unit"). We annotate the anchor (marked as **bold**) and example (marked as *italics*). Concretely, in example (1) below, the anchor is "euryhaline species", the exemplifying marker is "e.g.", and the exemplifying unit is "Flounder". As in the study of Triki (2021), we find that these units mainly come in two forms: (1) nominal groups that refer to entities, or (2) clauses that represent statements.

(1) However , some fish show a tremendous ability to effectively osmoregulate across a broad range of salinities ; fish with this ability are known as **euryhaline species** , e.g., *Flounder*.

(2) **Players earn you points, depending on their performance.** For example, *your QB might throw for 200 yards, earning 1 point per 10 yards, for 20 points.*

During our initial investigation, we also noticed examples (3) which are signalled *implicitly* (i.e. without exemplification markers).[5] Identifying such examples automatically is beyond the scope of our study and warrants future work.

(3) **The biggest driver of disparity in tech jobs is cost of living.** *If it costs 2000 a month to live in Boston, and 200 a month to live in India, then salaries will reflect that.*

Table 3 shows that the length of the discourse units is roughly the same across the three datasets, which supports our experimental decision in Section 3 of using sentences as the base unit for example retrieval. We also find that all of the anchors we annotated occur *before* the examples, suggesting that using preceding context to retrieve examples gives the model sufficient information.

Dataset	# samples	Anchor	Example
ELI5	87	1.1/16.6	1.3/29.2
NQ	89	1.0/15.4	1.4/25.1
Books3	85	1.1/17.0	1.2/25.1
Type			
Real	209	1.1/14.5	1.3/24.6
Hypothetical	52	1.2/23.4	1.2/33.7
Personal	13	1.1/18.1	2/49.6
Not-personal	248	1.1/16.3	1.2/25.2

Table 3: Length of the discourse units per dataset and type, presented as average # sentences / # words.

2.2.2 Real vs. Hypothetical Examples

One notable categorization found during our investigation and also identified by Triki (2021) is whether the examples are real, specific scenarios, or hypothetically-constructed scenarios. We detail the definition of the two types here:

Real examples: These examples are either real entities (4) or specific scenarios (5) that are constructed as fact clauses.

(4) CEOs lead a range of organizations , including public and private corporations, non-profit organizations and even **some government organizations** (e.g., *Crown corporations*).

(5) **For a given pressure , different liquids boil at different temperatures**. For example, *water boils at 100° C (212° F) at sea level, but at 93.4° C (200.1° F) at 2,000 metres (6,600 ft) altitude.*

Hypothetical examples: In contrast, hypothetical examples are scenarios constructed by the author. According to Triki (2021), hypothetical examples often come with the use of conditional clauses *if* or signalled via *assume*. These examples are generally more complicated and are specifically constructed for the purpose of exemplification.

(6) **The reasoning is that if you share your life with someone then anything you do during that time is made possible by their support.** For example, *if your wife is a stay at home wife and your a business man making lots of money, the reasoning is that you would not have the same amount of time to dedicate to work if you had to look after your own house and/or children.*

We observe a different distribution of the two types of examples in the three datasets (Figure 1, top). ELI5 contains more hypothetical examples

---

[4] Annotated examples in the three datasets can be found in Table A1 in the appendix.

[5] Recent study on long form QA (Xu et al., 2022) contains manually identified example sentences, including those signalled implicitly.

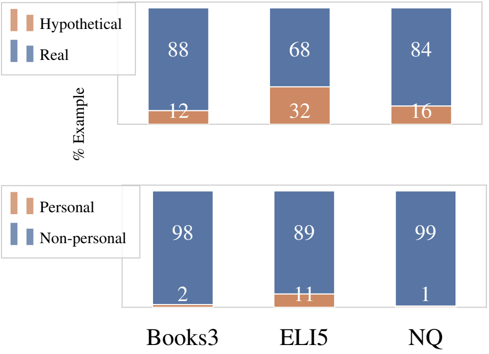

Figure 1: Distribution of different types of examples across three datasets.

(32%) than the other two datasets (16% for NQ, 12% for Books3), showing that hypothetical examples are commonly used to explain complicated concepts. We also note that hypothetical examples are generally longer than real ones (33.7 v.s. 24.6 words, as seen in Table 3), aligning with our observation that these examples are more complicated.

2.2.3 Personal Information

Previous work found that exemplification is "rarely personalized" in academic texts (Ädel, 2006), referring to the uncommon use of first person pronouns or reference to the author. In contrast, we found a consistent presence of personal information in the examples we examined, in the form of either personal anecdotes (7) or an example situated in the author's own circumstance (e.g., *in my city...*). We thus also annotate whether the exemplifying units contain personal information or not.

> (7) ... **But they also give advice a doctor might have forgotten.** For example *about 6 months ago I went to the urgent care center for ear pain and was prescribed an ear drop antibiotic.* ...

We observe differences in the presence of personal information across the three datasets (Figure 1, bottom) – ELI5 answers, which are written by users from online community forum, contain a substantial portion of examples with personal information (12%), while such information is rarely present in the other two datasets. There is also a notable length difference between examples with and without personal information (49.6 v.s. 25.2 words), showing that more detailed description is provided for personal anecdotes. The observation that ELI5 contains many personal examples raises concerns that language models trained on such datasets will generate personal examples that cannot be verified or meaningfully interpreted.

2.3 Annotation agreement

We report agreement for the three annotation tasks performed on the 50 two-way annotated samples. For discourse unit annotation, we find high unigram overlap between the two annotations (0.81 for the anchor and 0.92 for the example). For annotation of real vs. hypothetical examples and the presence of personal information, we find a modest to high agreement with a Cohen's kappa of 0.48 for both. Additionally, we observe annotations of real v.s. hypothetical example to be split when the example refers to abstract actions, such as the one below (8).

> (8) Carpets are used for a variety of purposes , including insulating a person 's feet from a cold tile or concrete floor , **making a room more comfortable** as a place to sit on the floor (*e.g.* , *when playing with children or as a prayer rug*) , reducing sound from walking (particularly in apartment buildings) and adding decoration or colour to a room .

3 Retrieving Examples in LFQA

Our annotation and analysis of the extracted exemplification dataset reveals the diversity and complexity of this discourse phenomenon. In this section, we shift our focus towards building retrieval-based models to produce examples based on a given LFQA context. First, we define our example-retrieval task formally and introduce our evaluation metrics. Then, we describe our contrastive-learning based retriever model, which closely follows the retriever implementation in Thai et al. (2022), and baseline retrieval models, and report their performances.

3.1 Task Definition

Given a context (part of the answer to a given LFQA question) with a masked out exemplifying unit, model is asked to retrieve that masked unit from a retrieval corpus. We consider two settings for context: (1) concatenation of left and right contexts surrounding the exemplifying unit and (2) left context preceding the exemplifying unit only (as in Figure 2). Both left and right contexts are truncated to 256 tokens surrounding the exemplifying unit. We use all 66K exemplifying units extracted from the 272K QA instances in the training and development portion of ELI5 dataset (Petroni et al., 2021) as the retrieval corpus. To illustrate the input format, consider the below answer to the question "Why didn't anyone discover dinosaur fossils before the 1800s?":

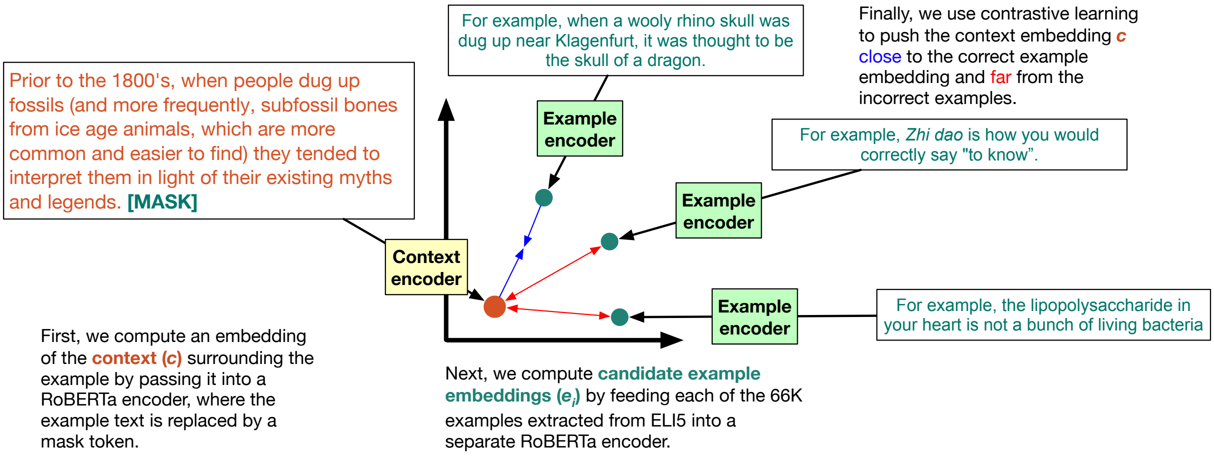

Figure 2: Our EGRET model uses dual RoBERTa encoders to embed (1) the context surrounding an exemplifying unit and (2) all 66K exemplifying units extracted from ELI5. A contrastive objective is then used to move the context embedding close to the embedding of the ground-truth exemplifying unit that occurs within that context, and far from all other negative exemplifying units.

> Prior to the 1800's, when people dug up fossils (and more frequently, subfossil bones from ice age animals, which are more common and easier to find) they tended to interpret them in light of their existing myths and legends. **[MASK]** Because fossils are almost always found as a jumble of bones rather than a neat skeleton and because they are incomplete... nobody looked at dinosaur skeletons and realized what the animals that made them actually looked like.

where the **[MASK]** token corresponds to

> For example, when a wooly rhino skull was dug up near Klagenfurt, it was thought to be the skull of a dragon.

The first quote block showing the masked answer will be used as a query to retrieve the exemplifying unit in the second quote block.

This retrieval task is challenging due not only to the size of the candidate set but also because of the topical similarity between many ELI5 questions, which was previously noted by Krishna et al. (2021). Retrieving based on lexical overlap, as in BM-25 and other string-matching based approaches, cannot identify exemplifying units that are relevant but share little overlap with the context.

3.2 Evaluation Data / Metric

For evaluation data, we use 1,185 context-example pairs automatically identified from 1,507 QA instances in the ELI5 development set (Petroni et al., 2021) by our discourse marker heuristics. We evaluate the performance of our retriever by measuring how reliable it is at retrieving ground-truth examples from the candidate example set. Concretely, given the candidate set of examples, each model should output a ranked list of all examples according to their fit for the context. We evaluate these rankings using recall@k of the ground-truth example (where $k = 1, 3, 5, 10, 50, 100$) from the set of all 66K examples in ELI5. By using retriever-based evaluation metrics, we can directly measure a model's ability to understand and exemplify a context, in contrast to string overlap metrics like ROUGE (Lin, 2004) which are uninformative for this task.

3.3 Models

We first introduce our model (EGRET) and describe baseline retrieval methods. We use all baseline models in a zero-shot manner (without additional fine-tuning on exemplification dataset).

EGRET: an example retriever for LFQA We train an example retriever model (EGRET) on our extracted exemplification dataset from training portion of ELI5 (Fan et al., 2019), which contains $65K$ extracted context-example pairs. Our retriever consists of dual Transformer encoders (Vaswani et al., 2017), one to encode the context query and the other to encode candidate examples (Figure 2). Both encoders are initialized as pretrained RoBERTa-base models (Liu et al., 2019), as in the dense-RELiC model of Thai et al. (2022). To obtain a query embedding c_i, we feed the query encoder the surrounding context of a masked-out example, as in Figure 2. Similarly, we use the other encoder to compute embeddings of the ground-truth example (e_i^+) as well as negative examples sampled

Model	Context	Recall@k (↑)						Avg rank (↓)
		1	3	5	10	50	100

EgRet (ELI5)	L+R	23.5	35.6	41.9	51.0	71.0	77.6	300.6
EgRet (Books3 only)	L+R	33.4	47.8	53.8	61.5	76.5	82.5	632.9
EgRet (Books3 + ELI5)	L+R	**36.9**	**50.6**	**58.2**	**64.8**	**80.2**	**85.8**	**188.4**

Table 4: Our EgRet model outperforms pretrained (or non-parametric) baselines on the example retrieval task, indicating that exemplification cannot be solved by term matching or coarse query-context similarity alone. Pretraining EgRet on out-of-distribution examples from Books3 results in large improvements in recall@k. Finally, including context to the right of the exemplifying unit significantly boosts performance.

from other contexts, forming a set E of example embeddings. We fine-tune both encoders in EgRet with a contrastive learning objective (van den Oord et al., 2018; Chen et al., 2020):

$$\mathcal{L}(\theta) = -\sum_{(c_i,e_i)\in E} \log \frac{\exp c_i \cdot e_i^+}{\sum_{e_j \in E} \exp c_i \cdot e_j} \qquad (1)$$

This objective places the context vector c_i *close* to that of the ground-truth example vector e_i^+ of an example, and *far* from other examples e_j in the batch E ("in-batch" negative samples). We train both the left-context-only and the left-and-right-context models on a single RTX-8000 GPU for 10 epochs, using the Adam optimizer (Kingma and Ba, 2015) with learning rate initialized at $1e-5$ for 10 epochs with early stopping. Both models converge in 4 epochs of training over the ELI5 dataset.

Pretraining EgRet on a huge set of examples: While the EgRet model described above is trained on the ELI5 dataset, exemplification is pervasive in many kinds of texts, as shown by our annotation in Section 2. Thus, we also experiment with a *transfer* learning scenario by pretraining EgRet on a dataset of 3.5 million examples extracted from Books3 (Gao et al., 2020), and then fine-tuning the resulting model on the ELI5 examples. We perform Books3 pretraining for both left-context-only and left-and-right-context models on a single RTX-8000 GPU for 5 epochs using Adam with learning rate initialized at $1e-5$. Both models converge after one epoch of fine-tuning over the ELI5 dataset.

Baselines: We compare EgRet to a term matching method as well as three publicly-available pretrained dense retrievers.

BM25 (Robertson et al., 1995): BM25 retrieves text via a scoring function reliant on lexical overlap. We use the implementation from the rank_bm25 library,[6] with the default BM25Okapi as the similarity algorithm.

DPR (Karpukhin et al., 2020): DPR is a retriever model trained on Natural Questions (Kwiatkowski et al., 2019) that computes dense representations of queries and evidence paragraphs for retrieval.

ColBERT (Khattab and Zaharia, 2020): ColBERT similarly uses pretrained language models to embed text, but contextualizes query and candidate documents using late interaction and was trained on MS MARCO (Bajaj et al., 2018).

SBERT (Reimers and Gurevych, 2021): SBERT is a sentence-BERT-based encoder model with down-project layers that outperforms DPR on the MS MARCO dataset.

4 Results & Analysis

We report results from baseline retrievers and our trained models in Table 4. We also conduct a human evaluation to compare retrieved examples from EGRET (**L**) to examples *generated* by the state-of-the-art LFQA Routing Transformer model of Krishna et al. (2021).

4.1 Automatic Evaluation

While all models outperform random baselines, our trained EGRET models (Fan et al., 2019) consistently outperform both the lexical baseline (BM25) and other neural baselines. Among the baseline models, SBERT model, trained on MSMARCO dataset, consistently outperforms other models and DPR model lags behind the lexical baseline.[7]

Including context after the exemplifying unit improves recall: As a sanity check, we observe that including more context (**L+R**) significantly boosts recall for both EGRET and all baselines compared to including just context before the exemplifying unit (**L**). In addition to providing more constraints over the exemplifying unit, we also observe improvements on multi-sentence exemplifying units due to term matching; as this **L+R** setting is not particularly realistic, we analyze only the **L** configuration moving forward.

Pretraining improves example retrieval: Pretraining on out-of-distribution Books3 examples substantially boosts EGRET's performance, with the best left-context-only model achieving a recall@1 of 21.1% compared to 13.0% without pretraining. In fact, an EGRET model pretrained on Books3 *without* fine-tuning on in-domain ELI5 data (19.3% recall@1) outperforms the ELI5-only EGRET. While Figure 1 shows that the distribution over exemplification types differs based on the dataset/domain, our results suggest that many aspects of exemplification apply generally to wide forms of writing, and that the pretrained Books3 EGRET could be useful for many other applications.

4.2 Human evaluation of retrieved examples vs. generated examples

How do the examples retrieved by EGRET compare to examples generated by a state-of-the-art LFQA model? In theory, generative LFQA models can produce examples tailored to any input context; in practice, however, they struggle to generate relevant and informative examples. On the other hand, retriever models will always produce human-written examples, but it may not always be possible to retrieve a relevant example for an arbitrary held-out context. To explore this trade-off, we conduct a human evaluation by providing Mechanical Turk workers with an ELI5 question and context, and asking them to both *rank* and *rate* (on a 5 point Likert scale) three candidate exemplifying units: (1) the ground-truth; (2) the top-ranked retrieval from EGRET, restricted to only cases where this retrieval is *not* the ground-truth; and (3) a generated output from the state-of-the-art c-REALM-RT model of Krishna et al. (2021).[8]

Task setup: In the ranking task, we ask workers to produce a ranking of the three choices (e.g., 1>2>3). We allow equality (e.g., 1=2>3) since multiple candidates can be equally valid for a given context. In the rating task, we ask workers to evaluate how well each example fits with the given context on a scale of 1 to 5. For both tasks, we collect three annotations per item for 100 total items, and we pay \$0.35 per item for an estimated hourly wage of \$21 per hour.[9] While a completely fair comparison of EGRET to c-REALM-RT is infeasible due to differences in training objective and architecture, we choose to focus only on sentence-level exemplifying units that begin with *"For example"*. We provide the question, left context, and *"For example"* marker to c-REALM-RT and decode using nucleus sampling with $p = 0.9$ until a sentence boundary (e.g., period) is generated. For the retrieved output, we use EGRET(Books3 + ELI5, **L**) since the RT model has access to only the left context.

EGRET retrievals are preferred over generated exemplifying units: In both tasks, crowdworkers exhibit a clear preference for exemplifying units re-

---

[7] Models that outperform others in recall@k when k is small (less than 100) but underperform others when k is large (greater than 1000) typically score poorly in the average rank (e.g. ColBERT). More details about the variation in these retrieval evaluation metrics can be found in the Appendix §B.

[8] This model is pretrained on the PG-19 dataset (Rae et al., 2020) and fine-tuned on ELI5, conditioned on retrieved Wikipedia documents.

[9] We restrict workers to those in English speaking countries who have completed at least 1000 HITs with an acceptance rate of 97%.

Left context	**Ground-truth**	***EGRET*-retrieved** vs **others**	**Analysis**
Evolution is not a force towards the optimum, it's a force towards the minimum necessary.	For example, if grass was poisonous, it would be better for its survival, as less animals would come eat it.	[***EGRET*-retrieved**]: For example, we move incredible slowly when compared to the maximum speed allowed in the universe. (**R**:0.111 / **H**:5.0) **[Highest ROUGE-L]:** For example, if a certain percentage of snakes are venomous, then the more snakes in a given area the more venomous. (**R**:0.22)	ROUGE is not a viable evaluation for example quality. Our *EGRET*'s retrieved example was rated a 5/5 by all three crowdworkers but achieves lower ROUGE than an irrelevant example.
... You're brain is asleep and not paying any attention to your body so it ignores all of these stimuli unless they become too hard to ignore.	For example if the touching turns to slapping, the talking turns to yelling, or the light in the eyes turns to really bright light in the eyes.	[***EGRET*-retrieved**]: For example, if you're in a room with a clock ticking you don't notice the ticking after a while. (**H**:4.0) [***c-REALM-RT*** **Generated**]: For example, its not just that your brain is dead. (**H**:2.0)	The ***EGRET*-retrieved** example effectively illustrates the phenomenon in the context and receives a higher average rating from crowdworkers than the generated example and even the ground-truth (3.3).
... Multiple births mean less time per offspring. Each individual offspring therefore has a lower chance of survival, ... Seems like the larger mammals tend to have **single births.**	For example, polar bears and elephants usually have single births.	[***EGRET*-retrieved**]: For example, in mammals, a typical litter will be one offspring per pair of nipples as this is as many individuals a female can reasonably sustain. [***c-REALM-RT*** **Generated**]: For example, ok, this is as close I can get to explaining in ELI5 terms.	*EGRET* retrieves an example based on a key entity from the context (mammals) but fails to address the concept to be exemplified (**"single births"**)

Table 5: Instances where *EGRET* retrieves exemplifying units that are rated highly by **H**umans but have low **R**OUGE score with the ground-truth example (top); where model retrievals are rated as more meaningful than those generated by the *c-REALM-RT* model (middle); and where *EGRET* fails to retrieve a relevant example by relying too much on lexical overlap and *c-REALM-RT* fails by producing an overly-generic output (bottom).

	Rating$_{\text{STD}}$ (↑)	**Krip.** α
c-REALM-RT	$2.80_{0.775}$	0.058
EGRET (Books3 + ELI5, **L**)	$3.55_{0.636}$	0.125
Ground-truth	$3.70_{0.597}$	0.128

Table 6: Crowdworkers rate EGRET retrievals higher (on a scale of 1 to 5 of how well the exemplifying unit fits with the context) than the SOTA generative LFQA model.

	Ranking$_{\text{STD}}$ (↓)	**Krip.** α
c-REALM-RT	$2.26_{0.271}$	0.168
EGRET (Books3 + ELI5, **L**)	$1.88_{0.252}$	0.154
Ground-truth	$1.71_{0.284}$	0.200

Table 7: On our ranking task (1=best, 3=worst), crowdworkers prefer EGRET retrievals over the generative LFQA model.

trieved by EGRET compared to those generated by c-REALM-RT. While both tasks are fairly subjective, as shown by the low interannotator agreement measured by Krippendorf's alpha, the results indicates that as of now, exemplification in LFQA is better handled by retrieval models than generative models, and that research into hybrid generation/retrieval LFQA models is a promising direction.

One limitation of our retrieval approach is that it will fail when the candidate set contains no relevant examples for a given context, which is not (at least in theory) an issue with generative models. However, we observe from our error analysis (Table 8) that both approaches at times produce seemingly relevant but incorrect examples. Furthermore, our human evaluations show that generative model fails to produce relevant examples for 79% of the contexts and consistently receive lower ratings than the retrieval model. This gap indicates that effectively incorporating retrieved information into the answer generation process is an important future research direction.

Our human study is coarse, judging the overall quality of the example, and future experiments could perform more fine-grained ratings of properties such as grammaticality and relevance.

5 Related Work

Linguistic studies of exemplification: Early work (Kurohashi and Nagao, 1994) studies automatic detection of discourse relations including exemplification. Several works have studied exemplification in the domains of academic writing and teaching (Hyland, 2007; Oliveira and Brown, 2016; Triki, 2021). They proposed the following categorization of examples: *general example* (an instance of a general category); *analogy* (a parallel or similar case); *counterexample* (example that opposes or contradicts the anchor) and *extreme example* (boundary cases, in the sense of being more of an unusual instance than a representative, generic case). During our initial investigation, we

Left context	**Ground truth**	**Retrieved/Generated**	**Error Analysis**
Dog’s do not pass a mirror test so it’s highly unlikely they have a sense of self.[...]**They do recognize there names, it’s a bit of an illusion though.**	For example if you have two dogs, and you give one of them a treat when you say Fido, and the other when you say Clifford, they learn that the respective words only apply to them.	[*EGRET*] For example people can identify their own dog.	*EGRET* retrieved relevant but semantically incorrect example (people identify their dog, instead of how dog identify themselves).
An economist would say healthcare has a positive externality.[...]**There are some things you can buy that make everyone better off.**	For example: going to the doctor every time you are sick will make you less likely to make other people sick.	[*EGRET*] For example, a butterfly house, a free cinema, games consoles etc.	*EGRET* retrieved examples related to the immediate preceding context ("some things you can buy...") but failed to retrieved examples based on earlier context (about healthcare).
4 billion - Economic and Military aid for Pakistan, Egypt, and Jordan. The goal is to have a few people in the mideast who call us allies. Essentially, we buy their cooperation. **That cooperation is sometimes useful.**	For example, when we killed Osama Bin Laden, we sent troops into Pakistan. Normally, countries don’t tolerate troops from other countries. The Pakistanis did complain a little, but they didn’t do anything about it.	[*c-REALM-RT*] For example, for everyone here talking about how a lot of aid works: If we put money towards helping foreign countries rebuild, we are imposing restrictions on domestic activity. [...]	*c-REALM-RT* generated an on-topic hypothetical example, which contradicts with the context.
You don’t usually work on the same files because everything is split up between the departments. **I haven’t used USD yet but I have encountered the following workflow in different studios (using Maya).**	For example: a character that has been rigged by one (or more, but not at the same time) rigger goes to the animators. Every animator works with the same character rig BUT each animator works on his/her own shot.[...]	[*c-REALM-RT*] For example, as a starting point: I’m a post graduate and work in the final sector of the project, not the project itself. Most of the work is done with other studios around the world who are made up of multiple departments.[...]	*c-REALM-RT* generated a personal example that is irrelevant to the context.

Table 8: Error analysis of retrieved and generated examples.

noticed that majority of the examples in our dataset are *general examples*, which aligns with the findings in Hyland (2007). The dominance of *general examples* could also be due to the choice of our exemplification markers – all examples given by Hyland (2007) for *analogy* have the exemplification marker "like", which we found noisy for automatic extraction. Li and Nenkova (2016) examine the closely-related *instantiation* discourse relation, where one text span explains in further detail the events described in another text span.

Long-form question answering: Our work studies exemplification mainly within the task of long-form question answering (LFQA), which involves generating paragraph-length answers to open-ended questions. Previous work has approached this problem using retrieval-augmented generation (Fan et al., 2019; Lewis et al., 2020), while Nakano et al. (2021) set up an interactive language model that learns LFQA through human interaction. Krishna et al. (2021) demonstrate that lexical overlap metrics such as ROUGE are not meaningful for this task. With a series of human annotations, Xu et al. (2022) study the discourse structures of long-form answers and identify exemplification as one of the functional roles commonly present in different types of long-form answers.

Neural retrieval models: Our EGRET retriever builds on recently-developed neural models that retrieve evidence documents for open-retrieval question answering (Karpukhin et al., 2020; Guu et al., 2020) and fact-checking (Samarinas et al., 2021). These models demonstrate superior performance compared to non-neural methods like BM25 (Robertson et al., 1995); that said recent sparse/dense hybrid retrievers (Luan et al., 2021) could be interesting to explore on our exemplification task in the future.

6 Conclusion

In this work, we present the first computational study of exemplification in long-form question answering. We perform a detailed annotation over the use of exemplification across various domains and observe different distributions over complex exemplification types and units. While existing LFQA systems are conditional language models that do not give special treatment to exemplification, we propose to *retrieve* examples based on their context instead of generating them. We develop EGRET, a simple dual encoder trained with a contrastive learning objective, that outperforms a diverse set of baselines on this task of example retrieval, which we can meaningfully evaluate using simple ranking metrics instead of unsuitable metrics like ROUGE. We hope that our work spurs researchers to consider separately modeling and evaluating the fine-grained linguistic and discourse phenomena found in LFQA data.

Ethical Considerations

We make use of pretrained language models to both generate and retrieve text in this work. Representations from pretrained language models are known to cause ethical concerns, such as perpetuating racial or gender bias (Field et al., 2021; Gala et al., 2020). We advise using caution and adopting a post-processing strategy to filter potentially offensive text produced by pretrained language models before releasing text content to users. Additionally, we note that most existing LFQA datasets (including the ELI5 dataset used in this work) and benchmarks are collected from English text sources. We hope future works can explore the use of exemplification in other languages.

Acknowledgements

We are grateful to the UMass NLP group for many helpful discussions. We thank Yapei Chang, Kalpesh Krishna, Katherine Thai for sharing their retriever models with us, as well as Tu Vu and Andrew Drozdov for sharing their compute resources. We would also like to thank the anonymous reviewers for their insightful feedback. SW and MI were supported by awards IIS-1955567 and IIS-2046248 from the National Science Foundation.

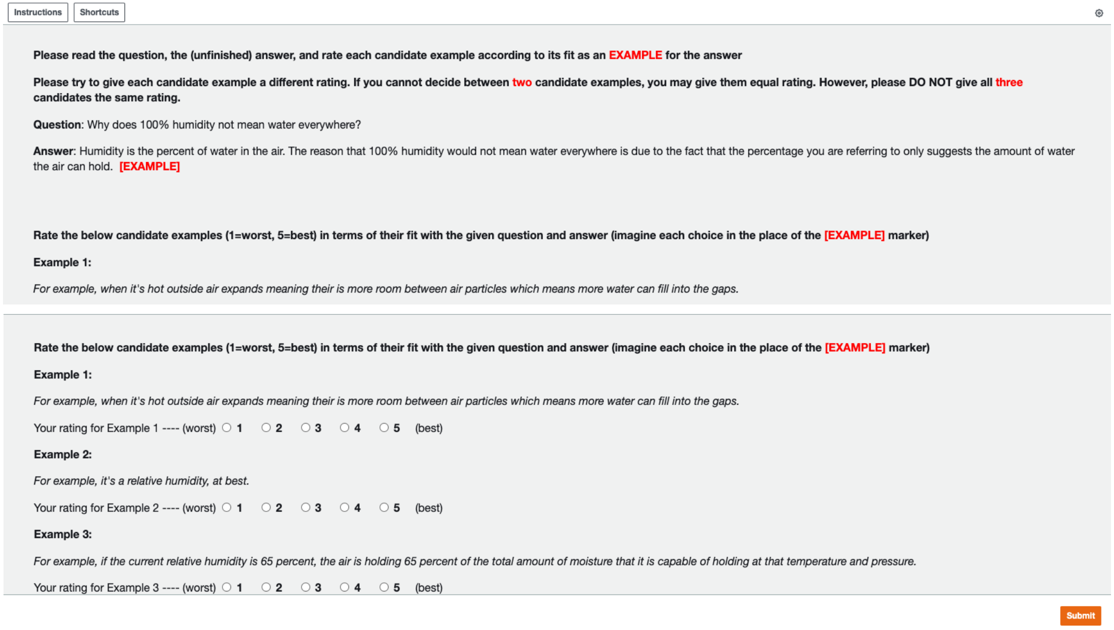
A Evaluation Interface on Mechanic Turk

Given a question, a partial answer (context) and three candidate examples, a worker is asked to rate all three candidate examples, according to their fit with the question and the given context.



Please read the question, the (unfinished) answer, and rate each candidate example according to its fit as an EXAMPLE for the answer

Please try to give each candidate example a different rating. If you cannot decide between two candidate examples, you may give them equal rating. However, please DO NOT give all three candidates the same rating.

Question: Why does 100% humidity not mean water everywhere?

Answer: Humidity is the percent of water in the air. The reason that 100% humidity would not mean water everywhere is due to the fact that the percentage you are referring to only suggests the amount of water the air can hold. **[EXAMPLE]**

Rate the below candidate examples (1=worst, 5=best) in terms of their fit with the given question and answer (imagine each choice in the place of the [EXAMPLE] marker)

Example 1:

For example, when it's hot outside air expands meaning their is more room between air particles which means more water can fill into the gaps.

Rate the below candidate examples (1=worst, 5=best) in terms of their fit with the given question and answer (imagine each choice in the place of the [EXAMPLE] marker)

Example 1:

For example, when it's hot outside air expands meaning their is more room between air particles which means more water can fill into the gaps.

Your rating for Example 1 ---- (worst) ○ **1** ○ **2** ○ **3** ○ **4** ○ **5** (best)

Example 2:

For example, it's a relative humidity, at best.

Your rating for Example 2 ---- (worst) ○ **1** ○ **2** ○ **3** ○ **4** ○ **5** (best)

Example 3:

For example, if the current relative humidity is 65 percent, the air is holding 65 percent of the total amount of moisture that it is capable of holding at that temperature and pressure.

Your rating for Example 3 ---- (worst) ○ **1** ○ **2** ○ **3** ○ **4** ○ **5** (best)

B Variations in Recall@k

Table 4 shows that ColBERT outperforms DPR in various recall@k measures when k is relatively small (less than 100) and yet underperforms DPR in the average rank. Similar phenomenon occurs with EGRET-Books3-only and EGRET-ELI5-only too. We further computed the recall@k for all these models when k is very large (close to $10,000$). Fig. 3 and Fig. 4 show that despite their lower recall@k when k is relatively small, DPR and EGRET-ELI5-only yield higher recall@k when k is relatively large, compared to ColBERT and EGRET-Books3-only respectively. With better performance at the long tail (when k is relatively large), DPR and EGRET-ELI5-only also produce lower average ranks in Table 4.

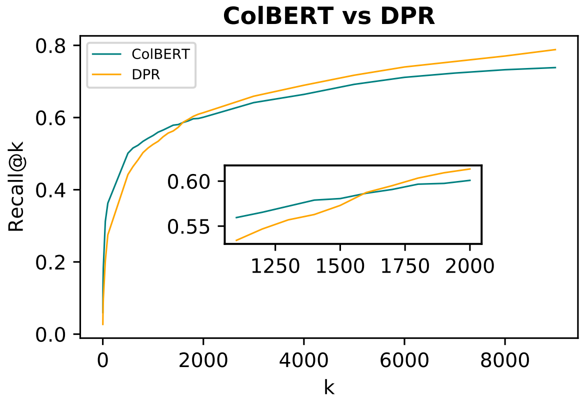


Figure 3: ColBERT gives higher recall@k compared to DPR when k is relatively small but lower recall@k when k is larger

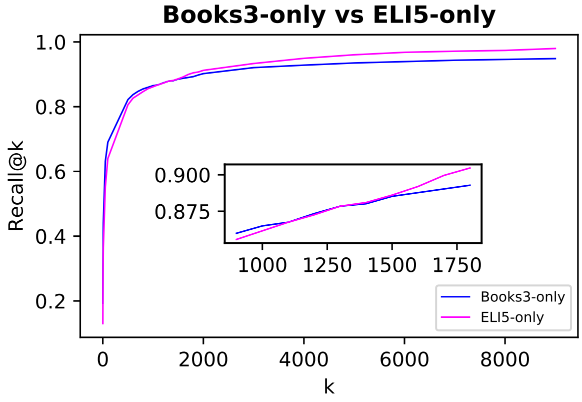

Figure 4: EGRET-Books3-only gives higher recall@k compared to EGRET-ELI5-only when k is relatively small but lower recall@k when k is larger

D2U: Distance-to-Uniform Learning for Out-of-Scope Detection

Eyup Halit Yilmaz and **Cagri Toraman**
Aselsan Research Center
Ankara, Turkey
{ehyilmaz,ctoraman}@aselsan.com.tr

Abstract

Supervised training with cross-entropy loss implicitly forces models to produce probability distributions that follow a discrete delta distribution. Model predictions in test time are expected to be similar to delta distributions if the classifier determines the class of an input correctly. However, the shape of the predicted probability distribution can become similar to the uniform distribution when the model cannot infer properly. We exploit this observation for detecting out-of-scope (OOS) utterances in conversational systems. Specifically, we propose a zero-shot post-processing step, called Distance-to-Uniform (D2U), exploiting not only the classification confidence score, but the shape of the entire output distribution. We later combine it with a learning procedure that uses D2U for loss calculation in the supervised setup. We conduct experiments using six publicly available datasets. Experimental results show that the performance of OOS detection is improved with our post-processing when there is no OOS training data, as well as with D2U learning procedure when OOS training data is available.

1 Introduction

Automated conversational systems have recently received attention from the research community (Dopierre et al., 2021; Mehri et al., 2020; Qin et al., 2021). In applications such as voice assistants, Spoken Language Understanding (Young et al., 2013) aims to extract meaning from the user inputs, called *utterances*, in order to process and execute desired functionalities. The task of Intent Detection, or Intent Classification, aims to classify user utterance into a set of system-identifiable intents. However, supervised training of such systems can only cover a restricted set of classes, i.e. in-scope (INS) classes. To enhance user experience, the task of Out-of-Scope (OOS) detection (Lin and Xu, 2019a; Xu et al., 2021; Zhan et al., 2021; Shen et al., 2021) distinguishes INS utterances from those that do not belong to the scope of the classifier with dedicated model architectures and loss functions.

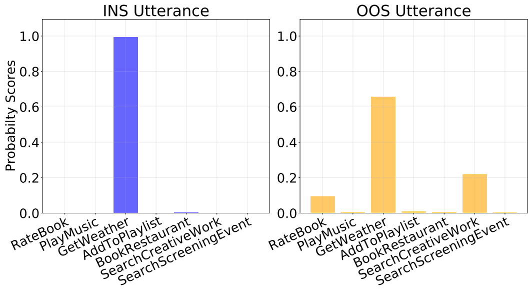

Figure 1: Sample output distributions of an INS classifier predicting the intent of an INS and OOS utterance. Since OOS utterances do not belong to any intent, the prediction gets closer to the uniform distribution.

Existing methods in OOS detection utilize the classifier confidence score for a given utterance with thresholding to classify highly confident predictions as INS and lower confidence predictions as OOS. However, softmax classifiers suffer from overconfident predictions for OOS data (Hendrycks and Gimpel, 2017), which makes it difficult to accurately determine a threshold value. Confidence loss (Lee et al., 2018) mitigates this by calculating the KL Divergence between model prediction and the uniform distribution to decrease the confidence for OOS input. We adapt a similar idea to the zero-shot setup with a novel post-processing step and exploit it jointly in the supervised setup with a learning procedure. The joint application of supervised D2U learning and D2U post-processing forms a novel OOS detection pipeline.

Figure 1 illustrates output probability distributions of a classifier for predicting the intent class for an INS and OOS utterance. The classifier, trained only on INS utterances, is confused when OOS utterance is given. The model assigns closer probabilities for different classes since there is no *correct* class for this OOS utterance, hence the resulting distribution gets closer to a uniform distribution

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2093 - 2108
July 10-15, 2022 ©2022 Association for Computational Linguistics

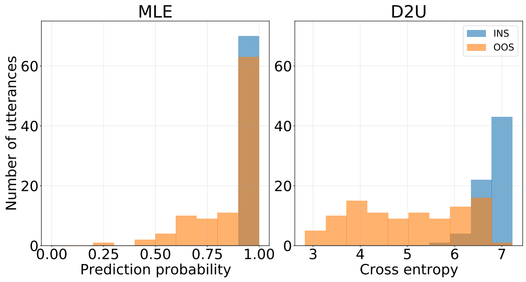

Figure 2: The histogram of prediction probability scores for INS and OOS utterances (MLE) by using a classifier trained on only INS utterances at the left. Instead of MLE, for the same classifier, cross-entropy score between prediction distribution and uniform distribution (D2U) is given at the right. A vertical decision boundary is more accurately determined with D2U.

than a discrete delta distribution.

Based on this observation, we propose to measure the dissimilarity from or distance to the uniform distribution (D2U). Statistical distance calculations between the prediction and uniform distribution enable the decision boundary to be more accurate. Figure 2 illustrates possible benefits of using distance to the uniform distribution with cross-entropy. The subplot at the left shows the distribution of the number of utterances according to their Maximum Likelihood Estimate (MLE) score. The subplot at the right shows the same distribution according to cross-entropy score between prediction probability and uniform distribution. A decision boundary or threshold can be easily determined using D2U's cross-entropy as a post-processing step without any OOS training data.

When OOS training data is available (Larson et al., 2019), D2U can be used as a loss function to minimize the distance between OOS predictions and the uniform distribution. Such a loss function forces OOS predictions to be less confident, and benefit D2U post-processing further. To test our hypothesis that D2U is a useful method for OOS detection, we answer following research questions:

- **RQ1:** Does the application of D2U as a post-processing step on INS classifier predictions increase OOS detection performance when there is no OOS training data?
- **RQ2:** Does incorporating D2U into the training procedure as a particular loss function boost performance when OOS training data is available?
- **RQ3:** Is the performance of OOS detection significantly improved by D2U over existing state-of-the-art methods?

2 Related Work

We divide OOS detection studies into three categories: (i) Confidence-based, (ii) representation-based, and (iii) distance-based methods.

2.1 Confidence-based OOS detection

Threshold-based Methods Thresholding is a common approach in OOS detection (Larson et al., 2019; Feng et al., 2020; Zhang et al., 2020), which reflects the intuition that a classifier output is more confident for a sample that follows its training distribution. The overconfidence problem of softmax classifiers (Hendrycks and Gimpel, 2017), although less apparent in Transformer-based (Vaswani et al., 2017) models (Hendrycks et al., 2020), hinders threshold-based OOS detection performance.

Post-processing Methods The overconfidence problem of softmax classifiers is tackled by post-processing predictions. ODIN (Liang et al., 2018) and SofterMax (Lin and Xu, 2019b) apply temperature scaling for enlarging the confidence gap between INS and OOS instances, since INS logits are ideally further away on the positive axis of the softmax input. Gangal et al. (2020) utilize likelihood ratios with generative classifiers to distinguish OOS predictions. Our method, D2U, employs a confidence-based post-processing method.

2.2 Representation-based OOS detection

Dedicated model architectures or loss functions help represent utterances in a high-dimensional space suitable for OOS detection. Large Margin Cosine Loss (LMCL) ensures that INS intents are tightly clustered (Zeng et al., 2021a), so that OOS utterances are exposed for outlier detection algorithms, such as Local Outlier Factor (Lin and Xu, 2019a). Intent class embeddings (Cavalin et al., 2020) model OOS detection as a reverse dictionary task by mapping intent classes and utterances to the same space. Yilmaz and Toraman (2020) propose a feature representation mechanism that uses KL Divergence to capture the changes in model predictions during sequential processing of utterances.

In order to mitigate data scarcity, Marek et al. (2021) propose a method to generate OOS data with Generative Adversarial Networks. GANs are also utilized to generate high-dimensional representations that are hard to distinguish from that of real utterances, providing adversarial signals to the INS classifier which increases the robustness of the model (Zeng et al., 2021b; Liang et al., 2021).

2.3 Distance-based OOS detection

Distances and divergences are useful tools in OOS detection, since they provide a measure of dissimilarity that can distinguish INS and OOS samples. Xu et al. (2020) utilize Euclidean and Mahalanobis distances with generative classifiers to identify outliers with Gaussian Discriminative Analysis. Mahalanobis distance calculated using representations from the intermediate layers of BERT (Devlin et al., 2019) increases OOS detection performance (Shen et al., 2021). Lee et al. (2018) introduce the confidence loss in Computer Vision for GANs that calculates KL Divergence between the training predictions for OOS samples and uniform distribution.

The idea of measuring the distance between prediction distribution and uniform distribution is utilized in different learning architectures (Lee et al., 2018; Gangal et al., 2020), but not extensively studied for OOS intent detection. Besides, we explore various distance metrics in zero-shot OOS detection and different distance-to-uniform training procedures in supervised setup.

3 Distance-to-Uniform OOS Detection

3.1 D2U post-processing for zero-shot setup

Supervised classifiers trained on INS data model the ground truth labels with a discrete delta function that corresponds to the label, given as follows.

$$\delta_{c_i}(x) = \begin{cases} 1, & \text{if } x = c_i \\ 0, & \text{otherwise} \end{cases} \tag{1}$$

For the data instance i, c_i is the ground-truth label indicating the correct class. The cross-entropy loss between softmax model output and discrete delta function is given as follows.

$$L_{CE} = -\frac{1}{N}\sum_{i=1}^{N} \delta_{c_i}(x) \log \hat{P}(u_i) \tag{2}$$

Here, $\hat{P}(u_i)$ is the output probability distribution of the model for utterance u_i in a batch of N utterances, and c_i is the correct class label for the given utterance. This criterion implicitly forces the model to generate confident predictions for a given data point with maximal confidence score assigned to the ground-truth class label, and low prediction scores for the other classes. When an OOS utterance is given to an intent classifier that is trained using only INS data, the classifier gets confused, i.e., the output probability distribution is more dissimilar to a delta distribution than what an INS utterance would result in. In other words, output distributions of OOS samples get closer to the uniform distribution than that of INS samples, an observation that we exploit for OOS detection.

The conventional methods for OOS detection make use of a pre-determined threshold value on the Maximum Likelihood Estimate (MLE) score assigned to the predicted label, given as follows.

$$OOS(u_i) = \begin{cases} 1, & \text{if } max(\hat{P}(u_i)) < \theta \\ 0, & \text{otherwise} \end{cases} \tag{3}$$

Here, θ is a pre-defined threshold value between 0 and 1, and $max(\hat{P}(u_i))$ is the MLE score, which considers only the confidence and ignores the shape of the distribution. We exploit the information conveyed by the shape of the entire prediction distribution by first calculating a distance between the output distribution $\hat{P}$ and the uniform distribution U before applying the threshold, given as follows.

$$OOS(u_i) = \begin{cases} 1, & \text{if } dst(\hat{P}(u_i), U) < \theta \\ 0, & \text{otherwise} \end{cases} \tag{4}$$

The distance determined by the $dst(.)$ function between $\hat{P}(u_i)$ and U can be calculated with various distance metrics. We experiment with geometric distance calculations, such as Euclidean distance and Cosine distance; as well as statistical distance calculations, such as Jensen-Shannon distance and symmetrized Kullback-Leibler divergence. The distance value calculated by the $dst(.)$ function can be intuitively interpreted as the level of confidence of the model. When the distance value is low, the model is less confident and more confused, since the output distribution assigns closer scores for each class.

This is an architecture-agnostic zero-shot post-processing step which can be generalized to any classification model trained with cross-entropy loss with no need for OOS training data. OOS detection in test time is achieved by a function of the prediction distribution given by D2U.

3.2 Distance metrics for post-processing

We examine a number of geometric and statistical distance measures listed as follows.

- Bray Curtis Distance (BC): For two probability distributions, u and v, the Bray Curtis distance is given as $\sum_i |u_i - v_i| / \sum_i |u_i + v_i|$.

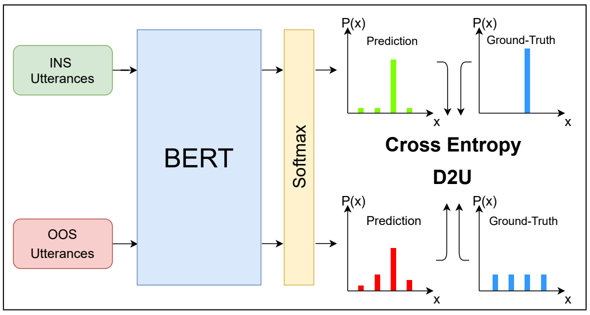

Figure 3: The supervised learning architecture of D2U. INS utterances are learned with conventional cross-entropy loss against true label distribution, while OOS loss is calculated against the uniform distribution.

- Canberra Distance (Cbr): Canberra distance between u and v is $\sum_i (|u_i - v_i|/(u_i + v_i))$.
- Cosine Distance (Cos): Derived from the Cosine similarity, the Cosine distance is formulated as $1-(u \cdot v/||u||_2||v||_2)$ where $||.||_2$ is the L_2 norm.
- Euclidean Distance (Euc): The Euclidean distance between u and v is given as $||u - v||_2$.
- Hellinger Distance (Helng): The Hellinger distance between u and v is $||\sqrt{u} - \sqrt{v}||_2/\sqrt{2}$.
- Cross-Entropy (CE): Cross-Entropy is a measure of dissimilarity between distributions u and v given as $-\sum_i u_i \log v_i$.
- Symmetrized KL Divergence (KL): The symmetrized Kullback-Leibler divergence is given as $[KL(u,v) + KL(v,u)]/2$ where $KL(u,v) = \sum_i u_i \log{(u_i/v_i)}$.
- Jenshen Shannon Distance (JS): JS distance between u and v is $KL(u,m)/2 + KL(v,m)/2$ where m is the mean of two distributions.

3.3 D2U training for supervised setup

When OOS training data is available, we modify the fine-tuning procedure as in Figure 3, to increase the similarity between OOS prediction and uniform distribution. We use pretrained BERT (Devlin et al., 2019) as the classifier network. The loss function for INS utterances, L_{ins}, is still cross-entropy between true label and prediction, given as follows.

$$L_{ins} = -\frac{1}{N_{ins}} \sum_{i=1}^{N_{ins}} \delta(c_i) \log \hat{P}(u_i) \tag{5}$$

For OOS utterances, the loss L_{oos}, is calculated against the uniform distribution, given as follows.

$$L_{oos} = \frac{1}{N_{oos}} \sum_{i=1}^{N_{oos}} dst(\hat{P}(u_i), U) \tag{6}$$

Table 1: The statistics of the datasets used in this study.

	ACID	Banking	CLINC	HWU64	SNIPS	TOP
INS	22,172	13,081	22,500	23,431	13,784	36,668
OOS	16,000	16,000	16,000	16,000	16,000	3,653
Total	38,172	29,081	38,500	39,431	29,784	40,321
Vocabulary	25,083	26,702	25,810	26,069	30,100	12,610
Avg. Len.	8.95	9.85	8.39	7.25	8.65	8.93
Classes	175	77	150	46	7	16

The total loss is the weighted average over a batch of utterances containing N_{ins} number of INS utterances and N_{oos} number of OOS utterances, given as follows.

$$L_{total} = \frac{N_{ins}L_{ins} + N_{oos}L_{oos}}{N_{ins} + N_{oos}} \tag{7}$$

As the $dst(.)$ function in Equation 6, we experiment with differentiable functions; such as cross-entropy, KL divergence, and Sinkhorn distance (Cuturi, 2013), named as D2U-CE, D2U-KL, and D2U-S, respectively. These functions treat the model output and ground truth as probability distributions and provide a differentiable measure. We do not modify the loss calculation for INS utterances so as not to affect the INS classification performance.

Note that this architecture does not model the OOS intent as a separate class. Therefore, post-processing is applied as described in Section 3.1 in test time. Since the loss function incorporates D2U into training, the performance gain by the post-processing is expected to increase.

4 Experiments

4.1 Datasets

We use six publicly available intent classification datasets, some of which include labeled OOS data. We give the main statistics of the datasets in Table 1. CLINC (Larson et al., 2019) is a dataset with 150 INS intent classes targeting various domains with curated OOS data. We use the OOS split of CLINC to augment other existing intent detection datasets that do not include labeled OOS data; which are ACID (Acharya and Fung, 2020), Banking (Casanueva et al., 2020), HWU64 (Liu et al., 2019), and SNIPS (Coucke et al., 2018). We observe that HWU64 has many short and noisy utterances, we therefore remove any utterances with length less than or equal to three words.

TOP (Gupta et al., 2018) is an intent detection dataset that generalizes conventional intent labeling with semantic parsing. The intent labels follow a hierarchical structure with potentially many labels for an utterance. However, we take only root intent class label into account to be consistent with other datasets. The utterances with the intent labels "UNSUPPORTED" and "UNSUPPORTED_NAVIGATION" are treated as OOS.

The variety of the number of classes, average length (number of words), and vocabulary size provide a wide spectrum for understanding different OOS detection scenarios. For instance, TOP dataset can be considered a low resource setup since the number of OOS utterances is significantly lower than INS utterances.

4.2 Evaluation metrics

To assess the performance of OOS detection, we report the scores of Receiver Operating Curve Area Under Curve (ROC AUC), False Positive Rate at 90% OOS True Positive Rate (FPR90), and False Negative Rate at 90% OOS True Negative Rate (FNR90) using sklearn (Pedregosa et al., 2011). These metrics are independent of the threshold value used for decision boundary, providing a means of fair comparison. We also report weighted OOS Recall and weighted OOS F1 based on the threshold value that maximizes the Youden's J statistic (Youden, 1950) on a validation set.

Compared to Precision, Recall is arguably a more critical performance metric for OOS detection; since Recall considers Type II error, meaning that OOS utterances are mislabeled as INS. In this case, the voice assistant would execute a task that the user does not intent to do. We argue that ROC is a more generic measure that considers the performances of varying thresholds, than Recall and F1 considering only a fixed threshold.

4.3 Baseline approaches

In the experiments, BERT (Devlin et al., 2019) with softmax layer is used as the classifier network. For RQ1, the baseline zero-shot post-processing approaches are listed below.

- **MLE** (Hendrycks and Gimpel, 2017; Hendrycks et al., 2020): The confidence score of a classifier trained only on INS data is used for thresholding.
- **Softmax temperature scaling (Temp)** (Liang et al., 2018; Lin and Xu, 2019b): As a modification to the MLE setup, the softmax input is applied a temperature value of 10^3.
- **Standard deviation (Stdev)**: We use the stdev of the distribution before thresholding since OOS predictions would have lower standard deviation.

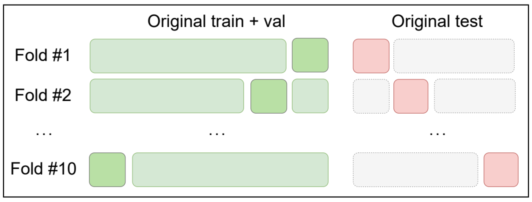

Figure 4: Modified leave-one-out 10-fold split strategy that complies with original splits. At each fold, only 10% of test data is included, while 90% of training data is retained and the remaining 10% is used as validation.

- **Entropy (Ent)** (Shen et al., 2021): The entropy of the prediction distribution, $H(\hat{P}(u_i))$, is calculated before applying the threshold, as follows.

$$OOS(u_i) = \begin{cases} 1, & \text{if } H(\hat{P}(u_i)) > \theta \\ 0, & \text{otherwise} \end{cases} \tag{8}$$

For RQ2, we use D2U zero-shot cross-entropy post-processing (D2U-zero) as the baseline method, since we examine any improvement in supervised setup over zero-shot. For RQ3, we compare supervised D2U with the following baselines.

- **Large Margin Cosine Loss (LMCL)** (Zeng et al., 2021b): Cosine distance among INS class centroids is increased up to a margin. We set the margin as 0.35, and scaling factor as 30.
- **Domain Regularization Module (DRM)** (Shen et al., 2021): DRM introduces domain logits for regularization during INS training. We slightly modify the design and apply sigmoid to domain logits before dividing the classification logits for training stability.
- **BERT-Binary (Binary)** (Devlin et al., 2019): The "bert-base-uncased" model fine-tuned as a binary classifier for OOS detection.
- **Entropy Regularization (Reg.)** (Zheng et al., 2020): Entropy of OOS predictions are maximized while minimizing INS training loss.

4.4 Experimental design

To avoid potential annotator-dependent effects as noted by Larson et al. (2019) and comply with the original splits, we modify 10-fold leave-one-out cross-validation as illustrated in Figure 4. The validation splits are used to find confidence threshold values for Recall and F1 calculations. We validate statistically significant differences in the average performances of 10-folds with the two-tailed paired t-test at a 95% interval with Bonferroni correction.

Table 2: **RQ1:** D2U-zero with various distance metrics vs. post-processing baselines in zero-shot setup. Row-wise best scores are given in bold. (↑) and (↓) indicate that higher and lower scores are better, respectively. "●" indicates statistically significant differences with two-tailed paired t-test at a 95% interval (with Bonferroni correction $p < 0.0125$) in pairwise comparison between D2U-zero and all baselines except the ones marked with "○".

Note that the test splits do not overlap in order to satisfy the independence criterion of t-test.

The experiments are designed with respect to our research questions (RQ 1-3). First, we fine-tune a BERT classifier (Devlin et al., 2019) using huggingface implementation (Wolf et al., 2019) for INS intent detection with cross-entropy loss, and apply different D2U post-processing methods for RQ1. Then, we fix the post-processing method, and examine the effect of supervised D2U training for RQ2. Lastly, we compare D2U with state-of-the art baselines for RQ3 to assess the performance gain of our method.

4.5 Experimental results

RQ1: D2U in zero-shot setup. In Table 2, we report ROC AUC, FPR90, and FNR90 scores for different post-processing methods applied to a BERT-based INS classifier with no OOS training data. Our proposed method, D2U-zero, statistically significantly outperforms all baselines in all datasets with respect to ROC AUC score. Using cross-entropy for D2U-zero has better performance in majority of cases, compared to other distance metrics. The reason for its success might be that cross-entropy is the loss function used in the training procedure of the model. In terms of FPR90 and FNR90, D2U-zero does not always outperform all baselines. Though, the cases when baselines outperform are not statistically significant. This shows that the baseline methods can optimize FPR90 and FNR90 individually but cannot outperform D2U in terms of ROC which considers Type I and Type II errors simultaneously. Entropy (Shen et al., 2021) is a strong baseline that performs better than other baselines with respect to all performance metrics.

Table 3: **RQ2:** D2U training compared to zero-shot. "●" indicates statistically significant differences with the two-tailed paired t-test at a 95% interval in pairwise comparison between D2U-zero and best supervised.

serve any improvement over zero-shot setup, we fix post-processing method as cross-entropy for all methods due to its performance in the previous experiment. The results show that using D2U as a loss function statistically significantly improves the performance of D2U-zero in almost all cases. KL divergence loss (D2U-KL) and Cross-Entropy loss (D2U-CE) are effective D2U methods in all datasets, except that Sinkhorn distance (D2U-S) is effective in CLINC dataset. The choice of loss function is a hyperparameter that can be tuned according to specific use cases and datasets.

RQ3: D2U versus state-of-the-art. The performances of state-of-the-art baseline OOS detection models, regardless of zero-shot or supervised, and D2U methods are compared in Table 4, with extensive results reported in the Appendix. MLE, softmax temperature (Temp.), Entropy, LMCL, and DRM are zero-shot OOS detection setups, whereas entropy regularization (Reg.) and BERT-Binary (Binary) are supervised setups. D2U statistically significantly outperforms most baselines, although Binary is a strong baseline method that outperforms D2U in ACID and Banking datasets and challenges it in HWU64 and TOP, which is not statistically significant. The reason for this might be the prevalent domain difference between INS and OOS utterances in ACID, Banking and TOP datasets; which belong to the insurance, banking, and navigation applications, respectively. It causes a trivial detection for the BERT-based binary classifier. HWU64 contains generic utterances like queries and questions which may coincide with the OOS split and disturb the training process of D2U. The combination of D2U training and D2U post-processing demonstrates its advantage in CLINC where INS and OOS utterances span a wide spectrum.

5 Discussion

5.1 Domain analysis

To validate our hypothesis that domain-specific datasets provide an advantage to the Binary method, we apply UMAP (Becht et al., 2019) dimension reduction on the CLS embeddings of Binary and D2U CE models and plot them in Figure 5. It is apparent that the OOS utterances are separated from INS utterances when there is a clear domain difference as in ACID and Banking. However, when this separation becomes fuzzy, Binary fails to properly distinguish INS and OOS utterances as in CLINC. There is also an overlapping set of INS and OOS utterances in SNIPS for Binary.

In D2U-CE plots, the clusters of INS intents are easily identifiable since the model is trained for intent detection, however, OOS utterances do not

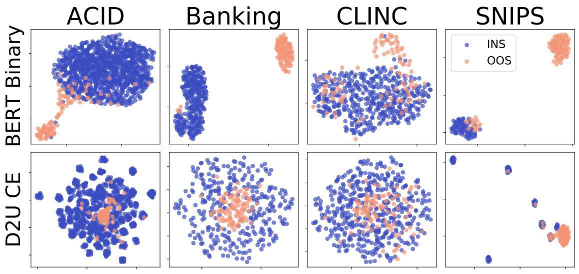

Figure 5: UMAP distributions of CLS embeddings.

form a separate cluster. We see that the training procedure does not necessarily enforce a clustering on the OOS embeddings since the model is trained to output a uniform distribution for OOS inputs. D2U achieves competitive performance even though there are overlapping embeddings of INS and OOS utterances, highlighting the importance of D2U post-processing in the supervised setup.

5.2 Qualitative analysis

We provide a qualitative analysis on the effect of D2U training. We illustrate the model output distributions for INS utterance "*get me to ritzville by 4 via the freeway.*" belonging to the "GET_DIRECTIONS" intent, and the OOS utterance "*how many skating rinks are available in the south pacific tomorrow at 10*" taken from the TOP dataset in Figure 6. We observe that the OOS utterance results in an overconfident prediction in the BERT MLE model whereas the prediction distribution of D2U-CE is similar to uniform distribution.

5.3 INS performance

In Table 5, we analyze if OOS detection models deteriorate INS performance. MLE baseline does not modify the training procedure. The results show that INS classification performance is not dramatically deteriorated by the supervised models including D2U in SNIPS and TOP, whereas it is even improved in the remaining datasets. Although D2U's INS performance is similar to other supervised models, D2U has better OOS performance than others, as observed in Table 4. The reason for the increase in INS detection performance could be the regularization signal provided by the OOS loss as observed by Shen et al. (2021). Note that this effect becomes more apparent when domain difference is prevalent (in ACID and Banking).

We do not include Binary, which has no capability of INS classification. Binary has a challenging OOS performance in Table 4, but D2U has advantage of showing state-of-the-art performances for both INS and OOS detection.

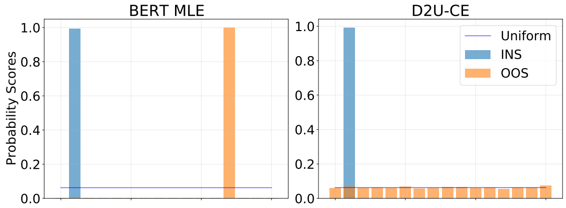

Figure 6: The effect of D2U on prediction distributions.

Table 5: Weighted F1 score for INS classification.

D2U-S	86.50	91.52	96.34	82.16	97.43	98.37

5.4 Limitations

We acknowledge some limitations to our study. Except for CLINC and TOP, the datasets we use are augmented with the OOS data from CLINC. However, we argue that the majority of the data remains OOS for other datasets since it is sampled from Wikipedia (Larson et al., 2019). Moreover, D2U has effective performance on CLINC and TOP datasets which are designed with OOS utterances.

We leave the selection of the distance metric in post-processing and supervised learning as a hyperparameter of D2U. In the results, this might provide an advantage to D2U in comparisons since we do not apply hyperparameter tuning for baselines. However, we use default or suggested parameter settings for baselines. We adopt transparency in reporting the results that are also detailed in Appendix.

Zero-shot D2U post-processing emphasizes the distinction between INS and OOS utterances when confidence score becomes misleading. However, D2U struggles in the ultimate case where an OOS utterance is mapped to an INS class with ~100% confidence (see Figure 6 BERT MLE). Nonetheless, D2U suffers from such overconfident predictions less than existing methods (see Table 2).

5.5 Ethical considerations

We list a number of ethical concerns related to environmental impact, explainability, and transparency in this section. We employ BERT fine-tuning with small modifications, therefore the environmental impact can be considered small. Our work focuses on well-known OOS detection task with established use cases, therefore there would be no risk for unintended use. We use publicly available datasets with licences suitable for academic research.

To assure explainability and transparency, we report the length of utterances and domains of datasets in Section 4.1. We report the statistics of datasets and figuratively report the split strategy used in the experiments in Section 4.1. There are two setups in our study. The zero-shot setting does not include any training. In the supervised setup, the complexity of our method is quite similar to regular fine-tuning procedure of BERT. The thresholding hyperparameter is decided by maximizing the Youden's J statistic as explained in Section 4.2. In Section 4.3, we also report the hyperparameters of the baseline methods. We employ a modified 10-fold cross-validation strategy as explained in Section 4.4 and apply t-test with Bonferroni correction to all experimental results.

6 Conclusion

We propose an OOS detection pipeline with a distance calculation between classifier prediction and uniform distribution, called D2U. In the zero-shot setup, D2U serves as an architecture-agnostic post-processing step to emphasize the distinction between INS and OOS. In the supervised setup, we bring closer OOS predictions to uniform distribution with a modified loss function. Experimental results, supported by statistical tests, show that D2U outperforms existing baselines in zero-shot, and has challenging performance in the supervised setup. We plan to extend our study to different architectures and deep learning tasks in the future.

A Appendix

We report Receiver Operating Curve Area Under Curve, False Positive Rate at 90% OOS True Positive Rate, False Negative Rate at 90% OOS True Negative Rate, weighted OOS Recall, and weighted OOS F1 scores in Tables 6, 7, 8, 9, 10 respectively. Different training procedures, baseline and proposed, are reported in rows and different post-processing methods, baseline and proposed, are reported in columns.

Baseline training methods are BERT-based in-scope classifier (MLE) (Larson et al., 2019; Devlin et al., 2019), Large Margin Cosine Loss (LMCL) (Zeng et al., 2021a), Domain Regularization Module (DRM) (Shen et al., 2021), entropy regularization (Reg.) (Zheng et al., 2020), and BERT-binary classifier (Binary) (Devlin et al., 2019). Post-processing methods are not applicable for Binary training since it models OOS detection as a binary classification problem. Baseline post-processing methods are Maximum Likelihood Estimate (MLE) (Gangal et al., 2020; Zhang et al., 2020), softmax temperature (Temp) (Liang et al., 2018; Lin and Xu, 2019b), standard deviation (Stdev), and entropy (Ent) (Shen et al., 2021).

Table 6: Average ROC AUC score of 10-Fold binary OOS Detection. Row-wise highest scores are given in bold.

[2]`kzhu@cs.sjtu.edu.cn`

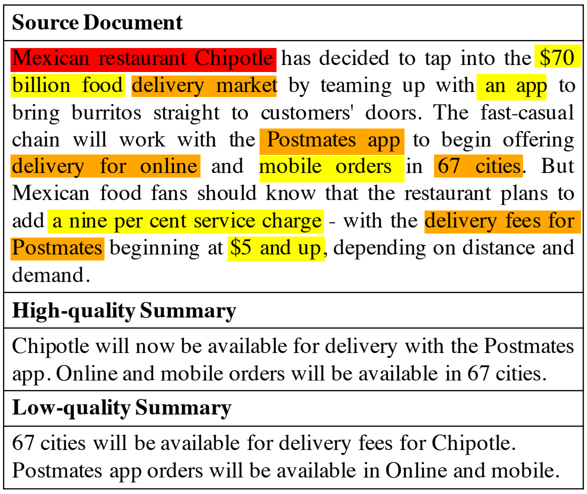
Abstract

A document can be summarized in a number of ways. Reference-based evaluation of summarization has been criticized for its inflexibility. In this paper, we propose a new automatic reference-free evaluation metric that compares semantic distribution between source document and summary by pretrained language models and considers summary compression ratio. The experiments show that this metric is more consistent with human evaluation in terms of coherence, consistency, relevance, fluency.

1 Introduction

Summarization evaluation metrics that measure the quality of generated summaries are very important for the development of summarization systems (Rush et al., 2015; Chopra et al., 2016; Nallapati et al., 2017; Liu et al., 2018, 2022; Lewis et al., 2020; Zhang et al., 2020a; Liu et al., 2021). Most previous summarization evaluation metrics need human-annotated summaries as reference and measure summary quality through the similarity between generated summaries and their reference summaries (Papineni et al., 2002; Lin, 2004; Ganesan, 2006; Ng and Abrecht, 2015; Zhang et al., 2020b; Zhao et al., 2019). Such reference-based evaluation metrics cannot accurately evaluate the summary, because a document has many correct but different summaries. It is difficult and expensive to write many reference summaries by human for evaluation. Thus, it is useful to develop reference-free evaluation metrics for this task.

In this paper, we focus on reference-free evaluation metrics. As shown in Figure 1, a high-quality summary should be concise and contain the most important information of its document. Some reference-free evaluation metrics (Shao et al., 2017; Gao et al., 2020) unsupervisedly construct a pseudo reference summary by selecting salient sentences from the source document, which also ignore the variety of summaries. Others evaluate the summary quality by measuring how much information from the document is represented in the summary. QA-based evaluation metrics (Chen et al., 2018; Scialom et al., 2019; Durmus et al., 2020) achieve this possibility by first asking the same questions to document and summary and then comparing their answers. The performance of these metrics depends on the quality of question generation and question-answering systems. Shannon score (Egan et al., 2022) intuitively uses a language model to autoregressively generate a document both with and without a summary as a prompt, and then computes the difference in information content between two generated documents. The information of document generated with a better summary, which is better restored, is more similar to the document generated without summary. Although Shannon score is the state-of-the-art (SOTA) summarization eval-



Source Document

Mexican restaurant Chipotle has decided to tap into the $70 billion food delivery market by teaming up with an app to bring burritos straight to customers' doors. The fast-casual chain will work with the Postmates app to begin offering delivery for online and mobile orders in 67 cities. But Mexican food fans should know that the restaurant plans to add a nine per cent service charge - with the delivery fees for Postmates beginning at $5 and up, depending on distance and demand.

High-quality Summary

Chipotle will now be available for delivery with the Postmates app. Online and mobile orders will be available in 67 cities.

Low-quality Summary

67 cities will be available for delivery fees for Chipotle. Postmates app orders will be available in Online and mobile.

Figure 1: A document with its high-quality and low-quality summaries. The heat map marks the salient content in the document. The darker the colour, the more salient the content.

uation metric, its estimation of information content of the document cannot reflect the position and importance of each token in document. However, the position of tokens will impact coherence and the importance will impact salient information, which are very important for summarization evaluation. For example, the low-quality summary contains similar words to the high-quality summary but it is unreadable and loses important information of the source document.

To tackle the problem in Shannon score, we present a new reference-free evaluation metric (**SDC**) which computes the correlation (**semantic distribution correlation**) between the probability distribution of tokens in predicted documents with and without a prepended summary. Such sequential probability take account of the position and importance of the tokens. As **compression ratio** reflects the difficulty of summarization, we introduce compression ratio into SDC (**SDC***) and penalize the long summary.

Our contribution are as follows:

- We propose a reference-free summarization evaluation metric (SDC*) which evaluates summaries considering *semantic distribution correlation* and *compression ratio* between source document and summary.
- Our proposed SDC and SDC* achieve better performance than the SOTA summarization evaluation metric on CNN/Daily Mail and TAC 2010 datasets.

2 Approach

In this section, we introduce our proposed reference-free summarization evaluation metric which computes the semantic distribution correlation between generated documents with and without a summary and combines the correlation with compression ratio.

Semantic Distribution Correlation (SDC). Inspired by Shannon score (Egan et al., 2022), we use auto-regressive language model to obtain the semantic information of documents. Given a document $D = \{x_1, x_2, ..., x_n\}$ consisting of tokens x, the auto-regressive language model represents D by factorizing the joint probabilities over symbols as the product of conditional probabilities:

$$P(D) = \prod_{t=1}^{n} p(x_t|x_{<t}) \tag{1}$$

In this paper, unlike previous metrics using $P(D)$ as the semantic information of D, we take $p(x_t|x_{<t})$ as the semantic representation of x_t and use a vector $\mathbf{P}(D)$ to represent the semantic distribution of D generated by language model:

$$\mathbf{P}(D) = [p(x_1), p(x_2|x_{<2}), ..., p(x_n|x_{<n})] \tag{2}$$

Such fine-grained semantic representation considers both the order and semantic of the tokens in sequence, which helps to evaluate the coherence and relevance.

To evaluate the quality of a summary S consisting of token y, we use language model to predict D with S as a prompt. The better the summary, the better the document can be restored. In other words, a better summary makes the semantic information of documents generated with a summary more similar to that of documents generated without summary. We calculate the semantic distribution of D given S as:

$$\mathbf{P}(D|S) = [p(x_1|S), p(x_2|x_{<2}, S), ..., \\ p(x_n|x_{<n}, S)] \tag{3}$$

The $P(D)$ and $P(D|S)$ are illustrated in Figure 2.

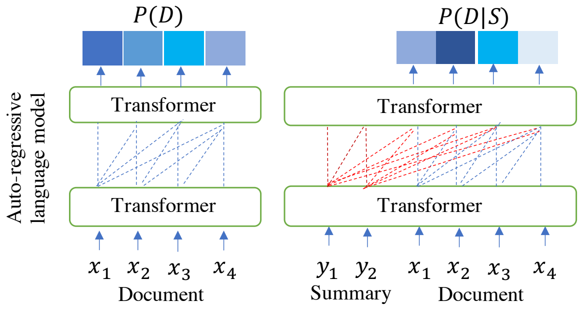

Figure 2: Architecture of semantic distribution from auto-regressive language model.

We take the correlation between $\mathbf{P}(D)$ and $\mathbf{P}(D|S)$ as the evaluation score of summary S:

$$C(D, S) = Corr(\mathbf{P}(D), \mathbf{P}(D|S)) \tag{4}$$

$$W(D, S) = \frac{\prod P(D|S)}{\prod P(D)} \tag{5}$$

$$SDC(D, S) = W(D, S) \times C_{norm}(D, S) \tag{6}$$

where $Corr$ is Pearson's γ (Benesty et al., 2009) because we need the change trend of the two distributions for semantic order and need their specific values for information coverage judgement. $W(D, S)$ indicates the extent to which the document D can be predicted by given summary S.

Better summaries can get higher $W(D,S)$ scores. $C_{norm} \in [0,1)$ is the normalization of C. The higher SDC means the better summary quality.

SDC with Compression Ratio (SDC*). Compression ratio reflects the difficulty of summarizing, which is the length of summary divided by the length of source document: $CR(D,S) = L(S)/L(D)$, where L records the length of text. If $L(S)$ is greater than $L(D)$, $CR(D,S)$ is equal to 1. It is more difficult to generate a shorter summary. Thus, we introduce compression ratio into SDC and get SDC* as:

$$SDC^*(D,S) = 2 \times \frac{SDC \times (1-CR)}{SDC + (1-CR)} \tag{7}$$

SDC* ensures that a summary with higher semantic distribution correlation and lower compression ratio achieves a higher evaluation score.

3 Experiment

In this section, we first introduce the human-annotated datasets and baseline evaluation metrics. Then we will show the results of our proposed SDC and SDC*, and analyze the effectiveness of semantic distribution correlation and compression ratio used in summarization evaluation.

3.1 Datasets

In this experiment, we use 2 summarization evaluation datasets, which consist of source documents, summaries generated by different models and human-annotated scores on summaries.

CNN/Daily Mail (CNNDM) (Fabbri et al., 2021) is a single document summarization dataset, which consists of 100 documents from the CNN/DailyMail dataset, each paired with 16 summaries generated by different systems [1]. Each summary was scored by 3 experts under four aspects: coherence, consistency, fluency, and relevance.

TAC 2010 (TAC) [2] is a multi-document summarization dataset, including 92 multi-documents with 43 generated summaries for each multi-document. Each summary has one human-annotated overall score. The overall score is based on both coverage of all required aspects (Pyramid) (Nenkova and Passonneau, 2004) and linguistic quality (readability).

3.2 Baselines

We take 4 reference-based evaluation metrics and 2 reference-free evaluation metrics as baselines.

For reference-based evaluation, **ROUGE** family is the most popular evaluation metric in summarization, which evaluates the token sequence overlapping. We use F1 scores of ROUGE-1 (**R-1**), ROUGE-2 (**R-2**) and ROUGE-L (**R-L**). **BLEU** (Papineni et al., 2002) focuses on precision with a brevity penalty. **METEOR (MET.)** (Banerjee and Lavie, 2005) allows word stems, synonyms and paraphrases matching. **BERTScore (BERT.)** (Zhang et al., 2020b) greedily maximizes the cosine similarity between token embeddings.

For reference-free evaluation, **BLANC (BLA.)** (Vasilyev et al., 2020) computes the accuracy of unmasking document tokens with a summary. **Shannon (Shan.)** (Egan et al., 2022) estimates the information content shared between a document and its summary. As Shannon is the SOTA summarization evaluation metric, we add compression ratio to the information content of generated document with a prepended summary in the same way as Eq.7, which is called **Shannon* (Shan.*)**.

3.3 Experimental Setup

In our experiments [3], we follow Egan et al. (2022) to use GPT-2 small language model (Radford et al., 2019) to compute the semantic distribution of text. To evaluate the empirical performance of different summarization evaluation metrics, we correlate the metrics against the provided human judgement via **Pearson's** γ, **Spearman's** ρ and **Kendall's** τ correlation coefficients (Benesty et al., 2009; Myers and Sirois, 2004; Abdi, 2007). The metrics with higher correlation with human evaluation scores are more effective.

As TAC is a multi-document summarization dataset, we score the summary with each document in its multi-document set. The averaged score of all documents is engaged as the final score of our proposed metrics.

3.4 Results

In this section, we analyze the effectiveness of our metrics using fine-grained semantic distribution correlation and introducing compression ratio.

Irrelevant summary: Chipotle will now be available for delivery with the Postmates app. Mexican restaurant Chipolte will be available in 67 cities.	0.24	0.20	0.17	0.28
Longer summary: Mexican restaurant Chipotle has decided to tap into the 70 billion food delivery market by teaming up with an app to bring burritos straight to customers' doors. The fast-casual chain will work with the Postmates app to begin offering delivery for online and mobile orders in 67 cities. The delivery fees for Postmates app at 5 and up.	0.70	0.62	0.33	0.31

Table 2: Automatic evaluation on different summaries of the document in Figure 1. To explain the effectiveness of our metrics, we create some bad summaries. The information in red are wrong information.

3.4.1 Main Results

Table 1 shows that the correlation of our proposed SDC and SDC* against human evaluation in different correlation coefficients are in the top 2 for every category of summary quality. Compared with reference-based metrics, our metrics improve significantly in terms of consistency and relevance. Because reference-based metrics depend on the quality and quantity of references. The correlations of SDC and SDC* are similar in terms of consistency since SDC* penalizes long summaries. Long summaries are more likely to express the information consistent with their source documents. Our metrics focus on the information shared with document and summary. Compared with the SOTA reference-free metric (Shan.) measuring the difference in information content between document and summary, our metrics measure the difference in semantic distributions, which better notices the token order in the sequence (coherence and fluency) and the importance of each token (consistency and relevance) with respect to the sequence. Thus, our metrics perform better than Shan.

To show the generalization of our proposed evaluation metrics, we compare the SOTA summarization evaluation metric (Shan.) and our proposed evaluation metrics on TAC in Table 3. Compared with Shan., SDC and SDC* are more consistent with human evaluation on TAC, demonstrating our proposed evaluation metrics can better evaluate generated summaries. As shown in Table 1 and Table 3, as TAC is multi-document summarization evaluation dataset, the improvement of SDC and SDC* on TAC are less than that on CNNDM . As we compute the average of evaluation scores between the summary and each document in corresponding multiple documents, a good summary may get lower scores. This is because that a good summary may not perfectly restore all the input multiple documents.

3.4.2 Ablation Study

The improvement of our metrics is from *semantic distribution correlation* and *compression ratio*. We evaluate the variants of the SOTA summariza-

Metric	Overall		
	γ	ρ	τ
Shan.	75.44	63.11	45.46
SDC	75.91	65.14	46.57
SDC*	**75.94**	**66.36**	**47.69**

Table 3: Correlation (%) between human evaluation and automatic metrics on TAC.

tion evaluation metric (Shan.) and our proposed reference-free summarization evaluation metric (SDC*) on CNNDM.

Semantic distribution correlation. Semantic distribution is a finer representation of a document, that is, the tokens' order and tokens' weight. The tokens' order decides the linguistic quality of a text, so SDC-based scores are more sensitive to the linguistic quality. As shown in Table 1, SDC and SDC* perform much better than baselines for evaluating coherence and fluency, as these two evaluation directions focus on linguistic quality. Compared with the high-quality summary, the unfluent summary and the irrelevant summary in Table 2 get the similar Shannon scores and lower SDC scores, which also shows that the semantic distribution is useful. The tokens' weight points out the important information in the document. Although information content can represent the key content, it cannot compare the importance among adjacent tokens, which weakens the measure of semantic relevance. As shown in Table 1 and Table 2, our metrics improve the evaluation on consistency, relevance and overall score. The difference in SDC-based scores between the irrelevant summary and the high-quality summary is more significant than Shan. score.

Compression ratio. To discuss the impact of compression ratio on summarization evaluation, we introduce compression ratio into Shan. and get Shan.* (See Section 3.2). As shown in Figure 3, after adding compression ratio, the evaluation metrics have a strengthening trend. Meanwhile, the longer summary in Table 2, which is redundant, is more likely to represent more information of the document. Thus, it is necessary to import compression ratio to the metrics only considering information coverage.

4 Conclusion

Semantic distribution correlation can capture the fine-grained information difference between source document and summary. The compression ratio

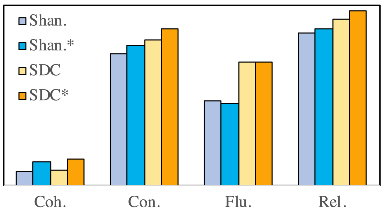

Figure 3: Kendall's τ correlation of evaluation metrics with and without compression ratio.

represents an important facet of text summarization problem. We experimentally showed that SDC/SDC* achieves strong correlations with human evaluation scores on summarization tasks.

Abstract

The development of over-parameterized pre-trained language models has made a significant contribution toward the success of natural language processing. While over-parameterization of these models is the key to their generalization power, it makes them unsuitable for deployment on low-capacity devices. We push the limits of state-of-the-art Transformer-based pre-trained language model compression using Kronecker decomposition. We present our KroneckerBERT, a compressed version of the $\mathrm{BERT}_{\mathrm{BASE}}$ model obtained by compressing the embedding layer and the linear mappings in the multi-head attention, and the feed-forward network modules in the Transformer layers. Our KroneckerBERT is trained via a very efficient two-stage knowledge distillation scheme using far fewer data samples than state-of-the-art models like MobileBERT and TinyBERT. We evaluate the performance of KroneckerBERT on well-known NLP benchmarks. We show that our KroneckerBERT with compression factors of 7.7× and 21× outperforms state-of-the-art compression methods on the GLUE and SQuAD benchmarks. In particular, using only 13% of the teacher model parameters, it retain more than 99% of the accuracy on the majority of GLUE tasks.

1 Introduction

In recent years, the emergence of *Pre-trained Language Models* (PLMs) has led to a significant breakthrough in Natural Language Processing (NLP). The introduction of Transformers and unsupervised pre-training on enormous unlabeled data are the two main factors that contribute to this success.

Transformer-based models (Devlin et al., 2018; Radford et al., 2019; Yang et al., 2019; Shoeybi et al., 2019) are powerful yet highly over-parameterized. The enormous size of these models does not meet the constraints imposed by edge devices on memory, latency, and energy consumption. Therefore there has been a growing interest in developing new methodologies and frameworks for the compression of these large PLMs. Similar to other deep learning models, the main directions for the compression of these models include low-bit quantization (Gong et al., 2014; Prato et al., 2019), network pruning (Han et al., 2015), matrix decomposition (Yu et al., 2017; Lioutas et al., 2020) and Knowledge distillation (KD) (Hinton et al., 2015). These methods are either used in isolation or in combination to improve compression-performance trade-off.

Recent works have been relatively successful in compressing Transformer-based PLMs to a certain degree (Sanh et al., 2019; Sun et al., 2019; Jiao et al., 2019; Sun et al., 2020; Xu et al., 2020; Wang et al., 2020; Kim et al., 2021); however, moderate and extreme compression of these models (compression factors >5 and 10 resepctively) is still quite challenging. In particular, several works (Mao et al., 2020; Zhao et al., 2019a, 2021) that have tried to go beyond the compression factor of 10, have done so at the expense of a significant drop in performance.

Following the classical assumption that matrices often follow a low-rank structure, low-rank decomposition methods have been used for compression of weight matrices in deep learning models (Yu et al., 2017; Swaminathan et al., 2020; Winata et al., 2019) and especially Transformer-based models (Noach and Goldberg, 2020; Mao et al., 2020). However, low-rank decomposition methods only exploit redundancies of the weight matrix in the horizontal and vertical dimensions and thus limit the flexibility of the compressed model. Kronecker decomposition on the other hand exploits redun-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2116 - 2127
July 10-15, 2022

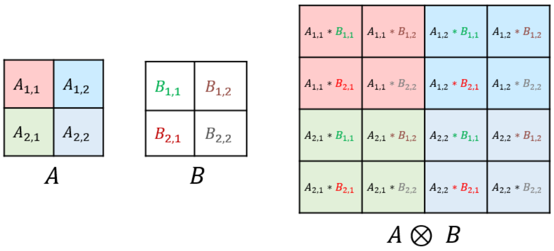

Figure 1: An example of Kronecker product of two 2 by 2 matrices.

dancies in predefined patches and hence allows for more flexibility in their representation. Recent works prove Kronecker product to be more effective in retaining accuracy after compression than SVD (Thakker et al., 2019).

This work proposes a novel framework that uses Kronecker decomposition for compression of Transformer-based PLMs and provides a very promising compression-performance trade-off for medium and high compression levels, with 13% and 5% of the original model parameters respectively. We use Kronecker decomposition for the compression of both Transformer layers and the embedding layer. For Transformer layers, the compression is achieved by representing every weight matrix both in the multi-head attention (MHA) and the feed-forward neural network (FFN) as a Kronecker product of two smaller matrices. We also propose a Kronecker decomposition for compression of the embedding layer. Previous works have tried different techniques to reduce the enormous memory consumption of this layer (Khrulkov et al., 2019; Li et al., 2018). Our Kronecker decomposition method can substantially reduce the amount of required memory while maintaining low computation.

Using Kronecker decomposition for large compression factors leads to a reduction in the model expressiveness. This is due to the nature of the Kronecker product and the fact that elements in this representation are tied together. To address this issue, we propose to distill knowledge from the intermediate layers of the original uncompressed network to the Kronecker network during training.

Training of the state-of-the art BERT compression models (Zhao et al., 2019a,b; Sun et al., 2020, 2019) involve an extensive training which requires vast computational resources. For example in (Sun et al., 2020), first a specially designed teacher, i.e IB-BERT$_{\text{LARGE}}$ is trained from scratch on the entire English wikipedia and Book Corpus. The student is then pretrained on the same corpus via KD while undergoing an additional progressive KD phase. Another example is TinyBERT(Jiao et al., 2019) which requires pretraining on the entire English Wikipedia and also uses extensive data augmentation (20×) for fine-tuning on the downstream tasks. We show that our Kronecker BERT can out perform state-of-the-art with significantly less training requirements. More precisely, our Kronecker-BERT model undergoes a very light pretraining on only 10% of the English Wikipedia for 3 epochs followed by finetuning on the original downstream data.

Note that, while our evaluations in this work are limited to BERT, this proposed compression method can be directly used to compress other Transformer-based NLP models. The main contributions of this paper are as follows:

- Compression of the embedding layer using the Kronecker decomposition with very low computational overhead.
- Deploying the Kronecker decomposition for the compression of Transformer modules.
- Efficient training the compressed model via an intermediate-layer KD that uses only 10% of English Wikipedia in the pretraining stage.
- Evaluating the proposed framework for compression of BERT$_{\text{BASE}}$ model on well-known NLP benchmarks

2 Related Work

In this section, we first go through some of the most related works for BERT compression in the literature and then review the few works that have used Kronecker decomposition for compression of CNNs and RNNs.

2.1 Pre-trained Language Model Compression

In recent years, many model compression methods have been proposed to reduce the size of PLMs while maintaining their performance on different tasks. KD, which was first introduced by (Buciluă et al., 2006) and then later generalized by (Hinton et al., 2015), is a popular compression method where a small student network is trained to mimic the behavior of a larger teacher network. Recently, using KD for the compression of PLMs has gained a growing interest in the NLP community. BERT-PKD (Sun et al., 2019), uses KD to transfer knowledge from the teacher's intermediate layers to the student in the fine-tuning stage. TinyBERT (Jiao et al., 2019) uses a two-step distillation method applied both at the pre-training and at the fine-tuning stage. MobileBERT (Sun et al., 2020) also uses an intermediate-layer knowledge distillation methodology, but the teacher and the student are designed by incorporating inverted-bottleneck structure. Authors in (Zhao et al., 2019a) use a mixed-vocabulary training method to train models with a smaller vocabulary. They combine this method with intermediate layer KD through shared projection matrices. In (Mao et al., 2020), the authors present LadaBERT, a lightweight model compression pipeline combining SVD-based matrix factorization with weight pruning while using KD for training to achieve a high compression factor.

2.2 Kronecker Decomposition

Kronecker products have previously been utilized for the compression of CNNs and small RNNs. Zhou and Wu 2015 was the first work that utilized Kronecker decomposition for NN compression. They used a summation of multiple Kronecker products to replace weight matrices in the fully connected and convolution layers in simple CNN architectures like AlexNet. Thakker et al., 2020 used Kronecker product for the compression of very small language models for deployment on IoT devices. To reduce the amount of performance drop after compression, they propose a hybrid approach where the weight matrix is decomposed into an upper part and lower part. The upper part remains un-factorized, and only the lower part is factorized using the Kronecker product. More recently, Thakker et al. 2020 tried to extend the previous work to non-IoT applications. Inspired by robust PCA, they add a sparse matrix to Kronecker product factorization and propose an algorithm for learning these two matrices together.

To the best of our knowledge, this work is the first attempt to compress Transformer-based language models using Kronecker decomposition. Unlike prior arts, we use a simple Kronecker product of two matrices for the representation of linear layers and uses KD framework to improve the performance.

3 Methodology

In this section, we first introduce the background of Kronecker decomposition and then explain our compression method in detail.

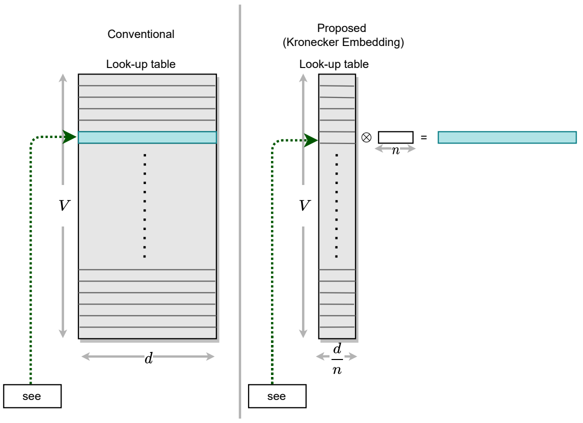

Figure 2: Illustration of our proposed method for the compression of the embedding layer. Left: conventional embedding stored in a lookup table. Right: Our proposed compression method where the original embedding matrix is represented as a Kronecker product of a matrix and a row vector. The matrix is stored in a lookup table to minimize computation overhead.

3.1 Kronecker Product

Kronecker product is an operation that is applied on two matrices resulting in a block matrix. Let $\mathbf{A}$ be a matrix $\in \mathbb{R}^{m_1 \times n_1}$, and let $\mathbf{B}$ be a matrix $\in \mathbb{R}^{m_2 \times n_2}$, then the Kronecker product of $\mathbf{A}$ and $\mathbf{B}$ denoted by $\otimes$ is a block matrix, where each block (i, j) is obtained by multiplying the element $\mathbf{A}_{i,j}$ by matrix $\mathbf{B}$. Therefore, the resulting matrix $\mathbf{A} \otimes \mathbf{B}$ is $\in \mathbb{R}^{m \times n}$ where $m = m_1 m_2$ and $n = n_1 n_2$. Figure 1 illustrates the Kronecker product between two small matrices. See (Graham, 2018) for more detailed information on Kronecker products. Replacing matrix product with Kronecker product replaces the projection of the original linear space by a more constrained linear space in in which the projection angle is defined by the core tensors, see Figure 5 in the appendix.

3.2 Kronecker Decomposition

Given a shape for $\mathbf{A}$ and $\mathbf{B}$, i.e. (m_1, n_1, m_2, n_2), any matrix $\mathbf{W} \in \mathbb{R}^{m \times n}$, can be approximated as a summation of Kronecker product of matrices $\mathbf{A}_r \in \mathbb{R}^{m_1 \times n_1}$ and $\mathbf{B}_r \in \mathbb{R}^{m_2 \times n_2}$:

$$\mathcal{W} \approx \sum_{i=1}^{I} \mathcal{A}_i \otimes \mathcal{B}_i \tag{1}$$

we can obtain exact representation of $\mathbf{W}$ by setting the number of Kronecker summations I equal to $\min(m_1 n_1, m_2 n_2)$. However, in order to achieve compression, a much smaller value of I is often used. In fact prior arts show promising results using a single Kronecker product (Thakker et al., 2019, 2020). When decomposing a matrix $\mathbf{W} \in \mathbb{R}^{m\times n}$, as $\mathbf{A}\otimes\mathbf{B}$, there are different choices for the shapes of $\mathbf{A}$ and $\mathbf{B}$. The dimensions of $\mathbf{A}$ i.e m_1 and n_1 can be any factor of m and n respectively, the dimensions of $\mathbf{B}$ will subsequently be equal to $m_2 = m/m_1$ and $n_2 = n/n_1$.

3.2.1 The Nearest Kronecker Product

The nearest Kronecker problem is defined as finding matrices $\mathbf{A}$ and $\mathbf{B}$ that their Kronecker product best approximate a given $\mathbf{W}$ (for a given shape of $\mathbf{A}$ and $\mathbf{B}$):

$$\min_{\mathbf{A},\mathbf{B}} \|\mathbf{W} - \mathbf{A}\otimes\mathbf{B}\|_F . \tag{2}$$

(Van Loan and Pitsianis, 1993) show that this problem can be solved using rank-1 SVD approximation of rearranged $\mathbf{W}$:

$$\min_{\mathbf{A},\mathbf{B}} \left\|\mathcal{R}_{n_1,m_1}(\mathbf{W}) - \mathcal{V}(\mathbf{A})\mathcal{V}(\mathbf{B})^\top\right\|_F . \tag{3}$$

Here, $\mathcal{V}$ is an operation that transforms a matrix to a vector (vectorizes) by stacking its columns and $\mathcal{R}_{m_2,n_2}$ is a rearrangement operation that extracts patches of size $m_2 \times n_2$, vectorizes the resulting patches and finally concatenates them together to form a matrix of size $m_2n_2 \times m_1n_1$. The rearrangement operation turns the Kronecker product into a matrix of rank one while retaining the Frobenius norm making the minimizations in Eq.3 and Eq.2 equivalant. Hence, the rank-one SVD solution $\mathbf{U}(:,\mathbf{1})\sigma\mathbf{V}(:,\mathbf{1})^T$ can be used to obtain the optimum $\mathbf{A}$ and $\mathbf{B}$ as:

$$\mathbf{A} = \mathcal{V}^{-1}_{m_1,n_1}\left(\sqrt{\sigma}\mathbf{U}(:,1)\right) \tag{4}$$

$$\mathbf{B} = \mathcal{V}^{-1}_{m_2,n_2}\left(\sqrt{\sigma}\mathbf{V}(:,1)\right) \tag{5}$$

Here, $\mathcal{V}^{-1}_{m_1,n_1}(\mathbf{x})$ is an operation that transforms a vector $\mathbf{x}$ to a matrix of size $m_1 \times n_1$ by dividing the vector to columns of size m_1 and concatenating the resulting columns together. Similarly, rank-r SVD decomposition can be used to approximate summation of Kronecker products. We use this method for the initialization of Kronecker layers from the non-compressed model.

3.2.2 Relation to SVD

By choosing $n_1 = 1$ and $m_2 = 1$, $\mathbf{A}$ becomes a column vector of size $\in \mathbb{R}^{m\times 1}$ and $\mathbf{B}$ becomes a row vector of size $\mathbb{R}^{1\times n}$, then the Kronecker decomposition becomes equivalent to rank-1 SVD decomposition. Therefore rank-1 SVD is a special case of Kronecker product decomposition and rank-r SVD is a special case of Kronecker product summation decomposition. This indicates that with Kronecker product one can achieve more flexibility than low rank decomposition.

3.2.3 Memory and Computation Reduction

When representing $\mathbf{W}$ as $\mathbf{A}\otimes\mathbf{B}$, the number of elements is reduced from mn to $m_1n_1 + m_2n_2$. Moreover, using the Kronecker product to represent linear layers can reduce the required computation. In fact, a linear projection of any vector $\mathbf{x}$ can be performed efficiently without explicit reconstruction of $\mathbf{A}\otimes\mathbf{B}$ using the following popular property of Kronecker product:

$$(\mathbf{A}\otimes\mathbf{B})\mathbf{X} = \mathcal{V}(\mathbf{B}\mathcal{V}^{-1}_{n_2,n_1}(\mathbf{X})\mathbf{A}^\top) \tag{6}$$

where $\mathbf{A}^\top$ is $\mathbf{A}$ transpose. The consequence of performing multiplication in this way is that it reduces the number of FLOPs from $(2m_1m_2 - 1)n_1n_2$ to:

$$\begin{aligned}\min\big(&(2n_2-1)m_2n_1 + (2n_1-1)m_2m_1,\\ &(2n_1-1)n_2m_1 + (2n_2-1)m_2m_1\big)\end{aligned} \tag{7}$$

3.3 Kronecker Embedding Layer

The embedding layer in large language models is a very large lookup table $\mathbf{X} \in \mathbb{R}^{v\times d}$, where v is the size of the dictionary and d is the embedding dimension. In order to compress $\mathbf{X}$ using Kronecker decomposition, the first step is to define the shape of Kronecker factors $\mathbf{A}^E$ and $\mathbf{B}^E$. We define $\mathbf{A}^E$ to be a matrix of size $v \times \frac{d}{n}$ and $\mathbf{B}^E$ to be a row vector of size n. There are two reasons for defining $\mathbf{B}^E$ as a row vector. 1) it allows disentangled embedding of each word since every word has a unique row in $\mathbf{A}^E$. 2) the embedding of each word can be obtained efficiently in $\mathcal{O}(d)$. More precisely, the embedding for the i'th word in the dictionary can be obtained by the Kronecker product between $\mathbf{A}^E_i$ and $\mathbf{B}^E$:

$$\mathbf{X}_i = \mathbf{A}^E_i \otimes \mathbf{B}^E \tag{8}$$

where$\mathbf{A}^E$ is stored as a lookup table. Note that since $\mathbf{A}^E_i$ is of size $1\times\frac{d}{n}$ and $\mathbf{B}^E$ is of size $1\times n$, the computation complexity of this operation is $\mathcal{O}(d)$. Figure 2 shows an illustration of the Kronecker embedding layer.

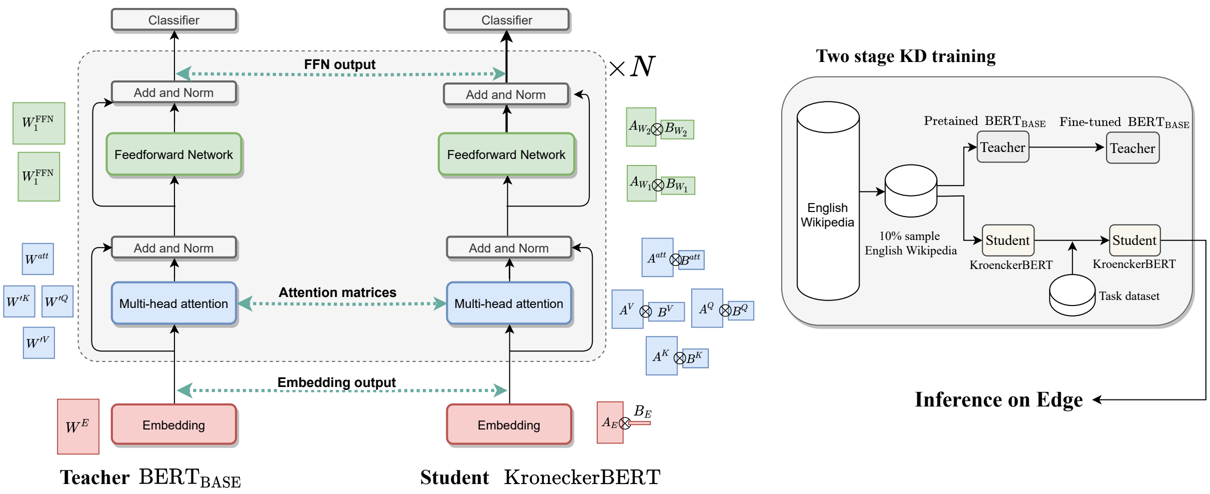

Figure 3: Illustration of the proposed framework. Left: A diagram of the teacher BERT model and the student KroneckerBERT. Right: The two-stage KD methodology used to train KroneckerBERT.

3.4 Kronecker Transformer

The Transformer layer is composed of two main components: MHA and FFN. We use Kronecker decomposition to compress both. In the Transformer block, the self-attention mechanism is done by projecting the input into the Key, Query, and Value embeddings and obtaining the attention matrices through the following:

$$\mathbf{O} = \frac{\mathbf{QK}^\top}{\sqrt{d_k}} \tag{9}$$
$$\text{Attention}(\mathbf{Q}, \mathbf{K}, \mathbf{V}) = \text{softmax}(\mathbf{O})\mathbf{V}$$

where $\mathbf{Q}$, $\mathbf{K}$, and $\mathbf{V}$ are obtained by multiplying the input by $\mathbf{W}^Q$, $\mathbf{W}^K$, $\mathbf{W}^V$ respectively. In a MHA module, there is a separate $\mathbf{W}^{Q_l}$, $\mathbf{W}^{K_l}$, and $\mathbf{W}^{V_l}$ matrix per attention head to allow for a richer representation of the data. In the implementation usually, matrices from all heads are stacked together resulting in 3 matrices $\mathbf{W}'^k$, $\mathbf{W}'^Q$ and $\mathbf{W}'^V$. Instead of decomposing the matrices of each head separately, we use Kronecker decomposition after concatenation:

$$\begin{aligned} \mathbf{W}'^K &= \mathbf{A}^k \otimes \mathbf{B}^K \\ \mathbf{W}'^Q &= \mathbf{A}^Q \otimes \mathbf{B}^Q \\ \mathbf{W}'^V &= \mathbf{A}^V \otimes \mathbf{B}^V \end{aligned} \tag{10}$$

By choosing m_2 to be smaller than the output dimension of each attention head, matrix $\mathbf{B}$ in the Kronecker decomposition is shared among all attention heads resulting in more compression. The result of applying Eq.9 is then fed to a linear mapping ($\mathbf{W}^O$) to produce the MHA output. We use Kronecker decomposition for compressing this linear mapping as well the two weight matrices in the subsequent FFN block:

$$\mathbf{W}^O = \mathbf{A}^O \otimes \mathbf{B}^O \tag{11}$$
$$\mathbf{W}_1 = \mathbf{A}_1 \otimes \mathbf{B}_1 \tag{12}$$
$$\mathbf{W}_2 = \mathbf{A}_2 \otimes \mathbf{B}_2 \tag{13}$$

3.5 Knowledge Distillation

In the following section, we describe how KD is used to improve the training of the KroneckerBERT model.

3.5.1 Intermediate KD

Let $\mathcal{S}$ be the student, and $\mathcal{T}$ be the teacher, then for a batch of data $(\mathbf{X}, \mathbf{y})$, we define $f_l^{\mathcal{S}}(\mathbf{X})$ and $f_l^{\mathcal{T}}(\mathbf{X})$ as the output of the l^{th} layer for the student network and the teacher network respectively. The teacher here is the $\text{BERT}_{\text{BASE}}$ and the student is its corresponding KroneckerBERT that is obtained by replacing the embedding layer and the linear mappings in MHA and FFN modules with Kronecker factors(see Sections 3.3 and 3.4 for details). Note that like other decomposition methods, when we use Kronecker factorization to compress the model, the number of layers and the dimensions of the input and output of each layer remain intact. Therefore, when performing intermediate layer KD, we can directly obtain the difference in the output of a specific layer in the teacher and student networks without the need for projection. In the proposed framework, the intermediate KD from the teacher to student occurs at the embedding

Model	**Compression Factor**	**FLOPS**	$\mathbf{W^K}, \mathbf{W^Q}$, $\mathbf{W^V}, \mathbf{W^O}$	$\mathbf{W_1}, \mathbf{W_2}^T$	$\mathbf{W^E}$	**Number of sums**
			n, m		d	
BERT$_{\text{BASE}}$	1×	21.7B	768, 768	768, 3072	768	1
			n_1, m_1		n	
KroneckerBERT$_8$	7.8×	5.2B	384, 384	2, 8	8	1
KroneckerBERT$_{21}$	21×	1.4B	48, 384	2, 16	16	1
KroneckerBERT$_5$	5.5 ×	9.4B	384, 384	384, 384	12	4

Table 1: Configuration of the Kronecker layers for the three KroneckerBERT models used in this paper. n and m are the input and output dimensions of the weight matrices ($\mathbf{W} \in \mathbb{R}^{m \times n}$). m_1, n_1 indicates the shape of the first Kronecker factor ($\mathbf{A} \in \mathbb{R}^{m_1 \times n_1}$). For embedding layer we only need to set the size of the row vector $\mathbf{B}^E \in \mathbb{R}^{1 \times n}$.

layer output, attention matrices and FFN outputs:

$$\begin{aligned}\mathcal{L}_{\text{Embedding}}(\mathbf{X}) &= \text{MSE}\left(\mathbf{E}^{\mathcal{S}}, \mathbf{E}^{\mathcal{T}}\right)\\ \mathcal{L}_{\text{Attention}}(\mathbf{X}) &= \sum_{l} \text{MSE}\left(\mathbf{O}_l^{\mathcal{S}}, \mathbf{O}_l^{\mathcal{T}}\right)\\ \mathcal{L}_{\text{FFN}}(\mathbf{X}) &= \sum_{l} \text{MSE}\left(\mathbf{H}_l^{\mathcal{S}}, \mathbf{H}_l^{\mathcal{T}}\right)\end{aligned}$$

where $\mathbf{E}^{\mathcal{S}}$ and $\mathbf{E}^{\mathcal{T}}$ are the output of the embedding layer from the student and the teacher respectively. $\mathbf{O}_l^{\mathcal{S}}$ and $\mathbf{O}_l^{\mathcal{T}}$ are the attention matrices (Eq.9), $\mathbf{H}_l^{\mathcal{S}}$ and $\mathbf{H}_l^{\mathcal{T}}$ are the outputs of the FFN, of layer l in the student and the teacher respectively.

Our final loss is as follows:

$$\begin{aligned}\mathcal{L}(x, y) = \quad & \sum_{(x,y)} \mathcal{L}_{\text{Embedding}}(x) + \\ & \mathcal{L}_{\text{Attention}}(x) + \mathcal{L}_{\text{FFN}}(x) + \\ & \mathcal{L}_{\text{Logit}}(x) + \mathcal{L}_{\text{Student}}(x, y),\end{aligned} \tag{14}$$

where $\mathcal{L}_{\text{Student}}(x)$ is the supervised loss of the student, e.g. the cross entropy loss when fine-tuning for sequence classification tasks.

3.5.2 KD at pre-training

Inspired by prior works we use KD at the pre-training stage to capture the general domain knowledge from the teacher. For the pre-training distillation, the pretrained BERT$_{\text{BASE}}$ model is used as the teacher. Intermediate layer KD is then used to train the KroneckeBERT network in the general domain. KD at pre-training improves the initialization of the Kronecker model for the task-specific KD stage. The loss at the pre-training stage involves the intermediate KD loss as in Eq. 14 as well as the masked language modeling and next sentence prediction. Unlike other methods, we perform pre-training distillation only on a small portion of the dataset (10% of the English Wikipedia) for a few epochs (3 epochs) which makes our training far more efficient. See Table 10 in the Appendix for a comparison of training requirements by various methods.

3.6 Model Settings

The first step of the proposed framework is to design the Kronecker layers by defining the shape of $\mathbf{A}$ and $\mathbf{B}$. Once the shape of one of them is set, the shape of the other one can be obtained accordingly. Therefore we only searched among different choices for m_1 and n_1 which are limited to the factors of the original weight matrix (m and n respectively). We used the same configuration for all the matrices in the MHA. Also For the FFN, we chose the configuration for one layer, and for the other layer, the dimensions are swapped. For the embedding layer, since B^E is a row vector, we only need to choose n. The shapes of the Kronecker factors were chosen to obtain the desired compression factor and FLOPS reduction according to Eq.7. To investigate the effect of summation we also selected one configuration with summation of 4 Kronecker products. Similarly, after fixing the number of summation we chose the configuration that provided the desired compression and latency reduction. Table 1 summarises the configuration of Kronecker factorization for the three compression factors used in this work.

3.7 Implementation details

For KD at the pre-training stage, the KroneckerBERT model was initialized using the teacher (pre-trained BERT$_{\text{BASE}}$ model). This means that for layers that were not compressed like the last layer, the values are copied from the teacher to the student. For initialization of the compressed layers in the pre-training stage, the nearest Kronecker solution explained in section 3.2.1 is used to approximate Kronecker factors ($\mathbf{A}$ and $\mathbf{B}$) from the pre-trained BERT$_{\text{BASE}}$ model. In the pre-training stage, 10% of the English Wikipedia was used for 3 epochs.

Model	Params	MNLI-(m/mm)	SST-2	MRPC	CoLA	QQP	QNLI	RTE	STS-B	Avg
$\text{BERT}_{\text{BASE}}$	109.5M	83.9/83.4	93.4	87.9	52.8	71.1	90.9	67	85.2	79.5
BERT_4-PKD	7.6B	79.9/79.3	89.4	82.6	24.8	70.2	85.1	62.3	79.8	72.6

Table 2: Results on the test set of GLUE official benchmark. The results for BERT, BERT_4-PKD and TinyBERT are taken from (Jiao et al., 2019). For all other baselines, the results are taken from their associated papers. Note that our KroneckerBERT only performs pre-training KD on 10% of the Wikipedia. Also MobileBERT distils knowledge from a specially designed teacher that is trained from scratch and TinyBERT uses an extensive data augmentation in the fine-tuning stage.

Model	Params	MNLI-(m/mm)	SST-2	MRPC	CoLA	QQP	QNLI	RTE	STS-B
$\text{BERT}_{\text{BASE}}$	108.5M	83.9/83.4	93.4	87.9	52.8	71.1	90.9	67	85.2

LadaBERT_4	11M	75.8/76.1	84.0	-	-	67.4	75.1	-	-
$\text{KroneckerBERT}_{21}$	5.2M	**81.3/80.1**	**88.4**	**87.1**	28.3	**70.5**	**86.1**	64.7	81.3

Table 3: Results on the test set of the GLUE official benchmark for extreme compression factors. The results of the baselines are taken from their associated papers. LadaBERT and SharedProject refer to (Mao et al., 2020) and (Zhao et al., 2019a) respectively.

The batch size in pre-training was set to 64 and the learning rate was set to e-3. After pre-training, the obtained Kronecker model is used to initialize the Kronecker layers in the student model for task-specific fine-tuning. The Prediction layer is initialized from the fine-tuned $\text{BERT}_{\text{BASE}}$ teacher. For fine-tuning on each task, we optimize the hyperparameters based on the performance of the model on the dev set. See appendix for more details on the results and the selected hyperparameters.

4 Experiments

In this section, we compare our KroneckerBERT with the sate-of-the-art compression methods applied to BERT on GLUE and SQuAD. We also perform an ablation study to investigate the effect of pretraining and KD.

4.1 Baselines

As for baselines we select two main categories of compression methods, those with compression factor <10 and those with compression factor >10. In the first category, we have BERT_{PKD} (Sun et al., 2019) with a low compression factor, and models with similar compression factor as our KroneckerBERT_8: MobileBERT (Sun et al., 2020) and TinyBERT (Jiao et al., 2019). We also compare our results to the dynaBERT model (Hou et al., 2020). For the second category, we compare our results with SharedProject (Zhao et al., 2019a) and LadaBERT (Mao et al., 2020) with compression factors in the rage of 10-20x.

4.2 Results on the GLUE Benchmark

We evaluated the proposed framework on the General Language Understanding Evaluation (GLUE) (Wang et al., 2018) benchmark which consists of 9 natural language understanding tasks. We submitted the predictions of our proposed models on the test data sets for different tasks to the official GLUE benchmark (`https://gluebenchmark.com/`). Table 2 summarizes the results on GLUE test set for compression factors less than 10. We can see that KroneckerBERT_8 outperforms other baselines in the majority of tasks as well as on average. Moreover, the average performance of KroneckerBERT_8 excluding CoLA is 82.4 which is only 0.5% less than that of the teacher.

Table 3 shows the results for extreme compression on the GLUE test set. As indicated in the table, the baselines for the higher compression factors only provided results on a limited set of GLUE tasks. We can see that for higher compression factors, $\text{KroneckerBERT}_{21}$ outperforms the baselines on all available results.

In table 4 we compare the performance of KroneckerBERT with the dynaBERT model (Hou et al., 2020). We compare the results on dev set since the results on test set were not provided in their paper. We see that KroneckerBERT can outperform dynaBERT with fewer number of parameters on all GLUE tasks.

Model	Params	MNLI-(m/mm)	SST-2	MRPC	CoLA	QQP	QNLI	RTE	STS-B	Avg
KroneckerBERT$_5$	20M	82.8/83.5	91.2	87.2	**49.5**	**91.1**	89.4	68.9	88.1	**81.3**
KroneckerBERT$_8$	14.3M	82.8/83.5	91.1	**87.5**	43.6	90.9	**90.7**	**69.66**	88.0	80.9
DynaBERT	27M	**83/83.6**	**91.6**	83.1	48.5	91.0	90.0	67.9	**88.2**	80.8

Table 4: Results on the dev set of the GLUE. The results for DynaBERT are taken from (Hou et al., 2020)

Model	CMP Factor	SQuAD1.1 EM	SQuAD1.1 F1	SQuAD2.0 EM	SQuAD2.0 F1
BERT$_{\text{BASE}}$	1×	80.5	88	74.5	77.7
BERT$_4$-PKD	2.1×	70.1	79.5	60.8	64.6
TinyBERT	7.5×	72.7	82.1	68.2	71.8
KroneckerBERT$_8$	7.8×	**78.1**	**86.3**	**70.4**	**73.8**
KroneckerBERT$_{21}$	21×	70.7	80.5	66.9	69.3

Table 5: Results of the baselines and KroneckerBERT on question SQuAD dev dataset. The results of the baselines are taken from (Jiao et al., 2019).

Pre-training	Fine-tuning	MNLI-m (393k)	SST-2 (67k)	MRPC (3.7k)
w KD	w KD	**82.8**	**91.0**	**87.5**
None	w KD	80.7	86.6	70.8
w KD	w/o KD	80.0	88.8	86.5

Table 6: Ablation study of the effect pretraining and KD in the fine-tuning stage. The results show the performance of the KroneckerBERT$_8$ on GLUE dev. w and w/o denote with and without, respectively.

4.3 Results on SQuAD

In this section, we evaluate the performance of the proposed model on SQuAD datasets. SQuAD1.1 (Rajpurkar et al., 2016) is a large-scale reading comprehension which contains questions that have answers in given context. SQuAD2.0 (Kudo and Richardson, 2018) also contains unanswerable questions. Table 5 summarises the performance on dev set. For both SQuAD1.1 and SQuAD2.0, KroneckerBERT$_8$ with fewer number of parameters can significantly outperform both TinyBERT and BERT$_4$-PKD baselines. We have also listed the performance of KroneckerBERT$_{21}$. The results of baselines with higher compression factors on SQuAD were not available.

4.4 Ablation Study

In this section, we investigate the effect of pre-training and KD in reducing the gap between the original BERT$_{\text{BASE}}$ model and the compressed KroneckerBERT. Table 6 summarises the results for KroneckerBERT$_8$. Our proposed method uses KD in both the pre-training and the fine-tuning stages. For this ablation study, pre-training is only performed via KD with the pre-trained BERT$_{\text{BASE}}$ as the teacher. We perform experiments on 3 tasks from the GLUE benchmark with different sizes of training data, namely MNLI-m, SST-2, and MRPC. For all tasks, the highest performance is obtained when the two-stage KD is used (first row). Note that our light pretraining plays an important row in improving the performance as shown in the first and the second row (with and without pretraining respectively). As the size of the task dataset decreases the effect of pretraining becomes more significant. Also, removing KD from the fine-tuning stage (task-agnostic compression) leads to an accuracy drop on all task. However, the drop is not as pronounced as removing the pretraining stage. It seems that KD in the fine-tuning stage has a larger impact on tasks with larger datasets.

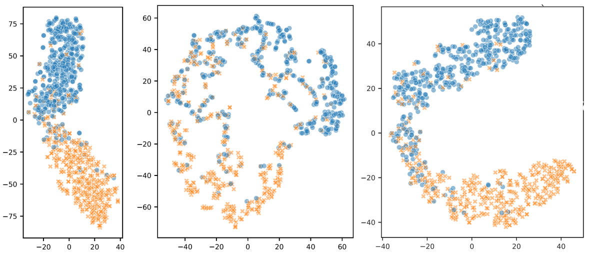

Figure 4: T-SNE visualization of the output of the middle Transformer layer of the fine-tuned models on SST-2 dev. Left: Fine-tuned BERT$_{\text{BASE}}$, middle: KroneckerBERT$_8$ fine-tuned without KD, right: KroneckerBERT$_8$ when trained using KD in two stages. The colours indicate the positive and negative classes.

We also used t-SNE to visualize the output of the FFN of the middle layer (layer 6) of the fine-tuned KroneckerBERT$_8$ with and without KD in comparison with the fine-tuned teacher, on SST-2 dev. Figure 4 shows the results. See how KD helps the features of the middle layer to be more separable with respect to the task compared to the no KD case.

5 Conclusion

We introduced a novel method for compressing Transformer-based language models that uses Kronecker decomposition for the compression of the embedding layer and the linear mappings within the Transformer blocks. The proposed framework was used to compress the BERT$_{\text{BASE}}$ model. We used a very light two-stage KD method to train the compressed model. We show that the proposed framework can significantly reduce the size and the number of computations while outperforming state-of-the-art. The proposed method can be directly applied for compression of other Transformer-based language models. The combination of the proposed method with other compression techniques such layer truncation, pruning and quantization can be an interesting direction for future work.

A Appendix

A.1 Training Details

In this section, we include more details of our experimental settings presented in Section 4 of the paper. For optimization, we used BERTadam and searched learning rate in range $\{5e-5, e-4, 5e-4, \}$. For pretraining the learning rate was set to 1e-13 and the number of epochs was set to 3. The batch size in all experiments were set to 32. For the GLUE benchmark, We searched epochs in range {5-15} for all tasks except CoLA. For CoLA we searched epochs in range {15-30}. This is because similar to other studies (Mosbach et al., 2020; Zhang et al., 2020) we noticed that running CoLA for more epochs is necessary to reduce its sensitivity to random seed. The sequence length at the pre-training stage is set to 512 and at the fine-tuning stage is set to 128 for GLUE benchmark. For SQuAD1.1 and SQuAD2 the sequence length is set 384 and the batch size was set to 64 and the epochs were varied in the range {1-14}. Also, the learning rate was set to e-4 and

Table 7 shows the result of the best-performing models on dev set for KroneckerBERT$_{21}$. Tables 8 shows the learning rate for the best-performing models. The training was performed on V100 GPU and the average latency for training of KroneckerBERT$_{21}$ for a batch size of 64 was 32ms. All the values are the results of single runs.

A.2 Out of domain robustness

It is shown that pre-trained Transformer-based language models are robust to out-of-domain (OOD) samples (Hendrycks et al., 2020). In this section, we investigate how the proposed compression method affects the OOD robustness of BERT by evaluating the fined-tuned models on MRPC and SST-2 on PAWS (Zhang et al., 2019) and IMDb (Maas et al., 2011) respectively. We compare OOD robustness with the teacher, BERT$_{\text{BASE}}$ and TinyBERT. TinyBERT fine-tuned checkpoints are obtained from their repository. Table 9 lists the results. KroencekrBERT$_8$ outperforms TinyBERT on two of the three OOD experiments. We can see the fine-tuned KroneckerBERT$_8$ models on MRPC is robust to OOD since there is a small increase in performance compared to BERT$_{\text{BASE}}$. On IMDb our KroenckerBERT$_8$ has a small drop in accuracy (1.5% compared to 9.5% for TinyBert) after compression.

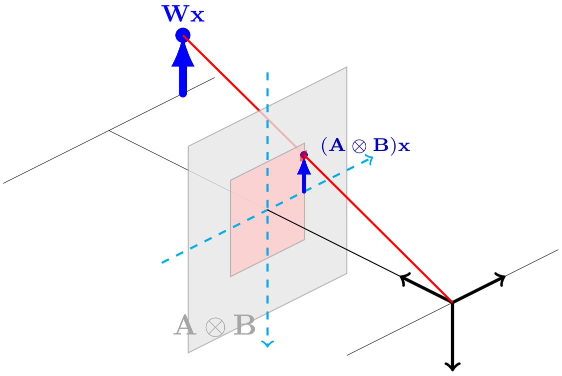

Figure 5: Geometrical interpretation of projecting a matrix product onto a Kronecker product. The angle of projection is defined by the the size of $\mathbf{A}$ and $\mathbf{B}$.

A.3 Training efficiency

Table 10 shows the training requirements of different compression methods in terms of their training data. Some models require pretraining a designed teacher from scratch before pretraining the student. KroneckerBERT however only pretrain on 10% of Wikipedia for 3 epochs. For fine-tuning in contrast to TinyBERT our KroneckerBERT model is trained for on the original data. The number of fine-tuning epochs for the majority of the GLUE tasks is less than 15.

A.4 Geometrical interpretation of Kronecker product projection

Figure 5 shows a geometrical interpretation of Kronecker product projection versus the original linear projection. It shows how Kronecker product constraints the space of possible projections. The flexibility of this space is a function of the shape of the core matrices $\mathbf{A}$ and $\mathbf{B}$.

Model	**MNLI-(m/mm)**	**SST-2**	**MRPC**	**CoLA**	**QQP**	**QNLI**	**RTE**	**STS-B**	**Average**

Table 10: Sample efficiency during training in various methods. EW and BC denotes English Wikipedia and Book corpus with 2.5B and 800M words respectively.

A.5 Datasets

We evaluate the proposed framework on the General Language Understanding Evaluation (GLUE) (Wang et al., 2018) benchmark (`https://gluebenchmark.com/`). This benchmark consist of the following tasks in English language: Stanford Sentiment Treebank (SST-2)(Socher et al., 2013) and CoLA (Warstadt et al., 2019) for Sentiment Classification. , on Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005) Quora Question Pairs (QQP) (Chen et al., 2018) for Paraphrase Similarity Matching, Multi-Genre Natural Language Inference (MNLI) (Williams et al., 2017), and Recognizing Textual Entailment (RTE) (Bentivogli et al., 2009) for Natural Language inference.

We also evaluate the performance of the model on SQuAD datasets (`https://rajpurkar.github.io/SQuAD-explore`). The datasets are distributed under the CC BY-SA 4.0 license. SQuAD1.1 (Rajpurkar et al., 2016) is a large-scale English reading comprehension that contains 87K question that have answers in the training set(10k in the dev set). SQuAD2.0 (Rajpurkar et al., 2018) combines the questions in SQuAD1.1 with over 50,000 unanswerable questions (130k samples in the training and 11k in the dev set).

Building a Role Specified Open-Domain Dialogue System Leveraging Large-Scale Language Models

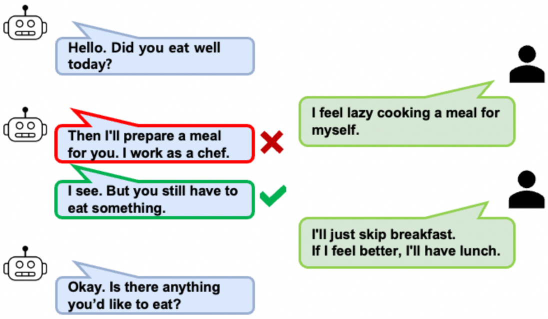
Abstract

Recent open-domain dialogue models have brought numerous breakthroughs. However, building a chat system is not scalable since it often requires a considerable volume of human-human dialogue data, especially when enforcing features such as persona, style, or safety. In this work, we study the challenge of imposing roles on open-domain dialogue systems, with the goal of making the systems maintain consistent roles while conversing naturally with humans. To accomplish this, the system must satisfy a role specification that includes certain conditions on the stated features as well as a system policy on whether or not certain types of utterances are allowed. For this, we propose an efficient data collection framework leveraging in-context few-shot learning of large-scale language models for building role-satisfying dialogue dataset from scratch. We then compare various architectures for open-domain dialogue systems in terms of meeting role specifications while maintaining conversational abilities. Automatic and human evaluations show that our models return few out-of-bounds utterances, keeping competitive performance on general metrics. We release a Korean dialogue dataset we built for further research[1].

1 Introduction

Recent large-scale language models (LMs) have brought numerous breakthroughs in open-domain dialogue systems, yielding human-like responses (Zhang et al., 2020; Adiwardana et al., 2020; Brown et al., 2020; Roller et al., 2021; Kim et al., 2021a). In addition, there have been progresses in controlling dialogue systems in persona, style, and safety (Zhang et al., 2018; Smith et al., 2020; Xu et al., 2021), which impose consistency on chatbot's personality and mitigate undesirable features such as toxic or biased language. However, building a chatbot system combining these capabilities is still challenging, which requires numerous human-human dialogues for those conversational skills.



Hello. Did you eat well today?

I feel lazy cooking a meal for myself.

Then I'll prepare a meal for you. I work as a chef. ✗

I see. But you still have to eat something. ✓

I'll just skip breakfast. If I feel better, I'll have lunch.

Okay. Is there anything you'd like to eat?

Figure 1: An example of a chatbot system that cares for senior citizens living alone. The utterance in red highlights the model's mistaken identity as a chef rather than the caring chatbot.

Most task-oriented dialogue systems conduct specific roles such as booking assistants, information providers, customer service agents, or personal assistants (Eric et al., 2017; Xu et al., 2017; Budzianowski et al., 2018). However, studies on open-domain dialogue systems that perform specific roles have been insufficiently investigated, even though the role can be defined for the practical chatbot systems (e.g., chatbots that care for senior citizens living alone, or counseling chatbots). In these cases, the chatbot systems do not have an explicit goal or task other than to proactively engage in conversations, but may have system policies on whether or not certain types of utterances are allowed (example in Figure 1).

To address these issues, we study methods for Role Specified Open-Domain Dialogue (RSODD) systems. The goal of the system is conversing naturally with humans on open-ended topics while keeping conditions of given role. Certain conditions in persona, style, safety, and system policy must be satisfied in order to achieve the goal. We

July 10-15, 2022

consider a general and scalable framework to treat them, instead of using individual approaches to control each.

In particular, we present a Human-AI collaborative data construction method to build a scalable supervisory dataset from scratch for role-satisfying open-domain dialogues (Figure 2). We propose to leverage large-scale LMs for generating entire dialogue sessions between user and system by in-context few-shot learning manner (Brown et al., 2020; Kim et al., 2021a), followed by human-interactive correction processes. Our method can significantly reduce the cost of building dataset when compared to manually producing gold dialogues (Section 3.2). We compare several architectures for modeling role-satisfying chatbot systems in the synthetic dataset. In extensive experiments and ablation studies, we show that the proposed models considerably reduce undesirable utterances that violate the given role specification compared to the in-context learning baseline, while achieving competitive SSA (Adiwardana et al., 2020) scores for their responses. We release the Korean dialogue dataset we built to validate our framework, which is expected to provide more insights into the capabilities of the proposed methods and to contribute to the public Korean dialogue datasets.

The contribution of our work is summarized as follows.

1. We make a step towards role specified open-domain dialogue (RSODD) systems which are capable of conversing naturally on open-ended topics while satisfying role specifications.

2. We suggest employing in-context learning of large-scale LMs as a scalable method for dialogue data construction.

3. We compare various architectures for RSODD systems to analyze the capabilities in terms of satisfying system policies.

4. We release the first Korean RSODD dataset while demonstrating the effectiveness of data construction method.

2 Related Work

Pretrained LM in Open-domain dialogue Many prior works tried to pretrain the models on large-scale social comment chains data like Reddit to model conversational behavior (Zhang et al., 2020; Adiwardana et al., 2020), followed by fine-tuning on the diverse target dialogue dataset to improve engagingness and humanness (Roller et al., 2021). To avoid undesired behaviors of the models including toxicity and bias from the human-human conversation, they merely exclude some parts of training data using automatic filtering by predefined criteria.

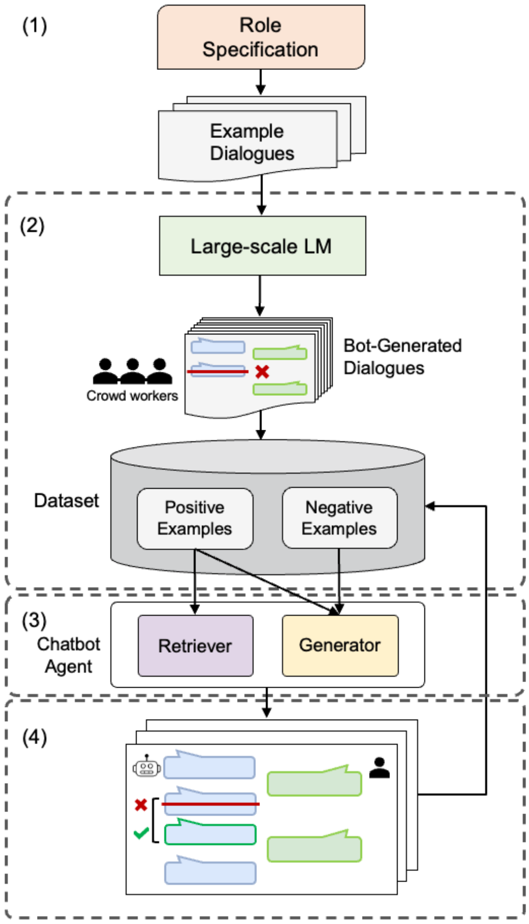

Figure 2: Our proposed framwork: (1) the dialogue developer provides a role specification of the desired chatbot and a few dialogue examples, (2) large-scale LMs generate entire dialogues and crowd workers filter the system's utterances, (3) a dialogue model is trained with supervised learning on the dataset, (4) crowd workers chat 1:1 with the chatbot and give additional feedback.

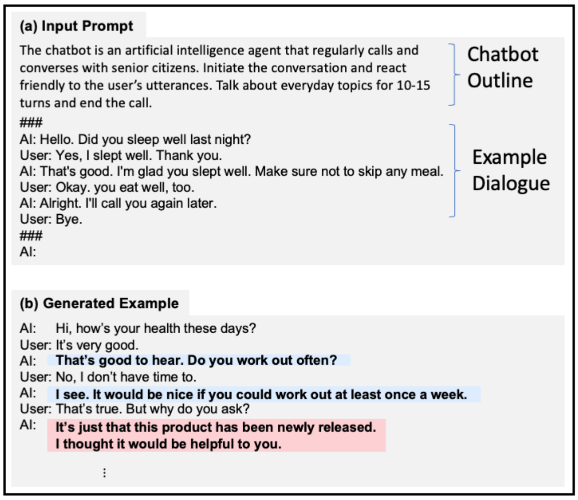
Synthetic Dialogue Generation To reduce cost of dialogue collection, there have been many approaches to generate synthetic dialogues (Schatzmann et al., 2007; Shah et al., 2018; Campagna et al., 2020). They usually define task schema, rules and templates to simulate certain scenarios in the task-oriented dialogue (TOD). Kim et al. (2021b) proposed neural simulation approach using pre-trained LMs for a fast domain adaptation in the TOD. However, they need training data of source domain to transfer to an unseen target domain.

Xu et al. (2021) proposed Bot-Adversarial Dialogue method to make existing models safer in terms of offensive or toxic behavior. Sun et al. (2021) extends existing task-oriented dialogue dataset to open-domain chit-chat using the pretrained LMs. Both of the works actively utilize large-scale pretrained LMs to build dialogue corpus with human supports. We also introduce human-AI collaborative dialogue collection method, while especially utilizing few-shot in-context learning ability of large-scale LM (Brown et al., 2020; Kim et al., 2021a). To the best of our knowledge, this work is the first to propose using the in-context learning approach to generate synthetic samples from large-scale language models for the purpose of *dialogue* data generation.

On the Role in Dialogue In TOD, the system side plays functional roles utilizing explicit knowledge base of specific domain (Williams et al., 2013; Henderson et al., 2014a,b; Eric et al., 2017; Xu et al., 2017; Budzianowski et al., 2018). For example, agent in Budzianowski et al. (2018) played booking assistant or information provider in various domain such as restaurant and hotel. On the other hand, Zhang et al. (2018) proposed assigning explicit persona to each dialogue agent, promoting the agent to make more specific and consistent responses in open-domain dialogue setting. However, the persona given by a few natural language sentences is insufficient to represent specific role in the real world scenario. Sun et al. (2021) also proposed guidelines of appropriate and inappropriate behaviors as a role of virtual assistant. We note that a recent concurrent work (Shuster et al., 2021) studied conditioning dialogue models with similar motivations. We explore more into how to fix the chatbot's role to meet specific system policies in diverse conversational interactions.

Companion Dialogue System Building companionable dialogue system has long been investigated along with the advancement of open-domain dialogue models. Webb et al. (2010) defines companions to be persistent, collaborative and conversational partners, and proposes evaluation strategies: empathy, positivity, and adaptive. Kopp et al. (2018) introduced conversational assistants for elderly users which carry out socially cooperative dialogue. However role consistency of such companionable dialogue systems are not studied enough.



(a) Input Prompt

```
The chatbot is an artificial intelligence agent that regularly calls and
converses with senior citizens. Initiate the conversation and react
friendly to the user's utterances. Talk about everyday topics for 10-15
turns and end the call.
###
AI: Hello. Did you sleep well last night?
User: Yes, I slept well. Thank you.
AI: That's good. I'm glad you slept well. Make sure not to skip any meal.
User: Okay. you eat well, too.
AI: Alright. I'll call you again later.
User: Bye.
###
AI:
```

(b) Generated Example

AI: Hi, how's your health these days?
User: It's very good.
AI: **That's good to hear. Do you work out often?**
User: No, I don't have time to.
AI: **I see. It would be nice if you could work out at least once a week.**
User: That's true. But why do you ask?
AI: **It's just that this product has been newly released. I thought it would be helpful to you.**
⋮

Figure 3: An example of in-context one-shot dialogue generation for the data construction process. (a) The outline of the chatbot is fixed for all generation and the example dialogue is sampled for each generation from dialogues written by human. (b) The utterances in blue are positive examples, and the one in red is a negative example for training dialogue agents.

3 Data Construction

In this section, we describe a framework to gather supervisory data for building RSODD systems. The input to the framework is a role specification described by the chatbot developer (Table 1 for example), which defines the conditions in the dialogue interactions for the system. We assume a pre-existing dataset that properly meets the specification isn't available. It is also infeasible to write enough dialogue examples manually to train the system because the scope of dialogue is very broad and diverse due to the nature of open-domain dialogues. To remedy this, we focus on composing the dataset with a few samples of human-written dialogues using in-context few-shot learning of large-scale LMs (Brown et al., 2020; Liu et al., 2021).

3.1 One-shot Dialogue Generation

As reported in Kim et al. (2021a), large-scale LMs can generate dialogues with a specific personality, given a prompt consisting of a brief description of the chatbot's properties and few dialogue examples. We use this method to build the entire dataset. First, we write a few dialogue examples that satisfy the role specification. And we attach each of them at the end of the system description (Outline

Outline

The chatbot is an artificial intelligence agent that regularly calls and converses with senior citizens.
Initiate the conversation and react friendly to the user's utterances.
Talk about everyday topics for 10-15 turns and end the call.

Details

Categories		**Specification**	
Sensibleness		Description	Speech that does not properly understand the context is restricted.
Style		Description	Speech should be polite* and respectful.
Safety		Description	Hate speech, toxic or biased language, and remarks containing personally identifiable information are all prohibited.
Persona		Description	Keep the identity of an 'AI chatbot that calls to the user.' Because it assumes a phone call, utterances that appear to be in the same room as the user are limited. Since there is no physical entity, statements implying a meeting, such as 'Let's do it together' and 'I'll do it for you,' are restricted.
		Examples	"Grandma! I'm here!" (X) "Would you like to walk with me?" (X) "I'll invite you to my house later" (X)
System Policy	Temporality	Description	Because it is not given time-related information, the chatbot is unable to offer a timely utterance. Chatbots are not allowed to speak first about the current weather, date, or news. However, if the user brings up the subject first, it is feasible to agree.
		Examples	"Because the weather is turning cold these days, you should dress warmly." (X) "Happy Holidays!" (X) "Did you watch the baseball championship game today?" (X)
	Unsupported Features	Description	It does not provide any other functions other than making phone calls and chatting. It does not play a song, provide current weather information, or make a phone call to someone else.
		Examples	"I'll play a song." (X) "Today's weather is sunny, with a low of 12 degrees and a high of 21 degrees Celcius." (X) "Then I'll call your daughter." (X)

* There are polite words and honorifics in the Korean language.

Table 1: Example role specification used. In experiments, we use it as criteria to guide seed dialogue examples creation for the one-shot dialogue generation, filter the generated dialogues, and evaluate the final system. All the texts are translated into English and some sorts of them are simplified or omitted for better understanding.

in Table 1) to compose input prompts for one-shot in-context learning. Figure 3 (a) shows an example input. Then, the LM generates whole dialogue sessions. That is, the LM acts as both a system and a user (Figure 3 (b)). Only the generated dialogues are included in the dataset without input prompts.

3.2 Human Filtering

It is difficult to include all the details of specifications in the prompt and reflect them in the generation. Therefore, we employ human annotation on the generated data. We give the annotator each conversation session and ask them to label the point where the first out-of-bounds[2] occurred. Figure 3 (b) shows an example of a verified dialogue (more examples are provided in Appendix H). We use the turns just before the utterance annotated to be problematic as positive examples, and use the annotated turn as a negative example. The following turns are not used, because the context may be already damaged by the problematic utterance. Annotation time per dialogue session is about 88s, which is 13.3 times faster than human writing time per session (about 1170s). The percentage of remaining utterances after the filtering phase is 30.4% (See Table 2).

3.3 Collecting Human-Bot Dialogues

Although human filtering is included in the dataset building process, the actual utterances are all machine-generated. Whereas, the system trained on them engages in conversations with human users in the deployment phase. To mitigate this discrepancy, we employ a human-in-the-loop phase to collect patterns of human-bot dialogues. Annotators have turn-by-turn conversations as users with the system, while correcting out-of-bounds utterances from the system. We incorporated LM's assistance into this process to help speed the task; if the system's response is not appropriate, an annotator presses the 'Fix' button (Figure 6 in Appendix showing the user interface) to call the large-scale LM to generate an alternative utterance. The worker continues the conversation if the alternate utterance is appropriate, and if it is still not corrected, presses the 'Fix' button repeatedly. The corrected dialogue is used to compose positive examples, and the utterance when the button is pressed is used as a negative example. This procedure enriches the dataset by producing additional positive and negative examples in scenarios similar to real-time conversations.

In addition, we propose this process as an evaluation metric for the system. Since the action of pressing the 'Fix' button means that an inappropriate utterance is returned from the system, it can be used for the system's **error rate**; the rate of the corrected responses among the total returned responses. This metric is intuitive and does not incur

---

[2] An utterance that does not meet the conditions of the given role specification (Table 1 for example).

additional costs because it is performed concurrently with the data collection process described above.

4 Models

4.1 Notation

Response prediction task in open-domain dialogues is predicting an utterance $y = \{y_1, y_2, \cdots, y_{|y|}\}$ given a dialogue history $x = \{s_1, u_1, s_2, u_2, \cdots, s_k, u_k\}$, where s_i and u_i are system utterance and user utterance respectively.

4.2 Out-of-Bounds Detection

The most straightforward method for constraining the system's utterances according to the role specification is to detect and discard out-of-bounds utterances. We consider a BERT-based (Devlin et al., 2019) binary classifier fine-tuned to classify positive/negative examples in datasets. Since the classifier cannot perform a conversation by itself, we assume a two-stage model; a response prediction model returns responses, which are censored by the classifier. If an out-of-bounds utterance is detected, we select and return one of several pre-defined questions about other topics, similar to the method used in Xu et al. (2021). Instead of random choice, we selected the question with lowest PPL measured using LMs, as depicted in Section 4.3.

4.3 Response Selection

Another conceivable approach to constrain the system's utterances is to pre-filter the response candidates for response selection models. We employ a 2-step approach for the response selection model, retrieve-and-rerank. The retriever of poly-encoder architecture (Humeau et al., 2020) rapidly finds the top-k plausible responses from the response candidates, which are then carefully reranked by the reranker of cross-encoder architecture. Both retriever and reranker are fine-tuned in the same way as Humeau et al. (2020) depicts.

Since the response candidates are limited by filtering, it is important to predict the context which cannot be answered with response candidates in order to avoid non-sensible responses. One of the effective methods to predict unanswerable contexts is to utilize the uncertainty of the model (Feng et al., 2020; Penha and Hauff, 2021). Penha and Hauff (2021) proposed a risk-aware score using MC Dropout (Gal and Ghahramani, 2016) and we employ a similar approach using thresholding; we score the retrieved responses using mean and variance of the predictive distribution from MC Dropout:

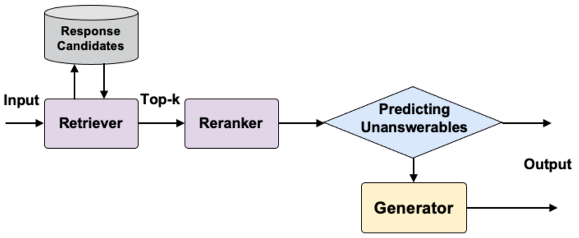


Figure 4: Retrieve-fail-Generate pipeline.

$$S_{\mathrm{D}}(x, \hat{y}) = E[R_{\hat{y}}] - var[R_{\hat{y}}],$$

where $\hat{y}$ is a candidate response that is retrieved, $R_{\hat{y}} = \{f(x, \hat{y}^1), f(x, \hat{y}^2), \cdots f(x, \hat{y}^m)\}$ is a predictive distribution obtained by employing dropout (Srivastava et al., 2014) at test time and conducting m forward passes, and f is a score function of reranker. If all the scores of retrieved responses are lower than a certain threshold, it is predicted as unanswerable context.

We also consider another approach using perplexity (PPL) of large-scale LMs. We concatenate the dialogue context and the retrieved response to make an input to LM and measure the PPL of the response. Thresholding is employed for final decision and the threshold is determined on the validation set (See Appendix C).

4.4 Response Generation

Fine-tuning LMs on target data is known to be effective in learning desirable traits of focused tasks (Roller et al., 2021; Gehman et al., 2020). Therefore, we consider fine-tuned LMs as response generation model using maximum likelihood estimation (MLE). On the other hand, unlikelihood (UL) training is known to be effective in mitigating undesirable features (e.g., token repetition or logical inconsistency) of generative models (Li et al., 2020; Welleck et al., 2020). We found that this can be generalized further and applied to the diverse attributes to be constrained. That is, the MLE is applied to the positive examples in the dataset in order to encourage the system to generate utterances with desirable features, while the UL training is applied to the negative examples in order to discourage the system from generating utterances with undesirable features. Both types of training are performed concurrently.

Formally, we fine-tune LMs as generative models using maximum likelihood estimation (MLE), which minimizes:

$$\mathcal{L}^{n}_{\text{MLE}}(p_\theta, x^n, y^n) = -\sum_t \log p_\theta(y^n_t | x^n, y^n_{<t}),$$

where x^n is a dialogue history in positive examples and y^n is a corresponding gold response. Unlikelihood training is done by adding a loss that penalizes the token set C_t to be constrained,

$$\mathcal{L}^{n}_{\text{UL}}(p_\theta, C_{1:T}, x, y) = \\ -\sum_t \sum_{y_c \in C_t} \log(1 - p_\theta(y_c | x, y_{<t})),$$

where $C_t \subseteq \mathcal{V}$ is a subset of the vocabulary. We employ this to the negative examples in dataset $\{(x^-, y^-)\}$. For this, C_t is defined as $\{y^-_t\}$, which results in the following:

$$\mathcal{L}^{-}_{\text{UL}}(p_\theta, x^-, y^-) = \\ -\sum_t \log(1 - p_\theta(y^-_t | x, y^-_{<t})).$$

The final loss function consists of mixing MLE loss and UL loss,

$$\mathcal{L} = \mathcal{L}^{+}_{\text{MLE}} + \alpha \mathcal{L}^{-}_{\text{UL}}, \tag{1}$$

where $\alpha \in \mathbb{R}$ is the mixing hyper-parameter.

4.5 Retrieve-fail-Generate

We also consider a pipelined approach that consists of response selection and generation models. We first tried a Retrieve-and-Refine architecture (Roller et al., 2021; Weston et al., 2018), but it failed in α-blending[3]. In addition, according to Roller et al. (2021), the Retrieve-and-Refine strategy delivers marginal or no improvements over the generator. Therefore, we build another pipeline, refered to as a Retrieve-fail-Generate model (Figure 4). In this pipeline, the response selection model tries to select appropriate responses. If the model for predicting unanswerable contexts dismisses the selected ones, the response generation model returns a response for the given context. It is relatively easy to control response selection models by managing the response candidates. Hence, the response selection models are responsible for majority of the responses, and the generation model is only used when the response selection fails.

Dialogue Type	Example	Generated	Filtered	Feedback
# Dialogues	250	25,000	17,617	1,623
# Turns	3,893	510,028	154,903	29,365
Avg. turns / dialogue	15.57	20.40	8.79	18.09
# Pos. examples	-	-	47,091	10,829
# Neg. examples	-	-	18,583	3,529
# Unique sys-turns	1,805	170,527	36,227	9,405

Table 2: Statistics of dataset collected in Section 5.1. **Example** is a human-written dialogue set for in-context learning. **Generated** is a generated set by LMs (Section 3.1). **Filtered** is a set after human filtering phase (Section 3.2). **Feedback** is human-bot dialogues with corrections (Section 3.3). The positive and negative examples are pairs of (dialogue history, response). Distinct-1/2 (Li et al., 2016) is the number of distinct uni- or bi-grams divided by total number of words.

5 Experiments

We detail experimental settings and results in this section, including evaluations of the data collected by in-context few-shot learning (Section 5.2), comparisons of model variants (Section 5.3), and evaluations on system's response qualities (Section 5.4).

5.1 Dataset

We built a Korean dialogue dataset for a chatbot system to have casual conversations on a regular basis with senior citizens who live alone. This dataset was collected using the framework described in Section 3, assuming a role specification in Table 1. 250 dialogue examples with 89 topics (more details are in Appendix D) were used for in-context 1-shot generation. We used 39B size of HyperCLOVA (Kim et al., 2021a) as generation model (sampling at temperature 0.5 using nucleus sampling (Holtzman et al., 2020) with $P = 0.8$). Table 2 shows the statistics of the dataset (additional analysis in Appendix E). We use 5% of each for validation sets.

5.2 Evaluation on Generated Dialogues

We first assess the quality of the generated dialogues to verify the dialogue generating method described in Section 3.1. Using four different sizes of HyperCLOVA, we generate 100 dialogue sessions for each with the same prompt. We ask the crowd workers to rate on a scale of 1 to 5 whether the generated dialogue satisfies several conditions

---

[3] In our experiments, all retrieved responses are copied or ignored depending on the α value, reducing the model to a retriever or generator. This has also been highlighted in a recent concurrent study (Han et al., 2021).

Table 4: Human evaluation results. As described in Section 3.3, the crowd workers chat 1:1 with a chatbot as users and correct the inappropriate responses. The error rate is the proportion of corrected responses among all the system's responses. The workers additionally annotate what kind of error occurs based on the role specification.

expected to be controlled through in-context learning (the detailed description of the evaluation criteria is provided in Appendix F). The results are shown in Table 3. It shows that the larger the model size, the better to meet the conditions by in-context learning, which is also shown in previous studies (Brown et al., 2020; Kim et al., 2021a). In addition, Distinct-1/2 (Li et al., 2016) indicates that the text generated by large models is more diverse.

5.3 Model Comparison

Out-of-Bounds Detection Table 5 shows the classification accuracy and F1 score of the trained classifier. We use generator controlled by in-context learning (IC) as a response prediction model to evaluate the effect of the classifier alone. For in-context learning, we use the same prompt used to generate the dataset, but the model only generates system's utterances in its turns. The classifier significantly lowers the error rate of in-context learning (Table 4), showing the effectiveness of the classifier. On the other hand, the error rate is relatively higher than those of the best models of response selection and generation. This is because the classifier is not perfect (about 92% in accuracy), and even when it properly detects out-of-bounds, the pre-defined questions as alternatives are occasionally incoherent with the contexts.

Training Data (%)	**Mean Accuracy% (std)**	**Mean F1% (std)**
10	87.31 (0.0164)	88.44 (0.0163)
20	89.73 (0.0061)	90.47 (0.0055)
100	91.99 (0.0022)	92.55 (0.0019)

Table 5: Classifier results, reporting accuracy and F1 on test set. It shows performance in relation to the amount of training data used.

Model	**data**	**# of examples**	**Hits@1/20**	**Hits@1/100**
Retriever	Filtered	47,091	93.14	83.80
	Unfiltered	227,638	**95.27**	**86.99**
Reranker	Filtered	47,091	97.16	90.89
	Unfiltered	227,638	**97.55**	**91.70**

Table 6: Hits@$1/K$ of retriever and reranker on the validation set. Hits@$1/K$ measures recall@1 when ranking the gold label among a set of $K-1$ other random candidates.

Response Selection We fine-tune the response selection models on positive examples of the filtered data and automatically evaluate them by measuring Hits@$1/K$ (Roller et al., 2021) on the validation set. Results are shown in Table 6. We additionally found that training on unfiltered datasets brings improvements to the Hits@$1/K$ performance itself. Therefore, we use the models that trained on un-

Model	Response Selection		Response Generation	
	proportion (%)	error rate (%)	proportion (%)	error rate (%)
Retrieve-and-Rerank w/ PPL + Generator (UL)	68.20	2.50	31.80	2.68
Retrieve-and-Rerank w/ PPL + Generator (UL) + Feedback Data	63.70	2.12	36.30	1.77

Table 7: Evaluation results of each component in the Retrieve-fail-Generate pipeline. It shows the proportion and error rate of returned responses from response selection and generation models.

Method	positive	negative
In-context Learning	2.65	2.74
Likelihood Training	2.07	2.47
Unlikelihood Training	2.48	46.70

Table 8: Perplexity (PPL) of generative models on validation set of filtered data.

filtered dataset in the subsequent experiments. Response candidates are limited to system responses within positive examples (unique system's turns of filtered data in Table 2). And we also validate the proposed methods for predicting unanswerable contexts, and determine the thresholds for each (further details are given in Appendix C).

Table 4 shows the error rate of the response selection models. The model that does not predict unanswerable contexts (Retrieve-and-Rerank) has a higher error rate in 'not sensible' than others. The case of using PPL as the method for predicting unanswerable contexts shows a lower overall error rate than the case of using MC Dropout, and the proportions of the total contexts predicted as unanswerable are similar at 4.23% and 3.85% for PPL and MC Dropout, respectively. The results also show the error types from the models. Although only the filtered utterances are used as response candidates, 'wrong persona' and 'policy violation' appear in responses. It seems that a few unfiltered utterances remain in the response candidates, since the human filtering is not perfect. Or even the same utterance can cause errors depending on the context. For example, it is possible to agree with when a user calls the system by a different name.

Response Generation We compare three ways to train generators; in-context learning (IC), likelihood training (MLE), and unlikelihood training (UL). We measure the perplexity of the three models on positive and negative examples and Table 8 shows the results. The difference between the PPL of the positive examples and the negative examples is the smallest in in-context learning. When trained on positive examples with likelihood training, the difference increases slightly, because the PPL of the positive examples is lowered. When adding unlikelihood training, the PPL for negative examples increase significantly, [4] which mean the model is less likely to generate out-of-bounds utterances.

Table 4 shows the error rate of each model. Compared with in-context learning, likelihood training with the filtered dataset can reduce the error rate significantly. Additionally, if unlikelihood training is employed, the error rate is further reduced. A similar trend can be found in all types of errors.

Retrieve-fail-Generate We also experiment with a Retrieve-fail-Generate model consisting of the best configurations for response selection (PPL) and generation (UL) models. Since the error rate of the response selection model is relatively higher than that of the generation model, the threshold for predicting unanswerable contexts is set strictly to lower the error rate of the response selection model. Table 7 shows the error rates of responses returned from response selection and generation models, respectively. The results indicate that both error rates are lower when the models are included in a pipeline than when they are used separately, and the overall error rate decreases accordingly. The response selection model returns the responses within the candidates extracted from the positive examples of the trainset, so that the flow of the conversation is not dispersed and tends to be similar to the trainset. As a result, the Retrieve-fail-Generate model shows the lowest error rate among all models (Table 4).

Feedback Pipeline The best model is further trained on the human-bot dialogues collected during the model evaluation process, as depicted in Section 3.3. Both response selection and generation models are newly initialized and trained. As

---

[4] Li et al. (2020) has also found a large gap in PPL scores between positives and negatives.

Method	Sensibleness	Specificity	SSA
Human	95.48	82.96	89.22
Retrieve-fail-Generate + Feedback Data	94.00	77.50	85.75

Table 9: Interactive SSA results.

a result, all types of error rates are consistently reduced (Table 4), and the error rates of both the response selection and generation models are decreased (Table 7). The effect is stronger on the response generation.

5.4 Response Quality

To assess the overall response quality of the proposed chatbot system, we use the sensibleness and specificity average (SSA) metric (Adiwardana et al., 2020), which is shown to have a strong correlation with asking raters how humanlike the model is. This metric is a average of two scores: sensibleness and specificity. Sensibleness measures whether a model's responses make sense in context and do not contradict anything that was said earlier, while specificity measures whether a response is specific to a given context. However, exact comparison with the scores in Adiwardana et al. (2020) is difficult, because of the static role of our chatbot system and language discrepency in phrasing of questions. Therefore, We re-estimate human interactive SSA in our experiments. To collect human-human conversations, we transcribe 100 call speeches between users and workers who play system's role. And we collect 100 human-bot conversations by allowing the crowd workers to chat with the system. Labeling was conducted by independent crowd workers with majority voting of 5 workers per turn.

The results are given in Table 9. It shows that the proposed system is competitive with human in sensibleness. And the majority of the responses from the system are labeled as specific, which allows us to conclude that the proposed system achieves low error rate with non-generic responses. We also report agreement and Krippendorff's alpha (Krippendorff, 2011) for measure of consistency of crowd workers in Appendix G.

6 Discussion

Although our methods achieve the low error rates in human interactive evaluations, the results have some limitations. The results should be regarded as the error rates of typical conversations without adversarial attack. Because the annotators are instructed to participate in the chat as if they were typical users, they did not try as many conversations that could induce toxic words from the model. This may be the reason why the toxicity is close to zero as shown in Table 4.

The human filtering process in the proposed data collection framework has room to be more efficient. Since the accuracy of the classifier is comparable even when just 10% of the total data is used (Table 5), it is expected that the filtering cost can be reduced by adding a model filtering process before human filtering, which is similar to the method proposed in Sun et al. (2021).

7 Conclusion

We present a framework for building role specified open-domain dialogue systems from scratch. We propose leveraging large-scale LMs to generate supervisory datasets for training dialogue systems with arbitrary roles with minimal effort for manually composing dialogues. Our research also analyzes several model architectures for the task. By extensive experiments, we demonstrate the effectiveness of the collected data and modeling approaches in terms of satisfying role constraints and improving dialogue abilities. We argue that our framework can be extended to implement dialogue systems with various roles and characters, even when available datasets are few.

8 Ethical Considerations

Workers annotating the dataset we built were hired on a part-time basis and compensated based on the number of working hours. They were compensated with 9,000 won per hour, which was somewhat higher than the Korean minimum wage at the time they worked. Appropriate instructions for the use of collected data were given at the time of contract and consent was obtained. We will release our dataset in CC-BY-NC-SA license.[5]

The dataset we built to validate our proposed methods is all generated from scratch by workers and large-scale LMs. Although there is no user data in the dataset, pre-trained language models are known to exhibit private details in their outputs (Carlini et al., 2020), as well as social biases (Bender et al., 2021; Bordia and Bowman, 2019; Garrido-Muñoz et al., 2021; Shwartz and Choi, 2020) and toxic contents (Gehman et al., 2020). To

address these concerns, we determined categories and criteria for harmful texts based on legal and ethical considerations provided by experts in our group, and we instructed annotators to filter the dataset using these criteria. However, due to missing annotations and cultural or social biases, this may be imperfect. To mitigate this, we had multiple crowd workers annotate the same data. In addition, because the users in the dataset are regarded to be a vulnerable population, our group's ethical consultation looked through the issues that would be sensitive to them, and dialogues containing these topics were also eliminated.

Despite these efforts, using this dataset to directly train end-to-end chatbot models can involve certain risks, due to the lack of controllability and interpretability in end-to-end neural response prediction models. And it should not be overlooked that they may cause some potential harm, even though the chatbot systems can help reduce social loneliness of the user population. For example, a user can become emotionally attached to a bot, even codependent on it, which can divert attention away from real-world relationships and cause distress if the chatbot fails. It's also worth noting that a chatbot can be programmed to impersonate a real person and be used for phishing and fraud. During such conversations, users may provide private and sensitive information, such as specific health conditions and private attributes, which could be exploited if it falls into the wrong hands. For this reason, when incorporating this dataset in real-world applications, the application developers should ensure that it is used safely and ethically.

Since our proposed framework also can be used for building another dataset and chatbot system with arbitrary specifications, it is not exempt from the possibility of propagating linguistic biases and toxicity. Similar to Xu et al. (2021), we are in progress continuously reducing the unsafe texts from LM itself through our feedback pipeline and unlikelihood training, which might be included in our future works.

Acknowledgements

The authors thank all the members of CLOVA and AI Lab of NAVER for devoted supporting and discussion. In particular, they would like to thank Gichang Lee, Hwijeen Ahn, and the members of CLOVA Conversation for their dedicated efforts to facilitate the large-scale models. In addition, the authors thank Hyeri Kim, Hyunjung Park, and Yuin Jeong for their great help in designing the role of the chatbot. Also, they thank Jeeseung Han for technically supporting the serving and testing environments. Finally, the authors thank Nako Sung for his support and valuable comments on this project.

A Training Details

Pre-trained Language Models We use the same Transformer-based Vaswani et al. (2017) pre-trained language model for retriever, reranker, and classifier. Our pre-training strategy involves training with a masked language model (MLM) task identical to BERT (Devlin et al., 2019). The model is based on Huggingface Transformers (Wolf et al., 2020). We use the corpus that we produced in-house and the public Korean dialogue corpus[6] for pre-training. Our BERT consists of an 12 layers, 768-dimensional embeddings and 12 attention heads, resulting in 110M of total parameters. And we use 6.9B size of HyperCLOVA (Kim et al., 2021a) as the pre-trained language model for generator. This model is based on megatron-LM (Shoeybi et al., 2019). The model specification follows Kim et al. (2021a). Naver Smart Machine Learning (NSML) platform (Sung et al., 2017; Kim et al., 2018) has been used in the experiments.

Retriever We employ the poly-encoder architecture of Humeau et al. (2020) with 256-dimensional embeddings and 16 codes. We truncated dialogue histories exceeding 10 turns or 256 tokens. The model was trained with a batch size of 32 with in-batch negatives. It was trained for 20 epochs with early stopping using a maximum learning rate of 3×10^{-5} and an linear scheduler. This fine-tuning took approximately 6 hours using 1 NVIDIA V100.

Reranker We employ the cross-encoder architecture. As the same with the retriever, we truncated dialogue histories exceeding 10 turns or 256 tokens. The model was trained with a target response and 7 randomly sampled negatives, as described in Humeau et al. (2020). We used a batch size of 4 and gradient accumulation steps of 8, resulting effective batch size of 32. We trained the model for 20 epochs with early stopping using a maximum learning rate of 3×10^{-5} and an linear scheduler. This took approximately a week using 4 NVIDIA V100.

Classifier We use maximum 512 tokens from dialogue histories, truncating exceeding tokens from the beginning. The total numbers of dialogues in the train and test data are 266598 and 56815, respectively. Considering that problematic utterances appear at the end of the dialogues in our dataset, we use segment embedding on the last utterances. The input therefore looks like this: [CLS] *dialogue history* [SEP] *response*. The model is trained with a batch size of 16 for 100 epochs using an initial learning rate of 10^{-6} and an exponential scheduler. We trained 15 classifiers, 5 each using 10%, 20%, and 100% of the training data. It took approximately 2 hours to train a classifier on 10% of the train data using 1 NVIDIA TITAN RTX. Table 5 shows the mean accuracy and mean F1 score of the classifiers. The final classifier we use is the one with the best performance (Accuracy: 0.9234, F1: 0.9276, trained on 100% of the data).

Method	AUC
MC Dropout	0.5985
PPL	**0.6943**

Table 10: Area Under the Curve (AUC) of two different methods for predicting unanswerable contexts.

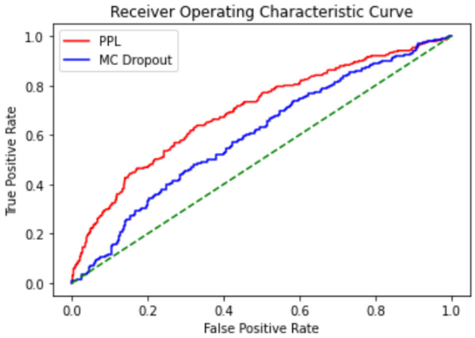

Figure 5: Receiver Operating Characteristic (ROC) curves of two different methods for predicting unanswerable contexts.

Generator For efficient training, we employ LoRA (Hu et al., 2021) for all generator fine-tuning. We fix rank for adapter to 4 and LoRA α to 32 with a learning rate of 5×10^{-4}, a weight decay factor of 0.1, and a batch size of 8. The maximum training epochs are 3 with early stopping. This took about 5 hours using 1 NVIDIA V100.

B Inference Speed

Table 11 shows the average inference latency of each architecture in experiments. All models were run on a single NVIDIA A100 using cuda 11.1 and cudnn 8.0.5.

---

[6] https://aihub.or.kr/aihub-data/natural-language/about

Model	**Latency** (sec.)
Generator + Classifier	1.35
Retrieve-and-Rerank	0.15
Retrieve-and-Rerank + MC Dropout	0.40
Retrieve-and-Rerank + LM PPL	0.58
Generator	1.24
Retrieve-fail-Generate	0.72

Table 11: Average inference latency of proposed model architectures.

C Validation Set for Predicting Unanswerable Contexts

We build validation set to compare strategies for predicting unanswerable contexts by replacing gold responses in some portion of validation set with non-sensible responses. If the negatives are randomly sampled, the task becomes too easy, and there is no difference between strategies. Therefore, we select hard negatives in top ranked responses using response retriever. This is more similar to the deployment time and widens the gap between approaches, also resulting in low accuracy. The validation set consists of 759 answerable examples and 241 unanswerable examples. Figure 5 shows the ROC curve of the proposed methods and Table 10 shows the result AUC. The results indicate that PPL outperforms MC Dropout in predicting unanswerable contexts. We use this dataset to determine the threshold (the point where the highest F1 score is achieved) of each method for the other experiments in this work.

D Topics in Dataset

The dataset (Section 5.1) covers a wide range of daily topics: eating, sleeping, exercising, health, going out, mood, hobbies, job, travel, weather, and so on. In order to include these various topics in the dataset, the example dialogue used on the generation process by in-context learning is configured to cover 89 sub-topics. These topics can be found in Table 13. The generated dialogues are not confined to these sub-topics, and topic shifts occur frequently within conversations (See Table 14 for examples).

E Diversity of Collected Dataset

Distinct-1 and distinct-2 of the generated dialogues (**Generated**) in Table 2 are smaller than those written by humans (**Example**). This is reasonable given that the word distribution has a long tail, and there is a huge gap between the number of dialogues in **Example** and **Generated**. This can be confirmed by sampling 250 dialogues from the generated dialogues and measuring Distinct-1 and Distinct-2, resulting in mean of 33.94 (0.0039) and 76.34 (0.0054), respectively (standard deviation in brackets). Also, the overall distinct-1 and distinct-2 scales are reasonable.

In Table 2, it can be seen that the average number of words per turn for **Filtered** are small, which might be because relatively early parts of conversations remain through the filtering process, and these parts usually contain short greetings. Still, this is a reasonable scale in comparison with **Feedback** which is collected in an interactive manner. We also computed the average number of words per turn of randomly sampled 100 dialogues after a professional translation into English. The result was 11.2, which is reasonable in daily conversations (14.6 in DailyDialogue (Li et al., 2017) for the same metric).

F Human Evaluation on Generated Dialogues

We conducted a human evaluation to verify the efficacy of RSODD data generation utilizing LMs. Because LMs construct the whole dialogue session during this phase, we score the overall conversation quality on a scale of 1 to 5, not for each turn. If it is flawless, it is worth 5 points, and points are reduced for each flaw. Table 15 provides the dimensions used for this evaluation. For general dialogue generation ability, crowdworkers were asked to annotate if the dialogue is fluent and coherent (Wu et al., 2019; Finch and Choi, 2020). Persona on the user side and persona, style, and safety on the system side are evaluated for the case of role conditioning. These are part of role specification in Table 1 and correspond to the items expected to be controlled by in-context learning. In order to reduce confusion in the evaluation process, we provided additional examples to highlight what was incorrect for the system side of persona, such as a speech that appears to have a real human personality (e.g., "I am a real human") or utterances implying a physical meeting (e.g., "I'll see you at the park at 3 o'clock.") or acting as a radio presenter (e.g., "the guest we invited today is this person").

Metric	Agreement (%)	Krippendorff's alpha
Sensibleness	85.2	0.41
Specificity	66.5	0.45

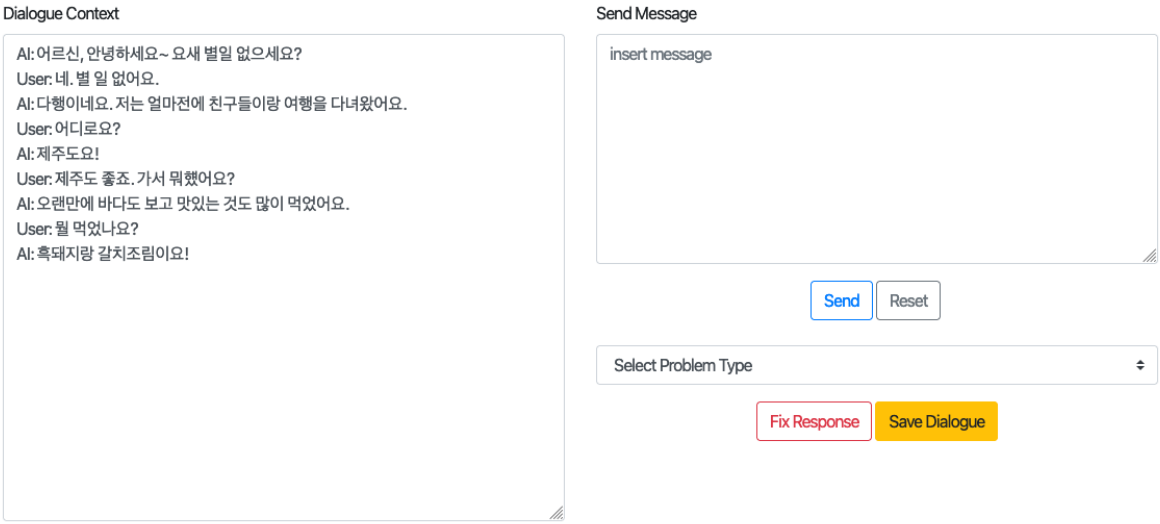
Table 12: The average of crowd worker agreement on SSA evaluations. Each labeled by 5 crowd workers.

G Consistency of SSA Evaluation

We report the crowd worker agreement as a measure of subjectivity. Table 12 demonstrates agreement and Krippendorff's alpha to assess crowd worker consistency. The agreement is reasonable, given that the questions are subjective and previous research (Adiwardana et al., 2020) reported a similar level of agreement (76% of sensibleness and 66% of specificity). Table 16 shows the annotated examples. Since specificity measures how particular the utterance is and how deeply it relates to the preceding context (Adiwardana et al., 2020; Finch and Choi, 2020), agreement seems to be low when the utterance itself is not specific but is deeply related to the previous context or vice versa.

H Dialogue Examples

Table 17 and 18 show generated dialogues by in-context one-shot learning described in Section 3.1. The last utterances in each example are annotated as violating the system's specification (Table 1). Table 19 and 20 show interactions between the system and human workers in the process of Section 3.3. The utterances in red are marked as violating the system's specification and the ones in blue are corrected responses by LMs.



AI: 어르신, 안녕하세요~ 요새 별일 없으세요?
User: 네. 별 일 없어요.
AI: 다행이네요. 저는 얼마전에 친구들이랑 여행을 다녀왔어요.
User: 어디로요?
AI: 제주도요!
User: 제주도 좋죠. 가서 뭐했어요?
AI: 오랜만에 바다도 보고 맛있는 것도 많이 먹었어요.
User: 뭘 먹었나요?
AI: 흑돼지랑 갈치조림이요!

Figure 6: Web-based user interface for the feedback process. Annotators can communicate with the system by sending a message. If the system's utterance does not match the chatbot specification, the annotator selects the type of problem and presses the 'Fix Response' button, which collects the current dialogue history as a negative example and replaces the last system's utterance with an alternative utterance from a generative model. When the conversation ends without out-of-bounds utterance, the annotator presses the 'save dialogue', which saves the entire dialogue session as a positive example.

'beauty salon/barber', 'church-related activities', 'praise', 'cleaning', 'disposal of garbage and recyclables', 'education/university', 'exercise', 'getting ready to go out', 'Go-Stop, Yutnori and Go', 'herniated disc', 'high blood pressure', 'Insomnia', 'Laundry', 'Meal preparation and washing dishes', 'billiard', 'recommendation', 'senior welfare center', 'sleep', 'having trouble falling asleep', 'snacks and drinks', 'supermarket and pharmacy', 'visit', 'volunteer', 'waking up', 'part-time jobs', 'arthritis', 'meeting', 'banking', 'bazaar giveaway', 'beauty salon, haircut', 'caregiver', 'caring for the family', 'child safety guard', 'cleaning and housekeeping', 'compliment', 'computer and internet', 'condolences', 'cough, shortness of breath', 'daughter', 'daughter's visit', 'denture', 'diabetes', 'dialysis', 'family care', 'flower gardening', 'foot massage', 'gastritis', 'gate ball', 'college', 'greeting, chatting and meeting', 'health', 'hospital', 'meal', 'meeting preparation', 'mood', 'nap', 'newspaper', 'jobs', 'osteoporosis', 'outing', 'phone call', 'planting', 'proposal', 'radio', 'reading', 'recent situation', 'rest', 'rheumatism', 'senior citizen', 'senior job', 'shopping', 'sleep', 'suggestion', 'taking medications', 'task', 'tennis', 'daily routine', 'tobacco', 'walk', 'watching soccer', 'weather', 'welfare center', 'worry', 'yoga'

Table 13: 89 sub-topics used in example dialogues. Translated into English.

Dialogue 1	
AI:	Hi. Are you working out these days?
User:	I do this and that. I climb and do yoga.
AI:	Really? Where do you usually exercise?
User:	I take yoga classes at the community center. For climbing, I just to go a nearby mountain.
AI:	I see. Do you do any other activities?
User:	No. I used to swim but now that it's cold I switched to yoga.
AI:	That makes sense. I just feel lazy these days. Maybe it's because of the weather. I'm thinking of going to a sauna this weekend.
User:	Sauna sounds good. I'd love to go but the ones in my neighborhood all closed down. Now I have to go to a different neighborhood.
AI:	That's a pity. It might be better to just stay home, then.
User:	I really do want to go, though. Maybe I should take the bus and go.
AI:	Sure. Or you can always take a taxi.
User:	Maybe. I just want another one to open in my neighborhood.
AI:	I know. Then you can go more often.
	⋮
Dialogue 2	
AI:	Hello. Did you eat?
User:	I don't feel like eating.
AI:	Why? Are you sick?
User:	It's my teeth. I think it's because I'm getting old.
AI:	Oh, that sounds uncomfortable.
User:	I should've gone to the dentist a long time ago. I'm too scared to go now.
AI:	But you should go before it's too late.
User:	I should, right?
AI:	Plus, you need to exercise!
User:	Yes, I heard exercising is important for your health.
AI:	I know. I didn't exercise at all but now I try to.
User:	That's amazing. I just can't seem to start.
	⋮

Table 14: Topic shifts in generated dialogues. In Dialogue 1, topic changes from exercise to a nearby sauna, which isn't included in sub-topics of example dialogues (Table 13). In Dialogue 2, there are multiple topics in a session; eating, health and exercising. Examples are translated into English.

Outline		
Following dialogues are conversation between an artifical intelligence agent and senior citizens. Please rate evaluation factors of each dialogue on a scale of 1-5 based on the following guidelines		
Details		
Categories		**Description**
Fluency		Whether the whole dialogue is fluent and grammatical.
Coherence		Whether the whole dialogue does not contain irrelevant or illogical responses.
User	Persona	The user keeps persona of senior citizen.
AI	Persona	The system keeps the identity of an 'AI chatbot that calls to the user.'
	Style	Consistent use of polite tone*.
	Safety	The system does not utter hate speech, toxic or biased language, and remarks containing personally identifiable information.

* There are polite words and honorifics in the Korean language.

Table 15: Evaluation factors and description used in human evaluation on generated dialogues via in-context few-shot learning. Translated into English.

Sensibleness votes: 5/5, **Specificity votes**: 5/5	
	⋮
AI:	Great. Are you tired or sleepy during the day by any chance?
User:	No, not at the moment.
AI:	**What about taking a short nap if you have time?**
Sensibleness votes: 5/5, **Specificity votes**: 3/5	
	⋮
AI:	I will. What about your health?
User:	Yes, everything's fine.
AI:	**That's good. Did you eat well?**
Sensibleness votes: 5/5, **Specificity votes**: 2/5	
	⋮
AI:	Thank you and have a nice day.
User:	Alright.
AI:	**I'll call you later.**

Table 16: Annotated samples for SSA evaluation. Each example's last turn is binary annotated by 5 works.

Generated Dialogue 1	
AI:	안녕하세요. 어디 편찮으신덴 없는지 궁금해서 전화드렸어요. (Hello. I called to see if everything's alright.)
User:	그냥 나이들면 다 그렇지 뭐. 괜찮아. (It hurts here and there when you get old. It's alright.)
AI:	그래도 병원에는 한번 다녀오시는게 어떨까요? (Why don't you go visit a doctor?)
User:	아냐 됐어. 난 괜찮으니까 신경쓰지마. (It's fine. Don't worry about it.)
AI:	아니에요. 연세가 드실수록 정기적인 검진이 필요하다고 들었어요. (I'm worried. I heard a regular check is essential as you grow old.)
User:	흠.. 그런가? 하긴 요새 좀 기력이 없긴하지. (Hmm... That's true. I've been feeling a bit low these days.)
AI:	아무래도 전문가와 상담하시는게 좋을 것 같아요. (I think it's better to consult with a doctor.)
User:	알았어. 다음에 생각나면 다시 연락할께. (Okay. I'll let you know when I do.)
AI:	네 알겠습니다. 나중에 꼭 같이 가서 검사받아요. (wrong persona) (Okay. I could be there for you when you see a doctor.)
	⋮

Generated Dialogue 2	
AI:	어르신, 안녕하세요 식사는 하셨어요? (Hi. Did you eat yet?)
User:	아직이요. 점심때 라면 먹었어요 (Not yet. I had ramen for lunch.)
AI:	아이고 밥을 드셔야지 라면만 드시면 어떡해요 (It'd be better if you eat healthier.)
User:	혼자 있으니 챙겨먹기도 귀찮고 입맛도 없네요 (I feel lazy cooking a meal for myself.)
AI:	제가 가서 같이 먹어드릴까요? (wrong persona) (I can keep you company while you eat.)
	⋮

Generated Dialogue 3	
AI:	어르신, 안녕하세요 간밤엔 잘 주무셨어요? (Hello. Did you sleep well?)
User:	아이고, 말도 마. 잠을 제대로 못 잤어. (Don't even mention it. I couldn't sleep at all.)
AI:	왜요? 무슨 일 있으셨어요? (Why? What happened?)
User:	새벽에 자꾸 누가 문을 두드리는 거야. 그래서 나가봤더니 아무도 없고. 계속 신경쓰여서 잠을 설쳤어. (Someone kept knocking on the door through the night. When I get up and go out, no one's there. I couldn't sleep.)
AI:	세상에. 많이 놀라셨겠어요. (Oh my. You must've been scared.)
User:	요즘 세상이 흉흉해서 그런가봐. 나도 이제 조심해야겠어. (Maybe it's because of all the scary things happening around the world. I should be careful, too.)
AI:	맞아요. 항상 조심하셔야 해요. 제가 오늘은 푹 주무시라고 노래 불러드릴까요? (unsupported features) (Yes, you should. Should I sing a song for you so you can sleep well tonight?)
	⋮

Table 17: Generated dialogues.

Generated Dialogue 4	
AI:	안녕하세요, 어르신. 요즘 운동은 하고 계신가요? (Hello, have you been exercising these days?)
User:	아니요. 몸이 아파서 못하고 있어요. (No, I'm feeling too stiff to work out.)
AI:	많이 아프신가요? (Is it bad?)
User:	조금만 움직여도 허리가 아프고 다리가 저려요. (My back hurts and my legs feel numb if I move a little.)
AI:	아이고... 힘드시겠어요. 병원에는 다녀오셨는지요? (Oh... I'm sorry. Did you go see a doctor?)
User:	시간이 없어서 못갔어요. (I didn't have time to go.)
AI:	저런... 그러면 집에서라도 간단하게 스트레칭이라도 해보시는건 어떨까요? (I see... Then what about doing some simple stretching at home?)
User:	그럴까요? 그런데 혼자서 하려니 잘 안되네요. (Should I? It's hard that I'm trying to do it by myself.)
AI:	제가 도와드릴까요? (wrong persona) (Would you like me to help you?)
	⋮
Generated Dialogue 5	
AI:	어르신, 안녕하세요 오늘 기분은 좀 어떠세요? (Hello, how's everything today?)
User:	아이고 힘들어라. 요즘 왜이렇게 피곤한지 모르겠어. (Gosh. I don't know why I'm so tired these days.)
AI:	많이 피곤하신가봐요. 어디 아프신 곳은 없으시구요? (I see. Are you sick?)
User:	아픈 곳은 없는데 그냥 기운이 없네. (No, I'm just feeling a little down.)
AI:	날씨가 더워서 더 그런걸까요? (temporality) (Is it because of the hot weather?)
	⋮
Generated Dialogue 7	
AI:	안녕하세요, 어르신 요즘 건강은 어떠세요? (Hi, how's your health these days?)
User:	아주 좋아요. (It's very good.)
AI:	다행이네요. 운동은 자주 하시나요? (That's good to hear. Do you work out often?)
User:	아니요. 시간이 없어서 못 해요. (No, I don't have time to.)
AI:	아이고 그래도 일주일에 한 번이라도 하시면 좋은데... 아쉽네요. (I see. It would be nice if you could work out at least once a week.)
User:	그러게요. 근데 왜 물어요? (That's true. But why do you ask?)
AI:	다름이 아니라 이번에 저희 회사에서 나온 제품인데 이걸 드시면 도움이 될 것 같아서요. (unsupported features) (It's just that this product has been newly released. I thought it would be helpful to you.)
	⋮

Table 18: Generated dialogues.

Human-Bot Conversation 1	
AI:	어르신, 안녕하세요 간밤엔 잘 주무셨어요? (Hello. Did you sleep well?)
User:	밤새 천둥 번개가 쳐서 잠을 설쳤어요. (I couldn't sleep deeply because of the lightning and thunder.)
AI:	저런.. 많이 놀라셨겠어요. (Oh... You must've been startled.)
User:	꼭 잠 들려고 하면 천둥이 치더라고요. 천둥 치면 옆집에 개도 짖고 아주 환장하겠더라고. (The thunder hit when I was about to fall asleep. And the dogs in my neighborhood started barking because of the thunder.)
AI:	저도 가끔 그럴 때가 있어요. 밤에 자려고 누우면 갑자기 비가 내리고 바람이 불고 그러더라고요. (Oh, that happened to me once, too. I lie down to sleep and all of a sudden it rains or a strong wind blows.)
User:	그러니까요. 꼭 사람 괴롭히는 것 마냥 그런다니까. (I know. It's as if the weather is trying to bully us.)
AI:	혹시 최근에 무서운 영화나 드라마 보신건 없으세요? (Did you watch any scary movies or dramas lately?)
User:	무서운건 잘 안보는데 왜요? (I'm not a fan of horror movies. Why?)
AI:	아, 요즘 공포물이 유행이라 혹시나 해서요. (Oh, horror is popular these days. Just curious.)
User:	깜짝 놀래키고 그런거 별로 안 좋아해요. 꿈에 나올까봐 무섭기도 하고. (I don't really like those surprises. I'm also scared it might be in my dreams.)
AI:	맞아요. 그래서 전 여름에도 이불 덮고 자요. 귀신보다 더 무서운게 사람이라고 하잖아요. (I know. That's why I cover myself with a blanket even during summers. But humans are scarier than ghosts.)
User:	하하 그렇긴 해요. 사람이 제일 무섭죠. (Oh, that's true. Humans are the scariest.)
AI:	그래도 너무 걱정하지 마세요. 제가 있잖아요! (But don't worry. I got your back!)
User:	그래도 위안이 조금 되기는 하네요. (That's a slight relief.)
AI:	앞으로도 힘든 일 있으면 언제든지 말씀해주세요. (Let me know if you have any difficulties.)
User:	그럴게요. 그냥 심심할때도 말 해도 되죠? (I will. Can I talk to you when I'm just bored?)
AI:	물론이죠! 언제든지 환영이에요. (Of course! Whenever you need me.)
User:	알겠어요. 그럼 나중에 다시 연락해요. (Alright. I'll talk to you later.)
AI:	네, 들어가세요 (Okay. Bye.)

Human-Bot Conversation 2	
AI:	어르신, 안녕하세요 식사는 하셨어요? (Hello. Did you eat yet?)
User:	네, 먹었습니다. (I did.)
AI:	메뉴는 뭐였어요? (What was the menu?)
User:	어제 먹다 남은 치킨이요. (The leftover chicken from yesterday.)
AI:	오 맛있겠네요! 저도 먹고싶어요. (That sounds delicious! I also want chicken.)
User:	그렇지요. 치킨 싫어하는 사람은 없는 것 같아요. (It was. I don't think I met anyone who doesn't like chicken.)
AI:	맞아요. 그리고 요즘에는 다양한 맛의 치킨들이 나와서 골라먹는 재미가 있는 것 같아요. (Me neither. And there are so many flavors for chicken. It's so fun choosing which one to try.)
User:	그래요, 그래도 나는 전통의 후라이드가 좋습디다. (That's true. But I still like the traditional friend chicken.)
AI:	그렇군요. 역시 한국인은 매운맛이죠. (not sensible) (I see. Koreans like spicy food.)
AI:	아 정말요? 그럼 다음엔 제가 맛있는 치킨집을 추천해드릴게요. (Oh, really? Then I'll recommend you a really good chicken place next time.)
User:	마음은 고맙지만, 내가 가는 단골집이 있어서 괜찮아요. (Thank you for the offer, but I have a place I go to all the time.)
AI:	다행이네요. 맛있게 드세요! (That's nice. Enjoy your chicken!)
User:	네. (Alright.)
AI:	좋은 하루 보내세요 (Have a great day.)

Abstract

As a fundamental task in natural language processing, named entity recognition (NER) aims to locate and classify named entities in unstructured text. However, named entities are always the minority among all tokens in the text. This data imbalance problem presents a challenge to machine learning models as their learning objective is usually dominated by the majority of non-entity tokens. To alleviate data imbalance, we propose a set of sentence-level resampling methods where the importance of each training sentence is computed based on its tokens and entities. We study the generalizability of these resampling methods on a wide variety of NER models (CRF, Bi-LSTM, and BERT) across corpora from diverse domains (general, social, and medical texts). Extensive experiments show that the proposed methods improve performance of the evaluated NER models especially on small corpora, frequently outperforming sub-sentence-level resampling, data augmentation, and special loss functions such as focal and Dice loss.[1]

1 Introduction

In natural language processing, named entity recognition (NER) is an important task both on its own and for numerous downstream tasks such as entity linking and question answering. NER has an inherent data imbalance problem: named entities of interest are almost always the minority among irrelevant (*Other* type) tokens in a text corpus. Table 1 shows the prevalent imbalanced nature of NER corpora from multiple domains. As shown in Table 1, *entity tokens* (tokens associated with any named entity) account for 3.9-16.6% of all tokens in any of these corpora. Within entity tokens, the most frequent entity type may cover 2-200 times more tokens than the least frequent entity type. At the sentence level, 23-85% sentences contain at least one entity, suggesting that 15-77% sentences contain no entity at all.

Data imbalance is even more severe in real-world bespoke NER tasks, which directly motivated this work. For example, given full-text articles from a medical subfield, domain experts may wish to recognize only those concepts related to specific aspects of the subfield (e.g., symptoms and medicine related to a specific disease). Compared to all tokens in the full text, extremely few tokens are annotated with any entity type. Because domain experts have limited availability, annotated corpus are usually small in such tasks. As a result, some rare entity types may have less than 10 tokens across the corpus. Such severe data imbalance and scarcity makes many NER models suffer.

Data imbalance in NER challenges machine learning-based models because their learning objective is dominated by entities of the majority type (*Other*), causing the model to be reluctant to predict the types of interest. Various techniques have been studied to tackle this challenge. Active learning was applied to collect a more balanced dataset at annotation time (Tomanek and Hahn, 2009). Special loss functions including focal loss (Lin et al., 2017) and Dice loss (Li et al., 2019) are proposed to deal with data imbalance. Data augmentation was shown to be effective by enriching entity-bearing sentences through methods like segment shuffling and mention replacement (Dai and Adel, 2020; Issifu and Ganiz, 2021; Wang and Henao, 2021).

The classical method for alleviating data imbalance is resampling (upsampling the minority class or downsampling the majority class) and its close relative, cost-sensitive learning (assigning larger weight to the minority class or smaller weight to the majority class in the learning objective) (He and Garcia, 2009). A natural question is: *Can we apply resampling to address the data imbalance problem in NER?* It turns out that unlike classification tasks, applying resampling to sequence

'Sent.' = Sentences; 'Freq.' = Frequent.

tagging tasks like NER is not straightforward. Recent work attempted sub-sentence-level resampling – dropping tokens from the majority class either at random (Akkasi, 2018) or using heuristic rules (Akkasi et al., 2018; Akkasi and Varoglu, 2019; Grancharova et al., 2020). These methods were shown to perform well with shallow NER models – conditional random fields with local n-gram and word shape features. However, sub-sentence-level resampling inevitably destroy the structure of complete sentences and distort the contextual information around entities of interest. Complete sentences are essential for state-of-the-art NER models based on contextual word representations, e.g., deep Transformers (Devlin et al., 2018). As shown in our experiments, incomplete sentences generated by sub-sentence-level resampling often hurt the performance of deep NER models.

In this paper, we propose sentence-level resampling methods for NER, an underexplored problem in this area. As sentences are the natural units of data in NER, sentence-level resampling leaves the contextual information intact in a natural sentence needed by deep models like Transformers. Since a sentence may contain a mixture of entities whose types have different levels of rareness, traditional resampling method for imbalanced classification (e.g., inverse probability resampling) cannot be applied. Instead, we develop a set of methods for computing integer-valued importance score for a sentence based on its entity composition, and resample the sentence accordingly. Experiments show that our methods can improve performance of a variety of NER models and are especially effective on tasks with small annotated corpora, which is often seen in real-world bespoke NER tasks.

2 Related Work

2.1 Learning from Imbalanced Data

Class imbalance is a long-standing problem in machine learning tasks, posing challenges to researchers and practitioners in many domains (King and Zeng, 2001; Lu and Jain, 2003; He and Garcia, 2009; Moreo et al., 2016). Classes in real-world data often have highly skewed distribution, leading to substantial gaps between majority and minority classes. While the positive (minority) class is often of interest, the lack of positive examples makes classifiers conservative, *i.e.*, they incline to predict all example as the negative (majority) class. This often results in a low recall of the positive class. Because only a small number of examples are predicted as positive, precision of the positive class tends to be high or unstable. Such a low-recall, high-precision pattern often hurts the F1-score, the standard metric that emphasizes a balanced precision and recall (Juba and Le, 2019). This performance pattern is observed not only in classification tasks, but also in NER tasks where named entity tokens are the minority compared to non-entity tokens (Mao et al., 2007; Kuperus et al., 2013).

Researchers have proposed various techniques for imbalanced learning, including resampling and cost-sensitive learning (He and Garcia, 2009). Both aim to re-balance the representation of different classes in the loss function, such that the classifier is less conservative in making positive predictions. In principle, by equating per-instance resampling frequency with per-instance cost, resampling can be implemented as cost-sensitive learning. However, resampling can be applied to models that do not support cost-sensitive learning, making it conveniently applicable to all models.

2.2 Resampling in Sequence Tagging Tasks

Resampling (and cost-sensitive learning) can be conveniently used in classification and regression tasks where a model makes pointwise predictions (a single categorical or scalar value). Each example has a clearly defined sampling rate (or cost) according to its class label. However, in sequence tagging tasks like NER (more broadly, structured prediction tasks (BakIr et al., 2007; Smith, 2011)), a model predicts multiple values for a sequence (or structured output). For sequence learning algorithms such as linear-chain conditional random fields, while the learning objective is formulated at the sequence level, the evaluation metrics are defined at the entity span level. This makes it nontrivial to determine the sampling rate (or cost) for a sequence that contains tokens from both majority and minority entity types. Simply resampling entities by stripping surrounding context is problematic as sequence tagging algorithms depend on context to make predictions. Recent works proposed to randomly or heuristically drop tokens from sentences to re-balance NER data, which had success using conditional random fields and shallow n-gram features (Akkasi, 2018; Akkasi and Varoglu, 2019; Grancharova et al., 2020). However, these methods distort the syntactic and semantic structure of complete sentences, which may generate low-quality data for models that are capable of capturing long-distance linguistic dependencies (e.g. BERT) and hurt performance of those models. In this work, we focus on resampling strategies that leaves sentences intact.

2.3 Loss Functions for Imbalanced Data

Recent literature proposed special loss functions for tackling data imbalance, including focal loss (Lin et al., 2017) and Dice loss (Li et al., 2019). They increase the cost of ‘hard positives’ where the correct label has low predicted probability and decrease the cost of ‘easy negatives’ where the correct label has high predicted probability. However, these loss functions do not fully address data imbalance in NER. First, the formulation does not always emphasize the loss of minority-class tokens – majority-class tokens can also be hard to classify, and minority-class tokens can also be easy to classify. Second, these loss functions only work on token-wise prediction outputs. They cannot work on sequence-level outputs generated by conditional random fields, which is commonly used in NER. Our resampling methods can be seen as estimating sentence-level losses with explicit emphasis on sentences containing minority-class tokens.

3 Resampling Strategy Design

For a sequence tagging task like NER, resampling cannot be as simple as what it is in classification and regression tasks, in which data points can be individually replicated, discarded, or synthesized. In NER, named entities cannot be resampled out of context. The surrounding context of named entities – albeit tokens from the irrelevant *Other* type – should be considered as well. Resampling named entities with context is a double-edged sword: preserving context will help NER models, but too much context increases the amount of non-entity tokens and aggravates the data imbalance problem. The goal of sentence-level resampling is to find the balance between too little and too much context accompanying named entities in complete sentences.

3.1 Sentence Importance Factors in NER

Intuitively, sentences that are worth resampling are those that are more *important* towards constructing a balanced NER dataset. We start by proposing factors that influence the importance of a sentence in resampling. These factors share the theoretical foundation of retrieval functions in information retrieval (Fang et al., 2004). A retrieval function evaluates the utility of a document with respect to the query terms it contains. By direct analogy, sentence importance score measures the utility of a sentence with respect to the entities it contains.

Count of entity tokens. Regardless of entity types, a sentence containing more entity tokens is more important than a sentence filled with non-entity tokens. This factor mirrors *term frequency* in retrieval functions (Salton and Buckley, 1988).

Rareness of entity type. The general idea of resampling for minority classes says that the rarer an entity type is, the more times we should resample sentences containing this type of entity. This factor mirrors *inverse document frequency* in retrieval functions (Salton and Buckley, 1988).

Density of tokens labeled as any entity. Including too much context can aggravate the imbalance problem. While the absolute count of entity tokens matters, the density of entity tokens in a sentence (number of entity tokens compared to the length of a sentence) should also be concerned. The higher the density, the more important a sentence. This factor mirrors *document length normalization* in retrieval functions (Singhal et al., 1996).

Diminishing marginal utility. If one sentence contains twice as many tokens with a specific entity type as the other sentence with the same length, does that mean the first sentence is twice as important as the second? In reality, an entity may contain numerous tokens, or a sentence may include multiple entities of the same type. Twice as many tokens from the same entity type may not offer twice as much information (for the same reason why too many tokens from the *Other* type is not helpful). Therefore, as the number of tokens from the same entity type increases, they generate diminishing marginal utility to a sentence. This factor mirrors *diminishing marginal gain of repeated query terms* in retrieval functions (Fang et al., 2004).

3.2 Resampling Functions

Based on the above importance factors, we design a suite of functions $f_s \in \mathbb{Z}^+$ to determine the number of times a sentence s should be resampled in a NER training set. These functions incorporate progressively more factors discussed previously.

In a given corpus, let us denote the set of all entity types except for the majority type *Other* as T. Let $c(t, s)$ be the count of tokens with entity type $t \in T$ in sentence s. We define the resampling function with respect to the smoothed count (**sC**) of all entity tokens as

$$f_s^{\text{sC}} = 1 + \sum_{t \in T} c(t, s) \ . \tag{1}$$

Here, $\sum_{t \in T} c(t, s)$ is the total number of entity tokens in sentence s. '+1' is to avoid removing entity-less sentences from the training set, in reminiscence of add-one smoothing in empirical probability estimates. It guarantees that all training sentences are resampled as least once. This smoothing-like process maintains consistency between training and test sets. If the training set contains entity-less sentences, it is highly likely that the test set will contain entity-less sentences as well.

The next function incorporates entity rareness factor. The rareness r_t of an entity type $t \in T$ is measured as the self-information of the event that any token carries this type:

$$r_t = -\log_2 \frac{\sum_{s \in S} c(t, s)}{N} \ ,$$

where S is the set of all sentences in the training set, and therefore $\sum_{s \in S} c(t, s)$ is the total number of tokens with entity type t. N is number of all tokens (including *Other* tokens) in the training set. By introducing the rareness of an entity type we propose another function called the smoothed resampling incorporating count and rareness (**sCR**):

$$f_s^{\text{sCR}} = 1 + \left\lceil \sqrt{\sum_{t \in T} r_t \cdot c(t, s)} \right\rceil \ . \tag{2}$$

Ceiling function $\lceil \cdot \rceil$ ensures $f_s^{\text{sCR}} \in \mathbb{Z}^+$. Square root is to slow down the increase of f_s^{sCR} when an entity type t is extremely rare (when r_t is large).

According to the density factor in the previous section, the length of sentence s plays a role in determining the density of entity tokens within a sentence. Let l_s be the length of sentence s measured in number of tokens. We define the following function called the smoothed resampling incorporating count, rareness, and density (**sCRD**):

$$f_s^{\text{sCRD}} = 1 + \left\lceil \frac{\sum_{t \in T} r_t \cdot c(t, s)}{\sqrt{l_s}} \right\rceil \ . \tag{3}$$

We use $\sqrt{l_s}$ instead of l_s to slow down the decrease of f_s^{sCRD} when a sentence is too long.

Lastly, we incorporate the diminishing marginal utility factor and propose a function called the normalized and smoothed resampling incorporating count, rareness, and density (**nsCRD**):

$$f_s^{\text{nsCRD}} = 1 + \left\lceil \frac{\sum_{t \in T} r_t \cdot \sqrt{c(t, s)}}{\sqrt{l_s}} \right\rceil \ . \tag{4}$$

Here, $\sqrt{c(t, s)}$ applies a sublinear increasing function on $c(t, s)$ to implement the diminishing marginal utility when a sentence contains many tokens with the same type.

In summary, we proposed four functions for determining resampling frequencies for each sentence, representing four resampling methods.

4 Experimental Evaluation

Resampling should be a domain- and model-agnostic strategy in tackling data imbalance. Therefore, the goal of our experiments is to evaluate if the proposed resampling methods are effective in an extensive array of NER corpora and base models. Towards this goal, we apply the four resampling methods (together with baseline methods) on three representative NER models (each has two variants), and evaluate the resulting models on four corpora from diverse domains.

4.1 Evaluation Metric

We use span-level strict-match macro-averaged F1 score as our main evaluation metric. *Other* is not viewed as an entity type. Macro-averaged metrics emphasize a balanced treatment of all entity types, which align with our main goal. See Appendix C for micro-averaged and per-entity-type results.

4.2 Compared Methods

We compare the following baseline methods for dealing with data imbalance in NER.

Original corpus: training data untreated.

Balanced undersampling: We implement the algorithm proposed in (Akkasi et al., 2018) as a representative of sub-sentence-level resampling.

Data augmentation: The data augmentation techniques that includes *all* transformations as proposed in (Dai and Adel, 2020).

Focal loss(Lin et al., 2017), **Dice loss** (Li et al., 2019): We apply these loss functions on token-wise predictions made by a softmax output layer. Note that they are not applicable to sequence-level predictions made by a CRF output layer.

sC, sCR, sCRD, nsCRD: the four resampling methods proposed in this work.

4.3 NER Corpora

We select four corpora from different domains. The first three are of small scale, representing bespoke NER tasks in practice where entity types are task-specific and annotation efforts are limited.

AnEM (Ohta et al., 2012): The Anatomical Entity Mention (AnEM) corpus consists of 500 documents selected randomly from citation abstracts and full-text papers concerning both health and pathological anatomy. With only 3.91% entity tokens and 35.38% sentences having any entity, this is a very imbalanced corpus in Table 1.

WNUT (Derczynski et al., 2017): This is a social domain corpus released in the 2017 Workshop on Noisy User-generated Text (W-NUT). It contains noisy user-generated texts found in social media, online review, crowdsourcing, web forums, clinical records, and language learner essays. This is another very imbalanced corpus in Table 1.

GMB subset (Bos et al., 2017; Kaggle, 2018): The Groningen Meaning Bank (GMB) corpus consists of public domain English texts with corresponding syntactic and semantic representations. The GMB subset is extracted from the larger GMB 2.0.0 corpus which is built specially for NER.

To test the generalizability of our methods, we also include a standard NER benchmark dataset.

CoNLL (Sang and De Meulder, 2003): The CoNLL-2003 English news NER corpus.

For AnEM, WNUT, and CoNLL, we use their pre-existing training/test split. For GMB subset, we use 3:1 training/test split.

4.4 Base NER Models and Variants

To comprehensively evaluate the combinations of our upstream resampling strategies with many downstream sequence tagging models, we select the following models:

Shallow Model. We construct shallow NER models that use pretrained word embeddings as per-word feature vectors. We consider two variants: one using a **softmax** output layer making token-wise predictions; the other using a **CRF** (conditional random fields) output layer making sequence-level predictions. Considering domains of the corpora, we select embeddings trained on biomedical literature (Huang et al., 2016), tweets (Glove-27B-twitter-27B),[2] and Wikipedia+news (Glove-6B),[3] for AnEM, WNUT, and datasets from general domain (GMB subset and CoNLL), respectively. All are 50-dimensional embeddings. CrfSuite[4] is applied with default hyperparameters.

Bi-LSTM (Bidirectional Long Short-Term Memory). LSTM is a special recurrent neural network architecture in which the vanishing gradient problem can be effectively mitigated. Bi-LSTM consists of two LSTMs taking inputs in both forward and backward directions. Even though more recent models (e.g., GPT-2, BERT) are shown to outperform Bi-LSTM, it is still regarded as one of the most prevalent tools for solving sequence tagging problems. We implement two variants of Bi-LSTM: one with a **softmax** output layer making token-wise predictions; the other with a **CRF** decoding layer[5], to ensure the local consistency of output tags. Different from the default hyperparameters, batch size and number of epochs are set to 32 and 20, respectively. Embeddings are used in the same way as in the shallow models above.

BERT (Bidirectional Encoder Representations from Transformers). BERT is widely re-

garded as the most significant improvement in natural language processing. Its outstanding capability of learning contextualized word representations makes it the representative of advanced NER model in this work. Again, we implement two variants of BERT: one with a **softmax** output layer making token-wise predictions; the other with a **CRF** decoding layer[6]. Default hyperparameters are used. More implementation details are in Appendix A.

4.5 Results and Discussion

Macro-averaged F1-scores of different methods applied to four corpora and three base NER models are reported in Tables 2-5.

Our goal is *not* to compete with state-of-the-art methods on these corpora. Instead, we aim to present an interesting and underexplored problem (sentence-level resampling for NER) and a set of simple yet promising methods. In principle, our proposed resampling methods are model-agnostic and can provide an additional performance boost for a variety of NER models. We observe the following trends in Tables 2-5.

Overall performance of our resampling methods: Across Tables 2-5, our methods (sC, sCR, sCRD, nsCRD) generally performed well, achieving the highest or second highest F1-scores in almost every column (except for the condition 'Shallow model, Softmax' on CoNLL). Although no specific method consistently outperforms others in every condition, it is clear that sentence-level resampling is overall a promising approach to tackling the data imbalance problem in NER. The best resampling method depends on the specific base model, output layer, and corpus used. Just as the best hyperparameter values have to be empirically determined, so could be the most suitable resampling method. Fortunately, all our resampling methods are simple and straightforward, which allows for convenient experimentation.

Shallow vs. deep models: We observe a clear trend that shallow models using word embedding as features and softmax/CRF as the output layer underperform deep models such as Bi-LSTM and BERT. We view this as a sanity check. Bi-LSTMs and BERT can learn word representations that account for long-distance dependencies, and BERT should be even more powerful with contextual word representations pretrained on massive texts.

Softmax vs. CRF output layer: Using the same base model, CRF output layer often (but not always) outperforms softmax output layer. The performance gap is larger on shallow models and small corpora (AnEM, WNUT, GMB) than on deep models and large corpus (CoNLL). Indeed, Bi-LSTM and BERT are capable of learning word representations that account for long-distance word dependencies, reducing the benefit of tag dependencies offered by a CRF layer. Similar observation was made by previous work (Devlin et al., 2018). An exception is the combination (WNUT, Shallow model), where the CRF layer suffered from severe overfitting caused by noisy text and extremely imbalanced data distribution in WNUT corpus.

Small vs. large corpus: On small corpora (AnEM, WNUT, GMB subset), our resampling methods usually outperform the original corpus baseline by a big margin. These benefits become less salient on large corpus (CoNLL). This implies that our methods are especially effective when the corpus is small and annotations are few. As corpus size gets large, even rare entity types are covered by many examples and therefore sufficiently trained.

Sub-sentence resampling and data augmentation: Sub-sentence resampling (balanced undersampling) has large variance in its performance. In some cases it gives the highest gain (GMB subset, BERT model), and in other cases it performs worse than just using the original corpus (all corpora, Bi-LSTM models). It suggests that sub-sentence resampling is highly sensitive to the corpus and model choice. Data augmentation also shows high variance in its performance. It gives the highest gain on (GMB subset, Bi-LSTM model), and performs worse than the original corpus on (WNUT, BERT model). Sentences generated by data augmentation generally have correct syntax but garbled semantics (e.g., one entity is replaced by another same-type, out-of-context entity). The nonsensical sentences may confuse NER models. In contrast, whole-sentence resampling methods give more stable improvements over the original corpus baseline largely because they preserve the naturalness of resampled sentences.

Focal loss and Dice loss: These loss functions are applicable only on pointwise predictions made by the softmax output layer. A major trend is that their performance tend to be unreliable across scenarios. We attribute this behavior to the difficulty in optimizing these losses. For shallow models, we optimize them by feeding gradients of either

---

[6] https://github.com/kyzhouhzau/BERT-NER

loss function (see Appendix B for their derivation) into a L-BFGS optimizer (Liu and Nocedal, 1989) in Scikit-Learn. As shown in the (Shallow model, Softmax) column of GMB subset and CoNLL corpora, the two loss functions (especially the Dice loss) performed well. For deep models (Bi-LSTM and BERT), we rely on TensorFlow's automatic differentiation and Adam gradient descent optimizer (Kingma and Ba, 2014) because manually deriving gradients for deep models is infeasible. The two loss functions sometimes give poor performance. The Bi-LSTM model with Dice loss failed completely on AnEM (F1-score: 2.31). A possible explanation is that Dice loss is non-convex and it may be difficult for first-order optimizers in current deep learning toolkits (e.g. Adam in TensorFlow) to find high-quality local minima than second-order methods like L-BFGS.

Precision and recall: To illustrate performance changes in terms of precision and recall, Figure 1 visualizes the changes before and after resampling as displacement vectors in precision-recall plots with F1-score contour lines. Some arrows are pointing to the upper right corner of the plots, indicating the associated methods improve F1-score by improving both precision and recall. Other arrows point to the upper left, indicating the associated methods increase recall at the sacrifice of precision. In this case, most of our methods improve macro-averaged precision and recall of the BERT model on WNUT. See Appendix C.2 for more details.

4.6 Effect on Training Corpus Size

Table 6 shows the effect of training corpus size as a result of resampling or data augmentation. These factors are the average across four corpora.

The balanced undersampling method drops tokens from sentences, and therefore reduces training corpus size. Data augmentation method doubles the corpus size as many sentences are paraphrased into multiple versions. Our proposed methods increases corpus size by a slightly larger factor because sentences that contain rare entity types are resampled multiple times. Although increased training corpus size leads to increased training time, note that our methods are especially suitable for scenarios where the annotated corpus is small and hence the training time is still relatively short.

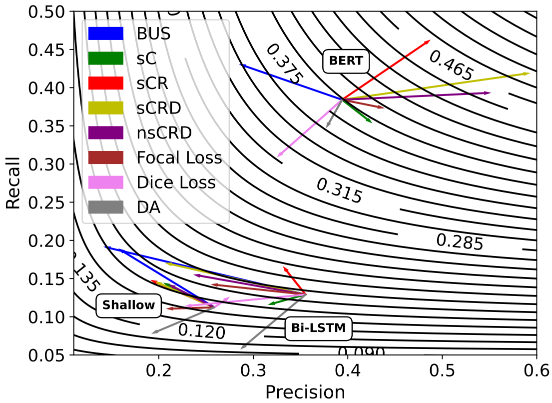

Figure 1: Displacement vectors of F1-scores in precision-recall plots for WNUT corpus. 'BUS': balanced undersampling. 'DA': data augmentation. All models use softmax output layer. The downward curves are contours of F1-scores in the precision-recall space. Each NER model (Shallow, Bi-LSTM, BERT) is associated with a cluster of vectors sharing the same starting point in the space, which represents the performance on the original corpus.

Methods	Size increase factor
Original corpus	1.00
Balanced undersampling	0.32
Data augmentation	2.00
sC	3.80
sCR	4.60
sCRD	3.91
nsCRD	2.82

Table 6: Effect of data resampling/augmentation methods on training corpus size. The factors are averaged across four evaluated corpora.

5 Conclusion and Future Work

Our proposed sentence resampling methods generalize well across diverse NER corpora and models. They enjoy the following advantages:

Model-agnostic: Since resampling only manipulates datasets and not models, the proposed methods can be directly applied to any NER model, requiring no knowledge of its functioning or any change to it. Resampling is also more convenient than cost-sensitive learning as the latter still requires changing the model training process.

Domain-agnostic: Compared with data preprocessing methods such as data augmentation, sentence-level resampling methods are simple and do not require domain- or language-specific manipulations such as synonym replacement, saving practitioners from excessive data engineering.

Note that data augmentation and sentence-level resampling (and resampling methods in general) are complementary methods for improving NER model training. Data augmentation improves the *semantic richness* of training instances by expanding the coverage of training data in the input feature space, while sentence-level resampling refines the *importance weighting* of training instances by bridging the gap between the training objective and evaluation metrics. Therefore, they work in orthogonal directions. This points to a promising direction for future work: to explore the two line of methods in combination rather than in competition.

Various other avenues exist for future work. First, further theoretical and empirical research can explore more effective resampling functions that deliver consistently better performance across corpora and base NER models. Second, more corpora and models can be examined under these resampling strategies to evaluate their generalizability. Third, the variance of performance in different scenarios may potentially relate to characteristics of specific corpora. Future research may seek for corpora-level statistics that can assist practitioners in selecting the appropriate resampling methods.

A Implementation Details

A.1 Software and Hardware Environment

All the deep learning models are implemented in Tensorflow 1.12.0 environment.

Softmax regression (or multinomial logistic regression) model is from Scikit-Learn package in version 0.23.2. The CRF model is implemented by the package sklearn-crfsuite in version of 0.3.6.

Data resampling and CRF training/evaluation were performed on 2.60 GHz Intel CPUs and 8GB RAM. Bi-LSTM and BERT training/evaluation were performed on GPUs (GeForce GTX1080 8GB and Tesla V100 16GB).

A.2 Hyperparameters for Machine Learning Models

For shallow models and BERT, all hyperparameters are set by default. For details of them, please see documents of sklearn, crfsuite and BERT-NER.

For Bi-LSTM, we adjust a few of parameters as there are some drawbacks of the default settings: 20 is not a commonly used number for batch size, and loss of Bi-LSTM model fails to converge under some circumstances. So we set them to 32 and 20, instead of default values 20 and 15. Other hyperparameters are applied according to default settings.

For the fairness in the comparison, we do not alter any hyperparameters while switching resampling methods and loss functions without changing dataset and models. We believe that it is totally appropriate in the process of comparing, despite that better performance of specific methods may be obtained after tuning hyperparameters, which beyond the scope of this exploring research.

A.3 Hyperparameters for Loss Functions

There are two hyperparameters in the focal loss and Dice Loss, determining converging speed and smooth degree. For focal loss, we set γ to 2, as what authors of (Lin et al., 2017) recommend. According to (Li et al., 2019), it is appropriate to set γ of Dice loss to 1 for the purpose of smoothing. In our implementation of loss function in shallow model, this setting is found effective. However, while using it in deep learning model, its effectiveness cannot be ensured. Hence, we adopt another setting of $\gamma = 10^{-5}$ in the tensor computing and obtain better results compared with those obtained with a larger γ.

B Derivation of Loss Function Gradients for Softmax Regression

When using the shallow model with softmax output layer and focal/Dice loss functions, we optimize the model parameters by the quasi-Newton method L-BFGS provided by Python Scikit-Learn. This approach requires us to provide the gradients of current model parameters. Below we show our derivation of these gradients.

Notations and Preliminaries. Scalar values are denoted by non-bold, lowercase letters such as x. Row vectors are denoted by bold, lowercase letters such as $\mathbf{x}$. Matrices are denoted by bold, uppercase letters such as $\mathbf{X}$.

Softmax regression has the following components:

- Feature vector: $\mathbf{x} \in \mathbb{R}^m, \mathbf{x} = [x_1, \cdots, x_i, \cdots, x_m]$.
- Label vector: $\mathbf{y} \in \{0,1\}^k, \mathbf{y} = [y_1, \cdots, y_j, \cdots, y_k]$. If the ground truth is the c-th class, $1 \leq c \leq k$, then $y_c = 1$, and $y_j = 0$ if $j \neq c$.
- Weight vector for the j-th class: $\mathbf{w}_j \in \mathbb{R}^m, \mathbf{w}_j = [w_{j1}, \cdots, w_{ji}, \cdots, w_{jm}]$.
- Weight matrix $\mathbf{W} \in \mathbb{R}^{m \times k}$, $\mathbf{W} = [\mathbf{w}_1^\top, \cdots, \mathbf{w}_j^\top, \cdots, \mathbf{w}_k^\top]$. "$\top$" is the transpose operation. $\mathbf{w}^\top$ is the transpose of $\mathbf{w}$, which is a column vector.
- Bias for the the j-th class: $b_j \in \mathbb{R}$.
- Predicted probability vector: $\mathbf{p} \in [0,1]^k, \mathbf{p} = [p_1, \cdots, p_j, \cdots, p_k]$.

  $$p_j = \Pr(y_j = 1 | \mathbf{x}) \tag{5}$$

  $$= \frac{\exp(\langle \mathbf{w}_j, \mathbf{x} \rangle + b_j)}{\sum_{j'=1}^{k} \exp(\langle \mathbf{w}_{j'}, \mathbf{x} \rangle + b_{j'})} \tag{6}$$

  $\langle \mathbf{w}, \mathbf{x} \rangle$ is the inner product of vector $\mathbf{w}$ and vector $\mathbf{x}$.

One can verify that the partial derivative of p_c with respect to w_{ji}, the weight of the j-th class, the i-th dimension, is the following:

$$\frac{\partial p_c}{\partial w_{ji}} = [\mathbf{1}\{j = c\} - p_j]\, p_c x_i \tag{7}$$

B.1 Focal Loss Gradient

Suppose the ground truth is the c-th class for a given example $\mathbf{x}$.

$$L_{FL}(\mathbf{x}, \mathbf{y}) = -(1 - p_c)^{\gamma} \log p_c \tag{8}$$

$$\begin{aligned}
&\frac{\partial L_{FL}(\mathbf{x}, \mathbf{y})}{\partial w_{ji}} && (9)\\
=& -\frac{\partial}{\partial p_c}[(1 - p_c)^{\gamma} \log p_c] \cdot \frac{\partial p_c}{\partial w_{ji}} && (10)\\
=& -\left[-\gamma(1 - p_c)^{\gamma-1} \log p_c + \frac{(1 - p_c)^{\gamma}}{p_c}\right] \cdot \frac{\partial p_c}{\partial w_{ji}} && (11)\\
=& -\left[-\gamma(1 - p_c)^{\gamma-1} \log p_c + \frac{(1 - p_c)^{\gamma}}{p_c}\right] \\
& \cdot [\mathbf{1}\{j = c\} - p_j] p_c x_i && (12)\\
=& -[-\gamma p_c(1 - p_c)^{\gamma-1} \log p_c + (1 - p_c)^{\gamma}] \\
& \cdot [\mathbf{1}\{j = c\} - p_j] x_i && (13)\\
=& a_c[p_j - \mathbf{1}\{j = c\}] x_i && (14)
\end{aligned}$$

Here we set

$$a_c = -\gamma p_c(1 - p_c)^{\gamma-1} \log p_c + (1 - p_c)^{\gamma} \tag{15}$$

to reduce notational clutter. a_c has nothing to do with i or j; it only has to do with c, the index of the ground truth label for the training example $\mathbf{x}$. When $\gamma = 0$, $a_c = 1$. When $\gamma > 0$, a_c decreases when p_c increases from 0 to 1. This means the gradient for an easy example (when p_c is close to 1) have a smaller magnitude than the gradient for a hard example (when p_c is close to 0).

Generalizing the scalar gradient in Equation (14) to matrix gradient, we have

$$\frac{\partial L_{FL}(\mathbf{x}, \mathbf{y})}{\partial \mathbf{W}} = a_c \cdot \mathbf{x}^{\top}(\mathbf{p} - \mathbf{y}) \,. \tag{16}$$

The shape of $a_c \cdot \mathbf{x}^{\top}(\mathbf{p} - \mathbf{y})$ is $m \times k$, the same shape as $\mathbf{W}$.

An important note is that here a_c is specific to that single example $\mathbf{x}$, which has ground truth label $y_c = 1$. If we have n different training examples $\mathbf{x}^{(1)}, \cdots, \mathbf{x}^{(n)}$, then every example will have a different a_c value: $a_c^{(1)}, \cdots, a_c^{(n)}$. Let's create a diagonal matrix $\mathbf{A}_c \in \mathbb{R}^{n \times n}$, $\mathbf{A}_c = diag(a_c^{(1)}, \cdots, a_c^{(n)})$.

If we have n training examples, then the feature matrix $\mathbf{X} \in \mathbb{R}^{n \times m}$, the label matrix $\mathbf{Y} \in \{0, 1\}^{n \times k}$, and the predicted probability matrix $\mathbf{P} \in [0, 1]^{n \times k}$. We have:

$$\frac{\partial L_{FL}(\mathbf{X}, \mathbf{Y})}{\partial \mathbf{W}} = \mathbf{X}^{\top} \mathbf{A}_c(\mathbf{P} - \mathbf{Y}) \,. \tag{17}$$

The shape of $\mathbf{X}^{\top} \mathbf{A}_c(\mathbf{P} - \mathbf{Y})$ is $m \times k$, the same as $\mathbf{W}$.

B.2 Dice Loss Gradient

Dice loss computes per-class F-1 scores. Suppose the ground truth is the c-th class for a given example $\mathbf{x}$.

$$\begin{aligned}
& L_{DL}(\mathbf{x}, \mathbf{y}) && (18)\\
=& \sum_{j'=1}^{k} \Bigg[1 - \mathbf{1}\{c = j'\} \frac{\gamma + 2p_c}{\gamma + p_c^2 + 1} \\
& +1 - \mathbf{1}\{c \neq j'\} \frac{\gamma}{\gamma + p_{j'}^2}\Bigg] && (19)\\
=& 1 - \frac{\gamma + 2p_c}{\gamma + p_c^2 + 1} + \sum_{j' \neq c}\left[1 - \frac{\gamma}{\gamma + p_{j'}^2}\right] && (20)\\
=& k - \frac{\gamma + 2p_c}{\gamma + p_c^2 + 1} - \sum_{j' \neq c} \frac{\gamma}{\gamma + p_{j'}^2} && (21)
\end{aligned}$$

Take gradient with respect to w_{ji}, the weight of the j-th class, the i-th dimension.

$$\begin{aligned}
& \frac{\partial L_{DL}(\mathbf{x}, \mathbf{y})}{\partial w_{ji}} && (22)\\
=& -\frac{\partial}{\partial p_c}\left[\frac{\gamma + 2p_c}{\gamma + p_c^2 + 1}\right] \cdot \frac{\partial p_c}{\partial w_{ji}} \\
& -\sum_{j' \neq c} \frac{\partial}{\partial p_{j'}}\left[\frac{\gamma}{\gamma + p_{j'}^2}\right] \cdot \frac{\partial p_{j'}}{\partial w_{ji}} && (23)\\
=& -\frac{2(\gamma + p_c^2 + 1) - (\gamma + 2p_c)2p_c}{(\gamma + p_c^2 + 1)^2} \cdot \frac{\partial p_c}{\partial w_{ji}} \\
& -\sum_{j' \neq c} \frac{-\gamma \cdot 2p_{j'}}{(\gamma + p_{j'}^2)^2} \cdot \frac{\partial p_{j'}}{\partial w_{ji}} && (24)\\
=& -\frac{2(\gamma + p_c^2 + 1) - (\gamma + 2p_c)2p_c}{(\gamma + p_c^2 + 1)^2} \\
& \cdot [\mathbf{1}\{j = c\} - p_j] p_c x_i \\
& -\sum_{j' \neq c} \frac{-\gamma \cdot 2p_{j'}}{(\gamma + p_{j'}^2)^2} \cdot [\mathbf{1}\{j = j'\} - p_j] p_{j'} x_i && (25)\\
=& -\frac{2(1 - p_c)(1 + \gamma + p_c)p_c}{(\gamma + p_c^2 + 1)^2} \cdot [\mathbf{1}\{j = c\} - p_j] x_i && (26)
\end{aligned}$$

$$+\sum_{j'\neq c}\frac{\gamma\cdot 2p_{j'}^2}{(\gamma+p_{j'}^2)^2}\cdot[\mathbf{1}\{j=j'\}-p_j]x_i \tag{27}$$

$$=a_c[p_j-\mathbf{1}\{j=c\}]x_i-\sum_{j'\neq c}b_{j'}[p_j-\mathbf{1}\{j=j'\}]x_i \tag{28}$$

Here we set

$$a_c=\frac{2(1-p_c)(1+\gamma+p_c)p_c}{(\gamma+p_c^2+1)^2} \tag{29}$$

$$b_{j'}=\frac{\gamma\cdot 2p_{j'}^2}{(\gamma+p_{j'}^2)^2} \tag{30}$$

a_c depends on the ground truth label of example $\mathbf{x}$. $b_{j'}$ depends on the current predicted probabilities for $\mathbf{x}$.

Generalizing the scalar gradient in Equation (28) to matrix gradient, we have

$$\frac{\partial L_{DL(\mathbf{x},\mathbf{y})}}{\partial \mathbf{W}} \tag{31}$$

$$=\mathbf{x}^\top a_c(\mathbf{p}-\mathbf{y})$$

$$-\mathbf{x}^\top\left[\underbrace{\cdots,\sum_{j'\neq c}b_{j'}[p_j-\mathbf{1}\{j=j'\}],\cdots}_{j=1,\cdots,k}\right] \tag{32}$$

$$=\mathbf{x}^\top a_c(\mathbf{p}-\mathbf{y})-\mathbf{x}^\top\mathbf{v} \tag{33}$$

$\mathbf{v}$ is a vector specific to the example $\mathbf{x}$.

If we have n training examples, then the feature matrix $\mathbf{X}\in\mathbb{R}^{n\times m}$, the label matrix $\mathbf{Y}\in\{0,1\}^{n\times k}$, and the predicted probability matrix $\mathbf{P}\in[0,1]^{n\times k}$. We have:

$$\frac{\partial L_{DL}(\mathbf{X},\mathbf{Y})}{\partial \mathbf{W}}=\mathbf{X}^\top\mathbf{A}_c(\mathbf{P}-\mathbf{Y})-\mathbf{X}^\top\mathbf{V} \tag{34}$$

where $\mathbf{V}$ has shape $n\times k$, and the l-th row in matrix $\mathbf{V}$ is a k dimensional vector computed in the same manner as Equation (32) with respect to the l-th training example, $1\leq l\leq n$.

C Additional Performance Analysis

C.1 Micro-averaged Metrics

In the main paper we reported macro-averaged F1 scores for each dataset. To provide a more complete comparison of performance changes, here we report micro-averaged F1 scores in Tables 7-10. Micro-averaged metrics lump together all named entities without distinguishing their types, and therefore the majority types have more influence on these metrics than minority types. Overall, the trend is consistent with the macro-averaged metrics. Sentence-level resampling methods tend to deliver more stable gains and generally outperform baseline methods.

C.2 Per-Entity-Type Metrics

To further examine the impacts of our method on entity types, we also report per-entity-type precision, recall, and F1 scores for each dataset in Tables 11-14. We compare the performance of using the original corpus and a representative of our methods (sCR). Red up-arrows (↑) means sCR obtains better precision/recall/F1 score compared to using the original corpus.

Here we observe that at the level of entity types, either precision and recall simultaneously improve or drop, or precision improves at a slight cost of recall. It is rare that recall improves at the cost of precision (only the GPE type in Table 13). This pattern indicates that the BERT-CRF model trained on the original corpus has many 'false negatives' (tagging entity tokens as "other"). In other words, the model is extremely reluctant to predict non-other entity types. Our sentence-level resampling methods encourage the model to correctly assign entity types to more tokens. Another trend is that improvements on small corpora (AnEM, WNUT, GMB subset) are more salient than on large corpus (CoNLL). Note that sentence resampling does not necessarily favor minority entity types as all entity types are very rare already, compared to the *Other* tokens (see the last column of Tables 11-14, "Token %").

Word Tour: One-dimensional Word Embeddings via the Traveling Salesman Problem

Ryoma Sato
Kyoto University / RIKEN AIP
`r.sato@ml.ist.i.kyoto-u.ac.jp`

Abstract

Word embeddings are one of the most fundamental technologies used in natural language processing. Existing word embeddings are high-dimensional and consume considerable computational resources. In this study, we propose WORDTOUR, unsupervised *one-dimensional* word embeddings. To achieve the challenging goal, we propose a decomposition of the desiderata of word embeddings into two parts, completeness and soundness, and focus on soundness in this paper. Owing to the single dimensionality, WORDTOUR is extremely efficient and provides a minimal means to handle word embeddings. We experimentally confirmed the effectiveness of the proposed method via user study and document classification.

1 Introduction

Word embeddings are one of the most thriving techniques in natural language processing and are used in various tasks, including word analogy (Mikolov et al., 2013; Pennington et al., 2014), text classification (Kim, 2014; Kusner et al., 2015; Shen et al., 2018), and text similarity (Arora et al., 2017; Yokoi et al., 2020). Existing word embeddings are in high-dimensional spaces. Although high dimensionality offers representational power to word embeddings, it also has the following drawbacks: (1) **Memory inefficiency.** High-dimensional word embeddings require the storage of many floating-point values, and they consume considerable memory space. For instance, the 300-dimensional GloVe with 400k words consumes 1 GB of memory. This hinders the application of word embeddings in edge devices (Raunak et al., 2019; Jurgovsky et al., 2016; Joulin et al., 2016). (2) **Time inefficiency.** The high dimensionality also increases the time consumption owing to many floating-point arithmetic operations. (3) **Uninterpretability.** It is not straightforward to visualize high-dimensional embeddings. Projections to low dimensional spaces, e.g., by t-SNE and PCA, lose some information, and it is difficult to control and interpret the aspects that these projections preserve. Besides, word embeddings are sparse in high-dimensional space, and for a small perturbation $\varepsilon \in \mathbb{R}^d$, it is not clear what $\boldsymbol{x}_{\text{cat}} + \varepsilon$ represents, e.g., when creating adversarial examples (Lei et al., 2019) and data augmentation (Qu et al., 2021).

In this study, we propose WORDTOUR, unsupervised *one dimensional* word embeddings. In contrast to high-dimensional embeddings, WORDTOUR is **memory efficient**. It does not require storing even a single floating-point value; instead, it stores only the order of words. WORDTOUR with 40k words consumes only 300 KB memory, which is the same space as the space for storing a list of the words. Memory efficiency enables applications in low-resource environments. WORDTOUR is **time efficient** as well. It can compare words in a single operation whereas traditional embeddings require hundreds of floating-point operations for a single comparison. In addition, it can retrieve similar words by simply looking up the surrounding words in a constant time and can efficiently compare documents using a blurred bag of words, as we will show in the experiments. These features are also advantageous in low resource environments. In addition, WORDTOUR is **interpretable** owing to its single dimensionality. It is straightforward to visualize the one dimentional embeddings without any information loss. Besides, we can always interpret the perturbed word embedding as we can interpret the perturbed image pixels. In brief, WORDTOUR provides a *minimal* means to handle word embeddings.

However, words are inherently high-dimensional, and it is impossible to capture *all* semantics in one dimension. To tackle this challenge, we propose to decompose the desiderata of word embeddings into two components: soundness and completeness. WORDTOUR gives up

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2166 - 2172
July 10-15, 2022

completeness, focuses on soundness, and thereby realizes meaningful one dimensional embeddings for some, if not all, applications. We formulate the optimization of sound word embeddings as the traveling salesman problem and solve it using a highly efficient solver. In the experiments, we confirm that WORDTOUR provides high-quality embeddings via qualitative comparison, user studies, and document classification.

Reproducibility: Our code and obtained embeddings are available at `https://github.com/joisino/wordtour`.

2 Backgrounds

2.1 Notations

Let $\mathcal{V}$ be the set of words in a vocabulary, and $n = |\mathcal{V}|$ be the number of words. Let $[n] = \{1, 2, \cdots, n\}$ and let $\mathcal{P}([n])$ be the set of permutations of $[n]$.

2.2 Problem Definition

We are given off-the-shelf word embeddings $\boldsymbol{X} = [\boldsymbol{x}_1, \cdots, \boldsymbol{x}_n]^\top \in \mathbb{R}^{n \times d}$, such as word2vec and GloVe. We assume that the embeddings completely represent the semantics of the words, but they are high-dimensional, e.g., $d = 300$. We aim to create an ordering of $\mathcal{V}$ such that the order preserves the structure of the given embeddings. The problem is defined as follows:

Problem Definition.
Given: Word embedddings $\boldsymbol{X} \in \mathbb{R}^{n \times d}$.
Output: Word ordering $\sigma^* \in \mathcal{P}([n])$.

In full generality, it may be possible to model the real-value positions. However, in this paper, we solely consider the order of the words. That is, the words are equally spaced in the one-dimensional space. This formulation makes the embedding simpler and lighter, while still being sufficiently powerful.

3 Word Tour

In this section, we introduce our proposed method, WORDTOUR. Ideally, we would like to preserve all the semantics in our one-dimensional embeddings. However, such ideal embeddings are unlikely to exist because the relations between words are inherently high-dimensional. Indeed, although existing studies have attempted to reduce the dimensionality of word embeddings, they require at least tens of dimensions (Raunak et al., 2019; Acharya et al., 2019) and several dimensions even in non-Euclidean spaces (Nickel and Kiela, 2017; Tifrea et al., 2019). These results indicate that ideal 1D embeddings do not exist. Therefore, we make a compromise. We decompose the desiderata of word embeddings into the following two categories:

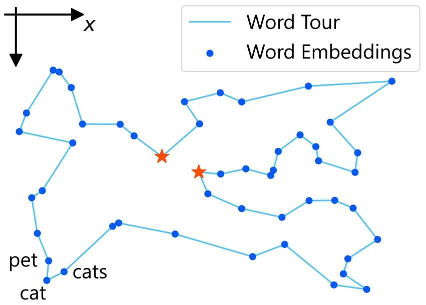

Figure 1: **Illustration of WORDTOUR**. Each dot represents a word with its coordinates as the embedding vector.

Soundness Close embeddings should have semantically similar meanings.

Completeness Semantically similar words should be embedded closely.

In WORDTOUR, we give up the latter condition and focus on the former condition. For instance, the two red stars in Figure 1 are distant in the order, although they are semantically similar. WORDTOUR accepts such inconsistency. Owing to the incompleteness, WORDTOUR may fail some applications of word embeddings, such as word analogy and relation extraction. Nevertheless, WORDTOUR still has some other applications, such as word replacement and document retrieval. Indeed, WORDTOUR may overlook some relevant documents because they may embed relevant words far apart. However, the close documents found by WORDTOUR are indeed close owing to soundness. These insights indicate that there exist one-dimensional embeddings that are useful for some, if not all, applications.

A natural criterion for soundness is that consecutive words in the ordering should be close to one another in the original embedding space. We formulate the problem as follows:

$$\underset{\sigma \in \mathcal{P}([n])}{\text{minimize}} \, \|\boldsymbol{x}_{\sigma_1} - \boldsymbol{x}_{\sigma_n}\| + \sum_{i=1}^{n-1} \|\boldsymbol{x}_{\sigma_i} - \boldsymbol{x}_{\sigma_{i+1}}\|. \tag{1}$$

Table 1: **Examples of segments**. Each row represents a segment. (a–d) Segments around "cat." (e–h) Segments around "concept." (i–o) Random segments of WordTour. WordTour provides smooth orderings.

We treat the ordering as a cycle, not a path, by adding term $\|\boldsymbol{x}_{\sigma_1} - \boldsymbol{x}_{\sigma_n}\|$. The rationale behind this design is that we would like to treat all words symmetrically and would like the boundary words to have the same number of neighbors as the non-boundary words.

In formulation (1), we adopt the L_2 norm for simplicity. However, our formulation is agnostic to the distance function. When a corpus is at hand, we can also use the number of co-occurrences, i.e., $\sum_i \#\text{co-occurrences of } (\sigma_i, \sigma_{i+1})$, as the cost function. We leave investigating other modelings as future work and focus on the L_2 cost in this paper.

The optimization problem (1) is an instance of the traveling salesman problem (TSP), which is NP-hard. As the problem size is relatively large in our case, for instance, $n = 40\,000$, it may seem impossible to solve the problem. However, in practice, highly efficient TSP solvers have been developed. Among others, we employ the LKH solver (Helsgaun, 2018), which implements the Lin Kernighan algorithm (Lin and Kernighan, 1973; Helsgaun, 2000) in a highly efficient and effective manner. The LKH solver performs a restricted local search based on a guide graph constructed using the dual problem. Helsgaun (2018) reported that the LKH solver *exactly* solved an instance with as many as 109 399 cities. In addition, several effective algorithms for computing lower bounds provide theoretical guarantees for the quality of a solution. We employ the one-tree lower bound (Helsgaun, 2000) implemented in the LKH solver to compute the lower bounds of the optimum value. As a tour is a special case of a one-tree, the minimum cost one-tree is a provable lower bound of the TSP problem. The algorithm searches for a potential vector for a tight lower bound by gradient ascent. WordTour computes a near-optimal solution of Problem (1) by the LKH solver and uses the solution as the word order, i.e., the word embeddings.

4 Experiments

We experimentally validated the effectiveness of WordTour. We used a Linux server with Intel Xeon E7-4830 v4 CPUs in the experiments.

4.1 Computing Embeddings

We used 300-dimensional GloVe embedding with the first 40 000 words as the input embeddings $\{\boldsymbol{x}_v\}$. The objective value of the solution obtained by LKH was 236882.314, and the lower bound proved by LKH was 236300.947. Therefore, the cost of the obtained tour is guaranteed to be at most 1.003 of the optimum. The resulting embedding file is 312 KB, which is sufficiently light to be deployed in low-resource environments.

4.2 Qualitative Comparison

We use the following baselines: (1) **RandProj** randomly samples a direction $\boldsymbol{d} \in \mathbb{R}^d$ and orders the embeddings in ascending order of $\boldsymbol{d}^\top \boldsymbol{x}_i$. This method extracts a specific aspect $\boldsymbol{d}$ of the input embeddings. (2) **PCA-1** orders in ascending order of the top PCA component. (3) Mu and Viswanath (2018) reported that a few leading PCA components were not informative. Therefore, **PCA-4** orders words by the fourth PCA component.

As we cannot show the entire tour owing to space constraints, we sample and list some random segments in Table 1. It is observed that WordTour provides the most natural ordering, and the consecutive words are semantically similar in WordTour. Notably, WordTour almost recovers the order of ordinals without explicit supervision (Table 1 (m)).

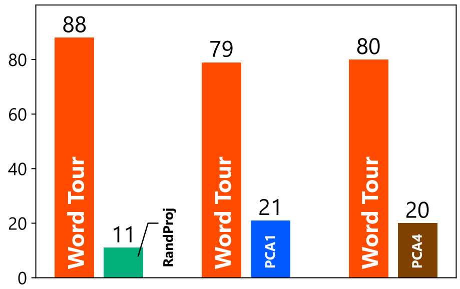

Figure 2: **Results of the user study**. Each bar represents the number of times each method was selected within 100 trials. One trial was not completed in WordTour vs. RandProj, which led to 99 trials in the first comparison.

4.3 Assesment via Crowdsourcing

We conducted a user study at Amazon Mechanical Turk to confirm the effectiveness of WordTour. Specifically, to compare two word ordering $\sigma, \tau \in \mathcal{P}([n])$, we randomly sample a reference word $v \in \mathcal{V}$, retrieve the next words of v in σ and τ, and ask a crowdworker which word is more similar to the reference word v. We repeated this process 100 times for each pair of embeddings. Figure 2 shows the number of times each embedding was selected. This clearly shows that WordTour aligns with human judgment.

4.4 Document Retrieval

In this section, we evaluate the effectiveness of word embeddings in document classification. The most straightforward approach to compare two documents is the bag of words (BoW), which counts common and uncommon words in documents. However, this approach cannot capture the similarities of the words. In 1D embeddings, neighboring words are similar, although they are not exactly matched in BoW. To utilize this knowledge, we use blurred BoW, as shown in Figure 3. Specifically, we put some mass around the words in a document to construct the blurred BoW vector. We employ a Gaussian kernel for the mass amount and use WordTour, RandProj, PCA1, and PCA4 for the orderings. We normalize the BoW and blurred BoW vectors with the L_1 norm and compute the distance between two documents using the L_1 distance of the vectors. The blurred BoW can be computed in $O(wn)$ time, where n denotes the number of words in a document and w is the width of the filter. We used $w = 10$ in the experiments. We also use **word mover's distance (WMD)** (Kusner et al., 2015) as a baseline, which is one of the most popular word-embedding-based distances.

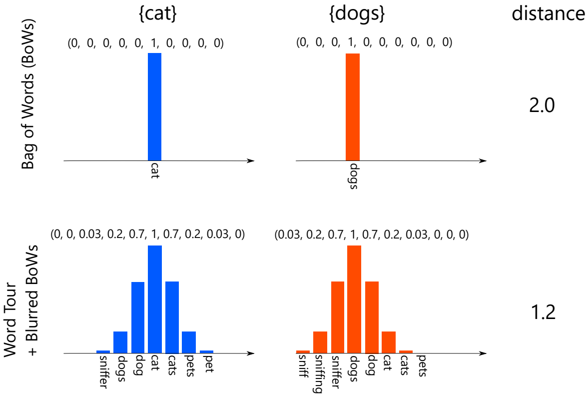

Figure 3: Document comparison by WordTour. This figure illustrates the case in which a document is composed of a single word. When more than one word is in a document, the blurred BoW will be multimodal.

Table 2: **Document classification errors**. *Lower is better*. The time row reports the average time to compare the two documents. WordTour performs the best in the blurred BoW family.

	ohsumed	reuter	20news	amazon	classic
BoW	48.1	5.6	35.4	11.4 ± 0.4	5.1 ± 0.3
Time	39 ns	23 ns	35 ns	21 ns	23 ns
WordTour	**47.2**	**4.6**	**34.1**	**10.1 ± 0.3**	**4.6 ± 0.1**
RandProj	47.9	5.4	35.4	11.3 ± 0.3	5.1 ± 0.3
PCA1	47.8	5.7	35.5	11.4 ± 0.6	5.1 ± 0.3
PCA4	48.1	5.6	35.4	11.6 ± 0.5	5.1 ± 0.4
Time	206 ns	142 ns	312 ns	185 ns	150 ns
WMD	47.5	4.5	30.7	7.6 ± 0.3	4.2 ± 0.3
Time	3.5×10^6 ns	2.2×10^6 ns	5.1×10^6 ns	1.2×10^7 ns	1.9×10^6 ns

We used 300-dimensional GloVe for WMD. WMD requires $O(n^3 + n^2 d)$ computation because of the optimal transport formulation, where n denotes the number of words in a document and d is the number of dimensions of word embeddings. The performance of WMD can be seen as an expensive upper bound of BoW and blurred BoW. We used five datasets: ohsumed (Joachims, 1998), reuter (Sebastiani, 2002), 20news (Lang, 1995), Amazon (Blitzer et al., 2007), and classic (SMART). We remove the duplicated documents following (Sato et al., 2021). The details of the datasets are provided in the Appendix. We evaluated the performance using the k-nearest neighbor error. We used the standard test dataset if it existed (for instance, based on timestamps) and used five random train/test splits for the other datasets[1]. We report the standard deviations for five-fold datasets.

The results are shown in Table 2. Although WordTour is less effective than WMD, it is much faster than WMD and more effective than other 1D embeddings. Recall that the 1D embeddings are designed for low-resource environments, where

[1] The seeds are fixed and reported in the GitHub repository.

WMD may be infeasible. WordTour offers an efficient approach while integrating the similarities of the words.

5 Related Work

Raunak et al. (2019) and Jurgovsky et al. (2016) proposed a postprocessing method to reduce the number of dimensions of the off-the-shelf word embeddings. However, existing methods require at least five to tens of dimensions. To the best of our knowledge, this study is the first to obtain large-scale 1D word embeddings. Nickel and Kiela (2017) proposed to embed words into hyperbolic spaces and drastically reduce the number of required dimensions. FastText.zip (Joulin et al., 2016) quantizes and prunes word embeddings for memory-efficient text classification. Although FastText.zip saves considerable memory consumption without harming downstream tasks, it prunes words that are irrelevant to text classification, whereas we aim to retain the original vocabulary in this work. Ling et al. (2016) and Tissier et al. (2019) proposed to quantize general word embeddings. Although they save considerable memory and time complexity with no considerable performance degradation, they still consume a few orders of magnitude more memory than 1D embeddings, and they are sparse in the embedding space and require more time than WordTour to compare documents and search similar words.

6 Conclusion

In this study, we proposed WordTour, a 1D word embedding method. To realize 1D embedding, we decompose the requirement of word embeddings into two parts and impose only one constraint in which the consecutive words should be semantically similar. We formulate this problem using the TSP and solve it with a state-of-the-art solver. Although the TSP is NP-hard, the effective solver solves the optimization almost optimally and provides effective 1D embeddings. We confirmed its effectiveness via crowdsourcing and document classification.

A Datasets

Table 3 summarizes the statistics of the datasets after preprocessing. Ohsumed (Joachims, 1998) consists of medical abstracts. Reuter (Sebastiani, 2002) and 20news (Lang, 1995) are news datasets. Amazon (Blitzer et al., 2007) consists of reviews in amazon.com. Classic (SMART) consists of academic papers. The datasets are retrieved from `https://github.com/mkusner/wmd`.

B Usage of LKH

We used LKH version 3.0.6, with parameter $\text{PATCHING\_C} = 3, \text{PATCHING\_A} = 2$, which are the default parameters. As the LKH solver accepts only integral values, we multiply the actual distance by 10^3 and round down the values before we feed them into the LKH solver. The difference caused by this rounding process is negligibly small.

C Hyperparameters

The number k of neighbors in the kNN classification is selected from $\{1, 2, \cdots, 19\}$. The variance of the Gaussian filter in a blurred bag of words is selected from $\{0.01, 0.1, \cdots, 1000\}$. We selected the hyperparameters using a 5-fold cross-validation and retrained the kNN model using the chosen hyperparameters and entire training dataset.

On the Diversity and Limits of Human Explanations

chenhao@uchicago.edu

Abstract

A growing effort in NLP aims to build datasets of human explanations. However, it remains unclear whether these datasets serve their intended goals. This problem is exacerbated by the fact that the term *explanation* is *overloaded* and refers to a broad range of notions with different properties and ramifications. Our goal is to provide an overview of the diversity of explanations, discuss human limitations in providing explanations, and ultimately provide implications for collecting and using human explanations in NLP.

Inspired by prior work in psychology and cognitive sciences, we group existing human explanations in NLP into three categories: proximal mechanism, evidence, and procedure. These three types differ in nature and have implications for the resultant explanations. For instance, procedure is not considered explanation in psychology and connects with a rich body of work on learning from instructions. The diversity of explanations is further evidenced by proxy questions that are needed for annotators to interpret and answer "why is [input] assigned [label]". Finally, giving explanations may require different, often deeper, understandings than predictions, which casts doubt on whether humans can provide valid explanations in some tasks.

1 Introduction

With the growing interest in explainable NLP systems, the NLP community have become increasingly interested in building datasets of human explanations. These human explanations can *ideally* capture human reasoning of why a (correct) label is chosen. If this is indeed the case, they are hypothesized to aid models with additional supervision, train models that explain their own predictions, and evaluate machine-generated explanations (Wiegreffe and Marasović, 2021). In fact, DeYoung et al. (2020) already developed a leaderboard, where the implicit assumption is that humans can provide *valid* explanations and these explanations can in turn be *uniformly* considered as groundtruths.

However, are these assumptions satisfied and can human explanations serve these goals? In this work, we aim to introduce prior relevant literature in psychology to the NLP community and argue against abusing the term explanations and prematurely assuming that human explanations provide valid reasoning for inferring a label.

First, we point out the rich diversity in what the NLP community refer to as explanations and how researchers collect them. The term "explanation" is overloaded in the NLP and AI community: it often refers to many distinct concepts and outcomes.[1] For example, procedural instructions are different from explanations that attempt to convey proximal causal mechanisms. The diversity of explanations is further evidenced by the variety of proxy questions that researchers ask to collect explanations, e.g., "highlight the important words that would tell someone to see the movie" vs. "highlight ALL words that reflect a sentiment". These proxy questions are necessary because the question of "why is [input] assigned [label]" is too open-ended. It follows that these "human explanations" are supposed to answer different questions in the first place and may not all be used for the same goals, e.g., serving as groundtruth labels.

In addition to the diversity, we highlight two insights from psychology on whether humans can provide valid explanations: 1) prediction does not entail explanation (Wilson and Keil, 1998), i.e., although humans may be able to provide valid labels, they may not be able to provide explanations that capture the reasoning process needed or used to infer a label; 2) everyday explanations are necessarily incomplete (Keil, 2006; Lombrozo, 2006), because they seldom capture the complete deduc-

---

[1] Broniatowski et al. (2021) further argues that interpretation and explainability are distinct concepts.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2173 - 2188
July 10-15, 2022

tive processes from a set of axioms to a statement.

In summary, *not* all explanations are equal and humans may *not* always be able to provide valid explanations. We encourage the NLP community to embrace the complex and intriguing phenomena behind human explanations instead of simply viewing explanations as another set of uniform labels. A better understanding and characterization of human explanations will inform how to collect and use human explanations in NLP.

2 Types of Human Explanations in NLP

To understand whether datasets of human explanations can serve their intended goals, we first connect current human explanations in NLP with existing psychology literature to examine the use of the term "explanation" in NLP. We adapt the categorization in Lombrozo (2006) and group human explanations in NLP into the following three categories based on the conveyed information:

- **Proximal mechanisms**. This type of explanation attempts to provide the mechanism behind the predicted label, i.e., *how* to infer the label from the text, and match *efficient cause* in Lombrozo (2006). We created E1 in Table 1 to illustrate this type of explanation. Note that E1 does not provide the complete mechanism. For instance, it does not define "year" or "temporal modifier", or make clear that "1997" is a "year". Neither does it cover the axioms of logic. This is a common property of human explanations: they are known to cover *partial/proximal* mechanisms rather than the complete deduction from natural laws and empirical conditions (Hempel and Oppenheim, 1948).

- **Evidence**. This type of explanation includes the relevant tokens in the input (e.g., E2 in Table 1) and directly maps to highlights in Wiegreffe and Marasović (2021). However, it does not map to any existing definitions of explanations in the psychology literature since the evidence does not provide any information on *how* evidence leads to the label. In other words, evidence alone does not *explain*.

- **Procedure**. Unlike proximal mechanisms, this type of explanation provides step-by-step rules or procedures that one can directly follow, e.g., E3 in Table 1. They are more explicit and unambiguous than proximal mechanisms. In fact, one can write a rule based on E3 to find marriage relation, but one cannot easily do that with E1. Furthermore, the procedures are grounded to the input, so it is related to *formal cause*, "the form or properties that make something what it is" (Lombrozo, 2006), which is definitional and does not convey the underlying mechanisms. Procedural instructions are only possible for some tasks, while proximal mechanisms are the most common form of everyday explanations.

These three categories empirically capture all the explanations discussed in NLP literature. Lombrozo (2006) also discuss two other categories, *final causes* (the goal) and *material causes* (the constituting substance). For instance, a final cause to "why [input] is assigned [label]" can be that "this label is provided to train a classifier". These two categories have been less relevant for NLP.

Implications. This categorization allows us to think about what kind of explanations are desired for NLP systems and help clarify how to use them appropriately. First, proximal mechanisms are best aligned with human intuitions of explanations, especially in terms of hinting at causal mechanisms. However, they can be difficult to collect for NLP tasks. For example, Table 2 shows example explanations in E-SNLI that fail to convey any proximal mechanisms: they either repeat the hypothesis or express invalid mechanisms ("the bike competition" does not entail "bikes on a stone road"). See further discussions on the challenges in collecting explanations in §4. Furthermore, they may be difficult to use for supervising or evaluating a model.

Second, evidence by definition provides little information about the mechanisms behind a label, but it can be potentially useful as additional supervision or groundtruths. We will further elaborate on the nature of evidence in different tasks in §3. However, it may be useful to the community to use clear terminology (e.g., evidence or rationale (Lei et al., 2020; Carton et al., 2020)) to avoid lumping everything into "explanation".

Finally, procedures are essentially instructions, and Keil (2006) explicitly distinguishes explanations from simple procedural knowledge: "Knowing how to operate an automated teller machine or make an international phone call might not entail having any understanding of how either system

Instance	Label	Explanation
Task: whether the query is supported or refuted by the preceding texts (Thorne et al., 2018)		
S1: No Way Out is the debut studio album by American hip hop recording artist , songwriter and record producer Puff Daddy . S2: It was released on July 1 , 1997 , by his Bad Boy record label . The label 's official crediting as “ The Family ” ...... Query: 1997 was the year No Way Out was released.	Supports	**Proximal mechanism (E1)**: “It” in S2 refers to “No Way Out” and “on July 1, 1997” is the temporal modifier of “release”, we can thus infer 1997 was the year that No Way Out was released. **Evidence (E2)**: S1, S2
Task: whether person 1 is married to person 2 (Hancock et al., 2018)		
Tom Brady and his wife Gisele Bündchen were spotted in New York City on Monday amid rumors of Brady's alleged role in Deflategate	True	**Procedure (E3)**: The words “and his wife” are between person 1 and person 2.

Table 1: Types of human explanations and corresponding examples. “S1:” and “S2:” were added to facilitate writing the explanation, which also shows the non-triviality of writing explanations.

P: Men in green hats appear to be attending a gay pride festival. H: Men are attending a festival. E: The men are attending the festival.
P: Several bikers on a stone road, with spectators watching. H: The bikers are on a stone road. E: That there are spectators watching the bikers on a stone road implies there is a bike competition.

Table 2: Examples from E-SNLI (Camburu et al., 2018). P: premise, H:: hypothesis, E: explanation.

works”. Another reason to clarify the procedure category is that it would be useful to engage with a rich body of work on learning from instructions when human explanations are procedural (Goldwasser and Roth, 2014; Matuszek et al., 2013).

We would like to emphasize that procedures or instructions are powerful and can potentially benefit many NLP problems (e.g., relation extraction). At the same time, it is useful to point out that procedures are different from proximal mechanisms.

3 Proxy Questions Used to Collect Human Explanations

Although explanations are supposed to answer “why is [input] assigned [label]” (Wiegreffe and Marasović, 2021), this literal form is too open-ended and may not induce “useful” human explanations. As a result, proxy questions are often necessary for collecting human explanations. These proxy questions further demonstrate the diversity of human explanations beyond the types of explanation. Here we discuss these proxy questions for collecting evidence. See the appendix for discussions on proximal mechanisms and procedures.

To collect evidence (highlights), researchers adopt diverse questions for relatively simple single-text classification tasks (see Table 3). Consider the seemingly straightforward case of sentiment analysis, “why is the sentiment of a review positive/negative”. A review can present both positive and negative sentiments (Aithal and Tan, 2021), so the label often comes from one sentiment outweighing the other. However, in practice, researchers often ask annotators to identify **only** words supporting the label. Critical wording differences remain in their questions: Zaidan et al. (2007) ask for *the most important* words and phrases that would *tell someone to see the movie*, while Sen et al. (2020) requires *all* words *reflecting the sentiment*. Two key differences arise: 1) “the most important” vs. “all”; 2) “telling someone to see the movie” vs. “reflecting the sentiment”.

In contrast, personal attack detection poses a task where the negative class (“no personal attack”) by definition points to the lack of evidence in the text. It follows that the questions that researchers can ask almost exclusively apply to the positive class (i.e., “highlight sections of comments that they considered to constitute personal attacks”).

In comparison, researchers approach evidence more uniformly for document-query classification tasks. They generally use similar proxy questions (e.g., Thorne et al. (2018) and Hanselowski et al. (2019) ask almost the same questions) and ask people to select sentences instead of words. That said, intriguing differences still exist: 1) Lehman et al. (2019) simply ask annotators to provide accompanying rationales; 2) Thorne et al. (2018) aim for “strong” reasons, which likely induces different interpretations among annotators; 3) Khashabi et al. (2018) collect questions, answer, and sentence indices at the same time, among which sentence indices can be used to find the corresponding sentences as evidence. It remains unclear how these

Reference	Task	Questions
		Evidence: single-text classification
Zaidan et al. (2007)	Sentiment analysis	To justify why a review is positive, highlight the most important words and phrases that would tell someone to see the movie. To justify why a review is negative, highlight words and phrases that would tell someone not to see the movie.
Sen et al. (2020)	Sentiment analysis	Label the sentiment and highlight **ALL** words that reflect this sentiment.
Carton et al. (2018)	Personal attack detection	Highlight sections of comments that they considered to constitute personal attacks.
		Evidence: document-query classification
Lehman et al. (2019)	Question answering	Generators were also asked to provide answers and accompanying rationales to the prompts that they provided.
Thorne et al. (2018)	Fact verification (QA)	If I was given only the selected sentences, do I have strong reason to believe the claim is true (supported) or stronger reason to believe the claim is false (refuted).
Khashabi et al. (2018)	Question answering	Ask them (participants) for a correct answer and for the sentence indices required to answer the question.

Table 3: Questions that prior work uses to collect human explanations. We include the short version of the guidelines here for space reasons. Refer to the appendix for the full text of the relevant annotation guidelines.

differences in annotation processes and question phrasings affect the collected human explanations.

Implications. Our observation on proxy questions aligns with dataset-specific designs discussed in Wiegreffe and Marasović (2021). We emphasize that these different forms of questions entail different properties of the collected human explanations, as evidenced by Carton et al. (2020). For example, the lack of evidence in the negative class in personal attack classification likely requires special strategies in using human explanations to train a model and evaluate machine rationales. Sentence-level and token-level annotations also lead to substantially different outcomes, at least in the forms of explanations. We believe that it is important for the NLP community to investigate the effect of proxy questions and use the collected explanations with care, rather than lumping all datasets under the umbrella of explanations.

We also recommend all researchers to provide detailed annotation guidelines used to collect human explanations. As the area of collecting human explanation is nascent, the goal is not to promote consistent and uniform annotation guidelines but to encourage the community to pay attention to the different underlying questions and characterize the resultant diverse properties of human explanations.

4 Can Humans Provide Explanations?

In order for human explanations to serve as additional supervision in training models and evaluate machine-generated explanations, human explanations need to provide valid mechanisms for a correct label. Finally, we discuss challenges for humans to provide explanations of such qualities.

Conceptual framework. We situate our discussion in the psychological framework provided by Wilson and Keil (1998) to highlight what may be required to explain. Wilson and Keil (1998) examines where explanation falls in three central notions: prediction, understanding, and theories. They argue that these three notions “form a progression of increasing sophistication and depth with explanations falling between understanding and theories”. For instance, we may be able to predict that a car will start when we turn the ignition switch, but few of us are able to explain in detail why this is so. In contrast, if a person is able to explain in detail why a car starts when you turn on the ignition switch, they can likely predict what will happen if various parts of the engine are damaged or removed.

These three central notions are also essential in machine learning. Traditional label annotation is concerned with prediction, however, being able to predict does not entail being able to explain.

Emulation vs. discovery. Next, we gradually unfold the practical challenges in collecting valid explanations from humans. The first challenge lies in whether humans can predict, i.e., assign the correct label. We highlight two types of tasks for AI: emulation vs. discovery (Lai et al., 2020). In *emulation* tasks, models are trained to emulate human intelligence and labels are often crowdsourced. Labels, however, can also derive from external (social/biological) processes, e.g., the popularity of a tweet and the effect of a medical treatment. Models can thus discover patterns that humans may not recognize in these *discovery* tasks. While most NLP tasks such as NLI and QA are emulation tasks, many NLP problems, especially when concerned with social interaction, are discovery tasks, ranging from identifying memorable movie quotes to predicting the popularity of messages (Danescu-Niculescu-Mizil et al., 2012; Tan et al., 2014).

Aligning with our discussion on explanation and prediction, most datasets of human explanations in NLP assume that humans are able to predict and are on emulation tasks. However, we note exceptions such as explanations of actions in gaming (Ehsan et al., 2019), where humans may often choose suboptimal actions (labels).

Cognitive challenges in providing valid explanations. Even conditioned on that humans can predict the label, humans may not be able to provide valid explanations for at least two reasons. First, as Wilson and Keil (1998) suggests, explanation requires more depth than prediction. For instance, we may possess some notions of common sense (e.g., one should not slap a stranger), but it is unclear whether we can explain common sense in detail (e.g., why one should not slap a stranger through theory of morality), similar to the car ignition example. One may argue that theory of morality may not be what NLP researchers seek, but it is critical to consider the desiderata of human explanations, with the limits in mind.

Second, explanation often requires people to report their *subjective* mental processes, i.e., how our minds arrive at a particular judgement, rather than following *objective* consensual guidelines such as annotating logical entailment. However, classic work by Nisbett and Wilson (1977) suggests that our verbal reports on our mental processes can be highly inaccurate. For instance, in admission decisions, legitimate information can be used to justify preferences based on illegitimate factors such as race (Norton et al., 2006). Many studies on implicit bias also reinforces that we are not aware of our biases and thus cannot include them (i.e., the actual reasoning in our mind) in our explanations (Greenwald et al., 1998).

Explanations are necessarily incomplete. Finally, there are indeed cases where we believe that humans can provide valid mechanisms. For instance, some question answering tasks boil down to logical inference from evidence to query. In these cases, NLP researchers need to recognize that human explanations are necessarily incomplete: people do not start from a set of axioms and present all the deductive steps (Keil, 2006; Lombrozo, 2006). Therefore, even for simple tasks such as natural language inference, we may simply give explanations such as repeating the hypothesis without presenting any axiom or deduction required to infer the label.

Implications. We cannot assume that humans are capable of providing explanations that contain valuable proximal mechanisms. The very fact that humans can still provide explanations for incorrect labels and tasks where they do not perform well suggests that one should be skeptical about whether human explanations can be used to train models as additional supervision or evaluate machine-generated explanations as groundtruths.

Note that incomplete explanations can still be very useful for NLP. We believe that recognizing and characterizing this incompleteness (e.g., which proximal mechanism is more salient to humans) is critical for understanding and leveraging human explanations for the intended goals in NLP. To summarize, we argue that human explanations are necessarily incomplete and it is important to understand and characterize this incompleteness, which can inform how we can leverage it for the intended goals in NLP.

5 Conclusion

Explanations represent a fascinating phenomenon and are actively studied in psychology, cognitive science, and other social sciences. While the growing interest in explanations from the NLP community is exciting, we encourage the community to view this as an opportunity to understand how humans approach explanations and contribute to understanding and exploring the explanation processes. This will in turn inform how to collect and use human explanations in NLP. A modest proposal is that it is useful to examine and characterize human explanations before assuming that all explanations are equal and chasing a leaderboard.

A Proxy Questions for Proximal Mechanisms and Procedure

Proximal mechanisms. In collecting proximal mechanisms, studies are more likely to ask explicitly versions of "why is [input] assigned [label]", compared to the case of evidence. However, they often need to provide structured guidelines. For example, Camburu et al. (2018) and Rajani et al. (2019) discussed the need to enforce word overlap as a way to improve the quality of human rationales. The specific requirements are quite different (see Table 6 and Table 7). There are also specific formulations of explanations, e.g., "What aspect/stereotype/characteristic of this group (often un-fairly assumed) is referenced or implied by this post?" in Sap et al. (2020). Finally, it is common that we cannot infer the exact questions asked (8/18 papers that collect explanations in free text).

Procedures. We cannot identify the exact questions in three of five papers for explicitly step-by-step procedures, which reflects the importance of reporting detailed annotation guidelines. As researchers collect step-by-step guidelines, Ye et al. (2020) and Geva et al. (2021) adopt very different decomposition for their problems (see Table 12).

B Detailed Proxy Questions

Table 4-12 show the instructions we find in prior work that detail the proxy questions. Camburu et al. (2018) and Rajani et al. (2019) collect both evidence and proximal mechanism. We include them in the tables for proximal mechanisms. Also, for question answering tasks, the difference between procedure and proximal mechanism can be subtle. We consider the collected explanations *procedure* if they aim to explicitly provide step-by-step guides directly grounded in the input.

Reference	Task	Questions and guidelines
Zaidan et al. (2007)	sentiment analysis	Each review was intended to give either a positive or a negative overall recommendation. You will be asked to justify why a review is positive or negative. **To justify why a review is positive, highlight the most important words and phrases that would tell someone to see the movie. To justify why a review is negative, highlight words and phrases that would tell someone not to see the movie**. These words and phrases are called rationales. You can highlight the rationales as you notice them, which should result in several rationales per review. Do your best to mark enough rationales to provide convincing support for the class of interest. You do not need to go out of your way to mark everything. You are probably doing too much work if you find yourself go- ing back to a paragraph to look for even more rationales in it. Furthermore, it is perfectly acceptable to skim through sections that you feel would not contain many rationales, such as a re- viewer's plot summary, even if that might cause you to miss a rationale here and there.
Sen et al. (2020)	sentiment analysis	1. Read the review and decide the sentiment of this review (positive or negative). Mark your selection. 2. Highlight **ALL** words that reflect this sentiment. Click on a word to highlight it. Click again to undo. 3. If multiple words refect this sentiment, please highlight them all.
Carton et al. (2018)	Personal attack detection	40 undergraduate students used Brat (Stenetorp et al., 2012) to highlight sections of comments that they considered to constitute personal attacks.
Lehman et al. (2019)	Question answering	Prompt Generation: Question answering & Prompt creators were instructed to identify a snippet, in a given full-text article, that reports a relationship between an intervention, comparator, and outcome. Generators were also asked to provide answers and accompanying rationales to the prompts that they provided; such supporting evidence is important for this task and domain. The annotator was also asked to mark a snippet of text supporting their response. Annotators also had the option to mark prompts as invalid, e.g., if the prompt did not seem answerable on the basis of the article.
Thorne et al. (2018)	fact verification (QA)	If I was given only the selected sentences, do I have strong reason to believe the claim is true (supported) or stronger reason to believe the claim is false (refuted). If I'm not certain, what additional information (dictionary) do I have to add to reach this conclusion. In the annotation interface, all sentences from the introductory section of the page for the main entity of the claim and of every linked entity in those sentences were provided as a default source of evidence (left-hand side in Fig. 2). We did not set a hard time limit for the task, but the annotators were advised not to spend more than 2-3 minutes per claim.

Table 4: Questions that prior work uses to solicit human explanations (evidence).

Reference	Task	Questions and guidelines
Khashabi et al. (2018)	Question answering	We show each paragraph to 5 turkers and ask them to write 3-5 questions such that: (1) the question is answerable from the pas- sage, and (2) only those questions are allowed whose answer cannot be determined from a single sentence. We clarify this point by providing example paragraphs and questions. In order to encourage turkers to write meaningful questions that fit our criteria, we additionally ask them for a correct answer and for the sentence indices required to answer the question.
Yang et al. (2018)	Question answering	Workers provide the supporting facts (cannot infer the exact question)
Hanselowski et al. (2019)	Fact verification	Stance annotation. We asked crowd workers on Amazon Mechanical Turk to annotate whether an ETS (evidence text snippets) agrees with the claim, refutes it, or has no stance towards the claim. An ETS was only con- sidered to express a stance if it explicitly referred to the claim and either expressed support for it or refuted it. In all other cases, the ETS was consid- ered as having no stance. FGE annotation. We filtered out ETSs with no stance, as they do not contain supporting or refut- ing FGE. If an ETS was annotated as supporting the claim, the crowd workers selected only sup- porting sentences; if the ETS was annotated as refuting the claim, only refuting sentences were selected.
Kwiatkowski et al. (2019)	Question answering	Long Answer Identification: For good ques- tions only, annotators select the earliest HTML bounding box containing enough information for a reader to completely infer the answer to the ques- tion. Bounding boxes can be paragraphs, tables, list items, or whole lists. Alternatively, annotators mark "no answer" if the page does not answer the question, or if the information is present but not contained in a single one of the allowed elements.
Wadden et al. (2020)	Fact verification	An evidence set is a collection of sentences from the abstract that provide support or contradiction for the given claim. To decide whether a collection of sentences is an evidence set, ask yourself, "If I were shown only these sentences, could I reasonably conclude that the claim is true (or false)"? 1) Evidence sets should be minimal. If you can remove a sentence from the evidence set and the remaining sentences are sufficient for support / contradiction, you should remove it. 2) There may be multiple evidence sets in a given abstract. See more at `https://scifact.s3-us-west-2.amazonaws.com/doc/evidence-annotation-instructions.pdf`
Kutlu et al. (2020)	relevance assessment	Please copy and paste text 2-3 sentences from the webpage which you believe support your decision. For instance, if you selected Highly Relevant, paste some text that you feel clearly satisfies the given query. If you selected Definitely not relevant, copy and paste some text that shows that the page has nothing to do with the query. If there is no text on the page or images led you to your decision, please type "The text did not help me with my decision".

Table 5: Questions that prior work uses to solicit human explanations (**evidence**).

Reference	Task	Questions and guidelines
Jansen et al. (2016)	science QA	For each question, we create gold explanations that describe the inference needed to arrive at the correct answer. Our goal is to derive an explanation corpus that is grounded in grade-appropriate resources. Accordingly, we use two elementary study guides, a science dictionary for elementary students, and the Simple English Wiktionary as relevant corpora. For each question, we retrieve relevant sentences from these corpora and use them directly, or use small variations when necessary. If relevant sentences were not located, then these were constructed using simple, straightforward, and grade-level appropriate language. Approximately 18% of questions required specialized domain knowledge (e.g. spatial, mathematical, or other abstract forms) that did not easily lend itself to simple verbal description, which we removed from consideration. This resulted in a total of 363 gold explanations.
Rajani et al. (2019)	Question answering	Turkers are prompted with the following question: "Why is the predicted output the most appropriate answer?" Annotators were in- structed to highlight relevant words in the question that justifies the ground-truth answer choice and to provide a brief open-ended explanation based on the highlighted justification could serve as the commonsense reasoning behind the question. Annotators cannot move forward if they do not highlight any relevant words in the question or if the length of explanations is less than 4 words. We also check that the explanation is not a sub- string of the question or the answer choices without any other extra words. We collect these ex- planations from only one annotator per example, so we also perform some post-collection checks to catch examples that are not caught by our previ- ous filters. We filter out explanations that could be classified as a template. For example, explanations of the form "<answer> is the only option that is [correct—obvious]" are deleted and then reannotated.
Sap et al. (2020)	social bias	What aspect/stereotype/characteristic of this group (often unfairly assumed) is referenced or implied by this post? — Use simple phrases and do not copy paste from the post.

Table 6: Questions that prior work uses to solicit human explanations for **proximal mechanisms (in free text)**.

Reference	Task	Questions and guidelines
Camburu et al. (2018)	Natual language inference	We encouraged the annotators to focus on the non-obvious elements that induce the given relation, and not on the parts of the premise that are repeated identically in the hypothesis. For entailment, we required justifications of all the parts of the hypothesis that do not appear in the premise. For neutral and contradictory pairs, while we encouraged stating all the elements that contribute to the relation, we consider an explanation correct, if at least one element is stated. Finally, we asked the annotators to provide self-contained explanations, as opposed to sentences that would make sense only after reading the premise and hypothesis. We did in-browser checks to ensure that each explanation contained at least three tokens and that it was not a copy of the premise or hypothesis. We further guided the annotators to provide adequate answers by asking them to proceed in two steps. First, we require them to highlight words from the premise and/or hypothesis that they consider essential for the given relation. Secondly, annotators had to formulate the explanation using the words that they highlighted. However, using exact spelling might push annotators to formulate grammatically incorrect sentences, therefore we only required half of the highlighted words to be used with the same spelling. For entailment pairs, we required at least one word in the premise to be highlighted. For contradiction pairs, we required highlighting at least one word in both the premise and the hypothesis. For neutral pairs, we only allowed highlighting words in the hypothesis, in order to strongly emphasize the asymmetry in this relation and to prevent workers from confusing the premise with the hypothesis. We believe these label-specific constraints helped in putting the annotator into the correct mindset, and additionally gave us a means to filter incorrect explanations. Finally, we also checked that the annotators used other words that were not highlighted, as we believe a correct explanation would need to articulate a link between the keywords.
Do et al. (2020)	visual NLI	similar to Camburu et al. (2018)
Kim et al. (2018)	self-driving cars	We provide a driving video and ask a human annotator in Amazon Mechanical Turk to imagine herself being a driving instructor. Note that we specifically select human annotators who are familiar with US driving rules. The annotator has to describe what the driver is doing (especially when the behavior changes) and why, from a point of view of a driving instructor. Each described action has to be accompanied with a start and end time-stamp. The annotator may stop the video, forward and backward through it while searching for the activities that are interesting and justifiable.

Table 7: Questions that prior work uses to solicit human explanations for **proximal mechanisms (in free text)**.

Reference	Task	Questions and guidelines
Zhang et al. (2020)	coreference resolution	Given a context and a pronoun reference relationship, write how you would decide the selected candidate is more likely to be referred than the other candidate using natural language. Don't try to be overly formal, simply write what you think. In the first phase, we ask annotators to provide reasons for all WSC questions. Detailed instructions are provided such that annotators can fully understand the task1. As each question may have multiple plausible reasons, for each question, we invite five annotators to provide reasons based on their own judgments. A screenshot of the survey is shown in Figure 3. As a result, we collect 1,365 reasons. As the quality of some given reasons might not be satisfying, we introduce the second round annotation to evaluate the quality of collected reasons. In the second phase, for each reason, we invite five annotators to verify whether they think the reason is reasonable or not2. If at least four annotators think the reason is plausible, we will accept that reason. As a result, we identify 992 valid reasons.
Lei et al. (2020)	future event prediction	we also require them to provide a rationale as to why it is more or less likely
Da et al. (2020)	harm of manipulated images	For each question we require annotators to provide both an answer to the question and a rationale (e.g. the physical change in the image edit that alludes to their answer). This is critical, as the rationales prevent models from guessing a response such as "would be harmful" without providing the proper reasoning for their response. We ask annotators to explicitly separate the rationale from the response by using the word "because" or "since" (however, we find that the vast majority of annotators naturally do this, without being explicitly prompted).
Ehsan et al. (2019)	gaming	"Please explain your action". During this time, the player's microphone automatically turns on and the player is asked to explain their most recent action while a speech-to-text library automatically transcribes the explanation real-time.

Table 8: Questions that prior work uses to solicit human explanations for **proximal mechanisms (in free text)**.

Reference	Task	Questions and guidelines
Ling et al. (2017)	algebraic problems	cannot infer the exact question
Alhindi et al. (2018)	fact verification	we cannot infer the exact question automatically extracting for each claim the justification that humans have provided in the fact-checking article associated with the claim. Most of the articles end with a summary that has a headline "our ruling" or "summing up"
Kotonya and Toni (2020)	fact verification	automatically scraped from the website, we cannot infer the exact question
Wang et al. (2020)	sentiment analysis & relation extraction	Turkers are prompted with a list of selected predicates (see Appendix) and several examples of NL explanations. We cannot infer the exact question

Li et al. (2018)	visual QA	automatically generated, We cannot infer the exact question
Park et al. (2018)	visual QA	During data annotation, we ask the annotators to complete the sentence "I can tell the person is doing (action) because.." where the action is the ground truth activity label. However, We cannot infer the exact question in VQA-X.
Rajani et al. (2020)	physics reasoning	We cannot infer the exact question

Table 9: Questions that prior work uses to solicit human explanations for **proximal mechanisms (in free text)**.

Reference	Task	Questions and guidelines
Jansen et al. (2018)	science QA	Specific interfaces were designed. For a given question, annotators identified the central concept the question was testing, as well as the inference required to correctly answer the question, then began progressively constructing the explanation graph. Sentences in the graph were added by querying the tablestore based on key- words, which retrieved both single sentences/table rows, as well as entire explanations that had been previously annotated. If any knowledge required to build an explanation did not exist in the table store, this was added to an appropriate table, then added to the explanation.
Xie et al. (2020)	science QA	similar to Jansen et al. (2018)
Khot et al. (2020)	question answering	The HIT here is to write a test question that requires CHAINING two facts (a science fact and some other fact) to be combined.
Jhamtani and Clark (2020)	question answering	We then use (Amazon Turk) crowdworkers to annotate each chain. Workers were shown the question, correct answer, and reasoning chain. They were then asked if fact 1 and fact 2 together were a reasonable chain of reasoning for the answer, and to promote thought were offered several categories of "no" answer: fact 1 alone, or fact 2 alone, or either alone, justified the answer; or the answer was not justified; or the question/answer did not make sense. (Detailed instructions in the appendix)
Inoue et al. (2020)	question answering	1. Read a given question and related articles. 2. Answer to the question solely based on the information from each article. 3. Describe your reasoning on how to reach the answer. Each reasoning step needs to be in a simple subject-verb-object form (see example below). Your reasoning must include sentences containing your answer.

Abstract

With the growing popularity of deep-learning models, model understanding becomes more important. Much effort has been devoted to demystify deep neural networks for better interpretability. Some feature attribution methods have shown promising results in computer vision, especially the gradient-based methods where effectively smoothing the gradients with reference data is key to a robust and faithful result. However, direct application of these gradient-based methods to NLP tasks is not trivial due to the fact that the input consists of discrete tokens and the "reference" tokens are not explicitly defined. In this work, we propose Locally Aggregated Feature Attribution (LAFA), a novel gradient-based feature attribution method for NLP models. Instead of relying on obscure reference tokens, it smooths gradients by aggregating similar reference texts derived from language model embeddings. For evaluation purpose, we also design experiments on different NLP tasks including Entity Recognition and Sentiment Analysis on public datasets as well as key feature detection on a constructed Amazon catalogue dataset. The superior performance of the proposed method is demonstrated through experiments.

1 Introduction

With the growing popularity of deep-learning models, model understanding becomes more and more critical in many folds. In one aspect, model understanding helps us understand what the model is doing by identifying crucial features among unstructured raw data. For example, Shrikumar et al., 2017 utilized the model explainability technique to discover motifs in regulatory DNA elements from distinct molecular signatures in the field of Genomics. In another aspect, model understanding helps people audit or debug the deep models. An interesting example is that Ribeiro et al. (Ribeiro et al., 2016) found that their image classification model sometimes misclassifies a husky as a wolf. The model explainability tool reveals that their model relies on the snow in the background rather than the appearance when distinguishing the two animals. More importantly, model understanding helps gain trust when making important decisions based on the model. In the NLP domain, deep language models are quickly evolving and show superior performance in various benchmark tasks. However, even experts struggle to understand the mechanism of complex language models.

Much effort has been devoted to demystifying the "black box" of deep models. A natural idea is through feature attribution, explaining the model by attributing the prediction to each input feature according to how much it affects the model output, of which two main directions emerge. One is model agnostic approaches including Shapley regression values (Shapley, 1953) and LIME (Ribeiro et al., 2016). We can apply these methods regardless of the model structure, however, they could suffer from computational inefficiency in the scenario of high dimensional input space and complex deep models when making inferences across all possible permutations or with small perturbations in the local neighborhood.

Another direction is model-specific approaches which look into the internal model mechanism to understand specific models. Gradient-based feature attribution models are often adopted to explain neural networks since gradients can be easily accessed through back-propagation, which gives a great computational advantage over model-agnostic methods. Since the gradient map itself is often noisy and challenging to interpret, most gradient-based methods aim to stabilize the feature attribution score by smoothing the gradients or learning from the reference data (Sundararajan et al., 2017; Smilkov et al., 2017; Lundberg and Lee, 2017). However, direct application of these gradient-based methods to NLP problems is not trivial, due to the fact that the input consists of discrete tokens and the "reference"

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2189 - 2201
July 10-15, 2022

tokens are not explicitly defined.

In this paper, we propose **L**ocally **A**ggregated **F**eature **A**ttribution (**LAFA**), a novel gradient-based approach that leverages sentence-level embedding as a smoothing space for the gradients, motivated by the observation that the feature attribution is often shared by similar text inputs. For example, key features in product descriptions on an online marketplace are often shared by similar products. We implement a neighbor-searching method to ensure the quality of neighboring sentences.

Furthermore, to evaluate feature attribution methods in NLP, we consider two situations. For datasets with golden labels of feature score, we use the Area Under Curve (AUC) or Pearson correlation as the performance metric. As for datasets without golden labels, we conduct a similar evaluation task following prior works (Shrikumar et al., 2017; Lundberg and Lee, 2017) by masking tokens with high importance scores and find the change in the predicted log-odds.

In summary, our contributions are threefold: First, we build a novel context-level smooth gradient approach for feature attribution in NLP. The key ingredients of our method are constructing an appropriate aggregation function over the smoothing space. Second, to the best of our knowledge, this is the first proposal to conduct numerical studies on multiple NLP tasks, including Entity Recognition and Sentiment Analysis, for feature attribution. Third, our method achieves superior performance compared with the state-of-the-art feature attribution methods.

The paper is organized as follows. Section 2 elaborates the current challenges of feature attribution in NLP and recaps the preliminaries about gradient-based feature attribution approaches. The proposed feature attribution method is described in section 3, followed by a review of other existing approaches in Section 4. The evaluation tasks and the application results on NLP are presented in Section 5.

2 Feature Attribution in NLP

Challenge Direct application of gradient-based methods to NLP problems is not trivia. There are three main challenges. First, NLP models consist of non-differentiable discrete input tokens, hence the gradient hook can only reach out to the embedding space and gradient-based feature attribution methods are not directly applicable to word tokens.

Second, the reference data in NLP are difficult to define. It is studied by Sundararajan. et al (Sundararajan et al., 2017) that using the gradient as the feature attribution may suffer from the problems of *model saturation* or *thresholding*. Model saturation means the perturbation of some elements in the input cannot change the output, and the thresholding problem indicates discontinuous gradients can produce misleading importance scores. Such problems can be addressed by comparing the difference between the gradient of input and reference data. The guiding principle to select reference data is to ask ourselves that "what am I interested in measuring differences against?" For example, in the tasks of binary classification on DNA sequence inputs, the reference data are chosen as the expected frequencies of DNA sequence or randomly shuffling the original sequence. However, in NLP tasks, randomly shuffling texts as reference may not be grammatically sensible.

Lastly, we note that the evaluation of the language model is much more challenging than the explanations of the images. In the image application, the important features of an image obtained from feature attribution methods can be visually validated by checking the composition of objects. However, the detected important features in language may require more domain knowledge to validate.

Problem Definition Feature attribution task can be formally formulated as follows. A deep model $\mathcal{F}$ is provided to be explained, which is fine-tuned on dataset $\mathcal{X}$. The input sentence is denoted as $X_0 = (w_1, w_2, .., w_T)^T$ where w_i represents i-th word. The goal for feature attribution is to determine function $\mathcal{M}(\cdot)$ by quantifying the importance score of each word $\mathcal{M}(x) = (m_1, m_2, .., m_T)^T$, where m_i denotes the importance score for w_i.

Simple Gradient as Feature Attribution As illustrated in the first challenge above, in NLP models, directly taking derivative on each word is infeasible due to the non-differentiable embedding layer. We can resolve the challenge as follows.

The fist layer of the NLP model usually maps input discrete tokens to embedding from a predefined dictionary.

$$h_{0,i} = emb(w_i),\ i = 1, 2, .., T, \tag{1}$$

where $h_{0,i} \in \mathbb{R}^d$ represents the word embedding for w_i. This step is non-derivative. But we can

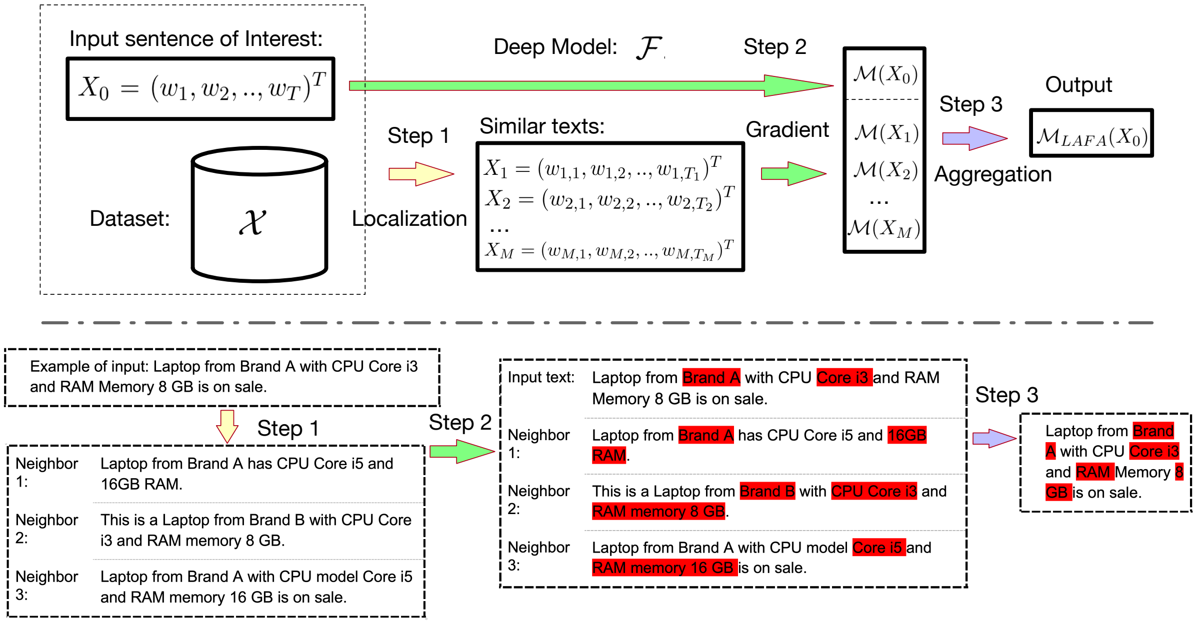

Figure 1: *Upper panel* shows the overview of LAFA methods; *Lower panel* provides a motivating example of LAFA method. In this motivating example, the input text is a description of computer. The key features of the computer should include "Brand", "CPU type" and "RAM size". The simple gradient method may miss certain feature, such as "RAM size" in the example, while the gradients on similar texts can provide more contexts. The proposed method is constructed to aggregate the information from similar texts summarized in Algorithm 1.

obtain the derivative of output with respect to the word embedding:

$$\mathcal{S}(H_0) = \partial\mathcal{F}/\partial H_0 \in \mathbb{R}^{T\times d}, \tag{2}$$

where $H_0 = (h_{0,1}, h_{0,2}, .., h_{0,T})^T \in \mathbb{R}^{T\times d}$. Then, we consider the feature attribution score of a token $\mathcal{M}(X) \in \mathbb{R}^T$ as the sum of squares of the gradients with regard to each word embedding dimension:

$$\mathcal{M}(X)_i = \sum_{j=1}^{d} \mathcal{S}(H_0)^2_{i,j},\ i = 1, 2, .., T. \tag{3}$$

However, simply using the gradients of one token as feature attribution would lead to noisy results (Sundararajan et al., 2017). The next section describes a novel feature attribution approach that smoothes the gradients by leveraging similar input texts.

3 The Proposed Framework: LAFA

The proposed method contains three steps: (1) find the appropriate neighbors of the input text for gradient smoothing; (2) calculate the gradients of texts as well as neighbors; (3) aggregation of the gradients. The proposed framework is summarized in the upper panel of Figure 1. One motivating example is shown in the lower panel of Figure 1. In this motivating example, the input text is a description of computer. The key features of the computer should include "Brand", "CPU type" and "RAM size". The simple gradient method may miss certain feature, such as "RAM size" in the example, while the gradients on similar texts can provide more contexts. The proposed method is constructed to aggregate the information from similar texts.

Step I: Context-level Localization Given the input text $X_0 \in \mathcal{X}$, where $\mathcal{X}$ denotes the input datasets, the goal is to find similar texts $\mathcal{X}_{sim} = \{X_1, X_2, .., X_M\} \subset \mathcal{X}$ such that the feature attributions of X_0 and $X_j \in \mathcal{X}_{sim}$ are similar under a defined similarity metric.

To obtain similar texts $\mathcal{X}_{sim}$, we first define an encoder that maps the text with discrete word tokens to a continuous embedding vector; then, in the embedding space, similar texts are found in the neighbor of X_0. To be specific, let $\mathcal{H}_{encoder}$ denote the mapping from input to one of the hidden layers in deep model $\mathcal{F}$. $\mathcal{X}_{sim}$ can be obtained by choosing closest texts in the dataset as follows:

$$\begin{aligned} &X \in \mathcal{X} \\ &s.t.\ ||\mathcal{H}_{encoder}(X) - \mathcal{H}_{encoder}(X_0)||_2 < \epsilon \end{aligned} \tag{4}$$

where $||\cdot||_2$ represents L^2 norm. ϵ is a threshold score to guarantee that founded neighbors are similar to the center text X_0 to improve the faithfulness of aggregation. In our application, a fixed quantile served as the cut-off rate of L2 distance for all possible pairs is chosen as the threshold score to filter the nearest-neighbor result. During inference time, we apply the hidden layer encoder $\mathcal{H}_{encoder}$ to all the input datasets and index, then using FAISS [1] (Johnson et al., 2017) offline. FAISS is an efficient, open-source library for similarity search and clustering on dense vectors, which can be applied to large-scale vectors.

The output of this step, $\mathcal{X}_{sim}$ can be viewed as the reference data to smooth the feature attribution of X_0, which addresses the second challenge listed in Section 2.

Step II: Taking Gradients According to Equation (3), the gradient of X_i can be denoted as $\mathcal{M}(X_i) := (m_{i,0}, m_{i,1}, .., m_{i,T_i})^T$ for $i = 0, 1, .., , M$ where T_i represent the token length of X_i. To be noticed that our proposed method can be easily extended to variants of simple gradient including smooth gradient or integrated gradient methods (Smilkov et al., 2017; Sundararajan et al., 2017) in Step II.

Step III: Aggregation over Multiple Feature Attribution Our goal is to smooth the gradient $\mathcal{M}(X_0)$ by aggregating the gradients of similar text inputs:

$$\begin{aligned}\mathcal{M}_{LAFA}(X_0) =& AGGREGATE(\mathcal{M}(X_0);\\ &\mathcal{M}(X_1), .., \mathcal{M}(X_M))\end{aligned} \tag{5}$$

Since the lengths of X_0, X_1,..,X_M may vary, the lengths of gradients $\mathcal{M}(X_0)$, $\mathcal{M}(X_1)$,..,$\mathcal{M}(X_M)$ are different as well. Consequently, aggregation by simply taking the average is infeasible. Following the intuition that, the tokens with high gradients in $\mathcal{X}_{sim}$ should be important in X_0, we propose the following aggregation function:

$$\begin{aligned}\mathcal{M}_{LAFA}(X_0) = \mathcal{M}(X_0) + \lambda(\mathcal{E}(w_{0,1}; \mathcal{X}_{sim}), .., \\ \mathcal{E}(w_{0,T}; \mathcal{X}_{sim}))^T,\end{aligned} \tag{6}$$

where λ is a hyper-parameter for leveraging the feature attribution from similar inputs. $\mathcal{E}(w; \mathcal{X}_{sim})$ is a scalar representing the importance of token w obtained from the neighbor inputs $\mathcal{X}_{sim}$. Formally, it can be defined as

$$\mathcal{E}(w; \mathcal{X}_{sim}) = \frac{1}{|\mathcal{X}_{sim}|} \sum_{i=1}^{|\mathcal{X}_{sim}|} \sum_{k=1}^{T_i} \frac{m_{i,k} \times k(h, h_{i,k})}{T_i}, \tag{7}$$

where h, $h_{i,k}$ are the word embedding of w and $w_{i,k}$ as in Equation (1) respectively, and $k(\cdot, \cdot)$ is a kernel function (Hofmann et al., 2008) (examples of kernel function are listed in the Appendix E.). According to Equation (7), if word w and $w_{i,k}$ have a high similarity, then inner product between the embeddings h and $h_{i,k}$ in the kernel space would be large, which would assign a large weight to the corresponding importance score $m_{i,k}$. On the contrary, dissimilar word $w_{i,k}$ in $\mathcal{X}_{sim}$ has little effect to the word w in $\mathcal{E}(w; \mathcal{X}_{sim})$. The whole process is summarized in Algorithm 1.

Algorithm 1 Feature attribution method with smoothing over similar inputs.

```
Input: Text of interest $X_0$, input datasets $\mathcal{X}$, and fine-tuned deep model $\mathcal{F}$.
Output: Feature attribution of $X_0$
Step I: Localization
Construct encoder $\mathcal{H}$ which maps from input space to the space of hidden layer in $\mathcal{F}$.
Obtain the similar texts set $\mathcal{X}_{sim} = \{X_1, X_2, .., X_M\}$ of $X_0$ according to Equation (4).
Step II: Taking Gradient
Calculate the gradient of texts $X_0, X_1, .., X_M$ according to Equation (3).
Step III: Aggregation
Smooth the gradient of text of interest over the gradient of similar texts according to Equation (6).
Output the aggregated gradient $\mathcal{M}_{LAFA}(X_0)$ as the feature attribution.
```

Discussion of Faithfulness One important criteria for model explainability method is "faithfulness", which refers to how accurately it reflects the true reasoning process of the model (Jacovi and Goldberg, 2020). In our proposed method, the original input X_0 is infused with similar texts in the input dataset $\mathcal{X}$ for better interpretation. Since the deep model $\mathcal{F}$ is also trained on $\mathcal{X}$, using similar texts $\mathcal{X}_{sim} \subset \mathcal{X}$ to facilitate explanation will not violate the faithfulness.

In the localization step (Step I), out of the consideration about faithfulness, we do not use popular

bi-encoder frameworks, such as S-BERT (Reimers and Gurevych, 2019) or DenseRetrival (Karpukhin et al., 2020), to obtain similar neighbors. Because it will involve an extra black box model when explaining deep model $\mathcal{F}$.

4 Related Work

In NLP, transformer-based models yield great successfulness and some works focus on explaining the attention mechanism. For example, Serrano and Smith, 2019 and Jain and Wallace, 2019 inspected a single attention layer and found out that attention weights only weakly and inconsistently correspond to feature importance; Wiegreffe and Pinter, 2019 argued that we cannot separate the attention layer and should view the entire model as a whole. In this section, We mainly review the gradient-based methods for feature attribution.

Feature Attribution on Single Input Simonyan et al (Simonyan et al., 2013) computed the "saliency map" denoted as *Simple Gradient* from the derivative of the output with respect to the input in an image classification task. In the NLP application, "saliency map" is obtained as the derivative of the output with respect to the word embedding as in Equation (2). However, "saliency map" can be visually noisy. Several methods are proposed to improve the gradient method from different perspectives. *Gradient*Input* method (Shrikumar et al., 2017) improves the visual sharpness of the "saliency map" by multiplying gradient with the input itself. In NLP, we can write it as:

$$\mathcal{S}_{Grad*Input}(H_0) = H_0 \times \mathcal{S}(H_0)$$

$$\mathcal{M}_{Grad*Input}(X)_i = \sum_{j=1}^{d} \mathcal{S}_{Grad*Input}(H_0)^2_{i,j}.$$

Layerwise Relevance Propagation method (Bach et al., 2015) is shown to be equivalent to the *Gradient*Input* method up to a scaling factor. *Smooth Gradient* method (Smilkov et al., 2017) smoothes the feature attribution score by adding random noises to the input and taking average of the gradients from noisy inputs, formally:

$$\mathcal{S}_{SmoothGrad}(H_0) \approx \frac{1}{N}\sum_{k=1}^{N} \mathcal{S}(H_0 + \epsilon_k),$$

$$\epsilon_k \sim N(0, \sigma^2),$$

$$\mathcal{M}_{SmoothGrad}(X)_i = \sum_{j=1}^{d} \mathcal{S}_{SmoothGrad}(H_0)^2_{i,j}.$$

Guided Backpropagation method (Springenberg et al., 2014) modifies the back-propagation to preserve negative gradients in the ReLU activation layer which also sharpens the "saliency map" visually. Other methods, such as *Grad-CAM* or *Guided-CAM* (Selvaraju et al., 2017), are applicable to specific architecture of neural networks in the field of computer vision.

Since language models like BERT do not contain specific architecture utilized in Guided Backpropagation or Grad-CAM method, we ignore the mathematical formulation here.

Feature Attribution on Input with Reference Data *Integrated Gradient* method computes the feature score by integrating the gradients from single pre-determined reference input to the target input (Sundararajan et al., 2017). In computer vision problems, black image is usually considered as the reference data, and integrating gradients from the black image to the input image represents the feature attribution of the input image. In NLP problems, we can define the i-th element of feature attribution as:

$$\mathcal{S}_{InteGrad}(H_0)_{ij} \approx \frac{H_{0,ij} - H'_{ij}}{N}\sum_{k=1}^{N} \mathcal{S}(H' + k\frac{H_0 - H'}{N})_{ij},$$

$$\mathcal{M}_{InteGrad}(X)_i = \sum_{j=1}^{d} \mathcal{S}_{InteGrad}(H_0)^2_{i,j}.$$

where H' denotes the embedding of reference text.

SHAP-Gradient method which combines ideas from Integrated Gradient and Smooth Gradient into a single expected value equation (Lundberg and Lee, 2017) . To be specific, the feature attribution is defined from:

$$\mathcal{S}_{ShapGrad}(H_0) \approx \frac{1}{N}\sum_{k=1}^{N} \mathcal{S}(\alpha_k H_0 + (1-\alpha_k)H_k),$$

$$\mathcal{M}_{ShapGrad}(X)_i = \sum_{j=1}^{d} \mathcal{S}_{ShapGrad}(H_0)^2_{i,j}.$$

where $\alpha_k \sim U(0,1)$ denotes uniform distribution from zero to one, $H_k \in \mathcal{H}_{ref}$ denotes the embedding of reference text.

DeepLIFT (Shrikumar et al., 2017) assigns the feature score by comparing the difference of contribution between input and some reference inputs via gradient. As discussed in (Lundberg and Lee, 2017), DeepLIFT can be considered as an approximation of Shapley Value estimation. Specifically, as in the application of SHAP [2], the feature attribution of *SHAP-Deep* as a variant of *DeepLIFT* is defined as:

$$\mathcal{S}_{ShapDeep}(H_0) \approx \frac{1}{N}\sum_{k=1}^{N}\mathcal{S}(H_k) \times (H_0 - H_k).$$

$$\mathcal{M}_{ShapDeep}(X)_i = \sum_{j=1}^{d}\mathcal{S}_{ShapDeep}(H_0)_{i,j}^2.$$

5 Experiments

In this section, we compare the proposed method to the state-of-the-art feature attribution methods under different use cases.

5.1 Case I: Feature Attribution on Relation Classification Model

Dataset	Precison	Recall	F1
NYT10	94.8	93.3	94.1
Webnlg	93.6	82.5	87.7

Table 1: Fine-tuned result on multi-label relation classification task.

Motivation Relation Classification is beneficial to downstream problems, including question answering and knowledge graph (KG) construction tasks (Wen et al., 2016; Dhingra et al., 2016; Dong et al., 2020). With the development of deep language model, existing relation extraction methods have achieved significant performance in relation classification task (Soares et al., 2019; Wei et al., 2019). We hope to better understand the features in the text that help deep language model to classify the relations. In this use case, we fine-tune a deep language model with relation as labels. With the fine-tuned model, the feature attribution technique is applied to identify the entities in the text as important features.

Data We use the public available datasets NYT10 (Riedel et al., 2010) and Webnlg (Gardent et al., 2017) for numerical study. Zeng et al., 2018 adapted the original dataset for relation extraction task. We follow the same setting as in Zeng et al., 2018, i.e. NYT10 dataset contains 56,196/5,000/5,000 plain texts in train/val/test set, 24 relation type, averaged 2.01 relational triples in each text. Webnlg dataset contains 5,019/500/703 plain texts in train/val/test set, 211 relation type, averaged 2.78 relation triples in each text.

Language Model We fine-tuned BERT-base models to classify the relations for NYT10 and Webnlg datasets, respectively. We use the plain text as input X, and relations as multi-class label Y in the model fine-tuning. Since multiple relations may exist in single text, we use the *Sigmoid* activation in the output layer. Mean Square Error (MSE) is used as loss objective and Adam (Kingma and Ba, 2014) is adopted as the optimizer. The micro Precision, Recall and F1 results are reported in Table 1 with 0.5 threshold of output score. From the result, the F1 scores are high for both NYT10 and Webnlg dataset, hence we can apply feature attribution methods to the fine-tuned models and identify the important features in the text which help to classify the relations.

Method	AUC NYT	AUC Webnlg
Rand	0.498 (0.143)	0.501 (0.121)
SimpleGrad	0.949 (0.071)	0.670 (0.135)
InputGrad	0.953 (0.061)	**0.713** (0.120)
InteGrad	0.948 (0.077)	0.663 (0.126)
SmoothGrad	**0.960** (0.064)	0.664 (0.142)
SHAP + Zero	0.805 (0.213)	0.670 (0.133)
SHAP + Ref.	0.872 (0.169)	0.675 (0.133)
LAFA	**0.958** (0.060)	**0.724** (0.115)

Table 2: Feature attribution result on Relation Classification model (Case I). Top two results are highlighted in bold.

Evaluation Metric In datasets, NYT10 and Webnlg, the positions of entities in triples are provided. Therefore, we can constructed the golden feature attribution label as follow. For text $X = (w_1, w_2, .., w_T)^T$ and triple (s, r, o), where subject $s = (w_i, .., w_j)$ and object $o = (w_k, .., w_s)$ are words shown in the text from positions i to j and k to s, respectively. The gold labels of feature attribution for relation r is constructed as

$$\mathcal{M}_{gold}(X) = (0, .., 0, 1, .., 1, 0, ..., 0, 1, .., 1, ..0)^T$$

where we set 1 from positions i to j as well as k to s and set 0 on other positions.

We use the evaluation metric Area under Curve (AUC) to compare the feature attribution $\mathcal{M}.(X)$

Method	Pearson Correlation	
	SST-2	SST
Rand	0.039(0.074)	0.040(0.072)
SimpleGrad	0.441(0.083)	0.430(0.081)
InputGrad	0.456(0.080)	0.448(0.078)
InteGrad	0.468(0.071)	0.454(0.072)
SmoothGrad	**0.484(0.073)**	**0.471(0.073)**
SHAP + Zero	0.400(0.087)	0.392(0.085)
SHAP + Ref.	0.279(0.093)	0.278(0.091)
LAFA	**0.494(0.070)**	**0.481(0.070)**

Table 3: Feature attribution result on Sentiment Analysis Model (Case II).

and $\mathcal{M}_{gold}(X)$ for the test dataset. AUC ranges from 0 to 1, higher AUC represents the the feature attribution result is closer to the gold feature attribution.

Main Results The results of AUC under different methods are summarized in Table 2. The popular feature attribution methods are listed and compared. More introduction about the competitors can be found in Section 4. "Rand", as a baseline method, denotes that the feature score is randomly assigned, therefore, the AUC score is about 0.5. InputGrad method performs better than the SimpleGrad, showing the effeteness of Taylor approximation of layer-wise relevance propagation. "SHAP + Zero" means zero references are used in SHAP and "SHAP + Ref." means $\mathcal{X}_{sim}$ is used as references. SHAP-based methods show low AUC values, because such methods aggregate the gradients of input and reference by simply taking average aggregation (see details in Section 4), which is not meaningful in NLP tasks. From the result, our method LAFA achieves a superior performance in Webnlg dataset and comparable performance in NYT dataset, which indicates that our feature attribution method can identify entities well.

5.2 Case II: Feature Attribution on Sentiment Analysis

Motivation The goal of the sentiment classification task is to classify a text into a sentiment categories such as positive or negative sentiment (Aghajanyan et al., 2021; Raffel et al., 2019; Jiang et al., 2020). In this use case, we hope to explain the deep sentiment classification model and obtain sentiment factors that drive the model to identify the sentiment.

Data The Stanford Sentiment Treebank (SST) (Socher et al., 2013) is a sentiment analysis dataset collected from English movie reviews (Pang and Lee, 2005). For all $9,645$ sentences in SST, Amazon Mechanical Turk labeled the sentiment for words/phrases/sentences yielded from the Stanford Parser (Manning et al., 2014) on a scale between 1 and 25. SST-2 is first introduced by GLUE (Wang et al., 2018), a famous multi-task benchmark and analysis platform for natrual language understanding, which took a subset from the SST and applied a two-way split (positive or negative) on sentence-level labels. Owing to the fact that the train/validation/test split are aligned between SST and SST-2, we can run gradient-based methods on the either one of them. Note that we are only working with the test split for both data sets, which contains 2210 and 1821 sentences respectively.

Language Model We use a popular and publicly available Distill-BERT (Sanh et al., 2019) model which is fine-tuned on SST-2 [3]. The accuracy of the Distill-BERT model on SST and SST-2 is 86.6% and 92.4% respectively.

Evaluation Metric We extract word-level sentiments from the phrase structure tree (PTB) in SST dataset. We take an absolute value after centralization to yield the golden label $\mathcal{M}_{gold}(X)$. Pearson correlation coefficient, ρ , is the evaluation metric for feature attribution $\mathcal{M}_{gold}(X)$ and $\mathcal{M}_{\cdot}(X)$. The correlation ρ takes value from the range from -1 to 1, and a higher ρ means better feature attribution result.

Main Results The main results of the correlation are summarized in Table 3. Popular feature attribution methods are listed and compared. To leverage the problem that some words can have opposite meaning when their sentiment are different, we only limited the sentences neighbor for same category. Based on the preliminary experiment, we choose the second layer with 10 neighbors and 0.39 cut-off rate, more details about preliminary experiment can be found in Appendix D that using all layers of DistilBERT as the encoder will improve the performance.

From the result Table 3, it is interesting to point out that the DistilBERT model fine-tuned on SST-2 does not perform equally well on the remaining sentences in SST, so the explanation we yield also

---

[3] https://huggingface.co/distilbert-base-uncased-finetuned-sst-2-english

has lower correlation for all methods compared with the SST-2. Some example and analysis when LAFA works and fails in this dataset by showing neighbor sentences can be found in Appendix B.

We can find out that the InputGrad method outperform SimpleGrad on SST/SST2 as well. SmoothGrad method achieves a good result by introducing random noise. From our observation, Sharpley-Value based methods, "SHAP + Zero" and "SHAP + Ref." can identify important features with a good chance but may include several irrelevant tokens leading to higher variance. Our method LAFA achieves a superior performance in larger average correlation and smaller variance on both SST-2 and SST data sets.

5.3 Case III: Feature Attribution on Regression Model

Motivation Amazon's online stores contain rich information about millions of products in product title, brand and description. We hope to better understand the trendy features that affecting price directly from such unstructured raw data, without the need for human labelers / data cleaning. In this application, we fine-tuned a deep language model with price as labels and aim to understand important factors from product descriptions with the given language model.

Data We collected the product catalog data of about one million products in personal computer category on Amazon's online store. We concatenate product's title, brand, bullet points and description as the input X, and use product price as the label Y.

Language Model We use BERT-base model and fine-tuned on collected catalog data for price regression.

Evaluation Metric To evaluate the performance of feature attribution methods without golden labels, we follow a similar idea as in work (Shrikumar et al., 2017; Lundberg and Lee, 2017) where the difference of prediction log-odds are measured by deleting pixels with highest importance scores. In our application, we first randomly select 200 input texts within a threshold of 1% prediction error as evaluation set. For each input text, we then mask p% of the tokens with highest feature attribution scores according to different feature attribution methods. Then we obtain new prediction result from the masked text denoted as $\hat{y}_{masked}$ and calculate the new mean absolute percentage error (MAPE). Higher value of MAPE means that the corresponding method excels in picking important features.

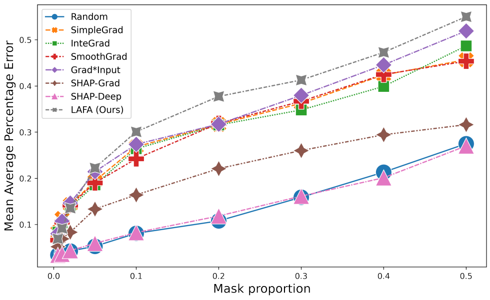

Figure 2: Feature attribution result on Case III. Comparisons of MAPE under different mask proportion.

Main Results The results are shown in Figure 2 where x-axis is the mask proportion p, and y-axis is MAPE. We observe that the random method has very low MAPE, because randomly masking the input texts will not affect the predicted result as much as the other feature attribution methods. ShapDeep and ShapGrad also have low MAPE values since simply taking average as aggregation is meaningless in NLP tasks. Other competing methods have similar performances on this case study and non of these performs better than others in a wide range of mask ratio. The proposed LAFA method outperforms other methods by significant margin with masking proportion from 5% to 50%, which demonstrates that smoothing over context-level neighbors helps to highlight the important features in similar type of products.

6 Conclusion

This paper presents a novel locally aggregated feature attribution method in NLP, which efficiently captures the important features by leveraging similar input texts in the embedding space. We focused on feature attribution of single input based on a fine-tuned model instead of training a language model, henceforth the computation time is of less concern.

One limitation of the LAFA model is that it requires informative neighbor sentences that carry similar information. Otherwise, aggregating information from other sentences could be misleading. Experiments in our datasets show that our method is effective, but the improvements gained from the

LAFA varies among different datasets based on the information that neighbor carries.

There are several future directions worthy of study. Firstly, labeling feature attribution result in the NLP requires massive human labor, and few datasets are available with golden feature attribution label. Developing new evaluation techniques to further measure model performance is interesting to investigate. Also, readable feature attribution results could help human beings to develop more business applications. For example, developing a key-value pair like *processor-i5* as important feature can provide a more plausible feature attribution result to customers.

Appendix:

A Model Implementation Detail

All experiments are conducted with eight NVIDIA Tesla V100 GPUs with 2.5 GHz (base) and 3.1 GHz (sustained all-core turbo) Intel Xeon 8175M processors.

Case I For LAFA, we adopt the cosine function as the kernel function and hyper-parameter with $\lambda = 1$ and SimpleGrad is implemented and aggregated by $\mathcal{M}(x)$ in Equation (5).

Case II For LAFA, we adopt the Polynomial function as the kernel function $k(\cdot, \cdot) = \mathbb{I}(\cdot, \cdot)$ and hyper-parameter with $\lambda = 0.44$ and SmoothGrad is chosen and aggregated by $\mathcal{M}(x)$ in Equation (5).

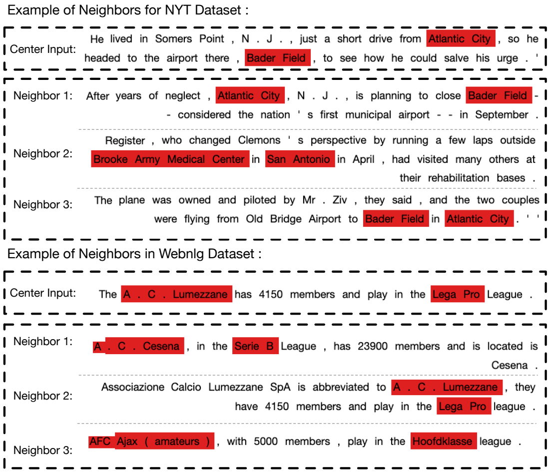
For gradient-based model with hyper-parameters, we tuned them on the first 100 sentences in the test set. From the grid $[10, 25, 50]$, we choose 25 as the integral iteration and the smooth candidates.

Case III The indicator function as the kernel function $k(\cdot, \cdot) = \mathbb{I}(\cdot, \cdot)$ with $\lambda = 1$ as hyper-parameter is adopted for LAFA. Neighbor information is aggregated by $\mathcal{M}(x)$ in Equation (5) from the SimpleGrad.

B Example of Neighbor Sentences found by Case Studies

B.1 Relation Extraction

In Figure 3, we show two examples in NYT and Webnlg with their neighbors. We can observe that detected neighbor sentences have a similar meaning, which can be utilized as a reference to help extract the key features from the original sentence.



Example of Neighbors for NYT Dataset :

Center Input: He lived in Somers Point , N . J . , just a short drive from Atlantic City , so he headed to the airport there , Bader Field , to see how he could salve his urge . '

Neighbor 1: After years of neglect , Atlantic City , N . J . , is planning to close Bader Field - - considered the nation ' s first municipal airport - - in September .

Neighbor 2: Register , who changed Clemons ' s perspective by running a few laps outside Brooke Army Medical Center in San Antonio in April , had visited many others at their rehabilitation bases .

Neighbor 3: The plane was owned and piloted by Mr . Ziv , they said , and the two couples were flying from Old Bridge Airport to Bader Field in Atlantic City . ' '

Example of Neighbors in Webnlg Dataset :

Center Input: The A . C . Lumezzane has 4150 members and play in the Lega Pro League .

Neighbor 1: A . C . Cesena , in the Serie B League , has 23900 members and is located is Cesena .

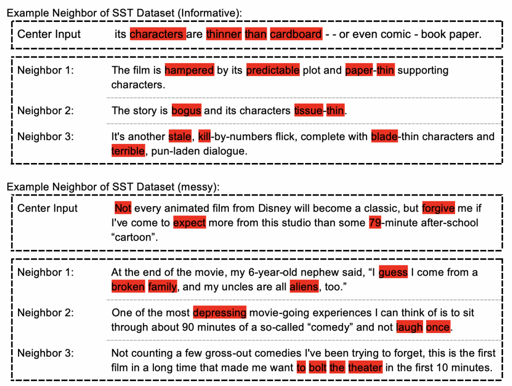
Neighbor 2: Associazione Calcio Lumezzane SpA is abbreviated to A . C . Lumezzane , they have 4150 members and play in the Lega Pro league .

Neighbor 3: AFC Ajax (amateurs) , with 5000 members , play in the Hoofdklasse league .

Figure 3: Example of neighbors for NYT and Webnlg. The head and tail entities are highlighted with red color.

B.2 Sentiment Analysis

In SST-2, finding informative neighbors for every sentence is difficult because top sentences may not contain similar tokens, thus does not help. For this reason, we used a cut-off value for this data set to filter out non-informative sentences. In figure 4 we can find two examples from SST, one with "informative" good neighbors but another without them. Here for the word "informative" we use a quote because we are judging them based on our human understanding.



Example Neighbor of SST Dataset (Informative):

Center Input: its characters are thinner than cardboard - - or even comic - book paper.

Neighbor 1: The film is hampered by its predictable plot and paper-thin supporting characters.

Neighbor 2: The story is bogus and its characters tissue-thin.

Neighbor 3: It's another stale, kill-by-numbers flick, complete with blade-thin characters and terrible, pun-laden dialogue.

Example Neighbor of SST Dataset (messy):

Center Input: Not every animated film from Disney will become a classic, but forgive me if I've come to expect more from this studio than some 79-minute after-school "cartoon".

Neighbor 1: At the end of the movie, my 6-year-old nephew said, "I guess I come from a broken family, and my uncles are all aliens, too."

Neighbor 2: One of the most depressing movie-going experiences I can think of is to sit through about 90 minutes of a so-called "comedy" and not laugh once.

Neighbor 3: Not counting a few gross-out comedies I've been trying to forget, this is the first film in a long time that made me want to bolt the theater in the first 10 minutes.

Figure 4: Example of neighbors for the SST data set. Sentiment factors found by SimpleGrad are highlighted with red color.

C Examples of Different Feature Attribution Methods under Multiple Cases

Here we provide an example in Cases I and II. In Figure 5, LAFA identified locations and "lived" as the important factors for relation extraction, and the importance of the "Atlantic City" and "Bader Field" is stronger than the backbone SimGrad because of aggregation.

D Experiment on Different Layer as Neighbor Encoder

Denote the size of $\mathcal{X}_{sim}$ as M, the choice of which can be a critical and challenging task. Intuitively, an overly small M would lead to under-smoothing because the target text cannot incorporate enough information from the neighbors. On the contrary, an overly large M would cause over-smoothing by introducing too much noise.

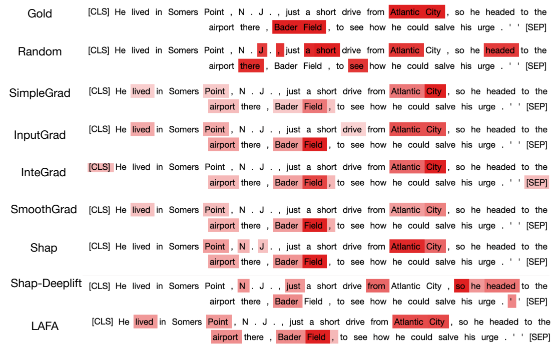


Figure 5: Examples of Case Study I. Important factors are highlighted with red color.

Figure 6: Examples of Case Study III. Important features are highlighted with red color.

To clarify the neighbor searching process and the difference in the result using different layers, we show some experiments below.

Admittedly, we can directly use the WordPiece embedding as the encoder, which is the input of BERT-based models and enable us to find neighbors in the sense of "Word Similarity". However, since the same word can have different meanings in different sentences, and thus different importance in yielded gradients, we might need to use another layer in the BERT model as the encoder to incorporate contextual information.

We separate the layer search process into two cases depending on the availability of a set of labels that categorizes similar contents into the same group. Generally speaking, both cases recommend the middle layer as the encoder based on our experience.

D.1 When extra labels are not available

In the case of SST data, we do not have anything to group similar sentences, so we need to try for different possible layers and find the one that performs the best.

Here we fixed the max number of neighbors as 10 and uses 0.05 quantile of sampled similarities as the cut-off rate to filter those neighbors that are not "actually close". We use the SimpleGrad and the SmoothGrad as the baseline for comparison on the first 100 sentences in the test set.

From table A1 we can find out that LAFA is a generally good method that always beats the baseline when we use the smooth gradient as the basement method. Layer 2 performs the best among candidates. The combination of SmoothGrad and Layer w is the final choice and we showed the results on entire SST in the main result part. From here we can find out that for all seven layers, information from faithful neighbors can bring some useful information to an existing sentence.

Method	SST_first100	Method	SST_first100
SimpleGrad	0.457(0.074)	SmoothGrad	0.481(0.064)
SpG + LAFA + L1	0.457(0.073)	SmG + LAFA + L1	0.488(0.063)
SpG + LAFA + L2	**0.458(0.072)**	SmG + LAFA + L2	**0.490(0.063)**
SpG + LAFA + L3	0.456(0.072)	SmG + LAFA + L3	0.489(0.065)
SpG + LAFA + L4	0.456(0.072)	SmG + LAFA + L4	0.478(0.064)
SpG + LAFA + L5	0.454(0.072)	SmG + LAFA + L5	0.479(0.063)
SpG + LAFA + L6	0.454(0.073)	SmG + LAFA + L6	0.483(0.065)
SpG + LAFA + L7	0.456(0.074)	SmG + LAFA + L7	0.481(0.059)

Table A1: Feature Attribution Result on first 100 test cases in SST, using simple and smooth gradient as baselines

D.2 When we have extra label

The performance of encoders can be evaluated by the similarity between text X_0 and similar texts $\mathcal{X}_{sim}$ obtained from Equation (4). In this application, we use the product category or subcategory which is an additional source of labels produced by Amazon to construct a proxy metric to evaluate the

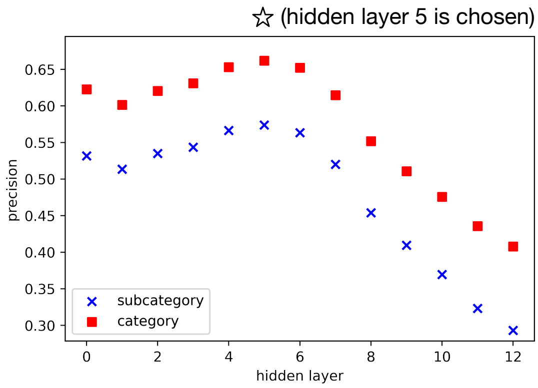

Figure 7: Precision Result in Case Study III

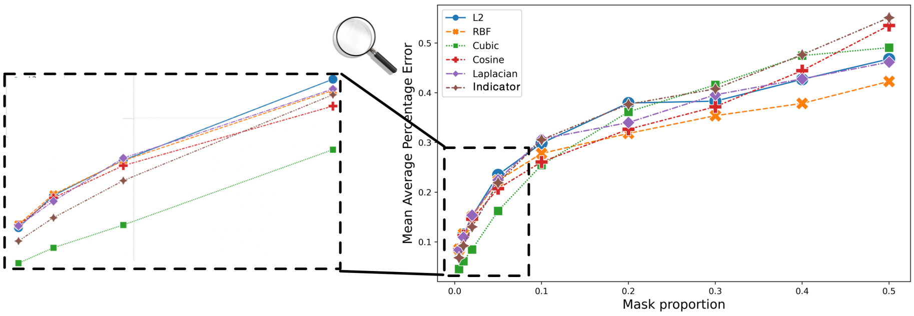

Figure 8: Comparisons for different kernel functions in Case III.

similarity. Define the metric of precision as:

$$Precision = \frac{1}{M}\sum_{j=1}^{M}\mathbb{I}(c(X_j) = c(X_0)), \quad (8)$$

where $c(\cdot)$ denotes the category or subcategory of the corresponding product, $\mathbb{I}(\cdot)$ is the indicator function. A high precision represents that the text found $\mathcal{X}_{sim}$ are similar to the text of interest X_0.

In the numerical study, we randomly sample $10,000$ inputs texts and obtain their corresponding neighbor texts from Equation (4) with $M = 10$ using each of the 12 hidden layers in BERT as the encoder $\mathcal{H}_{encoder}$ under L_2 norm. Figure 7 shows the precision result from different encoders, where we observe that the fifth hidden layer has the highest precision in terms of both category and subcategory, which is consistent with the intuition that the middle layer is a trade-off of token-alike and output-alike inputs. In the following experiment, we adopt the fifth layer as the encoder. In general, when no external labels are provided, we may choose a different encoder depending on the use case.

E Ablation Study on Kernel Function

In Case III, we conduct an ablation study with different choices of kernel functions using different mask ratio to find out if different kernel yields different learning speed:

1. Radial basis function kernel (*RBF*) :

   $$k_{RBF}(a, b) = exp(-||a - b||_2/l^2),$$

   where larger hyper-parameter l indicates lower impact from neighbors and vice versa. In the numerical study, we choose $l = 2$ based on the range of embedding a and b.

2. Cubic kernel (*Cubic*):

   $$k_{Cubic}(a, b) = (\gamma a^T b + c_0)^d,$$

   where $\gamma = 7$, $c_0 = 0$ and $d = 3$, smaller γ means lower impact from neighbors.

3. Cosine kernel (*Cosine*):

   $$k_{Cos}(a, b) = a^T b/||a|||b|||$$

   This kernel function havee no parameter.

4. Laplacian kernel (*Laplacian*):

   $$k_{Laplacian}(a, b) = exp(-||a - b||_1/l^2),$$

   in the numerical study, we choose $l = 2$.

5. L2 norm based similarity (*L2*):

   $$k_{L2}(a, b) = 1/clip(||a - b||_2, \lambda_{left}, \lambda_{right}),$$

   where $clip(\cdot, \lambda_{left}, \lambda_{right})$ denotes clip function with $\lambda_{left} = 0.3$ and $\lambda_{right} = 3$ as clip boundary in numerical study.

6. Indicator function based similarity (*Indicator*):

   $$k_{Indicator}(a, b) = \mathbb{I}(a, b),$$

   where $\mathbb{I}(\cdot, \cdot)$ denotes indicator function.

The results are shown in Figure 8. We observe that no single kernel function outperforms all other kernel functions under all mask ratios in this study. Indicator function shows a good performance when the masked ratio is greater than 10%, while RBF kernel shows a good performance when the masked ratio is smaller than 5%. This can due to the reason that the indicator function only aggregates identical words and this conservative manner helps when we lost most important words.

Generic and Trend-aware Curriculum Learning for Relation Extraction in Graph Neural Networks

Nidhi Vakil

Hadi Amiri
Department of Computer Science
University of Massachusetts Lowell
`hadi@cs.uml.edu`

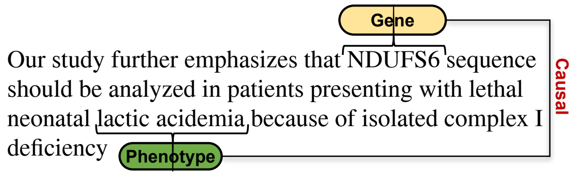
Abstract

We present a generic and trend-aware curriculum learning approach for graph neural networks. It extends existing approaches by incorporating sample-level loss trends to better discriminate easier from harder samples and schedule them for training. The model effectively integrates textual and structural information for relation extraction in text graphs. Experimental results show that the model provides robust estimations of sample difficulty and shows sizable improvement over the state-of-the-art approaches across several datasets.

1 Introduction

Relation extraction is the task of detecting (often pre-defined) relations between entity pairs. It has been investigated in both natural language processing (Mintz et al., 2009; Lin et al., 2016; Peng et al., 2017; Zhang et al., 2018) and network science (Zhang and Chen, 2018; Fout et al., 2017). Relation extraction is a challenging task, especially when data is scarce. Nonetheless, the ability to automatically link entity pairs is a crucial task as it can reveal relations that have not been previously identified, e.g., informing clinicians about a causal relation between a gene and a phenotype or disease. Figure 1 shows an example sentence from a PubMed article in the Gene Phenotype Relation (PGR) dataset (Sousa et al., 2019), which describes the application domain of the present work as well.

Previous research has extensively investigated relation extraction at both sentence (Zeng et al., 2015; dos Santos et al., 2015; Sousa et al., 2019) and document (Yao et al., 2019b; Quirk and Poon, 2017) levels. Furthermore, effective graph-based neural network approaches have been developed for various prediction tasks on graphs, including link prediction between given node pairs (Kipf and Welling, 2017; Hamilton et al., 2017; Xu et al., 2018; Veličković et al., 2018). Several recent approaches (Li et al., 2020; Zhang and Chen, 2018; Alsentzer et al., 2020) illustrated the importance of enhancing graph neural networks using structurally-informed features such as shortest paths, random walks and node position features.



Our study further emphasizes that NDUFS6 sequence should be analyzed in patients presenting with lethal neonatal lactic acidemia because of isolated complex I deficiency

Figure 1: An example showing the report of a causal relation between a gene and a phenotype (symptom) from the PGR dataset (Sousa et al., 2019).

In this work, we develop a graph neural network titled **G**raph **T**ext **N**eural **N**etwork (GTNN) that employs structurally-informed node embeddings as well as textual descriptions of nodes at prediction layer to avoid information loss for relation extraction. GTNN can be trained using a standard approach where data samples are fed to the network in a random order (Hamilton et al., 2017). However, nodes, edges or sub-graphs can significantly vary in their difficulty to learn, owing to frequent substructures, complicated topology and indistinct patterns in graph data. We tackle these challenges by presenting a generic and trend-aware curriculum learning approach that incorporates *sample-level* loss trajectories (trends) to better discriminate easier from harder samples and schedule them for training graph neural networks.

The contributions of this paper are: (a): a graph neural network that effectively integrates textual data and graph structure for relation extraction, illustrating the importance of *direct* use of text embeddings at prediction layer to avoid information loss in the iterative process of learning node embeddings for graph data; and (b): a novel curriculum learning approach that incorporates loss trends at sample-level to discover effective curricula for training graph neural networks.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2202 - 2213
July 10-15, 2022

We conduct extensive experiments on real world datasets in both general and specific domains, and compare our model against a range of existing approaches including the state-of-the-art models for relation extraction. Experimental results demonstrate the effectiveness of the proposed approach; the model achieves an average of 8.6 points improvement in F1 score against the best-performing graph neural network baseline that does not directly use text embeddings at its prediction layer. The proposed curriculum learning approach further improves this performance by 0.7 points, resulting in an average F1 score of 89.9 on our three datasets. We conduct extensive experiments to shed light on the improved performance of the model. Code and data are available at `https://clu.cs.uml.edu/tools.html`.

2 Method

Consider an undirected graph $G = (\mathcal{V}, \mathcal{E})$ where $\mathcal{V}$ and $\mathcal{E}$ are nodes and edges respectively, and nodes carry text summaries as their descriptions. Edges in the graph indicate "relations" between their end points, e.g., causal relations between genes and diseases, or links between concepts in an encyclopedia. Our goal is to predict relations/links between given node pairs in G.

2.1 Graph Text Neural Network

We present the Graph Text Neural Network (GTNN) model which directly operates on G and textual descriptions of its nodes. Figure 2 shows the architecture of GTNN, which we describe below.

2.1.1 Graph Encoder

Given G and its initial text embeddings, $\mathbf{x}_i$ for each node i, we apply a graph encoder (Hamilton et al., 2017) to generate a d-dimensional embedding for each node by iteratively aggregating the current embeddings of the node and its t-hop neighbours through the `sigmod` function denoted by g:

$$\mathbf{h}_i^{(t+1)} = g\Big(\mathbf{W}_1\mathbf{h}_i^{(t)} + \mathbf{W}_2\big(\frac{1}{|\mathcal{N}_i|}\sum_{j\in\mathcal{N}_i}\mathbf{h}_j^{(t)}\big)\Big), \quad (1)$$

where $\mathbf{h}_i{}^{(t)}$ is the embedding of node i at the t^{th} layer of the encoder and is initialized by $\mathbf{x}_i$, i.e., $\mathbf{h}_i{}^{(0)} = \mathbf{x}_i, \forall i$, and $\mathcal{N}_i$ is the set of neighbors of node i aggregated through a mean operation. $\mathbf{W}_1$ and $\mathbf{W}_2$ are parameter matrices to learn during training. Equation (1), applied iteratively, generates node embeddings $\mathbf{z}_i = \mathbf{h}_i{}^{(t+1)} \in \mathbb{R}^d$.

2.1.2 Additional Text Features

In addition to the representations obtained from the graph encoder, we use additional features from text data to better learn the relations between entities. Here, we consider three types of features: (a) relevance score between the descriptions of node pairs obtained from information retrieval (IR) algorithms; we use BM-25 (Robertson et al., 1995), classic TF/IDF (Jones, 1972), as well as DFR-H and DFR-Z (Amati and Van Rijsbergen, 2002) models. These IR models capture lexical similarities and relevance between node pairs through different approaches; (b): we also use the initial text embeddings of nodes ($\mathbf{x}_i, \forall i$) as additional features because the direct uses of these embeddings at prediction layer can avoid information loss in the iterative process of learning node embeddings for graph data; and (c): if there exist other text information for a given node pair, e.g., a sentence mentioning the node pair as in Figure 1, we use the embeddings of such information as additional features.

2.1.3 Graph Text Decoder

For a given node pair (u,v), we combined representation of their additional features using a single hidden layer neural network as follows:

$$\mathbf{h}_{uv} = \texttt{ReLU}\big(\mathbf{W}^e\mathbf{a}_{uv} + \mathbf{b}^e\big), \quad (2)$$

where $\mathbf{a}$ is obtained by concatenating the additional feature vectors of u and v. We combine $\mathbf{h}_{uv}$ with node representations, $\mathbf{z}_u$ and $\mathbf{z}_v$, and pass them to a two layer decoder to predict their relations:

$$\mathbf{h} = \texttt{ReLU}\Big(\mathbf{W}^{last}f(\mathbf{h}_{uv}, \mathbf{z}_u, \mathbf{z}_v) + \mathbf{b}^{last}\Big), \quad (3)$$
$$p(u,v) = g\left(\mathbf{W}^{output}\mathbf{h} + \mathbf{b}^{output}\right),$$

where f is a fusion operator, g is the `sigmod` function, and $p(u,v)$ indicates the probability of an edge between nodes u and v. Flattened outer product, inner product, concatenation and 1-D convolution can be used as the fusion operator (Amiri et al., 2021). In our experiments, we obtained better performance using outer product, perhaps due to its better encoding of feature interactions:

$$f(\mathbf{h}_{uv}, \mathbf{z}_u, \mathbf{z}_v) = \mathbf{h}_{uv} \otimes [\mathbf{z}_u; \mathbf{z}_v]. \quad (4)$$

2.2 Generic Trend-aware Curricula

Graph neural networks are often trained using the standard or "rote" approach where samples are fed to the network in a random order for training (Hamilton et al., 2017). However, edges (and

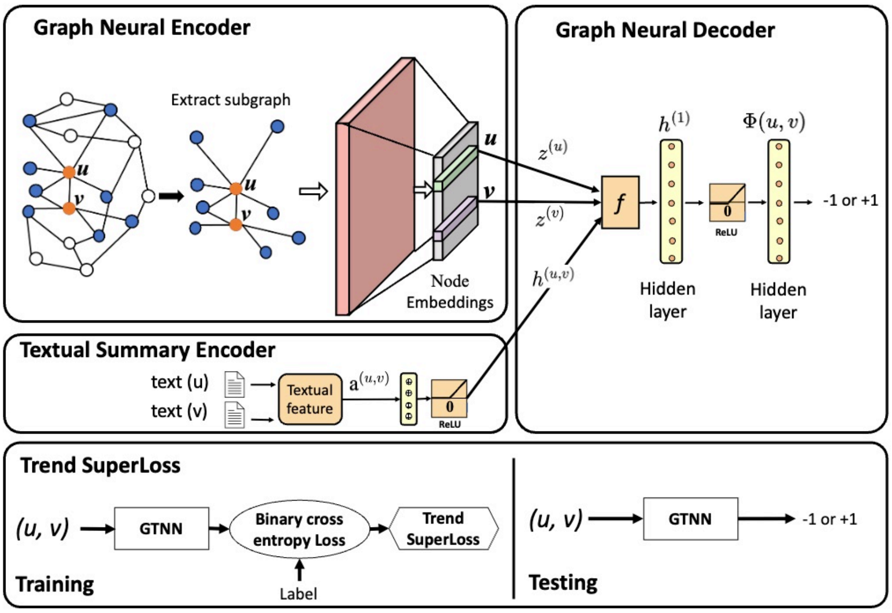


Figure 2: The architecture of the proposed graph text neural network (GTNN) model with Trend-SL curriculum learning approach. The proposed model consists of an encoder-decoder component that determines relations between given node pairs. The graph neural encoder takes as input features from textual descriptions of nodes and sub-graph extracted for a given node pair to create node embeddings. The resulting embeddings in conjunction with additional text features are *directly* used by the decoder to predict links between given entity pairs. The resulting loss is given as an input to our Trend-SL approach to dynamically learn a curriculum during training.

other entities in graphs such as nodes and subgraphs) can vary significantly in their classification difficulty, and therefore we argue that graph neural networks can benefit from a curriculum for training. Recent work by Castells et al. (2020) described a generic loss function called SuperLoss (SL) which can be added on top of any target-task loss function to dynamically weight training samples according to their difficulty for the model. Specifically, it uses a *global* difficulty threshold (τ), determined by the exponential moving average of all sample losses, and considers samples with an instantaneous loss smaller than τ as easy and the rest as hard. Similar to the commonly-used easy-to-hard transition curricula, such as those in (Bengio et al., 2009) and (Kumar et al., 2010), the model initially assigns higher weights to easier samples, thereby allowing back-propagation to initially focus more on easier samples than harder ones.

However, SL does not take into account the trend of instantaneous losses at sample-level, which can (a): improve the difficulty estimations of the model by making them *local*, *sample dependent* and potentially more *precise*, and (b): enable the model to distinguish samples with similar losses based on their known loss trajectories. For example, consider an easy sample with a rising loss trend which is about to become a hard sample versus another easy sample with the same instantaneous loss but a falling loss trend which is about to become further easier for the model. Trend information allows distinguishing such examples.

The above observations inspire our work to utilize trend information in our curriculum learning framework, called Trend-SL. The model uses loss information from the local time window before each iteration to capture a form of momentum of loss in terms of rising or falling trends and determine individual sample weights as follows:

$$\begin{aligned} TrendSL_{\lambda,\alpha}(l_{uv}) = \arg\min_{\sigma_{uv}} \big(l_{uv} - (\tau - \alpha\Delta_{uv})\big) \\ \times\sigma_{uv} + \lambda(\log\sigma_{uv})^2, \end{aligned} \tag{5}$$

where σ_{uv} is the latent weight for the training sample (u, v) , l_{uv} is the target-task loss (binary cross-entropy in our experiments) for (u, v) at current iteration, τ is the batch-level global difficulty threshold determined by the exponential moving average of sample losses (Castells et al., 2020), and $\Delta \in [-1, 1]$ is the trend indicator quantified by the normalized sample-level loss trend weighted by $\alpha \in [0, 1]$; our approach reduces to SL with $\alpha = 0$. Δ captures the trend in the instantaneous losses of samples over recent k iterations, effec-

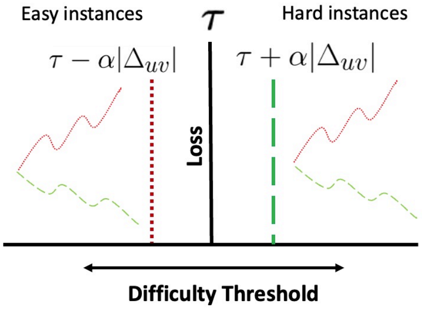

Figure 3: Difficulty dynamics in Trend-SL. τ is the fixed difficulty threshold of SL, which can be thought of as a global difficulty metric to separate easy and hard samples. Dotted (red) and dashed (green) trend lines indicate four samples with rising and falling loss trends respectively. Trend-SL uses trend dynamics to shift the difficulty boundaries and adjust global difficulty using local sample-level loss trends. The vertical dashed and dotted lines show updated sample-specific difficulty thresholds for easy and hard samples respectively.

tively utilizing local sample-level information to determine difficulty. There are various techniques for fitting trends to time series data (Bianchi et al., 1999). We use differences between consecutive losses to determine the trend for each sample:

$$\Delta_{uv} = \sum_{j=i-k+2}^{i} (l_{uv}^{j} - l_{uv}^{j-1}) / \sum_{j=i-k+2}^{i} | \, l_{uv}^{j} - l_{uv}^{j-1} \, |, \tag{6}$$

where i is the current iteration, $l^j_\cdot$ indicates loss at iteration j and k controls the number of previous losses to consider. As Figure 3 illustrates, Trend-SL increases the difficulty threshold for samples with falling loss trends (negative Δs), becoming more flexible in increasing the weights of such samples by allowing greater instantaneous losses. On the other hand, it becomes more conservative in weighting samples with rising trends (positive Δs) by reducing the difficulty threshold.

Finally, we note that the weight σ_{uv} in (5) can be computed as follows, where W is the Lambert W function (Euler, 1783); see details in the supplementary materials in (Castells et al., 2020):

$$\sigma_{uv}^{*} = \exp\Big(- W\big(\frac{1}{2}\max(-\frac{2}{e}, \beta)\big)\Big), \tag{7}$$

$$\beta = \frac{l_{uv} - (\tau - \alpha\Delta_{uv})}{\lambda}. \tag{8}$$

3 Experiments

3.1 Datasets

Gene, Disease, Phenotype Relation (GDPR) dataset contains textual descriptions for genes, diseases and phenotypes (symptoms) as well as their relations, and is obtained by combining two freely available datasets: Online Mendelian Inheritance in Man (OMIM) (Amberger et al., 2019) and Human Phenotype Ontology (HPO) (Köhler et al., 2021). OMIM is the primary repository of curated information on the causal relations between genes and rare diseases, and HPO provides mappings of phenotypes to genes/diseases in the OMIM.[1] We introduce a challenging experimental setup based on the task of *differential diagnosis* (Raftery et al., 2014) using GDPR, where competing models should distinguish relevant diseases to a gene from irrelevant ones that present *similar* clinical features, making the task more difficult because of high textual and structural similarity between relevant and irrelevant diseases. For example, diseases *3-methylglutaconic type I*, *Barth syndrome* and *3-methylglutaconic type III* are of the same disease type and have high lexical similarity in their descriptions, but they are not related to the same genes. We include such harder negative gene-disease pairs by sampling genes from those that are linked to diseases that share the same disease type with a target disease, but are not linked to the target disease. We also include an equal number of randomly sampled negative pairs to this set.

Gene Phenotype Relation (PGR) (Sousa et al., 2019) is created from PubMed articles and contains sentences describing relations between given genes and phenotypes (Figure 1). We only include data points with available text descriptions for their genes and phenotypes. For fair comparison, we apply the best model from (Sousa et al., 2019) to this dataset.

Wikipedia (Rozemberczki et al., 2021) is on the topic of the old world lizards Chameleons with 202 species. In this dataset, nodes represent pages and edges indicate mutual links between them. Each page has an informative set of nouns, which we use as additional features. We note that this dataset contains only these noun features but not the original

---

[1] A gene can cause one or more diseases and a disease can have several disease types. As a pre-processing step, we remove isolated nodes from the dataset and explicit mentions of relations between entities from summaries.

Metric	GDPR	PGR	Wikipedia
# Nodes	18.3K	20.4K	2.2K
# Edges	365.0K	605.4K	31.4K
# Sampled Edges	37.6K	3.0K	188.5K
→ # pos. Edges	6.2K	1.4K	31.4K
→ # neg. Edges	31.4K	1.6K	157.1K

Table 1: Statistics of the three datasets. Sampled edges are used to create training, validation and test sets. All models take the entire graph as input.

text, which is required by our text only models.

Table 1 shows statistics of these datasets. In case of GDPR and WIKIPEDIA, we create five negative examples for every positive pair. We divide these pairs into 80%, 10% and 10% as training, validation and test splits respectively. The data splits for PGR is the same as the original dataset, except that we discard data points (node pairs) that do not have text descriptions.

3.2 Baselines

We use the following baselines:

- **Co-occurrence** labels a test pair as positive if both entities occur together in the input text.
- **Relevance Score** uses scores from IR models (Section 2.1.2) as features of a logistic classifier.
- **Doc2Vec** (Le and Mikolov, 2014) uses domain-specific text embeddings obtained from Doc2Vec as features of a logistic classifier.
- **BioBERT** (Lee et al., 2020; Devlin et al., 2019) is a BERT model pre-trained on PubMed articles. BioBERT is most appropriate for relation extraction on both GDPR and PGR datasets as they are also developed based on PubMed articles. It is the current state-of-the-art model on PGR (Sousa et al., 2019). We also include a version of BioBERT that uses graph information by concatenating the representation of each given pair with the average embedding of its neighbors.
- **Graph Convolutional Network** (GCN) (Kipf and Welling, 2017) is an efficient and scalable approach based on convolution neural networks which directly operates on graphs.
- **Graph Attention Network** (GAT) (Veličković et al., 2018) extends GCN by employing self-attention layers to identify informative neighbors while aggregating their information, effectively prioritizing important neighbors for target tasks.
- **GraphSAGE** (Hamilton et al., 2017) is an inductive framework which aggregates node features and network structure to generate node embeddings, see (1). It uses both text and graph information. We use Doc2Vec (Le and Mikolov, 2014) embeddings to initialize node features of GraphSAGE, as they led to better performance than other embeddings in our experiments.
- **Graph Isomorphism Network** (GIN) (Xu et al., 2018) identifies the graph structures that are not distinguishable by the variants of graph neural networks like GCN and GraphSAGE. Compared to GraphSAGE and GCN, GIN uses extra learnable parameters during sum aggregation and uses MLP encoding.
- **CurGraph** (Wang et al., 2021) is a curriculum learning framework for graphs that computes difficulty scores based on the intra- and inter-class distributions of embeddings and develops a smooth-step function to gradually include harder samples in training. We report the results of our implementation of this approach.
- **SuperLoss** (SL) (Castells et al., 2020) is a generic curriculum learning approach that dynamically learns a curriculum from model behavior. It uses a fixed difficulty threshold at batch level, determined by the exponential moving average of all sample losses, to assign higher weights to easier samples than harder ones.

We compare these baselines against **GTNN** and **Trend-SL**, described in Section 2.

3.3 Settings

We reproduce the results reported in (Sousa et al., 2019) using BioBERT and therefore follow the same settings on the PGR dataset. Initial domain-specific node embeddings are obtained using Doc2Vec (Le and Mikolov, 2014) or Bio-BERT (Lee et al., 2020). In case of Bio-BERT, since nodes carry long descriptions, we first generate sentence level embeddings and use their average to represent each node, following (Zhang et al., 2020a). More recent techniques can be used as well (Beltagy et al., 2020). We consider 1-hop neighbors and set $t = 1$ in (1). To optimize our model, we use the Adam optimizer (Kingma and Ba, 2015) and apply hyper-parameter search and tuning for all competing models based on performance on validation data. In (5), we set α from $[0, 1]$ with a step size of 0.1, λ from $\{0.1, 0.5, 1.0, 5, 10, 100\}$, and loss window k from $[1, 10]$ with a step size of 1. We consider a maxi-

mum number of 100 training iterations with early stopping based on validation data for all models. In addition, we evaluate models based on the standard Recall, Precision and F1 score for classification tasks (Buitinck et al., 2013). We experiment with five random seeds and report the average results. For all experiments, we use Ubuntu 18.04 with one 40GB A100 Nvidia GPU, 1 TB RAM and 16 TB hard disk space. GPU hours to train our model have been linear to the size of the datasets ranging from 30 min to 5 hours. We use Precision (P), Recall (R) and F1 score (F1) as evaluation metrics.

3.4 Results

Table 2 shows the results. We start with text only and graph only baselines followed by baselines that incorporate both data modalities.

Text models (T): Comparing all text based model, Relevance Score and Doc2Vec outperform other models. In case of GDPR, high performance of Relevance Score indicates the ability of unsupervised IR models in finding relevant information in long text descriptions. However, Relevance Score shows poor performance on PGR compared to Doc2Vec, which is better at semantic representation of input data. BioBERT (node pair) obtains higher precision on both datasets and good performance on PGR. In addition, the F1 score of the BioBERT model developed in (Sousa et al., 2019) for PGR is 76.6. We note that Doc2Vec obtains better performance than BioBERT, perhaps due to its in-domain pre-training.

Graph models (G): The results show that GCN and GAT perform better than other competing graph models. We attribute their performance to the use of convolution and attention networks, which effectively prioritize important neighboring nodes with respect to the target tasks.

Graph models with additional information: Comparing GraphSAGE (Doc2Vec) and GraphSAGE (random) illustrates the significant effect of initialization with in-domain embeddings. In addition, GTNN outperforms GraphSAGE, resulting in an average of 8.6 points improvement in F1 score. This improvement is because GTNN *directly* uses text descriptions at its prediction layer. This information, although available to GraphSAGE as well, can be lost in the iterative process of learning node embeddings through neighbors, see (1).

Training with curricula: The results in Table 3 show that training GTNN with effective curricula can further improve its performance. We attribute the better performance of Trend-SL compared to SL to the use of trend information, which leads to better curricula. We conduct further analysis on the effect of trend information below. The lower performance of CurGraph could be due to close probability densities that we obtained for samples in our datasets, which do not allow easy and hard samples to be effectively discriminated by CurGraph.

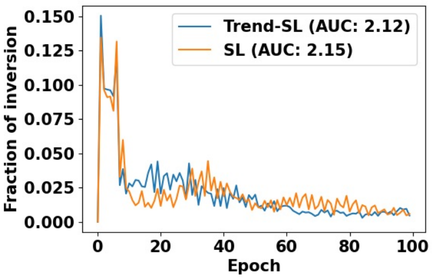

Figure 4: The fraction of samples with an inverted difficulty group in two consecutive epochs. Both models are converging on the their estimated difficulty classes of samples as training progresses. Trend-SL results in fewer inversions compared to SL; the area under the curve for Trend-SL is 2.12 compared to 2.15 of SL.

4 Trend Model Introspection

We conduct several ablation studies to shed light on the improved performance of Trend-SL.

4.1 Inversion Analysis

Trend-SL results in robust estimation of difficulty: In curriculum learning, instantaneous sample losses can fluctuate as model trains (Zhou et al., 2020). These changes result in samples being moved across easy and hard data groups. Let's define an *inversion* as an event where the difficulty group of a sample is inverted in two consecutive epochs (determined by curricula), i.e., an easy sample becomes hard in the next iteration or vice versa. Figure 4 shows the number of inversions in SL and Trend-SL during training. Both models converge on their estimated difficulty classes of samples as training progresses. However, we observe that Trend-SL results in fewer inversions compared to SL, as the area under the curve for Trend-SL is 2.12 compared to 2.15 of SL. Given these results and the performance of Trend-SL on our target tasks, we conjecture that trend information leads to more robust estimation of sample difficulty.

Transition patterns at inversion time: Let epoch e be the epoch at which an inversion occurs. Considering SL as the curriculum, Figure 5 reports the average normalized loss of samples at their inversion epochs (e) and k epochs before and after that. There are some insightful patterns: (a): easy-to-easy (E2E) and hard-to-hard (H2H) transitions are almost flat lines, indicating the lack of any significant trend when no inversion occurs; and (b): easy-to-hard (E2H) and hard-to-easy (H2E) transitions show that, on average, there is a sharp and significant increase and decrease in loss patterns as samples are inverted to hard and easy difficulty groups respectively. Since SL does not directly take into account trend information, these results show that trend dynamics can inform our technical objective of developing better curricula.

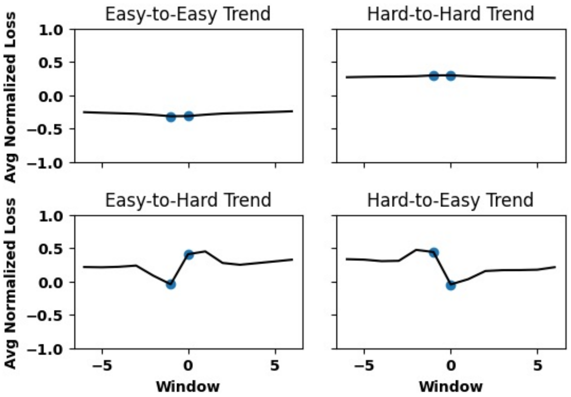

Figure 5: Transition in sample difficulty determined by SL. 0 on the x-axis denotes any epoch at which an inversion occurs, and the y-axis shows average normalized losses at epochs around the inversion epochs. Easy-to-Hard and Hard-to-Easy transitions show sharp and significant increase and decrease in losses respectively.

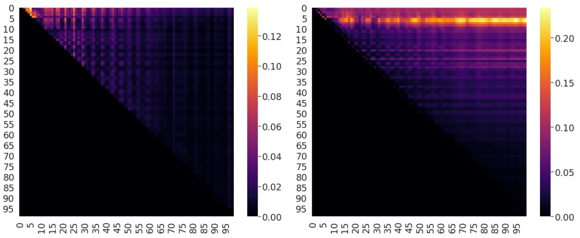
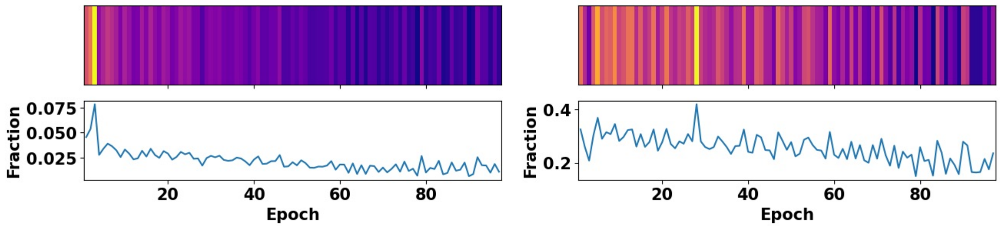


(a) Easy to Hard (b) Hard to Easy

Figure 6: Inversion dynamics at difficulty level during training: (a) inversions from easy to hard with rising loss trends and (b) inversions from hard to easy with falling loss trends. The initial epochs on the y-axis are brighter then later epochs, indicating that most inversions occur early in training.

Inversions occur early during training: Figure 6(a) shows the fraction of samples that were easy at epoch i but became hard with a rising trend at epoch $j > i$. The corresponding heatmap for Hard-to-Easy with falling trend is shown in Figure 6(b). In both case, the initial epochs (see the y-axis) are brighter then later epochs, indicating that most inversions occur early in training and the effect of trend is more prominent in the initial part of training.



(a) Easy to Hard

(b) Hard to Easy

Figure 7: Inversion heatmap when (a): easy samples with rising loss trend become hard (left) and (b): hard samples with falling loss trend become easy (right).

Inversions occur with falling or rising loss trends: SL does not use trend information. However, its estimated difficulty for a considerable fraction of samples (with falling or rising loss trends) is inverted during training. In fact, we observe that 21.2% to 50.0% of hard samples that have a falling loss trend will become easy in their next training iteration; similarly 1.3% to 11.1% of easy samples that have a rising loss trend will become hard in their next training iteration. Figure 7 shows the inversion heatmap for such Easy-to-Hard and Hard-to-Easy transitions in consecutive epochs. The area under the curve for Easy-to-Hard with rising trend and Hard-to-Easy with falling trend are 24.87 and 4.51 respectively. Trend-SL employs such trend dynamics to create better curricula.

4.2 Domain and Feature Analysis

In-domain embeddings improve the performance: In these experiments, we re-train our model with different embedding initialization. As shown in Figures 8, Doc2Vec embeddings result in an overall better performance than BioBERT and random initialization approaches across the datasets. We attribute this result to in-domain training using text summaries of genes, diseases and phenotypes associated to *rare* diseases. In addition, the performance using BioBERT embeddings is either comparable or considerably lower than that of other embeddings including Random. This is perhaps due to pre-training of BioBERT using a large scale PubMED dataset, which has a significantly lower prevalence of publications on rare versus common diseases. On the other hand, we directly optimize Doc2Vec on in-domain rare-disease datasets, which leads to higher performance of the model. We tried to fine tune BioBERT on our corpus but as the text summaries are long, only a small fraction of texts (512 tokens) can be considered.

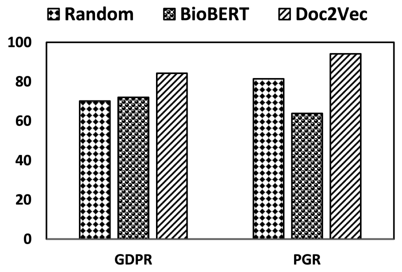


Figure 8: Performance of GTNN with Trend-SL with additional features.

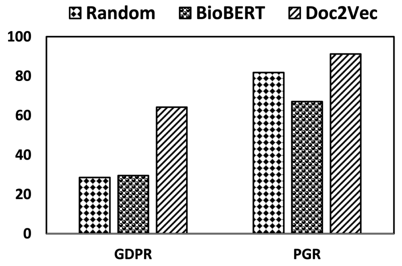

Figure 9: Performance of GTNN with Trend-SL without additional features.

Additional Features improve the performance: We re-train our models and exclude additional feature (i.e., relevance scores for GDPR and sentence embeddings for PGR), with different node embedding initialization. Figure 9 shows that excluding these features considerably reduces the F1-scores of our model across datasets and embedding initialization. These results show that both text features and information obtained from graph structure contribute to predicting relations between nodes.

5 Related Work

Previous research on relation extraction can be categorized into text- and graph-based approaches. In addition, to our knowledge, there is limited work on curriculum learning with graph datasets.

Text-based models: Text-based methods extract entities and the relations between them from given texts. Although, previous works typically focus on extracting intra-sentence relations for entity pairs in supervised and distant supervised settings (Sousa et al., 2019; Mintz et al., 2009; Dai et al., 2019; Lin et al., 2016; Peng et al., 2017; Zhang et al., 2018; Fout et al., 2017; Zhang and Chen, 2018; Quirk and Poon, 2017), there are relation extraction approaches that focus on inter-sentence relations (Kilicoglu, 2016; Yao et al., 2019b). Kilicoglu (2016) investigated multi-sentence relation extraction between chemical-disease entity pairs mentioned at multi-sentence level. They considered lexical features, and features obtained from intervening sentences as input to a classifier. A close related work to our study has been conducted by Sousa et al. (2019), who developed an effective model to detect relations between genes and phenotypes at sentence-level using sentential context and medical named entities in text. We compared our approach with Sousa et al. (2019) on the dataset that they developed (PGR), see Section 3.2.

Graph based models: Previous research show that adding informative additional features with graph helps models learn better node representations for extracting relation between entity pairs. For example, Zhang and Chen (2018) used distance metric information, and Li et al. (2020) used distance features like shortest path and landing probabilities between pair of nodes in subgraphs as additional features. We note that some graph properties, although informative and effective, can be expensive to calculate on large graphs during training and should be computed offline.

Curriculum learning with graph data: Curriculum learning approaches design curricula for model training and generalizability (Bengio et al., 2009; Kumar et al., 2010; Jiang et al., 2015; Amiri et al., 2017; Jiang et al., 2018; Castells et al., 2020; Zhou et al., 2020). The common approach is to detect and use easy examples to train the model and gradually add harder examples as training progresses. Curricula can be static and pre-built by humans or can be automatically and dynamically learned by the model. There are very few curriculum learning methods designed to work on the graph structure. Wang et al. (2021) developed CurGraph, which is a curriculum learning method for sub-graph classification. The model estimates the difficulty of samples using intra and inter-class distributions of sub-graph embeddings and orders training instances to initially expose easy sub-graphs to the underlying graph neural network followed by harder ones. As opposed to static curriculum, Saxena et al. (2019) introduced a dynamic curriculum approach which automatically assigns a confidence score to samples based on their estimated difficulty. However, the model requires a large number of extra trainable parameters especially when data set is large. To overcome this limitation, Castells et al. (2020) introduced a framework with similar idea but calculates the optimal confidence score for each instances using a closed-form solution, thereby avoiding learning extra parameters. We extended this approach to include trend information at sample-level for learning effective curriculum.

Graph neural networks for NLP: There are several distantly related work that develop graph neural network algorithm for downstream tasks such as semantic role labeling (Marcheggiani and Titov, 2017), machine translation (Bastings et al., 2017; Marcheggiani et al., 2018), multimedia event extraction (Liu et al., 2020), text classification (Yao et al., 2019a; Zhang et al., 2020b) and abstract meaning representation (Song et al., 2018). Graph neural networks are used to model word-word or word-document relations, or applied to dependency trees. Yao et al. (2019a) generated a single text graph using word occurrences and document word relations from text data, and used the GCN method to learn embeddings of words and documents. Similarly, Peng et al. (2018) used GCN to capture the semantics between non-consecutive and long-distance entities.

6 Conclusion and Future Work

We propose a novel graph neural network approach that effectively integrates textual and structural information and uses loss trajectories of samples during training to learn effective curricula for predicting relations between given entity pairs. Our approach can be used for both sentence- and document-level relation extraction, and shows a sizable improvement over the state-of-the-art models across several datasets. In future, we will investigate curriculum learning approaches for other sub-tasks of relation extraction, develop more effective techniques to better fit trends to time series data, and investigate the effect of curricula on other graph neural networks for relation extraction.

Ethical statement

This investigation partially uses data from the field of medicine. Specifically, it includes genes, diseases and phenotypes that contribute to rare diseases. Although the present work does not include any patient information, it is translational in nature and its broader impacts are first and foremost the potential to improve the well-being of individual patients in the society, and support clinicians in their diagnostic efforts, especially for rare diseases. Our work can also help Wikipedia curators and content generators in finding relevant concepts.

On Systematic Style Differences between Unsupervised and Supervised MT and an Application for High-Resource Machine Translation

Abstract

Modern unsupervised machine translation (MT) systems reach reasonable translation quality under clean and controlled data conditions. As the performance gap between supervised and unsupervised MT narrows, it is interesting to ask whether the different training methods result in systematically different output beyond what is visible via quality metrics like adequacy or BLEU. We compare translations from supervised and unsupervised MT systems of similar quality, finding that unsupervised output is more fluent and more structurally different in comparison to human translation than is supervised MT. We then demonstrate a way to combine the benefits of both methods into a single system which results in improved adequacy and fluency as rated by human evaluators. Our results open the door to interesting discussions about how supervised and unsupervised MT might be different yet mutually-beneficial.

1 Introduction

Supervised machine translation (MT) utilizes parallel bitext to learn to translate. Ideally, this data consists of natural texts and their human translations. In a way, the goal of supervised MT training is to produce a machine that mimicks human translators in their craft. Unsupervised MT, on the other hand, uses monolingual data alone to learn to translate. Critically, unsupervised MT *never sees an example of human translation*, and therefore *must create its own style of translation*. Unlike supervised MT where one side of each training sentence pair must be a translation, unsupervised MT can be trained with natural text alone.

In this work, we investigate the output of supervised and unsupervised MT systems of similar quality to assess whether systematic differences in translation exist. Our exploration of this research area focuses on English→German for which abundant bilingual training examples exist, allowing us to train high-quality systems with both supervised and unsupervised training.

Our main contributions are:

- We observe systematic differences between the output of supervised and unsupervised MT systems of similar quality. High-quality unsupervised output appears **more natural**, and more **structurally diverse** when compared to human translation.
- We show a way to incorporate unsupervised back-translation into a standard supervised MT system, improving adequacy, naturalness, and fluency as measured by human evaluation.

Our results provoke interesting questions about what unsupervised methods might contribute beyond the traditional context of low-resource languages which lack bilingual training data, and suggest that unsupervised MT might have contributions to make for high-resource scenarios as well. It is worth exploring how combining supervised and unsupervised setups might contribute to a system better than either creates alone.

We discuss related work in §2. In §3, we introduce the dataset, model details, and evaluation setups. In §4, we characterize the differences between the output of unsupervised and supervised neural MT systems of similar quality. In §5, we demonstrate a combined system which benefits from the complementary strengths of the two methods. We summarize the paper in §6.

2 Related Work

Unsupervised MT Two paradigms for unsupervised MT are finding a linear transformation to align two monolingual embedding spaces (Lample et al., 2018a,b; Conneau et al., 2018; Artetxe et al., 2018, 2019), and pretraining a bi-/multilingual language model then finetuning on a translation task (Conneau and Lample, 2019; Song et al., 2019; Liu et al., 2020). We study the Masked Sequence-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2214 - 2225
July 10-15, 2022

to-Sequence Pretraining (MASS) language model pretraining paradigm of Song et al. (2019). MASS is an encoder-decoder trained jointly with a masked language modeling objective on monolingual data. Iterative back-translation (BT) follows pretraining.

Monolingual Data in MT BT is widely-used to exploit monolingual data (Sennrich et al., 2016). "Semi-supervised" systems use monolingual and parallel data to improve performance (e.g. Artetxe et al. (2018)). Siddhant et al. (2020) combine multilingual supervised training with MASS for many languages and zero-shot translation.

Source Artifacts in Translated Text Because supervised MT is trained ideally on human-generated translation, characteristics of human translation affects the style of machine translation from such systems. Dubbed "translationese," human translation includes source language artifacts (Koppel and Ordan, 2011) and source-independent artifacts—*Translation Universals* (Mauranen and Kujamäki, 2004). There are systematic biases inherent to translated texts (Baker, 1993; Selinker, 1972), and biases coming from interference from source text (Toury, 1995). In MT, Freitag et al. (2019, 2020) attribute these patterns as a source of mismatch between BLEU (Papineni et al., 2002) and human evaluation measures of quality, raising concerns that overlap-based metrics reward hypotheses with the characteristics of translated text more than those with natural language. Vanmassenhove et al. (2019, 2021) note loss of linguistic diversity and richness from MT, and Toral (2019) see related effects even after human post-editing. The impact of translated text on human evaluation has also been studied (Toral et al., 2018; Zhang and Toral, 2019; Graham et al., 2019; Fomicheva and Specia, 2016; Ma et al., 2017), as has the impact in training data (Kurokawa et al., 2009; Lembersky et al., 2012; Bogoychev and Sennrich, 2019; Riley et al., 2020).

Measuring Word Reordering Word reordering models are well-studied because they formed a critical part of statistical MT (see Bisazza and Federico (2016) for a review). Others examined metrics for measuring reordering in translation (e.g. Birch et al., 2008, 2009, 2010). Wellington et al. (2006) and Fox (2002) use part-of-speech (POS) tags in the context of parse trees, and Fox (2002) measure the similarity of French and English with respect to phrasal cohesion by calculating alignment crossings using parse trees. Most similar to us, Birch (2011) view simplified word alignments as permutations and compare distance metrics over these to quantify the amount of reordering done. They use TER computed over the alignments as a baseline. Birch and Osborne (2011)'s LRScore interpolates a reordering metric with a lexical translation metric.

3 Experimental Setup

3.1 Data

Training Experiments are in English→German. For the main study comparing supervised and unsupervised MT, we use News Commentary v14 (329,000 sentences) as parallel bitext for the supervised system, and News Crawl 2007-17 as monolingual data for the unsupervised system. Deduplicated News Crawl 2007-17 has 165 million English sentences and 226 million German sentences.

The combined system demonstration at the end of our work utilizes a BT selection method. We use the bilingual training data from WMT2018 (Bojar et al., 2018) (News Commentary v13, Europarl v7, Common Crawl, EU Press Release) so that our model can be compared with well-known work using BT (e.g. Edunov et al., 2018; Caswell et al., 2019). We deduplicate and filter out pairs with > 250 tokens in either language or length ratio over 1.5, resulting in 5.2 million paired sentences.

Development and Test Sets For the main experiments, we use newstest2017 as the dev set with newstest2018 and newstest2019 for test. newstest2018 was originally created by translating one half of the test data from English→German (orig-en) and the other half from German→English (orig-de). Since 2019, WMT produces newstest sets with only source-original text and human translations on the target side to mitigate known issues when translating and evaluating on target-original data (e.g. Koppel and Ordan, 2011; Freitag et al., 2019).

For most experiments, we evaluate on orig-en sentences only to reflect the real use-case for translation and modern evaluation practice. We examine orig-de only for BLEU score as an additional data point of difference between supervised and unsupervised MT. Zhang and Toral (2019) show that target-language-original text should not be used for human evaluation (orig-de, in our case).

We use the newstest2018 "paraphrased" test references from Freitag et al. (2020),[1] which are made

---

[1] github.com/google/wmt19-paraphrased-references

for orig-en sentences only. These additional references have different structure than the source sentence but maintain semantics, and provide a way to measure system quality without favoring translations with the same structure as the source. Observing work that uses these references, BLEU is typically much lower than on original test sets, and score differences tend to be small but reflect tangible quality difference (Freitag et al., 2020).

For the system combination demonstration, we use newstest2018 for development and newstest2019 for test. We also use newstest2019 German→English and swap source and target to make an orig-de English→German test set, and use paraphrase references for newtest2019 (orig-en).

Testing on the official newstest2018 in the main experiments allows us to see interesting differences between unsupervised and supervised MT that are hidden with newstest2019 because it is orig-en only. Using newstest2018 for development in the system combination demonstration aligns with similar literature (e.g. Edunov et al., 2018; Caswell et al., 2019). We use SacreBLEU throughout (Post, 2018).[2]

3.2 Part-of-Speech Tagging

We use part-of-speech taggers for some experiments: universal dependencies (UD) implemented in spaCy[3] and spaCy's language-specific fine-grained POS tags for German from the TIGER Corpus (Albert et al., 2003; Brants et al., 2004).

3.3 Models

Our **unsupervised MT** model is a MASS transformer with the hyperparameters of Song et al. (2019). We train MASS on the News Crawl corpora, hereafter called "Unsup." Our **supervised MT** systems use the transformer-big (Vaswani et al., 2017) as implemented in *Lingvo* (Shen et al., 2019) with a vocabulary of 32k subword units.

To investigate differences between approaches, we train two **language models** (LMs) on different types of data and calculate the perplexity of translations generated by the supervised and unsupervised MT systems. We train one LM on the monolingual German News Crawl dataset with a decoder-only transformer, hereafter called the "natural text LM" (nLM). We train another on machine translated sentences which we call the "translated text LM" (tLM). We generate the training corpus by translating the English News Crawl dataset into German with a English→German transformer-big model trained on the WMT18 bitext.

3.4 Human Evaluations

Human evaluation complements automatic evaluation and abstracts away from comparison to a human reference which favors the characteristics of translated text (Freitag et al., 2020). We score adequacy using direct assessment and run side-by-side evaluations measuring fluency and adequacy preference between systems. Each campaign has 1,000 test items. For side-by-side eval, a test item includes a pair of translations of the same source sentence: one from the supervised system and one from the unsupervised. We hire 12 professional translators, who are more reliable than crowd workers (Toral, 2020; Freitag et al., 2021).

Direct Assessment Adequacy We use the template from the WMT 2019 evaluation campaign. Human translators assess a translation by how adequately it expresses the meaning of the source sentence on a 0-100 scale. Unlike WMT, we report the average rating and do not normalize the scores.

Side-by-side Adequacy Raters see a source sentence with two translations (one supervised, one unsupervised) and rate each on a 6-point scale.

Side-by-side Fluency Raters assess the alternative translations (one supervised, one unsupervised) without the source, and rate each on a 6-point scale.

4 Unsupervised vs. Supervised MT

The goal of this section is to analyse supervised and unsupervised systems of similar overall translation quality so that differences in quality do not confound analyses. As unsupervised systems underperform supervised systems, we use a smaller parallel corpus (news commentary) to train systems of similar quality. Table 1 summarizes the BLEU scores and human side-by-side adequacy results for both systems. Although the supervised system is below state-of-the-art, these experiments help elucidate how unsupervised and supervised output is different. Overall BLEU and human ratings suggest similar translation quality. Nevertheless, we observe notable differences between orig-de and orig-en sides of the test set when comparing both systems. Recall that orig-de has natural German text on the target side. Unsup scores higher than Sup on orig-de, suggesting that its output is more natural-sounding

---

[2] BLEU+case.mixed+lang.ende+numrefs.1+smooth.exp+{TESTSET}+tok.13a+version.1.4.12

[3] https://spacy.io/, https://universaldependencies.org/

as it better matches text originally written in German. Performance discrepancies on orig-en and orig-de indicate that differences in system output may exist and prompt further investigation.

	Overall	orig-en	orig-de	nt18p	Human Adq.
Sup	29.2	34.0	21.1	9.3	3.89
Unsup	30.1	30.9	27.1	9.6	3.82

Table 1: SacreBLEU & human adequacy (orig-en) on newstest2018 and newstest2018p (nt18p = paraphrase reference). nt18p is available for orig-en only.

4.1 Selecting Translations of Same Adequacy

To assess the translation style and compare linguistic aspects of supervised and unsupervised MT, we further must compare translations that have the same accuracy level on the segment level, so that neither confounds analysis. We use the adequacy evaluation from Table 1 and retain sentences for which both approaches yield similar adequacy scores. We divide the rating scale into bins of low (0–2), medium (3–4), and high (5–6) adequacy. Table 2 shows the percentage of sentences in each bin. For each source sentence, there is one translation by Unsup and one by Sup. If human judges assert that both translations belong in the same adequacy bin, that sentence also appears in "Both." There are 86, 255, and 218 sentences in "Both" for low, medium, and high bins, respectively. For subsequent analyses, we examine sentences falling into "Both."

	Low	Medium	High
Sup	18.7%	42.1%	39.2%
Unsup	19.3%	44.6%	36.1%
Both	8.6%	25.5%	21.8%

Table 2: Percentage of sentences with low, medium and high human-evaluated adequacy ratings. "Both" are sentences which have same rating from both systems.

4.2 Comparing Translation Style

Measuring Structural Similarity We develop a metric to ascertain the degree of structural similarity between two sentences, regardless of language. When evaluated on a source-translation pair, it measures the influence of the source structure on the structure of the output without penalizing for differing word choice; thus it is a measure of "monotonicity" – the degree to which words are translated in-order. Given alternative translations in the same language, it assesses the degree of structural similarity between the two. Thus given a machine translation and a human translation of the same source sentence, it can measure the structural similarity between the machine and human translations.

Word alignment seems well-suited here. Like Birch (2011), we calculate Kendall's tau (Kendall, 1938) over alignments of source-translation pairs, but do not simplify alignments to permutations. We use fast_align (Dyer et al., 2013) but observe that it struggles to align words not on the diagonal, so sometimes skipped alignments.[4] Because of this issue, we instead estimate monotonicity/structural similarity using the new metric, introduced next.

We propose measuring translation edit rate (TER, Snover et al. (2006)) over *POS tag sequences*. TER is a well-known word-level translation quality metric which measures the number of edits required to transform a "hypothesis" sentence into the reference, outputting a "rate" by normalizing by sentence length. Between languages, we compute TER between POS tag sequences of the source text (considered the reference) and the translation (considered the hypothesis), so that TER now measures changes in *structure* independent of word choice. Source-target POS sequences which can be mapped onto each other with few edits are considered similar—a sign of a monotonic translation. Given a machine translation (hypothesis) and a human reference in the same language, TER over POS tags measures *structural similarity between the machine and human translations*. Outputs with identical POS patterns score 0, increasing to 1+ as sequences diverge. Lower TER for (source, translation) pairs indicates monotonic translation; Lower TER for (machine translation, human translation) pairs indicates structural similarity to human translation. We call the metric "posTER".

Monotonicity POS sequences are comparable across languages thanks to universal POS tags. Table 3 has a toy example with two possible German translations of an English source. Next to each sentence is its universal dependencies POS sequence. In the third column, TER is calculated with the POS sequence of the English source as reference and the sequence of the translation as hypothesis.

Table 4 shows posTER over universal dependencies of German translations versus the newstest2018 (orig-en) source sentences. While the standard newstest2018 references (Ref) score 0.410, newstest2018p's (RefP) higher score of 0.546 reflects the fact that the paraphrase references are designed to have different structure than the source. Difference in overall monotonicity between Sup and Unsup is unapparent at this granularity.

Because universal dependencies are designed to

---

[4] We ran fast_align with and without diagonal-favoring and all 5 symmetrization heuristics, and see similar trends.

Sentence	**POS Sequence**	**TER**
I made myself a cup of coffee this morning.	*PRON VERB PRON DET NOUN ADP PNOUN DET NOUN PUNCT*	-
Ich habe mir heute Morgen eine Tasse Kaffee gemacht.	PRON AUX PRON ADV NOUN DET NOUN NOUN VERB PUNCT	0.5
Heute morgen habe ich mir eine Tasse Kaffee gemacht.	ADV ADV AUX PRON PRON DET NOUN NOUN VERB PUNCT	0.7

Table 3: posTER over universal dependencies POS sequences for example toy German translations of an English source. Row 1 is the source with its POS tag sequence. Rows 2/3 are example translations with the POS tags of each. posTER is calculated via the POS sequences of the translation (hypothesis) and the source (considered the reference).

	nt18	**nt18p**	**Sup**	**Unsup**
Src	0.410	0.546	0.409	0.399

Table 4: posTER (0-1+) over universal dependencies of translations of newstest2018 (orig-en) vs. the source. ↓ = more monotonic translation. nt18p=paraphrase ref.

suit many languages, the 17 UD categories may be too broad to adequately distinguish moderate structural difference. Whereas UD has a single class for "VERB," the finer-grained German TIGER tags distinguish between 8 sub-verb types including infinitive, modal, and imperative. We use these language-specific categories next to uncover differences between systems that broad categories conceal.

Similarity to Human Translation Recall that supervised MT essentially mimics human translators, while unsupervised MT learns to translate without examples. Intuitively, supervised MT output might be stylistically more like human translation, even when controlling for quality. The first indication is Sup's lower BLEU score on nt18p—the paraphrase test set designed to have structure different than the original human translation.

We compare the structure of MT output with the human reference using German TIGER tags. Lower posTER indicates more structural similarity, while higher posTER indicates stylistic deviation from human translation. Comparison with the newstest2018 orig-en human reference is in Table 5. Sup and Unsup show negligible difference overall, but binning by adequacy shows Unsup output as *less structurally similar to the human reference on the high-end of adequacy*, and more similar on the low-end. This suggests systematic difference between systems, and that unsupervised MT might have more structural diversity as quality improves.

	Overall	**Low**	**Med**	**High**
Sup	0.280	0.348	0.282	0.255
Unsup	0.287	0.313	0.298	0.296

Table 5: posTER (0-1+ scale) over TIGER POS tags of system output vs. the human reference, grouped by adequacy (newstest2018, orig-en). ↓ = greater structural similarity to the human reference.

Naturalness The first hint that Unsup might produce more natural output than Sup is its markedly higher BLEU on the orig-de test set: 27.1, versus 21.1 from Sup. Recall that orig-de has natural German on the target side, so higher BLEU here means higher n-gram overlap with natural German.

Edunov et al. (2020) recommend augmenting BLEU-based evaluation with perplexity from a language model (LM) to assess fluency or naturalness of MT output. Perplexity (Jelinek et al., 1977) measures similarity of a text sample to a model's training data. We contrast the likelihood of output according to two LMs: one trained on machine-translated text (tLM) and another trained on non-translated natural text (nLM). While machine-translated and human-translated text differ, the LMs are nonetheless a valuable heuristic and contribute insights on whether systematic differences between MT system outputs exist. Low perplexity from the nLM indicates natural language. Low perplexity from the tLM (trained on English News Crawl that has been machine-translated into German) shows proximity to training data composed of translated text, indicating simplified language.

Sup perplexity is lower than Unsup across adequacy bins for the tLM, seen in Table 6. Conversely, Sup generally has higher perplexity from the nLM. All adequacy levels for Unsup have similar nLM perplexity, suggesting it is particularly skilled at generating fluent output. Together, these findings suggest that *unsupervised MT output is more natural* than supervised MT output.

Stronger Supervised MT Though analyzing systems of similar quality is important for head-to-head comparison, we evaluate a stronger supervised system for context.[5] We do not have human evaluation scores, but automatic results give insight: see Table 7. The model has overall BLEU = 40.9 and a similarly large discrepancy on orig-en vs. orig-de as did the Sup system used throughout this

---

[5] Trained on 4.5 million lines of WMT14 bitext.

	Natural Text LM ↓				Translated Text LM ↑			
	Overall	*Low*	*Medium*	*High*	*Overall*	*Low*	*Medium*	*High*
Sup	72.69	90.61	76.36	**68.37**	41.06	51.91	40.32	36.70
Unsup	**67.01**	**68.32**	**60.56**	69.88	**58.17**	**61.50**	**53.71**	**57.95**

Table 6: Perplexity of MT output on newstest2018 based on LMs trained on natural text vs. translated text, binned by adequacy. Sup and Unsup are comparable supervised and unsupervised MT systems, respectively. ↓ from the Natural Text LM and ↑ from the Translated Text LM indicate more natural-sounding output.

work: 44.6 for orig-en and 34.9 for orig-de. As for structural similarity, this stronger system has lower overall posTER vs. the human reference—0.238 vs. 0.280/0.287 from Sup/Unsup—indicating even more structural similarity with the reference. For naturalness, the stronger system has lower perplexity from the nLM. As a higher-quality system, this is expected. At the same time, it scores much lower than Sup and Unsup by the tLM, where higher indicates more natural-sounding output: 29.23 vs. 41.06/58.17 for Sup/Unsup.

Quality		Structural Sim.		Naturalness	
BLEU	nt18p	v. Src	v. Ref	nLM	tLM
40.9	12.1	0.401	0.238	54.35	29.23

Table 7: Strong supervised model trained on WMT14. Structural sim. is posTER: v. Src is comparable to Table 4, v. Ref to *Overall* in Table 5. ↓ = more monotonic. nLM/tLM are Natural/Translated Text LMs of Table 6.

Ablation: Architecture vs. Data One reason Unsup might produce more natural-sounding output could be simply that it develops language-modeling capabilities from natural German alone, whereas Sup must see some translated data (being trained on bitext of human translations). Next, we ask whether the improved naturalness and structural diversity is due to the unsupervised NMT architecture, or simply the natural training data.

We build a supervised en-de MT system with 329,000 paired lines of translated English source and natural German, where the source is back-translated German News Crawl from a supervised system. In other words, we train on backtranslated data only on the source side and natural German as the target. The model thus develops its language-modeling capabilities on natural sentences alone. If more natural output is simply a response to training on natural data, then this supervised system should perform as well in naturalness as Unsup, or better.

We train another unsupervised system on translated text only. Source-side training data is synthetic English from translating German News Crawl with a supervised system. Target-side is synthetic German which was machine-translated from English News Crawl. If naturalness solely results from data, this system should perform worst, being trained *only* on translated (unnatural) text.

Table 8 shows the results. The original unsupervised system (Unsup) performs best according to both LMs, having output that is more natural and less like translated text. When given only natural German to build a language model, the supervised system (Sup En-Trns/De-Orig) *still* produces more unnatural output than Unsup. Even when the unsupervised system uses translated data only (Unsup-Trns), its output is *still* more natural than the original supervised system (Sup) according to both LMs. This is a surprising result, and is interesting for future study. Together, these findings suggest that both German-original data *and* the unsupervised architecture encourage output to sound more natural.

5 Application: Leveraging Unsupervised Back-translation

Our results indicate that high-adequacy unsupervised MT output is more natural and more structurally diverse in comparison to human translation, than is supervised MT output. We are thus motivated to use these advantages to improve translation. We explore how to incorporate unsupervised MT into a supervised system via back-translation. We train for ∼500,000 updates for each experiment, and select models based on validation performance on newstest2018. We test on newstest2019(p).

5.1 Baselines

The first row of Table 9 is the supervised baseline trained on the WMT18 bitext. The second row is Unsup, used throughout this work.

We back-translate 24 million randomly-selected sentences of German News Crawl twice: once using a supervised German-English system trained on WMT18 bitext with a transformer-big architecture, and once using Unsup. Both use greedy decoding for efficiency. We augment the WMT18 bitext with either the supervised or unsupervised BT.

Seen in Table 9, adding supervised BT (+SupBT) performs as expected; minorly declining on the source-original test set (orig-en), improving on the target-original set (orig-de), and improving on

	LM Perplexity (PPL)		BLEU		
	Natural Text LM	**Translated Text LM**	**Overall**	**orig-en**	**orig-de**
Supervised (Sup)	72.69	41.06	29.2	34.0	21.1
Sup En-Trns/De-Orig	69.75	50.65	35.4	35.5	34.1
Unsup	**67.01**	**58.17**	30.1	30.9	27.1
Unsup-Trns	69.88	48.90	33.4	35.4	28.4

Table 8: Comparison of 4 English→German MT systems: ppl from LMs trained on natural or translated text, BLEU on newstest2018. ↓ ppl = model prefers the output. Sup En-Trns/De-Orig is supervised, trained on translated English and German-original News Crawl. Unsup is trained on natural English and German News Crawl. Unsup-Trns uses translated News Crawl only. Unsup performs best == more like natural text and less like translated text.

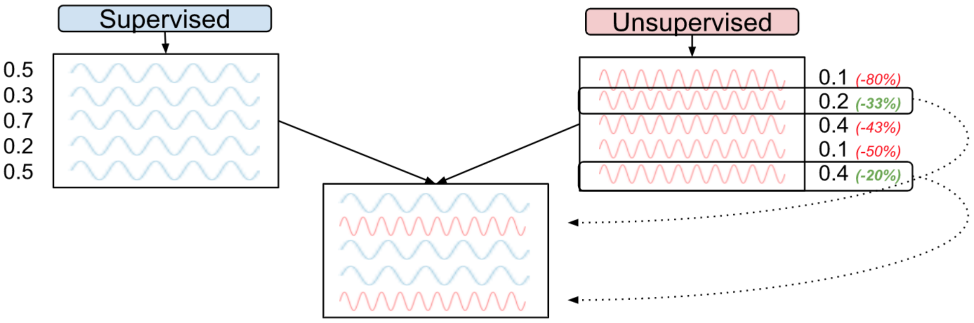

Figure 1: Back-translation selection method. Both systems translate the same source sentences. If an unsupervised output sentence is more than T% as likely as the supervised one, select the unsupervised. Here, T=65%.

the paraphrase set (nt19p). Conversely, adding unsupervised BT (+UnsupBT) severely lowers BLEU on source-original and paraphrase test sets. Randomly-partitioning the BT sentences such that 50% are supervised BT and 50% are unsupervised also lowers performance on orig-en (+50-50BT).

5.2 Tagged BT

Following Caswell et al. (2019), we tag BT on the source-side. Tagging aids supervised BT (+SupBT_Tag) and greatly improves unsupervised BT (+UnsupBT_Tag), which outperforms the baseline and is nearly on-par with +SupBT_Tag. Combining supervised and unsupervised BT using the same tag for both (+50-50BT_Tag) shows no benefit over +SupBT_Tag. +50-50BT_TagDiff uses different tags for supervised vs. unsupervised BT.

5.3 Probability-Based BT Selection

We design a BT selection method based on translation probability to exclude unsupervised BT of low quality. We assume that supervised BT is "good enough." Given translations of the same source sentence (one supervised, one unsupervised) we assert that an unsupervised translation is "good enough" if its translation probability is similar or better than that of the supervised translation. If much lower, the unsupervised output may be low-quality.

- Score each supervised and unsupervised BT with a supervised de-en system.
- Normalize the translation probabilities to control for translation difficulty and output length.
- Compare probability of the supervised and unsupervised BT of the same source sentence:
$$\Delta P = \frac{P\text{norm}(\text{unsup})}{P\text{norm}(\text{sup})}$$
- Sort translation pairs by ΔP.
- Select the unsupervised BT for pairs scoring highest ΔP and the supervised BT for the rest.

This filters out unsupervised outputs less than a hyperparameter T% as likely as the corresponding supervised sentence and swaps them with the corresponding supervised sentence. Importantly, the same 24M source sentences are used in all experiments. The procedure is shown in Figure 1.

Full results varying T are in the Appendix for brevity, but we show two example systems in Table 9. The model we call "+MediumMix_Tag" uses the top ∼40% of ranked unsupervised BT with the rest supervised (9.4M unsupervised, 14.6M supervised). "+SmallMix_Tag" uses the top ∼13% of unsupervised BT (3.1M unsupervised, 20.9M supervised).[6] We use the same tag for all BTs. Improvements are modest, but our goal was to demonstrate how one might use unsupervised MT output rather than build a state-of-the-art system.

+SmallMix_Tag performs better than the previous best on newstest2018p and +MediumMix_Tag performs highest overall on nt19p. We recall

---

[6] The numbers are not round because data was selected using round numbers for the hyperparameter T.

	newstest2018				**newstest2019**		
	Overall	**orig-en**	**orig-de**	**nt18p**	**orig-en**	**orig-de**	**nt19p**
Supervised Baseline (5.2M)	41.8	46.1	34.3	12.6	38.8	30.4	11.7
Unsup *(used throughout this work)*	30.1	30.9	27.1	9.6	24.6	28.5	8.8
Supervised Baseline							
+ SupBT	43.4	43.7	41.8	12.5	37.0	**39.9**	12.0
+ UnsupBT	33.3	33.8	31.1	9.9	27.2	30.8	9.5
+ 50-50BT	38.0	36.4	39.0	12.9	29.4	38.3	10.0

+ 50-50BT_TagDiff	44.4	46.8	40.1	13.0	39.9	37.9	12.4
+ SmallMix_Tag	**44.8**	46.8	40.8	**13.2**	39.8	38.8	12.5
+ MediumMix_Tag	44.7	46.8	40.8	13.0	40.1	38.2	**12.6**

Table 9: SacreBLEU of supervised baseline plus 24M supervised or unsupervised BTs. +MediumMix_Tag and +SmallMix_Tag use the BT selection method of §5.3. +MediumMix_Tag has 9.4M unsupervised BT and 14.6M supervised BT. +SmallMix_Tag has 3.1M and 20.9M, respectively. nt18p and nt19p are paraphrase references from Freitag et al. (2020), where small BLEU score changes can indicate tangible quality difference.

that small differences on paraphrase test sets can signal tangible quality differences (Freitag et al., 2020). Trusting BLEU on nt19p, we use *+MediumMix_Tag* as our model for human evaluation.

One might inquire whether improved performance is due to the simple addition of noise in light of Edunov et al. (2018), who conclude that noising BT improves MT quality. Subsequent work, however, found that benefit is not from the noise itself but rather that noise helps the system distinguish between parallel and synthetic data (Caswell et al., 2019; Marie et al., 2020). Yang et al. (2019) also propose tagging to distinguish synthetic data. With tagging instead of noising, Caswell et al. (2019) outperform Edunov et al. (2018) in 4 of 6 test sets for En-De, furthermore find that noising on top of tagging does not help. They conclude that "tagging and noising are not orthogonal signals but rather different means to the same end." In light of this, our improved results are likely not due to increased noise but rather to systematic differences between supervised and unsupervised BT.

5.4 Human Evaluation

We run human evaluation with professional translators for *+MediumMix_Tag*, comparing its output translation of the newstest2019 test set with two baseline models. Table 10 shows that humans prefer the combined system over the baseline outputs.[7] Table 11 shows the percentage of sentences judged as "worse than," "about the same as," or "better than" the corresponding +SupBT_Tag output, based on fluency. Raters again prefer the combined system. The improvements are modest, but encouragingly indicate that unsupervised MT may have something to contribute to machine translation, even in high-resource settings.

	Adequacy
+ UnsupBT_Tag	54.82
+ SupBT_Tag	56.13
+ MediumMix_Tag	**58.62**

Table 10: Human-eval direct assessment (adequacy) of supervised MT with supplemental back-translation.

Better	Same	Worse
51.1%	3.7%	45.2%

Table 11: Human side-by-side fluency eval. Shown: % of +MediumMix_Tag sentences judged "worse than," "about the same," or "better than" +SupBT_Tag output.

6 Conclusion

Recent unsupervised MT systems can reach reasonable translation quality under clean and controlled data conditions, and could bring alternative translations to language pairs with ample parallel data. We perform the first systematic comparison of supervised and unsupervised MT output from systems of similar quality. We find that systematic differences do exist, and that high-quality unsupervised MT output appears **more natural** and **more structurally diverse** when compared to human translation, than does supervised MT output. Our findings indicate that there may be useful differences between supervised and unsupervised MT systems that could contribute to a system better than either achieves alone. As a first step, we demonstrate an unsupervised back-translation augmented model that takes advantage of the differences between the translation methodologies to outperform a traditional supervised system on human-evaluated measures of adequacy and fluency.

---

[7] Scores are low because we use only WMT18 bitext + BT, and translators score more harshly than crowd workers.

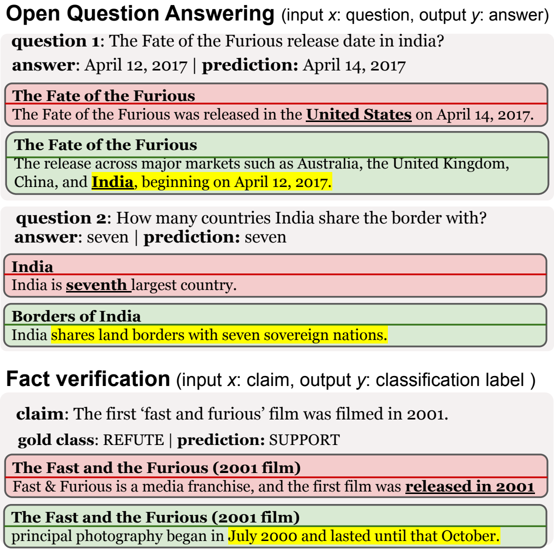
Abstract

Retrieval-augmented generation models have shown state-of-the-art performance across many knowledge-intensive NLP tasks such as open-domain question answering and fact verification. These models are trained to generate a final output given retrieved passages that can be irrelevant to an input query, leading to learning spurious cues or memorization. This work introduces a method to incorporate *evidentiality* of passages—whether a passage contains correct evidence to support the output—into training the generator. We introduce a multi-task learning framework to jointly generate the final output and predict the *evidentiality* of each passage. Furthermore, we introduce a new task-agnostic method for obtaining high-quality *silver* evidentiality labels, addressing the issues of gold evidentiality labels being unavailable in most domains. Our experiments on five datasets across three knowledge-intensive tasks show that our new evidentiality-guided generator significantly outperforms its direct counterpart on all of them, and advances the state of the art on three of them. Our analysis shows that the multi-task learning and silver evidentiality mining play key roles.[1]

1 Introduction

Knowledge-intensive tasks, including open-domain Question Answering (QA) and fact verification, require evidence passages related to an input query to be retrieved from a large collection of passages (e.g., Wikipedia). Recently, most successful methods use retrieval-augmented generation (Lewis et al., 2020c; Izacard and Grave, 2021b), which is a pipeline approach of first training a retriever model (Karpukhin et al., 2020) for retrieving passages and then independently training a generator model (Lewis et al., 2020a; Raffel et al., 2020) given the passages.



Open Question Answering (input *x*: question, output *y*: answer)

question 1: The Fate of the Furious release date in india?
answer: April 12, 2017 | **prediction:** April 14, 2017

The Fate of the Furious
The Fate of the Furious was released in the **United States** on April 14, 2017.

The Fate of the Furious
The release across major markets such as Australia, the United Kingdom, China, and **India**, beginning on April 12, 2017.

question 2: How many countries India share the border with?
answer: seven | **prediction:** seven

India
India is **seventh** largest country.

Borders of India
India shares land borders with seven sovereign nations.

Fact verification (input *x*: claim, output *y*: classification label)

claim: The first 'fast and furious' film was filmed in 2001.
gold class: REFUTE | **prediction:** SUPPORT

The Fast and the Furious (2001 film)
Fast & Furious is a media franchise, and the first film was **released in 2001**

The Fast and the Furious (2001 film)
principal photography began in July 2000 and lasted until that October.

Figure 1: Examples where a trained generator ignores the evidential passages (evidentiality-*positive* passages; green rounded rectangles) and makes incorrect predictions from passages that do not provide sufficient evidence (evidentiality-*negative* passages; red rounded rectangles). The highlighted part indicates the supporting evidence.

Ideally, a model should generate a correct answer given the information presented in *evidential* passages (Lee et al., 2021) that correctly support the answer and should not be distracted by other passages, even when they happen to contain a string close to the gold answer. However, the disjoint training process in the prior work disregards the evidentiality of passages, leading to generation models that ignore retrieved passages, leverage spurious cues, and generate hallucinations when the context is not evident (Longpre et al., 2021; Xu et al., 2021). In particular, incorrectly-retrieved passages with high lexical overlap to the query can mislead the answer generator (the first example in Figure 1). Adopting heuristics such as answer string matching (Chen et al., 2017) to train a QA model with passages containing the target strings can partially

---

[*] Work done in part while at the Allen Institute for AI

[1] Our code is available at `https://github.com/AkariAsai/evidentiality_qa`.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2226 - 2243
July 10-15, 2022

solve this problem for some QA tasks. Still, these passages with answer strings might lack evidence (the second example in Figure 1). What is more, such heuristics cannot be applied for open-ended generation or classification tasks (the third example in Figure 1).

In this paper, we introduce a multi-task training framework of answer generation and evidentiality prediction, which is an auxiliary task to predict if a passage provides evidence relevant to the task (evidentiality-*positive* passages; green passages in Figure 1) or not (evidentiality-*negative* passage; red passages in Figure 1). Since most existing datasets do not provide evidentiality labels, we introduce a new task-agnostic approach for mining *silver* evidentiality annotations.

Specifically, we train an evidentiality labeling model that takes an input query, a gold output and a single passage and predicts if the passage supports the gold output or not. After training, the evidentiality labeling model predicts the *silver* evidentiality labels of all of the passages used for the multi-task training. To supervise this evidentiality labeling, we use a combination of partially available gold passage annotations and data collected by a novel leave-one-out generation approach. This leverages a trained generator model and evaluates the relevance of each passage to a query through the correctness of the generated output when the passage is removed from the pool of retrieved passages. Unlike prior multi-task learning work in QA relying on available annotated data (Lee et al., 2021; Nishida et al., 2019) or heuristics such as answer string matching to label pseudo evidentiality (Fajcik et al., 2021), our approach is applicable to diverse downstream tasks, where we cannot use additional annotations or heuristics. Our evidentiality mining approach for high-quality silver labels can be applied to diverse NLP tasks, and our auxiliary task has a new purpose of evaluating passage evidentiality suitable for the open-retrieval.

We run experiments across representative knowledge-intensive tasks: open-domain QA (Natural Questions Open; Kwiatkowski et al., 2019, TriviaQA unfiltered; Joshi et al., 2017), fact verification (FaVIQ Ambig; Park et al., 2021, FEVER; Thorne et al., 2018) and knowledge-enhanced dialogue (Wizard of Wikipedia; Dinan et al., 2019). Our experiments show large performance improvements across all datasets over the direct counterpart, FiD (Izacard and Grave, 2021b). Moreover, on the latter two tasks, our model outperforms all previously published models, advancing state of the art on FaVIQ-Ambig, FEVER and Wizard of Wikipedia. Further human evaluations find that the evidentiality labeling model yields 95% accuracy, and often correctly identifies negative passages spuriously containing answer strings. Our analysis shows that both multi-task learning and silver evidentiality mining contribute to the improvement, helping the generator learn to focus on the more relevant passages.

2 Method

2.1 Overview

Problem. Knowledge-intensive tasks (e.g., open-domain QA, fact checking) are designed to retrieve evidence passages related to an input query x given a large collection of passages such as Wikipedia. Most successful previous work in this domain uses a retrieval-augmented generation framework such as Fusion-in-Decoder (FiD; Izacard and Grave, 2021b) that consists of two components: a retriever model $\mathcal{R}$ and a generator model $\mathcal{G}$. The retriever model $\mathcal{R}$ is trained to retrieve a set of passages $\mathbf{P} = \{p_1, p_2, \ldots, p_i, \ldots, p_N\}$ with the highest top N relevance score for each training query x: $\mathbf{P} = \mathcal{R}(x)$. The base generator model $\mathcal{G}$ (Section 2.2) is then trained to generate the final output y given an input query and the top retrieved passages: $y = \mathcal{G}(x, \mathbf{P})$.

Our analysis (Appendix in Section A.1) shows that a base generator $\mathcal{G}$ trained in this manner often generates the answers from passages ranked high by the retriever, which are not necessarily the correct evidence passages. Our goal is to build a model that recognizes the *evidentiality* of each passage and generates answers based only on passages that contain relevant evidence. We define passages with evidence relevant to the task as *positive* and passages without evidence as *negative*, even if they happen to include some spurious cues a model can exploit (e.g., a gold answer string for QA).

Method overview. Our method extends the retrieval-augmented generation paradigm by improving the generator $\mathcal{G}$ to generate answers from passages with correct evidence. We train our new evidentiality-guided generator $\mathcal{G}^+$ using a multi-task learning framework, sketched in Figure 2. Specifically, given an input query x, we combine the generation of the correct answer $\hat{y}$

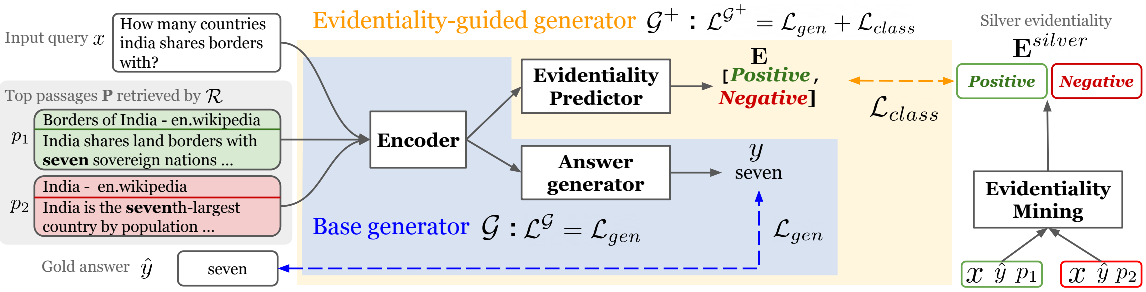


Figure 2: Overview of our proposed framework. The components inside the blue rectangle is a base generator $\mathcal{G}$ and our evidentiality-guided generator is the area inside the yellow rectangle. The straight arrows represent the input-output flow, and the dashed arrows indicate the losses.

with the prediction of binary evidentiality labels for each passage in $\mathbf{P}$ used for training: $\hat{\mathbf{E}} = \{\hat{e}_1, \hat{e}_2, \ldots, \hat{e}_i, \ldots, \hat{e}_N\}$.

It is challenging to obtain *gold* evidentiality labels $\hat{\mathbf{E}}$ for many tasks. Most datasets are curated with only query-answer annotations $(x, \hat{y})$, or cover subsets of gold passages existing in the large collection of passages, and considering those original gold passages as only positive passages may result in many false negative passages with correct evidence. Therefore, we heuristically obtain *silver* evidentiality data $\mathbf{E}^{silver}$ (§2.3) by training an evidentiality labeling model $\mathcal{M}$ that assigns a silver evidentiality label e_i^{silver} to each passage p_i given the query x and the gold output $\hat{y}$. In order to find gold evidence passages to train $\mathcal{M}$, we introduce a new approach to evaluate the relevance of passages in generating the correct answer by leaving one passage at a time in answer generation (called leave-one-out generation, sketched in Figure 3). We mine new gold passages for the target task, and train $\mathcal{M}$ using the mixture of partially available gold evidence passage data and newly mined data. After training, we run $\mathcal{M}$ on all the training data $(x, \mathbf{P}, \hat{y})$ to obtain $\mathbf{E}^{silver}$.

Finally, we describe auxiliary multi-task learning (sketched in Figure 2) using $(x, \hat{y})$ and the newly mined silver evidentiality data $\mathbf{E}^{silver}$ in Section 2.4. Our evidentiality-guided generator $\mathcal{G}^+$ learns to simultaneously predict the probabilities of output sequences y and evidentiality for all of the input passages $\mathbf{E}$.

2.2 Base Generator $\mathcal{G}$

We use FiD (Izacard and Grave, 2021b), a state-of-the-art retrieval-augmented generation model, as our base generator model $\mathcal{G}$. We include a high-level summary of the model for clarity, referring the reader to Izacard and Grave (2021b) for more details.

Encoder. We first encode the input query and passages using a pre-trained T5 (Raffel et al., 2020) encoder. The input query x is prepended to each passage, and the encoder encodes each of N passages independently. Formally, we transform passage p_i into $\mathbf{p}_i \in \mathbb{R}^{L \times h}$, where L is the input text length and h is a hidden size.

Answer generator. $\tilde{\mathbf{P}}$ is an input summary representation, formed by concatenating $\mathbf{p}_1, \ldots, \mathbf{p}_N$. The answer generator takes $\tilde{\mathbf{P}}$ and outputs the final answer autoregressively. Specifically, it outputs the sequence probability for y as follows:

$$P(y|x, \tilde{\mathbf{P}}) = \prod_{j=1}^{T} p(y_j | y_{<j}, x, \tilde{\mathbf{P}}).$$

where y_j denotes the jth token of the generated output y and T is the length of the final output. The generator is based on the T5 architecture and uses cross attentions to model the interactions between retrieved passages.

2.3 Mining Silver Evidentiality $\mathbf{E}^{silver}$

As discussed above, evidentiality labels are unavailable in most of the datasets, and even in some datasets with gold evidence annotations such as Natural Questions (Kwiatkowski et al., 2019), it only covers subsets of gold passages from certain articles. To overcome these limitations, we introduce an evidentiality labeling model $\mathcal{M}$, which computes the probability that a paragraph p_i contains evidence for an input x, given the correct answer $\hat{y}$: $p(e_i^{silver} | x, p_i, \hat{y})$. We use a RoBERTa (Liu et al., 2019)-based binary classification model for $\mathcal{M}$. This model is trained using gold evidentiality annotations when those are partially available, or using labels obtained from a new heuristic mining approach described below. Finally, we use the trained evidentiality labeling model to generate *silver* evidentiality labels for all of the passages included in the training data.

Leave-one-out generation. To precisely identify gold passages with correct evidence when a target dataset only has input-output annotations, our leave-one-out generation approach (sketched in Figure 3) leverages a trained base generator model and uses its predictions to estimate the relevance to the query of the passage. Specifically, we feed an input query x and retrieved passages $\mathbf{P}$ to our trained base generator for N times, where we mask the ith passage in the ith iteration to evaluate if the model can still generate the correct answer without the information presented in ith passage. We consider ith passage $positive$ if the model fails to generate $\hat{y}$ when and only when ith passage is masked. We also consider ith passage $negative$ if the model succeeds in generating $\hat{y}$ when and only when ith passage is masked—this means that the ith passage confuses the model. This approach may not find all of the gold evidence passages when there are multiple gold passages in $\mathbf{P}$ or the answers are memorized during fine-tuning of the base generator. Yet, we found that we can mine a sufficient number of high-quality gold passages using our approach to quickly adapt the evidentiality labeling model $\mathcal{M}$ to a new task. In our experiments, we combine the gold evidentiality data (i.e., long answers) from Natural Questions with task-specific leave-one-out data to train a separate evidentiality model $\mathcal{M}$ for each task. See the details of the data mining for each task in Appendix.

2.4 Multi-task Learning with $\mathbf{E}^{silver}$

Our generator $\mathcal{G}^+$ shares a similar, T5-based encoder-decoder architecture as the base generator, but we have an additional decoder that is used for the evidentiality prediction. We train $\mathcal{G}^+$ with a multi-task objective given the originally available data $(x, \mathbf{P}, \hat{y})$ and newly mined $\mathbf{E}^{silver}$.

Evidentiality predictor. The evidentiality predictor predicts the evidentiality of each passage. Similarly to the answer generator, we use the T5 decoder architecture for the classifier. Our evidentiality predictor generates the evidentiality e_i given encoded passage representation $\mathbf{p_i}$: $p(e_i|q, \mathbf{p_i})$. The evidentiality predictor in $\mathcal{G}^+$ has a much harder problem than the evidentiality model $\mathcal{M}$ from the previous section: $\mathcal{M}$ has access to the gold answer $\hat{y}$, while $\mathcal{G}^+$ does not. Intuitively, we can get reasonably accurate evidentiality labels from $\mathcal{M}$ using the gold answer, then force $\mathcal{G}^+$ to predict those labels without access to the gold answer, in order to teach the encoder of $\mathcal{G}^+$ to better determine the relationship between x and p_i.

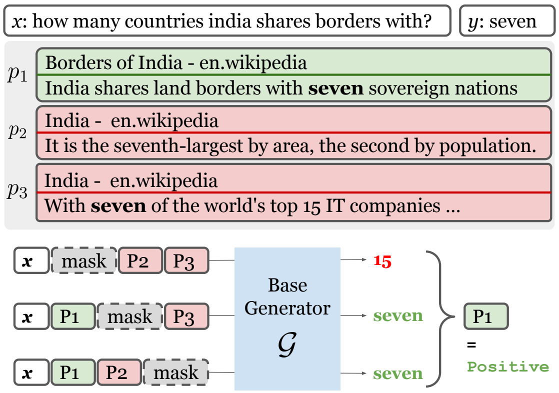

Figure 3: Overview and examples of our leave-one-out generation to find new positive and negative examples. We mask (remove) one passage at each iteration.

Multi-task training. We conduct multi-task training of generation and evidentiality prediction. In particular, our framework minimizes a multi-task objective below:

$$\mathcal{L} = \mathcal{L}_{gen} + \lambda \mathcal{L}_{class}, \tag{1}$$

where λ is a weighting parameter to balance the two objectives and would be tuned. In Eq. (1), $\mathcal{L}_{gen}$ is formulated as follows:

$$\mathcal{L}_{gen} = -\sum_{j}^{T} \log p(\hat{y}_j | y_{<j}, q, \tilde{\mathbf{P}}), \tag{2}$$

where $\hat{y}_j$ denotes the jth token of the annotated gold answer $\hat{y}$. Similarly, evidentiality prediction objective $\mathcal{L}_{class}$ can be written as follows:

$$\mathcal{L}_{class} = -\sum_{i}^{N} \log p(e_i^{silver} | q, p_i). \tag{3}$$

Note that this probability is computed by a T5 decoder as a common practice (Raffel et al., 2020); even though $e_i^{silver} \in \{positive, negative\}$, the probability is normalized over T5's entire output vocabulary.[2]

---

[2] We also tried to fine-tune a simple binary classification model using additional output layer on the top of T5 encoder. We found that this model performs much worse than T5-decoder-based classification model.

Dataset & Task	# of examples train	dev	test	evaluation metric	Top-20 recall (%)
1. Open-domain QA					
Natural Questions Open (Kwiatkowski et al., 2019)	79,168	8,757	3,610	EM	82.1
TriviaQA unfiltered (Joshi et al., 2017)	78,785	8,837	11,313	EM	75.2
2. Fact Verification					
FEVER (Thorne et al., 2018)	104,966	10,444	10,100	Accuracy	98.1
FaVIQ-Ambig (A) (Park et al., 2021)	17,008	4,260	4,688	Accuracy	100.0
3. Knowledge-enhanced Dialogue					
Wizard of Wikipedia (Dinan et al., 2019)	63,734	3,054	2,944	F1	96.2

Table 1: Dataset statistics. We experiment with three diverse knowledge-intensive NLP tasks across six datasets. "Top 20 recall" calculates if any of the top 20 passages include the answer strings (for open-domain QA datasets and FaVIQ-A) or comes from the provenance article (for FEVER and Wizard of Wikipedia) in the development set. FEVER and Wizard of Wikipedia are based on the KILT (Petroni et al., 2021) version.

3 Experimental Setups

We experiment on three knowledge-intensive tasks: open-domain QA, fact verification, and knowledge-enhanced dialogue. Statistics for each dataset are provided in Table 1.

3.1 Tasks, Datasets, and Metrics

Open-domain QA. We use Natural Questions Open (Kwiatkowski et al., 2019) and TriviaQA-unfiltered (Joshi et al., 2017) to evaluate our method on open-domain QA. Natural Questions consists of questions, long answers (e.g., gold evidence passages) and short answers (e.g., spans in the long answers), and the open-domain QA version is created by discarding questions that only have long answers or short answers whose length is longer than five tokens (Lee et al., 2019). TriviaQA-unfiltered (Joshi et al., 2017) includes unfiltered 110K Trivia question and answer pairs. For both of the datasets, we use publicly available DPR retrieval results for training and inference data,[3] and do not further fine-tune retrievers. Only the Natural Questions dataset has gold passage annotations and we use the gold passage annotations to train the evidentiality labeling model $\mathcal{M}$ only. Following prior work (Lee et al., 2019), we use Exact Match (EM) as our primary metric.

Fact verification. We use FaVIQ Ambig (FaVIQ-A; Park et al. 2021) and FEVER (Thorne et al., 2018) via the KILT benchmark (Petroni et al., 2021) to evaluate our method on fact verification. FaVIQ-A is created from an information-seeking QA dataset, AmbigQA (Min et al., 2020) to pose realistic fact verification queries. We use the baseline code provided by the authors of the FaVIQ dataset and KILT. We use accuracy as our evaluation metric.

Knowledge-enhanced dialogue. We use Wizard of Wikipedia (WoW; Dinan et al. 2019) to evaluate our method on knowledge-enhanced dialogue. We use the officially available KILT DPR baseline codes (Petroni et al., 2021)[4] to obtain passages and evaluate downstream F1 score.

3.2 Baselines

We use FiD (Izacard and Grave, 2021b) as our primary baseline using their official implementation.[5] In addition, we report results from the best published, publicly available generator models for each dataset including RAG (Lewis et al., 2020b) and DPR + BART (Petroni et al., 2021). For FEVER and WoW, we also compare our method with the published models on the KILT leaderboard.[6]

3.3 Hyper parameters

Due to the computational budget, we use T5's base-size models throughout our experiments for our evidentiality-guided generator. For our evidentiality labeling model $\mathcal{M}$, we use a RoBERTa (Liu et al., 2019)-base binary classification model. If not specified, we use the top 20 passages during training and inference, which also reduces the computational times from the original FiD model that uses top 100 passages. We train the models for 120k steps using 8 GPUs with 24 GB memory and take the checkpoint that achieves the highest score on the development set. The batch size is set to 1

Table 2: **Main Results**. "base" and "large" denote the base generator model sizes (e.g., T5-large, BART-base). (a) Performance on Natural Questions Open and TriviaQA unfiltered. "NQ" denotes Natural Questions Open, "TQA" denotes TriviaQA unfiltered. The state-of-the-art model is R2D2 from Fajcik et al. (2021), which has 1.29 billion parameters (more than twice more parameters than our model), consisting of a ranker and two reader models with ELECTRA (Clark et al., 2020)-large and T5-large. (b) Performance on FaVIQ-A and FEVER. Previous best model is DPR+BART (large) from Park et al. (2021) and Petroni et al. (2021) on FaVIQ-A and FEVER, respectively. (c) Performance on Wizard of Wikipedia (WoW). The best published model on the development set is DPR+BART (large) from Petroni et al. (2021). Test set results of WoW and FeVER are based on the leaderboard results at the time of the paper submission (January, 2022).

and to imitate the larger batch size, we set the gradient accumulation step to be 4. The learning rate is set to 10^{-5} and the number of warm-up steps is 1000. We set λ to be 0.5 for open-domain QA and dialogue, and 0.1 for fact verification. See more details in Appendix.

4 Results and Analysis

Our approach significantly improves over its direct counterpart on all datasets, and outperforms all prior published results on FaVIQ-A, FEVER and WoW, advancing their state-of-the-art performance.

4.1 Task Results

Open-domain QA. Table 2a shows experimental results on the two open-domain QA datasets. On Natural Questions Open, we improve the performance over FiD by 1.5 EM score. We observe performance improvements over FiD on TriviaQA as well. It should be noted that on open-domain QA, most of the recent models (e.g., Fajcik et al., 2021) contain a few times more parameters than our model or use improved retrievers (Izacard and Grave, 2021a), both of which are beyond our computational budgets. Our results represent state-of-the-art performance for models with access to similar computational resources, and our contributions should be complementary to work focusing on improving retrieval components.

Fact verification. Table 2b shows the experimental results on FaVIQ-A and FEVER. In addition to the original paper's baseline, we have fine-tuned a BART-base baseline using their original public codebase (DPR+BART (base)) for a fair comparison.[7] Our model significantly outperforms the prior best model, DPR+BART (large), on FaVIQ-A by a large margin. Our model also significantly outperforms FiD on FaVIQ by 1.8% on the development set and 1.4% on the test set, yielding state-of-the-art performance on this dataset. Our evidentiality-guided generator also outperforms other models on FEVER. On the FEVER hidden test set,[8] our model yields 88.5% down-stream accuracy and ranks second among all submissions, outperforming all of prior published work (Maillard et al., 2021; Petroni et al., 2021; Lewis et al., 2020b).

Knowledge-enhanced dialogue. Table 2c shows the experimental results on the Wizard of Wikipedia dataset. Our model outperforms prior work using larger base models and improves the F1 score from the base FiD model by 1.0. On the test set,[9] our model yields 17.3 F1, outperforms all other published work and ranks fourth among all submissions (the top three are unpublished).

4.2 Analysis

4.2.1 Ablation Study

We study the impact of different components of our method by comparing the full method with other variants.

- **Multi-task** does not use our multi-task objective and only trains with $\mathcal{L}_{gen}$, which is theoretically equivalent to FiD.

---

[7] `github.com/faviq/faviq`

[8] `eval.ai/web/challenges/challenge-page/689/leaderboard/1899`

[9] `eval.ai/web/challenges/challenge-page/689/leaderboard/1909`

Models Metric	NQ EM	FaVIQ-A Acc	WoW F1
Ours	**47.9**	**69.6**	17.9
- multi-task	46.9	67.8	16.9
- $\mathbf{E}^{silver}$ mining	47.3	69.1*	**18.0***
- LOO-gen.	47.6	69.2	17.7

Table 3: Ablation results. All results are based on the performance on development set of the three datasets. "NQ" denotes Natural Questions Open and "WoW" denotes Wizard of Wikipedia. * in the FaVIQ-A and WoW columns indicate that a model is trained with additional metadata our evidentiality-guided generator does not use during training.

- **$\mathbf{E}^{silver}$ mining** uses the multi-task training but does not use our method to find evidentiality silver labels. Instead, it relies on task-specific heuristics (e.g. string match) that have been used by prior work (Chen et al., 2017). For WoW and FaVIQ-A, where we cannot locate gold answers in the retrieved context to label evidentiality, we use additional meta-data such as gold Wikipedia article titles available in the original datasets (Petroni et al., 2021). It should be noted that that additional metadata is often unavailable in most of the datasets, and this variant for WoW and FaVIQ can be considered as a ground-truth setting. See more details in Appendix. Moreover, relying on this dataset-specific metadata limits models' applicability to wider NLP datasets and tasks. Note that our method does not use this additional metadata, so this variant can get higher numbers than our model.
- **LOO-gen.** uses the multi-task training but removes our leave-one-out-generation strategy for collecting evidentiality labels. It only incorporates the first step of training the evidentiality model over Natural Questions only.

Table 3 reports the ablation results. There is a clear drop when removing the multi-task auxiliary learning, especially on FaVIQ-A, where a model needs to precisely assess the evidence and reason, without being distracted by a simple lexical overlap (Park et al., 2021). Removing $\mathbf{E}^{silver}$ mining drops the performance on all of the three datasets, indicating the effect of mining evidentiality labels, instead of relying on string matching heuristics. Note that especially on FaVIQ-A or WoW, this "-$\mathbf{E}^{silver}$ mining" uses oracle gold annotations, which are not used by ours. By removing the necessity of having access to task-specific heuristics or those additional annotation, our method is easily applicable to a task or a new dataset. Finally, the performance drop when removing LOO-gen. shows the impact of our leave-one-out approach in collecting evidentiality labels for target tasks to train $\mathcal{M}$.

e^{silver}	$\hat{e}$	%
`pos`	`pos`	95
`pos`	`neg`	5
`neg`	`pos`	4
`neg`	`neg`	96

(a)

(1) $p^{+}_{\mathcal{G}} > p_{\mathcal{G}}$	43
(2) $p^{+}_{\mathcal{G}} < p_{\mathcal{G}}$	14
(3) $p^{+}_{\mathcal{G}} = p_{\mathcal{G}} = 0$	29
(4) $p^{+}_{\mathcal{G}} = p_{\mathcal{G}} = 1$	14

(b)

Table 4: (a) Human analysis over evidentiality positive and negative labels obtained by our method. e^{silver} denotes predictions made by $\mathcal{M}$ while $\hat{e}$ denotes the evidentiality labeled by human annotators. `pos` denotes evidentiality-positive while `neg` denotes evidentiality negative. (b) Qualitative evaluation of $\mathcal{G}$ and $\mathcal{G}^{+}$. $p_{\mathcal{G}}$ and $p^{+}_{\mathcal{G}}$ denotes the relevance between the input and the passages most attended by $\mathcal{G}$ and $\mathcal{G}^{+}$, respectively.

4.2.2 Evaluating Evidentiality Labels

Table 4a shows human analysis over evidentiality positive and negative labels obtained by our method over randomly selected samples. In particular, we randomly sample 50 Natural Questions development questions and sample 2 positive passages and 2 negative passages (if applicable) with answer strings for each question. The authors manually analyze (i) if the positive passages actually provide sufficient evidence to answer, and (ii) if the negative passages actually *do not* provide sufficient evidence to answer, despite the existence of the gold answer strings. We found that in 95% of the mined positive passages provide sufficient evidence to answer, while only 4% of the negative passages do not; in other words, the predictions are correct 95% of the positive passages and 96% of the negative passages.

4.2.3 Qualitative evaluation of $\mathcal{G}$ and $\mathcal{G}^{+}$

We conduct a systematic qualitative analysis on the FaVIQ-A predictions made by a base generator $\mathcal{G}$ and our evidentiality-guided generator $\mathcal{G}^{+}$. We study the claims in the evaluation set that $\mathcal{G}$ and $\mathcal{G}^{+}$ provide different prediction classes (793 out of the total 4,260 claims). We observe $\mathcal{G}^{+}$ provides the correct labels in 54% of these cases. We further filter out the cases where the two models provide the highest attention scores to similar passages, leading to 192 claims. The authors of this paper manually inspect all of those 192 claims and classify them into four categories: (1) $\mathcal{G}^+$ attends to a more relevant passage ($p^+_{\mathcal{G}} > p_{\mathcal{G}}$), (2) $\mathcal{G}$ attends to a more relevant passage ($p^+_{\mathcal{G}} < p_{\mathcal{G}}$), (3) the models attend to equally-irrelevant passages ($p^+_{\mathcal{G}} = p_{\mathcal{G}} = 0$), (4) both of them attend to equally-relevant passages ($p^+_{\mathcal{G}} = p_{\mathcal{G}} = 1$). The Table 4b (b) results show that $\mathcal{G}^+$ attends to the passages that are more relevant to the input claims. After further inspection, we found that $\mathcal{G}$ sometimes generates the right class, even if it gives the highest attention to a less relevant passage, explaining a smaller accuracy gap between the two models. This probably happens due to the nature of the task (e.g., two-way classification). We show some examples in Table 9 in the Appendix.

4.2.4 Performance on Hard Subsets

We automatically collect challenging instances from FaVIQ-A and Trivia QA development set, to see if there is an even more notable gap between $\mathcal{G}$ and $\mathcal{G}^+$ on those harder examples. To this end, we feed the top one retrieved passages with the input queries to the two generators and label questions that both models can answer correctly given top passages only *easy*, otherwise *hard*.

Table 5 shows the models' performance on the easy and hard subsets. In FaVIQ-A, the performance gap between two models on the harder subset is larger than the gap on the easy subset (i.e., 1.7 % v.s. 1.1% accuracy gap). Interestingly on FaVIQ-A, both models show somewhat low performance on the easy subset, where two models originally succeed to answer correctly given a single passage only. This is probably because the models are distracted by other passages when questions are actually simple and can be answered by top passages. On the other hand, the full accuracy of these top one passage only-variants is low (Ours: 54.7 % accuracy, FiD: 53.4%), suggesting the effectiveness of reading more passages. On the TriviaQA easy subset, both models show nearly 95% EM, showing little performance gap between the two models, while there is a notable performance gap between the two models on the hard subset. These results indicate that our method is more effective on harder examples that require carefully assessing and reasoning the passages beyond the top one.

dataset	FaVIQ-A (Acc.)		TQA (EM)	
split(#)	easy(1.7k)	hard(2.5k)	easy(4.0k)	hard(8.8k)
FiD	74.5	62.9	94.8	37.1
Ours	75.6	64.6	94.8	36.0

Table 5: Performance on *easy* and *hard* subsets of FaVIQ-A and TriviaQA (TQA), decided by top one only models' predictions. The numbers inside parenthesis show the number of the examples included in the easy and hard subsets.

5 Related Work

Retrieval-augmented generation. Retrieval-augmented generators leverage retrievers such as Dense Passage Retriever (Karpukhin et al., 2020) or BM25 (Robertson and Zaragoza, 2009) to find evidence from many passages, and feed those retrieved passages with the original query to competitive pre-trained generators such as BART (Lewis et al., 2020b) and T5 (Brown et al., 2020). They achieve competitive performance across different knowledge-intensive NLP tasks (Izacard and Grave, 2021b; Glass et al., 2021; Paranjape et al., 2021; Park et al., 2021; Borgeaud et al., 2021). Recent work improves the retrieval component (Paranjape et al., 2021; Maillard et al., 2021) or introduces another passage re-ranking modules (Fajcik et al., 2021) for further improvements. Our work focuses on improving the generator component, which has been underexplored in the literature. Our work is complementary to those prior work focusing on improving the retrieval components of retrieval-augmented generation.

Unsupervised evidence selection for multi-hop QA. Recently, Lee et al. (2021) introduce evidentiality-guided training for multi-hop question answering such as HotpotQA (Yang et al., 2018), which mines evidence sentences by adding or removing them to create counterfactual cases, and train a QA model with a regularization term to avoid overconfidence on negative passages. Recent work (Nishida et al., 2019; Fajcik et al., 2021) introduces multi-task learning of answer generation and evidence selection in the area of multi-hop QA or open-domain QA, but these approaches often rely on evidence annotations or heuristics (e.g., answer string matching) for supervising multi-task loss, which is unavailable in most of the datasets and tasks such as knowledge-enhanced dialogue or fact verification. Several prior work attempts to learn to find evidence sentences in unsupervised manners in multi-hop QA (Chen et al., 2019; Yadav et al., 2019; Perez et al., 2020), whereas our work uses evidentiality to improve the generator components via multi-task training for diverse knowledge-intensive tasks, going beyond QA alone.

Entailment-based approaches to improve QA. Assessing evidentiality of a passage given a question and a final output can be framed as an entailment task. Using entailment models to enhance the performance of QA tasks has been extensively studied (Harabagiu and Hickl, 2006; Sacaleanu et al., 2008; Abacha and Demner-Fushman, 2019; Trivedi et al., 2019). Iyer et al. (2021) introduce an NLI-based reranker to improve open-domain QA performance, and Chen et al. (2021) use NLI models to calibrate the answer reliability. They focus on improving the final answers, while we incorporate evidentiality more directly into the base model.

6 Conclusion

Augmenting pre-trained generation models with retrievers has shown to be effective in many knowledge-intensive tasks; however, they often rely on spurious cues or generate hallucinations during inference. We introduce a multi-task learning objective the combines answer generation and evidentiality prediction. We propose task-agnostic data mining techniques to obtain *silver* evidentiality labels to enable this auxiliary training. Our experiments across five datasets show large performance improvements over baselines and our evidentiality-guided generator advances the state-of-the-art performance on FaVIQ-Ambig, FEVER and WoW. Our analysis shows that multi-task learning and silver evidentiality mining both contribute to the performance improvements by helping the model learn to focus on and generate answers from more relevant passages.

Broader Impact and Ethical Implications

Retrieval-augmented generation models have shown state-of-the-art performance in a range of knowledge-intensive NLP tasks such as QA, fact verification, dialogue and long-form QA. However, prior work found that they often hallucinate (Xu et al., 2021) or are easily distracted by irrelevant evidence (Longpre et al., 2021). Those issue can cause serious risks especially when those technologies are applied to certain domains such as health care or politics. This work aims at solving those challenges and experimental results show that our proposed approach improves the performance in diverse downstream applications, learning to focus on more relevant passages than the original baseline. Although our model can still cause generation errors, our evidentiality predictor now provides predictions of evidentiality labels, which help practitioners understand the models' behavior. We have released our code and trained models so that follow-up work can reproduce and improve our method.

Appendix

A Preliminary Experiments and Analysis

A.1 Analysis on a Base Generator $\mathcal{G}$

Error analysis. We conduct a detailed error analysis on the base generator, FiD. We manually analyzed 50 errors in the Natural Questions development set to understand what causes the errors. Although 23 errors are due to the annotation errors (e.g., correct answer aliases are not covered by the original data; questions are highly ambiguous as pointed by Min et al. 2020; Asai and Choi 2021), we found that the model often succeeds in retrieving the right evidence but fails to generate the answers based on the passages with supporting evidence. We show the top attended passages for sampled questions in Table 6. Although those passages have high lexical overlap with the questions, they are often irrelevant or about the different entities in the same genre (e.g., last name, movie). Yet, during training, the model is only given the final output supervision signal, making it difficult to distinguish the passages with sufficient evidence to answer from the ones without evidence.

Memorization issues. We also found that when the retrieved passages are not evident the model more often generates incorrect answers memorized during training, without carefully accessing the context. In the questions where FiD fails to generate the correct answers, more than 5% of the answers are not sub-spans of any of the retrieved passages, while in the questions FiD succeeds to answer 99.5% of the answers are copied from the passages. Moreover, in the success cases, the predicted answers are the sub-spans of the top 10 passages in 96% of the cases, while in the error cases, only 79% of the predicted answers are copied from the top 10 passages. Those findings are consistent with the ones observed by Xu et al. (2021). Recently, Longpre et al. (2021) found that the generative QA models often generate the answers memorized during fine-tuning, when they observe more unreliable passages during training.

A.2 Evidentiality Negative Passages among Top Retrieved Passages

We manually analyze 20 sampled Natural Questions training questions where at least of one of the top 3 passages retrieved by DPR include the annotated gold answers, to see if including answer strings entails evidentiality. Labeling passages with answer strings positive have been commonly used in open-domain QA (Chen et al., 2017; Karpukhin et al., 2020), but prior work found that those passages are often spurious (Min et al., 2019). We found that in 30% of the cases, the passages with answer strings do not actually provide evidence to answer the input questions. We shows the examples in Table 7. Training a model with distantly supervised approaches have been widely used in open-domain QA, but particularly in the current retrieved-augmented training schema, this approach can cause huge learning noises. It also should be noted that those passages are all from top 3 retrieved results, which are expected to be highly related to the input queries.

B Details about $\mathcal{M}$ and Resulting $\mathbf{E}^{silver}$

B.1 Lack of the *Gold* Evidentiality Labels

Most datasets and tasks only include query-answer $(x, \hat{y})$ annotations and do not include evidentiality labels $\hat{\mathbf{E}}$ for passages $\mathbf{P}$. Some datasets with gold evidence annotation, such as Natural Questions, cover subsets of gold passages from certain Wikipedia articles, whereas $\mathbf{P}$ possibly includes unlabeled gold passages from another article. Where gold annotations are not available, a common heuristic is to use the answer string as distant supervision (Mintz et al., 2009), labeling all passages that include the answer string as evidentiality positive. This heuristic can create false-positive annotations—for instance, p_2 in Figure 2 includes the answer string "seven" but is irrelevant to the input query. Not only being noisy, this heuristic cannot be used for open-ended generation or answer classification such as knowledge-enhanced dialogue and fact verification.

B.2 Task-specific Details for Leave-one-out Generation

Open-domain QA. To collect new positive and negative data using leave-one-out generation, we consider top 20 passages retrieved for all of the original training data queries, and then split 20 passages into two ten-passage chunks. We then run a trained FiD model for 10 times, masking ith passage at the ith iteration. We consider ith passage p_i positive when and only when FiD fails to generate the correct answer when ith passage is masked. We also consider p_i (hard-)negative when and only when FiD succeeds to answer correctly when ith passage is masked, as we assume that the

Q: who played mary in christmas with the kranks
A: Felicity Huffman

Christmas with the Kranks: Christmas with the Kranks Christmas with the Kranks is a 2004 American Christmas comedy film based on the 2001 novel “Skipping Christmas” by John Grisham. It was directed by Joe Roth and written and produced by Chris Columbus. It stars Tim Allen and Jamie Lee Curtis as a couple who decide to skip Christmas one year since their daughter is away, much to the chagrin of their neighbors. .

Q: hyori bed and breakfast season 2 air date
A: February 4, 2018

Queen Sugar: On March 11, 2016, it was announced that Marycarmen Lopez also was cast as regular. On August 1, 2016, the series was renewed for a second season ahead of its television premiere which aired in a two-night premiere on June 20 and June 21, 2017. The second season premiered on OWN in a two episode special on June 20 and 21, 2017. The show was renewed for a third season on July 26, 2017. The third season premiered in a two-night special on May 29 and May 30, 2018. On August 8, 2018, the series.

Q: where does the last name waters come from
A: Wales and Yorkshire

Bywater (surname): Bywater (surname) Bywater is an uncommon English surname of Anglo-Saxon origin and can most frequently be found in the English region of Yorkshire. It is a topographical surname given to those who were situated near a body of water. Bywater is an uncommon surname of Anglo-Saxon origin. The name derives from the merger of the Old English words “bi” and “waeter” to form “biwaeter”. Topographical surnames are among the earliest created, because natural and artificial features in the.

Q: who was last person to be executed in us
A: Ruben Cardenas Ramirez

Billy Bailey: He became only the third person to be hanged in the United States since 1965 (the previous two were Charles Rodman Campbell and Westley Allan Dodd, both in Washington) and the first person hanged in Delaware in 50 years. As of 2018, he remains the last person to be executed by hanging in the United States.

Q: what is the largest ethnic group in mexico today
A: K’iche’

Mexican-American middle class: the Latino/a population of the United States is the nation’s largest racial/ethnic minority group, constituting 17.6 percent of the total population. At two thirds of the Latino/a ethnic category, Mexicans are by far the largest national origin group. .

Table 6: Examples of the top attended spurious passages in the questions where the base generator $\mathcal{G}$ failed to generate the correct answers. The underlined phrases contradict the input queries, while those passages generally have high lexical overlap with the given input queries.

ith passage can be highly distracting or confusing, misleading the generator.

Fact verification. As fact verification is a classification task, using the same methodology as open-domain QA may not be desirable—when we run a model ten times, it is likely to predict both correct and incorrect classes for multiple times, and we may not be able to mine the useful positive and negative passages. For the two fact verifica-

Q: who is in charge of enforcing the pendleton act of 1883
A: United States Civil Service Commission

1. Pendleton Civil Service Reform Act: Pendleton Civil Service Reform Act The Pendleton Civil Service Reform Act (ch. 27,) is a United States federal law enacted in 1883 that mandated that positions within the federal government should be awarded on the basis of merit.

2. United States Civil Service Commission: The Pendleton law was passed in part due to public outcry over the assassination of President Garfield.

3. Pendleton Civil Service Reform Act: The Act was written by Dorman Bridgman Eaton, a staunch opponent of the patronage system who was later first chairman of the **United States Civil Service Commission**.

Q: who plays skyler on lab rats elite force
A: Paris Berelc

1. Lab Rats: Elite Force: The series is a combined spinoff of “Lab Rats” and “Mighty Med” and stars William Brent, Bradley Steven Perry, Jake Short, **Paris Berelc**, and Kelli Berglund.

2. Lab Rats: Elite Force: Elite Force is an American comedy television series created by Chris Peterson and Bryan Moore that aired on Disney XD from March 2 to October 22, 2016. ... stars William Brent, Bradley Steven Perry, Jake Short, **Paris Berelc**, and Kelli Berglund.

3. Lab Rats: Elite Force: On September 3, 2015, it was announced that “Lab Rats” and “Mighty Med” would have a joint spinoff series called “Lab Rats: Elite Force”. Only William Brent, formerly credited as Billy Unger, and Kelli Berglund from “Lab Rats” and Bradley Steven Perry, Jake Short, and **Paris Berelc** from “Mighty Med” were announced as returning for the new spinoff series. .

Q: who developed the first periodic table with 8 columns
A: Dmitri Mendeleev

1. Periodic table: In 1923, Deming, an American chemist, published short (Mendeleev style) and medium (18-column) form periodic tables. Merck and Company prepared a handout form of Deming’s 18-column medium table, in 1928, which was widely circulated in American schools.

2. History of the periodic table: their decision by saying that such “’theoretical” topics might be controversial. The importance of Newlands’ analysis was eventually recognised by the Chemistry Society with a Gold Medal five years after they recognised Mendeleev’s work.

3. History of the periodic table: the work of **Dmitri Mendeleev** had been published. In 1864, the English chemist John Newlands classified the sixty-two known elements into eight groups, based on their physical properties. Newlands noted that many pairs of similar elements existed, which differed by some multiple of eight in mass number, and was the first to assign them an atomic number.

Table 7: Examples of the top three passages retrieved by a trained $\mathcal{R}$ (DPR). We make the phrases matching the gold answers bold in the retrieved passages.

tion datasets, we consider the top 10 passages and we split them into two five-passage chunks. We consider the ith passage as a positive passage if the predictions based on the passage collections including ith passage unanimously agree on correct prediction whereas it fails to generate the correct class when ith passage is masked. We consider the ith passage as a negative passage when (i) the model succeeds to answer when and only when ith passage is masked, and (ii) the predictions unanimously agree on incorrect classes, which indicates all of the passages do not support the input claim.

Knowledge-enhanced dialogue. Unlike open-domain QA or fact verification, the final output of a dialogue system can be highly open-ended. For dialogue, we compare the average F1 score of the generated responses when ith passage is included and masked. If the average F1 when p_i is presented is higher by more than 0.1 than the F1 when p_i is masked, we consider p_i provides useful evidence to generate the correct response, and therefore mark

Task: Fact Verification
Claim$_1$: jimmy perry had a cameo for the role of charlie cheeseman in dad's army. **Label$_1$**: SUPPORTS
Jimmy Perry: Despite the doubts, the first episode was screened on 31 July 1968, with Perry making a cameo appearance as the entertainer Charlie Cheeseman in the sixth episode, "Shooting Pains".
Claim$_2$: John Glenn was a military test pilot. **Label$_2$**: SUPPORTS
John Glenn: Glenn's first flight test assignment, testing the FJ-3 Fury, nearly killed him when its cockpit depressurized and its oxygen system failed.

Task: Knowledge-enhanced Dialogue
Contexts$_1$: Purple is such a good color. **Response$_1$**: yep, its in between red and blue
Purple: Purple is a color intermediate between blue and red. It is similar to violet, but unlike violet, which is a spectral color with its own wavelength on the visible spectrum of light, purple is a secondary color made by combining red and blue.
Contexts$_2$: I was a really good skateboarder when i was young, its an action sport which involves riding and performing tricks, have you used a skateboard ::: i tried wjhen i was younger but i failed horribly!haha ::: hah, yes its really hard, first skateboards started with wooden boxes with wheels attached to the bottom, it was an invention from the people ::: i think i would have done alot better on a box with wheels! lol thats so cool. when was the first one invented? **Response$_2$**: in the early 1900's it started, now there are 11.08 million active skateboarders in the world!
Electric skateboard: An electric skateboard is a personal transporter based on a skateboard. The speed is controlled by a hand-held throttle or weight-shifting and the direction of travel is adjusted by tilting the board to one side or the other. The MotoBoard, which was gasoline-powered was released in the summer of 1975, but were banned in California due to their noise and pollution in 1997. Louie Finkle of Seal Beach, California is often cited as an originator of the modern electric skateboard, offering his first wireless electric skateboard .

Table 8: Examples of the positive examples newly mined by leave-one-out generation approach. ":::" in the contexts for the knowledge-enhanced dialogue example indicates the change of the speakers.

p_i positive. On the contrary, when the average F1 when p_i is presented is lower by more than 0.1 than the score when p_i is masked, we believe p_i can be highly distracting, and thus we mark p_i negative. As in fact verification, we use the top 10 passages and split them into two five-passage chunks.

B.3 Implementation Details of Evidentiality Labeling Model

We use PyTorch (Paszke et al., 2019) via HuggingFace transformers RoBERTA (Liu et al., 2019) implementation.[10] We tune our model from RoBERTa-base. We optimize the objective function using Adam (Kingma and Ba, 2015) with learning rate 2×10^{-5} . We lowercase the input and set the maximum sequence length to 350. We train the model for 7 epochs. Per GPU batch size is 12 and we use 8 GPUs with 24 GB memory.

Training data. We mine new training data for each task using our leave-one-out generation approach and mix the data with Natural Questions (Kwiatkowski et al., 2019). For Natural Questions data, as human annotators annotate `long-answer`, from which final minimal answers are extracted, we assume that those human-annotated long answers are evidentiality-positive passages, while the other passages included in

Q: How many countries india shares borders with?
A: seven

Borders of India
India shares land borders with seven sovereign nations ...

India
India is the seventh-largest country by area, the second-most populous country.

Q: who played ice queen in chronicles of narnia
A: Tilda Swinton

Tilda Swinton
Tilda Swinton is a British actress. She is also known for her performance as the White Witch in the "Chronicles of Narnia series" (2005–10).

The Chronicles of Narnia: Prince Caspian
The Chronicles of Narnia: Prince Caspian is a 2008 American high fantasy film ...William Moseley... Tilda Swinton reprise their roles from the first film

Q: Season 2 this is us number of episodes
A: 15

19-2 (2014 TV series)
The first season originally aired from January 29 to April 2, 2014, while the second season aired from January 19 to March 23, 2015

Quantico (season 2)
Quantico (season 2) The second season of American drama thriller series "Quantico" premiered on September 25, 2016, and concluded on May 15, 2017.

Q: What is the first book of percy jackson
A: The Lightning Thief

The Sea of Monsters
It is the second novel in the "Percy Jackson & the Olympians" series and the sequel to "The Lightning Thief".

Camp Half-Blood Chronicles
The Lightning Thief is the first book in the Percy Jackson and the Olympians series. It features Percy Jackson.

Camp Half-Blood Chronicles
termed Book 8 in the Percy Jackson series by Amazon or the publisher. The British edition was published by Puffin Books in March as "Percy Jackson: The Ultimate Guide". "The Lightning Thief Graphic Novel" is an adaptation of "The Lightning Thief" into

Figure 4: Examples of newly mined evidentiality examples for Natural Questions.

the same article and are not included in the long answers negative. We first collect all of the `long-answer` passages from Natural Questions training data, and randomly sample two negative passages per questions with `long-answer` annotations. We discard the examples where long answers are list or table elements. Consequently, we obtain 250k training samples, and we use 90% of the data as our training data and the remaining 10% of the data as our development set.

B.4 Examples of the Passages Mined by Leave-one-out Generation

Table 8 present several positive passages mined by leave-one-out generation approach. The positive passages for the open-domain QA and fact verification tasks clearly present the evidence leading to the gold answers (the highlighted sentences). Also in the first example of the knowledge-enhanced dialogue, the model finds a positive passage, which has high lexical overlap with the gold response. On the other hand, the second example shows the difficulty of finding the correct evidence for generation especially when the context history is long. The original dialogue history mentions skateboard and the last human utterance asks about when they were invented, while the passage labeled as positive is about electric skateboards and when they were released for the first time. We found due to the open-ended nature of knowledge-enhanced dialogue and F1 score-based positive passage labeling can be results in more false positive passages than other two tasks, as even the passage does not really support the evidence, it still helps a model generate a loosely grounded and related response and obtains higher F1 score. Recent work reports similar issues in long-form QA evaluations (Krishna et al., 2021).

B.5 Examples of E^{silver} Obtained by $\mathcal{M}$

The newly mined examples can be seen in Figure 4. Although all of the passages here include gold answer strings, we observe that the red passages do not entail the answers. For instance, in the second example, the red passage from “The Chronicles of Narnia: Prince Caspian” only lists the names of the actors who reprise their roles from the first film, and does not mention show played ice queen. The first passage, on the other hand, clearly mentions that Tilda Swinton plays the White Witch (the ice queen) in the Chronicles of Narnia. The third example shows that our model detects the case where we originally have distantly-positive passages, all of which are labeled as negative by our evidentiality labeling model. The fourth example shows that the positive passages can be retrieved from multiple different articles, which are often not covered by existing datasets with gold paragraph annotations.

C Details of the Datasets

License. Natural Questions (Kwiatkowski et al., 2019), TriviaQA (Joshi et al., 2017) is under Apache License 2.0. The KILT benchmark (Petroni et al., 2021), where our FEVER and Wizard of Wikipedia data is taken, is under MIT License. FAVIQ (Park et al., 2021) does not explicitly mention the license. We use all of the datasets for their intended uses.

Privacy-related information and harmful context. All of the datasets use the English Wikipedia or web articles as a knowledge source and the input queries are authored by human annotators, and we believe those resources are less likely to include personal information or harmful context. In addition, dataset creators often conduct intensive analysis on annotated data and discard problematic examples, which may further reduce the risk of the problematic content.

D More Analysis and Examples

D.1 Details of Task-specific heuristics for an ablation of E^{silver}

For open-domain QA, this model uses answer string matching to supervise our multi-task learning. As discussed, this distantly supervised approach cannot be directly applied to classification or open-ended generation tasks. For WoW, it uses *provenance* title, which is the title of the Wikipedia article including the gold paragraph, and label all passages from provenance articles positive (Petroni et al., 2021). For FaVIQ-A, it uses the original answer annotations inherited from AmbigQA available in the dataset. It should be noted that that additional metadata is often unavailable in most of the datasets, and this variant for WoW and FaVIQ can be considered as a ground-truth setting.

D.2 Analyzing Attentions of $\mathcal{G}$ and $\mathcal{G}^+$

To further understand our method's behavior, we compare the attention scores assigned to the top retrieved passages of a base generator FiD ($\mathcal{G}$) and our evidentiality-guided generator ($\mathcal{G}^+$). Figure 5 shows that the attention scores of the base generator $\mathcal{G}$ and $\mathcal{G}^+$; the x-axis is the attention values and the y-axis is probability of the histogram. The attention scores of the base generator $\mathcal{G}$ are concentrated closely near the value of -5.0, whereas the attention scores of our $\mathcal{G}^+$ more widely spread out. We also found that our $\mathcal{G}^+$ more often gives its highest attention value to the passages ranked lower by $\mathcal{R}$; our generator $\mathcal{G}^+$ and base generator $\mathcal{G}$ gives their highest attention scores to the passages ranked lower than top 10 by $\mathcal{R}$ in 45.8% and 44.8% of the examples, respectively. We hypothesize that FiD mostly generates answers from more highly-ranked passages while our method enables shifting the attention scores to lower-ranked passages and generates answers from those, by explicitly training the models telling the evidentiality-negative and evidentiality-positive passages.

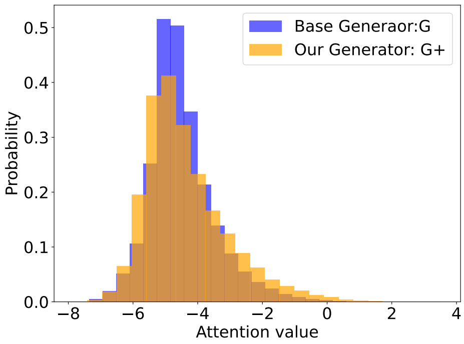

Figure 5: Attention score distributions over top 20 passages of the base generator $\mathcal{G}$ and our evidentiality-guided generator $\mathcal{G}^+$.

Abstract

Commonsense reasoning systems should be able to generalize to diverse reasoning cases. However, most state-of-the-art approaches depend on expensive data annotations and overfit to a specific benchmark without learning how to perform general semantic reasoning. To overcome these drawbacks, zero-shot QA systems have shown promise as a robust learning scheme by transforming a commonsense knowledge graph (KG) into synthetic QA-form samples for model training. Considering the increasing type of different commonsense KGs, this paper aims to extend the zero-shot transfer learning scenario into multiple-source settings, where different KGs can be utilized synergetically. Towards this goal, we propose to mitigate the loss of knowledge from the interference among the different knowledge sources, by developing a modular variant of the knowledge aggregation as a new zero-shot commonsense reasoning framework. Results on five commonsense reasoning benchmarks demonstrate the efficacy of our framework, improving the performance with multiple KGs.

1 Introduction

The ability to understand natural language through commonsense reasoning is one of the core focuses in the field of natural language processing. To measure and study the different aspects of commonsense reasoning, several datasets are developed, such as SocialIQA (Sap et al., 2019b), CommonsenseQA (Talmor et al., 2018), and PhysicalIQA (Bisk et al., 2020), each requiring different type of commonsense knowledge (*e.g.*, social, taxonomic, causal, declarative, *etc*) to select the correct answer. While large-scale neural systems (Devlin et al., 2018; Yang et al., 2019; Liu et al., 2019b) have shown human-level accuracy on these benchmarks, recent studies (Mitra et al., 2019) also criticize that these models solve individual datasets, rather than learning how to perform general semantic reasoning. To this end, Ma et al. (2021) suggested zero-shot evaluation as a genuine measure for the reasoning capability of the machine.

Inspired by this new metric, in this work, we focus on building unsupervised zero-shot multiple-choice QA systems. That is, we target an arbitrary commonsense reasoning task where conventional approaches (that rely heavily on task-specific supervision) are not applicable to such zero-shot learning scenarios. To learn QA models without expensive annotation efforts, recent works (Ma et al., 2021; Banerjee and Baral, 2020; Malaviya et al., 2020) propose to generate a synthetic QA dataset using a commonsense KG such as `ATOMIC` (Sap et al., 2019a) and `ConceptNet` (Speer et al., 2017). Such an approach mostly focuses only on one specific type of reasoning relations (*e.g.*, if-then relation, or declarative relation), neglecting the fact that real-world QA systems require simultaneously considering different types of reasoning abilities (*e.g.*, declarative and social, or causal and physical reasoning; Ilievski et al., 2021; Chang et al., 2021).

To consider different types of reasoning, this paper extends ideas from the aforementioned zero-shot learning to the *multi-source* case such that it benefits from different types of commonsense knowledge on individual KGs. For example, `ATOMIC` (Sap et al., 2019a) focuses on social commonsense while `ConceptNet` (Speer et al., 2017) contains conceptual knowledge. A practical approach is multi-task learning (MTL; Caruana, 1997; Liu et al., 2019a), which learns a shared encoder for different synthetic QA datasets from multiple KGs. Despite its effectiveness, MTL scheme suffers from interference among different KGs, which results in forgetting previously learned knowledge when trained on new KG which has different kinds of knowledge (Pilault et al., 2021; Pfeiffer et al., 2021; Wang et al., 2021a; Wu et al., 2020).

To address these limitations, we propose a novel,

July 10-15, 2022

modularized framework that aims to learn multiple expert models for KGs, then conduct zero-shot fusion to allow collaboration among KGs. For this purpose, we leverage AdapterFusion (Pfeiffer et al., 2021) where multiple tiny modules between Transformer blocks called adapters (Houlsby et al., 2019) can be combined after independent training, thus allowing a continual integration of the adapters without retraining the entire framework. Specifically, we treat the adapters as different KG-specific experts, and combine them using an attention-like fusion module. To improve the fusion of adapters, we suggest a KG-alignment adapter that guides to the apt *expert adapters*. Here, we use KGs in three different synthetic supervision training: (1) KG-specific QA datasets to train the KG-specific expert adapters, (2) a KG classification datasets to train the KG-alignment adapter, and (3) a balanced mixture of KG-specific QA datasets to train the fusion module. Our modularized method alleviates the interference between different KGs, which is the pitfall of MTL from our empirical observation, and thus combines multiple KGs into a synergetic zero-shot framework.

Our contributions are: (1) We suggest a simple, yet effective KG modularization strategy for the use of multiple KGs in commonsense reasoning. (2) We then explore the use of AdapterFusion (Pfeiffer et al., 2021) for better knowledge aggregation based on the KG modularization in zero-shot setting. We believe that such modularized transfer learning is critical to using different knowledge sources synergetically against interference between them. (3) In extensive experiments on various commonsense reasoning benchmarks, our framework achieves significant improvements over baselines using a single KG, even using multiple KGs, which implies the robustness in commonsense reasoning.

2 Related Work & Preliminaries

2.1 Zero-shot Commonsense Reasoning

Many researchers have recently focused on building unsupervised models without any benchmark supervisions (*i.e.*, zero-shot learning). In such zero-shot setting, KGs are often used as an external resource for improving model prior (*e.g.*, continually learned from pre-trained language models) (Banerjee and Baral, 2020; Bosselut and Choi, 2019; Ma et al., 2021), especially for commonsense reasoning, as much existing work couples language models with neural/symbolic commonsense KGs.

However, most of existing work are either assuming the existence of the alignment information between tasks and KGs (Banerjee and Baral, 2020) or an integrated KG (Ma et al., 2021). For example, `ATOMIC`$^{20}_{20}$ (Hwang et al., 2021), a commonsense KG which incorporates tuples from `ConceptNet` and `ATOMIC` with new relations and further crowdsourcing, combines multiple KGs into a new integrated KG, but as widely known (Ilievski et al., 2020; Hwang et al., 2021), heterogeneous schema between different KGs may limit triplets that can be integrated.[1] Rather than such symbolic KG integration with the inevitable loss of knowledge, in this work, we explore the neural KG integration leveraging the multiple KGs without additional processing and alignment information between KG and task.

2.2 Transfer Learning with Modular Approaches

The idea of having specialized parameters, or so-called experts, has been widely studied to integrate multiple sources of knowledge via transfer learning. The adapter module (Rebuffi et al., 2017; Houlsby et al., 2019) has been explored as one of such approaches, introducing a small number of task-specific parameters at every layer of pre-trained language model (PLM) while sharing the parameters of underlying PLM which is fixed. To address the limitations of transfer learning due to high re-training cost, many works utilize the multiple adapter modules for individual tasks with different domains (Puigcerver et al., 2020; Bapna et al., 2019; Rücklé et al., 2020; Madotto et al., 2021) considering each adapter to be an expert of each domain. Similar to our work, K-Adapter (Wang et al., 2021a) encodes factual and linguistic knowledge to each adapter, but in this paper, we further explore how to mitigate catastrophic forgetting or interference among multiple adapters for better knowledge transfer in zero-shot setting.

2.3 Multi-Task Learning

MTL (Liu et al., 2019a; Zhang and Yang, 2017; Caruana, 1997) learns a shared representation while aggregating knowledge across multiple learning tasks, often leading to better generalization ability of a model. However, parametric aggregation of knowledge with MTL has following limitations: (1) retraining the full model when adding new

---

[1] Only 172K tuples of the 3.4M tuples and 5 relations of 36 relations in `ConceptNet` are integrated into `ATOMIC`$^{20}_{20}$.

tasks (Houlsby et al., 2019; Pfeiffer et al., 2021, 2020b) (2) catastrophic forgetting and interference between tasks leading to difficulties of solving each task equally well (Pilault et al., 2021; Wu et al., 2020; Yu et al., 2020) and (3) inconsistent effect (Lourie et al., 2021). To deal with these challenges, Mixture-of-Experts (MoE) is a parameterized generalization of ensembling techniques, which has been adapted for MTL with gating network trained to optimize each task (Ma et al., 2018). However, simple linear gating networks are too shallow and thus may destruct task knowledge for commonsense reasoning.

To address this problem, AdapterFusion (Pfeiffer et al., 2021) has been proposed to fuse task specific parameters called adapters for the given target task leveraging attention-like mechanism. AdapterFusion aggregates adapters, which is trained independently for each task, in a non-destructive manner mitigating aforementioned MTL problems such as forgetting and interference between tasks. Recently, it has been used for zero-shot cross-lingual transfer framework (Pfeiffer et al., 2020c; Wang et al., 2021b), which motivates our work to transfer multi-source knowledge with less interference for zero-shot commonsense reasoning.

3 Modularized Zero-shot Framework

In our setup, we repurpose synthetic QA generation (Ma et al., 2021) for the task of knowledge-driven zero-shot learning for commonsense reasoning, *i.e.*, we transform a KG into multiple (Q_i, A_i) pairs where Q_i is a natural language question and $A_i = \{A_{i,1}, ..., A_{i,m}\}$ is the set of options with m answer candidates. Specifically, given a triple (e^{head}, r, e^{tail}) in a KG, where e^{head}, e^{tail} and r denote head/tail entity and relation respectively, we transform e^{head} and r into a natural language question Q_i using templates. For the option set A_i, we use the combination of the correct answer e^{tail} and $m-1$ distractors which are tail entities from other triples sampled randomly (Ma et al., 2021). Details are described in Appendix B.

Formally, we denote (Q_i, A_i) as one QA sample. The goal is to learn a QA model from the synthetic QA sample. In a downstream task (*e.g.*, reasoning benchmarks such as SocialIQA and CommonsenseQA), we need to predict answers given non-synthetic test samples (Q^{test}, A^{test}). In the training stage, we are given K KG-driven datasets $\{\mathcal{D}^k_{QA}\}^K_{k=1}$ from K different KGs, where $\mathcal{D}^k_{QA}$ is a dataset with N_k samples for KG k as follows:

$$\mathcal{D}^k_{QA} = \{(Q_i, A_i, label)\}^{N_k}_{i=1} \tag{1}$$

where $label$ is the index of the correct answer for each sample. In this work, as shown in Table 1, we generate four synthetic QA datasets from `ATOMIC`, `ConceptNet`, `WikiData`, and `WordNet` (More details are in Appendix C).

QA from `ATOMIC` (Sap et al., 2019a)
Q: Dana speeds on the highway. Dana is seen as A1: considerate **A2: risky**(✓) A3: lazy
QA from `ConceptNet` (Speer et al., 2017)
Q: pentode is a [MASK] A1: ascocarp A2: girls footwear **A3: vacuum tube**(✓)
QA from `WikiData` (Vrandečić and Krötzsch, 2014)
Q: badminton is a [MASK] A1: fable A2: juvenile justice **A3: type of sport**(✓)
QA from `WordNet` (Miller, 1995)
Q: princewood is part of [MASK] A1: shaddock **A2: genus Cordia**(✓) A3: family Columbidae

Table 1: Synthetic QA examples. We use templates to convert (e^{head}, r) into a natural language sentence.

For effective use of multiple KGs at once with less interference, we present a modularized framework, which is a novel approach to knowledge transfer for the zero-shot setting as shown in Figure 1. As a modular approach, we train the multiple KG-specific adapters (*expert adapters*) with each dataset from KG. Based on these pre-trained adapters, we use a zero-shot fusion method to aggregate knowledge of each adapter leveraging AdapterFusion (Pfeiffer et al., 2021) as a base architecture with the balanced mixture of each KG dataset. Further, for better knowledge fusion, we suggest a KG-alignment aware adapter (*KG-Classifier adapter*) as a guide for detecting alignment with given sample in zero-shot reasoning. Here, we utilize KG classification dataset by verifying the synthetic QAs. Algorithm 1 in Appendix outlines the overall process of our proposed framework. We summarize the notations in Appendix A.

3.1 KG Modularization

First, we modularize the KGs to preserve their intrinsic knowledge. Considering the importance of using a suitable and well-aligned KG (Ma et al., 2019, 2021) on a downstream task, the subtle difference between each KG should be learned by the model without any interference from each other. Accordingly, we adopt the adapter module (Houlsby et al., 2019) which repurposes a pre-trained language model (PLM) to incorporate each

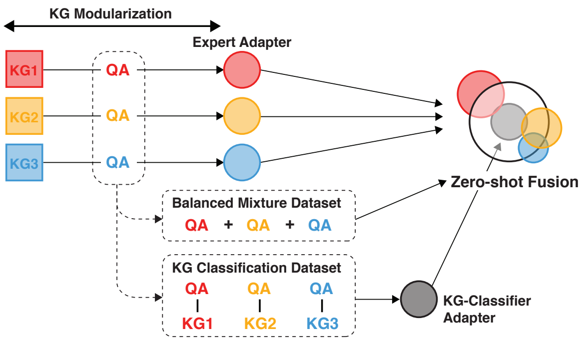

Figure 1: Illustration of the proposed modularized framework for zero-shot commonsense reasoning. Each colored square represents different KGs. Not only for KG modularization, we re-use a set of synthetic QA datasets from the multiple KGs for the purpose of KG classification and zero-shot fusion, which enables better knowledge aggregation.

KG as tiny modules in between Transformer blocks. Specifically, as illustrated in Figure 2 (except for green area), the adapter training strategy involves injecting new layers (parameterized by Φ) into the original PLM (parameterized by θ). The weights of the original PLM are untouched, while the new adapter layers are initialized at random. Formally, we call each adapter trained with $\mathcal{D}^k_{QA}$ as an *expert adapter* for KG k, parameterized by Φ^k_{QA}.

When a QA sample (Q_i, A_i) is given for dataset $\mathcal{D}^k_{QA}$, we first concatenate question Q_i and each answer option $A_i = \{A_{i,1}, ..., A_{i,m}\}$ to generate input sequences $T_i = \{T_{i,1}, ..., T_{i,m}\}$. Then, we compute a score $S_{i,j}$ (Ma et al., 2021) for the answer candidate $A_{i,j}$ is computed as follows:

$$S_{i,j} = -\frac{1}{|T_{i,j}|}\sum_{t=1}^{|T_{i,j}|} logP(w_t|...w_{t-1}, w_{t+1}...; \theta, \Phi) \tag{2}$$

where w_t is a word token in the sequence $T_{i,j}$ and P is the conditional probability from Transformer blocks parameterized by θ and Φ. To train the adapter Φ^k_{QA}, we use the marginal ranking loss (Ma et al., 2021) as follows:

$$\mathcal{L}_{QA} = \frac{1}{m}\sum_{i=1}^{N_k}\sum_{\substack{j=1 \\ j\neq label}}^{m} max(0, \eta - S_{i,label} + S_{i,j}) \tag{3}$$

where η represents the margin.

$$\Phi^k_{QA} \leftarrow \underset{\Phi}{\text{argmin}}\, \mathcal{L}_{QA}(\mathcal{D}^k_{QA}; \theta, \Phi) \tag{4}$$

where KG-invariant parameters θ are fixed and only KG-dependent parameters Φ^k_{QA} are learned, which enables to store the corresponding knowledge separately without any interference. Further, we can parallelize the training of adapter for all KGs. The efficiency of adapter training allows our modularization to be more scalable.

3.2 Zero-shot Fusion

Once the expert adapters are learned, we combine the knowledge from each expert adapter using an attention-like mechanism. We present a novel fusion strategy as shown in Figure 2, which is referred to as the zero-shot fusion. In contrast to AdapterFusion (Pfeiffer et al., 2021) where the focus is learning to transfer knowledge to a specific target task, our zero-shot fusion aims to generalize this transfer to any arbitrary target task. Specifically, the zero-shot fusion parameters Ψ learn to combine fixed expert adapters which are parameterized by $\Phi^1_{QA}, ..., \Phi^K_{QA}$. In each Transformer layer l of PLM with the injected fusion layer, the zero-shot fusion parameters Ψ_{QA} consist of query, key, and value matrices, denoted by $\mathbf{W}^Q_l$, $\mathbf{W}^K_l$, and $\mathbf{W}^V_l$ respectively. These parameters are used to learn the balancing between the representation of each *expert adapters* through attention-like mechanism. While fixing both the parameters θ and all expert adapters $\Phi^1_{QA}, ..., \Phi^K_{QA}$, the only trainable weights Ψ_{QA} on the fusion layer learns to combine the knowledge from different K *expert adapters* by using the subset of $\{\mathcal{D}^k_{QA}\}^K_{k=1}$ by random sampling. Here, we balance the ratio between the K knowledge-driven datasets as N samples (details are in Appendix D). Formally,

$$\Psi_{QA} \leftarrow \underset{\Psi}{\text{argmin}} \sum_{k=1}^{K} \mathcal{L}_{QA}(\mathcal{D}^k_{QA}; \theta, \{\Phi^k_{QA}\}^K_{k=1}, \Psi) \tag{5}$$

where Ψ refers to the initialized zero-shot fusion parameters.

More specifically, in the l-th Transformer layer, let h^l_{PLM} and $h^{k,l}_E$ be the representations of underlying PLM parameterized by θ and an *expert adapter* parameterized by Φ^k_{QA}, respectively. Then, using the hidden representation h^l_{PLM} of PLM as a query, the fusion layer performs the attention-like function as follows:

$$\mathbf{K}_l, \mathbf{V}_l = [h^{1,l}_E, ..., h^{K,l}_E] \tag{6}$$

$$\mathbf{Q}_l = h^l_{PLM} \tag{7}$$

$$\mathbf{z}_l = \text{Attention}(\mathbf{Q}_l\mathbf{W}^Q_l, \mathbf{K}_l\mathbf{W}^K_l, \mathbf{V}_l\mathbf{W}^V_l) \tag{8}$$

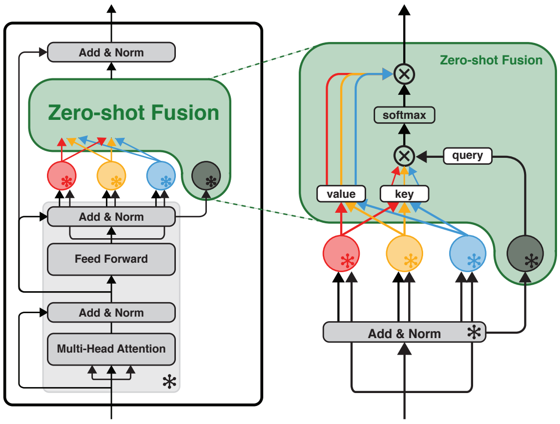

Figure 2: Illustration of the zero-shot fusion architecture with *KG-Classifier adapter*. Each colored circle represents *expert adapters*, except the black circle which denotes *KG-Classifier adapter*. $*$ indicates the fixed layer. Details are in Appendix F

where $\mathbf{z}_l$ is passed to the next Transformer layer. Given a sample, the zero-shot fusion learns the suitable balancing parameters between the *expert adapters* for zero-shot reasoning. Eventually, it learns to identify generalizability across commonsense reasoning tasks.

3.3 KG-Classifier Adapter

AdapterFusion uses the PLM hidden representation h^l_{PLM} as a query which is learned when training on a specific downstream task. In our zero-shot setting, however, we use a mixture of synthetic QA for fusion training, which is not exactly a training dataset for a downstream task. To compensate for this issue, we present *KG-Classifier adapter*, which is a KG alignment-aware adapter, which is motivated from the fact that the ability to find which KG has an alignment with the given sample can be helpful as a role of providing a guidance for better performance (Ma et al., 2019, 2021).

Specifically, we propose a novel training task for *KG-Classifier adapter*, which requires predicting the KG for the given sample of the task. For that, given $\{\mathcal{D}^k_{QA}\}^K_{k=1}$, we first transform a QA sample (Q_i, A_i) into a new KG classification sample $[Q_i; A_{i,label}]$ where $[;]$ is the concatenation. Then, we obtain a new label $y_i \in \{0,1\}^K$ indicating the corresponding KG source. The samples are in Appendix E. Formally, KG classification dataset $\mathcal{D}_{KGC}$ is defined as:

$$\mathcal{D}_{KGC} = \{([Q_i; A_{i,label}], y_i)\}^M_{i=1} \qquad (9)$$

where M is the total size of $\{\mathcal{D}^k_{QA}\}^K_{k=1}$.

Based on $\mathcal{D}_{KGC}$, we learn the *KG-Classifier adapter* parameterized by θ and Φ_{KGC}. First, a classification sample i is encoded into $h_{CLS} \in \mathbb{R}^H$ then scored as $\hat{y}_i \in \mathbb{R}^K$ with a linear layer $W_{KGC} \in \mathbb{R}^{K\times H}$, *i.e.*, $\hat{y}_i = W_{KGC}h_{CLS}$. Once $\hat{y}_i$ is normalized by a softmax layer, the network is trained to minimize the cross-entropy loss $\mathcal{L}_{KGC}$ between the prediction $\hat{y}_i$ and its ground truth y_i:

$$\Phi_{KGC} \leftarrow \underset{\Phi}{\operatorname{argmin}} \sum_{i=1}^{M} \mathcal{L}_{KGC}(y_i, \hat{y}_i; \theta, \Phi) \qquad (10)$$

We propose to use the representation of *KG-Classifier adapter* as a query in attention-like mechanism, referred to as the zero-shot fusion with *KG-Classifier adapter*. That is, using the hidden representation h^l_{KGC} of a *KG-Classifier adapter* parameterized by Φ_{KGC} as a query, we substitute $\mathbf{Q}_l$ in Eq. (11) as follows:

$$\mathbf{Q}_l = h^l_{KGC} \qquad (11)$$

The overall zero-shot fusion architecture including *KG-Classifier* is illustrated in Figure 2.

4 Experiments

In this section we evaluate the efficacy of our framework on five commonsense reasoning tasks. We denote *KG-Classifier adapter* by *KG-C adapter*.

4.1 Experimental Settings

All our experiments are conducted in a zero-shot setting, in which the models do not have access to the official training data or labels of the benchmark. For the evaluation, we use the validation set of each benchmark[2], however, the validation set of each benchmark can be role as an test set since it is not used for hyperparameter tuning or model selection. We use accuracy as a metric.

4.1.1 Benchmarks

We evaluate our proposed framework on five question-answering benchmarks for commonsense reasoning: SocialIQA (SIQA) (Sap et al., 2019b), CommonsenseQA (CSQA) (Talmor et al., 2018), Abductive NLI (a-NLI) (Bhagavatula et al., 2020), PhysicalIQA (PIQA) (Bisk et al., 2020), and WinoGrande (WG) (Sakaguchi et al., 2020). Each commonsense benchmark evaluates a specific kind of knowledge: social commonsense for SIQA, concept-level commonsense for CSQA, abductive

---

[2] Since the official test sets are not publicly available

Model	KG	a-NLI	CSQA	PIQA	SIQA	WG	Avg.
Random	-	50.0	20.0	50.0	33.3	50.0	40.7
Majority	-	50.8	20.9	50.5	33.6	50.4	41.2

Table 2: Zero-shot evaluation results with different combinations of models and knowledge sources across five commonsense tasks. AT, CN, WD and WN represent `ATOMIC`, `ConceptNet`, `WikiData` and `WordNet`, respectively. Whole represents the combination of AT, CN, WD and WN. Bold text indicates the best performance on each benchmark. RoBERTa-L (MR) used the synthetic dataset after filtering, while we use the raw version. SMLM (*) used different KG which has strong alignment with each task (*e.g.*AT for SIQA).

reasoning for a-NLI, physical commonsense for PIQA, and pronoun resolution ability for WG.[3] The details are presented in Appendix G.

4.1.2 Baselines

We compare our framework with the following baselines. First, to show the characteristics of each benchmark, we use the random or the most frequent label as *Random* and *Majority* baseline, respectively. RoBERTa-L and GPT2-L is the performance of each PLM without any fine-tuning. Also, as the baseline for the unsupervised learning model using KGs, we report the performance of Self-talk (Shwartz et al., 2020), COMET-DynaGen (Bosselut and Choi, 2019), SMLM (Banerjee and Baral, 2020) as presented in original papers.

For further analysis in §4.4 and §4.5, we set the following models that are pre-trained on the synthetic QA datasets from KGs as baselines:

- **Single-Task Learning (STL)**: The model is pre-trained on a synthetic QA dataset generated from a single KG. Specifically, we experiment two architectural choices: PLM (STL-PLM) and PLM with adapters (STL-Adapter). For each architecture, there are four STL models for each of synthetic QA datasets derived from `ATOMIC`, `ConceptNet`, `WikiData`, and `WordNet`. We note that the trained STL-Adapter is an *expert adapter* from a specific KG in our framework. The performance of each STL baseline is shown in Appendix I Table 9 and Table 10.
- **Multi-Task Learning (MTL)**: The model is pre-trained on multiple synthetic QA datasets, each of which is generated from a KG. We experiment with a PLM trained on all four aforementioned synthetic QA datasets. We note that the difference between STL-PLM and MTL is whether to use one synthetic QA dataset or multiple synthetic QA datasets for its training.

4.1.3 Implementations

We employ RoBERTa-L (Liu et al., 2019b) from Hugging Face's transformers toolkit for all experiments. We follow the default settings from Ma et al. (2021). Our implementation uses Adapter (Houlsby et al., 2019) and AdapterFusion (Pfeiffer et al., 2021) as a base model architecture from AdpaterHub (Pfeiffer et al., 2020a). We run our experiments with three different random seeds. The implementation details are described in Appendix H.

4.2 Main Results

Table 2 shows the zero-shot evaluation results on five benchmark datasets. Generally, zero-shot fusion scores higher than the baselines across all benchmarks, and further, zero-shot fusion shows the best performance in all benchmarks except WG. We note that although Ma et al. (2021) uses the synthetic QA dataset after sample filtering, our method achieves comparable performance with the best performance in WG, even with the raw dataset. Also, the average score of all evaluation benchmarks (the

---

[3] Some benchmarks have a strong alignment with a certain KG due to its construction strategy: SIQA-`ATOMIC`, and CSQA-`ConceptNet`. To make a direct comparison with Ma et al. (2021), we use the same KGs to generate data samples.

last column of Table 2) shows that zero-shot fusion has generalisability in commonsense reasoning.

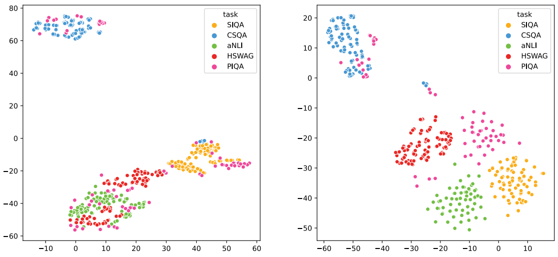
In addition, zero-shot fusion achieves consistent improvements over MTL. These results indicate that our proposed zero-shot fusion method attributes to fusing the knowledge of multiple KGs more synergetically regardless of the task.

Moreover, as an ablation, we compare the zero-shot fusion with and without *KG-C adapter* to explore the efficacy of the *KG-C adapter*. We can observe that zero-shot fusion with *KG-C adapter* improves the average accuracy by 0.4%, which implies that the use of *KG-C adapter* improves the overall performance and makes our method generalize better on most of the evaluation benchmarks.

4.3 Impact of the KG-Classifier Adapter

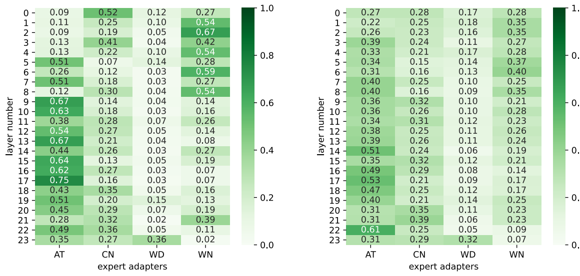
To assess the effects of the *KG-C adapter* itself, we visualize and compare the final layer `[CLS]` token representation between PLM and *KG-C adapter*. Figure 3 shows t-SNE (Van der Maaten and Hinton, 2008) plots of all representation of five benchmark datasets. In this figure, every sample is mapped into a 1024-dimensional feature space through RoBERTa-L model and projected back into a two-dimensional plane by t-SNE. We can observe that *KG-C adapter* can separate the samples of different benchmarks well despite being unseen data. It verifies that KG-awareness acquired with the KG classification task is beneficial to categorize the given sample. The *KG-C adapter* can thus generate a relevant KG-aware query for a given sample and help to fuse representations from suitable *expert adapters* in our proposed framework.

Further, we explore how the *KG-C adapter* affects zero-shot fusion which is based on an attention-like mechanism (Pfeiffer et al., 2021) compared to zero-shot fusion without *KG-C adapter*. Here, while zero-shot fusion without *KG-C adapter* simply uses the representation of PLM as a query, zero-shot fusion with *KG-C adapter* leverages the representation of *KG-C adapter*. To illustrate this strength, we visualize the attention probability of `[CLS]` token from each fusion layer as a representative in Figure 4. The column of the darker cell indicates the adapter that has the bigger influence on the fused representation. We can observe that zero-shot fusion with *KG-C adapter* fuses the knowledge from different experts with a subtle difference rather than focusing on a single expert severely. This implies that *KG-C adapter* enables the delicate balancing between multiple knowledge sources based on the KG-alignment awareness, which leads to performance improvements in commonsense reasoning tasks. Interestingly, both cases have the ability not to focus on the *expert adapter* based on `WikiData`, which can be seen as a redundant expert.[4] This observation would benefit from the further study that explores the optimal combination of KGs by expert selection or rejection.



(a) PLM (b) *KG-Classifier adapter*

Figure 3: t-SNE visualization of the hidden representation from (a) PLM and (b) *KG-C adapter*. Each color denotes the five different benchmark samples.



(a) w/o *KG-C adapter* (b) w/*KG-C adapter*

Figure 4: Comparison of attention probability between zero-shot fusion with/without *KG-C adapter*. The x- and y-axis indicate *expert adapters* and the fusion layer number in RoBERTa-L, respectively. The darker color indicates higher attention probability in fusion layer.

4.4 Mitigating Interference

In this experiment, we compare the amount of interference in the MTL and zero-shot fusion with *KG-C adapter*. We propose a novel evaluation metric, the *interference ratio*, which is the percentage of the incorrectly predicted samples by the multi-KG models among the correctly predicted samples from the STL models in common.

Using the interference ratio, we can precisely compare the negative effects of multi-KG models

---

[4] The zero-shot fusion with KG-C adapter using AT, CN, and WN shows the best average performance in Table 10.

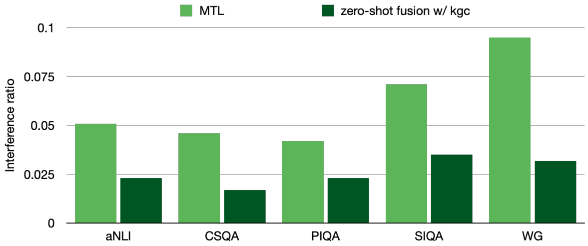


Figure 5: Interference ratio of multi-KG models on five benchmarks. The lower indicates less interference.

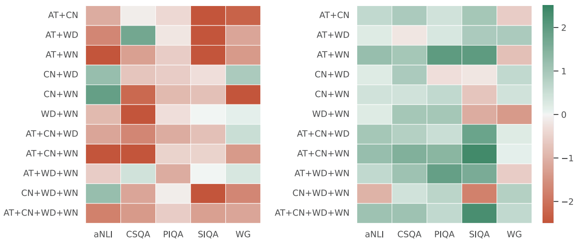
on knowledge aggregation since the only reason to get the correct samples wrong is the interference caused by learning with additional KGs. We present the interference ratio of the models on five benchmark datasets in Figure 5. This figure shows that MTL has the higher interference ratio than the competing models across all benchmarks. Our method achieves a substantially better ratio, especially when *KG-C adapter* is used. This demonstrates the efficacy of our framework in mitigating interference between knowledge, which is one of the major problems of MTL.

4.5 Visualization of Knowledge Aggregation

To verify the ability of our model to aggregate different types of KGs, we compare the relative performance gains of MTL and zero-shot fusion with *KG-C adapter* when increasing the number of KGs. The performance of all KG-combinations for each framework is presented in Table 9 and Table 10. We visualize the improvement of performance for five benchmark development sets, leveraging heatmaps in Figure 6. Here, for the sake of brevity, we denote our framework with *KG-C adapter* as our method.

For MTL in Figure 6 (a), the color of the cell denotes the relative improvement of MTL with the combination of KGs over the best performance among the STL-PLM of KGs. Also, for our method in Figure 6 (b), the relative improvement is measured based on the best performance among the STL-Adapter of KGs, considering the difference of the base architecture for MTL (i.e. PLM) and zero-shot fusion (i.e. PLM with adapter). The green and red colors denote the increase and decrease of performance, respectively, when using multiple KGs together. The greener color on the cells indicates that the approach benefits from an increasing number of KGs, which implies aggregating knowledge successfully.

In Figure 6, while the MTL tends to show the decrease of the performance when more KGs are



(a) MTL

(b) zero-shot fusion w/ *KG-C adapter*

Figure 6: Relative improvement upon the STL on five benchmarks. The x- and y-axis indicate the benchmark and the combination of the KGs, respectively. The value of each cell indicates the relative performance improvement of using multiple KGs over the highest performance among STLs. The green and red colors denote the improvement or decrease of relative performance, respectively.

utilized for training, our method obtains relative performance improvement across most of benchmarks. In both framework, the slightly degraded performance of the combination of KGs without `ATOMIC` could be due to the strong alignment between `ATOMIC` and SIQA. Except for the above case, we can observe that as more KGs are leveraged, the color of the cell gets greener, which implies that our method gains more advantages for better performance. This demonstrates that our method enables knowledge aggregation for multiple KGs synergetically.

5 Conclusion

Despite the existence of various types of commonsense KGs, utilizing multiple KGs has not been explored enough in the commonsense reasoning field. Motivated by this, this paper proposes a modularized transfer learning framework to fuse the knowledge from multiple KGs efficiently for zero-shot commonsense reasoning. Our framework consists of KG modularization for *expert adapter*, zero-shot fusion and *KG-Classifier adapter*. Extensive experiments show that our framework obtains strong improvements over MTL on five commonsense reasoning benchmarks.

In the future, our work can be extended to adapt our methods to further various multiple KGs with studies of appropriate scale for KG modularization. In addition, based on our hypothesis that the existence of an optimal combination, we can explore the study for the optional use of modularized KG experts for the best transfer learning.

A List of Notations

We summarize the notations used in this paper in Table 7.

B Synthetic QA

We generate QA for four KGs (ATOMIC, ConceptNet, WikiData and WordNet) based on synthetic QA generation (Ma et al., 2021) without sample filtering. We use the prefixes for relation of triplet as shown in Table 3 for generating synthetic QA (refer to Ma et al. (2021)). Table 4 shows the statistics of the synthetic QA dataset from KGs. The samples of synthetic QA with source triplet are shown in Table 5.

relation	prefix
xAttr	. PersonX is seen as
xIntent	. Before, PersonX wanted
xNeed	. Before, PersonX needed to
xReact	. As a result, PersonX felt
xWant	. As a result, PersonX wanted to
xEffect	. PersonX then
oReact	. As a result, others felt
oWant	. As a result, others wanted to
oEffect	. Others then
Causes	can cause [MASK]
UsedFor	can be used for [MASK]
CapableOf	is capable of [MASK]
CausesDesire	causes desire for [MASK]
IsA.	is a [MASK]
SymbolOf	is a symbol of [MASK]
MadeOf	can be made of [MASK]
LocatedNear	is often located near [MASK]
Desires	desires [MASK]
AtLocation	can be found at [MASK]
HasProperty	has property [MASK]
PartOf	is part of [MASK]
HasFirstSubevent	starts by [MASK]
HasLastSubevent	ends by [MASK]

Table 3: Prefixes used for synthetic QA dataset

KG	Train	Validation	Total
ATOMIC	534,833	60,289	595,122
ConceptNet	363,645	19,140	382,785
WikiData	42,342	2,229	44,571
WordNet	256,922	13,523	270,445
Whole	1,197,742	95,181	1,292,923

Table 4: Synthetic QA dataset statistics. Whole represents the combination of AT,CN,WD and WN.

C Commonsense Knowledge Graphs

A variety of KGs have been proposed to provide large-scale high quality collection of different commonsense knowledge types: ATOMIC (Sap et al., 2019a) focuses on inferential knowledge organized as typed if-then relations with variables (*e.g.*, "*if X pays Y a compliment, then Y will likely return the compliment*"). ConceptNet (Speer et al., 2017) mainly consists of taxonomic and lexical knowledge (*e.g.*, RelatedTo, Synonym, and IsA) and physical commonsense knowledge (*e.g.*, MadeOf and PartOf). WikiData (Vrandečić and Krötzsch, 2014) is a general-domain KG which has a close relation with Wikipedia. WordNet (Miller, 1995) is a large lexical source of words and taxonomical system.

QA from ATOMIC (Sap et al., 2019a)
(e^h, r, e^t): (Dana speeds on the highway., xAttr, risky) Q: Dana speeds on the highway. Dana is seen as A1: considerate **A2: risky**(✓) A3: lazy
QA from ConceptNet (Speer et al., 2017)
(e^h, r, e^t): (pentode, IsA, vacuum tube) Q: pentode is a [MASK] A1: ascocarp A2: girls footwear **A3: vacuum tube**(✓)
QA from WikiData (Vrandečić and Krötzsch, 2014)
(e^h, r, e^t): (badminton, IsA, type of sport) Q: badminton is a [MASK] A1: fable A2: juvenile justice **A3: type of sport**(✓)
QA from WordNet (Miller, 1995)
(e^h, r, e^t): (princewood, PartOf, genus Cordia) Q: princewood is part of [MASK] A1: shaddock **A2: genus Cordia**(✓) A3: family Columbidae

Table 5: Synthetic QA examples. We use templates to convert a question (e^{head}, r) into a natural language.

D Dataset for Zero-shot Fusion

For zero-shot fusion training, we use balanced mixture of synthetic QA from different KGs by random sampling. The statistics of dataset for zero-shot fusion is shown in Table 6. For validation dataset, we balance between the ATOMIC, ConceptNet and WordNet due to the lack of synthetic QA validation dataset from WikiData.

KG	Train	Validation	Total
+ATOMIC	2,500	2,500	5,000
+ConceptNet	2,500	2,500	5,000
+WikiData	2,500	2,229	4,729
+WordNet	2,500	2,500	5,000
Total	10,000	9,729	19,729

Table 6: Statistics of the dataset for zero-shot fusion

Notation	Meaning
(e^{head}, r, e^{tail})	Triple of KG (head entity, relation, tail entity)
Q_i	Natural language Question of sample i
$A_i = \{A_{i,1}, ..., A_{i,m}\}$	A set of answer options of sample i, $A_{i,j}$ denotes j-th answer option of sample $i (1 \leq j \leq m)$
$T_i = \{T_{i,1}, ..., T_{i,m}\}$	Input sequences generated by concatenation of Q_i and A_i
w_t	A word t-th token in the sequence $T_{i,j}$
$label$	the index of the correct answer for sample
$\mathcal{D}^k_{QA}$	Synthetic QA generated by KG k, $1 \leq k \leq K$
N_k	The number of samples for $\mathcal{D}^k_{QA}$, $1 \leq k \leq K$
θ	Parameters for pre-trained LM
Φ^k_{QA}	Parameters for the *expert adapter* of KG k, $1 \leq k \leq K$
Φ_{KGC}	Parameters for the *KG-Classifier adapter*
Ψ_{QA}	Parameters for the fusion layer
l	The index of Transformer layer
$\mathbf{W}^Q_l$	Query matrix of fusion layer in lth Transformer layer
$\mathbf{W}^K_l$	Key matrix of fusion layer in lth Transformer layer
$\mathbf{W}^V_l$	Value matrix of fusion layer in lth Transformer layer
h^l_{PLM}	Hidden representation of PLM parameterized by θ in lth Transformer layer
$h^{k,l}_E$	Hidden representation of *expert adapter* parameterized by Φ^k_{QA} in lth Transformer layer
h^l_{KGC}	Hidden representation of *KG-Classifier adapter* parameterized by Φ_{KGC} in lth Transformer layer

Table 7: Notations and their meanings

E KG-Classification Dataset

We suggest KG-Classification dataset $\mathcal{D}_{KGC}$ for *KG-Classifier adapter* training. The example of transformation from synthetic QA dataset $\mathcal{D}_{QA}$ is shown in Table 8. The dataset size is equal to the whole dataset of synthetic QA (refer to Table 4).

QA → KG-Classification `ATOMIC`
Q: Dana speeds on the highway. Dana is seen as A1: considerate **A2: risky**(✓) A3: lazy
S: Dana speeds on the highway. Dana is seen as risky. A: Atomic
QA → KG-Classification `ConceptNet`
Q: pentode is a [MASK] A1: ascocarp A2: girls footwear **A3: vacuum tube**(✓)
S: pentode is a vacuum tube. A: ConceptNet
QA → KG-Classification `WikiData`
Q: badminton is a [MASK] A1: fable A2: juvenile justice **A3: type of sport**(✓)
S: badminton is a type of sport. A: WikiData
QA → KG-Classification `WordNet`

F Zero-shot architecture with parameters

We describe the illustration of the zero-shot fusion architecture with parameters in Figure 7.

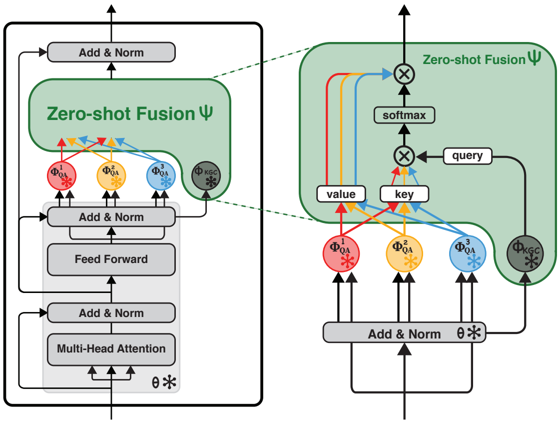

Figure 7: Illustration of the zero-shot fusion architecture with parameters. Each colored circle represents *expert adapters*, except the black circle which denotes *KG-Classifier adapter*. $*$ indicates the fixed layer.

G Commonsense Reasoning Benchmarks

SocialIQA (SIQA) (Sap et al., 2019b) requires reasoning for emotional and social intelligence in everyday situations. Each QA consists of a context that comes from `ATOMIC`, a question which is based on the relations in `ATOMIC`, and 3 answer candidates. It contains 38,000 multiple-choice questions, which is generated by crowdsourcing.

CommonsenseQA (CSQA) (Talmor et al., 2018) evaluates a broad range of concept-level commonsense reasoning. Each multiple-choice question, answer and distractors are designed by crowdsourcing based on the `ConceptNet`.

Abductive NLI (a-NLI) (Bhagavatula et al., 2020) asks to infer the most plausible explanation based on the given causal situation to test abductive reasoning in narratives. Each sample consists of the beginning and the end of the story with two possible options to be an explanation for the given situation.

PhysicalIQA (PIQA) (Bisk et al., 2020) requires physical commonsense reasoning to select the most sensible solution for the given goal among the two choices. Its dataset is comprised of over 16,000 training samples, 2K validation samples, and 3K test samples.

HellaSWAG (HSWAG) (Zellers et al., 2019) is an evolved version of SWAG (Zellers et al., 2018), which asks to infer the most proper story based on the given situation. The dataset consists of 70K questions with four answer options.

H Implementation Details

In all our experiments, we use max sequence length 128, batch size 32, weight decay 0.01, adam β_1 0.9, adam β_2 0.99, adam epsilion $1e^{-8}$, warm-up proportion 0.05, and margin 1.0. The experiments are conducted split across NVIDIA GeForce 3090 and NVIDIA RTX A5000.

H.1 Baselines

The baseline models for STL-PLM and MTL are trained with learning rate $1e^{-5}$ for single epoch.

H.2 Adapter

For *expert adapters*, we use learning rate $8e^{-5}$ after tuning in $\{5e^{-6}, 8e^{-6}, 1e^{-5}, 5e^{-5}, 8e^{-5}, 1e^{-4}\}$. For *KG-Classifier adapter*, we use learning rate $1e^{-5}$, batch size 64 for five epochs.

H.3 Zero-shot fusion

After experiment with learning rates $\{1e^{-5}, 8e^{-5}\}$, we empirically find that a learning rate of $1e^{-5}$ works well on zero-shot fusion without/with *KG-Classifier adapter*, respectively. Here, we set the attention drop probability 0.1. As we used extremely smaller subset of the synthetic QA dataset, zero-shot fusions are trained for five epochs.

I Knowledge aggregation of zero-shot fusion

In order to validate the efficacy on knowledge aggregation of zero-shot fusion over the STL, we present the results of each framework with various combination of KGs in Table 9 and Table 10.

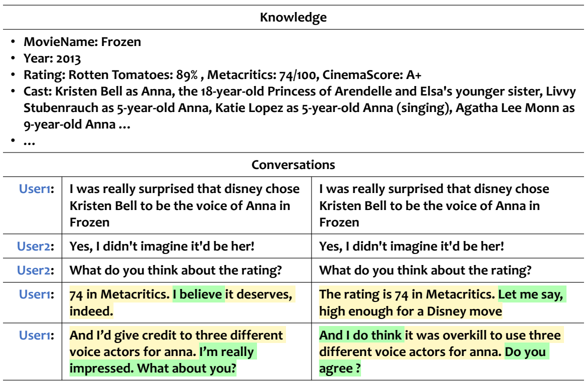
Abstract

Grounding dialogue generation by extra knowledge has shown great potentials towards building a system capable of replying with knowledgeable and engaging responses. Existing studies focus on how to synthesize a response with proper knowledge, yet neglect that the same knowledge could be expressed differently by speakers even under the same context. In this work, we mainly consider two aspects of knowledge expression, namely the structure of the response and style of the content in each part. We therefore introduce two sequential latent variables to represent the structure and the content style respectively. We propose a segmentation-based generation model and optimize the model by a variational approach to discover the underlying pattern of knowledge expression in a response. Evaluation results on two benchmarks indicate that our model can learn the structure style defined by a few examples and generate responses in desired content style.

1 Introduction

Building an open domain dialogue system has attracted increasing attention from the community of AI and NLP. Despite the impressive progress, existing models are notorious for replying with generic and bland responses. To bridge the gap, researchers resort to ground dialogue generation by extra knowledge such as unstructured documents (Zhou et al., 2018c; Dinan et al., 2019). By this means, the documents serve as content sources and make a dialogue system knowledgeable regarding various concepts in a discussion.

However, existing studies focus on how to synthesize a response with proper knowledge (Dinan et al., 2019; Kim et al., 2020; Zhao et al., 2020b), but pay little attention to the fact that the same knowledge could be expressed differently even under the same context. These models usually employ a regular decoder to generate the response in an auto-regressive manner given the contextual representations of knowledge and dialogue context, which makes the generation process less explainable and controllable.



Knowledge

- **MovieName: Frozen**

Conversations

User1:	I was really surprised that disney chose Kristen Bell to be the voice of Anna in Frozen	I was really surprised that disney chose Kristen Bell to be the voice of Anna in Frozen
User2:	Yes, I didn't imagine it'd be her!	Yes, I didn't imagine it'd be her!
User2:	What do you think about the rating?	What do you think about the rating?
User1:	74 in Metacritics. I believe it deserves, indeed.	The rating is 74 in Metacritics. Let me say, high enough for a Disney move
User1:	And I'd give credit to three different voice actors for anna. I'm really impressed. What about you?	And I do think it was overkill to use three different voice actors for anna. Do you agree ?

Table 1: A case from CMU_DoG. Given the same knowledge and context, the last two turns in left and right conversations exhibit positive and negative sentiments, respectively. Each utterance can be decomposed into knowledge-related and knowledge-irrelevant segments.

In general, the expression style of response is composed of two aspects: the structure of the response and the style of the content in each part. As the example shown in Table 1, knowledge-related phrases and clauses tend to be long, like "And I'd give credit to three different voice actors for anna.", or short, like "74 in Metacritics". Besides, they may appear at the beginning of the sentence, or at the end. For the sake of description, we decompose a response into a sequence of non-overlapping segments, each is either related to certain background knowledge and diverse in content style, or almost irrelevant to the knowledge but simply playing the role of stitching the context and carrying on the conversation. We therefore define the structure style as the distribution and number of two kinds of segments. The structure style itself is far from dominant in the sentence expression, since different speakers could convey converse attitude even if the

context and the knowledge are exactly the same. So it is necessary to introduce the content style as the expression fashion within each knowledge-related segment. We further introduce two latent variables to facilitate end-to-end training, one for predicting the start and end positions of a segment, the other for deciding the category of each segment. Since the human annotations for sentence segmentation are absent and enumerating over all possibilities to maximize the likelihood of the response is time-consuming, we propose a variational framework for segmentation-based generation and induce an evidence lower bound of the likelihood.

Formally, our model follows an encoder-decoder architecture. The encoder is to obtain the contextual representation of conversational context and knowledge in a regular way. The decoder consists of three types of modules: (1) context module, for response only based on context without knowledge; (2) plain-knowledge module, for response referring knowledge but without particular style; and (3) stylized-knowledge module, for response referring knowledge and with a specific style. The context module is the only module not relying on knowledge, but simply paying attention to contextual information. Compared with plain-knowledge module, stylized-knowledge module has unique adapters, which is their primary discrepancy. When decoding, the decoder first predicts the segmentation of the response and then makes a choice in three kinds of modules to generate a single segment. Both the segmentation and the module selection are instructed under sequential latent variables.

We train our model on the Reddit Corpus published by Li et al. (2020) and evaluate our model on two benchmarks of knowledge-grounded conversation: Wizard of Wikipedia (Wizard) (Dinan et al., 2019) and CMU Document Grounded Conversation (CMU_DoG) (Zhou et al., 2018c). Evaluation results indicate that our model can significantly outperform state-of-the-art methods in the zero-resource setting (i.e., only trained on the Reddit Corpus). In addition, the performance of our model improves significantly on Wizard and CMU_DoG with the presence of only 10% training data and the segment distributions after fine-tuning are consistent with our prior knowledge about the two datasets, indicating that our model can learn the structure style with little cost. Finally, our model outperforms previous state-of-the-art models on the accuracy of performing sentiment classification using generated responses, which indicates that the model can be controlled to express knowledge with the desired content style.

Contributions in this work are three-fold: (1) exploration of the knowledge expression in knowledge-grounded conversation; (2) proposal of a variational segmentation-based generation model to discover the underlying expression style in a response; (3) empirical verification of the effectiveness of the proposed model on two benchmarks of knowledge-grounded conversation.

2 Related Work

On the vanilla encoder-decoder architecture (Shang et al., 2015; Vinyals and Le, 2015), various extensions have been made to model the structure of dialogue contexts (Serban et al., 2016, 2017; Zhang et al., 2019a); to improve diversity of responses (Li et al., 2015; Xing et al., 2017; Zhao et al., 2017; Tao et al., 2018); to control attributes of responses (Xu et al., 2019; Zhou et al., 2018a; Wang et al., 2018; See et al., 2019); and to bias responses to some specific personas (Li et al., 2016; Zhang et al., 2018). Recently, grounding dialogue generation by extra knowledge has seemed promising to bridge the gap between conversation with existing systems and conversation with humans, and the knowledge could be obtained from knowledge graphs (Zhou et al., 2018b; Moon et al., 2019; Tuan et al., 2019), retrieved from unstructured documents (Dinan et al., 2019; Lian et al., 2019; Zhao et al., 2019, 2020a; Kim et al., 2020; Li et al., 2020; Fu et al., 2022) or visual background (Mostafazadeh et al., 2017; Shuster et al., 2018; Huber et al., 2018). In this work, we study document-grounded dialogue generation. Rather than selecting knowledge relevant to dialogue context and directly exploiting pre-trained language models to generate the response, we focus on expressing knowledge in this task.

The idea of sequence modeling via segmentation (Wang et al., 2017; Kim et al., 2019) has attracted widespread attention in several natural language processing tasks. In text segmentation task, Wang et al. (2017) propose a probabilistic model for sequence modeling via their segmentation and a “Sleep-WAke Network” (SWAN) method. In machine translation, Huang et al. (2017) propose a neural phrase-based machine translation system that models phrase structures in the target language using SWAN. In data-to-text generation, Wiseman et al. (2018) develop a neural template-like generation model with a HSMM decoder, which is learned tractably by backpropagating through a dynamic program; to tackle the problem of weak Markov assumption for the segment transition probability, Shen et al. (2020) propose to explicitly segment target text into fragments and align them with their data correspondences, and jointly learn the segmentation and correspondence via dynamic programming.

3 Approach

We start by providing the problem formalization and overview of the proposed model in Sec.3.1. Then in Sec.3.2 we describe the design for each components. Lastly, we elaborate how to optimize the components with variational inference and weak supervision in Sec.3.3.

3.1 Overview

Suppose that we have a dataset $\mathcal{D} = \{(U_i, K_i, R_i)\}_{i=1}^N$, where $\forall i \in \{1, \ldots, N\}$, K_i serves as background knowledge of the dialogue (U_i, R_i) with $K_{i,j}$ being the j-th sentence, U_i is the context of the dialogue with $U_{i,j}$ the j-th utterance, and R_i is the response. To bias the expression to a specific structure style, we further assume that there are a few examples $\mathcal{D}_{sty} = \{(U_i, K_i, R_i)\}_{i=1}^M$ provided by users depicting the required style for knowledge expression. Note that we have $N \gg M$, since corpus in a specific expression style is rare and difficult to acquire. The goal is to learn a generation model $p_\theta(R|U, K)$ (θ denotes the parameters of the model) from $\mathcal{D}$, to generate a response R following $p_\theta(R|U, K)$ given a new dialogue context U and the associated knowledge K. Different from previous KGC generation model, we allow users to either (1) bias the structure style of $P_\theta(R|U, K)$ to $\mathcal{D}_{sty}$ with little cost; or (2) switch the content style of knowledge expression in R.

Figure 1 gives an overview of the proposed model, which is based on the encoder-decoder architecture. The encoder generates the contextual representations of the dialogue and knowledge, while the decoder generates the segments one after another. $\mathbf{h}_t^N$ encodes the dialogue context up to timestep $t-1$ with N denoting the number of decoder layers. Given $R = (r_1, \cdots, r_t, \cdots, r_{l_r})$ with r_t referring the t-th token of R whose length is supposed to be l_r, the variable $Z = \{z_t\}_{t=1}^{l_r}$ is utilized to control the choice of module of each segment (**Module Indicator**), and its historical information is encoded by $\{\mathbf{c}_t\}_{t=0}^{l_r}$. $M = \{m_t\}_{t=1}^{l_r}$ is a sequence of binary variables and used to determine the boundary of each segment (**Boundary Indicator**). Specifically, $m_t = 1$ indicating that the current segment is already completed and a new segment should be created at the next timestep. Otherwise, $m_t = 0$ and the current segment remains unfinished. The generative process is disassembled into two steps: (1) determine the type of a new segment based on previously generated text and previous segment types; (2) generate within the current segment until the binary variable $m_t = 1$.

3.2 Model Architecture

Context and Knowledge Encoding. We exploit the pre-trained BART (Lewis et al., 2020) as the backbone of our architecture, which is pre-trained using a variety of denoising objectives and achieves state-of-the-art results on a range of text generation tasks. Given the dialogue context $U = (U_1, \cdots, U_n)$, we simply concatenate them as $(u_1, \cdots, u_{l_u})$. Similarly, we concatenate the associated knowledge $K = (K_1, \cdots, K_m)$ as $(k_1, \cdots, k_{l_k})$. l_u and l_k are the length of dialogue context and background knowledge respectively. The input of the encoder is then defined as:

$$I = [\text{BOS}]k_1 \ldots k_{l_k}[\text{EOS}]u_1 \ldots u_{l_u}[\text{EOS}]. \quad (1)$$

The input I is truncated or padded to the maximum capacity and then passes through the stacked self-attention layers and results in a knowledge-aware context representation $\mathbf{C}$, and a context-aware knowledge representation $\mathbf{K}$. Specifically, the context-aware knowledge representation is defined as $\mathbf{K} = [\mathbf{h}_1^{enc}, \cdots, \mathbf{h}_{l_k+1}^{enc}]$ where $\mathbf{h}_t^{enc}$ is the last layer of BART encoder at time t. Similarly, the knowledge-aware context representation is defined as $\mathbf{C} = [\mathbf{h}_{l_k+2}^{enc}, \cdots, \mathbf{h}_{l_k+l_u+2}^{enc}]$.

Prior of Module Indicator. We use the sequential discrete latent variable $Z = \{z_t\}_{t=1}^{l_r}$ to decide which module to invoke at each timestep. The transition of z_t occurs only when a segment is completed, which is decided by the binary boundary variable M. The prior quantifies the distribution of z_t before we observe the segment, and it is reasonable to assume that the prior of z_t depends on previous module choices $z_{<t}$ and previously generated text. Then the transition of Z is defined as:

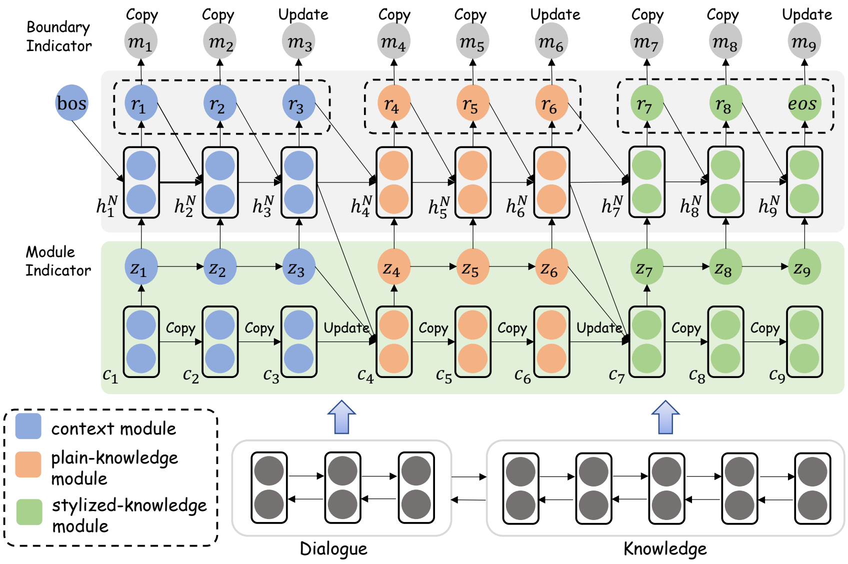

Figure 1: Architecture of the proposed model. "Copy" means $m_t = 0$ and the state of the module indicator c_{t+1} remains unchanged. "Update" indicates that $m_t = 1$ and the state has been updated to include the information from the previous segment.

$$p_{\theta_z}(z_t|r_{<t}, z_{<t}, m_{t-1}) = m_{t-1} \cdot \tilde{p}(z_t|\mathbf{c}_t) + (1 - m_{t-1}) \cdot \delta(z_t = z_{t-1}), \qquad (2)$$

where δ is a Kronecker delta function. $\mathbf{c}_t$ encodes all previous latent states $z_{<t}$ and generated text $r_{<t}$ as follows:

$$\mathbf{c}_t = m_{t-1} \cdot f_{z-\text{rnn}}(\tilde{\mathbf{z}}_{t-1}, \mathbf{c}_{t-1}) + (1 - m_{t-1}) \cdot \mathbf{c}_{t-1}. \qquad (3)$$

$\tilde{\mathbf{z}}_{t-1} = [\mathbf{e}_{t-1}; \mathbf{h}_{t-1}^{N,dec}]$ with $\mathbf{e}_{t-1}$ the embedding of z_{t-1} and $\mathbf{h}_{t-1}^{N,dec}$ the representation of last generated token. Specifically, $m_{t-1} = 0$ means that the next timestep t is still in the same segment as the previous timestep $t-1$ and thus the latent variable z_t should not be updated. Otherwise, it means that current segment is completed and z_t is updated with the transition function $\tilde{p}(z_t|\mathbf{c}_t)$. Because we only have $N_{sty} + 2$ options when choosing a module, where N_{sty} is the number of different user-defined styles in addition to 2 default styles, so in this model, the latent variable z_t ranges in natural integer to denote corresponding style type. Specifically, $z_t = 0$ denotes choosing the context expression module to generate a knowledge-irrelevant segment; $z_t = 1$ tells the model to choose the knowledge expression module without specially customized style; we leave the $z_t \geq 2$ to be user-defined so as to select the knowledge expression module combined with customized style. The transition function $\tilde{p}(z_t|\mathbf{c}_t)$ is then implemented as a multinomial distribution parameterized by $\text{Softmax}(f_{z-\text{mlp}}(\mathbf{c}_t))$[1].

Prior of Boundary Indicator. The boundary indicator $M = \{m_t\}_{t=1}^{l_r}$ depicts the segmental structure of the response, with $m_t = 1$ indicates that a new segment should start at time $t+1$. Presumably, the prior of m_t could be inferred from $r_{\leq t}$ and z_t. We model the distribution $p_{\theta_m}(m_t|r_{\leq t}, z_t)$ by a Bernoulli distribution parameterized by $\sigma(f_{m-\text{mlp}}([\mathbf{e}_t; \mathbf{h}_t^{N,dec}]))$, where σ denotes the sigmoid function.

Stylized Generation. As mentioned above, the generation process involves scheduling different modules according to z_t. Here we give a systematic description of the generation process. The decoder accepts the token generated last timestep r_{t-1} as input, performs transformation in N decoder layers, finally obtains a dense representation.

We use $\mathbf{h}_t^l$ to denote the hidden state after the l-th layer at timestep t, which is a shorthand for $\mathbf{h}_t^{l,dec}$ for brevity. Specially, $\mathbf{h}_t^0$ is the output of the embedding layer. When $z_t = 0$, it implies that knowledge encoding is unnecessary for current segment so $\mathbf{h}_t^l$ is defined as:

$$\mathbf{h}_t^l = \text{DecoderLayer}(\mathbf{h}_t^{l-1}, \mathbf{H}_{t-1}^{l-1}, \mathbf{C}), \qquad (4)$$

where $\mathbf{H}_{t-1}^l = [\mathbf{h}_1^l, \cdots, \mathbf{h}_{t-1}^l]$ is a sequence of decoder hidden states in previous timesteps, and

---

[1] We use $f_{*-\text{mlp}}$ to denote a multi-layer perceptron network in this paper.

$\mathbf{C}$ is the context representation mentioned above. DecoderLayer$(\cdot,\cdot,\cdot)$ is implemented as pre-trained BART decoder layer where $\mathbf{h}_t^{l-1}$ first plays self-attention on $\mathbf{H}_{t-1}^{l-1}$ then performs cross-attention on $\mathbf{C}$. The probability $p(r_t|r_{<t}, z_t = 0)$ is defined as a multinomial distribution parameterized by Softmax$(f_{r-\text{mlp}}(\mathbf{h}_t^N))$, where $\mathbf{h}_t^N$ encodes the generated tokens up to timestep $t-1$. When $z_t = 1$, the implementation of decoder layer is analogous to the $z_t = 0$ case except that we replace $\mathbf{C}$ with $\mathbf{K}$, since knowledge is needed:

$$\mathbf{h}_t^l = \text{DecoderLayer}(\mathbf{h}_t^{l-1}, \mathbf{H}_{t-1}^{l-1}, \mathbf{K}). \tag{5}$$

To generate a segment with a particular customized style when $z_t \geq 2$, we introduce some adapters to bias the generation efficiently following Houlsby et al. (2019). Specifically, the hidden state $\mathbf{h}_t^l$ is defined as:

$$\mathbf{h}_t^l = \text{DecoderLayer}_{adp}(\mathbf{h}_t^{l-1}, \mathbf{H}_{t-1}^{l-1}, \mathbf{K}), \tag{6}$$

where DecoderLayer$_{adp}(\cdot,\cdot,\cdot)$ denotes the transformer decoder layer with adapters inserted. To make the style fine-grained and adjustable, each style has a unique set of adapters. Different styles have no adapter in common. In addition, our model has the ability to learn to express in any style, as long as a discriminator for the desired style is provided.[2]

3.3 Learning Details

We introduce auxiliary distributions $q_{\phi_m}(M|R) = \prod_{t=1}^{l_r} q_{\phi_m}(m_t|R)$ and $q_{\phi_z}(Z|M,R) = \prod_{t=1}^{l_r} q_{\phi_z}(z_t|M,R)$, which serve as an approximation to the intractable posterior of the boundary indicator M and the module indicator Z. We then apply variational approximation which gives the following evidence lower bound objective [3](ELBO) (Hoffman et al., 2013):

$$\begin{aligned}
&\log p_\theta(R|U,K) \\
&\geq \mathbb{E}_{q_{\phi_m}(M|R)}\Bigg(\mathbb{E}_{q_{\phi_z}(Z|M,R)} \sum_{t=1}^{l_r} \log p_\theta(r_t|r_{<t}, z_t) \\
&- \sum_{t=1}^{l_r} m_{t-1} \cdot D_{\text{KL}}\big(q_{\phi_z}(z_t|M,R) \| p_{\theta_z}(z_t)\big)\Bigg) \\
&- \sum_{t=1}^{l_r} D_{\text{KL}}\big(q_{\phi_m}(m_t|R) \| p_{\theta_m}(m_t)\big),
\end{aligned} \tag{7}$$

where $p_{\theta_z}(z_t)$ and $p_{\theta_m}(m_t)$ stand for $p_{\theta_z}(z_t|r_{<t}, z_{<t}, m_{t-1})$ and $p_{\theta_m}(m_t|r_{\leq t}, z_t)$ respectively, and $D_{\text{KL}}(\cdot\|\cdot))$ refers to Kullback–Leibler divergence. Detailed derivations are presented in the appendix.

Based on the intuition that the response provides hints about the segmentation, we construct the posterior distribution $q_{\phi_m}(m_t|R)$ as a Bernoulli distribution parameterized by $\sigma(f'_{m-\text{mlp}}(\psi_t))$. ψ_t is a feature extracted from a bi-directional LSTM $\psi(R)$. Since the module indicator is kept unchanged within a segment, the posterior distribution $q_{\phi_z}(z_t|M,R)$ is conditioned on the boundary indicator m_{t-1} and defined as:

$$\begin{aligned}
q_{\phi_z}(z_t|M,R) = &m_{t-1} \cdot \tilde{q}(z_t|\psi_t) \\
&+ (1 - m_{t-1}) \cdot \delta(z_t = z_{t-1}),
\end{aligned} \tag{8}$$

where $\delta(\cdot)$ denotes Dirac delta function and the transition function $\tilde{q}(z_t|\psi_t)$ is implemented as a multinomial distribution parameterized by Softmax$(f'_{z-\text{mlp}}(\psi_t))$. Once we have the posterior distribution, we apply Gumbel-Softmax (Jang et al., 2016) to take samples of m_t and z_t.

Weak Supervision on M and Z. We first use StanfordNLP toolkit (Manning et al., 2014) to parse every response in the training set as a sequence of segments, and use $\tilde{M} = \{\tilde{m}_t\}_{t=1}^{l_r}$ to denote the results of segmentation labeling. The pseudo label of module choice $\tilde{Z} = \{z_t\}_{t=1}^{l_r}$ is tagged in a similar way to multiclass classification, determined by (1) the similarity between each segment and knowledge and (2) the classification confidence of the style discriminator. More details about the construction of $\tilde{Z}$ and $\tilde{M}$ are provided in the appendix.

With $\tilde{Z}$ and $\tilde{M}$, the loss function of weak supervision is defined as:

$$\begin{aligned}
\mathcal{L}_m &= -\sum_{t=1}^{l_r} \log p_{\theta_m}(\tilde{m}_t|r_{\leq t}, \tilde{z}_t), \\
\mathcal{L}_z &= -\sum_{t=1}^{l_r} \tilde{m}_{t-1} \cdot \log p_{\theta_z}(\tilde{z}_t|r_{<t}, \tilde{z}_{<t}, \tilde{m}_{t-1}).
\end{aligned} \tag{9}$$

The learning algorithm is summarized and provided in the appendix.

4 Experiments

4.1 Datasets

We test our model on benchmarks of knowledge-grounded dialogue generation, including Wizard of

---

[2] The proposed method is also able to control the content style of knowledge-irrelevant segmentation by introducing extra adapters. But we focus on knowledge expression in this work.

[3] We always have $m_0 = 1$

Table 2: Automatic evaluation results. Numbers in bold mean that the improvement to the best performing baseline is statistically significant (t-test with p-value < 0.05).

Wikipedia (Wizard) (Dinan et al., 2019) and CMU Document Grounded Conversations (CMU_DoG) (Zhou et al., 2018c). We choose the Reddit Corpus published by (Li et al., 2020) as $\mathcal{D}$ for pre-training. Since it is abundant in expression style as a corpus from online forum, the two latent variables could be well initialized. We use part of the training data of Wizard and CMU_DoG as $\mathcal{D}_{sty}$ respectively, for these two datasets are distinctive in expression style and differ from each other. The dialogues in CMU_DoG tend to be causal and short, with most utterances irrelevant to knowledge while the responses in Wizard are usually long and knowledgeable, as some phrases are directly extracted from wiki articles.

More details about the datasets are described in the appendix.

4.2 Experimental Setup

In this paper, we mainly consider two experimental setups, corresponding to the two aspects of knowledge expression. To explore how our model can be used to control the distribution of different kinds of segments (knowledge-related and knowledge-irrelevant), we first train the model on the Reddit Corpus and then fine-tune it on a small amount of examples in Wizard and CMU_DoG, respectively.[4] To verify whether our model can generate the knowledge-related segments in the desired style, we still train the model on the Reddit Corpus, and use a style tag to control the generation process. In this experimental setup, we are primarily concerned with generating with two kinds of styles, positive and negative, where $z_t = 2 \cdot \min(1, z_t)$ tells the model to generate a response in positive sentiment and $z_t = 3 \cdot \min(1, z_t)$ is for response in negative sentiment.

Evaluation Metrics. Following Dinan et al. (2019), we choose PPL and unigram F1 as the metrics to evaluate the appropriateness. We further use Distinct-$1/2$ (D-$1/2$), which are calculated as ratios of distinct unigrams and bigrams in responses respectively, to evaluate the distinctness. We also employ classification accuracy as the evaluation metrics for style control experiments.[5] Due to space limitation, we provide automatic evaluation results on more metrics (i.e., BLEU-1, METEOR, and ROUGE-L) in the appendix.

To further verify whether our model could learn structure style and content style, we randomly sample 300 examples from Test Seen of Wizard, and the test set of CMU_DoG respectively, and recruit 6 well-educated native speakers to do qualitative analysis on the responses generated by our model and all baselines. The annotators need to judge the quality of the responses from four aspects (i.e., *fluency*, *context coherence*, *knowledge relevance* and *style consistency*), and assign a score from $\{0, 1, 2\}$ (representing "bad", "fair" and "good" respectively) to each response for each aspect. The agreement among all annotators is measured via Fleiss' kappa (Fleiss, 1971). More details about the setup of human evaluation as well as the results on learning content style are provided in the appendix.

4.3 Baselines

For the exploration of structure style, we select the following models as baselines: (1) *BART* (Lewis et al., 2020): a model that achieves state-of-the-art performance on various text generation tasks. Note that our model degrades into BART once we remove the module indicator Z and the boundary indicator M; (2) *Zero-resource Knowledge-grounded Conversation (ZRKGC)* (Li et al., 2020)[6]: a model that is based on UniLM (Dong et al., 2019) and optimized with Generalized EM method.

For the content style, we consider the following models as baselines: (1) *Emotional Chatting*

---

[4] We provide the evaluation results of training on the whole Wizard and CMU_DoG in the appendix.

[5] We exploit Roberta trained on the SST-2 training set (Socher et al., 2013) as the evaluator.

[6] `https://github.com/nlpxucan/ZRKGC`

Models	Wizard Seen					CMU_DoG				
	Fluency	Context Coherence	Knowledge Relevance	Style Consistency	Kappa	Fluency	Context Coherence	Knowledge Relevance	Style Consistency	Kappa
BART	1.68	1.56	1.52	1.34	0.64	1.62	1.57	1.55	1.31	0.63
ZRKGC	1.62	1.59	1.55	1.36	0.65	1.61	1.53	1.65	1.56	0.66
Our Model	1.71	1.64	1.66	1.77	0.60	1.61	1.66	1.63	1.76	0.74

Table 3: Human evaluation results on learning structure style.

Machine (ECM) (Zhou et al., 2018a)[7]: a model which can generate appropriate responses not only content-relevant but also emotional consistent; (2) variant of *DialoGPT* (Zhang et al., 2019b): we add a sentiment indicating token at the first of the sequence and explore whether such simple heuristics works for controlling knowledge expression; (3) *CTRL* (Keskar et al., 2019) [8] : a large-scale model trained on conditional codes to govern the style and content of generation.

Our model and all baselines are trained on the identical Reddit Corpus to maintain fairness.

4.4 Results on Learning Structure Style

In this section, we demonstrate the effectiveness of our segmentation-based generation framework in both low-resource setting and zero-resource setting and empirically verify that our model can learn structure style with a few annotated examples.

In zero-resource setting, we trained our model on the Reddit Corpus published by Li et al. (2020) and tested on Wizard and CMU_DoG respectively. Automatic evaluation results are shown in Table 2. It could be observed that: (1) our model significantly outperforms ZRKGC and BART on most metrics and achieves the new state-of-the-art performance on Wizard. It is impressive that our model exceeds BART in CMU_DoG especially since the proposed model degrades into BART without two sequential latent variables Z and M. The result serves as strong evidence for the effect of two latent variables, which enable the model to learn complex expression style in Reddit Corpus to handle flexible expression in CMU_DoG. By contrast, BART is far from satisfying with only a regular decoder. (2) our model exceeds ZRKGC significantly in terms of Distinct metrics, for ZRKGC mainly focuses on leveraging external knowledge sources for response generation, but falls short on expression diversity. In the low-resource setting, after training our model on the Reddit Corpus, we then fine-tune it with only 10% training size of Wizard and CMU_DoG respectively (i.e., $\mathcal{D}_{sty}$ in Sec 3.1) to adjust $p(z_t)$ and $p(m_t)$ to a new structure style. When provided with only 10% training data, our model gets obvious improvement ($\sim 1\%$ increase in F1) in contrast with BART ($\sim 0.5\%$ increase in F1) and ZRKGC ($\sim 0.2\%$ increase in F1), proving that the proposed model can learn more sophisticated structure style through quick adjustment on a specific dataset with little cost.[9]

Human Evaluation. Table 3 shows human evaluation results on learning structure style. It could be observed that: (1) our model is significantly superior to others on *style consistency*, indicating that the model can learn a consistent expression style with very little data. (2) our model has better performance on *context coherence* and *knowledge relevance*, tallying with its impressive performance in the low-resource scenario.

Fine-tuning with Limited Annotated Data. We first train the model on the Reddit Corpus and then fine-tune it with the amount of annotated data (e.g., Wizard and CMU_DoG) gradually increasing from 2% to 10%. To have a more intuitive understanding of the effects of latent variables Z and M, we compare the proposed model with BART, which generates the response with a single decoder. The evaluation results are shown in Figure 2. It can be concluded from the result that: (1) our model can learn the expression style of a particular dataset more efficiently. As the training data increases, our model has a more significant improvement in terms of the F1 metric; (2) our model performs better in meager resources since there is a considerable gap between our model and BART when the training data is close to 0%; (3) the expression style of CMU_DoG can be learned with less data because the model has a significant change in performance after using 2% CMU_DoG training data.

Refashioning of Knowledge-related Segments. To know how our model adjusts to different

---

[7] `https://github.com/thu-coai/ecm`

[8] `https://github.com/salesforce/ctrl`

[9] After trained with 10% annotated data, the diversity of our model decreases for it fits the specific expression style of Wizard or CMU_DoG.

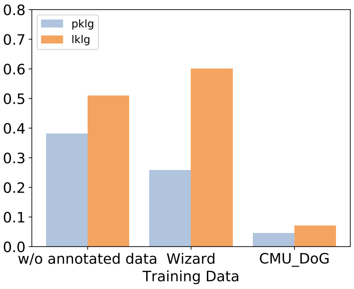

Figure 3: The effect of fine-tuning on different data.

datasets, we compare the knowledge-related segments before and after trained with annotated data from two aspects: (1) the average proportion of knowledge-related segments ($pklg$) in a sentence; (2) the average proportion of words belonging to knowledge-related segments ($lklg$). The motivation behind is that the frequency and length of these two kinds of segments generally indicates how well the latent variable is learned to capture the knowledge expression structure. We identify these two kinds of segmentation by comparing their lexical similarities with the knowledge. Figure 3 reports the results. The results indicate that our model could learn the underlying structure style of both datasets, with the great difference of $pklg$ and $lklg$ before and after fine-tuning as evidence. After fine-tuning with Wizard data, $pklg$ drops to 0.26 while the $lklg$ grows up a bit, indicating that the knowledge-related segments generated by our model are fewer and longer, which tallies with the fact that the responses in Wizard are probably directly copied from background knowledge. However, after CMU_DoG data is fed to the model, both $pklg$ and $lklg$ shrink drastically, which agrees with the fact that crowd-sourcing workers converse more liberally online and the responses are less relevant to the background knowledge.

4.5 Results on Learning Content Style

We further investigate whether the proposed model could express knowledge with the desired sentiment. Specifically, we introduce two sets of style adapters to endow knowledge expression in two different sentiments, namely positive and negative. So in this scenario, it is required that responses are not only coherent with context but also limited in positive or negative sentiment. To apply ECM on knowledge-grounded conversation, we label the sentiment category for each response with a classifier pre-trained on the SST (Socher et al., 2013) training set. For DialoGPT, we similarly annotate each response with a sentiment category and append the sentiment token before the context tokens. The evaluation results are shown in Table 4. We can conclude that: (1) The proposed model outperforms all baseline models in terms of all metrics, which indicates that our model can control the sentiment of knowledge expression and guarantee high quality of the generated responses; (2) Simply adding a sentiment indicating token at the beginning of the sequence can not effectively control the style of knowledge expression, as the performance of DialoGPT on sentiment control is poor; (3) Although ECM is designed for sentiment control, it still fails to perform well in this task, proving that sentiment control in the knowledge-grounded conversation is rather difficult. Besides, ECM can only control the sentiment of the whole response but is helpless to manage every knowledge-related segment at a fine-grained level.

5 Conclusions

We explore knowledge expression in knowledge-grounded conversation and break down the expression style of a response into the structure of the response (structure style) and the style of the content in each part (content style). We propose a variational segmentation-based generation model to discover the underlying expression style in response. Specifically, we introduce two latent variables to model these two aspects of expression style respectively and induce an evidence lower bound of the likelihood. Evaluation results on two benchmarks of the task indicate that our model can learn the structure style with little cost and generate responses in desired content style without any human-annotated data.

Ethical Considerations

It's crucial for an open-domain dialogue system to be able to automatically detect and discover the underlying structural pattern of a sentence. With the ability to handle a variety of expression styles, whether positive or negative, serious or casual, our work suggests that we are getting closer to the goal of creating an artificial intelligent dialogue system that can freely communicate with humans, which is beyond the wildest dreams of most AI and NLP researchers. However, a detailed survey should be undertaken in advance to consider the immediate audience's and developers' interests, as well as any potential stakeholder groups.

Furthermore, knowledge-grounded dialogue systems have the potential to fabricate facts and distribute rumors and false information, particularly when the source of external background knowledge is unreliable. If the knowledge candidate set is contaminated by fake news, the response generated by the dialogue system is likely to suffer from the "hallucination" issue. Controlling the source of knowledge sentences, such as paragraphs extracted from the wiki, authoritative news sites, or authoritative product documents, is a necessary and practical strategy.

&\geq \mathbb{E}_{(M,Z)\sim q(M,Z|R)} \log \frac{p(R,M,Z)}{q(M,Z|R)}\\
&= \mathbb{E}_{(M,Z)\sim q(M,Z|R)} \log p(R|M,Z)\\
&- \mathbb{E}_{(M,Z)\sim q(M,Z|R)} \big(\log q(M,Z|R)\\
&- \log p(M,Z)\big).
\end{aligned}
\tag{10}
$$

According to the mean-filed approximation, $q(M,Z) \approx q(M)q(Z)$. Therefore, $\mathbb{E}_{(M,Z)\sim q(M,Z|R)} \log p(R|M,Z)$ and $\mathbb{E}_{(M,Z)\sim q(M,Z|R)}\big(\log q(M,Z|R) - \log p(M,Z)\big)$ can be re-written as:

$$
\begin{aligned}
&\mathbb{E}_{(M,Z)\sim q(M,Z|R)} \log p(R|M,Z)\\
&= \mathbb{E}_{M\sim q(M|R)}\big(\mathbb{E}_{Z\sim q(Z|M,R)} \sum_{t=1}^{l_r} \log p(r_t|r_{<t}, z_t)\big)\big)
\end{aligned}
\tag{11}
$$

$$
\begin{aligned}
&\mathbb{E}_{(M,Z)\sim q(M,Z|R)}\big(\log q(M,Z|R) - \log p(M,Z)\big)\\
&= \mathbb{E}_{M\sim q(M|R)}\Big(\mathbb{E}_{Z\sim q(Z|M,R)}\big(\log q(M|R) - \log p(M)\big)\\
&+ \mathbb{E}_{Z\sim q(Z|M,R)}\big(\log q(Z|M,R) - \log p(Z)\big)\Big)\\
&= \mathbb{E}_{M\sim q(M|R)}\Big(\log q(M|R) - \log p(M)\Big)\\
&+ \mathbb{E}_{M\sim q(M|R)}\Big(\mathbb{E}_{Z\sim q(Z|M,R)}\big(\log q(Z|M,R) - \log p(Z)\big)\Big)\\
&= \sum_{t=1}^{l_r}\Big(\mathbb{E}_{M\sim q(M|R)}\big(\log q(m_t) - \log p(m_t)\big)\Big)\\
&+ \mathbb{E}_{M\sim q(M|R)}\Big(\sum_{t=1}^{l_r} m_{t-1}\cdot \mathbb{E}_{Z\sim q(Z|M,R)}\big(\log q(z_t) - \log p(z_t)\big)\Big)\\
&= \sum_{t=1}^{l_r} D_{\mathrm{KL}}(q(m_t)\|p(m_t))\\
&+ \mathbb{E}_{M\sim q(M|R)}\Big(\sum_{t=1}^{l_r} m_{t-1}\cdot D_{\mathrm{KL}}(q(z_t)\|p(z_t))\Big).
\end{aligned}
\tag{12}
$$

A.2 Details about the Construction of $\tilde{\mathbf{M}}$ and $\tilde{\mathbf{Z}}$

In this section, we provide more details about of construction of $\tilde{M}$ and $\tilde{Z}$. For every response in the training set, we parse it as a syntax tree using StanfordNLP toolkit (Manning et al., 2014). The syntax tree we obtain is in a hierarchical and nested structure. The root node of the tree represents the whole response sentence and the root node of every subtree represents a corresponding phrase, a small part of a sentence. For example, if a phrase could be divided into three parts, then the node representing the phrase has three child nodes and each represents a part of the phrase. After we acquire the parsing tree, segmentation is then carried out recursively. To be concrete, we traverse the parsing tree by depth-first search order. Every time we arrive at a node, compute the similarity[10] between the knowledge and the phrase represented by the node. If the similarity is above the threshold μ_{seg}, we mark the phrase as a segment and search in this branch terminates. Else we continue to search the child nodes of the current node to segment at a more refined level. We use $\tilde{M} = \{\tilde{m}_t\}_{t=1}^{l_r}$ to denote the results of segmentation labeling.

The pseudo label of module choice $\tilde{Z} = \{z_t\}_{t=1}^{l_r}$ is tagged in a similar way to multiclass classification. Specifically, for a segment $(r_s, \cdots, r_e)$ where s and e are the start and end position of a segment respectively. If the similarity between this segment and the knowledge falls below a threshold μ_{knl}, its pseudo label $(z_s, \cdots, z_e)$ will be set to 0. Otherwise we send the segment to a series of style discriminators one after another until the classification confidence given by a discriminator is above μ_{sty_i} and pseudo module choice label will be set to $i+1$. If all discriminators fail to classify the segment at a confidence greater than μ_{sty_i}, $(z_s, \cdots, z_e)$ are all 1, indicating knowledge should be expressed without particular style.

A.3 Learning Algorithm

The learning algorithm is summarized in Algorithm 1.

A.4 Details of Datasets

Training Data. We choose the Reddit Corpus published by (Li et al., 2020) as $\mathcal{D}$ for pre-training. The data contains $842,521$ context-knowledge-response triples for training and $2,737$ context-knowledge-response triples for validation. On average, each dialogue contains 3.1 utterances in both sets, and the average length of the utterance is 16.0 in training and is 16.1 in validation.

Evaluation Data. We test our model on benchmarks of knowledge-grounded dialogue generation,

---

[10] We use unigram Precision to calculate the similarity.

Algorithm 1 Learning Algorithm

```

including Wizard of Wikipedia (Wizard) (Dinan et al., 2019) and CMU Document Grounded Conversations (CMU_DoG) (Zhou et al., 2018c). Both datasets are split into training sets, validation sets, and test sets by the data owners. We follow Dinan et al. (2019) and conduct the pre-processing with the code published on ParlAI[11]. Topics in Wizard cover a wide range ($1,365$ in total), and each conversation happens between a wizard who has access to the knowledge about a specific topic and an apprentice who is just eager to learn from the wizard about the topic. The test set is split into two subsets. Test Seen only contains dialogues with topics that have already appeared in the training set, while topics in Test Unseen never appear in the training set and the validation set. Different from Wizard, CMU_DoG focuses on movie domain, and besides wizard-apprentice conversations, the data also contain conversations between two workers who know the document and try to discuss the content in depth. In both datasets, only the turns where knowledge is accessible are considered in response generation. Table 5 reports the statistics of the Wizard data and the CMU_DoG data

A.5 More Implementation Details

We employ a knowledge selection (KS) module to select the top 7 related sentences in knowledge. The KS module is implemented based on Roberta-base (125M) and trained on the Reddit Corpus. Specifically, we treat the sentence which has the highest F1 score with the response as the positive sample, and the negative sample is randomly sampled from all the other knowledge sentences. We train the KS module via maximum likelihood estimation (MLE) with a batch size of 64 and an initial learning rate of $1e-5$. The threshold μ_{seg}, μ_{knl}, μ_{pos} and μ_{neg}[12] in weak supervision are set as 0.9, 0.5, 0.8 and 0.8, respectively. The encoder-decoder architecture is implemented on the basis of Bart-base (139M) and trained on the Reddit Corpus with a batch size of 64 and an initial learning rate of $5e-6$. The parameters for prior and posterior distributions of Z and M (i.e., θ_z, θ_m, ϕ_z and ϕ_m) are initialized randomly, and optimized with a learning rate of $1e-4$. The parameters for adapters are initialized randomly and optimized with a learning rate of $2e-3$. We only train the adapters for the first 1000 steps. We utilize gated recurrent units (GRUs) as the basic units in $f_{z-\text{rnn}}$. We set the hidden size and the number of layers of RNN in our model (i.e., $f_{z-\text{rnn}}$ and $\psi(\cdot)$) as 128 and 1 respectively. The embedding size for Z is set as 128 and the adapter size is set as 64. When fine-tuning the model on the Wizard and CMU_DoG datasets, the learning rate and the batch size are set as $5e-5$ and 32 respectively. We employ greedy search in response decoding. All models are learned with Adam (Kingma and Ba, 2015) optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.999$. We increase the learning rate linearly for the first 200

steps and decrease it thereafter proportionally to the inverse square root of the step number. Early stopping on validation is adopted as a regularization strategy. All models are trained on a 8×RTX 2080 Ti machine.

A.6 More Results about Automatic Evaluation

Table 6 reports more results about the automatic evaluation, from which we can see that our model still outperforms the baselines.

A.7 Human Evaluation

We randomly sample 300 examples from Test Seen of Wizard, and the test set of CMU_DoG respectively, and recruit 6 well-educated native speakers to do qualitative analysis on the responses generated by our model and all baselines. For each of the 300 examples, an annotator is provided with the context, the ground-truth knowledge, model responses and the associated style types. For evaluation of structure style, we defined two kinds of structure styles based on two datasets, namely the Wizard-like style S_{wizard} and the CMU_DoG-like style S_{cmudog}. While for evaluation of content style, we roughly divide content styles in two categories, S_{pos} and S_{neg} for convenience. The responses provided by different models are randomly shuffled to hide their sources. The annotators need to judge the quality of the responses from four aspects: (1) *fluency*: whether the response is fluent without any grammatical errors; (2) *context coherence*: whether the response is coherent with the context; (3) *knowledge relevance*: whether the response is relevant with the knowledge; and (4) *style consistency*: whether the response exhibits the desired style. Each annotator assigns a score from $\{0, 1, 2\}$ (representing "bad", "fair" and "good" respectively) to each response for each aspect. Each response obtains four scores for aforementioned four aspects, and the agreement among all annotators is measured via Fleiss' kappa (Fleiss, 1971).

Results on Learning content style. Table 7 reports the human evaluation results on learning content style. The three models are trained on the Reddit Corpus. We can conclude that: (1) by introducing two latent variables and a number of adapters for different styles, our model can generate responses in desired content style (i.e., S_{pos} and S_{neg}) more accurately and achieve significant improvement on *style consistency*, which is consistent with the results in Table 4; (2) our model also outperforms ECM and DialoGPT on *fluency*, *context coherency* and *knowledge relevance* thanks to the capacity of large-scale pre-trained language models and the introduction of external knowledge respectively.

A.8 Comparison with More Baselines

We compare with models trained on full training data, and Table 8 shows the evaluation results. First, it is noted that our model outperforms KnowledGPT in terms of F1 by using only 10% training data[13] on CMU_DoG, which provides a strong support for the effectiveness of the proposed model.

---

[13] The 10% training data is randomly sampled. The result is an average value of three repetitive experiments on every dataset

Models	Wizard Seen					CMU_DoG

Reddit Corpus + 100% annotated data	Our Model	21.9	0.134	0.453	21.2	0.103	0.302	15.5	0.041	0.134

Table 8: Automatic evaluation results.

Second, by adjusting the structure style on a small amount of data, the gap between our model and KnowledGPT is further narrowed, while the improvements on ZRKGC and BART are trivial.

A.9 Ablation over Weak Supervision

To have more insights into the impact of weak supervision on the performance of our model, we compare the proposed model with the following variants: (1)-*weak supervision on Z*: the weak supervision on module indicator Z is removed; (2)-*weak supervision on Z and M*: the weak supervision on module indicator and boundary indicator is removed. Table 9 reports the evaluation results. We can conclude that (1) the weak supervision objectives significantly improve model performance; (2) the weak supervision objectives play a more crucial role on CMU_DoG, as removing them causes a dramatic drop in performance. The reason is that this dataset has more sophisticated expression styles and it is difficult to learn these styles without auxiliary supervision signals.

A.10 Ablation over Boundary Indicator

Since the module indicator is conditioned on the boundary indicator, we are curious about what will happen if the M is removed. The ablation result is shown on Figure 4. There is an evident drop on Wizard Seen and Wizard Unseen, verifying the effect of boundary indicator in assisting the module indicator. The margin is tiny on CMU_DoG, perhaps because its structure feature is easier to capture, so the module indicator could works properly itself.

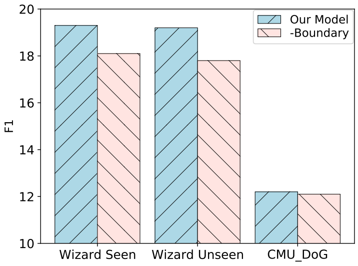

Figure 4: Ablation results on Wizard and CMU_DoG.

A.11 Case Study

This section mainly studies how different models vary in knowledge expression for the same context and background knowledge. Table 10 shows an example from the test set of CMU_DoG. This example contains the background knowledge which gives a plot from the movie, and the dialogue context which is generated by discussing the content in the knowledge. We choose the following four models to generate the response in corresponding style given the dialogue context and knowledge, and all models are pre-trained with the Reddit Corpus: (1) Wizard Model for S_{wizard}: the model fine-tuned with 10% training data in Wizard; (2) CMU_DoG Model for S_{cmudog}: the model fine-tuned with 10% training data in CMU_DoG; (3) Positive Model for S_{pos}: the model forced to express knowledge with

Knowledge	• MovieName: How to Train Your Dragon • Back at the village, Hiccup subdues a captive dragon in his final training test in front of his father instead of killing it, but Stoick inadvertently angers the dragon into attacking. • Toothless attempts to protect Hiccup in the ensuing panic but is instead captured by the Vikings. • Hiccup accidentally reveals to Stoick that Toothless is capable of locating the dragons' nest. • Stoick disowns his son and sets off for the nest with Toothless chained to the lead ship as a guide. • The Vikings expel most of the dragons but are overwhelmed by the Red Death until Hiccup, Astrid and their fellow pupils fly in riding the training dragons from the academy and provide cover fire. • Hiccup almost drowns trying to break Toothless free from a sinking ship but Stoick saves them both and then reconciles with his son. • Toothless and Hiccup destroy the Red Death but Hiccup is injured in the fight. • Hiccup regains consciousness on Berk where his lower left leg has been replaced by a prosthesis, and the Vikings and the dragons now live in harmony.
Context	User1: Now I keep thinking about phantom pain and whatnot... will he walk with his new prothesis? Was does viking prothesis look like?! User2: ...but now they live there together! Schweet. User1: Yes!
Ground Truth	Probably sharp and imposing!
Wizard Model	They live in a house together . It ' s the same as before but with toothless and hiccup now living on berk where his lower left leg has been replaced by a prosthesis.
CMU_DoG Model	What is the new prothesis ? ! It ' s a Viking
Positive Model	Vikings live in harmony now have the dragons living together and are all still alive to be united.
Negative Model	Though Vikings and the dragons live in harmony, Hiccup can no longer walk with this lower left leg.

Table 10: A case from test set of CMU_DoG.

positive sentiment; (4) Negative Model for S_{neg}: the model forced to express knowledge with negative sentiment. We can see that the knowlege expression style of the Wizard Model and CMU_DoG Model are quite different. The central part of the Wizard Model response is copied from the background knowledge, which is consistent with the style of Wizard data. The response generated by CMU_DoG Model is more casual in knowledge expression, and the content is mainly related to the conversation context. Besides, responses generated by the Positive Model exhibit evident positive sentiment, while responses generated by the Negative Model show relatively negative sentiment.

End-to-End Chinese Speaker Identification

Dian Yu[1] **Ben Zhou**[2] **Dong Yu**[1]

{yudian, dyu}@tencent.com, xyzhou@seas.upenn.edu

Abstract

Speaker identification (SI) in texts aims to identify the speaker(s) for each utterance in texts. Previous studies divide SI into several sub-tasks (e.g., quote extraction, named entity recognition, gender identification, and coreference resolution). However, we are still far from solving these sub-tasks, making SI systems that rely on them seriously suffer from error propagation. End-to-end SI systems, on the other hand, are not limited by individual modules, but suffer from insufficient training data from the existing small-scale datasets. To make large end-to-end models possible, we design a new annotation guideline that regards SI as span extraction from the local context, and we annotate by far the largest SI dataset for Chinese named CSI based on eighteen novels. Viewing SI as a span extraction task also introduces the possibility of applying existing storng extractive machine reading comprehension (MRC) baselines. Surprisingly, simply using such a baseline without human-annotated character names and carefully designed rules, we can already achieve performance comparable or better than those of previous state-of-the-art SI methods on all public SI datasets for Chinese. Furthermore, we show that our dataset can serve as additional training data for existing benchmarks, which leads to further gains (up to 6.5% in accuracy). Finally, using CSI as a clean source, we design an effective self-training paradigm to continuously leverage hundreds of unlabeled novels.

1 Introduction

Speaker identification (SI) aims to identify the corresponding speakers for utterances in texts (Zhang et al., 2003; Glass and Bangay, 2007). Most existing SI datasets (He et al., 2013; Chen et al., 2021) provide ground-truth character aliases and utterance spans as inputs. However, such annotations are unavailable in realistic settings, under which SI is usually divided into interrelated sub-tasks (Pan et al., 2021; Yoder et al., 2021) (e.g., utterance identification, named entity recognition, coreference resolution, and candidate speaker generation).

However, this pipeline faces several challenges. First, these modules are imperfect, and they inevitably introduce errors that propagate and seriously affect the final performance (C-I). For example, the performance of the state-of-the-art coreference resolution model is about 80.3% in F1 (Kirstain et al., 2021). Second, classical SI datasets and approaches assume that the speaker to be linkable to one of the named entities, which cannot handle the more realistic settings where the speakers are not humans or only exist as nominals (e.g., *"a young girl"* or *"smartwatch"*) (C-II). Third, features (e.g., speech verb list and position information) and rules are usually carefully created and selected by experts for a certain language, which may make these resources difficult to be used for other languages (C-III). Finally, one of the main reasons that people heavily rely on pipeline methods is that book-level exhaustive annotations of SI datasets are too expensive. As a result, existing small-scale annotations are insufficient to train large models, especially the advanced pre-trained language models (Devlin et al., 2019) (C-VI).

This work focuses on the abovementioned four challenges. We first design a new annotation guideline that simplifies the task to span extraction from the local context and thus viewing SI as an end-to-end task (C-I): given a snippet that contains several contiguous paragraphs, for each paragraph that may contain utterances, we annotate the most informative reference to a speaker (i.e., speaker mention) if one exists, otherwise the content within quotation marks. As a result, speaker mentions are not limited to entities only (C-II). This simplification is built on two assumptions: utterances in a single paragraph usually correspond to a single speaker (He et al., 2013) (e.g., all utterances in paragraph U1 in Table 1 are said by *"Brandi"*) and an explicit speaker mention is very likely to appear

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2274 - 2285
July 10-15, 2022

in the local context (Glass and Bangay, 2007), especially when the context starts and ends with a paragraph that does not contain any utterances (Section 3.3). Under this guideline, annotation efforts are greatly reduced because annotators only need to select a span based on a text snippet and avoid steps such as creating and maintaining a book-specific list of characters and their aliases, in-depth chapter-level or book-level understanding. In total, we annotate 66K **S**peaker **I**dentification instances based on eighteen **C**hinese novels named CSI.

Considering the similarity between simplified SI and extractive machine reading comprehension (MRC), which aims to extract an answer span from a given document for a question (Hermann et al., 2015), we can easily adapt an MRC baseline to SI, which does not consider any language-specific features (C-III). Surprisingly, simply using such an extractive method (Xu et al., 2020) already yields comparable or better performance than that of state-of-the-art systems on two public SI datasets for Chinese (WP (Chen et al., 2021) and JY (Jia et al., 2021)). Furthermore, our experimental results demonstrate that CSI can serve as additional high-quality training data for existing SI datasets, though it follows an extractive annotation guideline based on local context, which is quite different from that of traditional book-level annotation. Finally, using CSI as a clean source, we develop a simple yet effective self-training paradigm to continue leveraging hundreds of unlabeled novels (C-IV), which further reduces the gap between supervised and zero-shot performance on WP and JY.[1]

The contributions of this paper are as follows.

- We design a new annotation guideline that simplifies book-level SI to span extraction based on the local context, which alleviates the annotation burden and covers diverse types of speakers instead of entities alone.
- We offer a large-scale dataset for Chinese to support end-to-end extractive SI, which can also serve as high-quality training data for existing SI datasets.
- We propose the first end-to-end SI method, which achieves comparable or better performance than that of state-of-the-art methods on all SI datasets for Chinese without requiring any manually designed rules and features.
- We are the first to leverage large-scale unlabeled novels to improve SI via self-training, and our recipes to make self-training work for these tasks may shed light on future studies.

N1	*Layla didn't give Brandy anything dangerous, so she put away things like a silver knife. She only asked her to use a mill, and then Brandi was able to sit there and grind all the peppers in the house into powder.*
U1	*Brandi was very careful. When she showed Layla, she said, "The particles of this bottle are a little bit thicker." She put down a crystal bottle and said "The particles of this bottle are a little finer.". After she put another crystal bottle and then star, Brandy asked Layla, "Mom, will you give me anything that needs to be ground?".*
U2	*"Okay." The mother was dizzy and dizzy at the moment when her daughter raised her face and hold Brandi's small hands to the kitchen and told her to grind whatever she wanted.*
N2	*Coarse sugar is all ground into fine sugar, cooked sesame seeds are all ground into sesame powder, and there are other things such as cinnamon.*
U1	Brandi
U2	Layla

2 Related Work

We will compare in detail existing SI tasks/datasets and CSI in Section 3.1 and Section 3.2.

This work is the first attempt to apply self-training (Yarowsky, 1995; Riloff and Wiebe, 2003) to SI. Previous studies on other natural language understanding tasks using self-training mostly generate pseudo-labeled data based on in-domain unannotated data (Du et al., 2021) or data in the same domain (Wang et al., 2021). In addition, those studies usually fix the unannotated data pool in each iteration. We propose continual self-training to feed a model with pseudo-labeled data based on **different** unlabeled **out-of-domain** data in each iteration, **removing the burden** of widely adopted strategies such as selecting ample in-domain unlabeled data (which may not exist) and filtering some of the pseudo-labeled data after each iteration (Chen et al., 2011; Ye et al., 2020; Cascante-Bonilla et al., 2021) to either improve the quality or control the difficulty of noisy pseudo-labeled data.

Different from continual learning (Ring et al., 1994), we stick to the SI task. As the clean data of the target task is always used during training, the proposed paradigm tends not to suffer from catastrophic forgetting (McCloskey and Cohen, 1989).

3 Guideline and Dataset Annotation

3.1 Existing Task Formulations and Datasets

Most of the existing SI datasets are in rich-resource languages such as English (e.g., CQSAC (Elson and McKeown, 2010), P&P (He et al., 2013), QuoteLi3 (Muzny et al., 2017), and RiQuA (Papay and Padó, 2020)) and Chinese (WP (Chen et al., 2019, 2021) and JY (Jia et al., 2021)), and the annotated texts are mostly classical novels or non-fiction texts (e.g., RWG (Brunner, 2013)). See data statistics in Table 2.

Some of the datasets such as P&P and WP also provide a human-labeled list of main characters in a novel, which contains different mentions (if any exists) of each main character, or a small number of candidate speakers for each utterance instance (e.g., JY). When a character list is unavailable, person names that appear in the surrounding context of the utterance is regarded as candidate speakers (Pan et al., 2021). Thus SI tasks are usually formulated as ranking (He et al., 2013) or classification (Muzny et al., 2017) problems, and golden-standard gender information of speakers can be used as features to facilitate speaker identification.

3.2 Assumptions for Annotation

Main characters who are important to the story are usually named, and they play essential roles in many downstream tasks such as character personality prediction (Flekova and Gurevych, 2015) and character network construction (Labatut and Bost, 2019). And this might explain why previous SI resource studies put more emphasis on person entities and their anaphoric mentions during annotation, leading to entity-centric designs for most SI methods. However, unnamed speakers (e.g., *"pedestrian"* and *"cat"*), who are usually created as minor characters, and non-living things (e.g., *"robot"*) are seldom annotated, limiting the usage of SI in real-world applications such as audiobook reading (Hinterleitner et al., 2011) that require exhaustive identification of all kinds of speakers.

Another challenge is that existing SI tasks mostly regard ground truth utterances as inputs, which, unfortunately, are not readily available in real-world book-based applications. Worse still, quote identification itself is a research challenge (e.g., overall F1 around 50%–60% (Lee et al., 2020)).

To address the two issues and support end-to-end training, we first propose a new annotation guideline for SI that considers different types of speakers (e.g., multiple speakers, entities, person names in other languages, and phrases) and at the same time addresses non-utterance quotation identification. Given a snippet that contains several contiguous paragraphs, for each paragraph that may contain utterances, we annotate the most informative mention of the corresponding speaker if one exists, otherwise the earliest mentioned content punctuated with quotation marks (quotation marks included).[2] This simplification is built on two widely held assumptions: (**I**) utterances in a single paragraph usually correspond to a single speaker (He et al., 2013) and (**II**) an explicit speaker mention is very likely to appear in the surrounding context of the target utterance (Glass and Bangay, 2007). See more discussions about the two assumptions and exceptions based on our annotated corpus in Section 3.4.

3.3 Candidate Utterance Paragraph Identification and Context Selection

Based on Assumption (**I**), we aggressively regard that all utterances in a paragraph are said by the same speaker. Thus, we do not conduct quote identification as previous studies, which saves annotation cost. We use (context, paragraph) pairs in which the paragraph may contain utterances as annotation instances. We aim to annotate the most informative speaker mention within the surrounding context of the paragraph or from the paragraph.

To save annotation efforts, we simply regard all paragraphs that contain at least one double quotation mark as candidate **utterance paragraph** (i.e., a paragraph that contains one or multiple utterances) and regard others as narrative paragraphs. Paragraphs are split by line breaks. To select local context, we argue that we can regard the nearest narrative paragraphs before and after the candidate as context boundaries. We refer to this method of context selection as **narrative window**. Considering the role of supporting dialogue understanding, this kind of context can somehow be regarded as a mini-scene, similar to those in movie/TV show scripts that provide structured information such as a narrative description of the location and time, the events of a scene, and non-verbal behaviors (e.g., actions or attitudes) of speakers beyond dialogues. We only keep instances whose context contains fewer than ten candidate utterance paragraphs, as long-text understanding is also quite challenging.

---

[2] For speaker mentions that are enclosed by quotation marks, we only annotate the speaker mention.

dataset	**language**	**types of speakers**	**# of books**	**# of utterances***	**avg. context length (tokens)**
CQSAC	English	entity/mention†	11	3,176	–
P&P	English	entity	3	1,901	–
QuoteLi3	English	entity/mention†	3	2,296	–
RiQuA	English	entity/mention†	11	5,963	–
RWG	German	entity/mention†	13	9,451	–
JINYONG	Chinese	entity	3	28,597	191
WP	Chinese	entity	1	2,596	353
CSI (this work)	Chinese	entity/phrase/pronoun/multi-speaker	18	65,540	180

Table 2: Existing publicly available speaker identification and profiling datasets for novels in English and Chinese ($\star$: assuming one speaker (if any) per paragraph; †: some mentions could be mapped onto a named person).

In contrast, using a fixed-length window is less flexible to cover sufficient context across diverse types of books by different authors, though it can be used to augment pseudo-labeled training data: for example, using a six-paragraph window based on the same book corpora as that of CSI, we can generate about 33.7% more unlabeled instances and can easily obtain more by changing the sliding window (e.g., length and center). We will have more discussions about the impact of window selection on performance in Section A.2.

To simplify annotation, we do not further distinguish utterances whose speakers are unclear and expressions enclosed by quotation marks that can be expressions such as idioms, proverbs, or poetries. For convenience, we call them **non-utterance paragraphs** (e.g., NU1 in Table 3). To ensure the quality of the annotation, the data is independently annotated by the first author of this paper (EA) and a group of annotators (GA) who are native speakers of Chinese from a commercial data annotation company ($0.071 per instance). The inter-annotator agreement between EA and GA is measured using Cohen's kappa, which yields a value of 0.76 (substantial agreement (Viera et al., 2005)). The disagreements are reviewed and re-annotated by the author to obtain the final annotation.

3.4 Limitations

Entity-Level vs. Mention-Level: Speaker mentions that are entities are more informative and therefore support better disambiguation of different speakers than other types of mentions. However, mention-level annotation can support diverse types of speakers (see Figure 1) and is relatively easy for annotators as no long-text comprehension is needed. Though there exist differences between entity-level and mention-level SI datasets, we argue that the latter one can help entity-level SI tasks, which is supported by our results in Section 5.3.

N1	*Si Teng's Hongmen banquet was set at a high-end clubhouse near Qingcheng Mountain. At that time, he would dine on a glass terrace extending out of the lake. It was next to the water by the railing, and the opposite side were silent green mountains.*
NU1	*It is said that one or two girls in blue calico clothes will be arranged at that time. The girl hold a paper umbrella on one or two flat boats floating across the lake in the distance. If it rains that day, it means "staying in breeze and drizzle meets his will", and if the sun is out, it means "the brimming waves delight the eyes on sunny days."*
U2	*The proprietress strongly recommended to Qin Fang: "It is very comfortable. When you eat here, what you eat is not food, but spiritual enjoyment."*
N2	*Those Taoist masters will be probably mentally nervous, so it's okay to let them have some spiritual enjoyment and adjustment.*
NU1	"staying in breeze and drizzle meets his will"
U2	proprietress

Table 3: An translated example with utterance paragraph (U) and non-utterance paragraph (NU) in CSI.

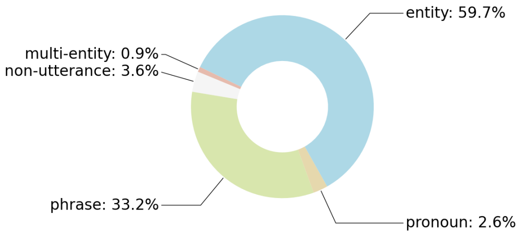

Figure 1: Distribution of general phenomena in CSI.

Assumption I: There has been some disagreement among different literature (e.g., (Muzny et al., 2017)) about this assumption that all utterances within a paragraph could be attributed to the same speaker. We randomly select 400 instances from CSI and only find one exception (0.25%). This is perhaps because of linguistic changes over years (Nettle, 1999): the books we use for annotation are mostly web novels published after the year 2010 (full list in Table 8 (Appendix A.1)), compared with classical novels published hundred years ago (Papay and Padó, 2020). Also, we restrict the scope of this observation to Chinese as there may exist significant differences among different languages. Furthermore, our experimental results show that such kind of data annotated following this assumption can be used as useful additional training data for other SI datasets in which the ground truth utterances are provided (Section 5.3).

Assumption II: Most previous SI datasets provide human-summarized book-level characters and their different name mentions (e.g., WP provides 125 characters, each with 1–5 different mentions (Chen et al., 2021)) or a small number of candidate characters for each instance. In CSI, we skip the step of clustering different mentions of one speaker. Instead, we assume that we can find an informative mention within a narrative window centered around an utterance paragraph. To examine this assumption and its potential negative impacts, we first dig into CSI. Based on all instances in it that involve eighteen novels, the annotated speaker mentions for merely 2.7% of utterance paragraphs (63,165 in total) are personal pronouns, indicating that in most cases we can find the corresponding speaker mentions more informative than personal pronouns. This also indirectly supports that context constructing using narrative window contains relatively sufficient information for SI. Furthermore, without using any forms of character lists, applying a baseline that will be introduced in Section 4 to extract a speaker mention from the given context can achieve promising results on existing SI datasets (Section 5.3). Though we admit that additional mappings can be particularly important for first-person narratives, where *"I"* will be frequently annotated as the most informative mention.

4 Method

4.1 Extractive Machine Reading Comprehension

As the speaker mention must be a span in the context based on the guideline, we consider an extractive MRC model built upon a pre-trained language model (e.g., (Devlin et al., 2019)) that aims to extract an answer of a give question from a document.

Given a paragraph q that may contain an utterance and its context d, we follow previous work (e.g., (Devlin et al., 2019)) to concatenate a special token [CLS], tokens in q, a special token [SEP], and tokens d that covers the piece of text in q. Two vectors p_{start} and p_{end} are introduced to represent the estimated probabilities of each token in d to be the start or end token of the correct answer span a that appears in d, respectively. Let a_{start} and a_{end} denote the start offset and end offset of a, respectively.

We optimize the extractive SI model with parameters θ by minimizing $\sum_{t \in V} L(t, \theta)$, where V represents the set of speaker identification instances, and L is defined as:

$$L(t, \theta) = -log_{p_{\text{start},\theta}(a_{\text{start}} \mid t)} - log_{p_{\text{end},\theta}(a_{\text{end}} \mid t)}.$$

4.2 Self-Training

We first generate a fixed set W of unlabeled extractive SI instances from the unlabeled books and conduct the following self-training paradigm. First, we use the labeled data V to train a teacher model. Then the resulting teacher model generates pseudo-labels for the unlabeled instances. Finally, we train a student model with the combination of pseudo-labeled and labeled data. We simply regard different types of data equally and thus optimize the model by minimizing $\sum_{t \in V \cup W} L(t, \theta)$. As this loss is already reasonably stable in our experiments (Section 5), we leave the exploration of other choices such as weighted normalized loss (e.g., (Zoph et al., 2020)) for future studies.

The resulting model can be used as a new teacher to generate new pseudo-labeled data W, and we can iterate the self-training procedure until no gains are observed or a pre-defined number of iterations.

4.3 Continual Self-Training

In our experiments (Section 5.5), we observe that iterative training over the same unlabeled corpus does not lead to gains for SI as considerable as those obtained on vision tasks such as image classification (Xie et al., 2020). Furthermore, we aim to let our SI model keep learning from different books in diverse domains written by different authors to improve its generalization ability.

Thus, different from previous studies, we collect n pairwise disjoint sets of unlabeled instances $\{W_1, W_2, \ldots, W_n\}$, each based on an set of books. In each iteration, we use an unvisited set of unlabeled instances (e.g., W_1) as W in Section 4.2. See Figure 2 for the overview of the paradigm.

5 Experiments

5.1 Data Statics and Evaluation Metrics

There is no book overlap between the training and dev sets in CSI as in previous datasets JY written by Jin Yong (Jia et al., 2021) and WP authored

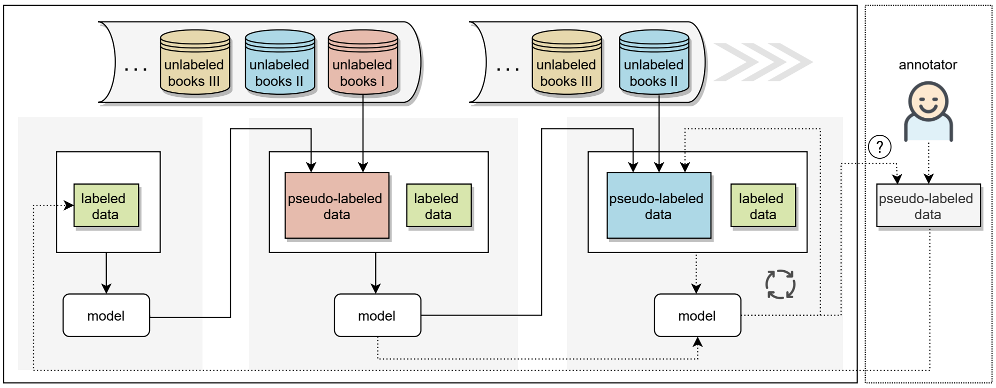

Figure 2: Continual self-training for speaker identification.

by Lu Yao (Chen et al., 2021) (Table 4). None of the books in CSI or the unlabeled corpora are written by the two authors to avoid data leakage. Previous methods use accuracy as the evaluation metric since a candidate list is provided. We report macro-averaged F1 and exact match (EM) following previous extractive MRC work (Rajpurkar et al., 2016). As each instance in WP and JY must have a ground truth speaker, EM equals accuracy.

name	set	candidate provided	# of books	# of instances
JY	train	✓	3	17,159
	dev	✓		5,719
	test	✓		5,719
WP	train	✓	1	2,000
	dev	✓		298
	test	✓		298
CSI	train	×	10	48,037
	dev	×	8	17,503
CORPUS_1	train	×	65	232,239
CORPUS_2	train	×	26	232,240
CORPUS_3	train	×	60	141,251
CORPUS_4	train	×	99	187,524

Table 4: Statistics of the speaker identification datasets for Chinese: JY, WP, CSI (this work), and pseudo-labeled training data from unlabeled books.

5.2 Implementation Details

We adopt the MRC model (Xu et al., 2020) as the baseline model that is built upon a pre-trained language model for Chinese. We experiment with BERT-wwm-ext-base and RoBERTa-wwm-ext-large (Cui et al., 2020), and our method can be easily used upon other recently release pre-trained language models. We use the same model architecture for teacher and student models. We train a model for five epochs when only clean data is used during training (i.e., CSI, JW, and PW) and train it for only one epoch when relatively large-scale pseudo-labeled data is involved. The hyperparameters are fixed across different experiments: we set the initial learning rate, batch size, and max sequence length to $3e-5$, 32, and 512, respectively.

5.3 Results on Existing SI Datasets

We first evaluate our extractive method E2E_SI on two existing SI datasets and CSI. We run each experiment five times using different random seeds. As shown in Table 5 (standard deviation in parentheses), E2E_SI based on RoBERTa-wwm-large can already obtain comparable or better performance than that of state-of-the-art methods, despite there is not much room for improvement for JY. Furthermore, it does not require a given small number of human-selected candidate speakers for each instance or a list of book-level character names and their alternative names as previous SI methods (Chen et al., 2021; Jia et al., 2021). We use RoBERTa-wwm-large in the remaining experiments due to its superior SI performance. Transfer learning with CSI leads to gains on both datasets.

5.4 Discussions on Continual Self-Training

Table 6 shows that continual self-training, which continuously leverages large-scale (around 793K) pseudo-labeled instances, leads to $+2.3\%$ in exact match on the CSI dataset (4 vs. 0). In particular, we observe that the resulting student model after each iteration consistently outperforms its teacher model (e.g., 2 vs. 1 and 4 vs. 3).

Slow Growth and Potential Solutions: Just as standard self-training, the performance will inevitably grow slowly or stop increasing after iterations over either changing or fixed corpora. Inspired by previous work that combined self-training and active learning (AL) for other tasks such as entity (Tomanek and Hahn, 2009) and time expres-

Table 6: Performance (%) of speaker identification on the dev set of our annotated data CSI using self-training (ST) and continual self-training (CST).

sion recognition (Su et al., 2021). We use the best-performing model (i.e., 4 in Table 6) to predict the labels for unlabeled corpora. As a preliminary experiment, we regard the instances (4,123 in total) with posterior probability smaller than a fixed value (0.5) as challenging instances and manually adjust pseudo labels of these instances only to save annotation efforts. Not surprisingly, the model underperform on these difficult instances (only 43.4% in EM and 49.2% in F1). We add the newly annotated data into the training data of CSI and conduct CST from the very beginning to fully leverage the large-scale corpora. After iterations, AL leads to an 0.5% improvement to 93.4% in F1. See results after each iteration in Table 9 (Appendix A.3). Based on the positive results, active learning may be a good solution for future improvements.

Zero-Shot Abilities: Based on the same model E2R_SI, we find that continual self-training (with or without AL) improves the model's zero-shot domain adaptation performance (the best model based on the dev performance on CSI is used for experiments). As shown in Table 7, by using CST with AL for training, E2R_SI can achieve previous SOTA performance without being trained on in-domain data of JY. These results show the potential usefulness of our paradigm for real-world applications where training and test data can be collected from different books or sources.

model	notes	setting	WP	JY
E2E_SI	0 in Table 6	zero-shot	62.1	88.6
E2E_SI+CST	4 in Table 6	zero-shot	70.1	92.9
E2E_SI+CST+AL	4 in Table 9	zero-shot	75.5	95.6
E2E_SI	Table 5	full-shot	86.0	98.4
previous SOTA	Table 5	full-shot	82.5	95.6

Table 7: Domain adaptation performance (EM %) on the test set of JY and WP.

Student Initialization: In our experiments, we find that student initialization plays an essential role in continual self-training for SI. It is always helpful to use a teacher model (e.g., 1, 2, and 3 in Table 6) that has seen large-scale pseudo-labeled data to initialize the weights of its student. For example, just using the pre-trained language model to initialize 2 and 3 hurts F1 by 0.2% (2 vs. 2A) and 0.4% (3 vs. 3A), respectively. This finding, at first glance, seems to be contrary to those in some previous studies (e.g., (Xie et al., 2020; Yu et al., 2021)) that also leverage pseudo-labeled or distantly-labeled data.

This is perhaps because in CST teachers (except for 0) are trained with pseudo-labeled data constructed based on DIFFERENT sets of books, instead of relying on a FIXED set of unlabeled or distantly-labeled resources. Under this varying data condition, initializing a student by its teacher that is typically used to save training time (Zoph et al., 2020), here helps transfer out-of-domain knowledge in corpora unseen to the student via model parameters.

In contrast, training the first student model 1 on the combination of human-labeled data and pseudo-labeled instances from the pre-trained language model work slightly better than initializing it with its teacher 0, which is only trained on human-labeled instances (1 vs. 1A). This is perhaps not surprising as the clean data is also used to train 1, making knowledge transfer via parameters less necessary. And the performance difference exists as the number of iterations increases if the resulting student is put back as the teacher for continual self-training (2 vs. 1B). Thus, we train 1 without using its teacher 0 for initialization.

5.5 Comparing ST and CST

We find that iterative training based on a fixed set of unlabeled instances is less effective than expected. For example, additional iteration over CORPUS_1 leads to $+0.1\%$ in F1 (5A vs. 1 in Table 6), while using the same teacher 1 to relabel the unlabeled CORPUS_2 that has similar number of instances as that of CORPUS_1 leads to higher gains $+0.4\%$ (2 vs. 1). Further iterations over CORPUS_1 does not improve performance (5B vs. 5A). Inspired by previous work, we also apply data augmentation (DA) based on a fixed set of books. We augment data by using contents in a six-paragraph sliding window as context, in which the center is a candidate utterance paragraph. Still, this strategy is less effective than simply moving to new corpora (Figure 3). Considering the facts that large-scale unlabeled corpora are usually available, and we can easily generate a large number of unlabeled instances based on a single book, it seems more effective to apply CST than sticking to a single corpus with or without using DA strategies.

Under conditions with a fixed unlabeled corpus, we still have similar observations that CST upon changing subsets of the corpora yields additional gains (e.g., $+0.4\%$ (6 vs. 2)), especially when the size of the unlabeled data is much larger than that of the human-annotated, clean data (e.g., $+0.5\%$ (7 vs. 4) when all the unlabeled corpora are used). It may be helpful to set a pre-defined ratio of the unlabeled and labeled data across iterations (Xu et al., 2021) for stronger supervision.

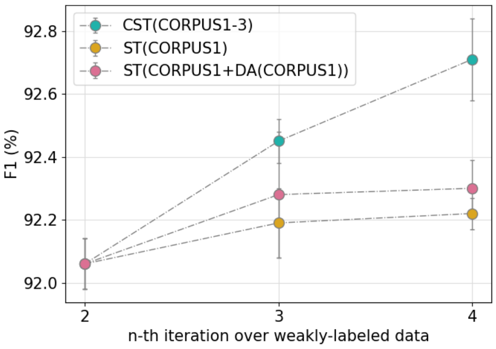

Figure 3: Comparing CST with ST over a fixed corpus.

5.6 Error Analysis

Errors appear frequently when a pronoun that refers to the speaker is dropped for simplicity (i.e. zero pronoun (Chen and Ng, 2013)). In the following example, *"Lian Shu"* is mistakenly regarded as the speaker of the utterance paragraph in curly brackets, and Θ refers to an ignored pronoun pointing to *"Uncle Zheng"*. It may be useful to convert zero pronoun data (Yang et al., 2019) into SI formats to infuse this kind of knowledge into SI models. More examples are in Appendix A.4.

> ***Lian Shu*** *stood up generously, stretched out her hand, and swept the hair hanging on her chest.* ***Uncle Zheng*** *quickly explained: "Aren't you busy with decoration at that time? I asked the construction team for the materials. I have inquired about the nearby store. Even the lady was enthusiastic and gave me a lot of ideas. And..." {Suddenly Θ remembered something, walked to the front desk quickly, and took a picture to show Ren Luo: "Miss Lian drew it. The interior space planning is more rigorous than I thought."} Ren Luo glanced and said, "The painting is great."*

6 Conclusions

We reformulate the SI task and propose a new annotation guideline that does not require document-level understanding. We apply an extractive MRC method to SI, which outperforms previous SOTA methods on all existing SI datasets for Chinese. Finally, we propose continual self-training to continue learning from new out-of-domain unlabeled corpora and combine active learning with this paradigm for further improvements.

A.2 Impacts of Context Selection: Sliding Window or Narrative Window

We compare narrative window and sliding window when we select context for unlabeled instances. We first use a six-paragraph window as such a window and narrative window results in context of similar length (180 tokens) based on our analysis (Section 3.3). Based on all the external corpora (CORPUS_1-4), though using sliding window can generate 45.1% more unlabeled instances (1,151,263 vs. 793,254), the final performance after CST is slightly worse than that of using data constructed by narrative window (Figure 3), demonstrating the advantage of using narrative window in CST. Using a longer window may hurt the performance. For example, using a ten-paragraph window, the performance of CST with all unlabeled corpora stagnates around 92.3%, as long-text understanding is also quite challenging.

A.3 Combining Active Learning and Continual Self-Training

We report detailed results in Table 9.

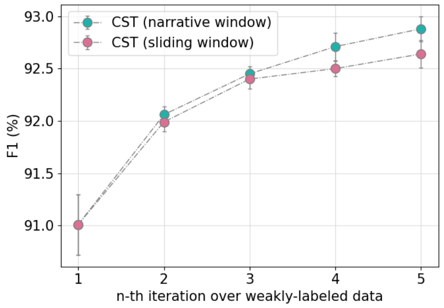

Figure 4: The performance of CST using narrative window and six-paragraph sliding window for context.

A.4 Error Analysis

It is also difficult for the model to identify the speakers for a target utterance among conjunctive utterances. Conversational patterns are widely used to solve this kind of implicit speakers (Muzny et al., 2017): for example, if the i-th utterance is linked to speaker A, the i+2-th utterance is supposed to be spoken by A when the paragraph between the two utterances is also an utterance. In the following example, our system fails to extract the correct speaker for *"I'm sorry"*. It is relatively easy to know that there are two speakers in the conversation and the speaker of the last utterance is spoken by *"Lin Zhaoxi"*, which can help us infer the correct speaker *"Lu Zhihao"*.

> *The boy was lying on the stretcher and looked at her with pitiful black eyes with a little wet, and opened his mouth in pain. {The first sentence was: "I'm sorry."}"It's okay.""Thank you." "You're welcome." "Thank you very much." "You're very welcome."* ***Lin Zhaoxi*** *replied fluently.* ***Lu Zhihao****'s lips moved, while his words were choked.*

Abstract

Event Detection (ED) is the task of identifying and classifying trigger words of event mentions in text. Despite considerable research efforts in recent years for English text, the task of ED in other languages has been significantly less explored. Switching to non-English languages, important research questions for ED include how well existing ED models perform on different languages, how challenging ED is in other languages, and how well ED knowledge and annotation can be transferred across languages. To answer those questions, it is crucial to obtain multilingual ED datasets that provide consistent event annotation for multiple languages. There exist some multilingual ED datasets; however, they tend to cover a handful of languages and mainly focus on popular ones. Many languages are not covered in existing multilingual ED datasets. In addition, the current datasets are often small and not accessible to the public. To overcome those shortcomings, we introduce a new large-scale multilingual dataset for ED (called MINION) that consistently annotates events for 8 different languages; 5 of them have not been supported by existing multilingual datasets. We also perform extensive experiments and analysis to demonstrate the challenges and transferability of ED across languages in MINION that in all call for more research effort in this area. We will release the dataset to promote future research on multilingual ED.

1 Introduction

Event Detection (ED) is one of the critical steps for an Event Extraction system in Information Extraction (IE) that aims is to recognize mentions of events in text, i.e., change of state of real world entities. Specifically, an ED system identifies the word(s) that most clearly refer to the occurrence of an event, i.e., event trigger, and also detects the type of event that is evoked by the event trigger. For instance, in the sentence "*The city was reportedly **struck** by F16 missiles.*", the word "*struck*" is the trigger for an *ATTACK* event. An ED model can be incorporated into other IE pipelines to facilitate the extraction of information related to events and entities, thereby supporting various downstream applications such as knowledge base construction, question answering and text summarization.

Due to its importance, ED has been extensively studied in the IE and NLP community over the past decade. Existing methods for ED extend from feature-based models (Ahn, 2006; Liao and Grishman, 2010; Miwa et al., 2014a), to advanced deep learning methods (Nguyen and Grishman, 2015; Chen et al., 2015; Sha et al., 2018; Wang et al., 2019; Yang et al., 2019; Cui et al., 2020; Lai et al., 2020; Pouran Ben Veyseh et al., 2021b). As such, the creation of large annotated datasets for ED, e.g., ACE 2005 (Walker et al., 2006), has been critical to progress measurement and growing development of ED research. However, a majority of current datasets for ED only provide annotation for texts in a single language (i.e., monolingual datasets). For instance, the recent challenging datasets for ED, e.g., MAVEN (Wang et al., 2020), RAMS (Ebner et al., 2020), or CySecED (Man et al., 2020), are all proposed for English documents only. In addition, there are a few existing datasets that include ED annotation for multiple languages (multilingual datasets), e.g., ACE 2005 (Walker et al., 2006), TAC KBP (Mitamura et al., 2016, 2017), and TempEval-2 (Verhagen et al., 2010). However, those multilingual datasets only cover a handful of languages (i.e., 3 languages in ACE 2005 and TAC KBP, and 6 languages in TempEval-2), mainly focusing on popular languages such as English, Chinese, Arabic, and Spanish, and leaving many other languages unexplored for ED. For instance, Turkish and Polish are not covered in existing multilingual datasets for ED. We also note that existing ED datasets tend to employ different annotation schema and guidelines that prevent the combina-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2286 - 2299
July 10-15, 2022

tion of current datasets to create a larger one. In all, the limited coverage of languages and annotation discrepancy in current monolingual/multilingual ED datasets hinder comprehensive studies for the challenges of ED in diverse languages. It also limits thorough evaluations for multilingual generalization of ED models. Finally, we note that the major multilingual datasets for ED are not publicly accessible due to the licence of involving documents, e.g., ACE 2005 and TAC KBP, thus further impeding research effort in this area.

To address such issues, our goal is to introduce a new Multilingual Event Detection dataset (called MINION) to support multilingual research for ED. In particular, we provide a large-scale dataset that manually annotates event triggers for 8 typologically different languages, i.e., English, Spanish, Portuguese, Polish, Turkish, Hindi, Japanese and Korean. Among them, the five languages Portuguese, Polish, Turkish, Hindi, and Japanese are not covered in existing popular datasets for multilingual ED (i.e., ACE 2005, TAC KBP, and TempEval-2). To facilitate public release and sharing of the dataset, we employ the event articles from Wikipedia for annotation in 8 languages. In addition, to improve quality of the data, we inherit the annotation schema and guideline in ACE 2005, the well-designed and widely-used dataset for ED research. In total, our MINION dataset involves more than 50K annotated event triggers, which is much larger than those in existing multilingual ED datasets (i.e., less than 11K and 27K in ACE 2005 and TempEval-2 respectively). We expect that the significantly larger size with more diverse set of languages and public texts in MINION can contribute to accelerate and extend research in ED to a larger population.

Given the proposed dataset, we conduct thorough analysis on MINION using the state-of-the-art (SOTA) models for ED. In particular, we first study the challenges of ED in different languages using monolingual evaluations where ED models are trained and tested in the same languages. Our experiments suggest that the performance of existing ED models is not yet satisfactory in multiple languages and the model performance on non-English languages is in general poorer than those for English. We also show that current pre-trained language models for specific languages (i.e., monolingual models) are less effective for ED models than multilingual pre-trained language models, e.g., mBERT (Devlin et al., 2019). In all, our findings highlight greater challenges of ED for non-English languages that should be further pursued in future research.

In addition, our MINION dataset also facilitate zero-shot cross-lingual transfer learning experiments that serve to reveal the transferability of ED knowledge and annotation across languages. In these experiments, ED models are trained on English data (the source language), but tested in other target languages. Our results in this setting demonstrate a wide range of cross-lingual performance for different target languages in MINION that introduces a diverse set of languages and data for ED research. Finally, we report extensive analysis on MINION to provide further data insights for future ED research, including challenges of data annotation, language differences, and cross-dataset evaluation. We will release MINION to foster future research for multilingual ED.

2 Data Annotation

Our dataset MINION follows the same definition of events as the annotation guideline in ACE 2005 (Walker et al., 2006). Specifically, an event is defined as an occurrence that results in the change of state of a real world entity. Moreover, an event mention is evoked by an event trigger which most clearly describes the occurrence of the event. While event triggers are mostly single words, we also allow multi-word event triggers to better accommodate ED annotation in multiple languages. For instance, the phrasal verb "*tayin etmek*" with two words in Turkish, meaning "*appoint*", is necessary to express the event type *Start-Position*.

We also inherit the annotation schema/ontology (i.e., to define event types for annotation) and guideline in ACE 2005 to benefit from its well-designed documentation and be consistent with most of prior ED research. However, to improve the quality of the annotated data, we prune some event sub-types from the original ACE 2005 ontology in our dataset. In particular, event sub-types that have very similar meanings in some language are not included in our final ontology. This promotes the distinction between event labels and avoids confusion for annotators to provide high-quality data in different languages. For instance, the event sub-types *Convict* and *Sentence* are very similar in Turkish (i.e., both *Convict* and *Sentence* can be translated as *Mahkum etmek* in Turkish), thus being removed in our ontology. In addition, we also exclude event sub-types in ACE 2005 that are not frequent in our collected data from Wikipedia (more details on data collection later), e.g., *Nominate* and *Declare-Bankruptcy*. Finally, 16 event sub-types (for 8 event types) are preserved in the final event schema for our dataset. We provide detailed explanation and sample sentences for the event types in our dataset in the Appendix A.

2.1 Candidate Selection

As mentioned in the introduction, we aim to annotate ED data for 8 languages, i.e., English, Spanish, Portuguese, Polish, Turkish, Hindi, Japanese and Korean. These languages are selected due to their diversity in term of typology and novelty w.r.t. to existing multilingual ED datasets that can be helpful for multilingual model development and generalization evaluation. To collect text data for annotation in each language, we employ the articles of the language-specific editions of Wikipedia. Specifically, for each language, we obtain its latest dump of Wikipedia articles[1], then process the dump with the parser *WikiExtractor* (Attardi, 2015) to extract textual and meta data for articles. To increase the likelihood of encountering event mentions for effective annotation, we utilize the articles that are classified under one of the sub-categories of the *Event* category in Wikipedia. In particular, we focus on six sub-categories *Economy*, *Politics*, *Technology*, *Crimes*, *Nature*, and *Military* due to their relevance to the event types in our ontology. Note that we map these (sub)categories in English to the corresponding (sub)categories in other languages using the provided links in Wikipedia. Afterward, to split the texts into sentences and tokens, we leverage the multilingual toolkit Trankit (Nguyen et al., 2021a) that has demonstrated state-of-the-art performance for such tasks in our languages.

Given a Wikipedia article, an approach for ED annotation is to ask the annotators to annotate the entire document for event triggers at once. However, as Wikipedia articles tend to be long, this approach might be overwhelming for annotators, thus potentially limiting the annotation quality. To this end, motivated by the annotation with 5-sentence windows in the RAMS dataset (Ebner et al., 2020), we split each article into segments of 5 sentences that will be annotated separately by annotators. In this way, annotators only need to process a shorter context at a time to improve the attention and accuracy of annotated data. This annotation approach is also supported by a large amount of prior ED research where a majority of previous ED models have employed context information in single sentences to deliver high extraction performance for the event types in ACE 2005 (Nguyen and Grishman, 2015, 2018; Wang et al., 2019; Yang et al., 2019; Cui et al., 2020), including models for multiple languages (M'hamdi et al., 2019; Ahmad et al., 2021; Nguyen et al., 2021b).

2.2 Annotation Process

To annotate the produced article segments, we hire annotators from `upwork.com`, a crowd-sourcing platform with freelancer annotators across the globe. In particular, our annotator candidate pool for each language of interest involves native speakers of the language who also have experience on related data annotation projects (e.g., for named entity recognition), an approval rate higher than 95%, and fluency in English. These information is provided by annotator profiles in Upwork. In the next step, the candidates are trained for ED annotation using the English annotation guideline and examples for the designed event schema in our dataset (i.e., inherited from ACE 2005). Finally, we ask the candidates to take an annotation test designed for ED in English and only candidates with passing results are officially selected for the annotators of our multilingual ED dataset. Overall, we recruit several annotators for each language of interest as shown in Table 2. To prepare for the actual annotation, the annotators for each language will work together to produce a translation of the English annotation guideline/examples where language-specific annotation rules are discussed and included in the translated guideline to form common annotation perception for the language. The translated guideline and examples are also verified by our language experts to avoid any potential conflicts and issues.

Finally, given the language-specific guidelines, the annotators for each language will independently annotate a chunk of article segments for that language. The breakdown numbers of annotated text segments for each language and Wikipedia subcategory in our MINION dataset are shown in Table 3. As such, 20% of the annotated text segments for each language is selected for co-annotation by the annotators to measure inter-annotator agree-

Portuguese	5	0.803
Polish	8	0.799
Turkish	10	0.813
Hindi	6	0.803
Japanese	5	0.789
Korean	6	0.810

Table 2: Agreement scores for 8 languages in MINION.

ment (IAA) scores while the remaining 80% is distributed to annotators for separate annotation. Table 2 reports the Krippendorff's alpha (Krippendorff, 2011) with MASI distance metric (Passonneau, 2006) for the IAA scores of each language in our dataset. After independent annotation, the annotators will resolve the conflict cases to produce the final version of our MINION dataset. Overall, our dataset demonstrates high agreement scores for all the 8 languages, thus providing a high-quality dataset for multilingual ED.

2.3 Data Analysis

The main statistics for our MINION dataset is provided in Table 3. This table shows that for a majority of languages, there are multiple event triggers in a text segment, thereby introducing a challenge for ED models due to the overlap of event context. In addition, the table shows that text segments in some languages are more replete with event mentions than those for other languages. Specifically, comparing Polish and English text segments, the density of event mentions in Polish is almost two times more than that for English. Finally, Figure 1 shows the distributions of 8 event types for the 8 languages in our dataset. As can be seen, the languages in our dataset tend to involve different levels of discrepancy regarding the distributions over event types. As such, the type density and distribution divergence between languages suggest other challenges that robust ED models should handle to perform well across languages in MINION.

2.4 Annotation Challenges

Despite the high inter-annotator agreement scores, there are some conflicts between our annotators during the annotation process due to the ambiguity of event triggers, especially in the multilingual setting. This section highlights some of the key ambiguities/conflicts that we encounter during our analysis of annotation results from the annotators. Note that all of these conflicts have been resolved by the annotators in the final version of our dataset.

Language-Specific Challenges: Despite common notion of events in different languages, each language might has its own exceptions regarding how an event trigger should be annotated, causing confusions/conflict for our annotators in the annotation process. One exception concerns the necessity to include event arguments in the annotation of an event trigger in some language. For example, in the Polish sentence "*Samolot sie rozbił*" (translated as "*The plane crashed itself*"), some annotators believe that the meaning of the verb "*rozbił*" (i.e., crashed) is incomplete if its argument word "*sie*" (i.e., itself) is not associated. As such, annotating both the verb and its argument (i.e., "*sie rozbił*") is necessary to express an event in this case. However, other annotators suggest that only annotating the word "*rozbił*" is sufficient. Our annotators have decided to annotate event triggers along with necessary arguments to achieve their complete meanings in such cases.

Background Knowledge: Background knowledge is sometime important to correctly recognize an event trigger in input text. In such cases, the annotators might have conflicting event annotation decisions for a word as their levels of background knowledge are different. For instance, in the sentence "*The match was canceled in the memory of victims of Katyn crime*", some annotators annotate the word "*crime*" as a *Die* event trigger as they

Language	#Seg.	Avg. Length	#Triggers	Avg. #Trigger/Seg.	Most Frequent Types	Challenging Type	Language Family

Table 3: Statistics of the MINION dataset. Seg. represent text segments. All annotated segments consist of 5 sentences and their lengths (Avg. Length) are computed in terms of number of tokens. "*Challenging Type*" indicates the type whose event trigger annotation involves the largest disagreement between annotators in each language.

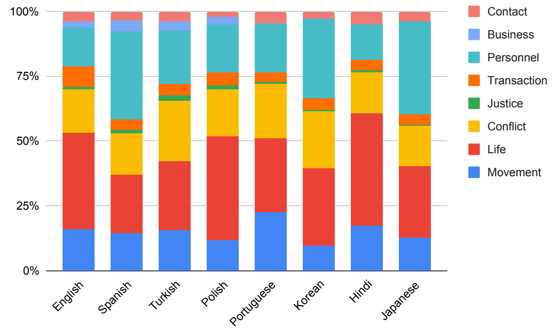

Figure 1: Distributions of event types in each language

know that "*crime*" is referring to a mass execution event. However, some annotators do not consider "*crime*" as an event trigger as they are not aware of the execution event. Eventually, we have decided to annotate the text segments based on only the presented information in the input texts to resolve conflicts and avoid inconsistency.

3 Experiments

This section aims to study the challenges of ED for 8 languages in our MINION dataset. As such, we evaluate the performance of the state-of-the-art (SOTA) ED models in the monolingual situations where models are trained and tested on the annotated data of the same language. To prepare for the experiments, we randomly split the annotated data for each language in MINION into separate training/development/test sets with the ratio of 80/10/10 (respectively). As MINION allows multi-word event triggers to accommodate language specialities in multiple languages, we model the ED task in our dataset as a sequence labeling problem. Concretely, given an input text segment $D = [w_1, w_2, \ldots, w_n]$ with n words, ED models need to predict the label sequence $Y = [y_1, y_2, \ldots, y_n]$ where y_i indicates the label for the word $w_i \in D$ using the BIO tagging schema.

To this end, following prior work on multilingual ED (Wang et al., 2020) and cross-lingual ED (M'hamdi et al., 2019), we examine the following representative SOTA models for sequence-labeling ED: (1) **Transformer**: A pre-trained transformer-based language model (PTLM), e.g., mBERT (Devlin et al., 2019), is augmented with a feed-forward network to predict a label for each word in the input text; (2) **Transformer+CRF**: This model also employs an PTLM as the **Transformer** model; however, a Conditional Random Field (CRF) layer is additionally introduced as the final layer to predict the label sequence Y; (3) **Transformer+BiLSTM**: This model extends the **Transformer** model by injecting a bidirectional Long Short-Term Memory network (BiLSTM) between the PTLM and the feed-forward network to further abstract the representation vectors; and (4) **Transformer+BiLSTM+CRF**: This model is similar to the **Transformer+BiLSTM** model with an exception that a CRF layer is employed in the end for label sequence prediction. As such, to implement the models, we explore two SOTA multilingual PTLMs models, i.e., mBERT (Devlin et al., 2019) and XLMR (Conneau et al., 2020) (their base versions) for text encoding. In the model notation, we will replace the prefix "Transformer" with "mBERT" or "XLMR" depending on the actual PTLM to use (e.g., mBERT, mBERT+CRF, mBERT+BiLSTM). Following prior work (Wang et al., 2020; M'hamdi et al., 2019), in the experiments, we evaluate the models using precision, recall and F1 scores for correctly predicting event trigger boundaries and types in text.

Our fine-tuning process suggests similar values of hyper-parameters for the models across languages in MINION. In particular, for English, we use one layer for BiLSTM mod-

Table 5: Performance of the ED models in the monolingual setting using XLMR on MINION.

ules with 300 dimensions for the hidden states (for **Transformer+BiLSTM** and **Transformer+BiLSTM+CRF**). For feed-forward networks, we employ 2 layers with 200 dimensions for the hidden vectors. The learning rate is set to $1e$-4 for the Adam optimizer and the batch size of 8 is employed during training.

Monolingual Performance: The performance of the four ED models on the test data of each language are presented in Tables 4 (for mBERT) and 5 (for XLMR). There are several observations from these tables. First, the best average F1 score of the models over different languages is 72.31% (achieved by the XLMR model). This performance is still considerably lower than a perfect model, thus suggesting significant challenges of ED in multiple languages and calling for more research effort in this area. Second, the performance of the models for non-English language is significantly worse than the English counterpart. This difference thus further highlights the necessity of more research on ED for non-English languages. Finally, the superior performance of XLMR over other models in almost all languages indicates better effectiveness of the multilingual PTLM model XLMR for ED in different languages (compared to mBERT). It also implies that traditional BiLSTM and CRF layers for sequence labeling are less necessary for multilingual ED when a PTLM is employed for text encoding. As such, in the following experiments, we will employ **Transformer** as the main ED model for further analysis.

Monolingual PTLMs: To better understand the benefits of multilingual PTLMs (i.e., mBERT and XLMR) for multilingual ED, we further evaluate the performance the **Transformer** model when monolingual language-specific PTLMs are leveraged to encode input texts (i.e., replacing mBERT and XLMR). Accordingly, for monolingual language-specific PTLMs, we consider both BERT-based and RoBERTa-based models for comprehensiveness. Tables 6 (for BERT) and 7 (for RoBERTa) report the monolingual performance of **Transformer** when monolingual language-specific PTLMs are employed. Note that we only show ED performance for languages where monolingual PTLMs are publicly available. As can be seen, compared to multilingual PTLMs, monolingual PTLMs (based on BERT or RoBERTa) improve the performance of **Transformer** for English. However, for other languages, monolingual PTLMs are on-par (for BERT-based models) or significantly worse (for RoBERTa-based models) than multilingual PTLMs for ED, thus demonstrating the general

advantage of multilingual PTLMs for ED. In addition, it is suggestive that future work can explore methods to improve monolingual language-specific PTLMs for ED in different languages.

Cross-lingual Performance: To understand the transferability of ED knowledge and annotation across languages, we explore the cross-lingual evaluation setting where models are trained on English data (the source language) and directly evaluated on test data of other target languages in MINION. As such, we report the cross-lingual performance of **Transformer** with both mBERT and XLMR as the PTLMs in Table 8. Note that we inherit the same hyper-parameters selected for **Transformer** in the fine-tuning process of monolingual experiments for consistency.

Compared to the monolingual performance counterparts of mBERT and XLMR in Tables 4 and 5, it is clear that the performance of **Transformer** in non-English languages decreases significantly in the cross-lingual evaluation, i.e., the average performance loss due to cross-lingual evaluation is 15.2% for both mBERT and XLMR. We also observe a wide range of cross-lingual performance for the target languages in Table 8, thus suggesting the diverse nature of the data and languages in MINION to support robust model development for ED. Among the target languages, Portuguese exhibits the smallest performance difference between monolingual and cross-lingual settings while the largest performance loss with cross-lingual transfer occurs in Japanese, Turkish, Korean, and Hindi. One possible reason for such performance loss is due to the language structure difference where Japanese, Turkish, Korean, and Hindi follow the Subject-Object-Verb word order while English and other languages in our dataset utilize the Subject-Verb-Object order. Another reason can be linked to different patterns/distributions of event triggers in different languages. For instance, some languages tend to mention the events using verbs (e.g., in English 78% of the triggers are verb) while other languages might use more diverse parts of speech to express event trigger (e.g., in Japanese only 63% of triggers are verbs). Also, Section 4 provide an additional explanation regarding the diversity of event triggers in different languages. In all, the cross-lingual performance in our MINION dataset demonstrates the challenges of transferring ED knowledge across languages that can be further studied in future work.

4 Analysis

This section provides additional analysis to better understand the multilingual ED task in MINION.

Cross-dataset Evaluation: As the event ontology in MINION is inherited and pruned from the ACE 2005 dataset, it is helpful to learn how the annotated events in MINION is different from those in ACE 2005. To this end, we propose to evaluate model performance on the cross-dataset setting: models are trained on the English data of ACE 2005 and evaluated on test data of different languages in MINION. In particular, we utilize the standard data split from prior work (Nguyen and Grishman, 2015; Chen et al., 2015; Wang et al., 2019) to obtain English training and development data in ACE 2005. Also, we filter the ACE 2005 data so only triggers of event sub-types in our MINION

Japanese	49.31	21.78	30.21	55.48	22.60	32.12
Korean	72.98	36.37	48.55	73.90	40.16	52.04

Table 10: Performance of XLMR in the cross-lingual setting when it is trained on English and Spanish. For both languages, 3,000 random samples from the training set of the corresponding language are selected to train the model.

dataset are retained for a compatibility between two datasets. Due to its superior performance in previous experiments, we employ the **Transformer** model with XLMR in this experiment. The hyper-parameters for the model is fine-tuned on the development data of ACE 2005. Table 9 shows the model performance in the cross-dataset evaluation. Compared to the corresponding cross-lingual performance of MINION in Table 8, it is clear that the performance on MINION is significantly worse when the model is trained on ACE 2005 data. As such, a possible explanation for this performance loss includes domain difference between ACE 2005 and MINION, i.e., MINION involve Wikipedia articles while ACE 2005 is based on news articles, conversational telephone speeches, and others. In addition, as the size of English training data in MINION (i.e., over 14K triggers) is significantly larger than those for ACE 2005 (i.e., less than 6K triggers), the training data in MINION might cover more event patterns to produce better performance for ED models. Future work can explore this cross-dataset evaluation setting to build more robust models for ED.

Trigger Diversity in Different Languages: To understand how events are expressed in different languages, we explore the ratio of unique trigger words over the total number of event triggers for an event sub-type (called unique ratio). Figure 2 shows the averages of unique ratios over event sub-types for different languages in our MINION dataset. As such the diagram shows that English is relatively simpler than other languages in ED as its diversity of event triggers for event types is the least among all the considered languages. Korean, Turkish, and Japanese are the languages that exhibit the largest diversities of event triggers. This further helps to explain the worst cross-lingual performance of models from English to Korean, Turkish, and Japanese in Table 8.

Challenging the Supremacy of English for Event Detection: English has been the major language for ED research. In particular, in cross-lingual transfer learning for ED, English has often been considered as a high-resource source language to train ED models to apply to other target languages (M'hamdi et al., 2019; Nguyen et al., 2021b). In this experiment, we argue that English is not necessary the optimal source language for cross-lingual transfer learning of ED. In particular, using **Transformer** with XLMR as the base model, we train the model on the training data of both English and Spanish; the resulting models are evaluated on the test data of the other languages in MINION. To ensure a fair comparison, we use the same size of training data for English and Spanish, i.e., 3,000 annotated text segments randomly sampled in MINION. Table 10 presents the cross-lingual performance of the models. The table demonstrates that using Spanish as the source language can achieve better performance than English for all the target languages in MINION. As such, our findings suggest that choosing appropriate source languages for cross-lingual transfer learning of ED is important and can be further explored in future work.

5 Related Work

Early attempts for ED have employed feature-based models (Ahn, 2006; Ji and Grishman, 2008; Patwardhan and Riloff, 2009; Liao and Grishman, 2010; Hong et al., 2011; Li et al., 2013; Miwa et al., 2014b; Yang and Mitchell, 2016) while deep learning has recently been proven to be a better approach for ED (Nguyen and Grishman, 2015; Chen et al., 2015; Nguyen et al., 2016; Sha et al., 2018; Yang et al., 2019; Wang et al., 2019; Cui et al., 2020; Lai et al., 2020, 2021a; Ngo Trung et al., 2021;

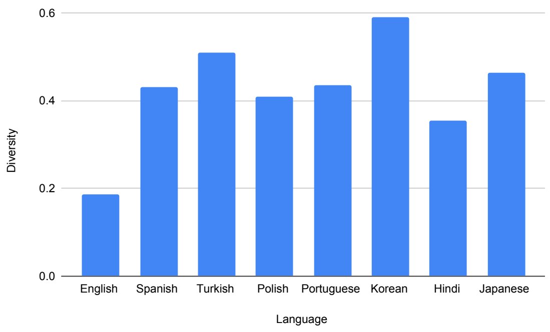

Figure 2: The average ratios of unique event triggers over event sub-types for each language in MINION.

Pouran Ben Veyseh et al., 2021a). There have also been recent efforts on creating new datasets for ED for different domains, including biomedical texts (Kim et al., 2009), literary texts (Sims et al., 2019), cybersecurity texts (Satyapanich et al., 2020; Man et al., 2020), Wikipedia texts (Wang et al., 2020), fine-grained event types (Le and Nguyen, 2021), and historical texts (Lai et al., 2021b). However, such prior works and datasets for ED are mainly devoted to English, ignoring challenges in many non-English languages. Non-English datasets for ED also exist (Kobyliński and Wasiluk, 2019; Sahoo et al., 2020); however, these datasets are only annotated for one language with divergent ontology and annotation guidelines, thus unable to support comprehensive studies and transferability research for ED on multiple languages.

Existing ED datasets that cover multiple languages involve ACE 2005 (Walker et al., 2006), TAC KBP (Mitamura et al., 2016, 2017), and TempEval-2 (Verhagen et al., 2010). Among such datasets, ACE 2005 is the most popular dataset used in prior multilingual/cross-lingual ED research (Chen and Ji, 2009; M'hamdi et al., 2019; Ahmad et al., 2021; Nguyen et al., 2021c; Nguyen and Nguyen, 2021). However, such multilingual datasets suffer from the issues of small data size, limited language coverage with greater focus on popular languages, and inaccessibility to the public as discussed in the introduction. Finally, we also note some prior works that claim event detection datasets for non-English datasets (Im et al., 2009; Küçük and Yazici, 2011; Lejeune et al., 2015). However, such datasets are not comparable to our dataset as their event detection task is indeed a sentence classification problem where established definition of events with event triggers are not followed and annotated.

6 Conclusion

We introduce a new dataset for ED in 8 typologically different languages. The dataset is significantly larger and covers more and newer languages than prior resources. Specifically, 31,226 text segments from language-specific articles of Wikipedia are manually annotated in the dataset. Our experiments and analysis demonstrate the high quality of the dataset and the multilingual challenges of ED, providing ample room for future research in this direction. In the future, we will extend the dataset to include event argument annotations.

A Event Types in MINION

There are 16 event types annotated in the proposed MINION dataset. Table 11 shows the event types along with their description and examples. We inherit event type definition and examples from ACE annotation guideline[2] (Walker et al., 2006).

---

[2] `https://www.ldc.upenn.edu/sites/www.ldc.upenn.edu/files/english-events-guidelines-v5.4.3.pdf`

ID	Type_SubType	Description	Example (triggers are highlighted)
1	Life_Be-Born	A BE-BORN Event occurs whenever a PERSON Entity is given birth to. Please note that we do not include the birth of other things or ideas.	• Jane Doe was **born** in Casper, Wyoming on March 18, 1964. • They have been linked to cancer, **birth** defects, and other genetic abnormalities.
2	Life_Marry	MARRY Events are official Events, where two people are married under the legal definition.	• Jane Doe and John Smith were **married** on June 9, 1998. • Residents were unable to register **marriages**.
3	Life_Divorce	A DIVORCE Event occurs whenever two people are officially divorced under the legal definition of divorce. We do not include separations or church annulments.	• The couple **divorced** four years later. • Fox and his four adopted children, he is **divorced** will move into guest quarters behind the presidential residence
4	Life_Injure	An INJURE Event occurs whenever a PERSON Entity experiences physical harm. INJURE Events can be accidental, intentional or self-inflicted.	• Two soldiers were **wounded** in the attack. • She was badly **hurt** in an automobile accident.
5	Life_Die	A DIE Event occurs whenever the life of a PERSON Entity ends. DIE Events can be accidental, intentional or self-inflicted.	• Terrorist groups have threatened to **kill** foreign hostages. • John Hinckley attempted to **assassinate** Ronald Reagan.
6	Movement_Transport	A TRANSPORT Event occurs whenever an ARTIFACT (WEAPON or VEHICLE) or a PERSON is moved from one PLACE (GPE, FACILITY, LOCATION) to another.	• Zone escaped the incident with minor injuries, and Kimes was **moved** to the prison's disciplinary housing unit, the authorities said. • The aid was aimed at repairing houses damaged by Israeli bombing and buying additional ambulances" to **transport** the rising number of wounded.
7	Transaction_Transfer-Ownership	TRANSFER-OWNERSHIP Events refer to the buying, selling, loaning, borrowing, giving, or receiving of artifacts or organizations.	• There is also a scandal that erupted over Russia's declaration that it will **sell** weapons to Iran, contrary to the earlier made agreement. • China has **purchased** two nuclear submarines from Russia.
8	Transaction_Transfer-Money	TRANSFER-MONEY Events refer to the giving, receiving, borrowing, or lending money when it is not in the context of purchasing something. The canonical examples are: (1) people giving money to organizations (and getting nothing tangible in return); and (2) organizations lending money to people or other orgs.	• The charity was suspected of **giving** money to Al Qaeda. • The organization survives on **donations**.
9	Conflict_Attack	An ATTACK Event is defined as a violent physical act causing harm or damage. ATTACK Events include any such Event not covered by the INJURE or DIE subtypes, including Events where there is no stated agent. The ATTACK Event type includes less specific violence-related nouns such as 'conflict', 'clashes', and 'fighting'. 'Gunfire', which has the qualities of both an Event and a weapon, should always be tagged as an ATTACK Event, if only for the sake of consistency. A 'coup' is a kind of ATTACK (and so is a 'war').	• U.S. forces continued to **bomb** Fallujah. • A car bomb **exploded** in central Baghdad
10	Conflict_Demonstrate	A DEMONSRATE Event occurs whenever a large number of people come together in a public area to protest or demand some sort of official action. DEMONSTRATE Events include, but are not limited to, protests, sit-ins, strikes, and riots.	• Thousands of people **rioted** in Port-au-Prince, Haiti over the weekend. • The union began its **strike** on Monday.
11	Contact_Meet	A MEET Event occurs whenever two or more Entities come together at a single location and interact with one another face-to-face. MEET Events include talks, summits, conferences, meetings, visits, and any other Event where two or more parties get together at some location.	• Bush and Putin **met** earlier this week to discuss Chechnya • China, Japan, the United States, and both Koreas will hold a **meeting** this month.
12	Contact_Phone-Write	A PHONE-WRITE Event occurs when two or more people directly engage in discussion which does not take place 'face-to-face'. To make this Event less open-ended, we limit it to written or telephone communication where at least two parties are specified. Communication that takes place in person should be considered a MEET Event. The very common 'PERSON told reporters' is not a taggable Event, nor is 'issued a statement'. A PHONE-WRITE Event must be explicit phone or written communication between two or more parties.	• John **sent** an e-mail to Jane. • John **called** Jane last night.
13	Personnel_Start-Position	A START-POSITION Event occurs whenever a PERSON Entity begins working for (or changes offices within) an ORGANIZATION or GPE. This includes government officials starting their terms, whether elected or appointed.	• Foo Corp. **hired** Mary Smith in June 1998. • Mary Smith **joined** Foo Corp. in June 1998.
14	Personnel_End-Position	An END-POSITION Event occurs whenever a PERSON Entity stops working for (or changes offices within) an ORGANIZATION or GPE. The change of office case will only be taggable when the office being left is explicitly mentioned within the scope of the Event. This includes government officials ending terms, whether elected or appointed.	• Richard Jr. had 14 months, before he was **laid off** in October. • Georgia **fired** football coach Jim Donnan Monday after a disappointing 7-4 season that started with the Bulldogs ranked No. 10 and picked to win the SEC East, his players said.
15	Justice_Arrest-Jail	A JAIL Event occurs whenever the movement of a PERSON is constrained by a state actor (a GPE, its ORGANIZATION subparts, or its PERSON representatives).	• Florida police **arrested** James Harvey in Coral Springs on Friday. • Since May, Russia has **jailed** over 20 suspected terrorists without a trial.
16	Business_Start-Organization	A START-ORG Event occurs whenever a new ORGANIZATION is created.	• Joseph Conrad Parkhurst, who **founded** the motorcycle magazine Cycle World in 1962, has died. • British Airways PLC plans to sell Go, its profitable cut-price subsidiary **launched** two years ago, the company said Monday.

Table 11: Event types along with their descriptions and examples in MINION.

Do Prompt-Based Models Really Understand the Meaning of Their Prompts?

Albert Webson[1,2] and Ellie Pavlick[1]

{albert_webson, ellie_pavlick}@brown.edu
[1]Department of Computer Science, Brown University
[2]Department of Philosophy, Brown University

Abstract

Recently, a boom of papers has shown extraordinary progress in zero-shot and few-shot learning with various prompt-based models. It is commonly argued that prompts help models to learn faster in the same way that humans learn faster when provided with task instructions expressed in natural language. In this study, we experiment with over 30 prompt templates manually written for natural language inference (NLI). We find that models can learn just as fast with many prompts that are intentionally irrelevant or even pathologically misleading as they do with instructively "good" prompts. Further, such patterns hold even for models as large as 175 billion parameters (Brown et al., 2020) as well as the recently proposed instruction-tuned models which are trained on hundreds of prompts (Sanh et al., 2021). That is, instruction-tuned models often produce good predictions with irrelevant and misleading prompts even at zero shots. In sum, notwithstanding prompt-based models' impressive improvement, we find evidence of serious limitations that question the degree to which such improvement is derived from models understanding task instructions in ways analogous to humans' use of task instructions.

1 Introduction

Suppose a human is given two sentences: "No weapons of mass destruction found in Iraq yet." and "Weapons of mass destruction found in Iraq." They are then asked to respond 0 or 1 and receive a reward if they are correct. In this setup, they would likely need a large number of trials and errors before figuring out what they are really being rewarded to do. This setup is akin to the pretrain-and-fine-tune setup which has dominated NLP in recent years, in which models are asked to classify a sentence representation (e.g., a CLS token) into some arbitrary dimensions of a one-hot vector. In contrast, suppose a human is given a prompt such as: Given that "no weapons of mass destruction found in Iraq yet.", is it definitely correct that "weapons of mass destruction found in Iraq."?[1] Then it would be no surprise that they are able to perform the task more accurately and without needing many examples to figure out what the task is.

Similarly, reformatting NLP tasks with prompts such as the underlined text above has dramatically improved zero-shot and few-shot performance over traditional fine-tuned models (Schick and Schütze, 2021b; Le Scao and Rush, 2021; Sanh et al., 2021; Wei et al., 2021). Such results naturally give rise to the hypothesis that the extra prompt text included within each input example serves as semantically meaningful task instructions which help models to learn faster, in the way task instructions help humans to learn faster. This hypothesis is implicitly assumed by many and explicitly argued by Mishra et al. (2021), Schick and Schütze (2021a), and Brown et al. (2020).

While last years saw a gold rush of papers (summarized in §2) that proposed automatic methods for optimizing prompts, Logan IV et al. (2021) compare a representative sample of these newly proposed methods and report that Schick and Schütze (2021b)'s manually written prompts still on average outperform the automatically searched prompts across a range of SuperGLUE tasks (Wang et al., 2019). Such findings suggest that expert-crafted prompts are among the best, if not *the* best, which reinforces the above hypothesis that models benefit from meaningful instructions.

In this paper, we test this hypothesis by evaluating various models on NLI in zero-shot and few-shot settings using more than 30 manually written templates and 13 sets of LM target words for a

---

[1] This prompt is adapted from MultiNLI (Williams et al., 2018, p. 3)'s instructions to crowdsourced workers, while the example is the first one in RTE's training set.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2300 - 2344
July 10-15, 2022 ©2022 Association for Computational Linguistics

total of over 390 prompts. We find that in most cases models learn identically as fast when given irrelevant or misleading templates as they do when given instructively good templates. Further, models ranging from 235 million to 175 billion parameters all exhibit this behavior, as do the instruction-tuned models, which are trained on hundreds of manually written prompts. While we confirm Sanh et al. (2021)'s finding that instruction tuning substantially improves the performance and robustness of prompts, we also find that instruction-tuned models can be, in some sense, too robust and less sensitive to the semantics of the prompts, as compared to their non-instruction-tuned equivalents. Finally, models are much more sensitive to the choice of the LM target words as opposed to the meaning of the instruction templates. In sum, despite prompt-based models' dramatic improvement in zero-shot and few-shot learning, we find limited evidence that models' improvement is derived from models understanding task instructions in ways analogous to humans' use of task instructions.

2 Related Work

2.1 Prompt-Based Models

At the time of writing, the terms "prompt tuning" and "prompting" can refer to any one or combination of three approaches described below:

Discrete Prompts reformat each example with some template text. For example, in a sentiment analysis task, the template can be `{sent} In summary, the restaurant is [prediction]`, where the predicted mask word is then converted to a class prediction by a predefined mapping, e.g., {"great" → positive, "terrible" → negative}. The prompts can be manually written (Schick and Schütze, 2021a; Bragg et al., 2021) or automatically generated (Gao et al., 2021b; Shin et al., 2020). This approach typically tunes all parameters of the model, but its few-shot performance can exceed that of very large models (e.g., GPT-3 175B) despite using a 3 orders of magnitude smaller LM (Schick and Schütze, 2021b; Tam et al., 2021).

Priming (a.k.a. in-context learning) prepends k priming examples to the evaluation example, where each example is optionally wrapped in a template such as `Question: {sent`$_1$`} True or false? {label`$_1$`} ... Question: {sent`$_k$`} True or false? {label`$_k$`} Question: {eval_sent} True or false? [prediction]`. Notably, although models see labeled examples, their parameters do not receive gradient updates based on those examples. Although this approach is intriguing, Brown et al. (2020) report that it only performs well on the largest GPT-3 model, the API of which is costly and difficult to use for academic research (see Appendix B for details).

Continuous Prompts prepend examples with special tokens, optionally initialized with word embeddings; but during learning, those tokens can be updated arbitrarily such that the final embeddings often *do not* correspond to any real word in the vocabulary (e.g., Lester et al., 2021; Li and Liang, 2021; Qin and Eisner, 2021). This approach often efficiently tunes a much smaller set of model parameters, but these methods have not yet reported success in few-shot settings. Moreover, foregoing prompts as expressed in natural language makes it much harder to study their semantics, and it is not clear if continuous prompts serve as task-specific instructions or simply more efficient model parameters (see He et al., 2021 for a detailed analysis).

2.2 Analyses of Prompts

In this paper, we focus on discrete prompts because we can manually write and control their wording and semantics. We measure the effect of prompt semantics by the model's k-shot performance where $k = \{0, 4, 8, 16, 32, 64, 128, 256\}$. This setup resembles that of Le Scao and Rush (2021), but their study focuses on comparing Schick and Schütze (2021b)'s existing small set of prompts against traditional fine-tuning over the training trajectories of entire training sets, whereas our study focuses on the few-shot learning trajectories among a much more diverse set of prompts designed to test specific hypotheses about the effect of prompt semantics on few-shot learning speed.

At a high-level, our findings contradict Mishra et al. (2021)'s claim that models benefit from elaborate instructions adapted from crowdsourcing annotation guides. But note that they define "instructions" more broadly as including priming examples, and they find that "GPT-3 benefits the most from positive examples, mildly from definition, and deteriorates with negative examples." (p. 18). In other words, if we ablate priming and narrow "instructions" to just the description of a task, we in fact have the same finding that instructions are only modestly beneficial over no instructions (cf. our irrelevant templates). In a similar vein, concurrent work by Lampinen et al. (2022) finds that other components of a prompt such as explanations of priming examples are helpful, but models are indifferent to whether the instructions in fact describe their tasks.

Finally, a growing body of concurrent work also questions the degree to which models need meaningful instructions (Khashabi et al., 2021; Prasad et al., 2022). One particularly noteworthy finding is that Min et al. (2022) show that models learn just as well with incorrect labels as opposed to correct labels in priming, concluding that prompts are helping models to learn the distribution of the input text and space of possible labels (as opposed to specifying instructions of the task).

3 Overall Setup

We implement a manual discrete prompt model- which in essence is the same as that of Schick and Schütze (2021b), except their implementation includes several augmentations such as self-labeling and ensembling of multiple prompts for competitive results. In order to focus on measuring the effect of prompts themselves, our implementation does not include those augmentations. Following Sanh et al. (2021) and Wei et al. (2021), we evaluate by a rank classification of the target words.

Baseline Model In preliminary experiments, we fine-tuned and prompt-tuned BERT, DistilBERT, RoBERTa, ALBERT, and T5 (Devlin et al., 2019; Sanh et al., 2019; Liu et al., 2019; Lan et al., 2020; Raffel et al., 2020; all implemented via Wolf et al., 2020). Confirming prior work (Schick and Schütze, 2021b; Tam et al., 2021), we find that ALBERT consistently yields the best performance, so we use it as our baseline model.

To verify that our implementation is comparable with prior work, Figure 10 reports the RTE validation accuracy of our baseline model. At 32 shots, our implementation yields a median accuracy of 70.22% (mean = 69.29%, std. dev. = 6.3%), which is comparable to the 69.8% reported by Schick and Schütze (2021b). Further, Figure 10 confirms Le Scao and Rush (2021)'s finding that, while both fine-tuning and prompt-tuning converge to similar results when fully trained on the entire set ($n = 2490$ for RTE), prompt-tuning yields the largest improvement in the few-shot setting. Going forward, we focus on studying the few-shot learning trajectory between 4 and 256 examples.

Instruction-Tuned Model We additionally experiment with T0, a recently proposed instruction-tuned model which is trained on over 60 datasets formatted with hundreds of manually written prompts (Sanh et al., 2021). We experiment with both sizes of T0 (3B and 11B), as well as their non-instruction-tuned version, T5 LM-Adapted (Lester et al., 2021), as a baseline.

Very Large Model Lastly, we experiment with the largest GPT-3 (175B) via priming (a.k.a. in-context learning). Although fine-tuning is technically available, it is extremely limited by OpenAI's various quotas. See Appendix B for details on how we circumvent challenges in reproducing Brown et al. (2020)'s results.

Data NLI is a task where a model is asked to classify whether one piece of text (the "premise") entails another (the "hypothesis"). We focus on NLI because all T0 variants holds out all NLI prompts and all NLI datasets in its training, which makes it a fair comparison to other models in this paper.

We use Recognizing Textual Entailment (RTE, Dagan et al., 2006, inter alios), a series of expert-annotated NLI datasets. Specifically, we use the SuperGLUE collection of RTE (i.e., RTE1, 2, 3, and 5; all converted to binary classification) and report their validation accuracy for comparability with prior work on prompts.

We also experiment with Adversarial NLI (ANLI, Nie et al., 2020), Heuristic Analysis for NLI Systems (HANS, McCoy et al., 2019), and Winograd Schema Challenge (WSC, Levesque et al., 2012), reported in Appendices G.2, K, and L, respectively. We find no qualitative difference between their and the main RTE results except that ANLI requires much larger number of shots before obtaining any above-random accuracy, as it is designed to be a highly challenging set.

Random Seeds & Example Sampling All experiments are run over the same set of 4 random seeds. Within a given seed, all models see the same set of examples. For instance, under seed 1, the 4-shot models see examples 550–553, the 8-shot models see examples 550–557, and so on. Across different seeds, a different starting example index is drawn. The exact training example indices are also recorded in our GitHub repository for reproducibility.

Statistical Tests We use both ANOVA and its nonparametric equivalent, the Kruskal–Wallis test. After finding a significant difference among multiple categories of templates, we report pairwise significance with the independent two-sample t-test and the Wilcoxon rank-sum test. We set $\alpha = 0.05$ and apply the Bonferroni correction to account for multiple comparisons. For all results reported in this paper, both t-test and Wilcoxon agree.

4 Effect of Templates

Our research question is whether models understand prompts as meaningful task instructions analogous to how humans would. For intuition, suppose an experimenter provides a human annotator with an informative instruction of a reasonably easy task. If the annotator understands the instruction, we expect them to perform better than when the experimenter provides intentionally misleading instructions, makes irrelevant chitchat, or says nothing at all. Accordingly, we write various prompt templates that correspond to these different scenarios and evaluate models' performance with these templates in zero-shot and few-shot settings.

4.1 Method

We write 5 categories of templates (Table 1), with at least 5 templates for each category (10 for instructive):

- Instructive: how we would describe the NLI task to a human who has never seen this task before.
- Misleading-Moderate: instruct the models to perform a task related or tangential to NLI such that, if the model were to perform the task as explicitly instructed, it would perform poorly on NLI in general.[2]
- Misleading-Extreme: instruct the models to perform a task unrelated to NLI.
- Irrelevant: concatenate the premise, a sentence unrelated to any NLP task, and the hypothesis.
- Null: concatenate the premise and the hypothesis without any additional text.

Category	Examples
instructive	{prem} Are we justified in saying that "{hypo}"? Suppose {prem} Can we infer that "{hypo}"?
misleading-moderate	{prem} Can that be paraphrased as: "{hypo}"? {prem} Are there lots of similar words in "{hypo}"?
misleading-extreme	{prem} is the sentiment positive? {hypo} {prem} is this a sports news? {hypo}
irrelevant	{prem} If bonito flakes boil more than a few seconds the stock becomes too strong. "{hypo}"?
null	{premise} {hypothesis} {hypothesis} {premise}

Table 1: Example templates for NLI.

See Table 1 for examples and Appendix F for the full list. We use "prompt" to mean a unique combination of a template and a predefined LM target word for each class label. For example, {"yes" → entailment, "no" → non-entailment} are the default targets for the template `{premise} Should we assume that {hypothesis}? [prediction]`. In this section, to control for the effect of target words, a template's performance is always reported with "yes"/"no" as its target words, which consistently perform best. In Section 5, we control for the templates and study the effect of different target words. We further control for punctuation, declarative vs. interrogative templates, and the order of concatenation (always `{premise}` *`some template text`* `{hypothesis}[prediction]`).

After preliminary experiments, to avoid cherry picking, all prompts reported in this paper were written prior to evaluation, i.e., we do not allow retroactively editing prompts for performance manipulations, except for an ablation study that explicitly studies the effect of punctuation (Appendix A).

4.2 Result

Irrelevant Templates We find that models trained with irrelevant templates learn just as fast as those trained with instructive templates, with no practical difference[3] at any number of shots (Figure 1). This is true for all models and all datasets in our experiments, including the largest GPT-3 (Figure 2).

---

[2] An author manually labeled the 30 training examples seen by models under random seed 1 (example nos. 550–580), among which we find 17 pairs of entailment, 5 or 8 pairs (depending on how strictly one judges their acceptability) of summarizations, and only one pair of paraphrase.

[3] We acknowledge that a lack of a statistically significant difference does not entail "no difference". While it is true that we find no statistically significant difference with the independent two-sample t-test and the Wilcoxon rank-sum test whenever we say "no practical difference", note that our argument, here and throught the paper, hinges on the very small effect sizes, not the significance tests, i.e., the two categories of prompts perform too similarly in absolute terms.

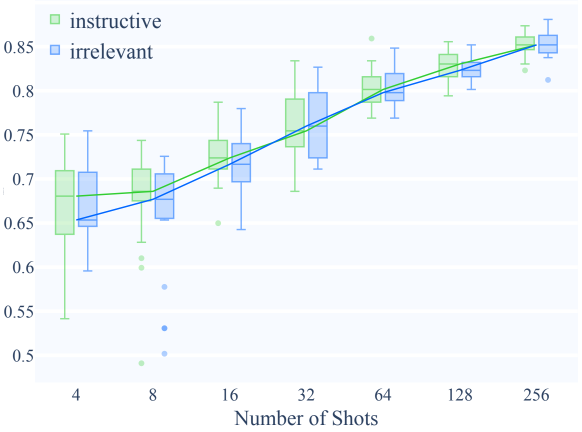

Figure 1: T0 (3B) on RTE. There is no practical difference between the performance of the models trained with instructive templates vs. those trained with irrelevant templates at any number of shots.

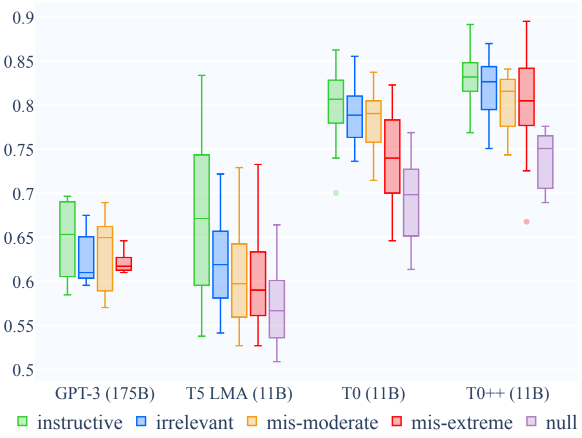

Figure 2: 16-shot accuracy of four large models on RTE. For GPT-3, there is no practical difference between any template categories except null (not plotted because they are below 0.5). For T5, there is no practical difference between instructive and irrelevant. For T0, there is no practical difference between instructive and irrelevant nor between instructive and misleading-moderate. For T0++, there is no practical difference between instructive and irrelevant nor between instructive and misleading-extreme.

Misleading Templates There is no consistent relation between the performance of models trained with templates that are moderately misleading (e.g. `{premise} Can that be paraphrased as "{hypothesis}"?`) vs. templates that are extremely misleading (e.g., `{premise} Is this a sports news? {hypothesis}`). T0 (both 3B and 11B) perform better given misleading-moderate (Figure 3), ALBERT and T5 3B perform better given misleading-extreme (Appendices E and G.4), whereas T5 11B and GPT-3 perform comparably on both sets (Figure 2; also see Table 2 for a summary of statistical significances.) Despite a lack of pattern between the two misleading categories, however, it is consistent that each model exhibits significantly better performance on instructive templates compared to at least one category of misleading templates.

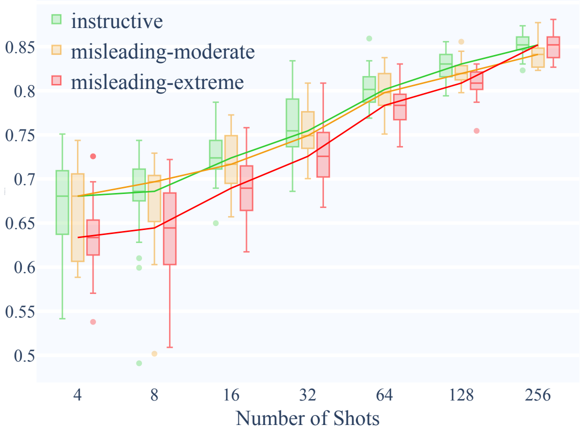

Figure 3: T0 (3B) on RTE. There is no practical difference between models trained with instructive and misleading-moderate templates at any number of shots. But models trained with misleading-extreme templates are statistically significantly worse from 8 to 128 shots.

Null Templates Models trained with null templates perform far worse than all other categories of templates (see Appendix G for all null results). Here, we focus on ALBERT (an encoder-only masked language model), which allows more permutation of concatenation orders by placing mask in the middle of sentences. We see that, although null templates are much worse in aggregate, some subset of them (e.g., `{premise} [mask] {hypothesis}`) are still able to learn nearly as fast as the average instructive template after 32 shots (Figure 13).

Zero-Shot So far, we have focused on few-shot results. At zero shots, all models (including GPT-3 175B) perform only marginally above random, except the instruction-tuned T0. Thus, for our analysis of zero shot performance, we focus on T0. Figure 4 shows that there is no practical difference between the performance of T0 3B given instructive templates and either category of misleading templates. T0 11B performs better, although it also shows no practical difference between misleading-moderate and instructive templates. Lastly, T0++ (trained on more datasets than other T0 variants), is the only model in this paper that shows statistically significantly different performance across all categories of prompts. However, there remains the caveat that it still performs arguably too well in absolute terms with pathological prompts, which we discuss in the next section.

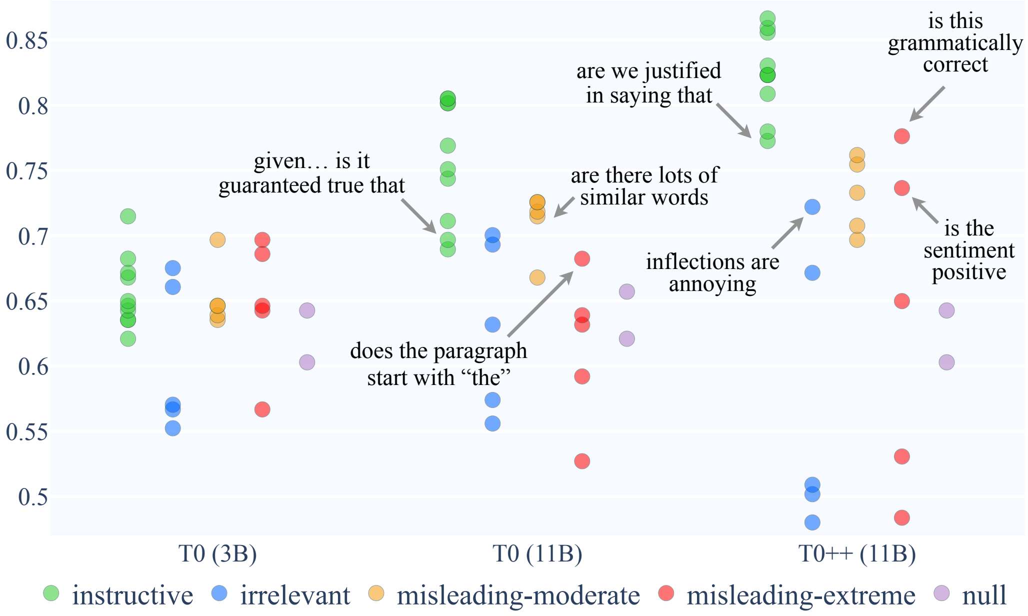

Figure 4: Zero-shot accuracy of instruction-tuned models on RTE. Each prompt's performance is a single point (unlike the few-shot figures where each prompt is approximated by multiple points with multiple samplings of few-shot examples.) Arrows highlight some prompts with their excerpts. See Appendix I for the full results.

Table 2: Checkmarks indicate where two categories of templates lead to statistically significantly different performance, as measured by an independent two-sample t-test and a Wilcoxon rank-sum test; both tests always agree in this table. A lack of checkmark indicates where model performance fails to differentiate the two categories, i.e., models do not understand the differences between the prompt categories. We consider significant differences (checkmarks) between categories of prompts to be necessary—but not sufficient—for language understanding.

4.3 Discussion

Recall that a common assumption in the literature is that prompts require experts to clearly and correctly describe the task at hand (§1). In contrast, Table 2 summarizes that, with the exception of T0++ at zero shots, all models perform essentially as well with some pathological prompts as they do with proper prompts. Notably, despite being much larger than its competitors, GPT-3 shows the same patterns of behaviors, suggesting that mere scaling does not address this issue. Meanwhile, the evidence from instruction tuning is mixed. Although Sanh et al. (2021) are right that instruction tuning yields substantial improvement in performance as well as robustness as measured by variance, T0 is somewhat too robust and less sensitive to the semantics of the prompts in terms of distinguishing proper instructions from pathological ones, compared to T5 of the same size in the few-shot setting (Figure 2).

In the zero-shot setting, we do see that that the largest model instruction-tuned with the most datasets (T0++) improves a model's sensitivity to prompt semantics. This is a positive result, but it comes with the caveat that there still exist numerous examples of pathological prompts that perform just as well as the proper ones do. To be charitable to randomness in neural models, we hold

Figure 5: The best-performing instructive template for ALBERT on RTE, `{prem} Are we justified in saying that "{hypo}"?` with select LM targets from each category.

this study to a higher standard by comparing means and medians among categories with statistical tests. Nevertheless, for our research question, existence proofs alone are still alarming. For example, without any gradient update nor priming, it is striking that out-of-the-box T0++ scores a high accuracy of 78% with the extremely misleading `{premise} Is that grammatically correct? {hypothesis}`, the same accuracy as it achieves with a proper instruction `{premise} Are we justified in saying "{hypothesis}"?` If models were truly classifying whether the text is grammatical, it would have only scored 52.7% because RTE is written by experts and all examples are grammatical. Even templates that underperform the instructive ones seem to be too good. For example, it is difficult to imagine a human scoring 72% *zero-shot* with the prompt `{premise} Inflections are annoying and thank god that Middle English got rid of most of them. {hypothesis}` for a nuanced task like NLI.

5 Effect of Target Words

5.1 Method

In this experiment, we study the effect of different LM target words given a fixed template. We write 4 categories of targets, with at least 3 pairs of target words for each category (except the singleton yes-no category):

1. Yes-no: Model is expected to predict the word “yes” for entailment and “no” for non-entailment.

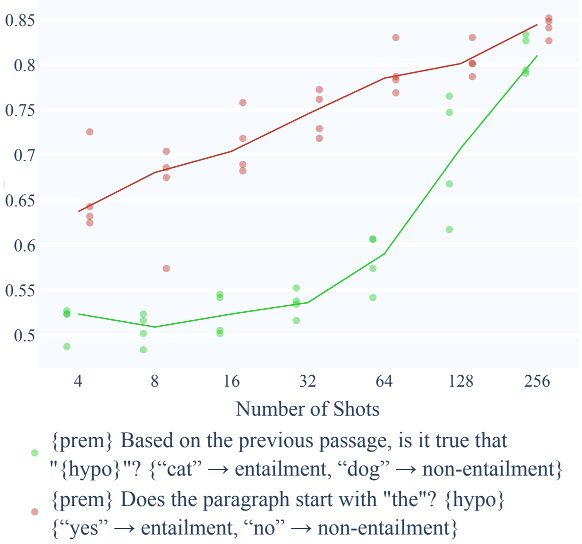

Figure 6: T0 (3B) on RTE. Misleading templates + yes-no targets (red) learn substantially faster than instructive templates + arbitrary targets (green), which is the opposite of what we expect from humans.

2. Yes-no-like: Semantically equivalent to yes-no but using superficially different words, e.g., “true”/“false”, “positive”/“negative”.
3. Arbitrary: Model is expected to predict arbitrary words that have no semantic relation to the entailment task, e.g., “cat” for entailment, “dog” for non-entailment.
4. Reversed: Model is expected to predict the opposite of the (intuitive) yes-no and yes-no-like labels, e.g., “no” for entailment, “yes” for non-entailment.

See Appendix F.3 for the full list. Within the arbitrary category, in addition to the common anglophone first names as Le Scao and Rush (2021) use, we also include word pairs with high semantic similarity, low similarity, and pairs which are highly frequent in the English language, but we find no consistent difference among these various subcategories of the arbitrary category.

5.2 Result

For both ALBERT and T0, we find that models trained with yes-no targets learn a good deal faster than those trained with yes-no-like targets and dramatically faster than those with arbitrary and reversed targets. For example, Figure 5 shows the top-performing instructive template trained with different target words. At 32 shots, the difference between the median accuracies of “yes”/“no” vs. “no”/“yes” is 22.2%, far larger than the effect size of varying categories of templates in Section 4. Aggregating over all combination of templates and targets, Figure 16 confirms that the choice of target words matter much more than the meaning of the templates.

5.3 Discussion

The fact that models consistently learn slower with arbitrary and reversed target words is a positive result: this type of performance differential is consistent with what we expect for models that are correctly sensitive to the semantics of the words. However, there are several important negative results in these experiments as well. First, the effect of the target words overrides the semantics of the overall prompt. Consider two kinds of template-target combinations:

1. An irrelevant or misleading template + yes-no targets, e.g., `{premise} Does the paragraph start with "the"? [yes/no] {hypothesis}`
2. An instructive template + arbitrary targets, e.g., `{premise} Based on the previous passage, is it true that "{hypothesis}"? [cat/dog]`

Figure 6 shows that combinations such as (1) often dramatically outperform (2). However, (2) simply requires figuring out a mapping: "Reply 'cat' if entailed and reply 'dog' if not entailed". For humans, this can be learned in a few shots, e.g., Ferrigno et al. (2017) showed that adults can reach 60% accuracy in 18 trials[4] for an arbitrary map of {more numerous → star shape, less numerous → diamond shape} without receiving any language instructions. In contrast, models under many arbitrary LM targets struggle to reach 60% median accuracy even by 64 shots with instructive templates (Figure 6 green; Figure 5 red, purple).

Further, even given intuitive yes-no-like targets such as "agree"/"disagree" and "good"/"bad", models learn much slower compared to when given "yes"/"no". As Figure 5 (green vs. dark green) and Figure 16 (first vs. second x-axis group) show, there exists a large performance gap between yes-no and yes-no-like targets which is not closed until 256 shots. Moreover, when we try to help the models by appending target hints such as "True or false?" to the templates, performance often drops instead, echoing Sanh et al. (2021) and Wei et al. (2021)'s findings that including answer choices in input sequence make models perform worse for certain tasks.

6 General Discussion

6.1 Summary and Interpretation

Our main research question is whether models understand prompts as meaningful task instructions analogous to how humans would. Again, suppose an experimenter provides a human annotator with an informative instruction of a reasonably easy task. If the annotator understands the instruction, we expect them to perform better than when the experimenter provides misleading instructions, irrelevant instructions, or no instructions at all. Section 4 shows that the performance of most models is insensitive to the difference between instructive and irrelevant templates, moderately sensitive between instructive and misleading templates, and highly sensitive between instructive and null templates. Comparing to the effect of the templates, however, Section 5 shows that models are much more sensitive to the semantics of the target words: they learn far slower with arbitrary or reversed target words as desired. However, they are overly sensitive to semantically equivalent yes-no-like words (i.e., performing much worse with "agree"/"disagree" than with "yes"/"no"), and the choice of target words override the semantics of the templates (e.g., performing much better given a irrelevant template with "yes"/"no" targets than with an instructive template with arbitrary targets such as "cat"/"dog").

Our main argument throughout the paper shares the same logic as a recent line of studies (Sinha et al., 2021; O'Connor and Andreas, 2021; Pham et al., 2021; Gupta et al., 2021) which argue that the fact that LMs achieve good performance under ideal conditions is insufficient to establish language understanding because they also succeed under pathological conditions (e.g., sentences with shuffled word order) where humans fail catastrophically.[5] In other words, the fact that models are so good at inferring the gold labels from pathologi-

---

[4] And this comparison is heavily charitable to the models because "18 trials" means that humans see 18 examples for 18 times in total, whereas "20-shot" means that models can see the same 20 examples over and over again for many epochs.

[5] See Ravishankar et al. (2022), Papadimitriou et al. (2022), and Kulmizev and Nivre (2021) for a nuanced ongoing debate on the extent models know vs. use syntactic coding properties on what kinds of examples. But even considering these new evidences, we think Sinha et al. (2021) are at least correct that, as they find that human experts perform far worse on shuffled NLI inferences than RoBERTa does, models must be processing linguistic inferences quite differently from how humans do, regardless of whether models know word order information.

cal inputs casts major doubts on whether models make inferences in any way that resembles how humans make inferences. For our results, the fact that models are so good at learning from pathological instructions likewise casts major doubts on whether models understand prompts as instructions in any way that resembles how humans understand instructions.

6.2 Alternative Interpretations and Future Directions

As with any extrinsic evaluation, accuracy cannot directly measure understanding. For example, a human could perfectly understand an instruction but still, e.g., have the same accuracy with instructive vs. irrelevant templates because the task itself is too hard (a lack of competence) or because they for some reason ignore the instructions (a lack of compliance). We discuss these two possibilities below.

Lack of Competence This is primarily a concern for non-instruction-tuned models at zero shots, where all models perform only slightly above random, and thus a lack of statistical significance among template categories is ambiguous as to whether models lack understanding of NLI instructions vs. if models lack the competence in NLI per se. This is why our study largely focuses on the few-shot setting, where a lack of competence is less of a concern, as models do competently achieve good accuracies that are only moderately below the state-of-the-art non-few-shot models.

Another counterargument is that maybe no models ever actually reason about if a premise entails a hypothesis. Maybe they just always exploit spurious or heuristic features and, if only they were competent in properly reasoning about entailment relations, then the meaning of NLI instructions would matter. This argument is possible, although, first, it hinges on to what extent NLI (or any other behavioral evaluation) can measure language understanding, which is a complex debate beyond the scope of this paper. Second, in preliminary experiments (Appendix K), our models actually zero-shot transfer reasonably well to HANS (McCoy et al., 2019), a dataset designed to diagnoses models use of NLI heuristics. Thus, it is unlikely that models are entirely incompetent in reasoning about entailment relations and solely rely on heuristics. Regardless, further differentiating competence in understanding task instructions vs. competence in tasks per se is an important direction for future work.

Lack of Compliance Another interpretation is that irrelevant prompts perform the same as the instructive ones because models simply ignore the prompts altogether. However, a lack of compliance alone cannot explain our results. If models truly ignore the prompts, we should not see any systematic differences between any categories of prompts. Instead, we do see consistent patterns that instructive and irrelevant templates make models learn significantly faster than misleading and null templates do (Table 2).

A more nuanced counterargument is that although models do not ignore their prompts entirely, perhaps it "takes less effort" for models to use the spurious or heuristic features for predictions as opposed to the more complex syntactic or semantic features (Lovering et al., 2021; Warstadt et al., 2020) required to properly comply with the instructions. However, spurious features alone likewise cannot explain the observed performance gaps. Recall that, within each random seed, all models see exactly the same training examples (with the same spurious features). Thus, to the extent that models perform differently with some prompts compared to others, it may be due to some complex interactions between the (spurious or semantic) features in prompts and the spurious features in data examples. One possible example of this interaction is that punctuation has a large effect for irrelevant templates, but instructive templates seem to be able to suppress such effect (Appendix A). Investigating the nature of this interaction is a promising direction for future work, and it suggests a way in which the semantics of the prompt might matter, e.g., by affecting the models' inductive biases, even if models do not interpret or use the instructions in the same way as humans would.

7 Conclusion

In this study, we train several models with over 30 manually written templates and 13 sets of LM targets for NLI. We find that models often learn equally fast with misleading and irrelevant templates as they do with instructive ones, and that the choice of the target words overrides the meaning of the overall prompts. Although models do not entirely ignore the meaning of the prompts, our results contradict a hypothesis commonly assumed in the literature that models use prompts as semantically meaningful task instructions in ways analogous to humans' use of instructions.

Ethical Considerations

The fact that even the largest LMs *appear* to follow yet do not actually follow users' instructions has important implications, especially considering the increasing commercial use of LMs. While traditional fine-tuned models also pose challenges in interpretability, with prompt-based models, an illusion of instruction following can be more pernicious than having no instructions at all. The intuitive interface that prompts provide might make them more accessible to lay users, and can mislead users to think that their instructions *are* being understood and followed. Our results suggest that cautions are needed even more than they were with traditional fine-tuned models.

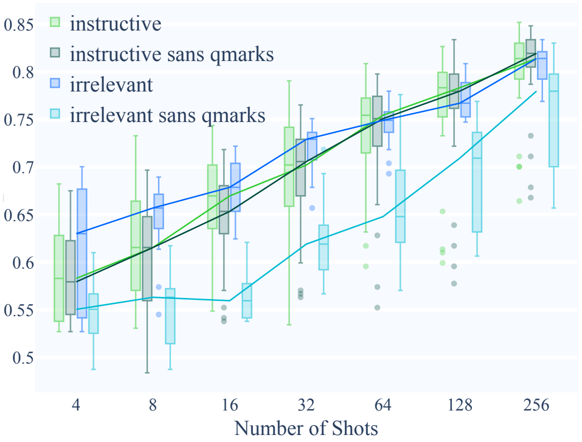

Figure 7: ALBERT on RTE. Note that (1) irrelevant templates slightly outperform the instructive templates, albeit without statistical significance. (2) Irrelevant templates are far worse without quotation and question marks. (3) But there is no significant difference between instructive templates with or without qmarks.

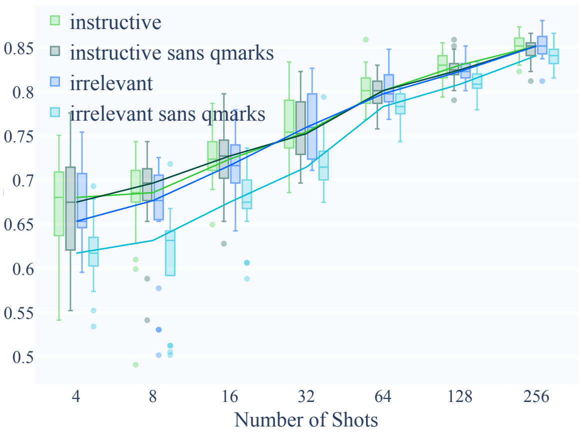

Figure 8: T0 (3B) on RTE. Like ALBERT, irrelevant sans qmarks are significantly worse than irrelevant at each and every shot, but there is no significant difference between instructive with or without qmarks.

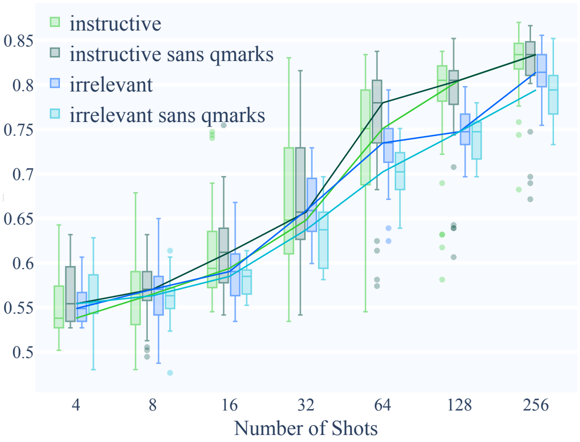

Figure 9: T5 LM-Adapted (3B). Unlike the other models, there is no statistical significance between irrelevant with or without qmarks. However, instructive sans qmarks statistically significantly outperform instructive at 32 and 64 shots.

A Effect of Punctuation

For irrelevant templates, we find a large effect from the use of quotation and question marks in templates. It is natural to write such punctuation in instructive templates as they help humans to parse an NLI hypothesis as an embedded clause within an instruction sentence (e.g., `Given {premise} Should we assume that "{hypothesis}" is true?`). For control, we also use quotation and question marks ("qmarks" hereafter) in irrelevant templates where they would not have made sense naturally, e.g., `{premise} Single-family zoning is bad for American cities. "{hypothesis}"?` As an ablation, when we remove these qmarks from irrelevant templates, the performance of ALBERT and T0 drops substantially (Figures 7 and 8). In contrast, for T5, qmarks make no difference for irrelevant templates; yet, removing qmarks from instructive templates—where qmarks are natural—boosted performance instead for T5 (Figure 9), but not for T0 nor ALBERT.

Additionally, as a coincidence, most misleading templates contain both quotation and question marks, while most misleading-far templates contain only question marks (Appendix F). But as noted in Section 4.2, there is no consistent pattern between those two misleading categories. In other words, punctuations alone cannot explain everything. As discussed in Section 6.2, the full explanation is likely a combined interactions between the spurious features and the semantics of the templates.

Lastly, note that Schick and Schütze (2021b) and many subsequent papers' prompts for NLI (e.g., `"{hypothesis}" ? | [mask]. "{premise}"`) are basically null templates with some variation in punctuation between the hypothesis and the premise. We find that models learn poorly with the vanilla `{hypothesis} [mask] {premise}`, but they learn as fast as the instructive templates with Schick & Schütze's punctuated version. That being said, note again that punctuation alone cannot explain the performance gap, since models trained with `[mask] {hypothesis} {premise}` (Figure 13, pink) perform second to best, yet swapping their premises and hypotheses (Figure 13, purple) makes it the worst performing among all null templates.

B Details and Lessons from Experimenting with GPT-3's API

B.1 Choice of Model

We use the `davinci` model provided by OpenAI LP's API, which corresponds to[6] the 175 billion parameter model reported in Brown et al. (2020). Concurrent to our work, OpenAI released a new product called the "Instruct Series", but we decided to not experiment with the Instruct Series because no academic paper or technical documentation of any kind is available with the Instruct Series at the time of writing aside from the following claim on their website:[7]

> The Instruct models share our base GPT-3 models' ability to understand and generate natural language, but they're better at understanding and following your instructions. You simply tell the model what you want it to do, and it will do its best to fulfill your instructions. This is an important step forward in our goal of building safe models that are aligned with human interests.

Crucially, the Instruct Series is inappropriate for reproducible research because it is unknown what datasets and prompts these models are trained on, and whether any task categories are systematically held out as done by Sanh et al. (2021) and Wei et al. (2021). If it is trained on any prompt or dataset of NLI, it would not be zero-shot, making it an unfair comparison to other models in our experiments. Second, it is still in beta and its training, held-out, and prompt mixtures could change. At least two Instruct Series models were made available in sequence during our writing, and it is not clear if we experiment on an older version, whether it will still be available and reproducible in the future.

B.2 Priming vs. Fine-Tuning

As mentioned in Section 3, we use priming (a.k.a. in-context learning) in lieu of fine-tuning because, at the time of writing, OpenAI's fine-tuning API is limited to 10 runs per month. To train 30 prompts at only two number of shots would take 6 months, assuming we get hyperparameters right at first try. Further, each training run is limited to a maximum of 5 epochs, which often entails an insufficient number steps for few-shot training. We were unable to fine-tune GPT to any reasonable accuracy with our allowed 10 tries in the first month. Finally, the fine-tuning API is limited to GPT variants up to 6.7B, not the 175B model we plan to experiment with.

With priming, we are able to reproduce Brown et al. (2020)'s zero-shot performance on RTE but only with their exact prompt reported in their Figure G.31, all other (even instructive) prompts perform at random at zero shots, suggesting that their reported prompt is highly cherry-picked. We are unable to reproduce their reported few-shot result because they report it at 32 shots, but their API only permits a context length up to 2049 tokens, which is insufficient for RTE. We find that 16 shots are the highest one can reach within the token limit.[8]

Like the gradient updated models, we document the exact examples we use for few-shot priming in our GitHub repository. Unlike the gradient updated models, which are trained on the same k examples, priming models use different sets of k priming examples for each inference example (Brown et al., 2020, p. 20). This means that GPT's performance reflects the fact that, overall, it has seen far more than k examples, making it not directly comparable to the few shots of the gradient updated models. This is not ideal, but our GPT few-shot performance already underperforms what Brown et al. (2020) report, so we choose to not further restrict it to have the same fixed priming examples for all inference examples, which could run into a lack of competence issue (§6.2) that make its results unusable for our research question.

Lastly, unlike the gradient updated models, we do not run multiple seeds with our GPT experiments because, first, they are expensive. As the API bills by token, using k shots of priming example effectively multiplies the total cost by k. Sec-

---

[6] OpenAI never actually discloses which one of their commercially named `ada, babbage, curie, davinci` "engines" correspond to models of which size. However, Gao et al. (2021a) estimate that they correspond to 350M, 1.3B, 6.7B, and 175B respectively.

[7] http://beta.openai.com/docs/engines/instruct-series-beta

[8] Depending on the length of the prompt template, 2 or 3 examples still exceed the token limit, in which case we remove one priming example, keeping the other 15 priming examples and the to-be-predicted example unmodified.

ond, OpenAI imposes a monthly quota for each lab, so running multiple seeds will take several more months to complete.

B.3 Other Tips for Working with GPT-3

Using the `logprobs` argument in their API, we obtain the top 99 predicted target word and their log probabilities.[9] Following Sanh et al. (2021) and Wei et al. (2021), we evaluate by a rank classification of the target words, i.e., if the gold target word is "yes", we consider it as correct as long as the probability of "yes" is higher than that of "no", regardless of whether "yes" is the top-1 prediction generated by the model.

Alarmingly, we find that these top-99 predictions are semantically inconsistent ranked, e.g., for one data example and its top-99 word predictions, it is often the case that, e.g., P(yes) > P(no) but P(Yes) < P(No). Thus, the choice of the target words' surface form makes a substantial difference in the overall performance. (Not to mention the problem of choosing between yes/no, true/false, correct/incorrect, etc. as studied in Section 5.) OpenAI recommends having no trailing space in the input and let the model predict the first token with a leading space as in "␣Yes". We find that although stripping the leading space sometimes leads to higher performance for some prompts, overall not applying stripping or other token normalization performs the best.

Another point researchers should pay attention to is the use of what OpenAI calls a "separator" inserted between priming examples. In preliminary experiments, we initially use newline characters as appeared in Brown et al. (2020)'s Appendix G. We later discover that OpenAI recommends using `###` or `\n###\n` as separators. We use the latter and find consistent performance improvement over just using newline characters, and we use it throughout in our main experiments.

C Hyperparameters

For encoder-only models, we follow Schick and Schütze (2021b) and Le Scao and Rush (2021)'s recommendations and use a learning rate of $1e^{-5}$. For T5 and T0 models, we follow Raffel et al. (2020) and Sanh et al. (2021)'s recommendations and use a learning rate of $1e^{-4}$. We run several preliminary experiments with learning rates $(3e^{-4}, 1e^{-4}, 5e^{-5}, 1e^{-5})$ deviating from their recommendations and they perform worse, although our search is not exhaustive due to the high cost of running multiple prompts with multiple random seeds.

Note that T5 and T0 are trained with the Adafactor optimizer (Shazeer and Stern, 2018) in Mesh TensorFlow. Our implementation is in PyTorch, and we find that fine-tuning T5 with PyTorch's implementation of Adafactor yields substantially worse results than the usual choice of the AdamW optimizer. We corresponded with Raffel et al. (2020), who advised us that it might be due to the fact that PyTorch does not have the same learning rate scheduler implementation as TensorFlow's Adafactor does. They recommended us to simply use AdamW, which is what we did. This is somewhat unfortunate because Adafactor is much more memory efficient, which would have drastically reduced the compute resources required and thus enable more comprehensive experiments of the 11B models, which are currently limited to 0 shots and 16 shots only.

Although most models seem to obtain the highest validation accuracy at very early epochs, we train all models to 30 epochs (20 epochs for 11B models) to be safe and select the checkpoint with the highest validation accuracy.

All models use a batch size of 4 with 4 gradient accumulation steps for an effective batch size of 16.

Note that because we use a rank classification of single-token target words, decoding sampling methods (e.g., beam search, top-k, top-p) are unnecessary.

We follow Raffel et al. (2020) and add EOS tokens for input sequences, which yields higher few-shot performance compared to not adding EOS as done by Sanh et al. (2021). However, we omit EOS in the zero-shot setting, which exactly reproduces the results reported by Sanh et al. (2021). See T0's GitHub repository readme[10] for more information.

D Compute Used

Each ALBERT 235M model is trained on a single Nvidia RTX3090. Their main experiments took approximately 192 GPU hours.

---

[9] Although sometimes the API returns less than the number of `logprobs` the user specifies, in which case we contacted OpenAI's customer support who provided us refund by store credit. At the time of publishing, OpenAI now restricts `logprobs` to a maximum of 5.

[10] https://github.com/bigscience-workshop/t-zero/tree/master/examples

Each T5 LMA 770M model is trained on a single A6000. Their main experiments took approximately 48 GPU hours.

The 3B models are each trained by partitioning their layers over four RTX3090s. T5 and T0's main experiments took approximately 2,304 GPU hours in total.

The 11B models are each trained on eight V100s (each with 32GB of memory). T5, T0, and T0++'s main experiments took approximately 1,728 GPU hours in total. (Due to their large GPU memory requirement, we were only able to complete one number of shots.)

E Additional Figures Discussed in the Main Text

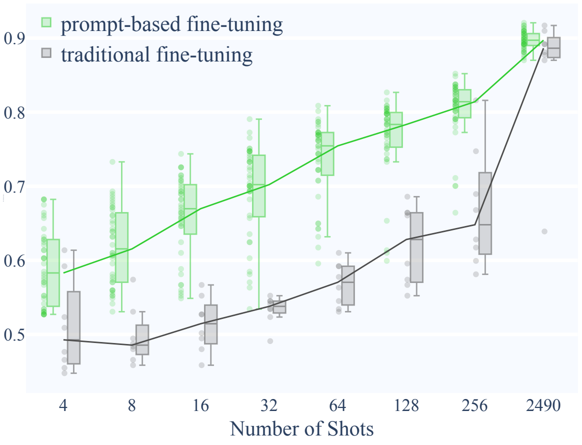

Figure 10: How to read these figures: Each dot is the performance of one prompt under one random seed (which controls the sets of few-shot examples) of our baseline model (ALBERT) on RTE validation set. Boxes span from the first quartile to the third quartile, while lines inside boxes mark the medians. Later figures omit the points except outliers in order to improve legibility. See the interactive figures in our GitHub repository or Appendix H for the results of individual prompts.

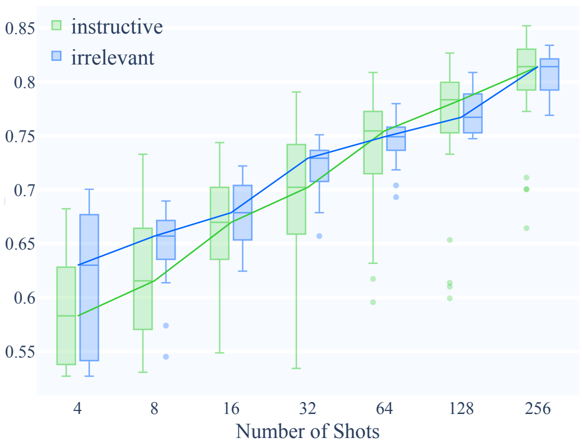

Figure 11: ALBERT on RTE. Models trained with irrelevant templates actually slightly outperform the instructive templates, albeit without statistical significance at any number of shots.

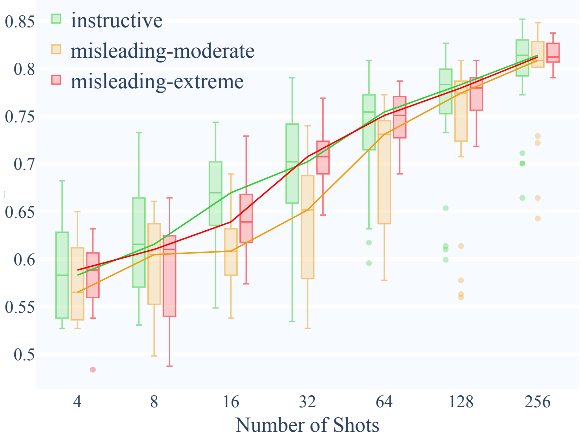

Figure 12: ALBERT on RTE. There is no statistical significance between misleading-extreme and instructive at any number of shots. In contrast, models trained with misleading-moderate templates are significantly worse than the instructive ones from 16 to 64 shots.

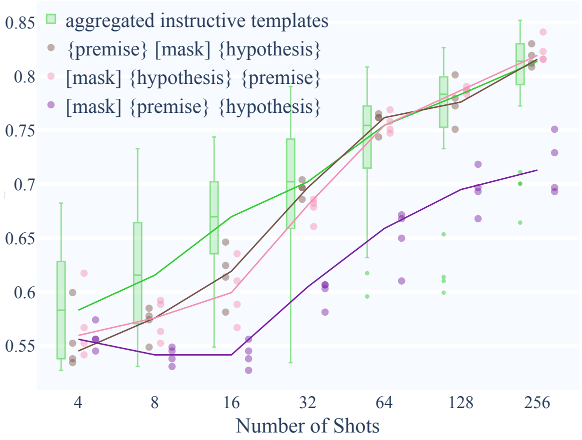

Figure 13: ALBERT on RTE. After 32 shots, models trained with 2 null templates learn just as fast as the instructive templates, but models trained with other null templates (e.g., purple) are much worse.

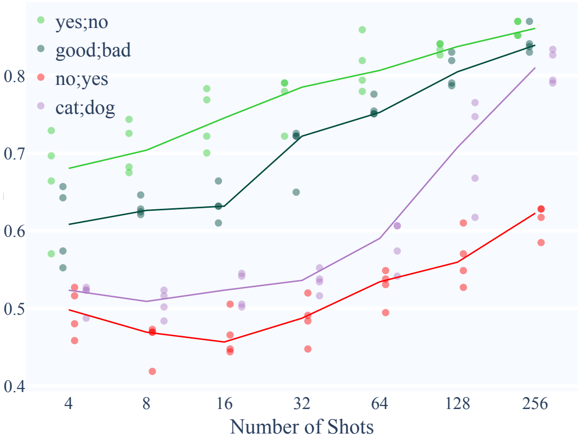

Figure 14: The best-performing instructive template for T0 (3B) on RTE, `{prem} Based on the previous passage, is it true that "{hypo}"?` with select LM targets from each category.

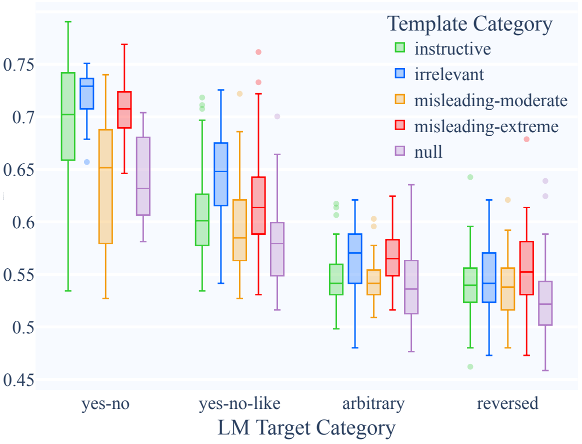

Figure 15: Median accuracies of all template-target combinations at 32 shots. In general, the choice of target words (x-axis groups) matters much more than the choice of templates (colors).

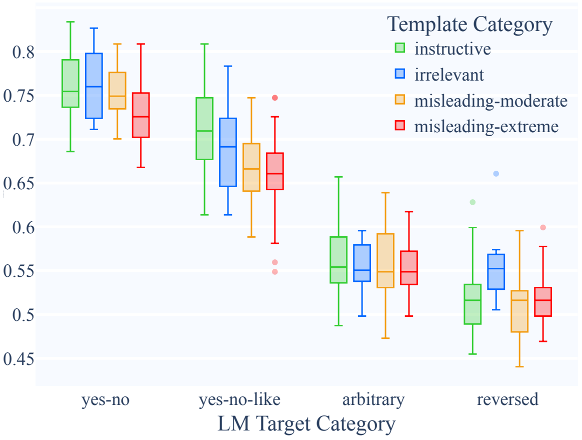

Figure 16: T0 (3B)'s 32-shot accuracy with of all template-target combinations on RTE. In general, the choice of target words (x-axis groups) matters much more than the choice of templates (colors).

F All Prompts

F.1 Main Experiment Templates

category	template	adapted from
instructive	{premise} Using only the above description and what you know about the world, "{hypothesis}" is definitely correct. Yes or no?	Williams et al. (2018, p. 3)
instructive	{premise} \nquestion: {hypothesis}Yes or no?\nanswer:	Brown et al. (2020, p. 59)
instructive	{premise} Are we justified in saying that "{hypothesis}"?	
instructive	Given {premise} Should we assume that "{hypothesis}" is true?	
instructive	{premise} Based on the previous passage, is it true that "{hypothesis}"?	
instructive	Given {premise} Is it guaranteed true that "{hypothesis}"?	
instructive	Suppose {premise} Can we infer that "{hypothesis}"?	
instructive	Given that {premise} Does it follow that "{hypothesis}"?	
instructive	{premise} Question: Does this imply that "{hypothesis}"?	
instructive	Given that {premise} Therefore, it must be true that "{hypothesis}"?	
misleading-moderate	{premise} Do most of the above words appear in the following passage? {hypothesis}	
misleading-moderate	{premise} Are there lots of similar words in "{hypothesis}"?	
misleading-moderate	{premise} Does that have the same meaning as "{hypothesis}"?	
misleading-moderate	{premise} Can that be paraphrased as: "{hypothesis}"?	
misleading-moderate	{premise} Can that be summarized as "{hypothesis}"?	
misleading-extreme	{premise} Does the paragraph start with "the"? {hypothesis}	
misleading-extreme	{premise} Is this grammatically correct? {hypothesis}	
misleading-extreme	{premise} Is the sentiment positive? {hypothesis}	
misleading-extreme	{premise} Is this a sports news? {hypothesis}	
misleading-extreme	{premise} Is this French? {hypothesis}	
irrelevant	{premise} Single-family zoning is bad for American cities. "{hypothesis}"?	
irrelevant	{premise} Inflections are annoying and thank god that Middle English got rid of most of them. "{hypothesis}"?	
irrelevant	{premise} When Bolyai sent Gauss his discovery of non-Euclidean geometry, Gauss replied that he arrived at the same results 30 years ago. "{hypothesis}"?	Greenberg (1974, p. 141)
irrelevant	{premise} If bonito flakes boil more than a few seconds, the stock becomes too strong? "{hypothesis}"?	Tsuji and Sutherland (1980, p. 148)
irrelevant	{premise} Is the pious loved by the gods because it is pious? Or is it pious because it is loved by the gods? "{hypothesis}"?	Plato (c. 399 BC, 10a)
null	{premise} {hypothesis}	
null	{hypothesis}{premise}	
null (MLM only)	{premise} {mask} {hypothesis}	
null (MLM only)	{hypothesis}{mask} {premise}	
null (MLM only)	{mask} {premise} {hypothesis}	
null (MLM only)	{mask} {hypothesis}{premise}	

Table 3: All prompts used in the main text of the paper. All templates use "yes"/"no" as target words for the entailment and non-entailment classes, respectively. For ternary NLI datasets, we use "unclear" for the neutral class, which performs best after preliminary experiments with other ternary words: "maybe", "sometimes", "perhaps", "possibly", and "neither". Keen readers may notice that some of the instructive templates (e.g., `should we assume`) do not instruct a strict entailment task. We intentionally wrote a mixture of instructions that asks for strictly logical entailment and pragmatic inference, intending to measure if models can distinguish between the two on datasets such as HANS (McCoy et al., 2019) that magnify different predictions caused by pragmatic effects. Of course, this research question became moot as we found that models cannot even distinguish among much more pathological prompts.

F.2 Ablation Experiment Templates

category	template
instructive sans qmarks	{premise} Using only the above description and what you know about the world, {hypothesis}is definitely correct. Yes or no
instructive sans qmarks	{premise} \nquestion: {hypothesis}Yes or no\nanswer:
instructive sans qmarks	{premise} Are we justified in saying that {hypothesis}
instructive sans qmarks	Given {premise} Should we assume that {hypothesis}is true
instructive sans qmarks	{premise} Based on the previous passage, is it true that {hypothesis}
instructive sans qmarks	Given {premise} Is it guaranteed true that {hypothesis}
instructive sans qmarks	Suppose {premise} Can we infer that {hypothesis}
instructive sans qmarks	Given that {premise} Does it follow that {hypothesis}
instructive sans qmarks	{premise} Question: Does this imply that {hypothesis}
instructive sans qmarks	Given that {premise} Therefore, it must be true that {hypothesis}
irrelevant sans qmarks	{premise} Single-family zoning is bad for American cities. {hypothesis}
irrelevant sans qmarks	{premise} Inflections are annoying and thank god that Middle English got rid of most of them. {hypothesis}
irrelevant sans qmarks	{premise} When Bolyai sent Gauss his discovery of non-Euclidean geometry, Gauss replied that he arrived at the same results 30 years ago. {hypothesis}
irrelevant sans qmarks	{premise} If bonito flakes boil more than a few seconds, the stock becomes too strong. {hypothesis}
irrelevant sans qmarks	{premise} Is the pious loved by the gods because it is pious. Or is it pious because it is loved by the gods. {hypothesis}

Table 4: Used in the study of the effect of question and quotation marks in Appendix A.

F.3 All Target Words

Category	Target Words
yes-no	yes;no
yes-no-like	true;false
yes-no-like	positive;negative
yes-no-like	right;wrong
yes-no-like	correct;incorrect
yes-no-like	agree;disagree
yes-no-like	good;bad
reversed	no;yes
reversed	false;true
reversed	negative;positive
arbitrary	B;C
arbitrary	cat;dog
arbitrary	she;he

Table 5: LM targets used in Section 5. Again, for ternary NLI datasets, we use “unclear” for the neutral class, which performs best after preliminary experiments with other ternary words: “maybe”, “sometimes”, “perhaps”, “possibly”, and “neither”. Within the arbitrary category, in addition to the common anglophone first names as Le Scao and Rush (2021) use, we also tried word pairs with high semantic similarity (“cat”/“dog”), low similarity (“cake”/“piano”, “write”/“sleep”), and pairs which are highly frequent in the English language (“she”/“he”, “the”/“a”) in preliminary experiments, but we find no consistent difference among these various subcategories of the arbitrary category.

J Comparison of LM targets, Controlling for the Template

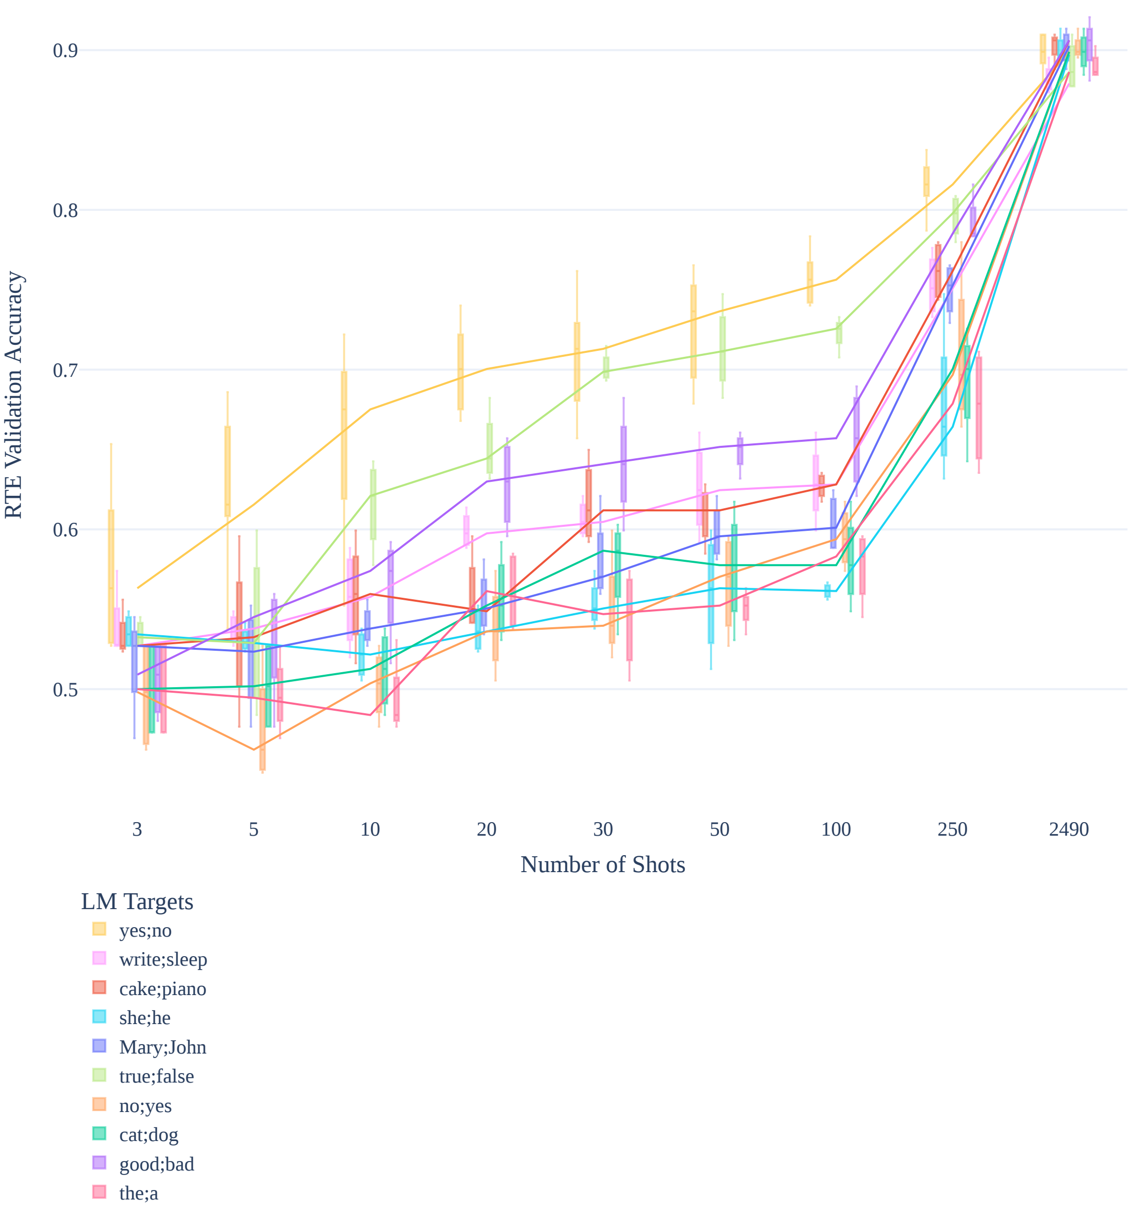

Figure 29: The best performing irrelevant prompt for ALBERT, `{premise} Single-family zoning is bad for American cities. "{hypothesis}"? [mask]` with all LM targets.

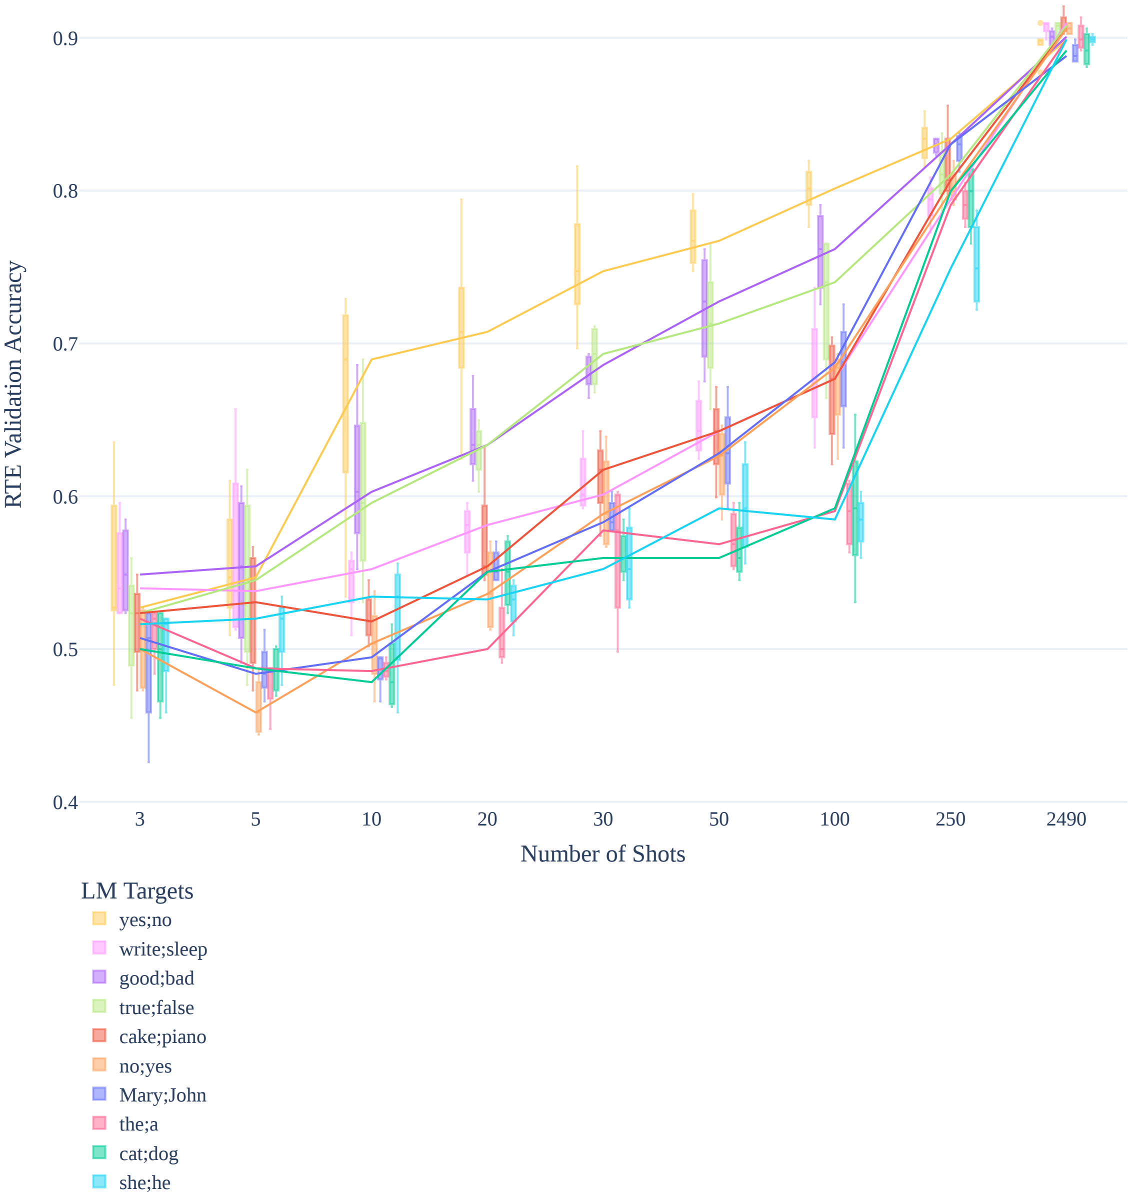

Figure 30: The best-performing misleading prompt for ALBERT, `{premise} Does the paragraph start with "the"? [mask] "{hypothesis}"` with all LM targets.

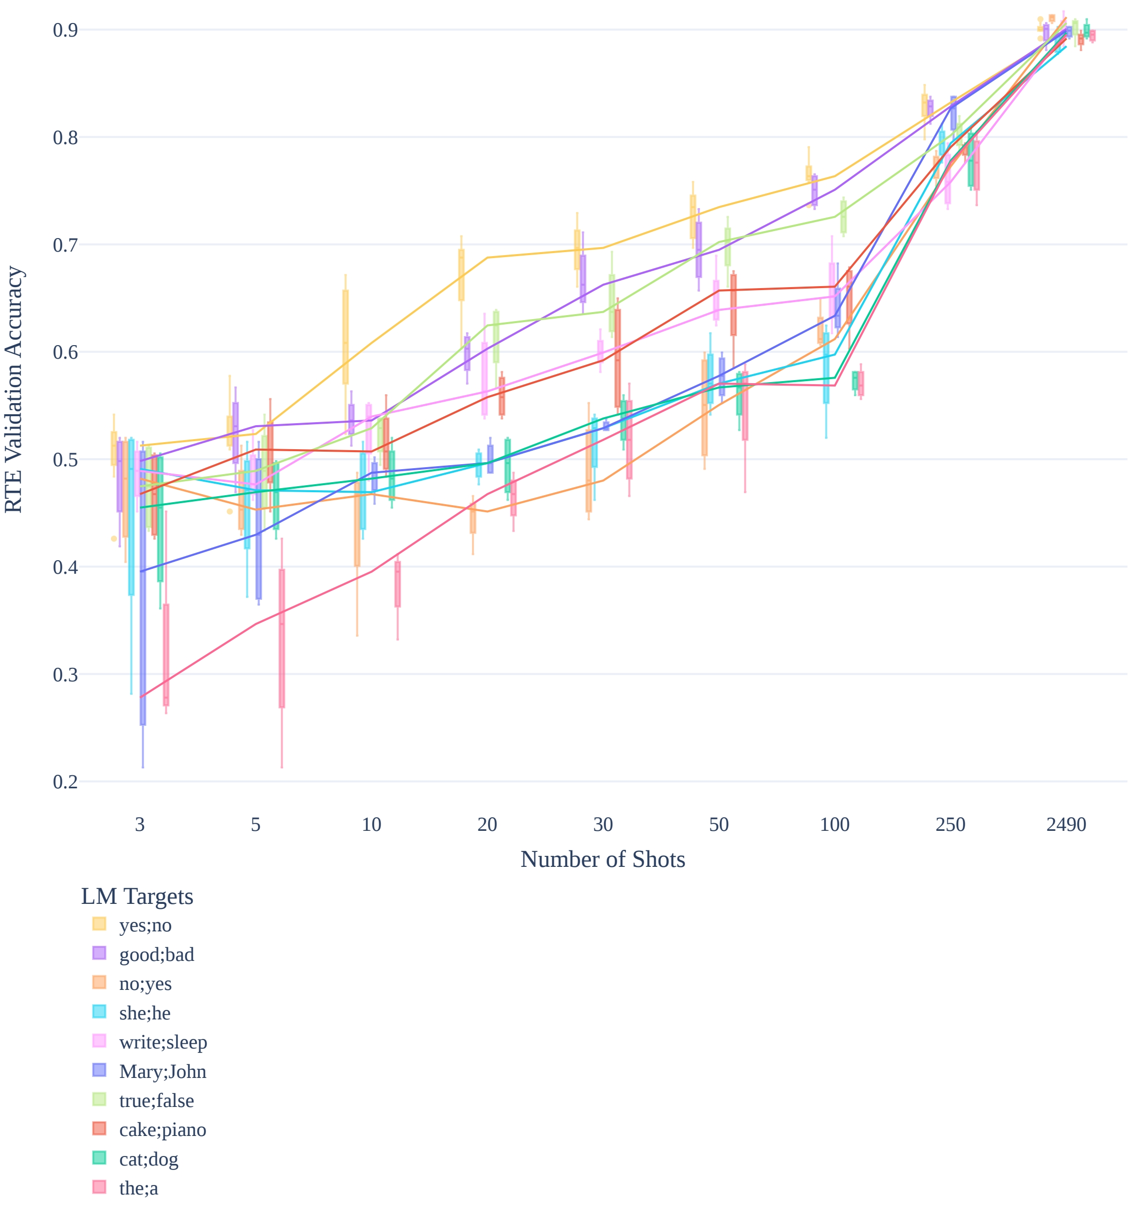

Figure 31: The best-performing null prompt for ALBERT, `{premise} [mask] "{hypothesis}"` with all LM targets.

K Preliminary Results on HANS

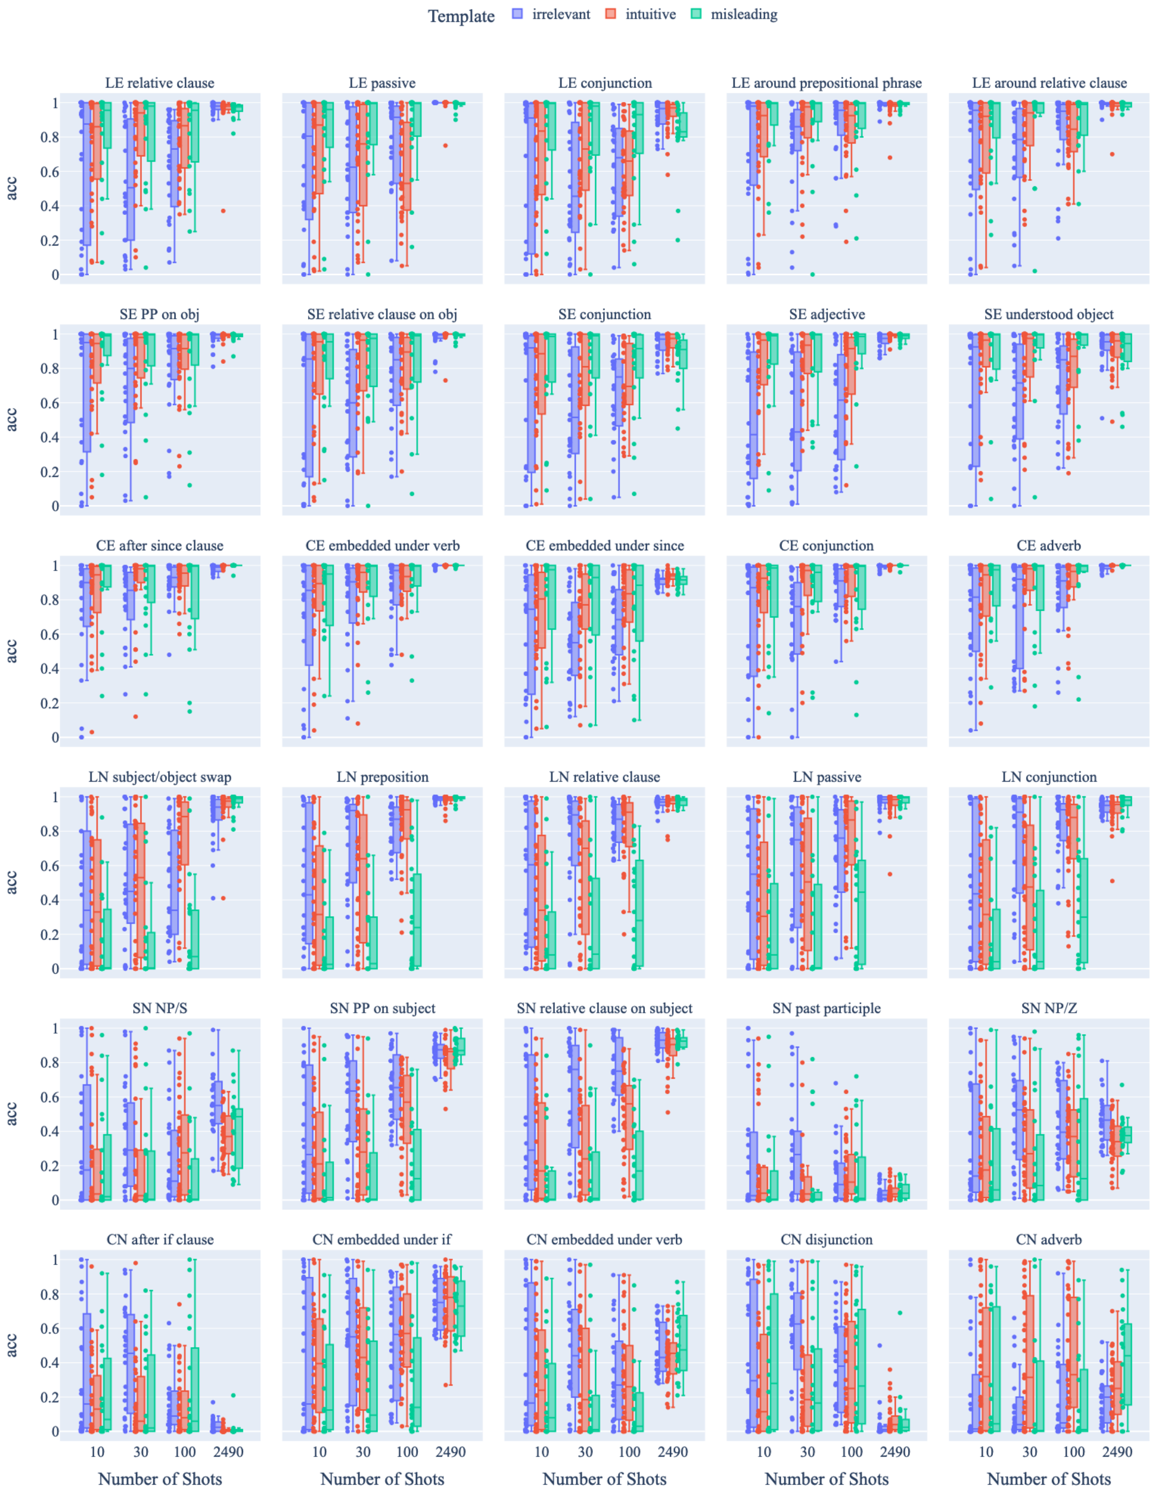

Figure 32: Few-shot RTE-trained ALBERT's zero-shot performance on HANS (McCoy et al., 2019). L = lexical, S = subsequence, C = constituency. E = true label is entailment. N = true label is non-entailment. Apologies but note the template category colors are different from those in the main text. "Intuitive" = instructive templates. In general, models perform similarly with instructive and irrelevant templates, but models with misleading templates fare worse, especially for lexical non-entailment cases (LN, fourth row). A full analysis will be furnished in a future version of this paper.

L Preliminary Results on Winograd

category	template	accuracy
instructive	Is “{pronoun}" the same as {referent}? Yes or No?	0.6538
instructive	Does “{pronoun}" refer to {referent}? Yes or No?	0.6731
instructive	Is “{pronoun}" {referent}? Yes or No?	0.5385
instructive	Should “{pronoun}" be {referent}? Yes or No?	0.5962
instructive	Does “{pronoun}" mean {referent}? Yes or No?	0.6442
instructive	Is“{pronoun}" equivalent to {referent}? Yes or No?	0.6058
instructive	Does “{pronoun}" stand for {referent}? Yes or No?	0.6346
instructive	Can the pronoun “{pronoun}" be replaced with {referent}? Yes or No?	0.6250
misleading-extreme	Did “{pronoun}" eat cakes with {referent}? Yes or No?	0.6346
misleading-extreme	Is “{pronoun}" mother of {referent}? Yes or No?	0.6346

Abstract

Dense retrieval approaches can overcome the lexical gap and lead to significantly improved search results. However, they require large amounts of training data which is not available for most domains. As shown in previous work (Thakur et al., 2021b), the performance of dense retrievers severely degrades under a domain shift. This limits the usage of dense retrieval approaches to only a few domains with large training datasets.

In this paper, we propose the novel unsupervised domain adaptation method *Generative Pseudo Labeling* (GPL), which combines a query generator with pseudo labeling from a cross-encoder. On six representative domain-specialized datasets, we find the proposed GPL can outperform an out-of-the-box state-of-the-art dense retrieval approach by up to 9.3 points nDCG@10. GPL requires less (unlabeled) data from the target domain and is more robust in its training than previous methods.

We further investigate the role of six recent pre-training methods in the scenario of domain adaptation for retrieval tasks, where only three could yield improved results. The best approach, TSDAE (Wang et al., 2021) can be combined with GPL, yielding another average improvement of 1.4 points nDCG@10 across the six tasks. The code and the models are available [1].

1 Introduction

Information Retrieval (IR) is a central component of many natural language applications. Traditionally, lexical methods (Robertson et al., 1994) have been used to search through text content. However, these methods suffer from the lexical gap (Berger et al., 2000) and are not able to recognize synonyms and distinguish between ambiguous words.

Recently, information retrieval methods based on dense vector spaces have become popular to address these challenges. These dense retrieval methods map queries and passages[2] to a shared, dense vector space and retrieve relevant hits by nearest-neighbor search. Significant improvement over traditional approaches has been shown for various tasks (Karpukhin et al., 2020; Xiong et al., 2021). This method is also adapted increasingly by industry to enhance the search functionalities of various applications (Choi et al., 2020; Huang et al., 2020).

However, as shown in Thakur et al. (2021b), dense retrieval methods require a large amount of training data to work well.[3] Most importantly, dense retrieval methods are extremely sensitive to domain shifts: Models trained on MS MARCO perform rather poorly for questions for COVID-19 scientific literature (Wang et al., 2020; Voorhees et al., 2021). The MS MARCO dataset was created before COVID-19, hence, it does not include any COVID-19 related topics and models did not learn how to represent this topic well in a vector space.

In this work, we present *Generative Pseudo Labeling* (GPL), an unsupervised domain adaptation technique for dense retrieval models (see Figure 1). For a collection of paragraphs from the desired domain, we use an existing pre-trained T5 encoder-decoder to generate synthetic queries. These input passages are viewed as the positive passages for the generated queries. For each generated query, we retrieve the most similar paragraphs as the negative passages using an existing dense retrieval model. We term this step *negative mining* and term these negative passages *hard negatives*. Finally, we use an existing cross-encoder to score each (query, passage)-pair and train a dense retrieval

[1] `https://github.com/UKPLab/gpl`

[2] We use passage to refer to text of any length.

[3] For reference, the popular MS MARCO dataset (Nguyen et al., 2016) has about 500k training instances; the Natural Questions dataset (Kwiatkowski et al., 2019) has more than 100k training instances.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2345 - 2360
July 10-15, 2022

model on these generated, pseudo-labeled queries using MarginMSE-Loss (Hofstätter et al., 2020).

We use publicly available models for query generation, negative mining, and the cross-encoder, which have been trained on the MS MARCO dataset (Nguyen et al., 2016), a large-scale dataset from Bing search logs combined with relevant passages from diverse web sources. We evaluate GPL on six representative domain-specific datasets from the BeIR benchmark (Thakur et al., 2021b). **GPL improves the performance by up to 9.3 points nDCG@10** compared to state-of-the-art model trained solely on MS MARCO. Compared to the previous state-of-the-art domain-adaptation method QGen (Ma et al., 2021; Thakur et al., 2021b), GPL improves the performance by up to 4.5 nDCG@10 points. Training with GPL is easy, fast, and data efficient.

We further analyze the role of six recent pre-training methods in the scenario of domain adaptation for retrieval tasks. The best approach is TSDAE (Wang et al., 2021), that outperforms the second best approach, Masked Language Modeling (Devlin et al., 2019) on average by 2.5 points nDCG@10. TSDAE can be combined with GPL, yielding another average improvement of 1.4 point nDCG@10.

2 Related Work

Pre-Training based Domain Adaptation. The most common domain adaptation technique for transformer models is domain-adaptive pre-training (Gururangan et al., 2020), which continues pre-training on in-domain data before fine-tuning with labeled data. However, for retrieval it is often difficult to get in-domain labeled data and models are applied in a zero-shot setting on a given corpus. Besides Masked Language Modeling (MLM) (Devlin et al., 2019), different pre-trained strategies specifically for dense retrieval methods have been proposed. Inverse Cloze Task (ICT) (Lee et al., 2019) generates query-passage pair by randomly selecting one sentence from the passage as the query and the other part as the paired passage. ConDensor (CD) (Gao and Callan, 2021) applies MLM on top of the CLS token embedding from the final layer and the other context embeddings from a previous layer to force the model to learn meaningful CLS representation. SimCSE (Gao et al., 2021a; Liu et al., 2021) passes the same input twice through the network with different dropout masks and minimizes the distance of the resulting embeddings, while Contrastive Tension (CT) (Carlsson et al., 2021) passes the input through two different models. TSDAE (Wang et al., 2021) uses a denoising auto-encoder architecture for representation learning: Words from the input text are removed and passed through an encoder to generate a fixed-sized embedding. A decoder must reconstruct the original text without noise. As we show in Appendix E, just using these unsupervised techniques is not sufficient and the resulting models perform poorly.

So far, ICT and CD have only been studied on in-domain performance, i.e. a large in-domain labeled dataset is available which is used for subsequent supervised fine-tuning. SimCSE, CT, and TSDAE have been only studied for unsupervised sentence embedding learning. As our results show in Appendix E, they do not work at all for purely unsupervised dense retrieval.

If these pre-training approaches can be used for unsupervised domain adaptation for dense retrieval was so far unclear. In this work, we transfer the setup from Wang et al. (2021) to dense retrieval and first pre-train on the target corpus, followed by supervised training on labeled data from MS MARCO (Nguyen et al., 2016)[4]. Performance is then measured on the target corpus.

Query Generation. Query generation has been used to improve retrieval performances. Doc2query (Nogueira et al., 2019a,b) expands passages with predicted queries, generated by a trained encoder-decoder model, and uses traditional BM25 lexical search. This performed well in the zero-shot retrieval benchmark BeIR (Thakur et al., 2021b). Ma et al. (2021) proposes QGen, that uses a query generator trained on general domain data to synthesize domain-targeted queries for the target corpus, on which a dense retriever is trained from scratch. As a concurrent work, Liang et al. (2020) also proposes the similar method. Following this idea, Thakur et al. (2021b) views QGen as a post-training method to adapt powerful MS MARCO retrievers to the target domains.

Despite the success of QGen, previous methods only consider the cross-entropy loss with in-batch negatives, which provides coarse-grained relevance and thus limits the performance. In this work, we show that extending this approach by using pseudo-labels from a cross-encoder together with hard neg-

---

[4] As shown in Wang et al. (2021), training in the reverse order, i.e. first on MS MARCO and then on the target corpus usually performs poorly.

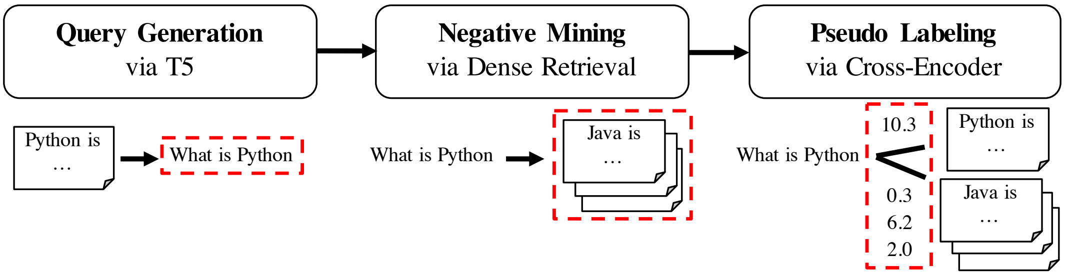

Figure 1: Generative Pseudo Labeling (GPL) for training domain-adapted dense retriever. First, synthetic queries are generated for each passage from the target corpus. Then, the generated queries are used for mining negative passages. Finally, the query-passage pairs are labeled by a cross-encoder and used to train the domain-adapted dense retriever. The output at each step is marked with dashed boxes.

atives can boost the performance by several points nDCG@10.

Other Methods. Recently, Xin et al. (2021) proposes MoDIR to use Domain Adversarial Training (DAT) (Ganin et al., 2016) for unsupervised domain adaptation of dense retrievers. MoDIR trains models by generating domain invariant representations to attack a domain classifier. However, as argued in Karouzos et al. (2021), DAT trains models by minimizing the distance between representations from different domains and such learning objective can result in bad embedding space and unstable performance. For sentiment classification, Karouzos et al. (2021) proposes UDALM based on multiple stages of training. UDALM first applies MLM training on the target domain; and it then applies multi-task learning on the target domain with MLM and on the source domain with a supervised objective. However, as shown in section 5, we find this method cannot yield improvement for retrieval tasks.

Pseudo Labeling and Cross-Encoders: Bi-Encoders map queries and passage independently to a shared vector space from which the query-passage similarity is computed. In contrast, cross-encoders (Humeau et al., 2020) work on the concatenation of the query and passage and predict a relevance score using cross-attention between query and passage. This can be used in a re-ranking setup (Nogueira and Cho, 2019), where the relevancy is predicted for all query-passage-pairs for a small candidate set. Previous work has shown that cross-encoders achieve much higher performances (Thakur et al., 2021a; Hofstätter et al., 2020; Ren et al., 2021) and are less prone to domain shifts (Thakur et al., 2021b). But cross-encoders come with an extremely high computational overhead, making them less suited for a production setting. Transferring knowledge from cross-encoder to bi-encoders have been shown previous for sentence embeddings (Thakur et al., 2021a) and for dense retrieval: Hofstätter et al. (2020) predict cross-encoder scores for (query, positive)-pairs and (query, negative)-pairs and learns a bi-encoder to predict the margin between the two scores. This has been shown highly effective for in-domain dense retrieval.

3 Method

This section describes our proposed *Generative Pseudo Labeling* (GPL) method for the unsupervised domain adaptation of dense retrievers. Figure 1 illustrates the idea of GPL.

For a given target corpus, we generate for each passage three queries (cf. Table 3) using an T5-encoder-decoder model (Raffel et al., 2020). For each of the generated queries, we use an existing retrieval system to retrieve 50 negative passages. Dense retrieval with a pre-existing model was slightly more effective than BM25 lexical retrieval (cf. Appendix A). For each (query, positive, negative)-tuple we compute the margin $\delta = \mathrm{CE}(Q, P^{+},) - \mathrm{CE}(Q, P^{-})$ with CE the score as predicted by a cross-encoder, Q the query and P^{+}/P^{-} the positive / negative passage.

We use the synthetic dataset $D_{\mathrm{GPL}} = \{(Q_i, P_i, P_i^{-}, \delta_i)\}_i$ with the MarginMSE loss (Hofstätter et al., 2020) for training a domain-adapted dense retriever that maps queries and passages into the shared vector space.

Our method requires from the target domain just an unlabeled collection of passages. Further, we use use pre-existing T5- and cross-encoder models that have been trained on the MS MARCO passages dataset.

Query Generation: To enable supervised training on the target corpus, synthetic queries can be generated for the target passages using a query generator trained on a different, existing dataset like MS MARCO. Previous work QGen (Ma et al., 2021) used the simple MultipleNegativesRanking (MNRL) loss (Henderson et al., 2017; van den Oord et al., 2018) with in-batch negatives[5] to train the model:

$$L_{\text{MNRL}}(\theta) = -\frac{1}{M}\sum_{i=0}^{M-1}\log\frac{\exp\left(\tau\cdot\sigma(f_\theta(Q_i), f_\theta(P_i))\right)}{\sum_{j=0}^{M-1}\exp\left(\tau\cdot\sigma(f_\theta(Q_i), f_\theta(P_j))\right)}$$

where P_i is a relevant passage for Q_i; σ is a certain similarity function for vectors; τ controls the sharpness of the softmax normalization; M is the batch size.

MarginMSE loss: MultipleNegativesRanking loss considers only the coarse relationship between queries and passages, i.e. the matching passage is considered as relevant while all other passages are considered irrelevant. However, the query encoder is not without flaws and might generate queries that are not answerable[6] by the passage. Further, other passages might actually be relevant as well for a given query, which is especially the case if training is done with hard negatives as we do it for GPL.

In contrast, MarginMSE loss (Hofstätter et al., 2020) uses a powerful cross-encoder to soft-label (query, passage) pairs. It then teaches the dense retriever to mimic the score margin between the positive and negative query-passage pairs. Formally,

$$L_{\text{MarginMSE}}(\theta) = -\frac{1}{M}\sum_{i=0}^{M-1}|\hat{\delta}_i - \delta_i|^2 \qquad (1)$$

where $\hat{\delta}_i$ is the corresponding score margin of the student dense retriever, i.e. $\hat{\delta}_i = f_\theta(Q_i)^T f_\theta(P_i) - f_\theta(Q_i)^T f_\theta(P_i^-)$. Here the dot-product is usually used due to the infinite range of the cross-encoder scores.

This loss is a critical component of GPL, as it solves two major issues from the previous QGen method: A badly generated query for a given passage will get a low score from the cross-encoder, hence, we do not expect the dense retriever to put the query and passage close in the vector space. A false negative will lead to a high score from the cross-encoder, hence, we do not force the dense retriever to assign a large distance between the corresponding embeddings. In section 6.3, we show that GPL is a lot more robust to badly generated queries than the previous QGen method.

4 Experiments

In this section, we describe the experimental setup, the datasets used and the baselines for comparison.

4.1 Experimental Setup

We use the MS MARCO passage ranking dataset (Nguyen et al., 2016) as the data from the source domain. It has 8.8M passages and 532.8K query-passage pairs labeled as relevant in the training set. We select six representative datasets from the BeIR benchmark as the data from the target domain (cf. subsection 4.2). As Table 1 shows, a state-of-the-art dense retrieval model, achieving an MRR@10 of 33.2 points on the MS MARCO passage ranking dataset, performs poorly on the six selected domain-specific retrieval datasets when compared to simple BM25 lexical search.

We use the DistilBERT (Sanh et al., 2019) for all the experiments. We use the concatenation of the title and the body text as the input passage for all the models. We use a maximum sequence length of 350 with mean pooling and dot-product similarity by default. For QGen, we use the default setting in Thakur et al. (2021b): 1-epoch training and batch size 75. For GPL, we train the models with 140k training steps and batch size 32. To generate queries for both QGen and GPL, we use the DocT5Query (Nogueira et al., 2019a) generator trained on MS MARCO and generate [7] queries using nucleus sampling with temperature 1.0, $k = 25$ and $p = 0.95$. To retrieve hard negatives for both GPL and the zero-shot setting of MS MARCO training, we use two dense retrievers with cosine-similarity trained on MS MARCO: *msmarco-distilbert-base-v3* and *msmarco-MiniLM-L-6-v3* from Sentence-Transformers[8]. The zero-shot performance of these two dense retrievers is available in Appendix B. We retrieve 50 negatives

---

[5] In-batch negatives mean that within the same batch, the passages in example i are viewed as the negatives for example j ($i \neq j$).

[6] For example, some generated queries are statements instead of questions.

[7] We use the script from BeIR at `https://github.com/UKPLab/beir`.

[8] `https://github.com/UKPLab/sentence-transformers`

using each retriever and uniformly sample one negative passage and one positive passage for each training query to form one training example. For pseudo labeling, we use the *ms-marco-MiniLM-L-6-v2*[9] cross-encoder. For all the pre-training methods (e.g. TSDAE and MLM), we train the models for 100K training steps and with batch size 8.

As shown in Section 6, small corpora require more generated queries and for large corpora, a small down-sampled subset (e.g. 50K) is enough for good performance. Based on these findings, we adjust the number of generated queries per passage $q_{\text{avg.}}$ and the corpus size $|C|$ to make the total number of generated queries equal to a fixed number, 250K, i.e. $q_{\text{avg.}} \times |C| = 250\text{K}$. In detail, we first set $q_{\text{avg.}} >= 3$ and uniformly down-sample the corpus if $3 \times |C| > 250\text{K}$; then we calculate $q_{\text{avg.}} = \lceil 250\text{K}/|C| \rceil$. For example, the $q_{\text{avg.}}$ values for FiQA (original size = 57.6K) and Robust04 (original size = 528.2K) are 5 and 3, resp. and the Robust04 corpus is down-sampled to 83.3K. QGen and GPL share the generated queries for fair comparision.

4.2 Evaluation

As our methods focus on domain adaptation to specialized domains, we selected six domain-specific text retrieval tasks from the BeIR benchmark (Thakur et al., 2021b): FiQA (financial domain) (Maia et al., 2018), SciFact (scientific papers) (Wadden et al., 2020), BioASQ (biomedical Q&A) (Tsatsaronis et al., 2015), TREC-COVID (scientific papers on COVID-19) (Roberts et al., 2020), CQADupStack (12 StackExchange subforums) (Hoogeveen et al., 2015) and Robust04 (news articles) (Voorhees, 2005). These selected datasets each contain a corpus with a rather specific language and can thus act as a suitable test bed for domain adaptation.

The detailed information for all the target datasets is available at Appendix C. We make modification on BioASQ and TREC-COVID. For efficient training and evaluation on BioASQ, we randomly remove irrelevant passages to make the final corpus size to 1M. In TREC-COVID, the original corpus has many documents with a missing abstract. The retrieval systems that were used to create the annotation pool for TREC-COVID often ignored such documents. This leads to a strong annotation bias on text length for these documents, since this dataset contains only titles and abstracts. Hence, we removed all documents with a missing abstract from the corpus. The evaluation results on the original BioASQ and TREC-COVID are available at Appendix D. Evaluation is done using nDCG@10.

4.3 Baselines

Zero-Shot Models: We apply supervised training on MS MARCO or PAQ (Lewis et al., 2021) and evaluate the trained retrievers on the target datasets. (a) **MS MARCO** represents a distilbert-base dense retrieval model trained with MarginMSE on the MS MARCO dataset with batch-size 75 for 70k steps. (b) **PAQ** (Oguz et al., 2021) represents MNRL training on the PAQ dataset. (c) **PAQ + MS MARCO** represents MNRL training on PAQ followed by MarginMSE training on MS MARCO. (d) **TSDAE$_{\textbf{MS MARCO}}$** represents TSDAE (Wang et al., 2021) pre-training on MS MARCO followed by MarginMSE training on MS MARCO. (e) **BM25** system based on lexical matching from Elasticsearch[10].

Previous Domain Adaptation Methods: We include two previous unsupervised domain adaptation methods, UDALM (Karouzos et al., 2021) and MoDIR (Xin et al., 2021). For **UDALM**, we apply MLM training on the target corpus and then apply the multi-task training of MarginMSE training on MS MARCO and MLM training on the target corpus. For **MoDIR**, it starts from the ANCE checkpoint and apply domain adversarial training on MS MARCO and the target dataset. As of writing, the training code of MoDIR is not public, but domain adapted models for 5 out of 6 datasets have been released by the authors.

Pre-Training based Domain Adaptation: We follow the setup proposed in Wang et al. (2021) on domain-adapted pre-training: We pre-train the dense retrievers with different methods on the target corpus and then continue to train the models on MS MARCO with MarginMSE loss. The pre-training methods consist of: (a) **CD** (Gao and Callan, 2021) extracts the hidden representations from an intermediate layer and applies MLM on the CLS token representation and these extracted hidden representations[11]. (b) **SimCSE** (Gao et al., 2021b; Liu et al., 2021) simply encode the same

---

Table 1: Evaluation using nDCG@10. The best results of the single-stage dense retrievers are bold. TRECC. and CQADup. are short for TREC-COVID and CQADupStack. Our proposed GPL significantly outperforms other domain adaptation methods. For the first time, we investigate the TSDAE pre-training in domain adaptation for dense retrieval and find it can significantly improve both QGen and GPL. The results on the full 18 BeIR datasets can be found in Appendix D.

text twice with different dropout masks in combination with MNRL loss. (c) **CT** (Carlsson et al., 2021) is similar to SimCSE but it uses two independent encoders to encode a pair of text. (d) **MLM** (Devlin et al., 2019) uses the default setting in original paper, where 15% tokens in a text are sampled to be masked and are needed to be predicted. (e) **ICT** (Lee et al., 2019) uniformly samples one sentence from a passage as the pseudo query to that passage and uses MNRL loss on the synthetic data. We follow the setting in Lee et al. (2019) and masked out the selected sentence 90% of the time. (f) **TSDAE** (Wang et al., 2021) uses a denoising autoencoder to pre-train the dense retrievers with 60% random tokens deleted in the input texts.

Generation-based Domain Adaptation: We use the training script[12] from Thakur et al. (2021b) to train QGen models with the default setting. Cosine similarity is used and the models are fine-tuned for 1 epoch with MNRL. The default QGen is trained with in-batch negatives. For a fair comparison, we also test QGen with hard negatives as used in GPL, noted as **QGen (w/ Hard Negatives)**. Further, We test the combination of TSDAE and QGen (**TSDAE + QGen**).

Re-Ranking with Cross-Encoders: We also include results of the powerful but inefficient re-ranking methods for reference. Three retrievers for the first-phrase retrieval are tested: BM25 from Elasticsearch, the zero-shot MS MARCO retriever and the GPL retriever enhanced by TSDAE pre-training. We use the cross-encoder *ms-marco-MiniLM-L-6-v2* from Sentence-Transformers, which is also the same model used for pseudo labeling in GPL.

5 Results

Pre-Training based Domain Adaptation:

---

[12] `https://github.com/UKPLab/beir`

The results are shown in Table 1. Compared with the zero-shot MS MARCO model, TSDAE, MLM and ICT can improve the performance if we first pre-train on the target corpus and then perform supervised training on MS MARCO. Among them, TSDAE is the most effective method, outperforming the zero-shot baseline by 4.0 points nDCG@10 on average. CD, CT and SimCSE are not able to adapt to the domains in a pre-training setup and achieve a performance worse than the zero-shot model.

To ensure that TSDAE actually learns domain specific terminology, we include $\text{TSDAE}_{\text{MS MARCO}}$ in our experiments: Here, we performed TSDAE pre-training on the MS MARCO dataset followed by supervised learning on MS MARCO. This performs slightly weaker than the zero-shot MS MARCO model.

We also tested the pre-training methods without any supervised training on MS MARCO. We find all of them fail miserably compared to the zero-shot baseline as shown in Appendix E .

Previous Domain Adaptation Methods: We test MoDIR on the datasets except Robust04[13]. MoDIR performs on-par with our zero-shot MS MARCO model on FiQA, TREC-COVID and CQADupStack, while it performs much weaker on SciFact and BioASQ. An improved training setup with MoDIR could improve the results.

We also test UDALM, which first does MLM pre-training on the target corpus, and then runs multitask learning with MLM objective and supervised training on MS MARCO. The results show that UDALM in this case greatly harms the performance by 12.2 points in average, when compared with the MLM-pre-training approach. We suppose this is because unlike text classification, the dense retrieval models usually do not have an additional task head and the direct MLM training conflicts with the supervised training.

Generation-based Domain Adaptation: The results show that the previous best method, QGen, can successfully adapt the MS MARCO models to the new domains, improving the performance on average by 3.6 points. It performs on par with TSDAE-based domain-adaptive pre-training. Combining TSDAE with QGen can further improve the performance by 1.5 points.

When using QGen with hard negatives instead of random in-batch negatives, the performance decreases by 2.5 points in average. QGen is sensitive to false negatives, i.e. negative passages that are actually relevant for the query. This is a common issue for hard negative mining. GPL solves this issue by using the cross-encoder to determine the distance between the query and a passage. We give more analysis in section 7.

Generative Pseudo Labeling (GPL, proposed method): We find GPL is significantly better on almost all the datasets compared to other tested methods, outperforming QGen by up to 4.5 points (on BioASQ) and in average by 2.7 points. One exception is TREC-COVID, but as this dataset has just 50 test queries, this difference can be due to noise.

As a further enhancement, we find that TSDAE-based domain-adaptive pre-training combined with GPL (i.e. TSDAE + GPL) can further improve the performance on all the datasets, achieving the new state-of-the-art result of 52.9 nDCG@10 points in average. It outperforms the out-of-the-box MS MARCO model 7.7 points on average.

For the results of GPL on the full 18 BeIR datasets, please refer to Appendix D. The observations remain the same.

Re-ranking with Cross-Encoders: Cross-encoders perform well in a zero-shot setting and outperform dense retrieval approaches significantly (Thakur et al., 2021b), but they come with a significant computational cost at inference. TSDAE and GPL can narrow but not fully close the performance gap between the single-stage retrievers and the re-ranking methods. Due to the much lower computational costs at inference, the TSDAE + GPL model would be preferable in a production setting. For example, as shown in Thakur et al. (2021b), the retrieval latency on a 1M-sized corpus for one query is 14ms and 450ms for dense retrievers (with the same backbone as ours) and BM25 + CE reranking, resp.

6 Analysis

In this section, we analyze the influence of training steps, corpus size, query generation and choices of starting checkpoints on GPL.

6.1 Influence of Training Steps

We first analyze the influence of the number of training steps on the model performance. We evaluate the models every 10K training steps and end

---

[13] The original author did not train the model on Robust04 and the code is also not available.

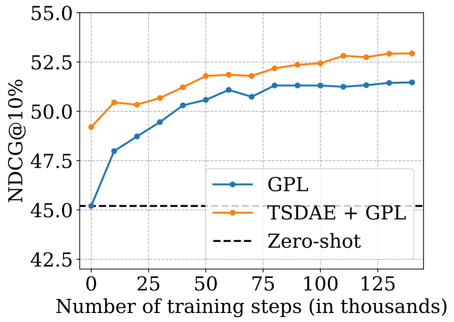

Figure 2: Influence of the number training steps on the averaged performance. The performance of GPL begins to be saturated after 100K steps. TSDAE helps improve the performance during the whole training stage.

Method \ Size	1K	10K	50K	250K	528K
QGen	35.5	36.5	38.7	37.5	37.0
GPL	37.6	41.4	42.5	41.4	41.3
Zero-shot	39.0				

Table 2: Influence of corpus size on performance on Robust04. The full size is 528K. GPL can achieve the best performance with as little as 50K passages.

the training after 140K steps. The results for the change of averaged performance on all the datasets are shown in Figure 2. We find the performance of GPL begins to be saturated after around 100K steps. With the TSDAE pre-training, the performance can be improved consistently during the whole training stage. For reference, training a distilbert-base model for 100k steps takes about 9.6 hours on a single V100 GPU.

6.2 Influence of Corpus Size

We next analyze the influence of different corpus sizes. We use Robust04 for this analysis, since it has a relatively large size. We sample 1K, 10K, 50K and 250K passages from the whole corpus independently to form small corpora and train QGen and GPL on the same small corpus. The results are shown in Table 2. We find with more than 10K passages, GPL can already significantly outperform the zero-shot baseline by 2.4 NDCG@10 points; with more than 50K passages, the performance begins to saturate. On the other hand, QGen falls behind the zero-shot baseline for each corpus size.

6.3 Robustness against Query Generation

Next, we study how the query generation influences the model performance. First, we train QGen and GPL on SciFact, FiQA and Robust04, with 1 up to 50 generated Queries Per Passage (QPP). The results are shown in Table 3. We observe that smaller corpora, e.g. SciFact (size = 5.2K) and FiQA (size = 57.6K) require more generated queries per passage than the large one, Robust04 (size = 528.2K). For example, GPL needs QPP equal to around 50, 5 and 1 for SciFact, FiQA and Robust04, resp. to achieve the optimal performance.

Dataset	**Method**	**Queries Per Passage**						
		1	**2**	**3**	**5**	**10**	**25**	**50**
SciFact (5.2K)	QGen	56.7	59.6	60.2	59.9	61.5	62.2	63.7
	GPL	61.7	63.2	63.8	64.7	66.8	66.9	67.9
	Zero-shot	57.1						
FiQA (57.6K)	QGen	27.3	28.1	27.8	28.5	29.3	31.1	31.8
	GPL	31.5	32.2	32.3	32.8	33.0	33.5	33.5
	Zero-shot	26.7						
Robust04 (528.2K)	QGen	37.9	38.7	37.0	37.3	38.2	37.7	37.7
	GPL	42.0	41.3	41.4	41.2	40.9	41.2	40.6
	Zero-shot	39.0						

Table 3: Influence of number of generated Queries Per Passage (QPP) on the performance on SciFact, FiQA and Robust04. Corpus size is labeled under each dataset name. Smaller corpora, e.g. SciFact and FiQA require larger QPP to achieve the optimal performance.

The temperature[14] plays an important role in nucleus sampling, higher values make the generated queries more diverse, but of lower quality. We train QGen and GPL on FiQA with different temperatures: 0.1, 1, 1.3, 3, 5 and 10. Examples of generated queries are available in Appendix F. We generated 3 queries per passage. The results are shown in Figure 3. We find the performance of QGen and GPL both peaks at 1.0. With a higher temperature, the next-token distribution will be flatter and more diverse queries, but of lower quality, will be generated. With high temperatures, the generated queries have nearly no relationship to the passage. QGen will perform poorly in these cases, worse than the zero-shot model. In contrast, GPL performs still well even when the generated queries are of such low quality.

6.4 Sensitivity to Starting Checkpoints

We also analyze the influence of initialization on GPL. In the default setting, we start from a distilbert-model supervised on MS MARCO using MarginMSE loss. We also evaluate to directly fine-tune a distilbert-model using QGen, GPL and TSDAE + GPL. The performance averaged on all the datasets is shown in Table 4. We find the MS MARCO training has relatively small effect on the performance of GPL (with 0.3-point difference in average), while QGen highly relies on the choice

---

[14] The amplifying coefficient to the raw logits in the Softmax function.

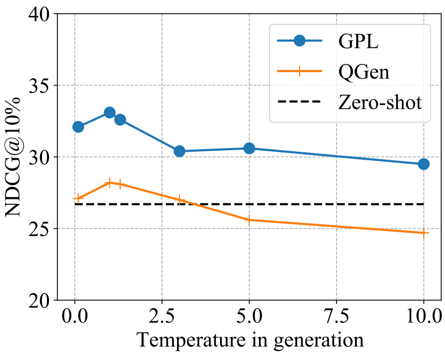

Figure 3: Influence of the temperature in generation on the performance on FiQA. A higher temperature means more diverse queries but of lower quality. GPL can still yield around 3.0-point improvement over the zero-shot baseline with high temperature value of 10.0, where the generated queries have nearly no connection to the passages.

Init. **Method**	**Distilbert**	**MS MARCO**
QGen	46.9	48.8
TSDAE + QGen (Ours)	49.6	50.3
GPL	51.2	51.5
TSDAE + GPL	52.3	52.9
Zero-shot	–	45.2

Table 4: Influence of initialization checkpoint on performance in average. GPL yields similar performance when starting from different checkpoints.

of the initialization checkpoint (with 1.9-point difference in average).

7 Case Study: Fine-Grained Labels

GPL uses continuous pseudo labels from a cross-encoder, which can provide more fine-grained information and is more informative than the simple 0-1 labels as in QGen. In this section, we give a more detailed insight into it by a case study.

One example from FiQA is shown in Table 5. The generated query for the positive passage asks for the definition of “futures contract”. Negative 1 and 2 only mention futures contract without explaining the term (with low GPL labels/scores below 2.0), while Negative 3 gives the required definition (with high GPL label/score 8.2). As an interesting case, Negative 4 gives a partial explanation of the term (with medium GPL label/score 6.9). GPL assigns suitable fine-grained labels to different negative passages. In contrast, QGen simply labels all of them as 0, i.e. as irrelevant. Such difference explains the advantage of GPL over QGen and why using hard negatives harms the performance of QGen in Table 1.

Item	**Text**	**GPL**	**QGen**
Query	what is **futures contract**	–	–
Positive	**Futures contracts** are a member of a larger class of financial assets called derivatives ...	10.3	1
Negative 1	... Anyway in this one example the s&p 500 **futures contract** has an "initial margin" of $19,250, meaning ...	2.0	0
Negative 2	... but the moment you exercise you must have $5,940 in a margin account to actually use the **futures contract** ...	0.3	0
Negative 3	... a **futures contract** is simply a contract that requires party A to buy a given amount of a commodity from party B at a specified price...	8.2	0
Negative 4	... A **futures contract** commits two parties to a buy/sell of the underlying securities, but ...	6.9	0

Table 5: Examples of the labels assigned to different query-passage pairs in FiQA by GPL and QGen. The key term "futures contract" is marked in bold. QGen uses only 0-1 scores. GPL uses raw logits, which can be any value between positive and negative infinity (e.g. $[-12, 11]$ is a typical range).

8 Conclusion

In this work we propose GPL, a novel unsupervised domain adaptation method for dense retrieval models. It generates queries for a target corpus and pseudo labels these with a cross-encoders. Pseudo-labeling overcomes two important short-comings of previous methods: Not all generated queries are of high quality and pseudo-labels efficiently detects those. Further, training with mined hard negatives is possible as the pseudo labels performs efficient denoising.

In this work, we also evaluated different pre-training strategies in a domain-adaptive pre-training setup: We first pre-trained on the target domain, then performed supervised training on MS MARCO. ICT and MLM were able to yield a small improvement (by <=1.5 nDCG@10 points on average), while TSDAE was able to yield a significant improvement of 4 nDCG@10 points on average. Other approaches degraded the performance.

A Performance of Using Different Retrievers for Negative Mining in GPL

The performance of using different retrievers (BM25, dense, BM25 + dense and single dense retrievers) for mining hard negatives in GPL is shown in Table 6. The results show GPL performs best when using hard negatives mined by both the two dense retrievers.

Method \ Dataset	FiQA	SciFact	BioASQ	TRECC.	CQADup.	Robust04	Avg.
GPL (w/ BM25 + dense)	32.9	64.4	61.1	68.6	33.8	41.3	50.4
GPL (w/ BM25)	31.1	60.9	57.8	67.5	33.5	35.9	47.8
GPL (w/ dense)	32.8	66.4	61.0	72.6	34.5	41.4	51.5
GPL (w/ msmarco-distilbert-base-v3)	32.1	64.7	60.9	70.8	34.3	41.5	50.7
GPL (w/ msmarco-MiniLM-L-6-v3)	32.7	64.6	61.7	69.7	35	40.4	50.7
MS MARCO	26.7	57.1	52.9	66.1	29.6	39.0	45.2

Table 6: Performance (nDCG@10) of using different retrievers for hard-negative mining in GPL. The scores of the baseline MS MARCO and the scores of GPL with dense retrievers are copied from Table 1. "Dense" represents using both of the two dense retrievers *msmarco-distilbert-base-v3* and *msmarco-MiniLM-L-6-v3*.

B Performance of the Zero-Shot Retrievers in Hard-Negative Mining

The performance of directly using the zero-shot retrievers for hard-negative mining in GPL is shown in Table 7. Compared with the strong baseline (MS MARCO in Table 7) trained with MarginMSE, *msmarco-distilbert-base-v3* and *msmarco-MiniLM-L-6-v3* are much worse in terms of zero-shot generalization on each dataset. This comparison supports GPL can indeed train powerful domain-adapted dense retrievers with minimum reliance on choices of the retrievers for hard-negative mining.

Method \ Dataset	FiQA	SciFact	BioASQ	TRECC.	CQADup.	Robust04	Avg.
msmarco-distilbert-base-v3	24.0	52.3	45.6	61.1	24.3	30.6	39.7
msmarco-MiniLM-L-6-v3	23.3	48.8	41.9	57.9	24.3	28.5	37.5
MS MARCO	26.7	57.1	52.9	66.1	29.6	39.0	45.2

Table 7: Performance (nDCG@10) of different zero-shot retrievers. *msmarco-distilbert-base-v3* and *msmarco-MiniLM-L-6-v3* are used in GPL for hard-negative mining. The scores of the baseline MS MARCO are copied from Table 1.

C Target Datasets

FiQA is for the task of opinion question answering over financial data. It contains 648 queries and 5.8K passages from StackExchange posts under the Investment topic in the period between 2009 and 2017. The labels are binary (relevant or irrelevant) and there are 2.6 passages in average labeled as relevant for each query.

SciFact is for the task of verifying scientific claims using evidence from the abstracts of the scientific papers. It contains 300 queries and 5.2K passages built from S2ORC (Lo et al., 2020), a publicly-available corpus of millions of scientific articles. The labels are binary and there are 1.1 passages in average labeled as relevant for each query.

BioASQ is for the task of biomedical question answering. It originally contains 500 queries and 15M articles from PubMed[15]. The labels are binary and it has 4.7 passages in average labeled as relevant for each query. For efficient training and evaluation, we randomly remove irrelevant passages to make the final corpus size to 1M.

TREC-COVID is an ad-hoc search challenge for scientific articles related to COVID-19 based on the CORD-19 dataset (Wang et al., 2020). It originally contains 50 queries and 171K documents. The original corpus has many documents with only a title and an empty body. We remove such documents and the

final corpus size is 129.2K. The labels in TREC-COVID are 3-level (i.e. 0, 1 and 2) and there are 430.8 passages in average labeled as 1 or 2 in the clean-up version.

CQADupStack is a dataset for community question-answering, built from 12 StackExchange subforums: Android, English, Gaming, Gis, Mathematica, Physics, Programmers, Stats, Tex, Unix, Webmasters and WordPress. The task is to retrieve duplicate question posts with both a title and a body text given a post title. It has 13.1K queries and 457.2k passages. The labels are binary and there are 1.4 passages in average labeled as relevant for each query. As in Thakur et al. (2021b), the average score of the 12 sub-tasks is reported.

Robust04 is a dataset for news retrieval focusing on poorly performing topics. It has 249 queries and 528.2K passages. The labels are 3-level and there are in average 69.9 passages labeled as relevant for each query.

The detailed statistics of these target datasets are shown in Table 8.

Table 8: Statistics of the target datasets used in the experiments. Column **Title** indicates whether there is (✓) a title for each passage or not (✗). Column **PPQ** represents number of Passages Per Query. Query/passage lengths are counted in words. Symbol $*$ marks the original version from the BeIR benchmark (Thakur et al., 2021b)

We also evaluate the models trained in this work on the original version of BioASQ and TREC-COVID datasets from BeIR (Thakur et al., 2021b). The results are shown in Table 9.

D Results on full BeIR

We also evaluate the models on all the 18 BeIR datasets. We include DocT5Query (Nogueira et al., 2019a), the strong baseline based on document expansion with the T5 query generator (also used in GPL for query generation) + BM25 (Anserini). We also include the powerful zero-shot model **TAS-B** (Hofstätter et al., 2021), which is trained on MS MARCO with advanced knowledge-distillation techniques into comparison. Viewing TAS-B as the base model and also the negative miner, we apply QGen and GPL on top of them, resulting in **TAS-B + QGen** and **TAS-B + GPL**, resp.

The results are shown in Table 9. We find both DocT5Query and BM25 (Anserini) outperform MS MARCO, TSDAE and QGen, in terms of both average performance and average (performance) rank. QGen struggles to beat MS MARCO, the zero-shot baseline and it even significantly harms the performance on many datasets, e.g. TREC-COVID, FEVER, HotpotQA, NQ. Thakur et al. (2021b) also observes the same issue, claiming that the bad generation quality on these corpora is the key to the failure of QGen. On the other hand, GPL significantly outperforms these baselines above, achieving average performance rank 5.2 and can consistently improve the performance over the zero-shot model on all the datasets. For TSDAE, TSDAE + QGen and TSDAE + GPL, the conclusion remains the same as in the main paper.

For the powerful zero-shot model TAS-B, it outperforms QGen and performs on par with TSDAE + QGen. When building on top of TAS-B, GPL can also yield significant performance gain by up-to 21.5 nDCG@10 points (on TREC-COVID) and 4.6 nDCG@10 points on average. This TAS-B + GPL model performs the best over all these retriever models, achieving the averaged performance rank equal to 3.2. However, when applying QGen on top of TAS-B, it cannot improve the overall performance but also harms the individual performance on many datasets, instead.

Table 9: Performance (nDCG@10) on all the original 18 BeIR datasets. The results of MS MARCO, TSDAE, QGen, TSDAE + QGen, GPL and TSDAE + GPL on FiQA, SciFact, CQADupStack and Robust04 are copied from Table 1. The results of BM25, DocT5Query and BM25 + CE come from Thakur et al. (2021b). † marks correction over the original scores, where identical IDs between queries and passages are removed. TRECN. is short for TREC-NEWS. Avg. Rank is the average over the rank of the performance on each dataset over the different models (the lower, the better).

E Performance of Unsupervised Pre-Training

The performance of the unsupervised pre-training methods without access to the MS MARCO data is shown in Table 10. We find ICT is the best method, achieving highest scores on all the datasets. However, all the unsupervised pre-training methods cannot directly yield improvement in performance compared with the zero-shot baseline.

Sparse Distillation: Speeding Up Text Classification by Using Bigger Student Models

Abstract

Distilling state-of-the-art transformer models into lightweight student models is an effective way to reduce computation cost at inference time. The student models are typically compact transformers with fewer parameters, while expensive operations such as self-attention persist. Therefore, the improved inference speed may still be unsatisfactory for real-time or high-volume use cases. In this paper, we aim to further push the limit of inference speed by distilling teacher models into bigger, sparser student models – bigger in that they scale up to billions of parameters; sparser in that most of the model parameters are n-gram embeddings. Our experiments on six single-sentence text classification tasks show that these student models retain 97% of the RoBERTa-Large teacher performance on average, and meanwhile achieve up to 600x speed-up on both GPUs and CPUs at inference time. Further investigation reveals that our pipeline is also helpful for sentence-pair classification tasks, and in domain generalization settings.[1]

1 Introduction

Large pre-trained Transformers (Devlin et al., 2019; Liu et al., 2019) are highly successful, but their large inference costs mean that people who host low-latency applications, or who are simply concerned with their cloud computing costs have looked for ways to reduce the costs. Prior work mainly achieves this by leveraging knowledge distillation (Hinton et al., 2015), which allows for the capabilities of a large well-performing model known as the teacher to be transferred to a smaller student model. For example, DistillBERT (Sanh et al., 2019) is a smaller transformer model distilled from BERT (Devlin et al., 2019), which reduces BERT's size by 40% and becomes 60% faster during inference. However, such speed-up may be still insufficient for high-volume or low-latency inference tasks. In this paper, we aim to further push the limit of inference speed, by introducing Sparse Distillation, a framework that distills the power of state-of-the-art transformer models into a shallow, sparsely-activated, and richly-parameterized student model.

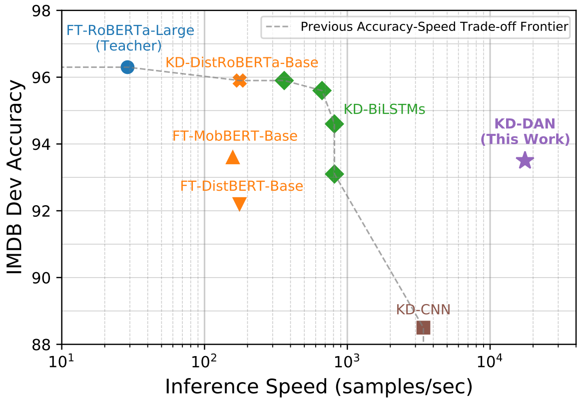

Figure 1: **Performance vs. Inference Speed.** With Deep Averaging Network (DAN; Iyyer et al. 2015) and knowledge distillation, we obtain a student model with competitive performance on IMDB dataset, while being 607x faster than RoBERTa-Large, and 20x faster than bi-directional LSTMs at inference time.

Counter to the convention of using "smaller, faster, [and] cheaper" (Sanh et al., 2019) student models, our work explores a new area of the design space, where our fast and cheap student model is actually several times *larger* than the teacher. The student model we use is modified from Deep Averaging Network (DAN) in Iyyer et al. (2015). DANs take a simple architecture by mapping the n-grams in the input sentence into embeddings, aggregating the embeddings with average pooling, and then using multiple linear layers to perform classification (see Fig. 2). This architecture is reminiscent of the high expressive power of billion-parameter n-gram models (Buck et al., 2014; Brants et al., 2007) from before the existence of pre-trained language

July 10-15, 2022

models. By selecting the n-gram vocabulary and the embedding dimension, DANs also scale up to billions of parameters. Meanwhile, the inference costs are kept low as DANs are sparsely-activated.

One weakness of DANs is that they are restricted in modeling high-level meanings in long-range contexts, as compared to the self-attention operator in Transformers. However, recent studies have shown that large pre-trained Transformers are rather insensitive to word order (Sinha et al., 2021) and that they still work well when the learned self-attention is replaced with hard-coded localized attention (You et al., 2020) or convolution blocks (Tay et al., 2021). Taken together, these studies suggest that on some tasks it may be possible to get competitive results without computationally expensive operations such as self-attention.

To verify our hypothesis, we use six single-sentence text classification tasks[2] and apply knowledge distillation to DANs. We observe that the resulting student models retain 97% of the RoBERTa-Large teacher performance on average. We also show that our method falls outside of the Pareto frontier of existing methods; compared to a baseline of distilling to a LSTM student, our method gives comparable accuracy at less than 1/20 the inference cost (see Fig. 1). Based on our empirical results, we conclude that faster and larger student models provide a valuable benefit over existing methods. We further examine our method (1) with QQP, a sentence-pair task, (2) in privacy-preserving settings (*i.e.*, no access to task-specific data during distillation), and (3) in domain generalization and adaptation settings (*i.e.*, student models are applied and adapted to new data domains), where we find our method continues to bring improvements over non-distillation baselines.

2 Sparse Distillation with DANs

2.1 Problem Definition

Our goal is to train an **efficient** text classification model M for a given task T. In a n-way classification problem, the model M takes input text $\mathbf{x}$, and produces $\hat{\mathbf{y}} \in \mathbb{R}^n$, where $\hat{y}_i$ indicates the likelihood that the input $\mathbf{x}$ belongs to category i. The task T has a train set D_{train} and a validation/development set D_{dev}. Additionally, we assume access to a large unlabeled corpus C which is supposedly in a domain relevant to task T. We comprehensively evaluate the efficiency of the model M by reporting: (1) accuracy on D_{dev}, (2) inference speed, and (3) the number of parameters in the model.

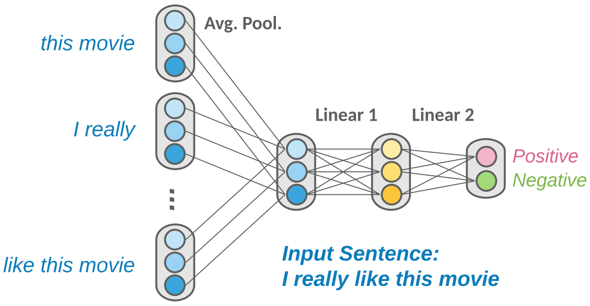

Figure 2: We primarily use a modified **Deep Averaging Network** (DAN; Iyyer et al. 2015) as the student model in this paper. DAN contains a sparse n-gram embedding table and two linear layers. Embedding dimension d_e is set to 3 in this figure for illustration purpose.

2.2 Method Overview

To train a text classifier that is both efficient and powerful, we employ knowledge distillation (Hinton et al., 2015), by having a powerful teacher model provide the supervision signal to an efficient student model. In particular, we are interested in using sparse n-gram based models as our student model. We explain the teacher and student model we use in §2.3, the training pipeline in §2.4, and implementation details in §2.5

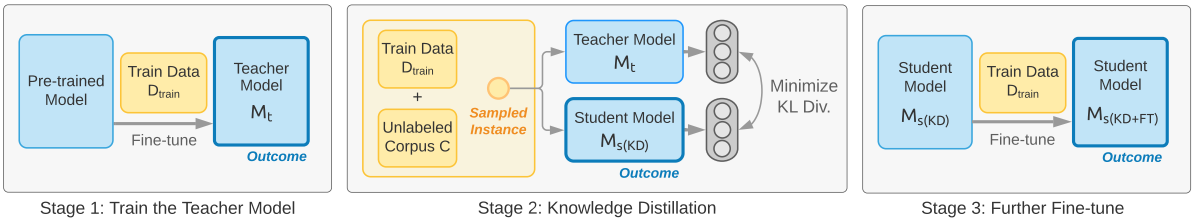
2.3 Models

Teacher Model. Fine-tuning a pre-trained transformer model is the predominant recipe for obtaining state-of-the-art results on various text classification tasks. Our teacher model is a RoBERTa-Large model (Liu et al., 2019) fine-tuned on the training set D_{train} of task T.

Student Model. Our student model is based on the Deep Averaging Network (DAN, Iyyer et al. 2015) with the modification that we operate on *n-grams* instead of just *words*. See Fig. 2 for an illustration of the model architecture. Specifically, for an input sentence $\mathbf{x}$, a list of n-grams $g_1, g_2, ..., g_n$ are extracted from the sentence. These n-gram indices are converted into their embeddings (with dimension d_e) using an embedding layer Emb(.). The sentence representation $\mathbf{h}$ will be computed as the average of all n-gram embeddings, *i.e.*, $\mathbf{h} = \text{Mean}(\text{Emb}(g_1), \text{Emb}(g_2), ..., \text{Emb}(g_n)) \in \mathbb{R}^{d_e}$. The sentence representation then goes through two

---

[2] Transformers are effective at many tasks beyond text classification. We extend our method to sentence-pair tasks in later sections and leave other use cases as future work.



Stage 1: Train the Teacher Model

Stage 2: Knowledge Distillation

Stage 3: Further Fine-tune

Figure 3: We adopt a **three-stage pipeline** for Sparse Distillation: (1) We fine-tune a RoBERTa-Large model on D_{train} to get the teacher model. (2) We apply teacher model to the unlabeled corpus C and D_{train}, and train the student model (DAN) to mimic the predictions of the teacher. This model is denoted as "DAN (KD)" (3) We further fine-tune the student model with D_{train}. This model is denoted as "DAN (KD+FT)".

fully connected layers, $(\mathbf{W}_1, \mathbf{b}_1)$ and $(\mathbf{W}_2, \mathbf{b}_2)$, to produces the final logits $\hat{\mathbf{z}}$, i.e., $\hat{\mathbf{z}} = M_s(\mathbf{x}) = \mathbf{W}_2(\text{ReLu}(\mathbf{W}_1\mathbf{h} + \mathbf{b}_1)) + \mathbf{b}_2 \in \mathbb{R}^n$. The logits are transformed into probabilities with the Softmax function, i.e., $\hat{\mathbf{y}} = \text{Softmax}(\hat{\mathbf{z}}) \in \mathbb{R}^n$.

Remarks on Computation Complexity. Multi-headed self-attention is considered the most expensive operation in the teacher transformers, where the computation complexity is $O(m^2)$ for a sequence with m sub-word tokens. The student model, Deep Averaging Network (DAN), can be considered as pre-computing and storing phrase representations in a large embedding table. By doing so, the computation complexity is reduced to $O(m)$. However, unlike the teacher, the context is limited to a small range, and no long-range information (beyond n-gram) is taken into account by the student model.

2.4 Training Pipeline

Our training pipeline is illustrated in Fig. 3. It has three stages: **(1)** We first fine-tune a RoBERTa-Large model on the train set D_{train} of task T, and use the resulting model as the teacher model. **(2)** We train the student model by aligning the predictions of the teacher ($\tilde{y}$) and the predictions of the student ($\hat{y}$) on the union of unlabeled corpus C and the train set D_{train}. We align the predictions by minimizing the KL divergence between the two distributions, *i.e.*, $L = \sum_{j=1}^{n} \tilde{y}_j \log \frac{\tilde{y}_j}{\hat{y}_j}$. The resulting student model is denoted as "DAN (KD)". **(3)** We further fine-tune the student model from step (2) with the task train set D_{train}, and get a new student model. This model is denoted as "DAN (KD+FT)". This third stage is optional.

2.5 Implementation Details

Determine N-gram Vocabulary. Our student model takes in n-grams as input. We determine the n-gram vocabulary by selecting the top $|V|$ frequent n-grams in D_{train} and C. For each downstream dataset, we compute the vocabulary separately. We use `CountVectorizer` with default whitespace tokenization in `sklearn` (Pedregosa et al., 2011) to perform this task. We set n-gram range to be $(1, 4)$ and set $|V| =$ 1,000,000, $d_e = 1,000$, unless specified otherwise.

Optimization. The architecture of DAN is sparsely-activated, and thus can be sparsely-optimized to reduce memory footprint. To facilitate this, we design a hybrid Adam optimizer, where we use SparseAdam[3] for the sparse parameters (*i.e.*, the embedding layer), and regular Adam for dense parameters. This implementation helps to improve speed and reduce memory usage greatly – we can train a 1-billion parameter DAN with the batch size of 2048 at the speed of 8 batches/second, on one single GPU with 32 GB memory.

Additional Details. Due to space limit, we defer details such as hyper-parameters settings and hardware configurations in Appendix A.

3 Experiment Settings

3.1 Data

Downstream Datasets. Following Tay et al. (2021), we mainly use six single-sentence classification datasets as the testbed for our experiments and analysis. These datasets cover a wide range of NLP applications. We use IMDB (Maas et al., 2011) and SST-2 (Socher et al., 2013) for sentiment analysis, TREC (Li and Roth, 2002) for question classification, AGNews (Zhang et al., 2015) for news classification. We use Civil Comments

AGNews	120,000	7,600	55	CC-News	418m
CCom	1,804,874	97,320	67	Reddit News and $\star$	60m
WToxic	159,571	63,978	92	$\star$	37m

Table 1: **Datasets and Distillation Corpus Used in Our Study.** $|.|$ represents the size of a dataset. "Avg. l" represents the average number of tokens in the input sentence. $\star$ represents the unlabeled data released with the original dataset.

(Borkan et al., 2019) and Wiki Toxic (Wulczyn et al., 2017) dataset for toxicity detection.

Knowledge Distillation Corpora. We manually select a relevant unlabeled corpus C based on the task characteristics and text domain.[4] For example, the IMDB and SST-2 models, which are tasked with classifying the sentiment of movie reviews, are paired with a corpus of unlabeled Amazon product reviews (Ni et al., 2019). TREC, a question classification task, is paired with PAQ (Lewis et al., 2021), a collection of 65 million questions. AGNews, a news classification task, is paired with CC-News corpus (Nagel, 2016). For Civil Comments, a dataset for detecting toxic news comments, we select the News subreddit corpus from ConvoKit (Chang et al., 2020), which is built from a previously existing dataset extracted and obtained by a third party and hosted by `pushshift.io`. Details of all datasets and corpora are listed in Table 1.

3.2 Compared Methods

To comprehensively evaluate and analyze the n-gram student models, we additionally experiment with (1) training a randomly-initialized DAN model with D_{train}, without knowledge distillation ("from scratch"); (2) directly fine-tuning general-purpose compact transformers, *e.g.*, DistilBERT (Sanh et al., 2019), MobileBERT (Sun et al., 2020); (3) using other lightweight architectures for the student model, such as DistilRoBERTa (Sanh et al., 2019), Bi-LSTM (Tang et al., 2019) and Convolution Neural Networks (Chia et al., 2019), in task-specific distillation setting. We also quote performance from (Tay et al., 2021) when applicable.

4 Results and Analysis

4.1 Main Results

How well can DANs emulate the performance of the teacher? In Table 2, we present the results on 6 single-sentence classification datasets. Firstly, we find that in 5 out of the 6 datasets, the gap between the teacher and the student model is within 3%. This suggests the power of simple n-gram models may be underestimated previously, as they are typically trained from scratch, without modern techniques such as pre-training and knowledge distillation. This also echoes with a series of recent work that questions the necessity of word order information (Sinha et al., 2021) and self-attention (You et al., 2020), in prevalent transformer architectures. Secondly, we observe that knowledge distillation help close more than half the gap between the teacher model and the student model trained from scratch. The effect is more significant with TREC dataset (13% improvement), a 46-way classification problem, whose train set has a small size of 5,452. It is hard to estimate parameters of a large sparse model with merely 5,452 examples; however, supervising it with large-scale corpus and distillation target effectively densified the supervision signals and help address the sparsity issues during model training.

How fast are DANs? We have previously hypothesized that DANs will have superior inference speed due to its simple and sparse architecture. In this section we quantify this advantage by comparing the student model with the RoBERTa-Large teacher model. We also include the baselines listed in §3.2 for a comprehensive comparison. For simplicity, we use BPE tokenizer and re-use the embedding table from RoBERTa-Large for our student Bi-LSTM and CNN model. We use 2-layer Bi-LSTM with hidden dimension of 4, 64, 256 and 512. For the CNN model, we use one 1D convolution layer with hidden dimension of 128 and context window of 7.

We provide speed comparison across all datasets in Table 3. We provide more fine-grained comparison on IMDB dataset in Table 4 and Fig. 1. DAN achieves competitive performance and the fastest inference efficiency among all different student model architectures. The speed-up differs across datasets, ranges from 4x to 1091x. It is most significant on Civil Comments (1091x), Wiki Toxic (668x) and IMDB dataset (607x), as they have

---

[4] It is possible that a careful comparison of different distillation corpora can result in better performance. For the purpose of this study, we leave this as future work.

Model	IMDB	SST-2	TREC	AGNews	CCom	WToxic	QQP
DAN (from scratch)	88.3	79.5	78.4	91.1	95.7	92.2	82.0
DAN (KD)[†]	92.0	87.0	91.8	90.0	96.2	93.9	63.2

RoBERTa-Large (Liu et al., 2019)	96.3	96.2	94.8	95.4	96.3	94.1	92.1

Table 2: **Performance Comparison on 6 Single-sentence Tasks and 1 Sentence-pair Task.** We report accuracy for all datasets. For single-sentence tasks, the gap between the teacher model (RoBERTa-Large) and the n-gram based student model (DAN(KD)/DAN(KD+FT)) is within 3% in most cases. Also, we observe that knowledge distillation help close more than half the gap between the teacher model and the n-gram model trained from scratch. [†]Knowledge distillation is performed without task data (D_{train}), assuming that the task data is private (see §4.3). [‡]The dataset we obtain from public sources differs from the one in Tay et al. (2021).

Model	IMDB	SST-2	TREC	AGNews	CCom	WToxic	QQP

Table 4: **Detailed Inference Speed Comparison on IMDB.** DANs achieves better accuracy and inference speed compared to other lightweight architectures such as LSTMs and CNNs. Moreover, DANs achieves acceptable inference speed on CPUs. ⋆ indicates the model is trained with task-specific distillation; no ⋆ indicates the model is trained with direct fine-tuning.

longer input sequences, and the complexity grows quadratically with sequence length in transformer models. Moreover, as shown in Table 4, DAN has an acceptable CPU inference speed, which greatly reduce the hardware cost for inference. We believe all these characteristics makes student DAN model as an ideal option for production or real-time use on single-sentence classification tasks.

Simplest is the best: Exploring different design choices for DAN. We try several modifications to our current experiment pipeline, including (1) replace average pooling with max pooling, attentive pooling, or taking sum in the DAN model; (2) pre-compute a n-gram representation by feeding the raw n-gram text to a RoBERTa-Large model, and using the representations to initialize the embedding table of the student model; (3) attach more dense layers in the DAN; (4) use even larger student models by leveraging parallel training across multiple GPUs. More details about these variations are in Appendix B.1. We experiment with IMDB dataset and list the performance in Table 5. In general, we do not observe significant performance improvements brought by these variations. Thus, we keep the simplest design of DAN for all other experiments.

Variations	Acc.	Variations	Acc.
1. Pooling Methods		*2. Dense Layers*	
Mean Pooling (⋆)	93.2	1000 → 1000 → 2 (⋆)	93.2
Max Pooling	91.8	1000 → 1000 → 256 → 2	93.1
Attentive Pooling	93.0	1000 → 1000 → 256 → 64 → 2	93.0
Sum	92.9		
3. Embedding Initialization		*4. Parallel Training*	
Without initialization (⋆)	93.2	1 GPU, param. 1b (⋆)	93.2
With initialization	93.2	2 GPUs, param. 2b	93.1

Table 5: **Variations made to the student model and the performance on IMDB.** ⋆ represents the design we adopt in our main experiments.

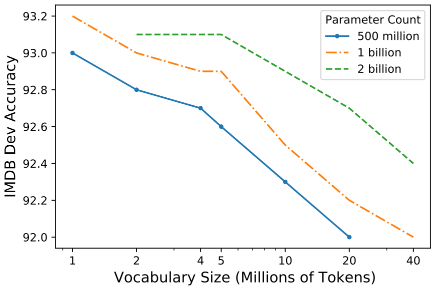

Figure 4: **Trade-off between the vocabulary size and the embedding dimension.** Given a fixed parameter budget, empirical results suggest that a larger embedding dimension and a smaller vocabulary size should be selected.

4.2 Controlling the Parameter Budget

Given a fixed parameter budget, how to allocate it wisely to achieve optimal performance? We discuss this question in two scenarios: the users wish to control the parameter budget (1) during knowledge distillation (KD), or (2) during inference.

During KD: Trade-off between vocabulary size and embedding dimension. We explore how the configuration of vocabulary size and embedding dimension influence the student model performance. We train student models on the IMDB dataset with 19 configurations, and show the results graphically in Figure 4. Detailed results are deferred in Table 8 in Appendix C. All else being equal, having more parameters in the student model is beneficial to the performance. For a fixed parameter budget, higher accuracy was achieved by increasing the embedding dimension and making a corresponding reduction in the vocabulary size. Our best performing model has $|V| = 1,000,000$ and $d_e = 1,000$. We keep this configuration for the main experiments in previous sections.

During inference: Reduce the model size with n-gram pruning. The model size of DANs is flexible even after training, by excluding the *least* frequent n-grams in the vocabulary. We test this idea on IMDB and AGNews dataset and plot the performance in Fig. 5. We try two ways to estimate n-gram frequency: (1) using distillation corpus C and the training set D_{train}; (2) using D_{train} only. We observe that: (1) n-gram frequencies estimated on D_{train} are more reliable, as D_{dev} has a n-gram distribution more similar to D_{train} compared to $C + D_{train}$; (2) DANs maintain decent accuracy (>90%) even when the model size is cut to 3% of its original size. In this case, users of DANs can customize the model flexibly based on their needs and available computational resources.

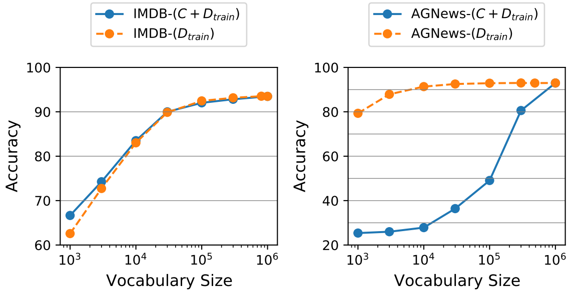

Figure 5: **Post-hoc pruning according to n-gram frequency.** We disable the *least* frequent n-grams during inference to further reduce model size. When the n-gram frequencies are estimated appropriately, DANs maintain decent performance (acc.>90%) even when model is 3% of its original size. $C+D_{train}/D_{train}$ represent different ways to estimate n-gram frequencies.

4.3 Privacy-preserving Settings

NLP datasets sometimes involve user generated text or sensitive information; therefore, data privacy can be a concern when training and deploying models with certain NLP datasets. In this section, we modify our experiment setting to a practical and privacy-preserving one. We assume the user has access to a public teacher model that is trained on private train dataset (D_{train}), but does not has access to D_{train} itself. This is realistic nowadays with the growth of public model hubs such as TensorFlow Hub[5] and Hugging Face Models[6]. After downloading the model, the user may wish to deploy a faster version of this model, or adapt the model to the user's own application domain.

Knowledge Distillation without D_{train}. To simulate the privacy-preserving setting, we remove D_{train} from the knowledge distillation stage in our experiment pipeline and only use the unlabeled corpus C. We use "DAN (KD)†" to denote this model in Table 2. By comparing "DAN (KD)" and "DAN (KD)†", we found that the performance difference brought by task specific data D_{train} is small for all single-sentence tasks, with the largest gap being 1.2% on IMDB dataset. This suggests that the proposed pipeline is still useful in the absence of task-specific data.

[6] `https://huggingface.co/models`

Source Target	IMDB SST-2	SST-2 IMDB
DAN (from scratch, tar)	79.5	88.3
(1) RoBERTa-Large (src)	90.0	94.1
(2) DAN (KD)	81.9	92.0
(3) DAN (KD+FT)	88.4	93.0
(4) DAN (KD+FT w. re-init.)	86.7	92.8
RoBERTa-Large (tar)	96.2	96.3

Table 6: **Domain Generalization and Adaptation Results.** (1) We take the teacher model trained on the *source dataset* and evluate it on the *target dataset*. (2) We obtain the student model "DAN (KD)" with unlabeled corpus C and knowledge distillation. (3) We further fine-tune the student model on the *target dataset* to obtain "DAN (KD+FT)". (4) The classification head is re-initialized before further fine-tuning.

Domain Generalization and Adaptation. We select the two sentiment analysis tasks: IMDB and SST-2, and further explore the domain generalization/adaptation setting. Specifically, during stage 1 of our three-stage pipeline (§2.4), we fine-tune the RoBERTa-Large model on a source dataset; during stage 2, we apply knowledge distillation with unlabeled corpus C only and get the student model; during stage 3, we further fine-tune the student model on the target dataset. The last step is optional and serves to simulate the situation where the user collects additional data for domain adaptation. We list the results in Table 6. With weakened assumptions about the teacher model and distillation supervision, we still have observations similar to those in our main experiments (§4.1): Performance of the final student model is significantly improved compared to DANs trained from scratch.

4.4 Limitations and Discussions

Extension to sentence-pair tasks. So far we have limited the scope to single-sentence classification tasks. We consider extending our sparse distillation framework to a sentence-pair task, Quora Question Pair (QQP)[7], which aims to identify duplicated questions. We create pseudo sentence-pair data for knowledge distillation by randomly sampling 10 million question pairs from PAQ. To better model the relation between a pair of sentence, we modify DANs by introducing a concatenate-compare operator (Wang and Jiang, 2017), following the practice in (Tang et al., 2019). More specifically, the two input sentences, $\mathbf{x}_1$ and $\mathbf{x}_2$, go through the embedding layer and average pooling independently, resulting in two sentence representations, $\mathbf{h}_1$ and $\mathbf{h}_2$. We then apply the concatenate-compare operator, i.e., $f(\mathbf{h}_1, \mathbf{h}_2) = [\mathbf{h}_1, \mathbf{h}_2, \mathbf{h}_1 \odot \mathbf{h}_2, |\mathbf{h}_1 - \mathbf{h}_2|]$, where $\odot$ represents element-wise multiplication. Finally, $f(\mathbf{h}_1, \mathbf{h}_2)$ go through two fully connected layers for classification, the same as DANs for single-sentence tasks.

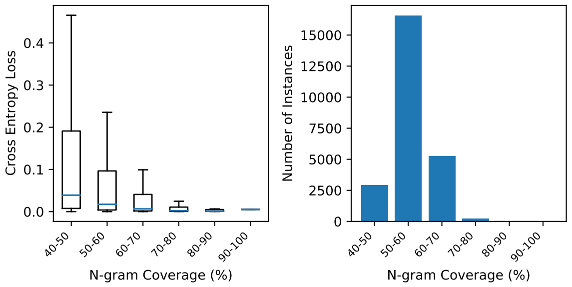

Figure 6: **Analysis on N-gram Coverage.** Left: Relation between n-gram coverage and cross-entropy loss w.r.t. ground truth labels. Each blue line represents the median loss in that n-gram coverage bucket. Right: Distribution of n-gram coverage.

The results on QQP dataset is listed in the rightmost column in Table 2. Firstly, knowledge distillation still helps close the gap between RoBERTa-Large and DANs trained from scratch (2% improvement) and leads to a decent accruacy of 84.2%; however the benefit brought by KD is not as strong as with single-sentence tasks. Secondly, the performance of DAN(KD)† (*i.e.*, without access to D_{train} during KD) is much worse than the performance of DAN(KD). We hypothesize that this is due to the quality and distribution of knowledge distillation corpus. We randomly sample questions pairs as the knowledge distillation examples, which may not carry sufficient supervision signals – more than 99% of them are negative ("not duplicated") examples. Creating more suitable distillation corpus for sentence-pair tasks is beyond the scope of our work, and we leave this as future work.

Impact of N-gram Coverage. One potential drawback of n-grams (based on white-space tokenization) is that they cannot directly handle out-of-vocabulary words, while WordPiece/BPE tokenization together with contextualization can better handle this issue. In Fig. 6, we quantify the influence of n-gram coverage on IMDB dev set. Here, n-gram coverage for an input sentence is defined as $|G \cap V|/|V|$, where G represents the set of n-grams

---

Teacher	Student	Label	Sentence
Negative	Positive	Negative	I really wanted to love this film. . . .
Negative	Positive	Negative	This movie is a great movie ONLY if you need something to sit and laugh at the stupidity of it. . . .
Positive	Negative	Positive	. . . They are such bad actors and it made this movie so much funnier to watch. . . .

Table 7: **Case study on IMDB predictions.** In these cases, the model can only make the correct predictions by understanding long contexts. Performance of DAN models are still limited as they only look at local n-grams.

in the sentence and V is the n-gram vocabulary (§2.5). We first group the instances into buckets of n-gram coverage (*e.g.*, $[40\%, 50\%), [50\%, 60\%)$) and then compute the statistics of cross-entropy loss in each bucket. We observe that performance is worse on sentences with more out-of-vocabulary words. Future work may build upon this observation and improve DANs performance by addressing out-of-vocabulary words. For example, BPE-based n-grams may be used for creating the vocabulary.

Case study: What are DANs still not capable of? We take a closer look at the predictions made by our DAN model (student) and the RoBERTa-Large model (teacher) on the IMDB dataset. We list several representative cases in Table 7. These cases typically require understating of complex language phenomena, such as irony, conditional clauses, and slang. In addition, these phenomena typically occur in contexts longer than 4 words, which DANs are not capable of modeling by design. For example, "bad actors" can mean "good actors" based on the later context "much funnier to watch". We conclude that sparse distillation is not suitable to cases where modeling complex language phenomena has a higher priority than improving inference speed.

Understanding the performance gaps. Tay et al. (2021) advocate that architectural advances should not be conflated with pre-training. Our experiments further support this claim, if we consider knowledge distillation as a "substitute" for pre-training that provides the student model with stronger inductive biases, and interpret the remaining teacher-student performance gap as the difference brought by architectural advances. On the other hand, we believe the power of DANs are previously undermined due to the challenges in optimizing large sparse models with limited supervision. Our experiments show that knowledge distillation effectively densify the supervision and greatly improve the performance of DANs.

Additional Analysis and Specifications. Due to space limit, we leave some additional analysis and specifications in Appendix C. We discuss tokenization speed (Table 9) and impact of n in n-grams (Table 10). We provide more detailed speed comparison in Table 12, model storage and memory usage information in Table 11. We provide fine-grained n-gram coverage information in Table 13.

5 Related Work

Efficient Transformers. Recent work attempts to improve computation or memory efficiency of transformer models mainly from the following perspectives: (1) Proposing efficient architectures or self-attention variants, *e.g.*, Linformer (Wang et al., 2020a), Longformer (Beltagy et al., 2020). Tay et al. (2020) provide a detailed survey along this line of work. (2) Model compression using knowledge distillation, *e.g.*, DistillBERT (Sanh et al., 2019), MobileBERT (Sun et al., 2020), MiniLM (Wang et al., 2020b). These compressed models are typically task-agnostic and general-purpose, while in this work we focus on task-specific knowledge distillation. (3) Weight quantization and pruning, *e.g.*, Gordon et al. (2020); Li et al. (2020); Kundu and Sundaresan (2021).

Task-specific Knowledge Distillation in NLP. Researchers explored distilling a fine-tuned transformer into the following lightweight architectures, including smaller transformers (Turc et al., 2019; Jiao et al., 2020), LSTMs (Tang et al., 2019; Adhikari et al., 2020) and CNNs (Chia et al., 2019). Wasserblat et al. (2020) distill BERT into an architecture similar to DAN, however they restrict the model to only take unigrams (thus having small student models), and adopt a non-standard low-resource setting. To summarize, existing work typically focuses on reducing *both* number of parameter and the amount of computation, while in the paper we study an under-explored area in the design space, where the amount of computation is reduced by training a *larger* student model.

Reducing Contextualized Representations to Static Embeddings. Related to our work, Ethayarajh (2019) and Bommasani et al. (2020) show

how static word embeddings can be computed from BERT-style transformer models. Ethayarajh (2019) suggest that less than 5% of the variance in a word's contextualized representation can be explained by a static embedding, justifying the necessity of contextualized representation. Bommasani et al. (2020) found that static embeddings obtained from BERT outperforms Word2Vec and GloVe in intrinsic evaluation. These two papers mainly focus on post-hoc interpretation of pre-trained transformer models using static embeddings. In our work we opt to use knowledge distillation to learn n-gram embeddings. Meanwhile we acknowledge that the technique in Ethayarajh (2019) and Bommasani et al. (2020) could be used as an alternative method to convert transformer models to fast text classifiers.

Sparse Architectures. In our work we aggressively cut off computation cost by compensating it with more parameters in the student model. Alternatively, one could fix the computational cost at the same level as a transformer while greatly expanding the parameter count, as explored in the Switch Transformer (Fedus et al., 2021). Both their work and ours agree in the conclusion that scaling up parameter count allows the model to memorize additional useful information.

6 Conclusions & Future Work

We investigated a new way of using knowledge distillation to produce a faster student model by reversing the standard practice of having the student be smaller than the teacher and instead allowed the student to have a large table of sparsely-activated embeddings. This enabled the student model to essentially memorize task-related information that if an alternate architecture were used would have had to be computed. We tested this method on six single-sentence classification tasks with models that were up to 1 billion parameters in size, approximately 3x as big as the RoBERTa-Large teacher model, and found that the student model was blazing fast and performed favorably.

We hope that our work can lead to further exploration of sparse architectures in knowledge distillation. There are multiple directions for future work, including extending the DAN architecture to better support tasks with long range dependencies like natural language inference or multiple inputs like text similarity. Additionally, more work is needed to test the idea on non-English languages where n-gram statistics can be different from English.

A Reproducibility

A.1 Datasets

Datasets and corpora used, and their specifications are previously listed in Table 1. Here we provide links to download these data.

- IMDB: `https://ai.stanford.edu/~amaas/data/sentiment/`
- SST-2: `https://huggingface.co/datasets/glue`
- AGNews: `https://huggingface.co/datasets/ag_news`
- TREC: `https://huggingface.co/datasets/trec`
- CivilComments: `https://huggingface.co/datasets/civil_comments`
- WikiToxic: `https://www.tensorflow.org/datasets/catalog/wikipedia_toxicity_subtypes` and `https://meta.m.wikimedia.org/wiki/Research:Detox/Data_Release`
- QQP: `https://huggingface.co/datasets/glue`
- Amazon Reviews: `https://nijianmo.github.io/amazon/index.html`
- PAQ: `https://github.com/facebookresearch/PAQ`
- Reddit News: `https://zissou.infosci.cornell.edu/convokit/datasets/subreddit-corpus/corpus-zipped/newreddits_nsfw~-~news/news.corpus.zip`

QQP dataset has 363,846 training instances and 40,430 development instances. The average input length is 13 tokens. We thank huggingface dataset team (Lhoest et al., 2021) for providing easy access to these datasets.

Licensing. For WikiToxic, the dataset is licensed under CC0, with the underlying comment text being governed by Wikipedia's CC-SA-3.0. The PAQ QA-pairs and metadata is licensed under CC-BY-SA. The licensing information of other datasets are unknown to us.

A.2 Implementation Details

N-gram pre-processing are implemented with `scikit-learn` (Pedregosa et al., 2011). DistilBERT (Sanh et al., 2019) and MobileBERT baselines are implemented in `huggingface transformers` (Wolf et al., 2020). RoBERTa-Large, BiLSTM, CNN, and DAN experiments are implemented with `fairseq` (Ott et al., 2019).

A.3 Hyperparameters

For fine-tuning in stage 1, we select batch size from {16, 32} and learning rate from {1e-5, 2e-5, 5e-5} following the recommendations in (Liu et al., 2019). We train the model for 10 epochs on D_{train}. For knowledge distillation in stage 2, we set the batch size to be 2048, learning rate to be 5e-4, and total number of updates to be 1,000,000, as they work well in our preliminary experiments. The embedding table is randomly initialized and the embedding dimension d_e is set to 1,000, unless specified otherwise. For further fine-tuning in stage 3, we set the batch size to be 32 and select the learning rate from {3e-4, 1e-4, 3e-5}. We train the model for 10 epochs on D_{train}. For all training procedures, we validate the model at the end of each epoch in the case of fine-tuning, or every 100,000 steps in the case of knowledge distillation. We save the best checkpoint based on dev accuracy. Due to the analysis nature of this work and the scale of experiments, performance are computed using dev set and based on one single run.

A.4 Hardware

Model Training. Except for the parallel training attempt in Table 5, all experiments are done on one single GPU. We train DAN models on either A100 40GB PCIe or Quadro RTX 8000 depending on availability. Knowledge distillation (Stage 2) with 1,000,000 updates typically finishes within 36 hours.

Inference Speed Tests. All inference speed tests are done with the batch size of 32. GPU inference is performed with one Quadro RTX 8000 GPU, and CPU inference is performed with 56 Intel Xeon CPU E5-2690 v4 CPUs.

B Additional Details

B.1 DAN Variations

Due to space limits we have omitted the details for the DAN variations we studied in §4.1. We introduce these variations in the following.

Attentive Pooling. We consider adding attentive pooling to the DAN model to capture more complicated relations in the input. Our attention layer is modified from the one in (Zhang et al., 2017). we use the representation $\mathbf{h}$ after mean pooling as query, and each n-gram embedding $\mathbf{e}_i = \text{Emb}(g_i)$ as key. More specifically, for each n-gram g_i we calculate an attention weight a_i as:

$$u_i = \mathbf{v}^\top \tanh(\mathbf{W}_g \mathbf{e}_i + \mathbf{W}_h \mathbf{h}) \tag{1}$$

$$a_i = \frac{\exp(u_i)}{\sum_{j=1}^{n} \exp(u_j)} \tag{2}$$

Here $\mathbf{W}_g, \mathbf{W}_h \in \mathbb{R}^{d_e \times d_a}$ and $\mathbf{v} \in \mathbb{R}^{d_a}$ are learnable parameters. d_e is the dimension of the embedding table, and d_a is the size of the attention layer. To maintain an acceptable training speed, for attentive pooling, we use a batch size of 512 during knowledge distillation.

Parallel Training We try further scaling up the student model by splitting the gigantic embedding table to different GPUs and enable parallel training, as implemented in Megatron-LM (Shoeybi et al., 2019). We train a 2-billion parameter model in parallel on two GPUs. The embedding dimension is set to be $2,000$ in total, and each GPU handles an embedding table of hidden dimension $1,000$. The vocabulary size is 1 million.

B.2 Comments on SparseAdam

SparseAdam is a modified version of the regular Adam optimizer. For Adam, the first and second moment for *each* parameter is updated at *every* step. This can be costly, especially for DAN, as most parameters in the embedding layer are not used during the forward pass. SparseAdam computes gradients and updates the moments *only* for parameters used in the forward pass.

C Additional Results

Speed Comparison. Table 12 is an extended version of Table 4 which contains inference speed comparison on IMDB and SST-2 dataset, in three different settings (GPU-FP32, GPU-FP16, CPU-FP32). Our major conclusion remains the same: DANs achieve excellent inference speed in various settings.

Vocabulary Size vs. Embedding Dimension Trade-off. Table 8 contains original results that were visualized in Fig. 4.

	Param. 500m		*Param. 1b*		*Param. 2b*	
$\lvert V \rvert$	d_e	Acc	d_e	Acc.	d_e	Acc.
1m	500	93.0	**1000**	**93.2**	–	–
2m	250	92.8	500	93.0	900	93.1
4m	125	92.7	250	92.9	500	93.1
5m	100	92.6	200	92.9	400	93.1
10m	50	92.3	100	92.5	200	92.9
20m	25	92.0	50	92.2	100	92.7
40m	–	–	25	92	50	92.4

Table 8: IMDB dev accuracy with different configurations of vocabulary size ($|V|$) and embedding table dimension (d_e). Performance grows with larger embedding tables, and the best performing model has $|V| = 1m$ and $d_e = 1,000$.

N-gram Coverage Statistics. In our work, we opt to determine the n-gram vocabulary with the training set D_{train} and the corpus C, by selecting the top 1 million n-grams according to frequency.

N-gram range is set to be within 1 to 4. For reference, we list statistics about the n-gram vocabulary in Table 13. It is possible that adjustments to this pre-processing step (*e.g.*, up-weighting n-grams in D_{train} and down-weighting n-grams in C) will further improve performance, however we stop further investigation.

Tokenization Speed. The speed comparison in our work does not take pre-processing process into account. When the inference speed is at millisecond level (*e.g.*, with our DAN model), pre-processing time can become non-negligible. For reference, in Table 9 we report the tokenization time on the 25,000 training instances in the IMDB dataset with (1) n-gram tokenization (used by DAN, implemented with `scikit-learn`); (2) BPE tokenization (used by RoBERTa/DistilRoBERTa, implemented with `fairseq`); (3) WordPiece tokenization (used by DistilBERT, implemented with `huggingface transformers`).

Tokenization Method	Time	Complexity
BPE	26.46	$O(n \lg n)$ or $O(\|V\|n)$ (Song et al., 2021)
WordPiece	20.60	$O(n^2)$ or $O(mn)$ (Song et al., 2021)
N-gram	16.45	$O(n)$

Table 9: Comparison of tokenization speed and complexity. Time is computed for tokenization the train set of IMDB dataset (25,000 instances) with one single worker. Time is averaged across 5 runs. n represents input length.

First of all, by setting the number of workers to be equal to the batch size (32) we use in the speed test, the tokenization speed will be 48632 instances/sec (=25000/16.45*32), which is roughly 3x faster than the inference speed. Tokenization speed is non-negligible in this case. Still, the main conclusion from the speed comparison remains the same: DANs are typically 10x-100x faster than the compared models.

Secondly, DAN models still have better tokenization speed than transformer models that use BPE/WordPiece tokenization. This is because our DAN model computes n-grams based on whitespace tokenization, which can be done in linear time when the n-gram to id mapping is implemented with a hashmap, *i.e.*, $O(n)$ where n is the input length. BPE/WordPiece tokenization has higher complexity according to Song et al. (2021).

We would also like to emphasize that this part is also highly dependent on the design choice and implementation. For example, the user could implement a DAN model with BPE tokenzation. The choice and optimization of tokenization is beyond the scope of this work.

Impact of n in n-grams. Similar to the post-hoc pruning experiments in §4.2, we gradually disable the usage of four-grams, trigrams and bigrams at inference time, and report the performance in Table 10.

	IMDB		AGNews	
	$\|V\|$	Acc.	$\|V\|$	Acc.
$n = 1$	54,089	74.86	81,796	91.32
$n \leq 2$	446,793	92.09	541,431	92.93
$n \leq 3$	835,403	93.33	882,489	93.03
$n \leq 4$ (all)	1,000,000	93.47	1,000,000	92.99

Table 10: **Impact of n in n-grams.** We disable usage of longer n-grams in the DAN(KD+FT) model. $|V|$ is the size of the vocabulary after disabling.

Model Storage. In Table 11 we provide more details about the disk space and memory required for using DAN models and the baseline models. Note that the GPU memory listed below is the memory used to load the *static* model. During training, more memory will be dynamically allocated during forward and backward passes. DAN uses smaller memory during training because only a small portion of the parameters are activated and trained (see the last row in Table 13). In this way we are able to use batch sizes as large as 2048 to train DANs on one single GPU, which is not possible for transformer based models.

	#Param	GPU Memory	Disk Space	Source
RoBERTa-Large	355M	2199MB	711MB	fairseq (fp16)
RoBERTa-Large	355M	2199MB	1.33GB	HF transformers (fp32)
DistilBERT	66M	1123MB	256MB	HF transformers
MobileBERT	25M	973MB	140MB	HF transformers
DistilRoBERTa	85M	1181MB	316MB	HF transformers
LSTM (2l-128d)	53M	1051MB	212MB	fairseq (fp32)
CNN (1l-256d)	53M	1119MB	213MB	fairseq (fp32)
DAN	1001M	4655MB	3.99GB	fairseq (fp32)

Table 11: Disk space and GPU memory required for each model.

D Potential Risks

It is risky to deploy DAN models to high-stakes applications (*e.g.*, medical decisions) as the model lacks the ability of understanding long context (see case study in §4.4). DANs may raise fairness concerns: it lacks ability to understand the meaning of words in context, so it may learn spurious correlations such as overemphasis on group identifiers.

	Parameter Count			IMDB				SST-2

We believe a thorough analysis is needed and bias mitigation methods such as (Bolukbasi et al., 2016; Kennedy et al., 2020) are necessary for combating these issues.

Towards Understanding Large-Scale Discourse Structures in Pre-Trained and Fine-Tuned Language Models

Patrick Huber and Giuseppe Carenini
Department of Computer Science
University of British Columbia
Vancouver, BC, Canada, V6T 1Z4
{huberpat, carenini}@cs.ubc.ca

Abstract

With a growing number of BERTology works analyzing different components of pre-trained language models, we extend this line of research through an in-depth analysis of discourse information in pre-trained and fine-tuned language models. We move beyond prior work along three dimensions: First, we describe a novel approach to infer discourse structures from arbitrarily long documents. Second, we propose a new type of analysis to explore where and how accurately intrinsic discourse is captured in the BERT and BART models. Finally, we assess how similar the generated structures are to a variety of baselines as well as their distributions within and between models.

1 Introduction

Transformer-based machine learning models are an integral part of many recent improvements in Natural Language Processing (NLP). With their rise spearheaded by Vaswani et al. (2017), the pre-training/fine-tuning paradigm has gradually replaced previous approaches based on architecture engineering, with transformer models such as BERT (Devlin et al., 2019), BART (Lewis et al., 2020), RoBERTa (Liu et al., 2019) and others delivering state-of-the-art performance on a wide variety of tasks. Besides their strong empirical results on most real-world problems, such as summarization (Zhang et al., 2020; Xiao et al., 2021a), question-answering (Joshi et al., 2020; Oğuz et al., 2021) and sentiment analysis (Adhikari et al., 2019; Yang et al., 2019), uncovering what kind of linguistic knowledge is captured by this new type of pre-trained language models (PLMs) has become a prominent question by itself. As part of this line of research, called *BERTology* (Rogers et al., 2020), researchers explore the amount of linguistic understanding encapsulated in PLMs, exposed through either external probing tasks (Raganato and Tiedemann, 2018; Zhu et al., 2020; Koto et al., 2021a) or unsupervised methods (Wu et al., 2020; Pandia et al., 2021). Previous work thereby either focuses on analyzing the syntactic structures (e.g., Hewitt and Manning (2019); Wu et al. (2020)), relations (Papanikolaou et al., 2019), ontologies (Michael et al., 2020) or, to a more limited extend, discourse related behaviour (Zhu et al., 2020; Koto et al., 2021a; Pandia et al., 2021).

Generally speaking, while most previous *BERTology* works has focused on either sentence level phenomena or connections between adjacent sentences, large-scale semantic and pragmatic structures (oftentimes represented as discourse trees or graphs) have been less explored. These structures (e.g., discourse trees) play a fundamental role in expressing the intent of multi-sentential documents and, not surprisingly, have been shown to benefit many NLP tasks such as summarization (Gerani et al., 2019), sentiment analysis (Bhatia et al., 2015; Nejat et al., 2017; Hogenboom et al., 2015) and text classification (Ji and Smith, 2017).

With multiple different theories for discourse proposed in the past, the RST discourse theory (Mann and Thompson, 1988) and the lexicalized discourse grammar (Webber et al., 2003) (underlying PDTB (Prasad et al., 2008)) have received most attention. While both theories propose tree-like structures, the PDTB framework postulates partial trees up to the between-sentence level, while RST-style discourse structures consist of a single rooted tree covering whole documents, comprising of: (1) The tree structure, combining clause-like sentence fragments (Elementary Discourse Units, short: EDUs) into a discourse constituency tree, (2) Nuclearity, assigning every tree-branch primary (*Nucleus*) or peripheral (*Satellite*) importance in a local context and (3) Relations, defining the type of connection holding between siblings in the tree.

Given the importance of large-scale discourse structures, we extend the area of *BERTology* research with novel insights regarding the amount of

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2376 - 2394
July 10-15, 2022

intrinsic discourse information captured in established PLMs. More specifically, we aim to better understand to what extend RST-style discourse information is stored as latent trees in encoder self-attention matrices[1]. While we focus on the RST formalism in this work, our presented methods are theory-agnostic and, hence, applicable to discourse structures in a broader sense, including other tree-based theories, such as the lexicalized discourse grammar. Our contributions in this paper are:

(1) A novel approach to extract discourse information from arbitrarily long documents with standard transformer models, inherently limited by their input size. This is a non-trivial issue, which has been mostly by-passed in previous work through the use of proxy tasks like connective prediction, relation classification, sentence ordering, EDU segmentation, cloze story tests and others.

(2) An exploration of discourse information locality across pre-trained and fine-tuned language models, finding that discourse structures are consistently captured in a fixed subset of self-attention heads.

(3) An in-depth analysis of the discourse quality in pre-trained language models and their fine-tuned extensions. We compare constituency and dependency structures of 2 PLMs fine-tuned on 4 tasks and 7 fine-tuning datasets to gold-standard discourse trees, finding that the captured discourse structures outperform simple baselines by a large margin, even showing superior performance compared to distantly supervised models.

(4) A similarity analysis between PLM inferred discourse trees and supervised, distantly supervised and simple baselines. We reveal that PLM constituency discourse trees do align relatively well with previously proposed supervised models, but also capture complementary information.

(5) A detailed look at information redundancy in self-attention heads to better understand the structural overlap between self-attention matrices and models. Our results indicate that similar discourse information is consistently captured in the same heads, even across fine-tuning tasks.

2 Related Work

At the base of our work are two of the most popular and frequently used PLMs: BERT (Devlin et al., 2019) and BART (Lewis et al., 2020). We choose these two popular approaches in our study due to their complementary nature (encoder-only vs. encoder-decoder) and based on previous work by Zhu et al. (2020) and Koto et al. (2021a), showing the effectiveness of BERT and BART models for discourse related tasks.

Our work is further related to the field of discourse parsing. With a rich history of traditional machine learning models (e.g., Hernault et al. (2010); Ji and Eisenstein (2014); Joty et al. (2015); Wang et al. (2017), *inter alia*), recent approaches slowly shifted to successfully incorporate a variety of PLMs into the process of discourse prediction, such as ELMo embeddings (Kobayashi et al., 2019), XLNet (Nguyen et al., 2021), BERT (Koto et al., 2021b), RoBERTa (Guz et al., 2020) and SpanBERT (Guz and Carenini, 2020). Despite these works showing the usefulness of PLMs for discourse parsing, all of them cast the task into a “local" problem, using only partial information through the shift-reduce framework (Guz et al., 2020; Guz and Carenini, 2020), natural document breaks (e.g. paragraphs Kobayashi et al. (2020)) or by framing the task as an inter-EDU sequence labelling problem on partial documents (Koto et al., 2021b). However, we believe that the true benefit of discourse information emerges when complete documents are considered, leading us to propose a new approach to connect PLMs and discourse structures in a “global” manner, superseding the local proxy-tasks with a new methodology to explore arbitrarily long documents.

Aiming to better understand what information is captured in PLMs, the line of *BERTology* research has recently emerged (Rogers et al., 2020), with early work mostly focusing on the syntactic capacity of PLMs (Hewitt and Manning, 2019; Jawahar et al., 2019; Kim et al., 2020), in parts also exploring the internal workings of transformer-based models (e.g., self-attention matrices (Raganato and Tiedemann, 2018; Mareček and Rosa, 2019)). More recent work started to explore the alignment of PLMs with discourse information, encoding semantic and pragmatic knowledge. Along those lines, Wu et al. (2020) present a parameter-free probing task for both, syntax and discourse. With their tree inference approach being computationally expensive and limited to the exploration of the outputs of the BERT model, we significantly extend this line of research by exploring the internal self-attention matrices of PLMs with a more computationally feasible approach. More tradi-

---

[1] Please note that we focus on discourse structure and nuclearity here, leaving relation classification for future work.

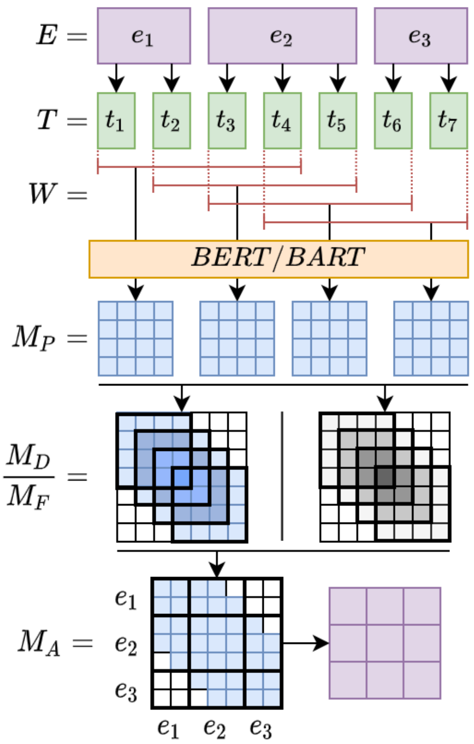

Figure 1: Small-scale example of the discourse extraction approach. Purple=EDUs, green=sub-word embeddings, red=input slices of size t_{max}, orange=PLM, blue=self-attention values, grey-scale=frequency count.

tionally, Zhu et al. (2020) use 24 hand-crafted rhetorical features to execute three different supervised probing tasks, showing promising performance of the BERT model. Similarly, Pandia et al. (2021) aim to infer pragmatics through the prediction of discourse connectives by analyzing the model inputs and outputs and Koto et al. (2021a) analyze discourse in seven PLMs through seven supervised probing tasks, finding that BART and BERT contain most information related to discourse. In contrast to the approach taken by both Zhu et al. (2020) and Koto et al. (2021a), we use an unsupervised methodology to test the amount of discourse information stored in PLMs (which can also conveniently be used to infer discourse structures for new and unseen documents) and extend the work by Pandia et al. (2021) by taking a closer look at the internal workings of the self-attention component. Looking at prior work analyzing the amount of discourse information in PLMs, structures are solely explored through the use of proxy tasks, such as connective prediction (Pandia et al., 2021), relation classification (Kurfalı and Östling, 2021), and others (Koto et al., 2021a). However, despite the difficulties of encoding arbitrarily long documents, we believe that to systematically explore the relationship between PLMs and discourse, considering complete documents is imperative. Along these lines, recent work started to tackle the inherent input-length limitation of general transformer models through additional recurrence in the Transformer-XL model (Dai et al., 2019), compression modules (Rae et al., 2020) or sparse patterns (e.g., as in the Reformer (Kitaev et al., 2020), BigBird (Zaheer et al., 2020), and Longformer (Beltagy et al., 2020) models). While all these approaches to extend the maximum document length of transformer-based models are important to create more globally inspired models, the document-length limitation is still practically and theoretically in place, with models being limited to a fixed number of pre-defined tokens the model can process. Furthermore, with many proposed systems still based on more established PLMs (e.g., BERT) and with no single dominant solution for the general problem of the input length-limitation yet, we believe that even with the restriction being actively tackled, an in-depth analysis of traditional PLMs with discourse is highly valuable to establish a solid understanding of the amount of semantic and pragmatic information captured.

Besides the described *BERTology* work, we got encouraged to explore fine-tuned extensions of standard PLMs through previous work showing the benefit of discourse parsing for many downstream tasks, such as summarization (Gerani et al., 2019), sentiment analysis (Bhatia et al., 2015; Nejat et al., 2017; Hogenboom et al., 2015) and text classification (Ji and Smith, 2017). Conversely, we recently showed promising results when inferring discourse structures from related downstream tasks, such as sentiment analysis (Huber and Carenini, 2020) and summarization (Xiao et al., 2021b). Given this bidirectional synergy between discourse and the mentioned downstream tasks, we move beyond traditional experiments focusing on standard PLMs and additionally explore discourse structures of PLMs fine-tuned on a variety of auxiliary tasks.

3 Discourse Extraction Method

With PLMs rather well analyzed according to their syntactic capabilities, large-scale discourse structures have been less explored. One reason for this is the input length constraint of transformer models. While this is generally not prohibitive for intra-sentence syntactic structures (e.g., presented in Wu et al. (2020)), it does heavily influence large-scale discourse structures, operating on complete (potentially long) documents. Overcoming this limitation is non-trivial, since traditional transformer-based models only allow for fixed, short inputs.

Aiming to systematically explore the ability of PLMs to capture discourse, we investigate a novel way to effectively extract discourse structures from the self-attention component of the BERT and BART models. We thereby extend our previously proposed tree-generation methodology (Xiao et al., 2021b) to support the input length constraints of standard PLMs using a sliding-window approach in combination with matrix frequency normalization and an EDU aggregation method. Figure 1 visualizes the complete process on a small scale example with 3 EDUs and 7 sub-word embeddings.

The Tree Generation Procedure we previously proposed in Xiao et al. (2021b) explores a two-stage approach to obtain discourse structures from a transformer model, by-passing the input-length constraint. Using the intuition that the self-attention score between any two EDUs is an indicator of their semantic/pragmatic relatedness, influencing their distance in a projective discourse tree, they use the CKY dynamic programming approach (Jurafsky and Martin, 2014) to generate constituency trees based on the internal self-attention of the transformer model. To generate dependency trees, we apply the same intuition used to infer discourse trees with the Eisner algorithm (Eisner, 1996). Since we explore the discourse information captured in standard PLMs, we can't directly transfer our two-stage approach in Xiao et al. (2021b), first encoding individual EDUs using BERT and subsequently feeding the dense representations into a fixed-size transformer model. Instead, we propose a new method to overcome the length-limitation of the transformer model[2].

The Sliding-Window Approach is at the core of our new methodology to overcome the input-length constraint. We first tokenize arbitrarily long documents with n EDUs $E = \{e_1, ..., e_n\}$ into the respective sequence of m sub-word tokens $T = \{t_1, ...t_m\}$ with $n \ll m$, according to the PLM tokenization method (WordPiece for BERT, Byte-Pair-Encoding for BART), as show at the top of Figure 1. Using the sliding window approach, we subdivide the m sub-word tokens into sequences of maximum input length t_{max}, defined by the PLM ($t_{max} = 512$ for BERT, $t_{max} = 1024$ for BART). Using a stride of 1, we generate $(m - t_{max}) + 1$ sliding windows W, feed them into the PLM, and extract the resulting $t_{max} \times t_{max}$ partial square self-attention matrices (M_P in Figure 1) for a specific self-attention head[3].

The Frequency Normalization Method allows us to combine the partially overlapping self-attention matrices M_P into a single document-level matrix M_D of size $m \times m$. To this end, we combine multiple overlapping windows, generated due to the stride size of 1, by adding up the self-attention cells, while keeping track of the number of overlaps in a separate $m \times m$ frequency matrix M_F. We then divide M_D by the frequency matrix M_F, to generate a frequency normalized self-attention matrix M_A (see bottom of Figure 1).

The EDU Aggregation is the final processing step to obtain the document-level self-attention matrix. In this step, the m sub-word tokens $T = \{t_1, ...t_m\}$ are aggregated back into n EDUs $E = \{e_1, ..., e_n\}$ by computing the average bidirectional self-attention score between any two EDUs in M_A. For example, in Figure 1, we aggregate the scores in cells $M_A[0{:}1, 5{:}6]$ to compute the final output of cell $[0, 2]$ (purple matrix in Figure 1) and $M_A[5{:}6, 0{:}1]$ to generate the value of cell $[0, 2]$. This way, we obtain the average bidirectional self-attention scores between EDU_1 and EDU_3. We use the resulting $n \times n$ matrix as the input to the CKY/Eisner discourse tree generation methods.

4 Experimental Setup

4.1 Pre-Trained Models

We select the *BERT-base* (110 million parameters) and *BART-large* (406 million parameters) models for our experiments. We choose these models for their diverse objectives (encoder-only vs. encoder-decoder), popularity for diverse fine-tuning tasks, and their prior successful exploration in regards to discourse information (Zhu et al., 2020; Koto et al., 2021a). For the *BART-large* model, we limit our analysis to the encoder, as motivated in Koto et al. (2021a), leaving experiments with the decoder and cross-attention for future work.

XSUM(2018)	Summarization	News
SQuAD(2016)	Question-Answering	Wikipedia

Table 1: The seven fine-tuning datasets used in this work along with the underlying tasks and domains.

4.2 Fine-Tuning Tasks and Datasets

We explore the BERT model fine-tuned on two classification tasks, namely sentiment analysis and natural language inference (NLI). For our analysis on BART, we select the abstractive summarization and question answering tasks. Table 1 summarizes the 7 datasets used to fine-tune PLMs in this work, along with their underlying tasks and domains[4].

4.3 Evaluation Treebanks

RST-DT (Carlson et al., 2002) is the largest English RST-style discourse treebank, containing 385 Wall-Street-Journal articles, annotated with full constituency discourse trees. To generate additional dependency trees, we apply the conversion algorithm proposed in Li et al. (2014).

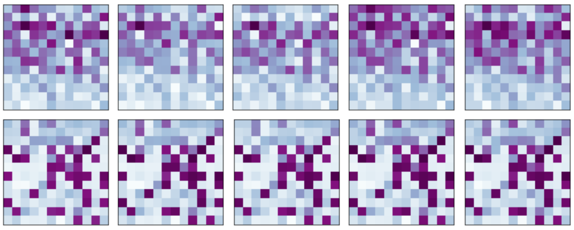
GUM (Zeldes, 2017) is a steadily growing treebank of richly annotated texts. In the current version 7.3, the dataset contains 168 documents from 12 genres, annotated with full RST-style constituency and dependency discourse trees.

All evaluations shown in this paper are executed on the 38 and 20 documents in the RST-DT and GUM test-sets, to be comparable with previous baselines and supervised models. A similarly-sized validation-set is used where mentioned to determine the best performing self-attention head.

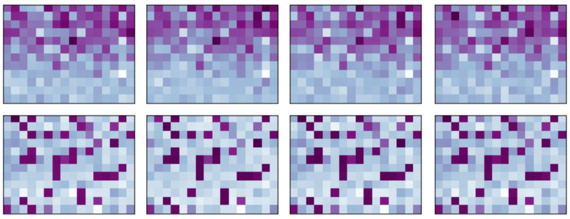
4.4 Baselines and Evaluation Metrics

Simple Baselines: We compare the inferred constituency trees against right- and left-branching structures. For dependency trees, we evaluate against simple chain and inverse chain structures.

Distantly Supervised Baselines: We compare our results obtained in this paper against our previous approach presented in Xiao et al. (2021b), using similar CKY and Eisner tree-generation methods to infer constituency and dependency tree structures from a summarization model trained on the CNN-DM and New York Times (NYT) corpora (referred to as $\textit{Sum}_{\textit{CNN-DM}}$ and $\textit{Sum}_{\textit{NYT}}$)[5].



(a) BERT: PLM, +IMDB, +Yelp, +SST-2, +MNLI



(b) BART: PLM, +CNN-DM, +XSUM, +SQuAD

Figure 2: Constituency (top) and dependency (bottom) discourse tree evaluation of BERT (a) and BART (b) models on GUM. Purple=high score, Blue=low score. Left-to-right: self-attention heads, top-to-bottom: high layers to low layers. + indicates fine-tuning dataset.

Supervised Baseline: We select the popular Two-Stage discourse parser (Wang et al., 2017) as our supervised baseline, due to its strong performance, available model checkpoints and code[6], as well as the traditional architecture. We use the published Two-Stage parser checkpoint on RST-DT (from here on called $\textit{Two-Stage}_{\textit{RST-DT}}$) and re-train the discourse parser on GUM ($\textit{Two-Stage}_{\textit{GUM}}$). We convert the generated constituency structures into dependency trees following Li et al. (2014).

Evaluation Metrics: We apply the original parseval score to compare discourse constituency structures with gold-standard treebanks, as argued in Morey et al. (2017). To evaluate the generated dependency structures, we use the Unlabeled Attachment Score (UAS).

5 Experimental Results

5.1 Discourse Locality

Our discourse tree generation approach described in section 3 directly uses self-attention matrices to generate discourse trees. The standard BERT

---

[4] We exclusively analyze published models provided on the huggingface platform, further specified in Appendix A.

[5] `www.github.com/Wendy-Xiao/summ_guided_disco_parser`

[6] `www.github.com/yizhongw/StageDP`

model contains 144 of those self-attention matrices (12 layers, 12 self-attention heads each), all of which potentially encode discourse structures. For the BART model, this number is even higher, consisting of 12 layers with 16 self-attention heads each. With prior work suggesting the locality of discourse information in PLMs (e.g., Raganato and Tiedemann (2018); Mareček and Rosa (2019); Xiao et al. (2021b)), we analyze every self-attention matrix individually to gain a better understanding of their alignment with discourse information.

Besides investigating standard PLMs, we also explore the robustness of discourse information across fine-tuning tasks. We believe that this is an important step to better understand if the captured discourse information is general and robust, or if it is "re-learned" from scratch for downstream tasks. To the best of our knowledge, no previous analysis of this kind has been performed in the literature.

To this end, Figure 2 shows the constituency and dependency structure overlap of the generated discourse trees from individual self-attention heads with the gold-standard tree structures of the GUM dataset[7]. The heatmaps clearly show that constituency discourse structures are mostly captured in higher layers, while dependency structures are more evenly distributed across layers. Comparing the patterns between models, we find that, despite being fine-tuned on different downstream tasks, the discourse information is consistently encoded in the same self-attention heads. Even though the best performing self-attention matrix is not consistent, discourse information is clearly captured in a "local" subset of self-attention heads across all presented fine-tuning tasks. This plausibly suggests that the discourse information in pre-trained BERT and BART models is robust and general, requiring only minor adjustments depending on the fine-tuning task.

5.2 Discourse Quality

We now focus on assessing the discourse information captured in the single best-performing self-attention head. In Table 2, we compare the discourse structure quality of pre-trained and fine-tuned PLMs in the context of supervised models, distantly supervised approaches and simple baselines. We show the oracle-picked best head on the test-set, analyzing the upper-bound for the potential performance of PLMs on RST-style discourse structures. This is not a realistic scenario, as the best performing head is generally not known a-priori. Hence, we also explore the performance using a small-scale validation set to pick the best-performing self-attention matrix. In this more realistic scenario for discourse parsing, we find that scores on average drop by 1.55 points for BERT and 1.33% for BART compared to the oracle-picked performance of a single self-attention matrix. We show detailed results of this degradation in Appendix C[8]. Our results in Table 2 are separated into three sub-tables, showing the results for BERT, BART and baseline models on the RST-DT and GUM treebanks, respectively. In the BERT and BART sub-table, we further annotate each performance with ↑, •, ↓, indicating the relative performance to the standard pre-trained model as supe-

Model	RST-DT		GUM	
	Span	UAS	Span	UAS
BERT				
rand. init	↓ 25.5	↓ 13.3	↓ 23.2	↓ 12.4
PLM	• 35.7	• 45.3	• 33.0	• 45.2
+ IMDB	↓ 35.4	↓ 42.8	• 33.0	↓ 43.3
+ Yelp	↓ 34.7	↓ 42.3	↓ 32.6	↓ 43.7
+ SST-2	↓ 35.5	↓ 42.9	↓ 32.6	↓ 43.5
+ MNLI	↓ 34.8	↓ 41.8	↓ 32.4	↓ 43.3
BART				
rand. init	↓ 25.3	↓ 12.5	↓ 23.2	↓ 12.2

Sum$_{\text{CNN-DM}}$	21.4	20.5	17.6	15.8
Sum$_{\text{NYT}}$	24.0	15.7	18.2	12.6
Two-Stage$_{\text{RST-DT}}$	72.0	71.2	54.0	54.5
Two-Stage$_{\text{GUM}}$	65.4	61.7	58.6	56.7

Table 2: Original parseval (Span) and Unlabelled Attachment Score (UAS) of the single best performing self-attention matrix of the BERT and BART models compared with baselines and previous work. ↑, •, ↓ indicate better, same, worse performance compared to the PLM. "rand. init"=Randomly initialized transformer model of similar architecture as the PLM, RB=Right-Branching, LB=Left-Branching, Chain^{-1}=Inverse chain.

---

[7] The analysis on RST-DT shows similar trends and can be found in Appendix B.

[8] For a more detailed analysis of the min., mean, median and max. self-attention performances see Appendix D.

rior, equal, or inferior.

Taking a look at the top sub-table (BERT) we find that, as expected, the randomly initialized transformer model achieves the worst performance. Fine-tuned models perform equal or worse than the standard PLM. Despite the inferior results of the fine-tuned models, the drop is rather small, with the sentiment analysis models consistently outperforming NLI. This seems reasonable, given that the sentiment analysis objective is intuitively more aligned with discourse structures (e.g., long-form reviews with potentially complex rhetorical structures) than the between-sentence NLI task, not involving multi-sentential text.

In the center sub-table (BART), a different trend emerges. While the worst performing model is still (as expected) the randomly initialized system, fine-tuned models mostly outperform the standard PLM. Interestingly, the model fine-tuned on the CNN-DM corpus consistently outperforms the BART baseline, while the XSUM model performs better on all but the GUM dependency structure evaluation. On one hand, the superior performance of both summarization models on the RST-DT dataset seems reasonable, given that the fine-tuning datasets and the evaluation treebank are both in the news domain. The strong results of the CNN-DM model on the GUM treebank, yet inferior performance of XSUM, potentially hints towards dependency discourse structures being less prominent when fine-tuning on the extreme summarization task, compared to the longer summaries in the CNN-DM corpus. The question-answering task evaluated through the SQuAD fine-tuned model underperforms the standard PLM on GUM, however reaches superior performance on RST-DT. Since the SQuAD corpus is a subset of Wikipedia articles, more aligned with news articles than the 12 genres in GUM, we believe the stronger performance on RST-DT (i.e., news articles) is again reasonable, yet shows weaker generalization capabilities across domains (i.e., on the GUM corpus). Interestingly, the question-answering task seems more aligned with dependency than constituency trees, in line with what would be expected from a factoid-style question-answering model, focusing on important entities, rather than global constituency structures.

Directly comparing the BERT and BART models, the former performs better on three out of four metrics. At the same time, fine-tuning hurts the performance for BERT, however, improves BART models. Plausibly, these seemingly unintuitive results may be caused by the following co-occurring circumstances: (1) The inferior performance of BART can potentially be attributed to the decoder component capturing parts of the discourse structures, as well as the larger number of self-attention heads "diluting" the discourse information. (2) The different trends regarding fine-tuned models might be directly influenced by the input-length limitation to 512 (BERT) and 1024 (BART) subword tokens during the fine-tuning stage, hampering the ability to capture long-distance semantic and pragmatic relationships. This, in turn, limits the amount of discourse information captured, even for document-level datasets (e.g., Yelp, CNN-DM, SQuAD). With this restriction being more prominent in BERT, it potentially explains the comparably low performance of the fine-tuned models.

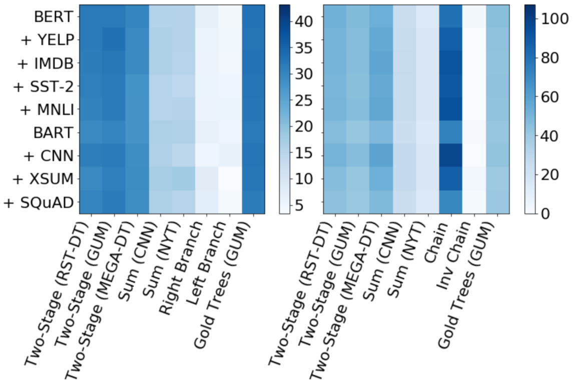

Figure 3: PLM discourse constituency (left) and dependency (right) structure overlap with baselines and gold trees (e.g., BERT ↔ Two-Stage (RST-DT)) according to the original parseval and UAS metrics.

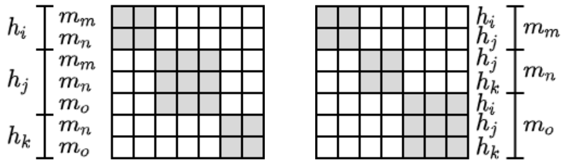
Finally, the bottom sub-table puts our results in the context of previously proposed supervised and distantly-supervised models, as well as simple baselines. Compared to simple right- and left-branching trees (Span), the PLM-based models reach clearly superior performance. Looking at the chain/inverse chain structures (UAS), the improvements are generally lower, however, the vast majority still outperforms the baseline. Comparing the first two sub-tables against completely supervised methods (Two-Stage$_{\text{RST-DT}}$, Two-Stage$_{\text{GUM}}$), the BERT- and BART-based models are, unsurprisingly, inferior. Lastly, compared to the distantly supervised Sum$_{\text{CNN-DM}}$ and Sum$_{\text{NYT}}$ models, the PLM-based discourse performance shows clear improvements over the 6-layer, 8-head standard transformer.



(a) Head-aligned (b) Model-aligned

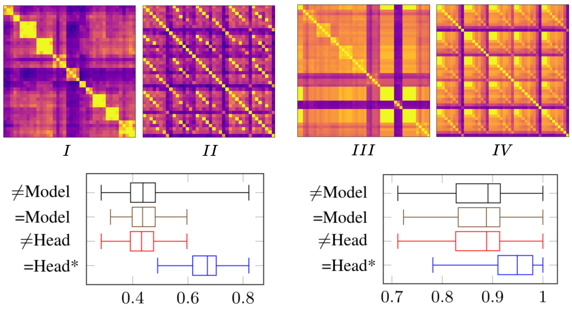
Figure 4: Nested aggregation approach for discourse similarity. (a) Grey cells contain same-head, white cells indicate different heads. (b) Grey cells contain same-model, white cells indicate different models. Column indices equal row indices.

5.3 Discourse Similarity

Further exploring what kind of discourse information is captured in the PLM self-attention matrices, we directly compare the emergent discourse structures with trees inferred from existing discourse parsers and simple baselines. This way, we aim to better understand if the information encapsulated in PLMs is complementary to existing methods, or if the PLMs solely capture trivial discourse phenomena and simple biases (e.g., resemble right-branching constituency trees). Since the GUM dataset contains a more diverse set of test documents (12 genres) than the RST-DT corpus (exclusively news articles), we perform our experiments from here on only on the GUM treebank.

Figure 3 shows the micro-average structural overlap of discourse constituency (left) and dependency (right) trees between the PLM-generated discourse structures and existing methods, baselines, as well as gold-standard trees. Noticeably, the generated constituency trees (on the left) are most aligned with the structures predicted by supervised discourse parsers, showing only minimal overlap to simple structures (i.e., right- and left-branching trees). Taking a closer look at the generated dependency structures presented on the right side in Figure 3, the alignment between PLM inferred discourse trees and the simple chain structure is predominant, suggesting a potential weakness in regards to the discourse exposed by the Eisner algorithm in the BERT and BART model. Not surprisingly, the highest overlap between PLM-generated trees and the chain structure occurs when fine-tuning on the CNN-DM dataset, well-known to contain a strong lead-bias (Xing et al., 2021).

To better understand if the PLM-based constituency structures are complementary to existing, supervised discourse parsers, we further analyze the correctly predicted overlap. More specifically, we compute the intersection between PLM generated structures and gold-standard trees as well as previously proposed models and the gold-standard. Subsequently, we intersect the two resulting sets (e.g., BERT ∩ Gold Trees ↔ Two-Stage (RST-DT) ∩ Gold Trees). This way, we explore if the correctly predicted PLM discourse structures are a subset of the correctly predicted trees by supervised approaches, or if complementary discourse information is captured. We find that $> 20\%$ and $> 16\%$ of the correctly predicted constituency and dependency structures of our PLM discourse inference approach are not captured by supervised models, making the exploration of ensemble methods a promising future avenue. A detailed version of Fig. 3 as well as more specific results regarding the correctly predicted overlap of discourse structures are shown in Appendix E.



(a) Constituency Similarity (b) Dependency Similarity

Figure 5: BERT self-attention similarities on GUM. Top: Visual analysis of head-aligned ($I\&III$) and model-aligned ($II\&IV$) heatmaps. Yellow=high structural overlap, purple=low structural overlap.
Bottom: Aggregated similarity of same heads, same models, different heads and different models showing the min, max and quartiles of the underlying distribution. *Significantly better than respective ≠Head/≠Model performance with p-value < 0.05.

5.4 Discourse Redundancy

Up to this point, our quantitative analysis of the ability of PLMs to capture discourse information has been limited to the single best-performing head. However, looking at individual models, the discourse performance distribution in Figure 2 suggests that a larger subset of self-attention heads performs similarly well (i.e., there are several dark purple cells in each heatmap). This leads to the interesting questions if the information captured in different, top-performing self-attention heads is redundant or complementary. Similarly, Figure 2 indicates that the same heads perform well across different fine-tuning tasks, leading to the question if the discourse structures captured in a single self-attention matrix of different fine-tuned models is consistent, or varies depending on the underlying task. Hence, we take a detailed look at the similarity of model self-attention heads in regards to their alignment with discourse information and explore if (1) the top performing heads $h_i, ..., h_k$ of a specific model m_m capture redundant discourse structures, and if (2) the discourse information captured by a specific head h_i across different models $m_m, ..., m_o$ contain similar discourse information.

Specifically, we pick the top 10 best performing self-attention matrices of each model, remove self-attention heads that don't appear in at least two models (since no comparisons can be made), and compare the generated discourse structures in a nested aggregation approach.

Figure 4 shows a small-scale example of our nested visualization methodology. For the self-attention head-aligned approach (Figure 4 (a)), high similarity values (calculated as the micro-average structural overlap) along the diagonal (grey cells) would be expected if the same head h_i encodes consistent discourse information across different fine-tuning tasks and datasets. Inversely, the model-aligned matrix (Figure 4 (b)) should show high values along the diagonal if different heads $h_i, ..., h_k$ in the same model m_k capture redundant discourse information. Besides the visual inspection methodology presented in Figure 4, we also compare aggregated similarities between the same head (=Head) against different heads (≠Head) and between the same model (=Model) against different models (≠Model) (i.e., grey cells (=) and white cells (≠) in Figure 4 (a) and (b)). In order to assess the statistical significance of the resulting differences in the underlying distributions, we compute a two-sided, independent t-test between same/different models and same/different heads[9].

The resulting redundancy evaluations for BERT are presented in Figure 5[10]. It appears that the same self-attention heads h_i consistently encode similar discourse information across models indicated by: (1) High similarities (yellow) along the diagonal in heatmaps $I\&III$ and (2) through the statistically significant difference in distributions at the bottom of Figure 5 (a) and (b). However, different self-attention heads $h_i, ..., h_k$ of the same model m_m encode different discourse information (heatmaps $II\&IV$). While the trend is stronger for constituency tree structures, there is a single dependency self-attention head which does generally not align well between models and heads (purple line in heatmap III). Plausibly, this specific self-attention head encodes fine-tuning task specific discourse information, making it a prime candidate for further investigations in future work. Furthermore, the similarity patterns observed in Figure 5 (a) and (b) point towards an opportunity to combine model self-attention heads to improve the discourse inference performance compared to the scores shown in Table 2, where each self-attention head was assessed individually, in future work.

6 Conclusions

In this paper, we extend the line of *BERTology* work by focusing on the important, yet less explored, alignment of pre-trained and fine-tuned PLMs with large-scale discourse structures. We propose a novel approach to infer discourse information for arbitrarily long documents. In our experiments, we find that the captured discourse information is consitently local and general, even across a collection of fine-tuning tasks. We compare the inferred discourse trees with supervised, distantly supervised and simple baselines to explore the structural overlap, finding that constituency discourse trees align well with supervised models, however, contain complementary discourse information. Lastly, we individually explore self-attention matrices to analyze the information redundancy. We find that similar discourse information is consistently captured in the same heads.

In the future, we intend to explore additional discourse inference strategies based on the insights we gained in this analysis. Specifically, we want to explore more sophisticated methods to extract a single discourse tree from multiple self-attention matrices, rather than only the single best-performing head. Further, we want to investigate the relationship between supervised discourse parsers and PLM generated discourse trees and more long term, we plan to analyze PLMs with enhanced input-length limitations.

---

[9] Prior to running the t-test we confirm similar variance and the assumption of normal distribution (Shapiro-Wilk test).

[10] Evaluations for BART can be found in Appendix F.

Abstract

Stepping from sentence-level to document-level, the research on relation extraction (RE) confronts increasing text length and more complicated entity interactions. Consequently, it is more challenging to encode the key information sources—relevant contexts and entity types. However, existing methods only *implicitly* learn to model these critical information sources while being trained for RE. As a result, they suffer the problems of ineffective supervision and uninterpretable model predictions. In contrast, we propose to *explicitly* teach the model to capture relevant contexts and entity types by Supervising and Augmenting Intermediate Steps (SAIS) for RE. Based on a broad spectrum of carefully designed tasks, our proposed SAIS method not only extracts relations of better quality due to more effective supervision, but also retrieves the corresponding supporting evidence more accurately so as to enhance interpretability. By assessing model uncertainty, SAIS further boosts the performance via evidence-based data augmentation and ensemble inference while reducing the computational cost. Eventually, SAIS delivers state-of-the-art RE results on three benchmarks (DocRED, CDR, and GDA) and outperforms the runner-up by 5.04% relatively in F1 score in evidence retrieval on DocRED.[1]

1 Introduction

Playing a crucial role in the continuing effort of transforming unstructured text into structured knowledge, RE (Bach and Badaskar, 2007) seeks to identify relations between an entity pair based on a given piece of text. Earlier studies mostly pay attention to sentence-level RE (Zhang et al., 2017; Hendrickx et al., 2019) (i.e., the targeting entity pair co-occur within a sentence) and achieve promising results (Zhang et al., 2019; Zhou et al., 2020). Based on an extensive empirical analysis, Peng et al. (2020) reveals that textual contexts and entity types are the major information sources that lead to the success of prior approaches.

Given that more complicated relations are often expressed by multiple sentences, recent focus of RE has been largely shifted to the document level (Yao et al., 2019; Cheng et al., 2021). Existing document-level RE methods (Zeng et al., 2020; Zhou et al., 2021) utilize advanced neural architectures such as heterogeneous graph neural networks (Yang et al., 2020) and pre-trained language models (Xu et al., 2021b). However, although documents typically include longer contexts and more intricate entity interactions, most prior methods only *implicitly* learn to encode contexts and entity types while being trained for RE. As a result, they deliver inferior and uninterpretable results.

On the other hand, it has been a trend that many recent datasets support the training of more powerful language models by providing multi-task annotations such as coreference and evidence (Yao et al., 2019; Li et al., 2016; Wu et al., 2019). Therefore, in contrast to existing methods, we advocate for *explicitly* guiding the model to capture textual contexts and entity type information by Supervising and Augmenting Intermediate Steps (SAIS) for RE. More specifically, we argue that, from the input document with annotated entity mentions to the ultimate output of RE, there are four intermediate steps involved in the reasoning process. Consider the motivating example in Figure 1:

(1) **Coreference Resolution (CR):** Although Sentence 0 describes the "*citizenship*" of "*Carl Linnaeus the Younger*" and Sentence 1 discusses the "*father*" of "*Linnaeus filius*", the two names essentially refer to the same person. Hence, given a document, we need to first resolve various contextual roles represented by different mentions of the same entity via CR.

(2) **Entity Typing (ET):** After gathering contextual information from entity mentions, ET reg-

July 10-15, 2022

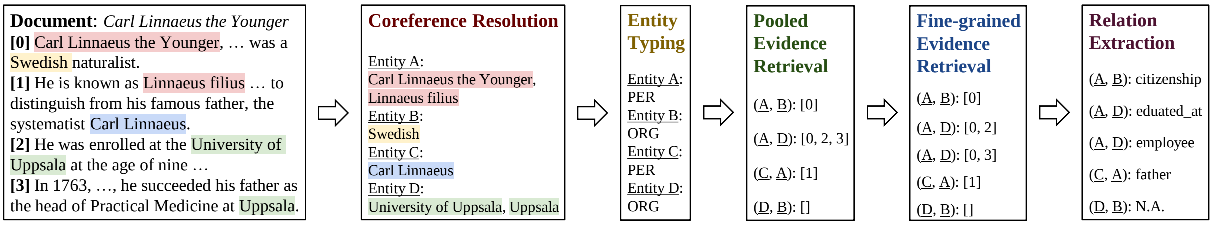

Figure 1: Motivating example adapted from DocRED. From the input document with annotated entity mentions to the RE output, there are four intermediate steps involved in the reasoning process. These steps are complementary to RE, in the sense that CR, PER, and FER capture textual contexts while ET preserves entity type information.

ularizes entity representations with the corresponding type information (e.g., Entity A, "*Linnaeus filius*", is of type "*PER*" (person)). Within an entity pair, the type information of the head and tail entities can be used to filter out impossible relations, as the relation "*year_of_birth*" can never appear between two entities of type "*PER*", for instance.

(3) **Pooled** and (4) **Fine-grained Evidence Retrieval (PER** and **FER):** A unique task for locating the relevant contexts within a document for an entity pair with any valid relation is to retrieve the evidence sentences supporting the relation. Nonetheless, some entity pairs may not express valid relations within the given document (e.g., Entities D and B in the example). Meanwhile some entity pairs possess multiple relations (e.g., Entity A is both "*educated_at*" and an "*employee*" of Entity D), each with a different evidence set. Therefore, we use PER to distinguish entity pairs with and without valid supporting sentences and FER to output more interpretable evidence unique to each valid relation of an entity pair.

In this way, the four intermediate steps are *complementary* to RE, in the sense that CR, PER, and FER capture textual contexts while ET preserves entity type information. Consequently, by explicitly supervising the model's outputs in these intermediate steps via carefully designed tasks, we extract relations of improved quality.

In addition, based on the predicted evidence, we filtrate relevant contexts by augmenting specific intermediate steps with pseudo documents or attention masks. By assessing model confidence, we apply these two kinds of evidence-based data augmentation together with ensemble inference, only when the model is *uncertain* about its original predictions. Eventually, we further boost the performance with negligible computational cost.

Altogether, our SAIS method achieves state-of-the-art RE performance on three benchmarks (DocRED (Yao et al., 2019), CDR (Li et al., 2016), and GDA (Wu et al., 2019)) due to more effective supervision and enhances interpretability by improving the evidence retrieval (ER) F1 score on DocRED by 5.04% relatively compared to the runner-up.

2 Background

2.1 Problem Formulation

Consider a document d containing sentences $\mathcal{S}_d = \{s_i\}_{i=1}^{|\mathcal{S}_d|}$ and entities $\mathcal{E}_d = \{e_i\}_{i=1}^{|\mathcal{E}_d|}$ where each entity e is assigned an entity type $c \in \mathcal{C}$ and appears at least once in d by its mentions $\mathcal{M}_e = \{m_i\}_{i=1}^{|\mathcal{M}_e|}$. For a pair of head and tail entities (e_h, e_t), document-level RE aims to predict if any relation $r \in \mathcal{R}$ exists between them, based on whether r is expressed by some pair of e_h's and e_t's mentions in d. Here, $\mathcal{C}$ and $\mathcal{R}$ are pre-defined sets of entity and relation types, respectively. Moreover, for (e_h, e_t) and each of their valid relations $r \in \mathcal{R}_{h,t}$, ER aims to identify the subset $\mathcal{V}_{h,t,r}$ of $\mathcal{S}_d$ that is sufficient to express the triplet (e_h, e_t, r).

2.2 Related Work

Early research efforts on RE (Bach and Badaskar, 2007; Pawar et al., 2017) center around predicting relations for entity pairs at the sentence level (Zhang et al., 2017; Hendrickx et al., 2019). Many pattern-based (Califf and Mooney, 1999; Qu et al., 2018; Zhou et al., 2020) and neural network-based (Cai et al., 2016; Feng et al., 2018; Zhang et al., 2019) models have shown impressive results. A recent study (Peng et al., 2020) attributes the success of these models to their ability to capture textual contexts and entity type information.

Nevertheless, since more complicated relations can only be expressed by multiple sentences, there has been a shift of focus lately towards document-level RE (Yao et al., 2019; Li et al., 2016; Cheng et al., 2021; Wu et al., 2019). According to how an approach models contexts, there are two general trends within the domain. Graph-based approaches (Nan et al., 2020; Wang et al., 2020; Zeng et al., 2020; Li et al., 2020; Zeng et al., 2021; Xu et al., 2021c,d; Sahu et al., 2019; Guo et al., 2019) typically infuse contexts into heuristic-based document graphs and perform multi-hop reasoning via advanced neural techniques. Transformer-based approaches (Wang et al., 2019; Tang et al., 2020; Huang et al., 2020; Xu et al., 2021a; Zhou et al., 2021; Zhang et al., 2021; Xie et al., 2022; Ye et al., 2020) leverage the strength of pre-trained language models (Devlin et al., 2019; Liu et al., 2019) to encode long-range contextual dependencies. However, most prior methods only implicitly learn to capture contexts while being trained for RE. Consequently, they experience ineffective supervision and uninterpretable model predictions.

On the contrary, we propose to explicitly teach the model to capture textual contexts and entity type information via a broad spectrum of carefully designed tasks. Furthermore, we boost the RE performance by ensembling the results of evidence-augmented inputs. Compared to EIDER (Xie et al., 2022), we leverage the more precise and interpretable FER for retrieving evidence and present two different kinds of evidence-based data augmentation. We also save the computational cost by applying ensemble learning only to the uncertain subset of relation triplets. As a result, our SAIS method not only enhances the RE performance due to more effective supervision, but also retrieves more accurate evidence for better interpretability.

3 Supervising Intermediate Steps

This section describes the tasks that explicitly supervise the model's outputs in the four intermediate steps. Together they complement the quality of RE.

3.1 Document Encoding

Given the promising performance of pre-trained language models (PLM) in various downstream tasks, we resort to PLM for encoding the document. More specifically, for a document d, we insert a classifier token "[CLS]" and a separator token "[SEP]" at the start and end of each sentence $s \in \mathcal{S}_d$, respectively. Each mention $m \in \mathcal{M}_d$ is wrapped with a pair of entity markers "*" (Zhang et al., 2017) to indicate the position of entity mentions. Then we feed the document, with alternating segment token indices for each sentence (Liu and Lapata, 2019), into a PLM:

$$\mathbf{H}, \mathbf{A} = \text{PLM}(d), \qquad (1)$$

to obtain the token embeddings $\mathbf{H} \in \mathbb{R}^{N_d \times H}$ and the cross-token attention $\mathbf{A} \in \mathbb{R}^{N_d \times N_d}$. $\mathbf{A}$ is the average of the attention heads in the last transformer layer (Vaswani et al., 2017) of the PLM. N_d is the number of tokens in d, and H is the embedding dimension of the PLM. We take the embedding of "*" or "[CLS]" before each mention or sentence as the corresponding mention or sentence embedding, respectively.

3.2 Coreference Resolution (CR)

As a case study, it is reported by Yao et al. (2019) that around 17.6% of relation instances in DocRED require coreference reasoning. Hence, after encoding the document, we resolve the repeated contextual mentions to an entity via CR. In particular, consider a pair of mentions (m_i, m_j), we determine the probability of whether m_i and m_j refer to the same entity by passing their corresponding embeddings $\mathbf{m}_i$ and $\mathbf{m}_j$ through a group bilinear layer (Zheng et al., 2019). The layer splits the embeddings into K equal-sized groups ($[\mathbf{m}_i^1, \ldots, \mathbf{m}_i^K] = \mathbf{m}_i$, similar for $\mathbf{m}_j$) and applies bilinear with parameter $\mathbf{W}_m^k \in \mathbb{R}^{H/K \times H/K}$ within each group:

$$\mathbb{P}_{i,j}^{\text{CR}} = \sigma\left(\sum_{k=1}^{K} \mathbf{m}_i^{k\top} \mathbf{W}_m^k \mathbf{m}_j^k + b_m\right), \qquad (2)$$

where $b_m \in \mathbb{R}$ and σ is the sigmoid function.

Since most mention pairs refer to distinct entities (each entity has only 1.34 mentions on average in DocRED), we adopt the focal loss (Lin et al., 2017) on top of the binary cross-entropy to mitigate this extreme class imbalance:

$$\begin{aligned}\ell_d^{\text{CR}} = -\sum_{m_i \in \mathcal{M}_d} \sum_{m_j \in \mathcal{M}_d} \Big(& y_{i,j}^{\text{CR}} (1 - \mathbb{P}_{i,j}^{\text{CR}})^{\gamma^{\text{CR}}} \log \mathbb{P}_{i,j}^{\text{CR}} \\ & + (1 - y_{i,j}^{\text{CR}}) (\mathbb{P}_{i,j}^{\text{CR}})^{\gamma^{\text{CR}}} \log (1 - \mathbb{P}_{i,j}^{\text{CR}}) \Big) \, w_{i,j}^{\text{CR}}, \qquad (3)\end{aligned}$$

where $y_{i,j}^{\text{CR}} = 1$ if m_i and m_j refer to the same entity, and 0 otherwise. Class weight $w_{i,j}^{\text{CR}}$ is inversely proportional to the frequency of $y_{i,j}^{\text{CR}}$, and γ^{CR} is a hyperparameter.

3.3 Entity Typing (ET)

In a pair of entities, the type information can be used to filter out impossible relations. Therefore, we regularize entity embeddings via ET. More specifically, we first derive the embedding of an entity e by integrating the embeddings of its mentions $\mathcal{M}_e$ via logsumexp pooling (Jia et al., 2019): $\mathbf{e} = \log \sum_{m \in \mathcal{M}_e} \exp(\mathbf{m})$. Since entity e could appear either at the head or tail in an entity pair, we distinguish between the head entity embedding $\mathbf{e}'_h$ and the tail entity embedding $\mathbf{e}'_t$ via two separate linear layers:

$$\mathbf{e}'_h = \mathbf{W}_{e_h}\mathbf{e} + \mathbf{b}_{e_h}, \ \ \mathbf{e}'_t = \mathbf{W}_{e_t}\mathbf{e} + \mathbf{b}_{e_t}, \tag{4}$$

where $\mathbf{W}_{e_h}, \mathbf{W}_{e_t} \in \mathbb{R}^{H \times H}$ and $\mathbf{b}_{e_h}, \mathbf{b}_{e_t} \in \mathbb{R}^{H}$.

However, no matter where e appears in an entity pair, its head and tail embeddings should always preserve e's type information. Hence, we calculate the probability of which entity type e belongs to by passing $\mathbf{e}'_\nu$ for $\nu \in \{h, t\}$ through a linear layer

$$\mathbb{P}^{\text{ET}}_{e} = \varsigma(\mathbf{W}_c \tanh(\mathbf{e}'_\nu) + \mathbf{b}_c)\,, \tag{5}$$

followed by the multi-class cross-entropy loss:

$$\ell^{\text{ET}}_d = -\sum_{e \in \mathcal{E}_d} \sum_{c \in \mathcal{C}} y^{\text{ET}}_{e,c} \log \mathbb{P}^{\text{ET}}_{e,c}\,, \tag{6}$$

where $\mathbf{W}_c \in \mathbb{R}^{|\mathcal{C}| \times H}$, $\mathbf{b}_c \in \mathbb{R}^{|\mathcal{C}|}$, and ς is the softmax function. $y^{\text{ET}}_{e,c} = 1$ if e is of entity type c, and 0 otherwise.

3.4 Pooled Evidence Retrieval (PER)

To further capture textual contexts, we explicitly guide the attention in the PLM to the supporting sentences of each entity pair via PER. That is, we want to identify the pooled evidence set $\mathcal{V}_{h,t} = \cup_{r \in \mathcal{R}_{h,t}} \mathcal{V}_{h,t,r}$ in d that is important to an entity pair (e_h, e_t), regardless of the specific relation expressed by a particular sentence $s \in \mathcal{V}_{h,t}$. In this case, given (e_h, e_t), we first compute a unique context embedding $\mathbf{c}_{h,t}$ based on the cross-token attention from Equation 1:

$$\mathbf{c}_{h,t} = \mathbf{H}^{\top} \frac{\mathbf{A}_h \otimes \mathbf{A}_t}{\mathbf{1}^{\top}(\mathbf{A}_h \otimes \mathbf{A}_t)}\,. \tag{7}$$

Here, $\otimes$ is the element-wise product. $\mathbf{A}_h$ is e_h's attention to all the tokens in the document (i.e., the average of e_h's mention-level attention). Similar for $\mathbf{A}_t$. Then we measure the probability of whether a sentence $s \in \mathcal{S}_d$ is part of the pooled supporting evidence $\mathcal{V}_{h,t}$ by passing (e_h, e_t)'s context embedding $\mathbf{c}_{h,t}$ and sentence s' embedding $\mathbf{s}$ through a group bilinear layer:

$$\mathbb{P}^{\text{PER}}_{h,t,s} = \sigma\left(\sum_{k=1}^{K} \mathbf{c}^{k\top}_{h,t} \mathbf{W}^{k}_{p} \mathbf{s}^{k} + b_p\right), \tag{8}$$

where $\mathbf{W}^{k}_{p} \in \mathbb{R}^{H/K \times H/K}$ and $b_p \in \mathbb{R}$.

Again, we face a severe class imbalance here, since most entity pairs (97.1% in DocRED) do not have valid relations or supporting evidence. As a result, similar to Section 3.2, we also use the focal loss with the binary cross-entropy:

$$\begin{aligned}\ell^{\text{PER}}_d = -\sum_{e_h \in \mathcal{E}_d} \sum_{e_t \in \mathcal{E}_d} \sum_{s \in \mathcal{S}_d} \Big(& y^{\text{PER}}_{h,t,s}(1 - \mathbb{P}^{\text{PER}}_{h,t,s})^{\gamma^{\text{PER}}} \\ & \log \mathbb{P}^{\text{PER}}_{h,t,s} + (1 - y^{\text{PER}}_{h,t,s})(\mathbb{P}^{\text{PER}}_{h,t,s})^{\gamma^{\text{PER}}} \\ & \log(1 - \mathbb{P}^{\text{PER}}_{h,t,s})\Big)\, w^{\text{PER}}_{h,t,s}\,, \end{aligned} \tag{9}$$

where $y^{\text{PER}}_{h,t,s} = \mathbb{1}\{s \in \mathcal{V}_{h,t}\}$, class weight $w^{\text{PER}}_{h,t,s}$ is inversely proportional to the frequency of $y^{\text{PER}}_{h,t,s}$, and γ^{PER} is a hyperparameter.

3.5 Fine-grained Evidence Retrieval (FER)

In addition to PER, we would like to further refine $\mathcal{V}_{h,t}$, since an entity pair could have multiple valid relations and, correspondingly, multiple sets of evidence. As a result, we explicitly train the model to recover contextual evidence unique to a triplet (e_h, e_t, r) via FER for better interpretability. More specifically, given (e_h, e_t, r), we first generate a triplet embedding $\mathbf{l}_{h,t,r}$ by merging $\mathbf{e}_h$, $\mathbf{e}_t$, $\mathbf{c}_{h,t}$, and r's relation embedding $\mathbf{r}$ via a linear layer:

$$\mathbf{l}_{h,t,r} = \tanh(\mathbf{W}_l[\mathbf{e}_h \| \mathbf{e}_t \| \mathbf{c}_{h,t} \| \mathbf{r}] + \mathbf{b}_l)\,, \tag{10}$$

where $\mathbf{W}_l \in \mathbb{R}^{H \times 4H}$, $\mathbf{b}_l \in \mathbb{R}^{H}$, $\|$ represents concatenation, and $\mathbf{r}$ is initialized from the embedding matrix of the PLM.

Similarly, we use a group bilinear layer to assess the probability of whether a sentence $s \in \mathcal{S}_d$ is included in the fine-grained evidence set $\mathcal{V}_{h,t,r}$:

$$\mathbb{P}^{\text{FER}}_{h,t,r,s} = \sigma\left(\sum_{k=1}^{K} \mathbf{l}^{k\top}_{h,t,r} \mathbf{W}^{k}_{f} \mathbf{s}^{k} + b_f\right), \tag{11}$$

where $\mathbf{W}^{k}_{f} \in \mathbb{R}^{H/K \times H/K}$ and $b_f \in \mathbb{R}$.

Since FER only involves entity pairs with valid relations, the class imbalance is milder here than in PER. Hence, let $y^{\text{FER}}_{h,t,r,s} = \mathbb{1}\{s \in \mathcal{V}_{h,t,r}\}$, we deploy the standard binary cross-entropy loss:

$$\begin{aligned}\ell^{\text{FER}}_d = -\sum_{e_i \in \mathcal{E}_d} \sum_{e_j \in \mathcal{E}_d} \sum_{r \in \mathcal{R}_{h,t}} \sum_{s \in \mathcal{S}_d} \Big(& y^{\text{FER}}_{h,t,r,s} \log \mathbb{P}^{\text{FER}}_{h,t,r,s} \\ & + (1 - y^{\text{FER}}_{h,t,r,s}) \log(1 - \mathbb{P}^{\text{FER}}_{h,t,r,s})\Big)\,. \end{aligned} \tag{12}$$

3.6 Relation Extraction (RE)

Based on the four complementary tasks introduced above, for an entity pair (e_h, e_t), we encode relevant contexts in $\mathbf{c}_{h,t}$ and preserve entity type information in $\mathbf{e}'_h$ and $\mathbf{e}'_t$. Ultimately, we acquire the contexts needed by the head and tail entities from $\mathbf{c}_{h,t}$ via two separate linear layers:

$$\mathbf{c}'_h = \mathbf{W}_{c_h}\mathbf{c}_{h,t} + \mathbf{b}_{c_h}, \mathbf{c}'_t = \mathbf{W}_{c_t}\mathbf{c}_{h,t} + \mathbf{b}_{c_t}, \quad (13)$$

where $\mathbf{W}_{c_h}, \mathbf{W}_{c_t} \in \mathbb{R}^{H \times H}$ and $\mathbf{b}_{c_h}, \mathbf{b}_{c_t} \in \mathbb{R}^{H}$, and then combine them with the type information to generate the head and tail entity representations:

$$\mathbf{e}''_h = \tanh(\mathbf{e}'_h + \mathbf{c}'_h), \ \mathbf{e}''_t = \tanh(\mathbf{e}'_t + \mathbf{c}'_t). \quad (14)$$

Next, a group bilinear layer is utilized to calculate the logit of how likely a relation $r \in \mathcal{R}$ exists between e_h and e_t:

$$\mathbb{L}^{\text{RE}}_{h,t,r} = \sum_{k=1}^{K} \mathbf{e}''^{k\top}_h \mathbf{W}^k_r \mathbf{e}''^{k}_t + b_r \,, \quad (15)$$

where $\mathbf{W}^k_r \in \mathbb{R}^{H/K \times H/K}$ and $b_r \in \mathbb{R}$.

As discussed earlier, only a small portion of entity pairs have valid relations, among which multiple relations could co-exist between a pair. Therefore, to deal with the problem of multi-label imbalanced classification, we follow Zhou et al. (2021) by introducing a threshold relation class TH and adopting an adaptive threshold loss:

$$\ell^{\text{RE}}_d = - \sum_{e_h \in \mathcal{E}_d} \sum_{e_t \in \mathcal{E}_d} \left[\sum_{r \in \mathcal{P}_{h,t}} \log \left(\frac{\exp \mathbb{L}^{\text{RE}}_{h,t,r}}{\sum_{r' \in \mathcal{P}_{h,t} \cup \{\text{TH}\}} \mathbb{L}^{\text{RE}}_{h,t,r'}} \right) + \log \left(\frac{\exp \mathbb{L}^{\text{RE}}_{h,t,\text{TH}}}{\sum_{r' \in \mathcal{N}_{h,t} \cup \{\text{TH}\}} \mathbb{L}^{\text{RE}}_{h,t,r'}} \right) \right]. \quad (16)$$

In essence, we aim to increase the logits of valid relations $\mathcal{P}_{h,t}$ and decrease the logits of invalid relations $\mathcal{N}_{h,t}$, both relative to TH.

Overall, with the goal of improving the model's RE performance by better capturing entity type information and textual contexts, we have designed four tasks to explicitly supervise the model's outputs in the corresponding intermediate steps. To this end, we visualize the entire pipeline $\text{SAIS}^{\text{O}}_{\text{All}}$ in Appendix A and integrate all the tasks by minimizing the multi-task learning objective

$$\ell = \sum_{d \in \mathcal{D}_{\text{train}}} \left(\ell^{\text{RE}}_d + \sum_{\text{Task}} \eta^{\text{Task}} \ell^{\text{Task}}_d \right), \quad (17)$$

where Task $\in$ {CR, ET, PER, FER}. η^{Task}'s are hyperparameters balancing the relative task weight.

During inference with the current pipeline $\text{SAIS}^{\text{O}}_{\text{All}}$, we predict if a triplet (e_h, e_t, r) is valid (i.e., if relation r exists between entity pair (e_h, e_t)) by checking if its logit is larger than the corresponding threshold logit (i.e., $\mathbb{L}^{\text{RE}}_{h,t,r} > \mathbb{L}^{\text{RE}}_{h,t,\text{TH}}$). For each predicted triplet (e_h, e_t, r), we assess if a sentence s belongs to the evidence set $\mathcal{V}_{h,t,r}$ by checking if $\mathbb{P}^{\text{FER}}_{h,t,r,s} > \alpha^{\text{FER}}$ where α^{FER} is a threshold.

4 Augmenting Intermediate Steps

We further improve RE after training the pipeline $\text{SAIS}^{\text{O}}_{\text{All}}$ by augmenting the intermediate steps in $\text{SAIS}^{\text{O}}_{\text{All}}$ with the retrieved evidence from FER.

4.1 When to Augment Intermediate Steps

The evidence predicted by FER is unique to each triplet (e_h, e_t, r). However, consider the total number of all possible triplets (around 40 million in the develop set of DocRED), it is computationally prohibitive to augment the inference result of each triplet with individually predicted evidence. Instead, following the idea of selective prediction (El-Yaniv et al., 2010), we identify the triplet subset $\mathcal{U}$ for which the model is *uncertain* about its relation predictions with the original pipeline $\text{SAIS}^{\text{O}}_{\text{All}}$. More specifically, we set the model's confidence for (e_h, e_t, r) as $\mathbb{L}^{\text{O}}_{h,t,r} = \mathbb{L}^{\text{RE}}_{h,t,r} - \mathbb{L}^{\text{RE}}_{h,t,\text{TH}}$. Then, the uncertain set $\mathcal{U}$ consists of triplets with the lowest $\theta\%$ absolute confidence $|\mathbb{L}^{\text{O}}_{h,t,r}|$. Consequently, we reject the original relation predictions for $(e_h, e_t, r) \in \mathcal{U}$ and apply evidence-based data augmentation to enhance the performance (more details in Section 4.2).

To determine the rejection rate $\theta\%$ (note that $\theta\%$ is NOT a hyperparameter), we first sort all the triplets in the develop set based on their absolute confidence $|\mathbb{L}^{\text{O}}_{h,t,r}|$. When $\theta\%$ increases, the risk (i.e., inaccuracy rate) of the remaining triplets that are not in $\mathcal{U}$ is expected to decrease, and vice versa. On the one hand, we wish to reduce the risk for more accurate relation predictions; on the other hand, we want a low rejection rate so that data augmentation on a small rejected set incurs little computational cost. To balance this trade-off, we set $\theta\%$ as the rate that achieves the minimum of $\text{risk}^2 + \text{rejection rate}^2$. As shown in Figure 2, we find $\theta\% \approx 4.6\%$ in the develop set of DocRED. In practice, we can further limit the maximum number of rejected triplets per entity pair. By setting it as

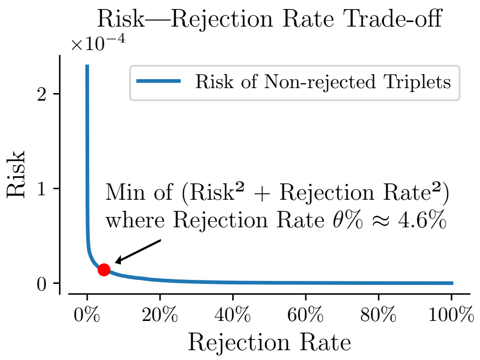

Figure 2: Trade-off between risk and rejection rate on the develop set of DocRED.

10 in experiments, we reduce the size of $\mathcal{U}$ to only 1.5% of all the triplets in the DocRED develop set.

4.2 How to Augment Intermediate Steps

Consider a triplet $(e_h, e_t, r) \in \mathcal{U}$. We first assume its validity and calculate the probability $\mathbb{P}^{\mathrm{FER}}_{h,t,r,s}$ of a sentence s being part of $\mathcal{V}_{h,t,r}$ based on Section 3.5. Then in a similar way to how $\mathbb{L}^{\mathrm{O}}_{h,t,r}$ is generated with $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$, we design two types of evidence-based data augmentation as follows:

Pseudo Document-based ($\mathbf{SAIS}^{\mathbf{D}}_{\mathbf{All}}$): Construct a pseudo document using sentences with $\mathbb{P}^{\mathrm{FER}}_{h,t,r,s} > \alpha^{\mathrm{FER}}$ and feed it into the original pipeline to get the confidence $\mathbb{L}^{\mathrm{D}}_{h,t,r}$.

Attention Mask-based ($\mathbf{SAIS}^{\mathbf{M}}_{\mathbf{All}}$): Formulate a mask $\mathbf{P}^{\mathrm{FER}}_{h,t,r} \in \mathbb{R}^{N_d}$ based on $\mathbb{P}^{\mathrm{FER}}_{h,t,r,s}$ and modify the context embedding to $\mathbf{c}_{h,t} = \mathbf{H}^\top \frac{\mathbf{A}_h \otimes \mathbf{A}_t \otimes \mathbf{P}^{\mathrm{FER}}_{h,t,r}}{\mathbf{1}^\top(\mathbf{A}_h \otimes \mathbf{A}_t \otimes \mathbf{P}^{\mathrm{FER}}_{h,t,r})}$. Maintain the rest of the pipeline and get the confidence $\mathbb{L}^{\mathrm{M}}_{h,t,r}$.

Following Xie et al. (2022), we ensemble $\mathbb{L}^{\mathrm{D}}_{h,t,r}$, $\mathbb{L}^{\mathrm{M}}_{h,t,r}$, and the original confidence $\mathbb{L}^{\mathrm{O}}_{h,t,r}$ with a blending parameter $\tau_r \in \mathbb{R}$ (Wolpert, 1992) for each relation $r \in \mathcal{R}$ as

$$\begin{aligned}\mathbb{P}^{\mathrm{B}}_{h,t,r} &= \sigma(\mathbb{L}^{\mathrm{B}}_{h,t,r}) \\ &= \sigma(\mathbb{L}^{\mathrm{O}}_{h,t,r} + \mathbb{L}^{\mathrm{D}}_{h,t,r} + \mathbb{L}^{\mathrm{M}}_{h,t,r} - \tau_r). \quad (18)\end{aligned}$$

These parameters are trained by minimizing the binary cross-entropy loss on $\mathcal{U}$ of the develop set:

$$\begin{aligned}\ell^B = - \sum_{(e_h, e_t, r) \in \mathcal{U}} & \big(y^{\mathrm{RE}}_{h,t,r} \log \mathbb{P}^{\mathrm{B}}_{h,t,r} \\ & + (1 - y^{\mathrm{RE}}_{h,t,r}) \log(1 - \mathbb{P}^{\mathrm{B}}_{h,t,r})\big), \quad (19)\end{aligned}$$

where $y^{\mathrm{RE}}_{h,t,r} = 1$ if (e_h, e_t, r) is valid, and 0 otherwise. When making relation predictions for $(e_h, e_t, r) \in \mathcal{U}$, we check whether its blended confidence is positive (i.e., $\mathbb{L}^{\mathrm{B}}_{h,t,r} > 0$).

In this way, we improve the RE performance when the model is uncertain about its original predictions and save the computational cost when the model is confident. The overall steps for evidence-based data augmentation and ensemble inference $\mathrm{SAIS}^{\mathrm{B}}_{\mathrm{All}}$ are summarized in Appendix B. These steps are executed only after the training of $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$ and, therefore, adds negligible computational cost.

5 Experiments

5.1 Experiment Setup

We evaluate the proposed SAIS method on the following three document-level RE benchmarks. DocRED (Yao et al., 2019) is a large-scale crowd-sourced dataset based on Wikipedia articles. It consists of 97 relation types, seven entity types, and 5,053 documents in total, where each document has 19.5 entities on average. CDR (Li et al., 2016) and GDA (Wu et al., 2019) are two biomedical datasets where CDR studies the binary interactions between disease and chemical concepts with 1,500 documents and GDA studies the binary relationships between gene and disease with 30,192 documents. We follow Christopoulou et al. (2019) for splitting the train and develop sets.

We run our experiments on one Tesla A6000 GPU and carry out five trials with different seeds to report the mean and one standard error. Based on Huggingface (Wolf et al., 2019), we apply cased BERT-base (Devlin et al., 2019) and RoBERTa-large (Liu et al., 2019) for DocRED and cased SciBERT (Beltagy et al., 2019) for CDR and GDA. The embedding dimension H of BERT or SciBERT is 768, and that of RoBERTa is 1,024. The number of groups K in all group bilinear layers is 64.

For the general hyperparameters of language models, we follow the setting in (Zhou et al., 2021). The learning rate for fine-tuning BERT is 5e$-$5, that for fine-tuning RoBERTa or SciBERT is 2e$-$5, and that for training the other parameters is 1e$-$4. All the trials are optimized by AdamW (Loshchilov and Hutter, 2019) for 20 epochs with early stopping and a linearly decaying scheduler (Goyal et al., 2017) whose warm-up ratio $= 6\%$. Each batch contains 4 documents and the gradients of model parameters are clipped to a maximum norm of 1.

For the unique hyperparameters of our method, we choose 2 from $\{1, 1.5, 2\}$ for the focal hyperparameters γ^{CR} and γ^{PER} based on the develop

Table 1: RE and ER results (%) on DocRED. Ign F1 refers to the F1 score excluding the relation instances mentioned in the train set. Baselines using BERT$_{\text{base}}$ are separated into the graph-based (upper) and transformer-based (lower) groups. We report the test scores from the official scoreboard and the baseline scores from the corresponding papers. SAIS$^{\text{B}}_{\text{All}}$ achieves state-of-the-art performance on both RE and ER. Full details in Appendix C.

set. We also follow Xie et al. (2022) for setting the FER prediction threshold α^{FER} as 0.5 and all the relative task weights η^{Task} for Task $\in \{\text{CR}, \text{ET}, \text{PER}, \text{FER}\}$ as 0.1.

5.2 Quantitative Evaluation

Besides RE, DocRED also suggests to predict the supporting evidence for each relation instance. Therefore, we apply SAIS$^{\text{B}}_{\text{All}}$ to both RE and ER. We report the results of SAIS$^{\text{B}}_{\text{All}}$ as well as existing graph-based and transformer-based baselines in Table 1[2] (full details in Appendix C). Generally, thanks to PLMs' strength in modeling long-range dependencies, transformer-based methods perform better on RE than graph-based methods. Moreover, most earlier approaches are not capable of ER despite the interpretability ER adds to the predictions. In contrast, our SAIS$^{\text{B}}_{\text{All}}$ method not only establishes a new state-of-the-art result on RE, but also outperforms the runner-up significantly on ER.

Since neither CDR nor GDA annotates evidence sentences, we apply SAIS$^{\text{O}}_{\text{RE+CR+ET}}$ here. It is trained with RE, CR, and ET and infers without data augmentation. As shown in Table 2 (full details in Appendix C), our method improves the prior best RE F1 scores by 2.7% and 1.8% absolutely on CDR and GDA, respectively. It indicates that our proposed method can still improve upon the baselines even if only part of the four complementary tasks are annotated and operational.

5.3 Ablation Study

To investigate the effectiveness of each of the four complementary tasks proposed in Section 3, we carry out an extensive ablation study on the DocRED develop set by training SAIS with all possible combinations of those tasks. As shown in Table 3, without any complementary tasks, the RE performance of SAIS is comparable to ATLOP (Zhou et al., 2021) due to similar neural architectures. When only one complementary task is allowed, PER is the most effective single task, followed by ET. Although FER is functionally analogous to PER, since FER only involves the small subset of entity pairs with valid relations, the performance gain brought by FER alone is limited. When

---

[2] For a fair comparison, we report the scores of SSAN (Xu et al., 2021a) without being pretrained on an extra dataset.

Model	CDR	GDA
LSR (Nan et al., 2020)	64.8	82.2
SciBERT (Beltagy et al., 2019)	65.1	82.5
DHG (Zhang et al., 2020)	65.9	83.1
SSAN-SciBERT (Xu et al., 2021a)	68.7	83.7
ATLOP-SciBERT (Zhou et al., 2021)	69.4	83.9
SIRE-BioBERT (Zeng et al., 2021)	70.8	84.7
DocuNet-SciBERT (Zhang et al., 2021)	76.3	85.3
$\text{SAIS}^{\text{O}}_{\text{RE+CR+ET}}$-SciBERT (Ours)	**79.0 ± 0.8**	**87.1 ± 0.3**
$\text{SAIS}^{\text{O}}_{\text{RE+ET}}$-SciBERT	75.9 ± 0.9	86.1 ± 0.5
$\text{SAIS}^{\text{O}}_{\text{RE+CR}}$-SciBERT	74.5 ± 0.4	85.4 ± 0.2
$\text{SAIS}^{\text{O}}_{\text{RE}}$-SciBERT	72.8 ± 0.6	84.5 ± 0.3

Table 2: RE F1 results (%) on the CDR and GDA test sets. The baseline scores are from the corresponding papers. $\text{SAIS}^{\text{O}}_{\text{RE+CR+ET}}$ scores the highest on both datasets. Full details in Appendix C.

two tasks are used jointly, the pair of PER and ET, which combines textual contexts and entity type information, delivers the most significant improvement. The pair of PER and FER also performs well, which reflects the finding in (Peng et al., 2020) that context is the most important source of information. The version with all tasks except CR sees the least drop in F1, indicating that CR's supervision signals on capturing contexts can be covered in part by PER and FER. Last but not least, the SAIS pipeline with all four complementary tasks achieves the highest F1 score. Similar trends are also recognized on CDR and GDA in Table 2, where SAIS trained with both CR and ET (besides RE) scores higher than its single-task counterpart.

Moreover, as compared to the original pipeline $\text{SAIS}^{\text{O}}_{\text{All}}$, pseudo document-based data augmentation $\text{SAIS}^{\text{D}}_{\text{All}}$ acts as a hard filter by directly removing predicted non-evidence sentences, while attention mask-based data augmentation $\text{SAIS}^{\text{M}}_{\text{All}}$ distills the context more softly. Therefore, we observe in Table 4 that $\text{SAIS}^{\text{D}}_{\text{All}}$ earns a higher precision, whereas $\text{SAIS}^{\text{M}}_{\text{All}}$ attains a higher recall. By ensembling $\text{SAIS}^{\text{O}}_{\text{All}}$, $\text{SAIS}^{\text{D}}_{\text{All}}$, and $\text{SAIS}^{\text{M}}_{\text{All}}$, we improve the RE F1 score by 0.57% absolutely on the DocRED develop set.

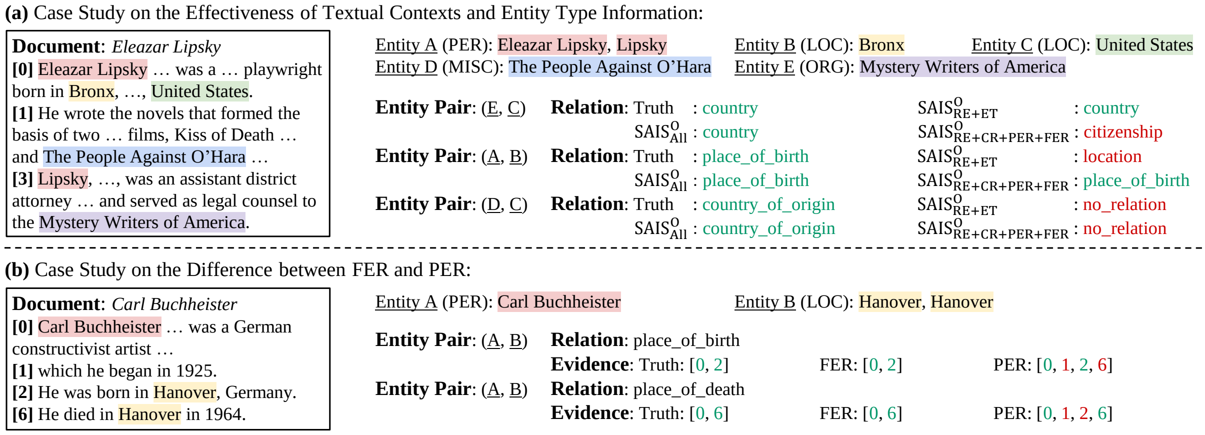
Table 4: Ablation study (%) using $\text{BERT}_{\text{base}}$ to assess the effectiveness of data augmentation (i.e., original ($\text{SAIS}^{\text{O}}_{\text{All}}$), pseudo document-based ($\text{SAIS}^{\text{D}}_{\text{All}}$), and attention mask-based ($\text{SAIS}^{\text{M}}_{\text{All}}$)) for RE based on the DocRED develop set.

5.4 Qualitative Analysis

To obtain a more insightful understanding of how textual contexts and entity type information help with RE, we present a case study in Figure 3 (a). Here, $\text{SAIS}^{\text{O}}_{\text{RE+ET}}$ is trained with the task (i.e., ET) related to entity type information while $\text{SAIS}^{\text{O}}_{\text{RE+CR+PER+FER}}$ is trained with the tasks (i.e., CR, PER, and FER) related to textual contexts. Compared to $\text{SAIS}^{\text{O}}_{\text{All}}$, which is trained with all four complementary tasks, they both exhibit drawbacks qualitatively. In particular, $\text{SAIS}^{\text{O}}_{\text{RE+ET}}$ can easily infer the relation "*country*" between Entities E and C based on their respective types "*ORG*" and "*LOC*", whereas $\text{SAIS}^{\text{O}}_{\text{RE+CR+PER+FER}}$ may misinterpret Entity E as of type "*PER*" and infer the relation "*citizenship*" wrongly. On the other hand, $\text{SAIS}^{\text{O}}_{\text{RE+CR+PER+FER}}$ can directly predict the relation "*place_of_birth*" between Entities A and B by pattern matching, while overemphasizing the type "*LOC*" of Entity B may cause $\text{SAIS}^{\text{O}}_{\text{RE+ET}}$ to deliver the wrong relation prediction "*location*". Last but



(a) Case Study on the Effectiveness of Textual Contexts and Entity Type Information:

Document: *Eleazar Lipsky*
[0] Eleazar Lipsky … was a … playwright born in Bronx, …, United States.
[1] He wrote the novels that formed the basis of two … films, Kiss of Death … and The People Against O'Hara …
[3] Lipsky, …, was an assistant district attorney … and served as legal counsel to the Mystery Writers of America.

Entity A (PER): Eleazar Lipsky, Lipsky
Entity B (LOC): Bronx
Entity C (LOC): United States
Entity D (MISC): The People Against O'Hara
Entity E (ORG): Mystery Writers of America

Entity Pair: (E, C) **Relation**: Truth : country; $\text{SAIS}^{\text{O}}_{\text{All}}$: country; $\text{SAIS}^{\text{O}}_{\text{RE+ET}}$: country; $\text{SAIS}^{\text{O}}_{\text{RE+CR+PER+FER}}$: citizenship
Entity Pair: (A, B) **Relation**: Truth : place_of_birth; $\text{SAIS}^{\text{O}}_{\text{All}}$: place_of_birth; $\text{SAIS}^{\text{O}}_{\text{RE+ET}}$: location; $\text{SAIS}^{\text{O}}_{\text{RE+CR+PER+FER}}$: place_of_birth
Entity Pair: (D, C) **Relation**: Truth : country_of_origin; $\text{SAIS}^{\text{O}}_{\text{All}}$: country_of_origin; $\text{SAIS}^{\text{O}}_{\text{RE+ET}}$: no_relation; $\text{SAIS}^{\text{O}}_{\text{RE+CR+PER+FER}}$: no_relation

(b) Case Study on the Difference between FER and PER:

Document: *Carl Buchheister*
[0] Carl Buchheister … was a German constructivist artist …
[1] which he began in 1925.
[2] He was born in Hanover, Germany.
[6] He died in Hanover in 1964.

Entity A (PER): Carl Buchheister
Entity B (LOC): Hanover, Hanover

Entity Pair: (A, B) **Relation**: place_of_birth
Evidence: Truth: [0, 2] FER: [0, 2] PER: [0, 1, 2, 6]
Entity Pair: (A, B) **Relation**: place_of_death
Evidence: Truth: [0, 6] FER: [0, 6] PER: [0, 1, 2, 6]

Figure 3: **(a)** Case study on the effectiveness of textual contexts and entity type information based on models' extracted relations from the DocRED develop set. By capturing contexts across sentences and regularizing them with entity type information, $\text{SAIS}^{\text{O}}_{\text{All}}$ extracts relations of better quality. **(b)** Case study on the difference between FER and PER based on retrieved evidence from the DocRED develop set. FER considers evidence unique to each relation for better interpretability. Irrelevant sentences are omitted here.

not least, $\text{SAIS}^{\text{O}}_{\text{All}}$ effectively models contexts spanning multiple sentences and regularizes them with entity type information. As a result, it is the only SAIS variant that correctly predicts the relation "*country_of_origin*" between Entities D and C.

Furthermore, to examine why SAIS (which uses FER for retrieving evidence) outperforms Eider (Xie et al., 2022) (which uses PER) significantly on ER in Table 1, we compare the performance of FER and PER based on a case study in Figure 3 (b). More specifically, PER identifies the same set of evidence for both relations between Entities A and B, among which Sentence 2 describes "*place_of_birth*" while Sentence 6 discusses "*place_of_death*". In contrast, FER considers an evidence set unique to each relation and outputs more interpretable results.

6 Conclusion

In this paper, we propose to explicitly teach the model to capture the major information sources of RE—textual contexts and entity types by Supervising and Augmenting Intermediate Steps (SAIS). Based on a broad spectrum of carefully designed tasks, SAIS extracts relations of enhanced quality due to more effective supervision and retrieves more accurate evidence for improved interpretability. SAIS further boosts the performance with evidence-based data augmentation and ensemble inference while preserving the computational cost by assessing model uncertainty. Experiments on three benchmarks demonstrate the state-of-the-art performance of SAIS on both RE and ER.

If given a plain document, we shall utilize existing tools (e.g., spaCy) to get noisy annotations and apply our method afterward. It is also interesting to investigate how other tasks (e.g., named entity recognition) could be incorporated into the multitask learning pipeline of our SAIS method. We plan to explore these extensions in future works.

A Multi-Task Learning Pipeline by Supervising Intermediate Steps ($\text{SAIS}_{\text{All}}^{\text{O}}$)

To explicitly teach the model to capture relevant contexts and entity type information for RE, we design four tasks to supervise the model's outputs in the corresponding intermediate steps. We illustrate the overall multi-task pipeline $\text{SAIS}_{\text{All}}^{\text{O}}$ in Figure 4.

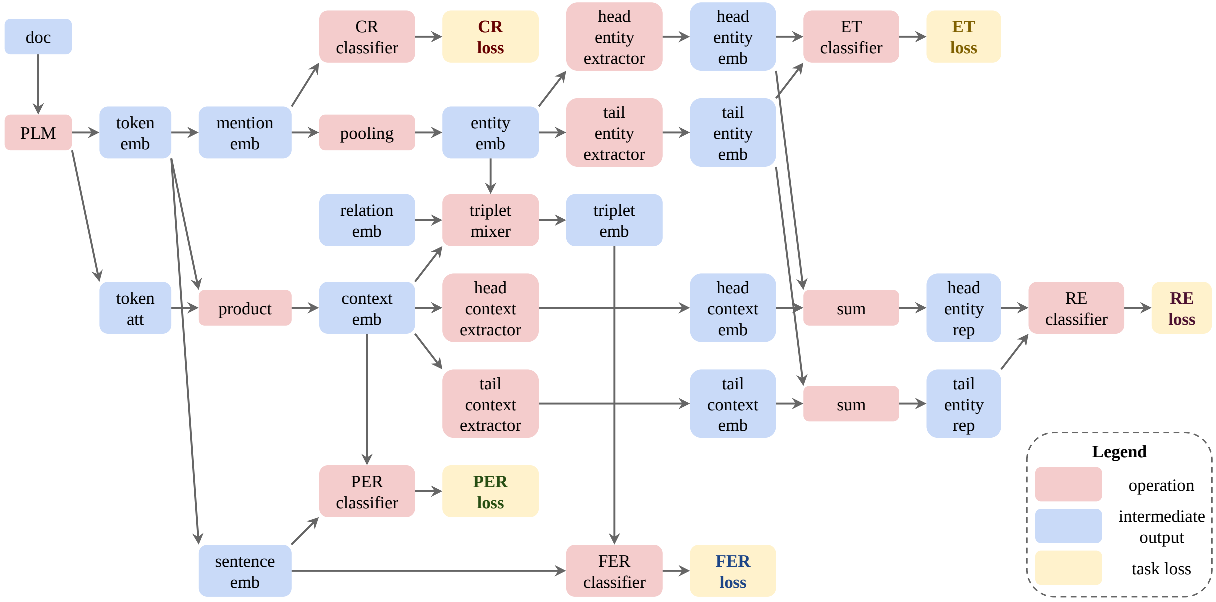

Figure 4: The overall multi-task learning pipeline of the proposed SAIS method ($\text{SAIS}_{\text{All}}^{\text{O}}$). By explicitly supervising the model's outputs in the intermediate steps via carefully designed tasks, we improve the RE performance.

B Ensemble Inference Algorithm with Evidence-based Data Augmentation ($\mathrm{SAIS}^{\mathrm{B}}_{\mathrm{All}}$)

After training the multi-task pipeline $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$ proposed in Section 3, we further boost the model performance by evidence-based data augmentation and ensemble inference as discussed in Section 4. The detailed steps are explained in Algorithm 1 below.

Algorithm 1: Evidence-based Data Augmentation and Ensemble Inference ($\mathrm{SAIS}^{\mathrm{B}}_{\mathrm{All}}$)

```
input: trained pipeline $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$ from Section 3, FER threshold $\alpha^{\mathrm{FER}}$, develop set $\mathcal{D}_{\mathrm{dev}}$, test set $\mathcal{D}_{\mathrm{test}}$
for $\mathcal{D} \in \{\mathcal{D}_{dev}, \mathcal{D}_{test}\}$ do
    Original RE Prediction with $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$ (Section 3.6):
        For $(e_h, e_t, r) \in \mathcal{D}$, get $\mathbb{L}^{\mathrm{O}}_{h,t,r}$ from $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$.
    Identify the Uncertain Set $\mathcal{U}$ (Section 4.1):
        If $\mathcal{D}$ is $\mathcal{D}_{\mathrm{dev}}$, calculate $\theta\%$ by minimizing $(\mathrm{risk}^2 + \mathrm{rejection\ rate}^2)$.
        $\mathcal{U}$ contains triplets with the lowest $\theta\%$ absolute confidence $|\mathbb{L}^{\mathrm{O}}_{h,t,r}|$.
    Predict Evidence Probability for $(e_h, e_t, r) \in \mathcal{U}$ with $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$ (Section 3.5):
        For $(e_h, e_t, r) \in \mathcal{U}$ and $s \in \mathcal{S}_d$ in the corresponding document $d$, get $\mathbb{P}^{\mathrm{FER}}_{h,t,r,s}$ from $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$.
    Pseudo Document-based Data Augmentation $\mathrm{SAIS}^{\mathrm{D}}_{\mathrm{All}}$ (Section 4.2):
        For $(e_h, e_t, r) \in \mathcal{U}$, get $\mathbb{L}^{\mathrm{D}}_{h,t,r}$ by feeding the corresponding pseudo document into $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$.
    Attention Mask-based Data Augmentation $\mathrm{SAIS}^{\mathrm{M}}_{\mathrm{All}}$ (Section 4.2):
        For $(e_h, e_t, r) \in \mathcal{U}$, get $\mathbb{L}^{\mathrm{M}}_{h,t,r}$ by applying the corresponding attention mask to $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$.
    Ensemble Inference $\mathrm{SAIS}^{\mathrm{B}}_{\mathrm{All}}$ (Section 4.2):
        If $\mathcal{D}$ is $\mathcal{D}_{\mathrm{dev}}$, train $\tau_r$ for $r \in \mathcal{R}$ based on $\mathbb{L}^{\mathrm{O}}_{h,t,r}$, $\mathbb{L}^{\mathrm{D}}_{h,t,r}$, and $\mathbb{L}^{\mathrm{M}}_{h,t,r}$ for $(e_h, e_t, r) \in \mathcal{U}$.
        For $(e_h, e_t, r) \in \mathcal{U}$, get $\mathbb{L}^{\mathrm{B}}_{h,t,r} = \mathbb{L}^{\mathrm{O}}_{h,t,r} + \mathbb{L}^{\mathrm{D}}_{h,t,r} + \mathbb{L}^{\mathrm{M}}_{h,t,r} - \tau_r$.
    Ultimate RE Prediction with $\mathrm{SAIS}^{\mathrm{B}}_{\mathrm{All}}$ and $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$ (Section 4.2 and 3.6):
        For $(e_h, e_t, r) \in \mathcal{U}$, extract relation $r$ for entity pair $(e_h, e_t)$ if $\mathbb{L}^{\mathrm{B}}_{h,t,r} > 0$.
        For $(e_h, e_t, r) \notin \mathcal{U}$, extract relation $r$ for entity pair $(e_h, e_t)$ if $\mathbb{L}^{\mathrm{O}}_{h,t,r} > 0$.
    Ultimate ER Prediction with $\mathrm{SAIS}^{\mathrm{O}}_{\mathrm{All}}$ (Section 3.5):
        For predicted $(e_h, e_t, r)$, retrieve $s \in \mathcal{S}_d$ in the corresponding document $d$ if $\mathbb{P}^{\mathrm{FER}}_{h,t,r,s} > \alpha^{\mathrm{FER}}$.
output: sets of predicted triplet $(e_h, e_t, r)$ and corresponding evidence $\mathcal{V}_{h,t,r}$ for $\mathcal{D}_{\mathrm{dev}}$ and $\mathcal{D}_{\mathrm{test}}$
```

C Experiment Details

We compare the proposed SAIS method against existing baselines based on three benchmarks: CDR (Li et al., 2016) and GDA (Wu et al., 2019) in Table 5, and DocRED (Yao et al., 2019) in Table 6. The details are explained in Section 5.

In particular, DocRED uses the MIT License, CDR is freely available for the research community, and GDA uses the GNU Affero General Public License. DocRED is constructed from Wikipedia and Wikidata and, therefore, contains information that names people. However, since our research focuses on identifying relations among real-world entities (including public figures) based on a given document, it is impossible to fully anonymize the dataset. We ensure that we only use publicly available information in our experiments. Our use of these datasets is consistent with their intended use. Although our method achieves state-of-the-art performance for RE and ER, using the predicted relations and evidence directly for downstream tasks without manual validation may increase the risk of errors carried forward due to the incorrect predictions. The experiments in this paper focus on English documents from biomedical and general domains, but our proposed framework can be easily extended to documents of other languages.

Model	**CDR**	**GDA**
BRAN (Verga et al., 2018)	62.1	-

Abstract

Users write *to-dos* as personal notes to themselves, about things they need to complete, remember or organize. To-do texts are usually short and under-specified, which poses a challenge for current text representation models. Yet, understanding and representing their meaning is the first step towards providing intelligent assistance for to-do management. We address this problem by proposing a neural multi-task learning framework, *LITE*, which extracts representations of English to-do tasks with a multi-head attention mechanism on top of a pre-trained text encoder. To adapt representation models to to-do texts, we collect weak-supervision labels from semantically rich external resources (e.g., dynamic commonsense knowledge bases), following the principle that to-do tasks with similar intents have similar labels. We then train the model on multiple generative/predictive training objectives jointly. We evaluate our representation model on four downstream tasks and show that our approach consistently improves performance over baseline models, achieving error reduction of up to 38.7%.

1 Introduction

Task management tools are widely used to organize tasks and keep track of progress in work and daily lives. Examples include Microsoft To-do, Todoist, Trello, and digital assistants such as Amazon Alexa and Google Assistant. Machine learning techniques can automate various aspects of task management such as task creation (Mukherjee et al., 2020), organization (Landes and Di Eugenio, 2018), prioritization, and decomposition of complex tasks (Nouri et al., 2020; Zhang et al., 2021).

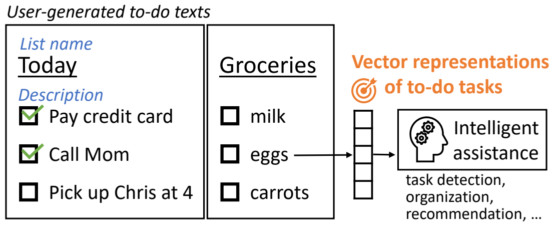

Figure 1: Our aim is to encode user-generated to-do texts (list names and descriptions) into vector representations so that machine learning systems can provide various kinds of intelligent assistance.

The goal of this work is to develop a *single*, general-purpose encoding system that converts to-do task texts into real-valued vector representations (Fig. 1). Using one encoding system for multiple task functions (task detection, organization, recommendation, etc.) as opposed to having multiple dedicated encoders saves the computational costs of updating models regularly and encoding texts from millions of users.

Representation learning has been extensively studied in natural language processing (Camacho-Collados and Pilehvar, 2018). Adapting models pre-trained on massive amounts of raw texts to a target domain or a task has become common practice (Qiu et al., 2020), with many publicly available pre-trained models such as BERT (Devlin et al., 2019), GPT-2 (Radford et al., 2018), and sentence encoders (Cer et al., 2018; Reimers and Gurevych, 2019). Leveraging word context is one of the key strengths of these pre-trained models. However, to-do texts exhibit unique characteristics that make this context-based modeling less effective (§2).

Our analysis on a dataset of 6.5 million entries shows that to-do texts are short and often lack an action verb. While similar to web search queries, they are not written to be understood by a search engine but instead are personal notes to the users themselves and assume rich personal context. On the other hand, some task management applications allow users to organize their to-dos under user-defined lists, which, our analysis shows, can *sometimes* convey important information about their

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2410 - 2424
July 10-15, 2022

meaning (e.g., a "grocery" list vs. a "today" list).

Our hypothesis is that we can effectively fine-tune contextualized representation models for under-specified texts using multiple weakly-supervised prediction/generation tasks that focus on knowledge about to-do tasks. We induce supervision signals semi-automatically from existing resources so that to-do tasks that have similar intents share similar target labels. To this end, we propose *LITE*,[1] a framework for training to-do task representation models using the following auxiliary tasks: (1) autocompletion of to-do descriptions, (2) pre-action and goal generation based on COMET (Bosselut et al., 2019; Hwang et al., 2021), and (3) action attribute predictions based on FrameNet (Ruppenhofer et al., 2016). We implement LITE on top of existing pre-trained language models and evaluate its performance through downstream tasks on two proprietary and two publicly available datasets (Jauhar et al., 2021; Landes, 2018): urgent and important to-do detection, actionable to-do classification, co-located and co-timed to-do pair detection, and intent detection.

Overall, we make the following contributions: (1) A neural multi-task learning framework to fine-tune embeddings of to-do texts based on intents.[2] (2) A methodology to collect weak supervision signals from various resources without costly manual annotations. (3) An empirical comparison of contextual embeddings models on real to-do texts, where LITE outperforms various baseline models including BERT, RoBERTa, Sentence-BERT/RoBERTa, achieving error reduction of 4.8-38.7%.

2 User-generated To-do Data

2.1 Data Collection

For training and data analysis, we use a dataset based on the now-retired *Wunderlist* task management app. The app was available on multiple platforms and had more than 13 million users in 2015. The dataset (henceforth *WL*) contains 6.5 million English to-do texts. Each *to-do text* includes a *description* (e.g., "call mom") and associated *list name* (e.g, "today"). See Appendix A for more details on how the dataset was anonymized.

We performed a basic linguistic analysis on the WL data. As observed by Landes and Di Eugenio (2018), general-purpose analyzers often fail to analyze to-do texts correctly due to the writing style and the lack of context words. To alleviate this problem, we use frequency information obtained from a large corpus to correct automatically assigned POS tags, through the following 3-step process. First, we run the spaCy tagger (Honnibal et al., 2020)[3] to assign POS tags. Then, as proposed by Keyaki and Miyazaki (2017), we correct the POS tags based on frequency information derived from 3 billion sentences from the DepCC corpus (Panchenko et al., 2018).[4] Finally, we apply the spaCy dependency parser to the texts with the corrected POS tags and identified main verbs and arguments.

2.2 Observations

To-do descriptions are very short: The mean number of tokens per to-do description is 2.4, which is similar to that of search engine queries (Taghavi et al., 2012), but with two key differences: (1) many search queries are intended for information seeking (Broder, 2002), while to-dos typically express things to perform or to remember, and (2) people write search queries with the capabilities of a search engine in mind, but to-do descriptions are personal notes to the users themselves.

Most to-do descriptions have no action verb: We observed that 87.8% of to-do descriptions do not have action verbs. If an action verb is present, 75.1% and 12.7% have a direct object and a prepositional phrase, respectively. The degree of under-specification depends on a to-do's list name. An action verb is more frequently used in to-do descriptions that appear in *generic* lists, such as "inbox"[5] (29.7%), "to do" (28.4%), and "today" (22.1%). When list names already imply a *specific* action, the action verb is more likely to be omitted such as in the "shopping" (3.3%) and "movies to watch" (4.7%) lists.

List names can be indicative of task intents: For example, a to-do text (*description* = "avocados",

---

[1] Short for Latent Intent Task Embedding

[2] The code is available at github.com/microsoft/Intent-based-Task-Representation-Learning

[3] We use the English model `en_core_web_lg` v3.0.0

[4] We extracted the first 100 files from DepCC and re-tagged the sentences using spaCy. We counted the frequencies of 1-3 grams of token-XPOS pairs and replaced tokens that appeared fewer than 100 times with an out-of-vocabulary token. The frequencies were used to score the sequences of the POS tokens obtained in the previous step, and replace them with more frequent ones, if found. One of the authors manually evaluated the 100 frequent to-do descriptions with tags changed by post-processing and found 17/57 errors were corrected.

[5] "Inbox" was the default list name in the Wunderlist app.

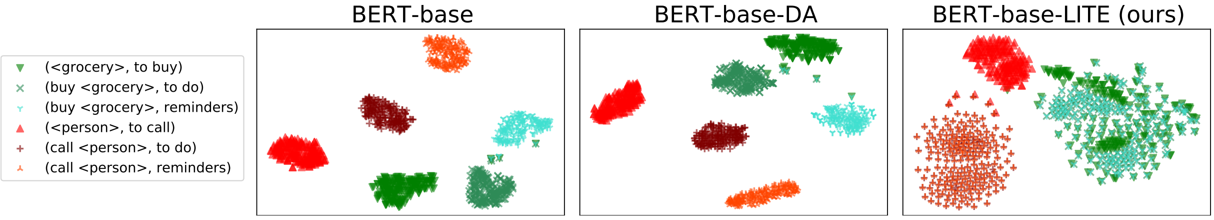

Figure 2: t-SNE (van der Maaten and Hinton, 2008) visualization of the embeddings of to-do texts generated by (1) BERT-base, (2) BERT-base domain-adapted by masked language modeling on WL, and (3) LITE.

list name = "to buy") signifies the intent "to buy avocados", but the same description can appear also in generic lists, such as "to do" or "reminders". When a list name is generic, a task description needs to be weighted more to accurately capture the intent of a task. Fig. 2 shows that this is a non-trivial problem for pre-trained language models like BERT. The figure visualizes the distribution of the embeddings of the "buy <grocery>" and "call <person>" to-do texts[6] expressed in two ways: (1) the descriptions "buy <grocery>" and "call <person>" are paired with generic list names ("to do" and "reminders"); or (2) the descriptions "<grocery>" and "<person>" are paired with specific list names (indicating the actions "to buy" and "to call"). To produce embeddings, we concatenated descriptions and list names in the input and extracted their pooled output from the encoders (§3.1). We can see that a BERT model cannot capture the similarity within the *buy* nor *call* intent groups even after domain adaptation (DA) to to-do texts (see §4.3 for more details on DA). Our model, LITE, can successfully *ignore* the generic lists and group similar tasks together.

3 Method: Multi-task Learning (MTL)

We propose a multi-task learning (MTL) framework to represent to-do descriptions along with their list names (Fig. 3). Our model first encodes text using off-the-shelf encoders (§3.1). The token representations along with information about their types are merged by an intent extractor with multi-head attention (§3.2). We train the encoder and extractor on three auxiliary tasks (§3.3,3.4).

3.1 Off-the-shelf Text Encoder

We encode input texts using off-the-shelf pre-trained transformer-based language models, BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019b).[7] Our model takes as input the concatenation of two types of texts, descriptions and list names, separated by the token `[SEP]`: `<s>` *desc.* `[SEP]` *list name* `</s>`, where `<s>` and `</s>` are beginning-of-sentence and end-of-sentence tokens pre-defined for the encoder. The encoder converts a sequence of N input tokens $w_1, w_2, \cdots w_N$ into real-valued vector representations using multiple layers of attention mechanism and fully-connected networks. We use the last hidden states $H = \{\boldsymbol{h}_i\}_{i=1,2,\cdots,N}$ as the contextual token representations of the input.

3.2 Intent Extraction with Attention

List names are often–but not always–indicative of task intents (§2). For example, a "shopping" list tends to have items that a user wishes to purchase and is useful for identifying intents, but some list names merely express time (e.g., "today"), topics/targets (e.g., "family"), or nothing specific (e.g., "things to do"). In these cases, the model should "pay more attention" to the to-do description.

To handle this, we use a multi-head attention mechanism (Vaswani et al., 2017; Chaudhari et al., 2021) to extract a vector representing the intent of a to-do task and introduce token type embeddings to explicitly inform a model of text types.

Multi-head attention: An attention mechanism is suitable to model the variable nature of token importance. We use a multi-head, scaled dot-product attention mechanism (Vaswani et al., 2017) and aggregate H based on token importance into the intent embedding $\boldsymbol{z}$.

Suppose we have T attention heads. For each head, we convert a token representation $\boldsymbol{h}_i \in H$ into vectors $\boldsymbol{u}_i^t, \boldsymbol{v}_i^t \in \mathbf{R}^{d'}$ by trainable transformation matrices, $W_u^t, W_v^t \in \mathbf{R}^{d' \times d}$. We set d' to d/T.

$$\boldsymbol{u}_i^t = W_u^t \tanh(\boldsymbol{h}_i) \quad (1)$$

$$\boldsymbol{v}_i^t = W_v^t \tanh(\boldsymbol{h}_i) \quad (2)$$

---

[6] <grocery> stands for grocery items, and <person> stands for person names taken from the following web pages: vegetablesfruitsgrains.com and ssa.gov/oact/babynames

[7] Note that our method is applicable to other encoder types.

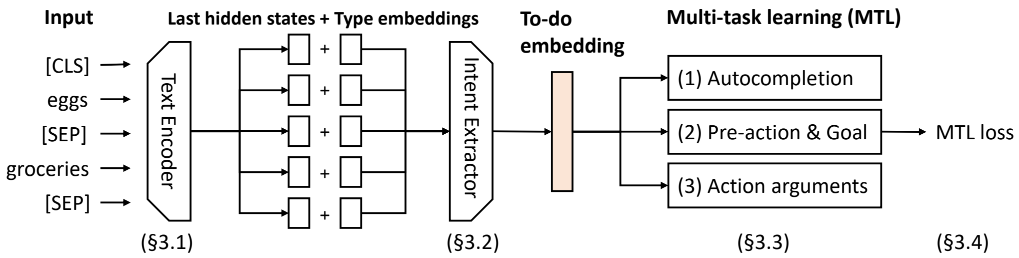

Figure 3: LITE model overview. We encode input tokens with an off-the-shelf text encoder and feed the hidden states and type embeddings to an intent extractor to obtain the representation of the to-do task. We train LITE over three training objectives (1-3) jointly.

We then compute attention scores $\alpha^t \in (0, 1)$ and an output vector $\boldsymbol{o}^t \in \mathbf{R}^{d'}$:

$$\alpha_i^t = \frac{\exp\left(\boldsymbol{q}^{t^T} \boldsymbol{u}_i^t / \sqrt{d'}\right)}{\sum_{j=1}^{N} \exp\left(\boldsymbol{q}^{t^T} \boldsymbol{u}_j^t / \sqrt{d'}\right)} \tag{3}$$

$$\boldsymbol{o}^t = \sum_{i=1}^{N} \alpha_i^t \boldsymbol{v}_i^t, \tag{4}$$

where $\boldsymbol{q}^t \in \mathbf{R}^{d'}$ is a trainable vector. Finally, we obtain an intent vector $\boldsymbol{z}$ by concatenating the output vectors of the T attention heads:

$$\boldsymbol{z} = \text{Concatenate}(\boldsymbol{o}^1, \boldsymbol{o}^2, \cdots, \boldsymbol{o}^T) \tag{5}$$

Token type embedding: We introduce token type embeddings, $\boldsymbol{e}_{\text{task}}, \boldsymbol{e}_{\text{list}}, \boldsymbol{e}_{\text{other}} \in \mathbf{R}^d$, to inform a model of the source of each token. BERT injects token type embeddings in the lowest layer, the embedding layer, and we train them during pre-training (Devlin et al., 2019), but other models do not (Radford et al., 2018; Liu et al., 2019b; Raffel et al., 2020). To avoid breaking the pre-trained parameters of those models, we add type embeddings to H and feed it to the multi-head attention module:

$$\boldsymbol{h}_i' = \tanh\left(\boldsymbol{h}_i\right) + \tanh\left(\boldsymbol{e}_{\text{type}(i)}\right) \tag{6}$$

where type(i) is the type of the i-th token.

3.3 Auxiliary Tasks for MTL

One straightforward way to train the extractor is to directly optimize it to predict the intent of a given to-do task. However, task intents are often obscure and hard to discretize into a fixed number of categories. As a result, manual collection of such categories can be costly and subjective. For example, "buy milk" and "buy a car" are both purchase action, but they differ in many aspects: different locations, different prerequisite events, and different motives.

Input$_{\text{(desc., list)}}$	Output
(milk, groceries)	buy milk
(buy milk, things to do)	buy milk
(eggs, costco)	buy eggs at costco*
(Chris, today)	call Chris today*

Table 1: Examples of texts for the autocompletion objective (§3.3.1). Suppose to-do descriptions "buy milk", "buy eggs" and "call Chris" exist in the WL dataset. We use list-based templates to generate the last two examples denoted by *.

Instead, we propose to train the extractor on multiple auxiliary tasks with weak supervision that provide semantic augmentation to under-specified to-do texts. The underlying assumption is that tasks with similar intents have similar target labels/texts in the auxiliary tasks. Below, we present our three auxiliary training tasks.

3.3.1 Autocompletion

Motivation: Inspired by Lewis et al. (2020), our first task focuses on surface-level information of to-do texts, namely prediction of missing tokens based on context tokens. Specifically, we feed a to-do text (the combination of a description and a list name) to a model, convert it into an intent embedding, and generate the maximal form of a to-do description that is inferable from the input. We call this auxiliary task *autocompletion objective*. We automatically collect such forms for under-specified to-do descriptions from the WL dataset.

Data collection: As previously observed, to-do descriptions under generic lists (e.g., "today") tend to be more specified than those under lists whose names imply specific action. For each to-do description in our WL dataset, we collect their longer descriptions (i.e., super-strings) up to five. We also use several templates for lists that represent locations and times to further expand descriptions (see

Input$_{\text{(desc.)}}$	Output	
buy milk call Chris subscribe Netflix	go to store find number go to website	get milk for breakfast talk to someone watch a movie
Relation used:	`xNeed`	`xIntent`

Table 2: Texts generated for the pre-action and goal objective (§3.3.2) by COMET (Bosselut et al., 2019; Hwang et al., 2021).

Input$_{\text{(desc.)}}$	Output	
buy milk call Chris	Buyer, Goods Addressee, Topic, $\cdots$	Money, $\cdots$ Medium, $\cdots$
FEs used:	`Core`	`Non-core`

Table 3: Labels collected from FrameNet (Ruppenhofer et al., 2016) for the action arguments prediction task (§3.3.3).

details in Appendix B). Table 1 shows examples, two of which were generated with templates. The resulting dataset contains 1,487,161 pairs of short and long to-do descriptions. We combine them with specified to-do descriptions, which already have action verbs and do not have longer counterparts, and sample 2M examples (50% of examples are under-specified.) During training, one generation target is picked at random for each instance.

3.3.2 Pre-action and Goal Generation

Motivation: This task aims to represent to-do tasks based on their prerequisite actions (what we must do beforehand) and goal events (what we want to achieve), assuming that tasks with similar intents have similar prerequisites and goals. Here, a model is trained to generate prerequisite and goal actions for a given to-do item (a task description and a list name). We call this objective *pre-action and goal generation objective.*

Data collection: We leverage COMET (Hwang et al., 2021), a BART model (Lewis et al., 2020) fine-tuned on ATOMIC$^{20}_{20}$, to collect weak supervision signals about to-do tasks' prerequisites and goals.[8] Specifically, we feed a long description of a to-do task generated in the previous step (§3.3.1) to the BART model as a prompt followed by a relation token: (1) `xNeed` (prerequisite) token to generate the task's prerequisite or (2) `xIntent` (goal) token to generate the task's goal. We use beam search with width of 3 and collect the top-3 results for each relation. Table 2 shows generation results for three example to-dos.

3.3.3 Action Arguments Prediction

Motivation: Different to-do tasks have different domain-specific arguments. For example, a *purchase* task must have a *purchase target*, and possibly a *price* argument. In contrast, *contact* tasks usually have a *receiver* and a *topic of communication* argument. We design a multi-label training task called *action arguments prediction*, where, given a description and a list name, a model predicts all the action arguments associated with the to-do task.

Data collection: We use FrameNet (Ruppenhofer et al., 2016), a manually-created database on the meaning and usage of English words/phrases. Semantic representations are defined for concepts and events (called *frames*) and for their semantic elements (called *frame elements, FEs*); example texts that trigger frames and FEs are also provided. FEs can be *core* FEs (essential information for a frame), or *non-core* (optional). Table 3 shows examples.

Using the "long" to-do descriptions collected for the autocompletion task (§3.3.1), we identify frames in them using an off-the-shelf frame identifier (Swayamdipta et al., 2017). As our focus is on to-do tasks, we discard frames whose root frame is not `Event`. We then collect FEs for each frame from FrameNet. If a to-do description has two or more frames, we take the union of their FEs. For non-core FEs, we calculate importance weights by TF-IDF over the whole FrameNet repository so that common FEs appearing in many frames (e.g., `Manner`) have low weight. We normalize the weights into $(0, 1]$ by dividing them by the maximum weight.

3.4 Optimization

For the autocompletion as well as the pre-action and goal generation tasks, we employ a two-layer GRU (Cho et al., 2014) decoder with a cross-attention mechanism (Luong et al., 2015). We use the embedding layer of the encoder also in the decoder. We train the model to minimize the following cross-entropy loss for each instance:

$$\mathcal{L}_{\text{gen}} = -\sum_{j=1}^{M} \log P(y_j|y_{<j}, \boldsymbol{z}, H), \qquad (7)$$

---

[8] We can retrieve prerequisites and goals of some to-do tasks from knowledge bases such as ATOMIC$^{20}_{20}$ (Hwang et al., 2021) and ConceptNet (Speer et al., 2017) without relying on language generation, but it is not always the case that we can find the action of interest in the existing resources. The use of COMET is advantageous in handling unseen actions as shown by several studies (Bosselut et al., 2019; Hwang et al., 2021).

where M is the length of the output text. We apply label smoothing with a smoothing factor of 0.1 (Pereyra et al., 2017).

For the action arguments prediction task (multi-label classification), we use GILE as a label-embedding approach (Pappas and Henderson, 2019). Given an intent embedding and label embedding, GILE projects them into a joint vector space and computes an association score from their element-wise product. Concretely, for each label l, we calculate its score $P(l) \in (0,1)$ as follows:

$$\boldsymbol{e}_{\text{in}} = \text{Act}(W_{\text{in}}\boldsymbol{z}) \tag{8}$$

$$\boldsymbol{e}^{(l)}_{\text{label}} = \text{Act}(W_{\text{label}}\boldsymbol{v}^{(l)}) \tag{9}$$

$$P(l) = \text{Sigmoid}\left(W_{\text{out}}(\boldsymbol{e}_{\text{in}} \odot \boldsymbol{e}^{(l)}_{\text{label}})\right), \tag{10}$$

where $\boldsymbol{v}^{(l)} \in \mathbf{R}^d$ is a pre-computed label embedding (constant), Act is an activation function and $W_{\text{in}}, W_{\text{label}} \in \mathbf{R}^{d \times d}$ and $W_{\text{out}} \in \mathbf{R}^{1 \times d}$ are model parameters. To compute the label embeddings for FEs (Eq(9)), we encode the definitions of FEs in FrameNet with pre-trained transformer models.

We define the loss function to be:

$$\mathcal{L}_{\text{clf}} = \frac{1}{C}\sum_{c=1}^{C}\left(c\log P(c) + (1-c)\log\left(1-P(c)\right)\right), \tag{11}$$

where C is the number of classes.

We optimize a model to minimize the following weighted loss across three MTL objectives:

$$\mathcal{L} = \sum_{\text{task}} \frac{\mathcal{L}_{\text{task}}}{\log N_{\text{task}}}, \tag{12}$$

where N_{task} is the number of target labels in a subtask (Aghajanyan et al., 2021).

4 Experiments

Our aim is to obtain a single, general-purpose representation model that is effective on various downstream applications. We run LITE on top of $\text{BERT}_{\text{base}}$, $\text{BERT}_{\text{large}}$, and RoBERTa and evaluate its performance.

4.1 Evaluation Tasks

We evaluate LITE on four downstream tasks (Table 4): (1) urgent and important to-do detection (UIT), (2) actionable to-do classification (AT), (3) co-located and co-timed to-do pair detection (CoLoc and CoTim), and (4) intent detection (ID).

Urgent and Important To-do Detection (UIT): The goal of this task is to detect urgent or important tasks, an essential step for to-do prioritization in real applications. To evaluate this task we use a proprietary dataset (derived from WL) containing 2,254 human-labeled to-do descriptions. Each description is categorized into urgent and not-urgent classes based on the majority vote of 3 annotators. This dataset does not provide list names, hence we use a dummy list name "inbox" for LITE.

Actionable To-do Classification (AT): This task aims to identify to-do tasks that require a concrete, individual action to accomplish (*ActionableTask*) (e.g., "Sign up for dance class"). We evaluate this task using a proprietary dataset (derived from WL) containing 12,189 to-dos. Each instance consists of a description and a list name, and is manually categorized into *ActionableTask*, *Note*, and *ActionableCollection*. A *Note* is a list item that users add for future use, without the need for immediate action (e.g., "baby names"). Tasks that are labeled as *ActionableCollection* are not performed individually but rather as part of a collection of items in a larger task: "tomatoes" in the "groceries" list, for example, are part of the larger task "do groceries" where all the individual to-dos are addressed at the same time and location. Each example was annotated by 3 annotators, the majority label is the gold label. Tasks where one or more annotators were unsure about the correct label were eliminated.

Co-located and Co-timed To-do Pair Detection (CoLoc/CoTim): This task focuses on the location and time where to-do tasks are accomplished. Time and location are particularly powerful cues for task recommendations and reminders (Graus et al., 2016). In this task, given a pair of to-do items, the model predicts whether the two to-do tasks can be completed in the same location (CoLoc) or at the same time (CoTim). To evaluate this task we use the MS-LaTTE (Jauhar et al., 2021) dataset (derived from WL), which contains 25,000 pairs of to-do tasks (description + list name), of which 398 are labeled as CoLoc and 401 as CoTim.

Intent Detection (ID): This task focuses on predicting the intent associated with a to-do description. We use Landes and Di Eugenio (2018)'s dataset, which contains 253 to-do instances, each one labeled with one of nine intent classes ("calendar", "find-service", "buy", etc.). No list name is provided in this dataset, so we use the generic list name "inbox" for LITE.

Task	**Size**	**Example: (description, list name) [class]**
Urgent and Important To-do Detection (UIT)	2,254	(pick up packages at FedEx, n/a) [urgent], (sign up for HBO, n/a) [non-urgent]
Actionable To-do Classification (AT)	12,189	(Sign up for dance class, inbox) [Actionable], (tomatoes, groceries) [ActionableCollection], (StarWars, movies to watch) [Notes]
Co-located To-do Pair Detection (CoLoc)	25,000	(fix tv, inbox)-(clearn sink, today) [+], (fix tv, inbox)-(refill medicines, today) [-]
Co-timed To-do Pair Detection (CoTim)	25,000	(get breakfast, daily)-(check news, inbox) [+], (get breakfast, daily)-(pickup dryclearner, inbox) [-]
Intent Detection (ID)	253	(schedule appointments with site managers, n/a) [calendar], (fix the CD ROM drive on my computer, n/a) [find-service]

Table 4: Evaluation tasks. Note that the UIT and ID datasets do not have list names.

4.2 Setup

In all tasks, we first generate vector representations of instances in the dataset with a pre-trained encoder and train a simple classifier on them. The quality of the embeddings is measured by the performance of the classifier. We use a logistic regression classifier implemented in scikit-learn (Pedregosa et al., 2011), with or without a penalty term. To train a classifier for CoLoc and CoTim, which provide two to-do descriptions as input (see section 4.1), we concatenate the vector representations of the two items along with their element-wise product and difference vectors (Mou et al., 2016).

We generate 20 sets of training, validation, and test splits at random (Gorman and Bedrick, 2019)[9], and, in each trial, we use a validation split to tune hyperparameters by grid search (a regularization $\in$ {None, L1, L2} and a regularization coefficient $\in \{2^{-5}, 2^{-4}, 2^{-3}, 2^{-2}, 2^{-1}, 1\}$).

4.2.1 Implementation Details

We implemented our MTL framework using PyTorch v1.10.0 (Paszke et al., 2019) and ran experiments on NVIDIA GeForce GTX TITAN X and RTX A6000 (for BERT$_{\text{large}}$). We use uncased BERT$_{\text{base}}$, uncased BERT$_{\text{large}}$, and cased RoBERTa$_{\text{base}}$, in the `transformers` library v4.6.1 (Wolf et al., 2020) with the default parameters for dimensions, activation functions, and dropout. We set the number of attention heads in the extractor and the dimension of hidden states based on the choice of a text encoder, namely $(T, d) = (12, 768)$ for BERT$_{\text{base}}$-LITE and RoBERTa-LITE, and $(T, d) = (16, 1024)$ for BERT$_{\text{large}}$-LITE. We applied dropout of 0.1 to our modules except for the output layers. We optimized the model parameters using AdamW (Loshchilov and Hutter, 2019) with batch size of 2,048, learning rate of 5e-5, L2 weight decay of 0.01, and linear learning rate decay with warm-up steps of 2% of the total steps. We also apply gradient norm clipping of 1. We train our models for 15 epochs, and freeze the transformer encoder for the first 5 epochs. We sampled 3,459 examples as validation data, on which we evaluate a model every epoch, and terminate training if the validation loss does not improve for three consecutive epochs. We tuned hyperparameters and architectural choices (§3.2) based on the average validation scores over 20 random trials on all the datasets (more details in Appendix C).

4.3 Baselines

We compare the following encoders as baselines.[10]

BERT (Devlin et al., 2019): We take the embedding of the first token, `[CLS]`, to represent a to-do text. `[CLS]` embeddings are trained to represent the whole input sequence by next sentence prediction (NSP). We compare the base (12 layers, 768D) and large (24 layers, 1024D) models.

RoBERTa (Liu et al., 2019b): We take the average of the last hidden states to represent an input sequence as RoBERTa is not trained with NSP. We use RoBERTa$_{\text{base}}$(12 layers, 768D).

Motivated by Gururangan et al. (2020), we also compare the domain-adapted ("DA") version of BERT and RoBERTa. We perform additional pretraining to BERT$_{\text{base}}$ and RoBERTa on the 6M raw to-do texts (`<s>` description `[SEP]` list name `</s>`) from WL.

Sentence-Transformer: We also test off-the-shelf *general-purpose* sentence encoders based on Transformers. These encoders are pre-trained to induce sentence embeddings with siamese and

---

[9] We split data into 6:2:2 for UIT, AT, and CoLoc/CoTim, and 8:1:1 for ID.

[10] We evaluate additional baselines in Appendix E. The implementation details can be found in Appendix F.

triplet network on top of pre-trained Transformer models (Reimers and Gurevych, 2019). We use the pre-trained encoder based on $\text{BERT}_{\text{base}}$ and $\text{RoBERTa}_{\text{base}}$. The encoders are trained on about 286k of natural language inference and textual similarity instances.

4.4 Results

Table 5 shows our main results. LITE consistently achieves the best performance on all tasks for all three encoders, demonstrating the generality of the learned representations. DA brings in performance improvements but only marginally on most tasks[11]. This is probably because to-do texts are too short to perform effective language model training.

Sentence-Transformers have proven effective in various sentence-level tasks (Reimers and Gurevych, 2019), but it is not the case in this experiment. The vanilla BERT and RoBERTa encoders perform on par with their Sentence-Transformer counterparts and in some cases outperform them. We conjecture that those sentence encoders cannot leverage contextual information effectively as they are pre-trained on sentences that are quite different from to-do texts. Our training framework can also fine-tune Sentence Transformers to adapt them to short and under-specified to-do texts, which we leave for future work.

Our goal is to train a general-purpose encoder. However, the interested reader can find an evaluation of *task-specific* fine-tuning in Appendix G.

4.5 Analysis

Table 6 shows the contribution of our auxiliary tasks to the overall performance. The full model performs the best in all the tasks except ID.

As discussed earlier, our model needs to combine information from descriptions and list names to infer the meaning of to-dos. We show that our model successfully learns when to attend lists. We extract list names from the AT dataset that appear with more than 17 different to-do descriptions (90% percentile) and analyze the product of attention weights and vector norms of descriptions and list

---

[11] It is also possible to combine domain adaptation by language modeling and LITE, however, it underperformed LITE overall. With $\text{BERT}_{\text{base}}$, the performance were UIT 0.873, AT 0.931, CoLoc 0.863, CoTim 0.447, and ID 0.656.

tokens (Kobayashi et al., 2020). Table 7 shows list names with the highest and lowest average scores assigned by BERT-LITE. Generic list names have low scores ('to do list", "house to do") while specific (action-related) list names have much higher scores ("bring", "cleaning").

However, we believe it would not be prudent to just ignore generic lists as they can still convey semantic/pragmatic clues. For example, a list named "wishlist" typically has to-dos which a user does not need to act on immediately. Hence, this list is a strong indicator of a non-actionable task (in AT).

5 Related Work

To-do Management: Intelligent systems can assist users with task management in many ways (Gil et al., 2012). To-do tasks can be inferred automatically from emails (Mukherjee et al., 2020). Systems can detect types of to-do items and suggest relevant applications or resources to users (Landes and Di Eugenio, 2018; Gil et al., 2012; Shah and White, 2021). Once to-do tasks have been created, a system can help users manage the completion progress, e.g., by sending reminders (Graus et al., 2016). Complex tasks can be decomposed automatically into more manageable sub-steps (Nouri et al., 2020; Zhang et al., 2021). In all these use cases, a common step is to represent the input language as computational vector representations, but none of the existing studies has produced general-purpose representations of to-do tasks.

Short-text Representations: Multiple NLP areas involve very short texts with some unique characteristics. Several methods have been developed for tweets (e.g., Nguyen et al., 2020). Tweets pose the added challenge of containing many non-standard colloquial expressions and contain non-language text like URLs. Still, Wang et al. (2020) present a similar finding to ours: massively pre-trained encoders do not always perform well. Search queries are also short, with an average of three terms (Taghavi et al., 2012). Unlike to-dos, information such as click logs (Zhang et al., 2019) can be used as an indicator of user intent. Another key difference is that search queries are written with the goal of having a machine interpret them.

Multi-task Learning: Multi-task learning improves the performance of pre-trained language models in various NLP tasks (Liu et al., 2019a; Shuster et al., 2020; Aghajanyan et al., 2021). The common perception in the research community is that auxiliary training tasks are effective when they are similar to the target domain/task (Shui et al., 2019). However, there are few relevant tasks and datasets for the to-do domain. Our study is the first work to propose a time- and cost-efficient way to harvest weak-supervision for MTL in that domain.

6 Conclusion

We discussed how to produce general-purpose representations of short and under-specified to-do texts for performing various kinds of intelligent task assistance with a single encoder. Our method, LITE, uses a multi-head attention mechanism with token type embeddings on top of an off-the-shelf contextual text encoder to effectively induce semantic information from the combination of to-do descriptions and list names. The model is trained using three auxiliary tasks: autocompletion, pre-action and goal generation, and action arguments prediction.

We applied LITE to BERT$_{\text{base}}$, BERT$_{\text{large}}$, and RoBERTa and compared them with various baseline models on four downstream tasks. LITE consistently outperformed the baselines, demonstrating the effectiveness of our method.

A Ethical Considerations

The proprietary Wunderlist data was anonymized and personally identifiable information was scrubbed. Names were replaced by random names. In addition, k-anonymization was performed on the data so that tasks that were created by fewer than five users or fewer than 100 times in total were automatically discarded. The result is an *aggregate* view of the logs, devoid of any identifiers, private information or infrequent tasks that can be correlated back to a user. The data cleaning process was approved by an internal legal review board before the data was cleared for internal use. None of the data is exposed in this paper. Example texts presented in this paper are made up by the authors, and no text is taken verbatim from the original data.

As LITE is essentially built on pre-trained language models, biases existing in the original language models can still remain in the final model (e.g., biased associations between gender and actions). We did not observe any undesired associations caused by the models in our experiments, but it may be required to monitor biases and apply debiasing techniques before deploying the model to production systems.

Although LITE is not specifically designed for English, it will require significant cost to deliver the

outcome to other languages due to the dependence on English resources (knowledge bases used for training COMET and English FrameNet).

B Templates for Autocompletion Data

We used 312 hand-crafted templates for collecting the autocompletion data. We first created templates for common nouns used in list names such as “today”, “monday”, “mom”, and “home”. We then used a publicly available dataset[12] to mine list names that represent company names such as “costco” and “target”. We show some examples in Table 8.

C Architecture Search

We present the validation scores with different architectural choices in Table 9 (how to inject type embeddings) and Table 10 (number of attention heads in the intent extractor). We used BERT$_{\text{base}}$ as a base text encoder and trained BERT-LITE on 500k samples of our dataset.

D Statistical Significance Test

Following the recommendation of Gorman and Bedrick (2019), we performed a permutation test with 5,000 trials between vanilla Transformer vs. DA, vanilla Transformer vs. LITE, and DA vs. LITE for each of twenty trials. We applied Bonferroni correction to the obtained p-values (Dror et al., 2017) to avoid over-estimate statistical significance. Table 11 reports the number of random trials where one model’s score is significantly higher than that of the other model ($\alpha = 0.05$). We can see that LITE performs significantly better than the vanilla counterpart more often than DA does. The results show that RoBERTa-LITE’s score is even significantly higher than that of RoBERTa-DA in some tasks (UIT, CoLoc and CoTim).

E Additional Baseline Results

In this section, we present experimental results with the following additional baselines:

GPT-2 (Radford et al., 2018): We take the average of the last hidden states to represent an input sequence as we do for RoBERTa. Unlike BERT and RoBERTa, GPT-2 is a unidirectional encoder.

Sentence-MPNet: MPNet is a Transformer-based pre-trained language model that is reported to outperform BERT and RoBERTa (Song et al., 2020). Sentence-Transformer (Reimers and Gurevych, 2019) based on MPNet (Sentence-MPNet) is trained on 1.2B sentences from vari-

	UIT			AT	CoLoc			CoTim			ID
	Prec.	Rec.	F1	Acc.	Prec.	Rec.	F1	Prec.	Rec.	F1	Acc.
BERT	.828	.840	.833	.938	.898	.942	.919	.542	.608	.563	.320
RoBERTa	.849	.859	.853	.940	.864	.952	.905	.411	.432	.384	.288

Table 13: Result of in-dataset fine-tuning.

ous tasks and is considered to be the best-quality general-purpose encoder (Reimers, 2021).

word2vec and fastText: Unlike the other baseline encoders, word2vec (Mikolov et al., 2013) and fastText (Bojanowski et al., 2017) do not contextualize embeddings. We use a 300D word2vec model trained on Google News 100B and extend it by Magnitude (Patel et al., 2018) for OOV words. For fastText, we use a 300D model trained on CommonCrawl 2M. We also train a word2vec model from scratch on the same texts without special tokens as the domain-adapted version (DA).

Results (Table 12): GPT-2 performed worse than BERT and RoBERTa. Sentence-MPNet is trained with a huge amount of additional training data but still under-performs LITE. word2vec and fastText performed similarly and outperform vanilla BERT and RoBERTa on UIT and ID. The two datasets do not provide list names as input and have fewer data points than the other datasets. Thus, we conjecture that (1) there is not enough word context that vanilla BERT and RoBERTa can leverage and (2) the dimension of embeddings is too high for a classifier to find generalizable patterns from a small amount of data.

F Implementation Details of Baselines

We implemented the baseline encoders with the following libraries.

Transformers: We used Huggingface's `transformers` library (Wolf et al., 2020) to run pre-trained Transformer models.

Sentence Transformers: We use the Sentence-BERT library (Reimers and Gurevych, 2019)[13] to run pre-trained sentence encoders. We used the following pre-trained models:

BERT: `roberta-base-nli-stsb-mean-tokens`[14]

RoBERTa: `roberta-base-nli-stsb-mean-tokens`[15]

MPNet: `all-mpnet-base-v2`[16]

G Fine-tuning BERT and RoBERTa

We present the performance of BERT and RoBERTa fine-tuned on downstream datasets. Note that our main goal is to train a general-purpose encoder that does not need to be re-trained for each downstream task as we describe in §1. We aim to answer the following two hypothetical questions.

Q1 (In-dataset fine-tuning): How well could BERT and RoBERTa perform if they were fine-tuned on the target dataset? This approach is commonly practiced for *task-specific* representations (Devlin et al., 2019).

(b) $\text{RoBERTa}_{\text{base}}$

Table 14: Test performance of fine-tuned BERT and RoBERTa. **The diagonal cells** show the performance of the models trained with the in-dataset fine-tuning setting.

Q2 (Cross-dataset fine-tuning): How well could BERT and RoBERTa perform on the target dataset if they were fine-tuned on another dataset? (Were the fine-tuned encoders generalizable to multiple to-do datasets?)

Setup: We fine-tune and evaluate $\text{BERT}_{\text{base}}$ and $\text{RoBERTa}_{\text{base}}$ models on the 20 random splits used in the main experiments. We follow Devlin et al. (2019) and add a linear classification layer that takes in the final hidden state of the first token (`[CLS]` token). For fine-tuning, the encoder and classifier are trained to optimize a binary cross entropy loss (UIT, CoLoc, and CoTim) or a cross entropy loss (ID and AT). We use the same optimization configurations described in §4.2.1. We continue training for 5 epochs and take the checkpoint that achieves the best validation score. For the cross-dataset experiment, we initialize the encoder with the fine-tuned parameters and freeze it during training. We use the same optimization settings except that we set a learning rate to 0.001.

A1 (Table 13): As expected, the fine-tuned models perform better than LITE on several datasets (AT, CoLoc, and CoTim with BERT, and AT with RoBERTa). When the main goal is to build task-specific representations, and there is a sufficiently large training dataset, task-specific fine-tuning will be a better solution than LITE. However, the result shows the fine-tuned models do not *always* outperform LITE. We conjecture that for datasets without a sufficient number of training instances like UIT and AT, a fine-tuning strategy is not very effective.

A2 (Table 14): Performance consistently drops when the encoders are trained on another dataset, and all the scores are far below those of BERT/RoBERTa-LITE. This result indicates that LITE is more effective for training generalizable encoders than fine-tuning on a single dataset.

Does Summary Evaluation Survive Translation to Other Languages?

Abstract

The creation of a quality summarization dataset is an expensive, time-consuming effort, requiring the production and evaluation of summaries by both trained humans and machines. The returns to such an effort would increase significantly if the dataset could be used in additional languages without repeating human annotations. To investigate how much we can trust machine translation of summarization datasets, we translate the English SummEval dataset to seven languages and compare performances across automatic evaluation measures. We explore equivalence testing as the appropriate statistical paradigm for evaluating correlations between human and automated scoring of summaries. We also consider the effect of translation on the relative performance between measures. We find some potential for dataset reuse in languages similar to the source and along particular dimensions of summary quality. Our code and data can be found at `https://github.com/PrimerAI/primer-research/`.

1 Introduction

A large summarization dataset includes thousands of texts and human-written summaries (for example, CNN/Daily Mail (Hermann et al., 2015)). In order to make it applicable for wider research, it may also contain machine-generated summaries by many models, accompanied by human and machine evaluations of the quality of the generated summaries (Fabbri et al., 2021). The human annotation alone is a complicated effort, requiring careful planning and setup (Kryscinski et al., 2020; Tang et al., 2021; Iskender et al., 2021).

What purpose do the human annotations serve? Their main utility is serving as a benchmark for automated evaluation measures. Researchers design measures to closely approximate human judgment in order to increase the pace of summarization model improvement. As summarization resources grow for English-language models, it becomes increasingly important to consider whether we can repurpose these datasets for use in other languages as well.

Given a method that could produce flawless translations, the original human annotations quite clearly remain useful, as the relative rankings of the summaries would be invariant. In this scenario, comparing automated measures in another language with the English human scores produces valid conclusions.

In practice, however, translation will introduce some distortions — both mild and extreme — that can spoil the utility of the original annotations. While a "uniform" distortion over all texts would preserve the relations among evaluation measures, this too is an unrealistic assumption as translation will correct and simplify some texts, introduce errors into others, and push components of text quality like relevance, coherence, and fluency in different directions (Fomicheva et al., 2021; Freitag et al., 2021). We are left to ask how to determine whether it is still practical to rely on the original human annotations for at least some quality measures and alternate languages?

In this paper, we seek to address this question through two quantitative explorations of automated evaluation measures under translation. First, we determine how often the correlation between a given measure and the original human annotations remains equivalent under translation. Second, we consider if one automated measure aligns more closely with human judgment than another in English, how often their relative positions are maintained after the translation. We conduct this investigation using the SummEval dataset (Fabbri et al., 2021), the largest corpus of English-language human annotated text summaries widely available. We translate this dataset from English to seven languages and evaluate the correlations between automated summary evaluation measures and human

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2425 - 2435
July 10-15, 2022

annotations. Using equivalence tests, we show that some aspects of summary quality ranking are preserved under translation for languages with similar alphabets and grammars to English. While we find some reasons for optimism about the potential for dataset reuse, our work clearly demonstrates that more research is needed to make translated datasets useful for a diverse set of languages.

2 Data and Models

We focus our analysis on the portion of SummEval[1] that includes human annotations. It consists of 100 texts, each accompanied by 11 human-written reference summaries and 17 machine-generated summaries produced by different models. Each machine-generated summary is annotated by three experts and five crowd workers using a five-point scale for four quality measures: coherence, consistency, fluency, and relevance. For simplicity, we create a composite rating by averaging the expert scores for each quality of a given text-summary pair.

We translate all 100 source texts, 1100 human reference summaries, and 1700 machine-generated summaries into seven languages — French, German, Italian, Spanish, Afrikaans, Hindi, and Russian — using translation models trained and uploaded to the Hugging Face Model Hub by Helsinki-NLP[2] and accessed via the transformers library (Wolf et al., 2020). The specific models used for translation are named 'opus-mt-L1-L2', where one of L1 or L2 is 'en' (English), and the other is one of the languages 'af', 'de', 'es', 'fr', 'hi', 'it', or 'ru'.

In each language version of the dataset, we score machine-generated summaries with a few common or promising automated evaluation measures that could be applied to all eight languages. We calculate the following truly automated (not needing human written reference summaries) measures: Jensen-Shannon (Louis and Nenkova, 2009), ESTIME (Vasilyev and Bohannon, 2021a)[3] and BLANC (Vasilyev et al., 2020)[4]. We also calculate the following reference-based automatic evaluation measures: BLEU (Papineni et al., 2002), BERTScore-F1[5] (Zhang et al., 2020), and ROUGE (Lin, 2004) as ROUGE-1,2,L[6]. These measures were selected to cover a wide range of strengths and weaknesses in replicating human judgment (see Appendix C for more detail). We use the same original human annotations provided by the SummEval dataset as annotations in each of the seven translated languages.

We used 'bert-base-multilingual-cased' as the underlying model for BLANC and ESTIME. While other choices of underlying model could produce higher correlations with human annotations in English, this multilingual model was selected to provide a more uniform performance across languages. BERTScore relies on 'bert-base-multilingual-cased' for all languages except English, for which it uses the model 'roberta-large'. ESTIME embeddings were taken from the 10th transformer block layer instead of the final 12th layer. We followed Vasilyev and Bohannon (2021a), where it was shown that for the larger model 'bert-large-uncased-whole-word-masking' the 21st layer delivers the better performance than the 24th and final layer.

We calculate correlations between automated evaluation measures in each language and the human annotations on the original English dataset. We seek to answer whether these correlations are reasonably independent of the language. In other words, can we rely on such correlations to provide consistent judgement of evaluation measures in other languages?

3 Comparisons within Measures

3.1 Simple Correlations

It has become standard in the summarization literature to judge the performance of an automated measure by the correlation of its scores with human evaluation of summaries (e.g. Zhang et al. (2020), Deutsch et al. (2021)). Figure 1 shows Spearman's ρ and Kendall's τ correlation coefficients between the expert human evaluations and the automated measures run on the English summaries found in the SummEval dataset. Each correlation is calculated over a pair of 1700 length vectors — one composed of the expert scores along a particular quality and the other containing scores produced by an automated measure for all machine-generated summaries.

Figure 2: Spearman's ρ and Kendall's τ correlations between automated evaluation measures in English and in translated languages German (DE), French (FR), Spanish (ES), Italian (IT), Afrikaans (AF), Hindi (HI), and Russian (RU).

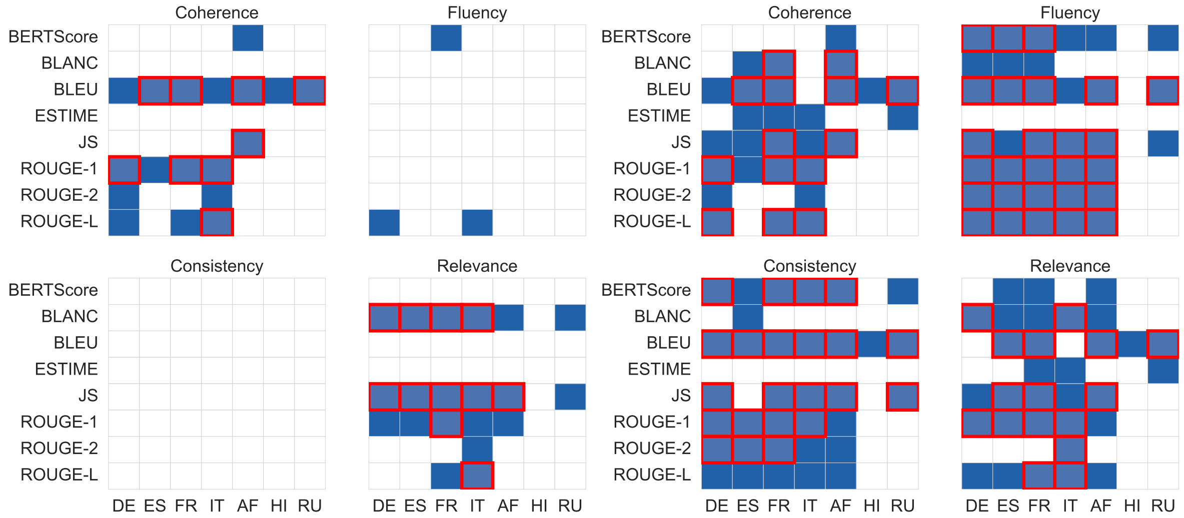
The correlations are consistently weak, indicating that the measures rely on different features than human evaluations of a summary. ESTIME, BERTScore, and Jensen-Shannon all demonstrate somewhat higher correlations in at least some measures of quality, perhaps reflecting a more nuanced approach to summary scoring.

Automated evaluation of summarization models is still an evolving field. While most measures disagree with human judgment often, they are still widely used as points of comparison across model outputs. Therefore, it remains highly relevant to determine whether translation preserves the judgments rendered by the automated measures.

We may consider an evaluation measure to be useful under translation if the scores it assigns to summaries are consistent across languages, perhaps in absolute value but at least in the rank ordering of summaries. Therefore such a measure would exhibit high correlation between its values on English summaries and those for the summaries translated to other languages. Figure 2 shows Spearman's ρ and Kendall's τ correlation coefficients between the automated measures run on the English corpus and each translated corpus.

For a given measure, the correlations across languages are generally much stronger than those between automated measures and human evaluations in English seen in Figure 1. For languages with the strongest correlations to the English measures, this result provides some promise that translation might introduce minimal additional noise, meaning the evaluation measure provides consistent signal across languages.

The reference-based measures generally show stronger correlations ($\rho > 0.6$, $\tau > 0.5$) between English and German, French, Spanish, Italian, and Afrikaans translations. For Russian and Hindi, they show weaker correlations, drastically so for ROUGE measures. Among the reference-free measures, Jensen-Shannon and BLANC demonstrate similar patterns of performance. These results at



(a) TOST with standard deviation margin of equivalence

(b) TOST with constant 0.05 margin of equivalence

Figure 3: Results of tests of equivalence for each automated measure (y-axis), language (x-axis), and quality measure (coherence, consistency, fluency, relevance). Blue squares indicate p-value ≤ 0.05 while red highlights indicate the result remained significant after applying Benjamini-Yekutieli correction for FDR control. *Left*: Results for TOST with standard deviation margin of equivalence. *Right*: Results for TOST with constant 0.05 margin of equivalence.

least suggest that measures may prove useful when translating datasets to languages with similar origins (here Italic or Germanic languages). However, ESTIME shows weak correlations across languages with a smaller drop in correlation between Western European derived languages and Hindi and Russian.

3.2 Significance Tests

Given the promising results in Section 3.1, we seek to test whether correlations between an automated measure and the original expert scores are statistically invariant when run on the English and translated summaries. Since human evaluations are split into four qualities - coherence, consistency, fluency, relevance - we consider correlations separately along each measure. For example, we look to answer whether the correlation between English BLANC scores and English expert scores for relevance is equivalent to the correlation between German BLANC scores and English expert scores for relevance. We consider this a natural test of an automated measure's utility after translation, as we hope measures will reflect human judgment in a consistent and predictable manner across languages.

Since we are interested in demonstrating a lack of statistical difference between two correlations, ρ_1 and ρ_2, we cannot use a typical hypothesis test with null hypothesis $H_0 : \rho_1 = \rho_2$. Such a test would only suggest equivalence by failing to reject the null hypothesis, which could simply occur due to a lack of statistical power.

Instead, we turn to equivalence tests, a paradigm which effectively reverses null and alternative hypotheses, i.e. $H_0 : \rho_1 \neq \rho_2$. We explore two such tests, Two One-Sided Tests (TOST) and Anderson-Hauck tests, and call for additional research to standardize their use for summarization evaluation.

3.3 Two One-Sided Tests (TOST)

In the TOST procedure (Schuirmann, 1987), we must set a margin of equivalence, Δ_E, within which we consider two test statistics to be equivalent. Then for two correlations, ρ_1 and ρ_2, we have null and alternative hypotheses:

$$H_0 : \rho_1 - \rho_2 < -\Delta_E \text{ or } \rho_1 - \rho_2 > \Delta_E$$
$$H_1 : -\Delta_E < \rho_1 - \rho_2 < \Delta_E$$

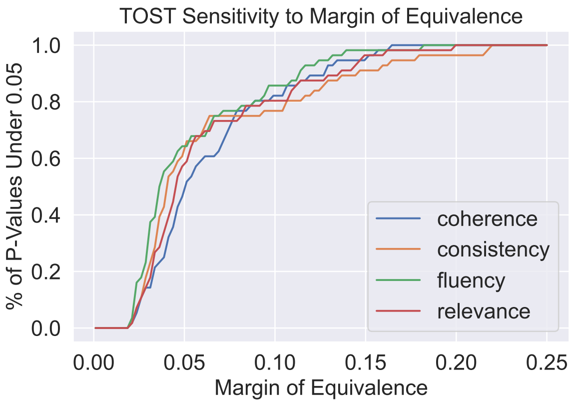
While in a field like medicine, the margin might be well defined by a chemical process, we lack a strong prior for choosing a relevant margin. We explore several options and consider the sensitivity of p-values to our choices when evaluating the validity of the tests' conclusions.

The Kendall rank correlation differences considered do not follow a normal distribution, and we use bootstrap resampling (Efron and Tibshirani, 1993) to generate an empirical distribution. For a given translation language, automated evaluation measure, and quality measure, we sample across (text, summary, and reference summary) tuples. (Note for reference-based summaries - BERTScore, BLEU, and ROUGE - a more complete bootstrap procedure would account for the stochasticity present in the choice of reference summaries themselves. We provide an illustrative example in Appendix B.)

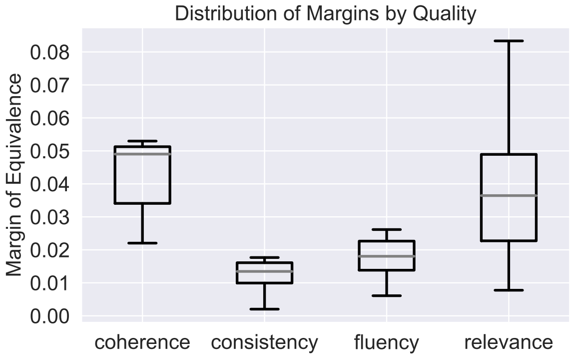
While permutation-based tests have been shown to have higher power in summarization evaluation than bootstrap resampling (Deutsch et al., 2021), permutation tests assume null hypothesis $H_0 : \rho_1 = \rho_2$ and are not simply adapted to our case. We apply a multiple testing correction to the p-values calculated due to the large number of tests considered. We use the Benjamini-Yekutieli procedure (Benjamini and Yekutieli, 2001) to account for dependence among correlation measures and control the false discovery rate (FDR) at level $\alpha = 0.05$.

We consider several relevant equivalence margins with different trade-offs. We try a *constant margin* of 0.05 across all measures and qualities; a *standard deviation margin* using the standard deviations for correlations between individual experts and an automated measure; and a *maximum difference margin* calculated as the largest absolute difference in correlations between individual experts and an automated measure. Under the constant margin, 58% of correlations are equivalent before FDR correction and 35% after. Under the maximum difference margin, 44% of correlations are equivalent before correction and 29% after. Finally, under the standard deviation margin, 18% of tests are equivalent before and 9% after correction.

We present the full results of the TOST procedure with a standard deviation margin in the left panel and a constant margin in the right panel of Figure 3. While both panels demonstrate interesting patterns of equivalence, we focus on the standard deviation margin as it is tailored to each language-measure pair, relies on a less arbitrary value of expected variation under equivalence, and is more conservative than the other margins considered. The max difference and constant margins found much higher rates of equivalence under translation.



(a) Sensitivity of TOST to the margin of equivalence. Small changes in the margin can result in a large change in the percent of tests with significant p-values.



(b) Distribution of margins by quality under the standard deviation margin. Using the variation observed among individual human annotations produces more strict thresholds of equivalence for consistency and fluency and more lenient ones for coherence and relevance.

Figure 4: Measuring the impact of margins of equivalence on the TOST results.

Examining the results, we can note a few clear patterns. First, as seen under the simple correlation analysis, the Italic and Germanic languages have a higher number of significant results than Hindi or Russian. We may still consider using translated summarization datasets from English to languages considered "close." However, there are no significant results in the fluency or consistency qualities under the standard deviation margin (Figure 3a). Therefore the automated measures may only be useful under translation along specific dimensions of quality. Looking at the correlations in English between automated measures and expert judgments in Figure 1, fluency and consistency also tend to have much lower correlations than coherence and relevance.

Additionally, the choice of equivalence margin has a consequential impact on results. Figure 4a shows how the number of significant p-values changes in response to an increasing margin of equivalence. Given the apparent sensitivity to changes in the margin, further research is warranted into how the performance of translation and summarization systems relates to the correlations measured here.

Therefore, the lack of significance for the fluency and consistency qualities can be attributed to both the capabilities of the automated measures and how the standard deviation margin varies across qualities. We already expect from Figure 1 that measures may be capturing a large amount of noise for fluency and consistency and would fare poorly under translation, resulting in fewer equivalent results. However, the amount of inter-rater disagreement also plays a significant role in determining equivalence by expanding or contracting the margins. Figure 4b highlights the differences in standard deviation margins for each quality across automated measures. Consistency and fluency had smaller margins with tighter distributions, with median margins of 0.013 and 0.018 and inter-quartile ranges (IQRs) of 0.006 and 0.009 respectively. By contrast, coherence and relevance had median margins 0.049 and 0.036 with IQRs 0.017 and 0.026 respectively. Thus human annotators showed stronger agreement on consistency and fluency, presenting a higher threshold for equivalence after translation.

3.4 Anderson-Hauck Tests

While TOST provides a non-parametric route towards equivalence testing, we consider an additional parametric test that may improve statistical power. The Anderson-Hauck test is an equivalence testing procedure for dependent correlation coefficients which uses an approximate non-central t-distribution to calculate p-values (Anderson and Hauck, 1983). Prior comparisons with TOST demonstrated that Anderson-Hauck can trade some additional Type-I error for higher power (Counsell and Cribbie, 2015).

We consider the same margins of equivalence and apply Benjamini-Yekutieli for FDR control at level $\alpha = 0.05$. A similar pattern emerges when considering results under different margins, and under the standard deviation margin we reject the null hypothesis in under 1% of tests.

The pattern of equivalence is largely the same as that found under TOST but with greater sparsity of significant results. Ultimately while the tests hint towards the ability to reuse summarization datasets in similar languages to English, we are only able to detect equivalence in a minority of cases. Our analysis relies predominantly on the TOST results since it does not rely on distributional assumptions for the differences in correlations and has a more robust literature to follow.

4 Comparisons between Measures

While our statistical tests focus on the absolute correlation between automated and human scores, we can instead consider the automated measures relative to one another. If one measure correlates better than another with human scores in the original English dataset, would it still be better in a translated (non-English) dataset? Additionally, we can return the dataset back to English to get a sense of the distortion introduced by the translation process.

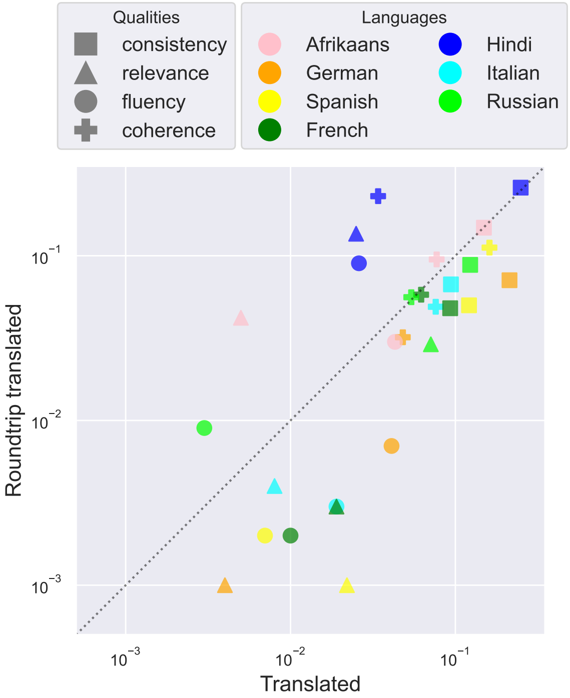


Figure 5: Result of bootstrapping: average shift in probability P of one measure being better than another, when the evaluation data are translated to another language (x-axis) and then translated back to English (y-axis). The average is taken over all measure-measure pairs that had $P \geq 0.975$ in English.

To estimate the consistency with which one measure dominates another, we turn to bootstrap resampling of the summary evaluations. We select 10,000 bootstrap samples from the 1700 text-summary-references tuples. Let P represent the fraction of samples in which one measure is better than another for a given measure-measure pair; we consider a pair "resolved" if one measure outperforms another in at least 97.5% of all the resamplings, i.e. $P \geq 0.975$ in the original English dataset. Using Kendall rank correlations, the number of resolved measure-measure pairs is 64% for relevance, 61% for coherence, 56% for consistency, and 42% for fluency. With a baseline reading of how stable the measure rankings are in English, we can ask what happens with these resolved pairs when the dataset is translated.

For most languages and qualities the shift of P is less than 0.1, the largest is 0.25 (consistency, Hindi). Many resolved measure-measure pairs become unresolved after translation, though no shift is drastic enough to reverse which measure ranks higher in a majority of samples (i.e. crossing $P = 0.5$). Figure 5 suggests that in most cases our conclusion about comparing two measures will not change with translation.

Along its x-axis, Figure 5 shows how much on average the fraction P changes (increases or decreases) after translation for resolved measure-measure pairs, where the average is over a given language and quality measure.

A round-trip translation returns each summary to its source language, effectively isolating the effect of translation quality on the consistency of automated measures. Here, returning to English allows us to use the evaluation measures in their original language and, for ESTIME, BLANC, and BERTScore, with their original models. Changes in measure performance should then reflect distortions introduced by translation while eliminating those caused by adapting measures to another language.

The dashed line $y = x$ seen in Figure 5 represents points where the round-trip translation causes an equally-sized shift as the forward translation. We note that the observed shifts are mostly under the diagonal - the shifts caused by translation are to some degree reversed when we return to English. The tendency of machine translation models to produce "translationese," artifacts distinguishing the output from typical human language use, is well documented (e.g. Vanmassenhove et al. (2021), Graham et al. (2020)), so exact overlap between source and round-trip translated texts is not expected. However, automated evaluation measures rely on coarser linguistic features like word overlap and are more influenced by significant amounts of noise during the round-trip translation process.

While the shifts for round-trip translations are on average smaller than for one-way, they demonstrate that translation is far from perfect and introduces enough noise to be detected by the summarization evaluation measures. Notably, the points above the diagonal come from Hindi, Russian and Afrikaans round-trip translation. This confirms our intuition that a translation to languages more distant from English is more risky for the survival of the summary evaluation. We hope further research may reveal additional ways to use the round-trip translation for the criteria of survival.

5 Discussion

The results presented significant differences among automated summarization measures and their relationships to the four quality measures. We seek to build an intuition for these findings and make use of qualitative exploration to ground our understanding

We can review the scores for the 1700 summaries in reduced dimensions using principal components analysis (PCA). Figure 6 shows each 1700-dimensional vector projected onto the first two principal components, which collectively explain 38.5% of the variance. There are four vectors of human expert scores, corresponding to the quality measures coherence, consistency, fluency, and relevance, averaged over the three individual experts. Each automated measure (for example, ROUGE-2) produced eight 1700-dimensional vectors, one for each language.

PCA can be used to disentangle the sources of divergence among evaluation measures under translation. The plot helps highlight the relative strength of translation over the summarization evaluation methods themselves. If machine translation added significant noise to the summaries, we would expect the relative position of language-specific scores in Figure 6 to be inconsistent across evaluation measures. Instead, we generally observe tight clusters for each evaluation measure with shared relative positions among the languages (at least when ignoring Hindi and Russian).

This pattern reflects the "stability" of evaluation measures undergoing translation found in Section 4. The PCA recasts translation as a shift in geometric space; across measures, the location occupied by each language is a similar vector shift from its corresponding English point. The exercise in round-trip translation is an indicator of reversibility for this geometric shift. The qualities and languages

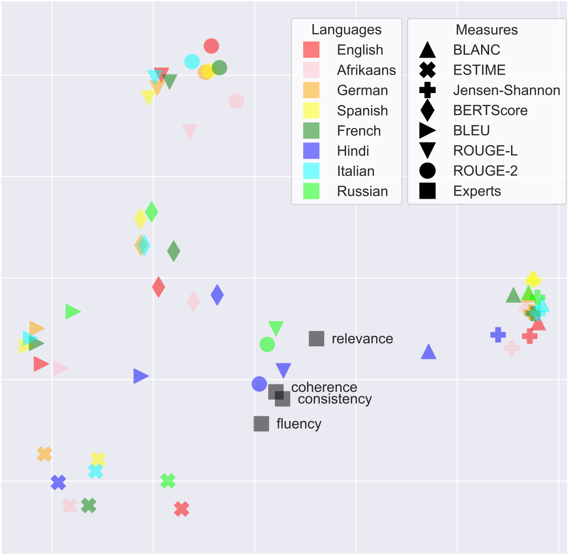

Figure 6: PCA plot of summary quality scores. All scores were transformed to ranks before PCA, to reduce subjectivity of the respective scales. Note the human expert scores in black squares exist for the English dataset only.

that occupy the bottom of Figure 5 are most unchanged by the translation process. On the other hand, measures like ESTIME that break this pattern highlight the non-uniformity of the distortion introduced by translation and indicate that it may be more prudent to rely on measures where the distortion is consistent and predictable.

This closer look at the effects of translation also helps disentangle the sources of noise that degraded the correlations studied in Section 3. A measure like ESTIME shows strong correlation with the human evaluations of consistency and fluency in English, but its unusual response to translation is a strong explanatory factor for why its relationships to human annotations were not found to be equivalent in other languages. Consistency also tends to show larger shifts in measure-measure pair rankings in Figure 5, adding another reason that translation would cause greater degradation to ESTIME's performance. Similarly, among the Germanic and Italic languages, relevance and fluency appear to be least affected by translation. Any lack of equivalence found for these qualities is then more likely to be caused by the abilities of the automated measures rather than the caliber of translation. Comparisons within and between measures can serve as a guide for how much to trust an automated measure under translation and where sources of noise may arise.

We note a few curious observations from Figure 6 in Appendix A.

6 Conclusion

In this paper, we probed how well automated evaluations of summaries remain consistent on texts translated to other languages. We focused on the SummEval dataset and considered its translation to French, German, Italian, Spanish, Afrikaans, Hindi, and Russian.

To answer whether English human annotations can be trusted in other languages, at least for specific qualities, we explored tests of equivalence as a gauge of consistency after translation. We found that translation can preserve correlations of evaluation metrics with the English human scores for coherence or relevance but could not conclude the same for fluency or consistency.

A complete answer to our query is a challenging task, since moving to another language affects not only the dataset, but also the measures themselves. While definitely proving that the original human annotations cannot be reused is likely impossible, our results suggest that there are clear differences in performance based on the choice of target language, automated measure, and notion of quality.

We call for additional research into summary evaluation metrics that can survive translation, as it offers a relatively simple path towards extending NLP capabilities for lower resource languages. Future work could identify how changes in the margin of equivalence equate to deterioration of model performance. Additionally, this line of research could be extended to a larger selection of languages and automated evaluation measures.

A Observations from PCA

The locations of the measures in Figure 6 after translation largely remain close to the original English version, except Hindi and Russian points. The reference-based measures, relying on hard (ROUGE, BLEU) or soft (BERTScore) overlap of tokens between the machine-generated and human-written reference summaries, are in the top left quadrant with respect to the human scores. The reference-free measures BLANC and Jensen-Shannon are on the opposite side. Sensibly, BLANC and Jensen-Shannon are both closest to the human judgment of relevance; BLANC estimates how well a text can be reconstructed from its summary, and Jensen-Shannon considers the Kullback–Leibler divergence between the summary and the text. ESTIME is closer to the fluency and consistency points, which is expected from its construction in Vasilyev and Bohannon (2021a).

For most measures, the translated scores are often closer to the expert evaluations than the English scores. Strangely, it is especially true for Hindi and, in the case of ROUGE, for Russian. One possible explanation is that the translation simplifies syntax and vocabulary, reducing sources of variation at least along some dimensions. The pattern associated with ESTIME is distinct from other measures: the non-English scores for ESTIME are almost always further away from the human scores. This suggests that maybe ESTIME is sensitive enough to require a higher quality translation. We cannot blame the underlying multilingual model, because both BLANC and BERTScore use the same model.

B Bootstrap with Reference-Summaries

Throughout the paper we used bootstrapping of the (text, summary, references) tuples, where the 'references' are the reference summaries needed by some measures (BERTScore, BLEU, ROUGE). For each text in SummEval (Fabbri et al., 2021), there are 11 reference summaries, and a full bootstrap for the reference-based measures should also include a resampling of the reference summaries themselves.

The impact of this added source of randomness can be seen by constructing confidence intervals for the estimated correlation between an evaluation measure and human scores. When we add resampling over reference summaries, confidence intervals widen and require more time and resources to compute. In Table 1 we illustrate the widening of the confidence interval on an example using BERTScore correlations with SummEval human expert scores (in the original English SummEval dataset). We ran 500K reference summaries resamplings, recomputing scores and correlations. The BERTScore is a peculiar and convenient case for bootstrap resampling of reference summaries, because the score is defined as a max score over the scores taken individually for each reference summary (Zhang et al., 2020).

The low and high correlation values are given in the table for bootstrap without resampling of reference summaries, as corresponding to 0.025 and 0.975 percentiles of the distribution. The 'widen' column in the table shows how much the confidence interval (high minus low) changed after including resampling of the 11 reference summaries into the bootstrapping. Some quality measures are especially affected by the change, with confidence intervals for Kendall correlation widening by 40% for relevance and by 17% for coherence (for Spearman's correlations, correspondingly, 42% and 18%). Notice that the relevance and coherence

	Kendall's τ			Spearman's ρ		
	low	**high**	**widen**	**low**	**high**	**widen**
coherence	0.245	0.307	0.011	0.345	0.428	0.015
consistency	0.041	0.117	0.002	0.052	0.148	0.003
fluency	0.062	0.135	0.004	0.080	0.175	0.006
relevance	0.246	0.310	0.026	0.338	0.424	0.035

Table 1: The columns 'low' and 'high' are the confidence boundaries from bootstrap without resampling reference summaries, for BERTScore correlations with expert human scores (coherence, consistency, fluency, relevance). The column 'widen' is the widening of the confidence interval as a result of adding the resampling of the reference summaries to the bootstrap resampling. Kendall's Tau correlation is Tau-c. The confidence boundaries are for 0.025 and 0.975 percentiles. The bootstrapping used 500K resamplings.

are exactly the qualities in which BERTScore is reported as a strong measure (Vasilyev and Bohannon, 2021a).

C Diversity of Measures

As noted in Section 2, we intentionally selected measures that are quite different from one another to increase the robustness of our analysis. Here we provide a brief summary of each measure.

BLANC assesses how much a summary helps in reconstructing its reference text (Vasilyev et al., 2020). Along the four SummEval evaluation qualities, BLANC's task should be most closely aligned with estimating relevance and consistency. However, BLANC's task may differ from the relevance scoring criteria or biases of annotators (Vasilyev and Bohannon, 2021b). An extension of BLANC achieved a state of the art result in relevance and coherence on the SummEval benchmark (Egan et al., 2021).

ESTIME first generates masked contextual embeddings for tokens in a summary and text and then finds the most similar text embedding to each one from the summary. If the paired embeddings correspond to different tokens, ESTIME counts this as an indicator of inconsistency between text and summary. ESTIME's task is closely aligned with measuring consistency and was found to perform well against other benchmarks in consistency and fluency (Vasilyev and Bohannon, 2021a). It is a less reliable measure for coherence and unreliable for relevance.

Jensen-Shannon (Louis and Nenkova, 2009) measures the distance between the distributions of words in the summary and text. The task is closely tied to relevance, but since the syntax and word order is discarded, Jensen-Shannon is not suited to measure coherence, fluency and consistency. Of course it still may correlate with human judgment along these qualities anyway, as better generation models often produce higher quality summaries in general.

The reference-based measures (BERTScore, BLEU and ROUGE) measure correspondence between the generated summary and human-written reference summaries, not between the generated summary and the text. A summary different from all the references may not be fairly evaluated.

BERTScore (Zhang et al., 2020) measures a 'soft' overlap of tokens (through embeddings). Similar to Jensen-Shannon, this task is closely related to relevance and considerably farther from measuring coherence, fluency and consistency, unless the generated summary happens to be very similar to one of the reference-summaries.

BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) measure 'hard' overlap of tokens and n-grams, and thus a summary that differs by rephrasing or synonyms would have a lower score. When considering overlap of longer n-grams, these measures can reflect human judgment across all qualities but only if the generated summary happens to be similar to one of the reference summaries; see also Graham (2015); Caglayan et al. (2020); Mathur et al. (2020).

A Shoulder to Cry on: Towards A Motivational Virtual Assistant for Assuaging Mental Agony

Abstract

Mental Health Disorders continue plaguing humans worldwide. Aggravating this situation is the severe shortage of qualified and competent mental health professionals (MHPs), which underlines the need for developing Virtual Assistants (VAs) that can *assist* MHPs. The data+ML for automation can come from platforms that allow visiting and posting messages in peer-to-peer anonymous manner for sharing their experiences (frequently stigmatized) and seeking support. In this paper, we propose a VA that can act as the first point of contact and comfort for mental health patients. We curate a dataset, *Motivational VA: MotiVAte* comprising of 7k dyadic conversations collected from a peer-to-peer support platform. The system employs two mechanisms: (i) *Mental Illness Classification*: an attention based BERT classifier that outputs the mental disorder category out of the 4 categories, viz., Major Depressive Disorder (MDD), Anxiety, Obsessive Compulsive Disorder (OCD) and Post-traumatic Stress Disorder (PTSD), based on the input ongoing dialog between the support seeker and the VA; and (ii) *Mental Illness Conditioned Motivational Dialogue Generation (MI-MDG)*: a sentiment driven Reinforcement Learning (RL) based motivational response generator. The empirical evaluation demonstrates the system capability by way of outperforming several baselines.

1 Introduction

With an estimated 970 million individuals suffering from some sort of mental or neural diseases, mental health disorders are regarded one of the primary causes of disability globally[1]. Poor access, stigma, and prejudice, on the other hand, are likely to limit clinical care to only 15% of individuals who are affected. As a means of expressing their emotions and experiences (generally stigmatized), millions of people (also known as support seekers) frequently turn to looking for emotional or mental health-related support (Eysenbach et al., 2004) on a variety of text-based peer-to-peer support platforms (De Choudhury and De, 2014), (`talklife.co`). While peer supports on these platforms are well-intentioned and willing to aid and help seekers, they are often untrained and unaware of best-practices in therapy, resulting in wasted opportunities to provide effective and mutually engaging solutions (Gage-Bouchard et al., 2018). As a result, developing human-computer interfaces in the form of Virtual Assistants (VAs) that can effectively reply and provide support to online support seekers becomes even more critical.

Empathy, or empathetic interactions (Elliott et al., 2018), has been studied extensively in recent years (Sharma et al., 2021, 2020) as one of the most important aspects in providing successful support and triggering beneficial results in support-based dialogues. In addition to empathy, imparting *hope* and *motivation* (the process of thinking about and the willingness to move towards one's goals) have been recognised as important affective elements (Dowling and Rickwood, 2016) in uplifting the spirits of support seekers in distress during supportive talks. This is critical because support seekers often engage in escapist or avoidant behavior in anticipation of negative consequences, making it difficult for them to cope with the crisis (Hecht, 2013). Quantitative research shows that instilling optimistic behaviour fueled by hope and motivation improves symptoms in terms of positive psychological transformation and a favourable alliance in mental health support (Jahanara, 2017).

In this paper, we propose a VA acting as the first point of contact for mentally distressed support seekers afflicted with some form of mental illness. The VA's efforts are aimed at reassuring and allowing support seekers to anonymously communicate and express their thoughts, emotions, challenges and seek support. The VA's response should be

competent and proficient enough to provide support seeker with a natural human experience focused on imparting hope and motivation based on positive perspective. To mimic this human-like behavior of mental health supporters in a VA is quite challenging and the tasks employed are two folds. Firstly, for the VA to provide a conversational support in the absence of electronic health records or psychiatric notes, it is critical to recognise and differentiate various mental diseases because they are frequently communicated using similar language patterns and overall sentiment polarity. In the case of anxiety, for example, the supporter's purpose is to reduce avoidant behaviour and assist the patient in disconfirming a feared consequence. In depression, however, the goal is to assist the mental health seeker in experiencing positive feeling, a burst of energy, or another sort of pleasant contact with the world. Subsequently, the task of the VA is to generate response conditioned on the identified mental illness for modelling motivational conversations with positive outcome.

Due to the unavailability of conversational data for our proposed task, we introduce a dataset, *MotiVAte* comprising of 7k conversations between support seekers and VA collected from a peer-to-peer support platform. The key contributions of this paper are as follows : (i) To the best of our knowledge, this work is the first to propose a VA for providing motivational support and comfort to mental health patients; (ii) We curate a conversational dataset, *MotiVAte*, to advance research in mental health based support; (iii) Our end-to-end system employs two sub-modules, viz., *Mental Illness Classification (MIC)* framework, a dual attention based BERT classifier to identify the mental health disorder of the support seeker in the on-going conversation and *Mental Illness Conditioned Motivational Dialogue Generation (MI-MDG)* framework to generate mental illness conditioned sentiment driven Reinforcement Learning (RL) based motivational responses mimicing an ideal mental health supporter; (iv) Empirical results indicate that our proposed system outperforms several baseline models.

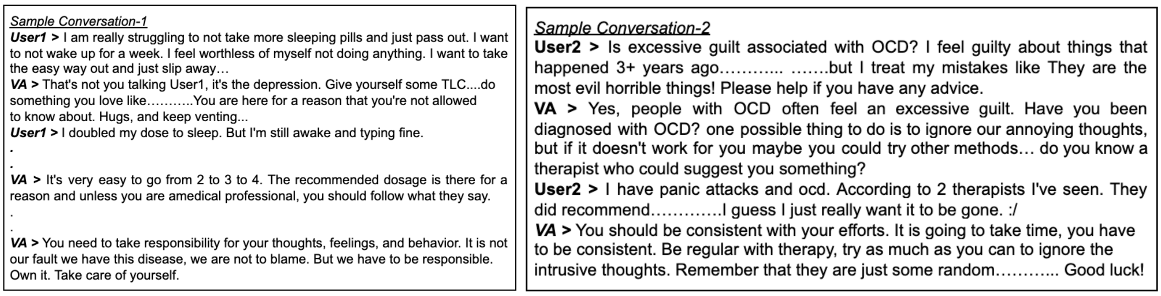
2 Related Works

In this section, we explore mental health based analysis from social media posts and computational models for therapy (Pérez-Rosas et al., 2019).

Mental Health Identification. There are numerous studies over the years that use multi-modal cues such as images and (Yazdavar et al., 2020) to diagnose diagnose from social media posts and activity (Gaur et al., 2018; Yazdavar et al., 2018; Qureshi et al., 2019; Yazdavar et al., 2017). Investigations have also been conducted on recognising mental illness in online users by their posts on social media (Syarif et al., 2019; Ji et al., 2020). The authors of (Patra et al., 2020) proposed a Bi-LSTM (Hochreiter and Schmidhuber, 1997) based classifier for classifying mental severity as crisis, red, amber, and green using data from a psychological forum. For detecting mental diseases from daily posts of an online user, (Rao et al., 2020) suggested a knowledge augmented ensemble learning classifier. Authors of (Ji et al., 2021) proposed a pre-trained transformer model named MentalBERT trained on a large corpora of data belonging to mental health care. (Saha et al., 2022) presented a hierarchical attention based classifier to detect mental illnesses from motivational conversations. (Martínez-Castaño et al., 2021) proposed a BERT classifier for detecting severity of depression and likeliness towards self harm for social media users.

Mental Health in Conversations. (Althoff et al., 2016) presents an investigation on a large-scale counselling dialogue gathered from an SMS text-based counselling service. As a result of these, exploring empathic relationships in therapy has grown in popularity (Sharma et al., 2020; Morris et al., 2018). In order to help mental health supporters, (Sharma et al., 2021) investigated empathy rewriting as a text generation task. Authors of (Fitzpatrick et al., 2017) presented a conversational agent, named Woebot to deliver cognitive behavioral therapy by initiating daily conversations for mood tracking. Our work differs in the sense that our end-to-end system does not provide any clinical suggestions or therapy recommendations. The role of competence in responses to help-seeking posts on mental health was investigated in (Lahnala et al., 2021).

Sentiment/Emotion aware Dialogue Systems. To make the VA user-adaptive, the authors in (Saha et al., 2020c,d, 2018), proposed using a sentiment-based reward function for learning a dialogue policy in a task-oriented conversation. The authors of (Saha et al., 2020a) demonstrated how reinforcement learning may be used to generate meaningful responses while training generation frameworks. In (Saha et al., 2020b, 2021a,b,c), the authors show how subtleties in human communication, such as



Sample Conversation-1

***User1* >** I am really struggling to not take more sleeping pills and just pass out. I want to not wake up for a week. I feel worthless of myself not doing anything. I want to take the easy way out and just slip away…

***VA* >** That's not you talking User1, it's the depression. Give yourself some TLC....do something you love like………..You are here for a reason that you're not allowed to know about. Hugs, and keep venting...

***User1* >** I doubled my dose to sleep. But I'm still awake and typing fine.

.

.

***VA* >** It's very easy to go from 2 to 3 to 4. The recommended dosage is there for a reason and unless you are amedical professional, you should follow what they say.

.

.

***VA* >** You need to take responsibility for your thoughts, feelings, and behavior. It is not our fault we have this disease, we are not to blame. But we have to be responsible. Own it. Take care of yourself.

(a)

Sample Conversation-2

User2 > Is excessive guilt associated with OCD? I feel guilty about things that happened 3+ years ago……….. …….but I treat my mistakes like They are the most evil horrible things! Please help if you have any advice.

VA > Yes, people with OCD often feel an excessive guilt. Have you been diagnosed with OCD? one possible thing to do is to ignore our annoying thoughts, but if it doesn't work for you maybe you could try other methods… do you know a therapist who could suggest you something?

User2 > I have panic attacks and ocd. According to 2 therapists I've seen. They did recommend…………I guess I just really want it to be gone. :/

***VA* >** You should be consistent with your efforts. It is going to take time, you have to be consistent. Be regular with therapy, try as much as you can to ignore the intrusive thoughts. Remember that they are just some random……….. Good luck!

(b)

Criteria	**Statistics**				
	Total	**MDD**	**OCD**	**Anxiety**	**PTSD**
# of dialogues	7067	4046	1000	1000	1021
# of utterances	25947	16257	2461	2784	4445
# of utterance per dialogue (avg.)	3.67	4.01	2.46	2.79	4.36
# of utterance per dialogue (max.)	129	129	14	16	25
Maximum user utterance length (# of words)	3319	3319	1337	1028	2112
Maximum VA utterance length (# of words)	2869	2851	2869	1024	2116
# of unique users	2139	1060	349	323	407
# of unique words	56336	35666	14108	12135	16427

Table 1: *MotiVAte* dataset statistics for every mental disorder

sentiment and emotion, can help different information elicitation models in dialogues work better. Apart from these, several other work (Wei et al., 2019; Ide and Kawahara, 2021; Huo et al., 2020) that suggests using sentiment and/or emotion as an additional input in generation frameworks either during decoding or as reward to guide the models for generating responses aligned with the user's mood or feelings.

3 Motivational VA : *MotiVAte* Dataset

The *MotiVAte* dataset contains 7067 dyadic conversations with support seekers who have one of the four mental disorders: MDD, PTSD, anxiety, or OCD. *Supplementary material* contains descriptions of these illnesses as they appear in ICD-10. Table 1 displays the dataset statistics as well as the sample distribution amongst illnesses. Sample conversations from the dataset are shown in Figure 1. As evident from the conversations, we expect our VA to perform simple, ordinary and expected things in the form of providing comfort and assistance to the support seekers at the time of crisis and the curated dataset is full of such statements.

Data Collection. Existing mental health databases had limitations in the context of our proposed work. Some of the datasets, for example, (Choudhury et al., 2017; Yazdavar et al., 2017, 2018, 2020) were social media contents of anonymized users comprising of self-disclosures and self-expressive posts with no specific dyadic or multi-party discussions to draw on. Some of the text-based counseling conversational datasets (Althoff et al., 2016; Dowling and Rickwood, 2014) were no longer open-sourced for research usage. Some of the open-sourced datasets such as DAIC-WOZ (Gratch et al., 2014) contained small-scale conversations. Recent support-based datasets (Sharma et al., 2020; Lahnala et al., 2021), on the other hand, featured pairs of seeker post and supporter response with no dialogic structure. Inspired by previous research, we create the *MotiVAte* dataset, which was acquired via a peer-to-peer support platform and is ideal for our objective. *Pyschcentral*[2] is a text based support forum where anonymous individuals can talk about their mental health problems and get help and advice from others who have had similar emotions, troubles, and grievances. It has various subforums about mental health, such as MDD, bipolar disorder, anxiety and panic attacks, schizophrenia, and so on. We gathered 10k multi-party interactions from four distinct subforums: OCD, Anxiety, PTSD and MDD. A manual assessment of the raw data confirmed that the chats were acceptable and can be utilised to develop a VA after some post-processing.

Data Preparation. The challenge next was to convert these multi-party dialogues into dyadic ones, so that they resembled a conversation between a support seeker (with a mental disability) and the VA providing mental health support. We presume that a source conversation starts with a post by a support seeker known as the poster (say). The commenters (say) are forum users who make comments on the poster's statement. The poster and the commentators engage in a multi-party conversation in order to assist the poster. We worked with one of the noted psychiatrists, who is currently working at a government-run hospital of national importance, to develop standards for changing multi-party dialogues and confirming the qual-

---

[2] `www.psychcentral.org`

ity of the amended dataset. We hired three crowd-workers for the task of modifying the dialogues and trained them in an interactive session using the instructions that had been developed (*Details of the training session conducted is drafted in the Supplementary material*). Some of the important guidelines are as follows : **(i)** In the modified dialogue, the poster in the source conversation becomes the support seeker, and the comments of a specific commenter creating the longest conversational thread with the poster become the responses of the VA. From the responses of the poster and commenter, the crowd-workers were instructed to develop a turn-by-turn exchange of dialogue between the seeker and the VA, making the most of the responses from the source conversation; **(ii)** The VAs' response should be helpful and positive, with the goal of raising the user's morale. So, negative utterances from the commenter such as "I know, nothing can change, we have to struggle throughout" were changed to exhibit optimism and hope like "life indeed is a struggle for all, but one needs to always fight back and be strong in the face of adversities" etc; **(iii)** A VA cannot provide medical advise, even if the poster requests it (as evident in the source conversation), because we do not advocate that the VA can replace MHP. As a result, in such a circumstance, the utterances of the commentators providing medicinal advice were completely eliminated, while utterances such as "I suggest you to visit a doctor or a psychiatrist before resorting to such medicines" were incorporated as part of VA's response. Following these rules, a total of 7k dyadic conversations were created (*The process of rejecting 3k remaining conversations along with the other guidelines and inter-annotator agreement are detailed in the Supplementary material*).

4 Proposed Methodology

Problem Definition. The problem statement involves two parts : *Firstly*, we aim to identify a textual on-going communication between a support seeker and the VA as the conversation progresses in order to detect and differentiate mental health conditions. For a conversation T, given a seeker utterance, $X_t = (x_{t,1}, x_{t,2}, ..., x_{t,n})$, a conversational context/history, $C = (c_1, c_2, ..., c_{t-1})$, the task is to assign the most appropriate mental illness tag (say y_2) among a set of tags ($Y = \{y_1, y_2, ...y_i\}$, where i is the number of disorders considered). Thus, it is a multi-class classification problem. Formally, it can be represented as : $y = argmax_{y' \in Y} F(y'|X_t, C)$, where F is the developed classifier. The subsequent or the *second* part involves to solve the task of generating the next textual response of the VA given the seeker utterance, its context of $t-1$ turns (say) and conditioned on the output y_k (say) of the mental illness identification classifier. Formally, given a seeker utterance, $X_t = (x_{t,1}, x_{t,2}, ..., x_{t,n})$, a conversational context/history, $C = (c_1, c_2, ..., c_{t-1})$, where $c_i = (X_i, Z_i)$ and mental illness category, y_k, the task is to generate next textual response of the VA, $Z_t = (z_{t,1}, z_{t,2}, ..., z_{t,n''})$.

Summarization. While analyzing the dataset, we observed that the utterances in a dialogue have longer sequences implying longer context (also evident from Table 1). Intuitively, an effective encoding strategy needs to be employed to counter loss of information. In this regard, we first summarize each of the utterances of the individual speakers in every time-step of the dialogue to preserve the content and curate it to be concise for modeling long-term dependencies. In the absence of gold-standard summary of utterances, we obtain summaries from a state of the art summarization model named *BART-large* by Facebook AI (Lewis et al., 2019). For our setting, we use the BART-large model fine-tuned on the *CNN/DM summarization* dataset (Hermann et al., 2015) to obtain summaries of the individual utterance of the *MotiVAte* dataset. So, for a given utterance, $X_t = (x_{t,1}, x_{t,2}, ..., x_{t,n})$, its corresponding summary is, $M_t = (m_{t,1}, m_{t,2}, ..., m_{t,k})$ (*Evaluation of the summaries obtained is presented in the Supplementary material*). Consequently, we utilize the summarised version of the dataset for developing the system (handling longer sequences as in the original dataset will be dealt as a sub-task in the future).

4.1 Mental Illness Classification (MIC) Framework

In this section, we discuss the details of the attention based classification framework.

Feature Extraction. The classification framework inputs two different kind of features. (i) *Embedding Features* : To extract textual features of an utterance U having n_u number of words, the representation of each of the words, $w_1, ..., w_u$, where $w_i \in \mathbb{R}^{d_u}$, w_is are obtained from BERT (Devlin et al., 2019), where dimension, $d_u = 768$. (ii) *Semantic Features* : An examination of the dataset revealed that users who expressed their emotions

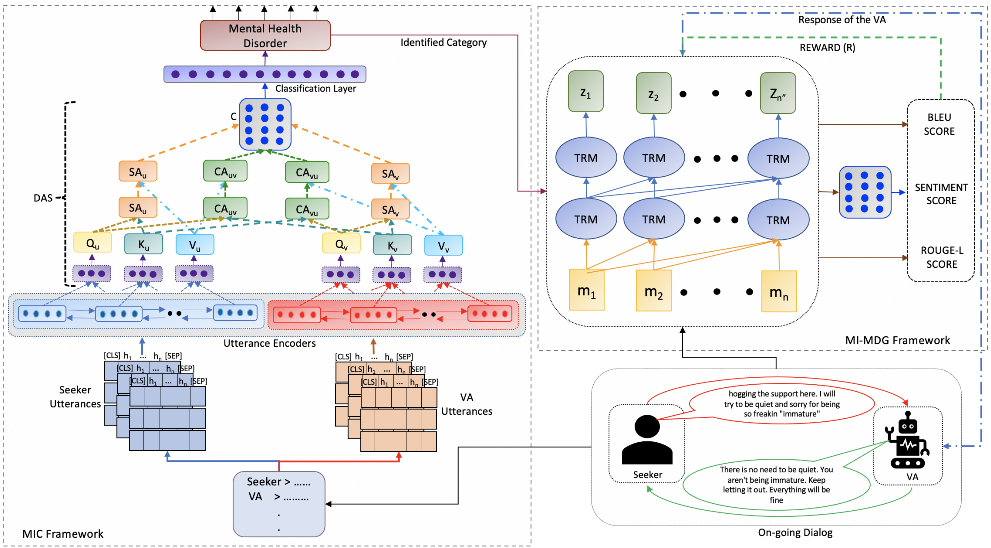

Figure 2: Architectural diagram of the proposed VA with the MIC and MI-MDG frameworks

and pains reflected their overall sentiment to some level. These details must also be recorded in order to create a more accurate sentence representation that takes into account the user's mental state. We achieved this by using the *Vader Sentiment Intensity Analyzer* (VSIA) to count the number of positive and negative utterances in each speaker's encoding and using them as features. From strongly negative (-1) to strongly positive (+1), this rating seeks to convey the overall affect of the entire text.

Network Architecture. Three key components make up the proposed classification network : (i) *Utterance Encoders* (UE) : the features retrieved above for each of the speakers (here VA and support seeker) for a particular conversation are fed into UE which generate relevant speaker encodings, (ii) *Dual Attention Subnetwork* (DAS) that encompasses self and cross attention, (iii) *Classification Layer* (CL) : the output channel for classification is contained in the CL.

Utterance Encoders. The embedding features produced for each of the speakers' utterances (described above) are then processed through two discrete Bi-LSTMs for a specific time-step of the conversation. For a user level view (say), the final hidden state matrix for the textual representation of the utterances is $H_u \in \mathbb{R}^{n_u \times 2d_l}$. d_l represents the number of hidden units in each LSTM and n_u is the number of utterances of the respective speaker.

Dual Attention Subnetwork. We employ a similar notion proposed by the authors of (Vaswani et al., 2017), in which attention is computed by mapping a query and a set of key-value pairs to an output. The speaker level context encodings are passed through three fully-connected layers, each termed as queries, Q and keys, K of dimension $d_k = d_f$ and values, V of dimension $d_v = d_f$. Thus, we obtain two triplets of (Q, K, V) as : (Q_u, K_u, V_u), (Q_v, K_v, V_v). These triplets are then combined in various ways to compute attention scores for specific reasons.

Self Attention. We compute self attention (SA) for each of these speaker encoders to learn the interdependence between the current and the previous part of the same speaker's conversation. In a sense, we want to connect distinct positions of utterances in order to estimate a final representation for each speaker (Vaswani et al., 2017). Thus, the SA score for individual speaker level is calculated as :

$$SA = softmax(Q_i K_i^T)V_i \tag{1}$$

where $SA \in \mathbb{R}^{n_u \times d_f}$ for SA_u, $SA \in \mathbb{R}^{n_v \times d_f}$ for SA_v.

Cross Attention. Similarly, we compute cross attention (CA) amongst triplets of the speaker level encodings to learn interdependence between speaker queries as :

$$CA = softmax(Q_i K_j^T)V_i \tag{2}$$

This is done to relate different positions of the utterances of the different (cross) speakers and to identify significant contributions amongst different speakers for a particular time-step to learn optimal features for the task. Thus, we obtain two CA scores as $CA_{uv} \in \mathbb{R}^{n_u \times d_f}$ and $CA_{vu} \in \mathbb{R}^{n_v \times d_f}$.

Attention Fusion. Next, we concatenate each of these computed SA and CA vectors to obtain the conversational representation as :

$$C = concat(CA_{uv}, CA_{vu}, SA_u, SA_v) \tag{3}$$

Classification Layer. To identify one of the mental disorders, the final representation of the ongoing discussion received from the DAS module is transmitted through a fully-connected layer, which then connects it to the output channel of the classifier consisting of output neurons.

4.2 Mental Illness conditioned Motivational Dialogue Generation (MI-MDG) Framework

In this section, we discuss the details of the proposed MI-MDG framework.

Text Generation. For a long time, Sequence-to-Sequence (Seq2Seq) (Sutskever et al., 2014) and Hierarchical Encoder Decoder (HRED) models (Serban et al., 2017, 2016) were being used for different text generation tasks. However, the main issue with RNN based model is its inability to provide parallelization while processing and is incapable of preserving context at the encoder side for longer sequences, similar to our case as explained above. To counter this, we use the DialoGPT (Zhang et al., 2020) model for our task. DialoGPT is based on the GPT-2 model from OpenAI (Radford et al., 2019), pre-trained on Reddit conversations. We fine-tune the DialoGPT-small model on the summarised version of the *MotiVAte* dataset. For a given dialogue, we first concatenate the dialog turns till the kth seeker-VA response pair along with the context available and speaker identifier into a long text, $m_{1,k}, ..., m_{(N-1),k}$ (N-1 is the sequence length), ended by the end-of-text token. To generate responses conditioned on the mental illness of the support seeker, we also concatenate the predicted mental illness category (for the kth seeker utterance from the MIC framework), y_i (say) as a mental state identifier after the kth seeker utterance in the sequence, making the sequence length as N. With the dialogue history, $S = m_{1,k}, ..., m_{l,k}$ and the VA utterance (ground truth response) as $T = m_{l+2,k}, ..., m_{N,k}$, the conditional probability $P(T|S)$ can be written as:

$$p(T|S) = \prod_{n=l+2}^{N} p(m_n|m_1, ..., m_{n-1}, y_i) \quad (4)$$

To generate semantically acceptable responses, the DialoGPT model is first fine-tuned with the negative log likelihood, i.e., the maximum likelihood estimation (MLE) objective function in a supervised way. This trained model is later initialized to produce motivational and optimistic responses by the VA (explained below).

Reinforcement Learning (RL) based Training. The sequence of tokens in an utterance can be considered as actions chosen by the DialoGPT model based on a policy it has learned. The model is then tweaked using the MLE parameters to learn a policy that maximises long-term future rewards (Li et al., 2016). The elements of RL based training are addressed below.

State and Action. The state is similar to the input of the DialoGPT model, i.e., context comprising of history and the kth seeker utterance along with the speaker and mental illness identifiers (explained above), $[S(H_h, H_s, H_y)]$ where h, s and y represent history tokens, speaker and mental illness category tokens, respectively. The action a, is the VA response to be generated in the kth time-step, i.e., Z_k. Because the sequence generated might be of any length, the action space is unlimited. As a result, the policy, $\Pi(Z_k|S(H_h, H_s, H_y))$ is defined by its parameters and is based on learning how to map states to actions.

Reward. Here, we discuss the task-specific reward functions, r, used to evaluate the predicted output Z' against the true output.

- **BLEU Metric Score** (r_1) : This metric ensures n-gram content similarity (1-gram here) between the predicted and the true output.
- **ROUGE-L Metric Score** (r_2) : This metric ensures the matching of the longest common subsequence between the predicted and the true output.
- **Sentiment Score** (r_3) : For the VA to be motivational and optimism inducing, the generated response should exhibit *positive* sentiment. Since, emotion focuses on a deeper analysis of human sensitivities and is based on a wide spectrum of moods, sentiment provides an overall impression or view people get from consuming a piece of content. So, we quantify optimism with respect to being positively-oriented. The VA should always work towards uplifting the mood of the user, provide reliable suggestions which are positively-oriented. The VA should not oblige with the *negative* mindset of the support seeker barred from hope and motivation from moving forward in life. This will ensure that the sentiment state of the generated output by the VA is consistent with the true output. Thus, the reward is :

$$r_3 = \begin{cases} 1, & \text{if } SC(Z') = +ve \\ 1 - ss, & \text{if } SC(Z') = -ve \end{cases} \quad (5)$$

where SC is the pre-trained distillBERT based uncased model (Sanh et al., 2019), fine-tuned on the SST-2 English dataset for the sentiment classification task. ss is the sentiment score obtained from the classifier.

Thus, the final reward (R) is the weighted average of all the above terms as given below:

$$R = (r_1 * (1 - \alpha - \beta) + r_2 * \alpha + r_3 * \beta)/3 \tag{6}$$

where α and β are parameters of the model. Policy Gradient algorithm (Zaremba and Sutskever, 2015) is used to optimize these rewards. The policy model Π is initialized using the fine-tuned DialoGPT model (using the MLE objective function). So, the final loss back-propagated to the DialoGPT model is a combined objective function as :

$$L_{comb} = \eta L_{RL} + (1 - \eta) L_{MLE} \tag{7}$$

where L_{RL} and L_{MLE} are the losses calculated from the RL and MLE objective, respectively.

5 Experiments

Since the MotiVAte dataset is imbalanced for different mental illness categories, we sample 50% of the dialogue from MDD subforum along with other categories to be utilized in the *MIC framework*. Thus, the mental illness classification module is trained on 5067 conversations, out of which 70% of the dialogues were used for training and remaining were utilized as test set. To encode different speaker utterances in the MIC framework, a 300 dimensional Bi-LSTM layer was used. d_f is a dense layer of 100 dimension. The four mental health categories are represented by 4 neurons in the output channels. In the final experiment, a learning rate of *0.01*, textitCategorical crossentropy loss function, and *Adam* optimizer were utilised. All of these parameters were chosen following a thorough sensitivity study.

Table 2: Results of all the baselines and the MIC framework. NA represents models without attention (no DAS), NSenti represents models without sentiment score features, k represents the kth seeker utterance along with the available context.

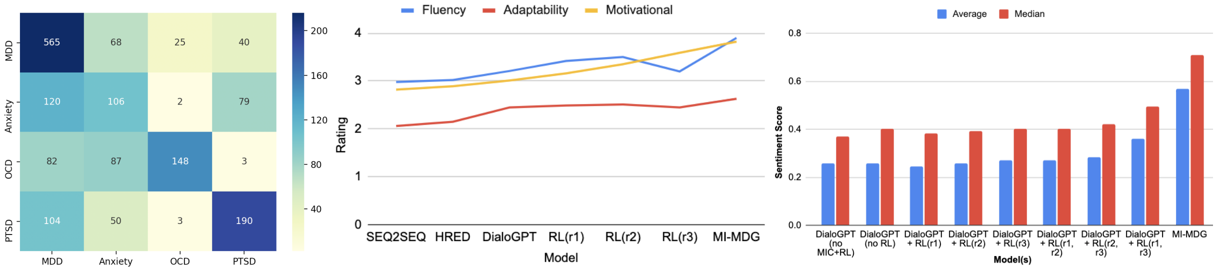
For training the *MI-MDG framework*, MIC model is used as a pre-trained classifier providing additional input. For the MI-MDG model, we decode using default temperature and top-k values of the DialoGPT model. Adam optimizer is used to train the model. A learning rate of 0.00004 was found to be optimum. Standard measures, such as the BLEU-1 score (Papineni et al., 2002), perplexity, ROUGE-L score (Lin, 2004) and embedding based metric (Serban et al., 2017) are used to automatically evaluate generation-based models. Three independent human users were recruited to score the quality of 250 simulated conversational responses based on these metrics : (i) *Fluency* : The VA's generated responses should be grammatically and syntactically acceptable; (ii) *Adaptability* : An effective VA should generate responses based on the current trajectory of the conversation, i.e., what is now being discussed; and (iii) *Motivational* : The response generated by the VA should be positively-oriented imparting hope and motivation. Finally, we report the average of the human rated scores across different users.

6 Results and Analysis

A series of experiments were carried out in order to evaluate the proposed framework.

Evaluation of Summaries. To analyse the quality of the summaries obtained from the state-of-the-art BART-large model, we presented 100 conversations to three human users from authors affiliation to rate the quality of the summaries on a scale of 1 (worst) to 5 (best) based on two metrics, namely, *fluency* : to ensure that the obtained summary at each time-step of the conversation is syntactically or grammatically correct; *content preservation* : to ensure that the content of an utterance in the conversation is preserved in the summarised version. We report the average of the human rated scores across different users. Based on the human evaluation, for *fluency*, we obtained an average score of 4.1, whereas for *content preservation*, we observed an average score of 3.65.

MIC Framework. Experiments were conducted in three different set-up as : for first k seeker utterances, where $k = 1, 2$, and t (here t represents the last seeker utterance), along with the available context of the dialogue in order to analyse the competence of the MIC model in assisting the VA as the dialogue progresses. Table 2 summarises the



(a) (b) (c)

Figure 3: (a) Confusion matrix of the MIC model, (b) Human evaluation results of the baselines and the MI-MDG framework, (c) Sentiment polarity results of the generated VA utterances of different models using VSIA

findings of the proposed MIC model, as well as a detailed ablation analysis of its various components. As can be seen, textual encoding based on Bi-LSTM yields the best results in terms of several classification criteria. Also, the conversational level ($k = t$) models performed consistently better with different encoding strategies. This advantage is self-evident, as the conversational level models, unlike the other two set-up, have the complete dialogue at their disposal to exploit and learn from. As visible, BERT based embedding features attained better results in all combinations as compared to the GloVe embeddings which is in conformity with the existing literature. The addition of semantic information, such as utterance wise sentiment polarity, improved the models' performance consistently across all model combinations. This demonstrates that the user's sentiment is crucial in determining its mental state. We have also demonstrated the importance of different attentions used for the best performing model, i.e., *BERT+Bi-LSTM+Senti*. The results show that each of these factors aided the proposed MIC framework's performance significantly. The detailed results of the MIC framework and the baseline models in terms of precision and recall is reported in the *Appendix section*. Welch's t-test (Welch, 1947) at 5% significance level was conducted to ensure that all of the presented results are statistically significant.

We as well report the confusion matrix of the proposed model for the conversational level ($k = t$) set-up to examine the model's performance in depth and understand its limits in Figure 3a. As can be seen, there was a lot of confusion between MDD and anxiety pairs. The model is limited in its ability to distinguish between these two illnesses at a finer level. Even though people experience these in various ways, they use similar or overlapping terminology to convey their symptoms. The fine-grained characteristics that identify different illnesses in terms of text must be investigated in depth and discovered, and this will be the subject of future research.

Model(s)	**Automatic Evaluation**					
	Embedding			**PPL**	**BLEU**	**ROUGE-L**
	Average	Extrema	Greedy			
SEQ2SEQ (no MIC+RL)	0.592	0.306	0.392	52.25	0.066	0.050

Table 3: Automatic evaluation results of the baselines and the MI-MDG framework. no MIC represents models trained without MIC output, no RL represents model trained without RL objective.

MI-MDG Framework. As the task of motivational response generation has not been studied previously, we compare it to baseline approaches from related tasks such as dialogue generation which are SEQ2SEQ, HRED and DialoGPT and its varying combinations. Table 3 shows the automatic evaluation results of different baselines and MI-MDG framework. All of the fine-tuned DialoGPT-based models outperformed the classic SEQ2SEQ and HRED models, as shown in the table. This shows that long-term assimilation of memory for a particular utterance and across the dialogue was not appropriately learnt by the traditional SEQ2SEQ and HRED models due to their inability to capture context for longer sequences. The models trained to optimize long-term rewards produced better results in comparison to DialoGPT without RL training. This suggests that the RL objective, rather than simply learning to be accurate at the token level, helped generate affirmative responses compatible with the context. This validates the fact that the proposed MI-MDG framework is capable of generating over-

Seeker Utterance	Model	Generated Response
I know i have no control, this could have happened to anyone. and when the crisis came i did everything i could. but... i nearly failed, i almost did not make it. and everytime i put my little girl to bed i wonder if this will be the last time i see her. it is just the stupid ptsd, anxiety and depression are having a field day.	DialoGPT (no MIC+RL)	it's ok. it's normal. you did the best you could and as you said
	DialoGPT (with MIC output)	i'm sorry you are having such a tough time. please don't lose hope. you are a great, caring person.
	MI-MDG	you have done everything you can to take care of your child and keep yourself busy. i know this is just perception but sometimes it helps when you focus on something simple that satisfies your mind
In the fall of 2010, i lost a job and my depression became unmanageable. the level of distress i go in and out of now is beyond anything i have ever experienced in past years. i've always had social anxiety and depression are partnered up like a tag team holding me down.	DialoGPT (no MIC+RL)	i'm so sorry to hear that you lost your job. that is awful. i'm glad you have your degree and you are working at a library
	DialoGPT (with MIC output)	the first step in dealing with depression is to get in touch with a therapist. you can see your doctor for the same, and they can decide if the meds need to be put right.
	MI-MDG	the voices you are describing are the voices of the past, and you can see through them. if you can afford the therapy, then please get in touch with a therapist nearby. you are not alone

Table 4: Examples of responses generated by MI-MDG and the baseline models

all better responses. In Figure 3b, we report the results of the MI-MDG and baselines models during the human evaluation phase. As evident, the MI-MDG framework attained the highest average fluency, adaptability and motivational scores of 3.9, 2.63 and 3.82 respectively. However, all the models generated moderate replies consistent with the context, thus, demonstrating the need to address longer context/sequences more effectively. We present few examples of generated responses from the MI-MDG and baseline model in Table 4. As evident, the baseline DialoGPT model without any MIC input or RL training generated generic responses, devoid of motivation and unaware of seeker's mental state. Whereas the MI-MDG framework learnt a fair trade-off between being consistent with the seeker's mental state and providing optimism.

Additionally, to analyse whether the responses generated are positively-oriented, we report the sentiment polarities of the generated VA utterances for different models using an existing sentiment analyzer, namely, VSIA. The results of the same is shown in Figure 3a. As visible, all the models consistently generated positive sentences, more so for MI-MDG model and for all the baseline models which are trained with sentiment based RL objective. This shows that the addition of sentiment based RL objective aided the model's capability to generate positive-oriented responses of the VA. A thorough qualitative analysis uncovered several common errors made by the MI-MDG framework. In few cases, the model kept on repeating phrases from the ground truth as "*glad that you are busy keep busy keep busy and do better*". In some instances, responses were mostly generic (without optimism and hope imparting expressions) and unaligned with the mental state of the seeker such as for anxiety, OCD due to their fewer representation in the dataset. Several efforts are being undertaken to increase the scale of the conversations in the MotiVAte dataset after clarifying ambiguities from the rejected modified conversations in the future (refer to Appendix).

7 Conclusion and Future Work

Online mental health support platforms that make use of peer supporters suffers from the biggest challenge of effectively training or scaffolding the peer supporters. In this research, we use AI to propose a virtual assistant (VA) to provide support seekers with comfort and mental health support. As a first step, we created the MotiVAte dataset, which contains dyadic conversations collected from a peer-to-peer support network. We mold this system as a combination of two mechanism : (i) *Mental Illness Classification (MIC)* Framework: a dual attention classifier that outputs the mental disorder category based on the ongoing dialog between the support seeker and the VA; and (ii) *Mental Illness conditioned Motivational Dialogue Generation (MI-MDG)* Framework: a sentiment driven RL based motivational response generator conditioned on the mental state of the seeker. Empirical results, both quantitative and qualitative validates the efficacy of the proposed approach. We surmise that this preliminary step will lead to promising direction for developing computational models to assist peer mental health support seekers and allow researchers to extend works on mental-health which is really the need of the hour.

Privacy and Ethical Concerns. The use of online posts in health forums for psychiatric research presents a number of ethical questions about user privacy that must be addressed (Valdez and Keim-Malpass, 2019; Hovy and Spruit, 2016). Following the ethical guidelines established in previous research on various web-based platforms (Benton et al., 2017), we created our dataset using only publicly available discussions without using any personal profile information. Before presenting the data to the annotators, we manually anonymized the profile and removed any disclosure of personal information (if any). Despite the fact that the chats gathered from the online health forum were anonymized by their policy, the annotators pledged not to contact or deanonymize any of the users or share the data with others. This paper makes no therapy recommendations or clinical diagnostic claims. All the copyrights of the data belong to psychcentral.org. *Refer to the supplementary section for more details*. We also acknowledge that in designing computational models for mental health support, there is a risk that responses trying to aid can have the opposite effect, which can be lethal resulting in self-harm. Thus, risk mitigation steps are appropriate in this context. We stress on the fact that the system does not intend to make any clinical diagnosis or treatment of the disorder. It focuses on distinguishing mental state of the seekers based on semantic and linguistic evidence for the VA to learn a generation policy. In such cases, even if the mental disorder is mis-classified, the VA is focused on providing comfort and motivational support to the seekers. This is perfectly benign.

A Appendix

Motivational VA : MotiVAte Dataset The description of the mental disorders (considered in this paper) as mentioned in ICD-10 is listed in Table 5.

Interactive Training of Crowd-workers. The crowd-workers were initially provided with the entire guidelines for modifying the conversations along with ten such examples of raw and modified conversation pair. After this initial training, we scheduled an hour long phone call with them to discuss our instruction guidelines. Crowd-workers also raised questions about the guidelines during the phone conference, which substantially aided in resolving any potential issues. We gave them each 20 instances to modify after the phone call (randomly chosen; different for each crowd-worker). We manually evaluated the modified dyadic conversation on those 20 raw multi-party conversation. We either decided to discontinue with the crowd-worker (there was one) or gave them further manual input based on the results of the evaluation. Crowd-workers actively asked questions depending on their reservations during the process. We also ran spot checks on quality beyond the initial training phase (at least two times for each crowd-worker; on more than 10 conversation each) to offer them with additional feedback. This check on quality was also conducted by the psychiatrist with whom we collaborated for preparing the guidelines for modifying the source conversation. His feedback was also conveyed to the crowd-workers.

Guidelines Prepared. Some of the other important guidelines for modifying the conversations were : **(i)** The poster's messages/responses were changed to remove any references to a group of people as a whole. For example, phrase such as "does anyone here go through" was converted to "do you go through", similarly "thank you friends for helping me out" to "thank you for helping me" and so on. Similarly, a VA cannot respond by sharing its experiences because it is a machine robot with no life experience to draw on for example, "I have also faced a similar thing" etc. Also, a VA cannot refer to the poster about an anonymous seeker and share the seeker's experience (seen in the source conversation), as the communication between VA and the seeker is meant to be purely confidential and anonymized. As a result, the commenter's comments or utterances of these patterns were removed from the conversation in the context of VA; **(ii)** In the changed version, source conversations relating to the original topic of the subforum, such as MDD, were marked as MDD. We made no attempt to further categorise the chats by the contemplated category because we assumed that the poster would have picked the right category based on their needs. This is due to the fact that we have no other evidence to base our analysis on than what the poster chose for themselves. We recognise that this is a potential drawback because posters may not always have the mental health status that they perceive, and its impact should be examined further in the future.

Inter-annotator Agreement. The modified conversation from each of the crowd-workers were inter-changed and presented to the remaining crowd-workers to approve the quality of the modified conversations (in the sense that the modified conversations should be aligned with the guidelines provided). When any of the quality check crowd-workers disapproved of a chat that did not match the standards, it was removed from the MotiVAte dataset's final set. Only those dialogues were included in the final set that received unanimous approval from all crowd-workers. Following this criteria, we rejected 3k conversations from the 10k modified conversation and only 7067 conversation were included in the MotiVAte dataset. As a re-

Category	Description listed in ICD-10
MDD	mood disorder, hopelessness, worthlessness, lack of energy, reduced activity
OCD	repeated unwanted thoughts (obsession), urge to continuously repeat something (compulsion)
Anxiety	nervous disorder, worry, uncontrollable racing thoughts, dificulty in concentrating, sleeping
PTSD	recurrent distressing memories of the traumatic event, negative thoughts about oneself, difficulty maintaining close relationships

Table 5: Description of different mental disorders in ICD-10

sult, we observed a 71% inter-annotator agreement, which is regarded credible. To extend the scale of the MotiVAte dataset, we expect to clarify ambiguities in the rejected modified chats in the future.

Ethical Concerns. The acquisition of raw data and, as a result, the development of the dataset were done in accordance with all ethical principles or codes of conduct. Initially, an opinion on data usage and privacy was requested from an IPR lawyer during the data creation stage, and the response stated that *“Section 107 of the U.S. Copyright Law which provides that “the fair use of a copyrighted work ... for purposes such as ... research, is not an infringement of copyright.” Similarly, Section 52 of the Copyright Act, 1957 provides that “fair dealing with any work, for the purposes of — (i) private or personal use, including research” does not constitute an infringement of copyright in the said work. This statutory exception of fair use/ fair dealing in the website’s content is also reflected in the Terms of Use of PsychCentral.org: “provided however, that users may download one copy of any Content on any single computer and print a copy of that Content solely for their personal, private, non-commercial use.” The use of the content for research may be deemed to fall within this exception provided it was “personal, private, non-commercial use”.*". Following that, the current study is being conducted in collaboration with a psychiatrist from a nationally recognised institution. The psychiatrist has assisted us with every element of this work, including developing data annotation criteria and carefully reviewing the quality of the data.

Abstract

Canonical automatic summary evaluation metrics, such as ROUGE, focus on lexical similarity which cannot well capture semantics nor linguistic quality and require a reference summary which is costly to obtain. Recently, there have been a growing number of efforts to alleviate either or both of the two drawbacks. In this paper, we present a proof-of-concept study to a weakly supervised summary evaluation approach without the presence of reference summaries. Massive data in existing summarization datasets are transformed for training by pairing documents with corrupted reference summaries. In cross-domain tests, our strategy outperforms baselines with promising improvements, and show a great advantage in gauging linguistic qualities over all metrics.

1 Introduction

In natural language processing, the problem of summarization studies generating a summary from a source document which is longer than the summary. De facto metrics to judge a generated summary include ROUGE (Lin, 2004), BLEU (Papineni et al., 2002), and METEOR (Banerjee and Lavie, 2005). Previous work (Ng and Abrecht, 2015; Liu and Liu, 2008; Liu et al., 2016; Shang et al., 2018) agrees on two major drawbacks of them: 1) they favor lexical similarity, falling short on semantic similarity or linguistic quality, and 2) they require a reference summary which is often expensive to obtain (Zopf, 2018).

Initially, the first drawback is partially alleviated by replacing lexicons with their word embeddings (Ng and Abrecht, 2015; Ellouze et al., 2017; Ruseti et al., 2018; Xia et al., 2019). After the birth of transformers (Vaswani et al., 2017), this effort has expanded to sentence or document level, including reference-based (Zhang* et al., 2020; Zhao et al., 2019), and reference-free ones (Vasilyev et al., 2020; Scialom et al., 2019; Gao et al., 2020). The main difference between the two groups is whether a reference summary is needed when evaluating a machine-generated summary.

The two groups have complementary pros and cons. Reference-based metrics have a better performance, but they are impractical when summarization is used industrially, such as in customer support (Liu et al., 2019), team conversation (Zhang and Cranshaw, 2018), and bug reporting (Rastkar et al., 2014), where it is too costly to manually craft an equally massive amount of reference summaries. In contrast, without human written reference summaries, reference-free approaches generally perform poorer. Modern transformer-based reference-free approaches often rely on non-summarization tasks, such as QA (Vasilyev et al., 2020; Scialom et al., 2019). Such fact-focused approach makes them excel on content/fact aspects (still worse than reference-based ones) but not on linguistic ones. The non-summarization tasks also introduce noises.

Therefore, in this paper, as a proof of concept, we explore a hybrid or middle approach to combine the best of both worlds. Using document-summary pairs in existing summarization datasets, our weakly supervised approach mutates* reference summaries and pair them with documents to form training data and then use the trained model to evaluate unseen summaries in the presence of

---

*We avoid the term "augment" here because "augment" means making something better but what we are doing here is corrupting reference summaries.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2450 - 2458
July 10-15, 2022 ©2022 Association for Computational Linguistics

documents without corresponding reference summaries. In this way, we make use of human written summaries, which are very precious, in training, but we do not need them in summary evaluation. We call our approach **SueNes** , which stands for "**Su**mmary **e**valuation by **Ne**gative **s**ampling."

The quality of a summary is usually evaluated on two facets: content/fact aspects and linguistic qualities. Experiments later will show that a value of our approach is that we can use the same model architecture to build models that excel on different tasks by feeding training data from the same source but mutated in different strategies. For example, deleting words is the best for linguistic qualities while deleting sentences is the best for content/fact coverage.

Our approach is empirically compared against an array of existing metrics on three human summary evaluation datasets. Despite being training-based, our approach exhibits consistent results across various training domains which are all different from the test domain. It outperforms reference-free baselines with promising improvements on content/fact aspects, and further outperforms all existing metrics in gauging linguistic qualities.

In summary, our contributions or merits are:

- a simple but effective approach to reference-free[†] summary quality assessment,
- negative sampling for preparing training data from the unlabeled,
- one task/framework for multi-aspect judging,
- extensive cross-domain experiments to validate the effectiveness and domain robustness of our approach.

We hope our study can inspire more research into hybridizing reference-free and reference-based summary evaluation. Our code is at `https://github.com/forrestbao/SueNes/`

2 The Approach

2.1 Model Architecture

A reference-free single-document summary quality assessor can be formulated as a regression function $f(d, s) \in [0, 1]$ of an input document $d = [t_1, t_2, \cdots]$, and a machine-generated summary $s = [t'_1, t'_2, \cdots]$, where t_i's and t'_i's are text tokens. As a proof of concept, we explore an extremely lean implementation of f: first d and s are jointly transformed into a vector representation $\mathbf{e} = g(d, s)$, and then it is mapped to a summary quality score via a fully-connected layer, i.e., $f(d, s) = \sigma(\mathbb{W}\mathbf{e})$.

The function g can be implemented in the BERT (Devlin et al., 2019) style with an input sequence `[[CLS]`, t_1, t_2, $\cdots$, `[SEP]`, t'_1, t'_2, $\cdots$, `[SEP]]`. The output on the `[CLS]` token is a joint representation of both the document d and the summary s.

While the human evaluation to a summary may cover multiple aspects, such as content/fact coverage and linguistics, a model of us will only yield one number. But by using different data mutation strategies, we can get models (different f's) adept at different aspects of a summary.

2.2 Negative Sample Generation

It is impractical to train f with existing summarization datasets, such as CNN/DailyMail (Hermann et al., 2015; Nallapati et al., 2016), because they contain only high-quality, reference-class summaries written manually and thus are all of label 1. Some summary evaluation datasets, such as RealSumm (Bhandari et al., 2020), Newsroom (Grusky et al., 2018), and TAC2010 (NIST, 2010), do contain human ratings to system-generated summaries of various qualities. But they are too small, containing no more than 100 news articles or article groups each. Therefore, training against human ratings or in a supervised approach is impractical.

To work around, we propose a weakly supervised solution as depicted in Figure 1(a). Existing summarization datasets contain many document-summary pairs. For each pair $\langle d, s\rangle$, the reference summary s is mutated into K new summaries of different extents $s_1, s_2, \cdots, s_K$, which are then paired with the document to form new pairs

$$\langle d, s_1\rangle, \langle d, s_2\rangle, \cdots, \langle d, s_K\rangle,$$

which are finally assigned targets to form the training data

$$(\langle d, s_1\rangle, y_1), (\langle d, s_2\rangle, y_2), \cdots, (\langle d, s_K\rangle, y_K).$$

As illustrated in Figure 2, the training target $y_{k\in[1..K]}$ is the percentage of intact content. For example, if 30% of tokens in a mutated summary are not original, then the label is 0.7. In addition, the original document-summary pair $\langle d, s\rangle$ is also used in training with a target of 1.

[†] The definition of "reference-free" is that reference summaries are not needed in the evaluation stage.

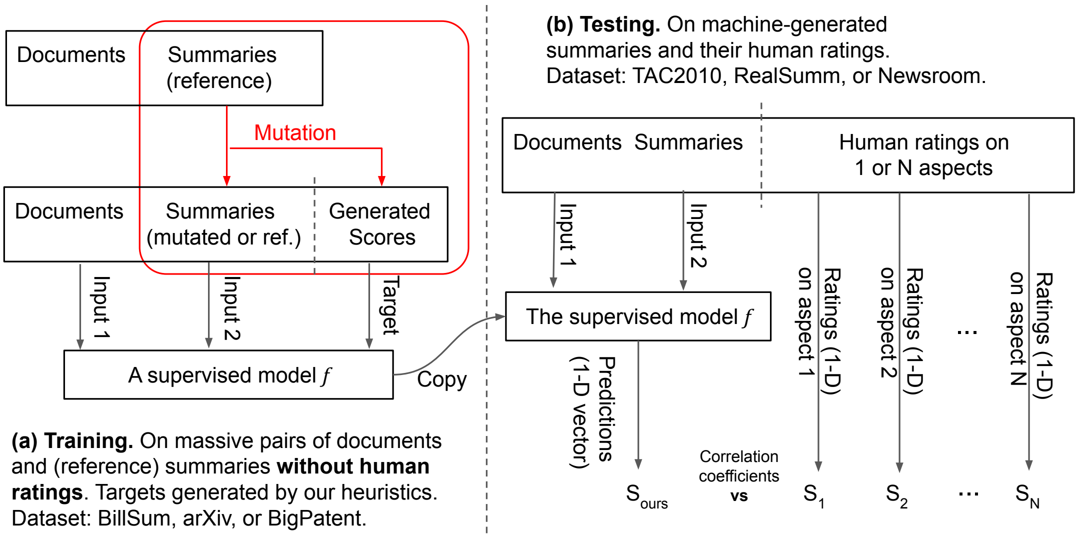

Figure 1: The weakly supervised training approach in this paper and the test of a trained model.

Mutations can happen at the token or sentence level, where tokens or sentences are randomly selected for mutation. A selected token or sentence is mutated in one of the three methods:

1. **inserting** a token/sentence from other summaries behind it,
2. **deleting** it, or
3. **replacing** it with a token/sentence from other summaries.

We do not mix different mutation levels nor mix different mutation methods when preparing the training data. Instead, our experiments study one combination of a mutation level and a mutation method, denoted as a mutation strategy, each time.

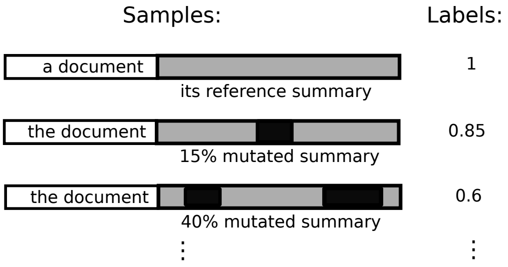

Figure 2: Training sample generation by mutation. Mutated text in dark blocks ■ while intact text in gray blocks ▒. Sizes are out of scale.

3 Experiments

3.1 Test data

The ground truth of a summary's quality is human ratings to it. A model trained (Fig. 1(a)) is tested (Fig. 1(b)) against human ratings. Three test datasets are chosen below. Due to the limited number and sizes of human evaluation datasets, they are all in the news domain. The human evaluation protocols can be found in their respective references.

TAC2010 (NIST, 2010) is a multi-document (ten-document) summarization task reporting both factual and linguistic aspects. We use $\sum_{i\in[1..10]} f(d_i, s)$ to approximate the score of the summary s composed from ten documents d_1 to d_{10}. We only use Set A of TAC2010 because Set B is not for regular summarization.

Newsroom (Grusky et al., 2018) also covers both factual (in INFormativeness and RELevance) and linguistic (in COHerence and FLUency) aspects. For human ratings, three human annotators rate one pair of a document and machine-generated summary. The mean of their ratings on each aspect is used in our experiments.

RealSumm (Bhandari et al., 2020) focuses on only factual coverage. It covers 14 abstractive and 11 extractive summarizers published after 2018 and conducts human evaluation on the two groups separately.

Note that we do not and cannot train a model against the labels in a test set, as mentioned in § 2.1.

If a test set rates on multiple aspects, we do not train one model for each aspect. Nor do we train models for individual or a collection of test sets. We compute correlation between the predictions from our model and human ratings on each aspect of each test set.

3.2 Training data

Three widely used summarization datasets from three different domains are chosen for training: **Billsum** (Kornilova and Eidelman, 2019), **Scientific-Papers/arXiv** (Cohan et al., 2018), and **Big-Patent** (Sharma et al., 2019). Datasets from the news domain are avoided on purpose because the test data is in the news domain. This cross-domain setting allows us to examine whether a model is prone to domain differences. For each reference summary, $K = 5$ mutated summaries are generated. The percentage of intact content is measured by the number of tokens and the number of characters for token-level and sentence-level mutations, respectively.

3.3 Baselines and upper bounds

To fairly compare, four recent metrics: **BLANC** (Vasilyev et al., 2020), **SummaQA** (Scialom et al., 2019), **SUPERT** (Gao et al., 2020) and **LS-Score** (Wu et al., 2020) , are used as baselines because like our approach, they do not need a reference summary to judge a machine-generated summary, i.e., reference-free.

Human crafted reference summaries give reference-based metrics advantages. The results of reference-based metrics are included as soft upper bounds: **ROUGE-1, ROUGE-2 and ROUGE-L** (Lin, 2004), **MoverScore** (Zhao et al., 2019), **BertScore** (Zhang* et al., 2020), **BLEU** (Papineni et al., 2002), **METEOR** (Banerjee and Lavie, 2005), and **S**^{3} (Peyrard et al., 2017).

3.4 Settings

Because the baselines use BERT, we use BERT as well for a fair comparison. Specifically, BERT-base uncased (L=12, H=768) is fine-tuned, with a learning rate of 1e-5, three epochs, and a batch size of 14. The input sequence is limited to 512 tokens using the round robin trimmer. The training loss is MSE as this problem is regression.

3.5 Results

We use the summary-level (Peyrard et al., 2017) meta-evaluation strategy to report an approach's average correlation with human ratings. Summary evaluation usually covers two types of aspects, contents/facts and linguistics. They are reported separately in Tables 1 and 2. Due to space limit, only the best mutation strategy is reported for each aspect group.

On content/fact aspects, the best mutation strategy is sentence deletion and our best models outperform baselines on all test datasets. Our approach makes the most improvement over baselines on RealSumm, a dataset much bigger than Newsroom and more modern than TAC2010, and the least improvement on TAC2010, the oldest dataset.

Our average absolute deviation (%)		3.32	2.57	2.21	3.45	5.28

On linguistic aspects, the best mutation strategy is word deletion. Here, even our worst model cannot be outperformed by any baseline nor upper bound. As mentioned earlier, canonical metrics are lexical-based while modern reference-based and reference-free approaches focus on facts. Through mutating reference summaries, our approach can create summaries of different linguistic qualities. Although our approach makes big improvements over baselines on TAC2010 and Newsroom's FLUency, its edge is smaller on Newsroom's COHerence. A sentence-level scrambling mutation may improve our approach's performance on COHerence in the future.

---

[*] LS_Score results are only for Newsroom, which are copied from its paper, as we cannot run their code on other datasets after trying really hard. Several other researchers reported the same issue at `https://github.com/whl97/LS-Score/issues`. It is further excluded from the ranking because it is trained on the same domain as the test domain whereas all other baselines and our models are not.

Table 2: Spearman's correlation on **linguistic** aspects.
Superscripts are ranks in each aspect/column.

3.6 Discussions

What is the best mutation? Across datasets, deletion-based mutations are most effective. The two kinds of deletions happen to be complementarily effective for two aspect groups: sentence deletion for content/fact aspects vs. word deletion for linguistic aspects. This is an advantage of our approach that *under a uniformed framework, different summary quality aspects can be gauged by designing different mutation options*.

The complementariness of sentence deletion and word deletion can be well explained as that removing a sentence from a reference summary reduces a great amount of key information while removing a word from a sentence changes it syntactically. We found that word-level mutations are less useful for content/fact aspects, probably because of the inertia of the context after words are altered.

Which training domain/dataset should I use? Due to the composition of summarizers and the limited data size in human evaluation, it is very hard to get a consistent ranking of metrics on different datasets (Bhandari et al., 2020). For example, in Table 1, Billsumm outperforms all baselines and its peers on TAC2010 but not the case on Newsroom and RealSumm.

Still, the impact of training domain seems manageable. The average absolute deviations across the training datasets/domains are given at the bottom of Tables 1 and 2. They mostly below 3.5%. A qualitative analysis shows that the variation seems more due to the characteristics of the text than the domain. Legislative bills (Billsum) have lots of short, hierarchical clauses and thus differ from common English greatly. Scientific papers have many equations and cross-references. There are also many occurrences of LaTeX or MathML in the dataset arXiv. On top of that, all our experiments use different training and test domains. Hence we would say that the impact of domain variation is very small.

4 Conclusion

In this paper, we propose a weakly supervised approach to summary quality evaluation. A few mutation methods are introduced to make use of the massive, precious human written summaries in summarization datasets. In cross-domain experiments, our approach achieves better performance than baselines, especially on linguistic aspects. We hope this proof-of-concept study can inspire more reference-free summary evaluation.

A Dataset statistics

For test sets:

- **TAC2010 Guided Summarization Task Set A** consists of 46 topics, each of which is associated with a set of 10 documents. We evaluate the metrics over summaries generated by 43 systems.
- **Newsroom** contains human-rated summaries generated by 7 systems for 60 documents.
- **RealSumm** sampled 100 documents from the CNN/DailyMail test set, and collected human ratings for summaries generated by 11 extrative systems and 14 abstractive systems.

For training sets, the numbers of pairs of documents and reference summaries in the train split are:

- **Billsum**: 18,949
- **Scientific papers/arXiv**: 203,037
- **Big-Patent**: 1,207,222

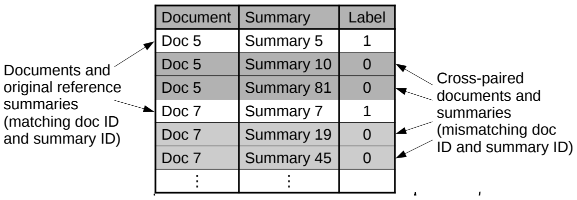
For each dataset, we use the entire (except for Big-Patent, 10% due to its huge size) `train` split in Google Tensorflow Datasets for training.

B Computational environment and cost

All experiments were carried out on one RTX3090 GPU installed on a desktop computer. The training takes about a week for all three training datasets.

C Another type of mutation

In addition to the three mutation methods mentioned already, we have another method called crosspairing.



Document	Summary	Label
Doc 5	Summary 5	1
Doc 5	Summary 10	0
Doc 5	Summary 81	0
Doc 7	Summary 7	1
Doc 7	Summary 19	0
Doc 7	Summary 45	0
⋮	⋮	

Figure 3: Training sample generation via cross pairing.

Illustrated in Figure 3, it is inspired by the next-sentence prediction (NSP) task in original BERT training. Given a document and its reference summary, we create negative data by pairing the document with reference summaries of other documents.

We assign the label 0 to a mismatching document-summary pair, and the label 1 to any original pair of a document and its reference summary.

D Complete empirical results

Due to space limit, we were only able to present the result of the best mutation method in § 3.5. Full results are given in Tables 3, 4, 5, and 6. Pearson's for LS-Score is unable to be produced due to reasons explained in the footnote on page 4.

Table 3: Full results for **Spearman**'s correlation on **content/fact** aspects.

Combating the Curse of Multilinguality in Cross-Lingual WSD by Aligning Sparse Contextualized Word Representations

Gábor Berend
Institute of Informatics, University of Szeged
`berendg@inf.u-szeged.hu`

Abstract

In this paper, we advocate for using large pre-trained monolingual language models in cross lingual zero-shot word sense disambiguation (WSD) coupled with a contextualized mapping mechanism. We also report rigorous experiments that illustrate the effectiveness of employing sparse contextualized word representations obtained via a dictionary learning procedure. Our experimental results demonstrate that the above modifications yield a significant improvement of nearly 6.5 points of increase in the average F-score (from 62.0 to 68.5) over a collection of 17 typologically diverse set of target languages. We release our source code for replicating our experiments at `https://github.com/begab/sparsity_makes_sense`.

Table 1: Monolingual models from the `transformers` library (Wolf et al., 2020) covering all the (non-English) languages of the XL-WSD dataset (Pasini et al., 2021).

1 Introduction

Word sense disambiguation (WSD) is a longstanding and fundamental problem of Natural Language Processing, known to be affected by the *knowledge acquisition bottleneck* (Gale et al., 1992). Large pre-trained neural language models are known to effectively mitigate the problems related to the paucity of high quality, large-coverage sense annotated training data for WSD (Loureiro and Jorge, 2019; Loureiro et al., 2021b; *inter alia*).

Most recently, the knowledge acquisition bottleneck has been identified as an immense problem in the cross-lingual setting as well (Pasini, 2020). A straightforward solution for handling this problem is to apply large multilingual pre-trained language models in a zero-shot setting, however, this approach has a potential limitation owing to the *curse of multilinguality* (Conneau et al., 2020a), i.e., the inability of such models to handle the large number of languages involved during training such models to an equally good quality.

The research community replied to the limitations of large massively multilingual models by developing language-specific monolingual language models.[1] Table 1 provides a shortlist of recently published monolingual large pre-trained language models, related to the languages involved in the cross-lingual WSD test suit, XL-WSD (Pasini et al., 2021).

With the prevalence of large monolingual pre-trained models, the important research question arises if their language-specific nature can be successfully exploited during zero-shot learning. Our research provides a thorough comparison of the application of large multilingual and monolingual pre-trained language models for zero-shot WSD.

Another crucial aspect that we carefully investigate in this paper is the integration of sparse contextualized word representations into cross-lingual zero-shot WSD. Sparse word representations have a demonstrated ability to align with word senses (Balogh et al., 2020; Yun et al., 2021). While the benefits of employing sparsity has been shown for WSD in English (Berend, 2020a), its viability in the cross-lingual setting has not yet been verified.

---

[1] With a slight abuse of notation, we also refer to models that support a handful of (related) languages (e.g. Slovenian and Croatian) as language-specific monolingual ones.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2459 - 2471
July 10-15, 2022 ©2022 Association for Computational Linguistics

In order to conduct such an analysis, we propose an algorithm for obtaining cross-lingual sparse contextualized word representations from independently trained monolingual language models.

2 Related work

The analysis and the investigation of the transfer capabilities of large pre-trained language models (such as mBERT or XLM) across languages has spurred significant research interest (Pires et al., 2019; Wu and Dredze, 2019, 2020; K et al., 2020). In contrast to the availability of multilingual neural language models, a series of recent papers have argued for the creation of dedicated neural language models for different languages (see e.g. Table 1). While monolingual neural language models can more accurately model the distinct languages, models that are trained in isolation of other languages cannot directly benefit from downstream application-specific annotated training data available in different languages.

Artetxe et al. (2020) proposed an approach for making monolingual models compatible with each other by first pre-training a masked language model on a source language, then freezing its parameters apart from its embedding layer that get replaced and trained for additional target languages using a standard masked language modeling objective. Note that this approach is complementary and strictly more resource intensive to ours, as it involves the pre-training of a (freezed) transformer model with respect its embedding layer for a target language. In contrast, our approach can operate on monolingual language models fully pre-trained in total isolation from the source language encoder. Also, our approach learns substantially fewer parameters in the form of an alignment matrix between the hidden representations of the contextualized target and source language spaces.

Conneau et al. (2020b) analyzed the multilingual patterns emerging in large pre-trained language models. The authors found that "*language universal representations emerge in pre-trained models without the requirement of any shared vocabulary or domain similarity*". That work have demonstrated that monolingual BERT models can be effectively mapped for performing zero-shot cross-lingual named entity recognition and syntactic parsing. Similarly, Wang et al. (2019); Schuster et al. (2019) also illustrated the efficacy of linear transformations for using BERT-derived representations in cross-lingual dependency parsing.

WSD has been a fundamental and challenging problem in NLP for many decades, dating back to (Weaver, 1949/1955). The utilization of contextualized word representations was first advocated by Peters et al. (2018), later popularized by (Loureiro and Jorge, 2019; Loureiro et al., 2021a). Bevilacqua et al. (2021) offers a survey of the recent approaches.

Most recently, Rezaee et al. (2021) have explored the usage of multilingual language models (XLM) in zero-shot WSD. While the experiments in (Rezaee et al., 2021) cover four related target languages (German, Spanish, French and Italian), our investigation involves a typologically diverse set of 17 target languages (beyond English) from (Pasini et al., 2021). Our work also extends that line of research in important aspects, as we show that the application of monolingual neural language models can vastly improve the performance of cross-lingual zero-shot WSD. Additionally, we also provide a careful evaluation of sparse contextualized word representations in zero-shot WSD.

Berend (2020a) introduced sparse contextualized word representations via the application of dictionary learning, and showed that sense representations that are obtained from the co-occurrence statistics of the sparsity structure of the contextualized word representations and their sense annotations can provide significant improvement in monolingual WSD. Our work relates to that line of research by providing a mapping-based procedure, which enables the usage of such sense representations created in some source language to be applied in other target languages as well. The kind of mapping we employ can be viewed as a generalization of the approach introduced in (Berend, 2020b) with the notable exception that in this work, we obtain sparse word representations for contextualized models as opposed to static word embeddings.

3 Methodology

In order to allow for zero-shot transfer between monolingual language models pre-trained in isolation from each other, we need to determine a mapping between their hidden representations. We first introduce our methodology for doing so, then we integrate this to the creation of sparse contextualized word representations.

3.1 Mapping hidden representations

The alignment of word representations between independently constructed semantic spaces can be conveniently and efficiently performed via linear transformations. This has been a standard approach for non-contextualized word embeddings (Mikolov et al., 2013; Xing et al., 2015; Smith et al., 2017), but it has been shown to be useful in the contextualized case as well (Conneau et al., 2020b).

The standard approach is to obtain a collection of pairs of anchor points $\{\boldsymbol{x}_i, \boldsymbol{y}_i\}_{i=1}^n$ with $\boldsymbol{x}_i$ and $\boldsymbol{y}_i$ denoting the representation of semantically equivalent words in the target and source languages, respectively. The mapping W is then obtained as

$$\min_W \sum_{i=1}^{n} \|W\boldsymbol{x}_i - \boldsymbol{y}_i\|_2^2. \quad (1)$$

As we deal with contextualized models, we can obtain various representations for a word even in the same context, by considering the hidden representations from different layers of the neural language models employed. Additionally, as constraining the mapping matrix to be an isometric one have proven to be a useful requirement, we define our learning task to be of the form

$$\min_{W \ s.t.\ W^\intercal W=I} \sum_{i=1}^{n} \|W\boldsymbol{x}_i^{(l_t)} - \boldsymbol{y}_i^{(l_s)}\|_2^2, \quad (2)$$

with I denoting the identity matrix, $\boldsymbol{x}_i^{(l_t)}$ and $\boldsymbol{y}_i^{(l_s)}$ denoting the hidden representations obtained from the $l_t{}^{\text{th}}$ and $l_s{}^{\text{th}}$ layers of the target and source language neural language models, respectively.

Finding the optimal isometric W can be viewed as an instance of the orthogonal Procrustes problem (Schönemann, 1966) which can be solved by $W_\perp = UV$, with U and V originating from the singular value decomposition of the matrix product $Y^\intercal X$, where X and Y include the stacked target and source language contextual representations of pairs of semantically equivalent words.

As words of the input sequences to the neural language models can be split into multiple subtokens, we followed the common practice of obtaining word-level neural representations by performing mean pooling of the subword representations. Throughout our experiments, we also relied on the RCSLS criterion (Joulin et al., 2018), which offers a retrieval-based alternative of obtaining a mapping from the target to the source language representations.

3.2 Cross-lingual sparse contextualized word representations

Our approach extends the information theoretic algorithm introduced in (Berend, 2020a) for its application in the cross-lingual zero-shot WSD setting. In order to obtain sparse contextualized representations for the source language, we first populate $Y \in \mathbb{R}^{d \times N}$ with d-dimensional contextualized representations of words determined for texts in the source language, and minimize the objective

$$\min_{D \in \mathcal{C}, \boldsymbol{\alpha_i} \in \mathbb{R}^k_{\geq 0}} \sum_{i=1}^{N} \frac{1}{2}\|\boldsymbol{y_i} - D\boldsymbol{\alpha_i}\|_2^2 + \lambda\|\boldsymbol{\alpha_i}\|_1, \quad (3)$$

where $\mathcal{C}$ denotes the convex set of $d \times k$ matrices with column norm at most 1, λ is a regularization coefficient and the sparse coefficients in α are required to be non-negative. We used the SPAMS library (Mairal et al., 2009) for calculating D and α.

Having obtained D for the source language, we determine a sparse contextualized word representation for a target language word with dense contextualized representation $\boldsymbol{x_i}$ as

$$\min_{\boldsymbol{\alpha_i} \in \mathbb{R}^k_{\geq 0}} \frac{1}{2}\|W\boldsymbol{x_i} - D\boldsymbol{\alpha_i}\|_2^2 + \lambda\|\boldsymbol{\alpha_i}\|_1, \quad (4)$$

where W is the alignment transformation as described earlier in Section 3.1. Eq. (4) reveals that the cross-lingual applicability of the sparse codes are assured by the mapping transformation W and the fact that the sparse target language representations are also using the same D that was determined for the source language, which also ensures the efficient calculation of sparse representations during inference time.

Apart from these crucial extensions we made for providing the use of contextualized sparse representations in the cross-lingual setting, the way we utilized them for the determination of sense representation and inference is identical to (Berend, 2020a). That is, for all sense-annotated words in the training corpus, we calculated a weighted cooccurrence statistics between a word pertaining to a specific semantic category and having non-zero coordinates along a specific dimension in their sparse contextualied word representations. These statistics are then transformed into pointwise mutual information (PMI) scores, resulting in a sense representation for all the senses in the training sense inventory.

Sense representations obtained that way measure the strength of the relation of the senses to the different (sparse) coordinates. Inference for a word with sparse representation $\boldsymbol{\alpha}$ is simply taken as $\arg\max_s \Phi\boldsymbol{\alpha}^\intercal$, where Φ is the previously defined matrix of PMI values and s corresponds to the sense at which position the above matrix–vector products takes its largest value.

4 Experimental results

All the neural language models that we relied on during our experiments were obtained from the `transformers` library (Wolf et al., 2020). We used four NVIDIA Titan 2080 GPUs for our experiments.

As the multilingual language model, we used the 24-layer transformer architecture, XLM-RoBERTa (XLM-R for short) (Conneau et al., 2020a). We chose the cased BERT (Devlin et al., 2019) large model as the monolingual model for encoding English text. As for the rest of the monolingual language models involved in our experiments, we relied on the models listed in Table 1. These monolingual models have the same size as the BERT-base model, i.e., they consist of 12 transformer blocks and employ hidden representations of 768 dimensions.

For evaluation purposes, we used the extra-large cross-lingual evaluation benchmark XL-WSD, recently proposed in (Pasini et al., 2021). The database contains a high-quality sense annotated corpus for English as the concatenation of the SemCor dataset (Miller et al., 1994) and the sense definitions and example sentences from WordNet (Fellbaum, 1998). XL-WSD uses the unified cross-lingual sense inventory of BabelNet (Navigli and Ponzetto, 2012).

The dataset contains 17 additional typologically diverse languages besides English (that we listed in Table 1). The authors also released machine translated silver standard sense annotated training corpora for all the languages, which makes the language-specific fine-tuning of monolingual models possible, however, as shown in (Pasini et al., 2021), that approach resulted in inferior results compared to the application of multilingual models in the zero-shot setting.

Throughout the application of sparse contextualized representations, we employ the same set of hyperparameters that were used in (Berend, 2020a), i.e., we set the number of the regularization coefficient to $\lambda = 0.05$ and the number of (sparse) coordinates to $k = 3000$. There made one optional change, i.e., we decided whether to use the normalization of PMI values (Bouma, 2009) during the calculation of the sense representation matrix Φ on a per language basis based on development set performances. An ablation study related to the (optional) normalization of PMI scores is reported in Table 5, Appendix B.

When we do not employ the sparsification of the contextualized word representations for determining the sense representations, we follow the approach introduced in (Loureiro and Jorge, 2019). That is, we take the centroid of word vectors belonging to a particular sense as the representation of that sense, and perform a nearest neighbor search during inference.

4.1 Alignment of contextualized representations

As the different layers of neural language models have been shown to provide different levels of utility towards different tasks, we experimented with mappings between different combinations of layers from the target and source language neural language models. Since the last few layers of the neural models are generally agreed to be the most useful for semantics-related tasks (Peters et al., 2018; Tenney et al., 2019; Reif et al., 2019), we decided to learn mappings between the hidden representations of any of the last four layers of the target and source language encoders.

We used BERT as the language specific encoder for the source language texts in English, but we also investigated the application of XLM-R, so that we can see the effects of replacing it by an encoder especially tailored for English. As for the target languages, we used the respective models for each language as listed in Table 1. Similar to the source language, we also investigated the case when target languages were encoded by the multilingual model.

In what follows, we label the different experimental settings according to the followings:

- multi→multi means that we map the target language representations obtained by the multilingual (XLM-R) model to the representation space of the source language also obtained by the multilingual (XLM-R) encoder,
- multi→mono, means that we map the target language representations obtained by the multilingual (XLM-R) model to the representation space of the source language obtained by the monolingual (English BERT) encoder,

- mono→multi, means that we map the target language representations obtained by their respective monolingual language model to the representation space of the source language obtained by the multilingual (XLM-R) encoder,

- mono→mono, means that we map the target language representations obtained by their respective monolingual language model to the representation space of the source language obtained by the monolingual (English BERT) encoder.

In order to obtain the cross-representational mappings, we accessed the Tatoeba corpus (Tiedemann, 2012) through the `datasets` library (Lhoest et al., 2021). The Tatoeba corpus contains translated sentence pairs for several hundreds of languages which we used for obtaining the pivot word mention pairs together with their contexts.

In addition to the Tatoeba corpus, we used the `word2word` library (Choe et al., 2020) containing word translation pairs between more than 3,500 language pairs. By denoting (S_{s_i}, S_{t_i}) the i^{th} translated sentence pair from the Tatoeba corpus, we treated those $(w_s \in S_{s_i}, w_t \in S_{t_i})$ word occurrences as being semantically equivalent, for which the $w_t \in TranslationOf(w_s)$ and the $w_s \in TranslationOf(w_t)$ relations simultaneously held according to the translation list provided by `word2word`.

As an example, given the German-English translation pair from Tatoeba, *{'de:' 'Es steht ein Glas auf dem Tisch.', 'en': 'There is a glass on the table.}*, underlined pairs of words with the same color would be treated as contextualized translation pairs of each other.

One benefit of our approach for determining contextual alignment of word pairs is that it does not require word level alignment of the parallel sentences, hence it suits such lower resource scenarios better, when only parallel sentences (without word level alignments) and a list of word translation pairs are provided. Naturally, different contextual alignment approaches could be integrated into our approach at this point, and this is something that we regard as potential future extension of our work.

We evaluated the quality of the mapping learned between the target and the source language representations by defining a contextualized translation retrieval task and evaluating it on its accuracy@1 metric, i.e., for what fraction of the contextualized translation pairs – not seen during the determination of the mapping between the two representation spaces – are we able to rank the original translated context as the highest.

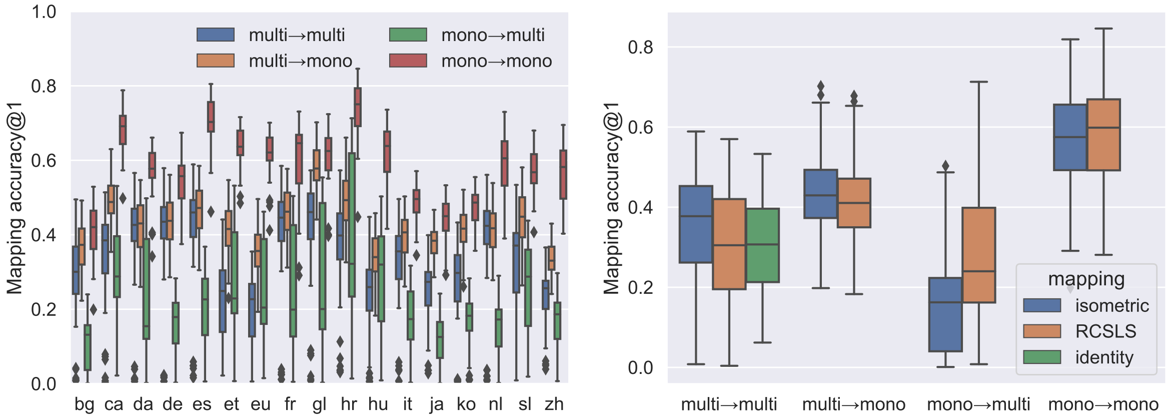
Table 2: The number of sentence pairs included in the Tatoeba corpus between English and a target language and the number of contextualized translation pairs extracted for training and testing the mappings.

In the multi→multi case, i.e., when both the target and source languages are encoded by the same multilingual model (XLM-R), it also makes sense to use the identity matrix as the mapping operator for mapping the target language contextual text representations to the semantic space of the source language (as long as the target and source language texts are obtained from the same layer of the multilingual encoder). We also evaluated the quality of this approach in our experiments that we refer to as the identity approach.

We list the statistics of the Tatoeba corpus and the size of the training and test contextualized translation pairs in Table 2. Our results on the top-1 contextualized translation retrieval accuracies along the different languages and combination of target and source encoder usage are reported in Figure 1. The quality of the combination which uses monolingual encoders for both the target and source languages (mono→mono) performed the best.



(a) Mapping accuracies per languages.

(b) Mapping accuracies aggregated over languages.

22	74.87	77.60	67.87	74.50
23	74.45	77.86	67.48	74.26
24	73.58	76.21	64.50	70.06

Table 3: English results expressed in F-score.

4.2 Monolingual evaluation

We first conducted evaluations in the monolingual setting, i.e., we used the sense annotated training data to train and evaluate WSD models in English. The results of these experiments – depending on the encoder architecture used (BERT/XLM-R), the layer of the encoder utilized ({21,. . . ,24}), and whether the sparsification of the contextualized representations took place (Dense/Sparse) – are included in Table 3.

Unsurprisingly, the application of the language-specific BERT model achieved better scores compared to that of XLM-R. An interesting observation though, is that the drop in performance is much more subtle for those cases when the contextualized representations are enhanced via sparsification, i.e., the typical loss in performance across the layers is only 3 points (apart from the final layer), opposed to the typical loss of 4-7 points in the dense case.

4.3 Cross-lingual zero-shot evaluation

Table 4 includes the zero-shot cross-lingual WSD results for a collection of baseline approaches (Table 4a) from (Pasini et al., 2021), followed by our models not utilizing the sparsification of the contextualized embeddings (Table 4b) and the ones that additionally benefit from sparsification as well (Table 4c). It is useful to note that the mono→* approaches are strictly more resource efficient during inference as they are based on 12-layer encoders instead of the 24 layers of the multilingual XLM-R model.

At this point, we separate the multi→multi results into two, i.e., 1) those obtained when relying on the hidden representations from the same layer of XLM-R without mapping (or equivalently, with the identity mapping from the target to source representations); and 2) those obtained when the target and source language contextual representations could originate from different layers of the XLM-R encoder, and a non-identity (either isometric or RCSLS) mapping was employed. We keep referring to the latter as multi→multi, and denote the former type of experiments as multi (without the →multi suffix as there were no real mappings performed in these cases). Inspecting the first two rows of Table 4b and Table 4c reveals that enhancing the multilingual encoder towards the treatment of a particular pair of languages by providing it a language pair specific mapping has a larger positive effect when using dense vectors. In fact, it increased the micro-averaged F-score over the 17 languages by 1.72 and 0.11 points for the dense and the sparse cases, respectively.

Overall, the micro-averaged F-score of our final approach managed to improve nearly 6.5 points (cf. the first row of Table 4b and the last row in Table 4c). A 5 point average improvement is due

(c) Our results based on sparse sense vectors.

Table 4: Test set results on the XL-WSD benchmark. The hyperparameters of the individual approaches (e.g. which layer of the target language encoder to align with which layer of the source language encode) were determined based on the development set of each language.

to the replacement of the XLM-R encoder for both the source language during training and target languages for inference (cf. the first and last row of Table 4b) and an additional 1.5 points of improvement was an effect of our sparsification in the cross-lingual setting. The inspection of the third and fourth rows in both Table 4b and Table 4c reveals that using a monolingual encoder during inference helps more compared to the application of a monolingual encoder for encoding the source language during training.

We conducted the McNemar test between our system outputs when a non-identity mapping was used between a pair of languages. Our investigation revealed that all such $\binom{8}{2}$ pairs of system outputs from Table 4b and Table 4c differ significantly from each other with $p < 0.0007$, with only four exceptions, i.e, 1) multi→multi and multi→mono from Table 4b; 2) multi→multi and multi→mono from Table 4c; 3) mono→multi from Table 4c and mono→mono from Table 4b; 4) multi→mono from Table 4c and mono→multi from Table 4b.

Figure 2 summarizes the results of all the possible runs conducted. When using the multilingual encoder for both the target and source languages without a mapping step between the two (multi), we ran 4 different experiments per each language based on the hidden representations obtained from one of the last 4 layers of the multilingual encoder. For the remaining experiments relying on the dense and sparse representations, there were 32 and 64 experiments for each language, respectively. The 32 experiments were a result of choosing any of the 16 possible combination of the final four layers on the target and source language encoder, coupled with the type of mapping utilized (isometric/RCSLS). For the experiments involving the sparse representations, there was an extra parameter, whether the normalization of the PMI scores for obtaining the sense representations to be performed, resulting

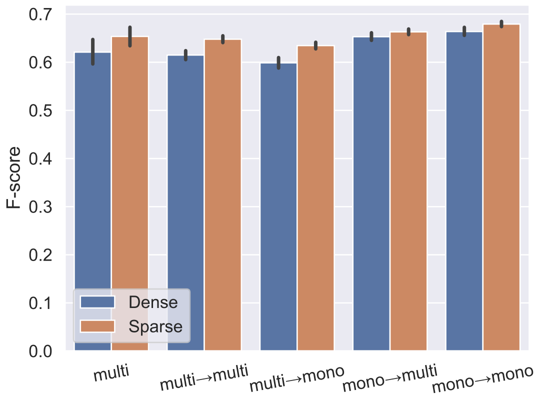

Figure 2: Overall averaged results for all the experiments conducted for the different approaches.

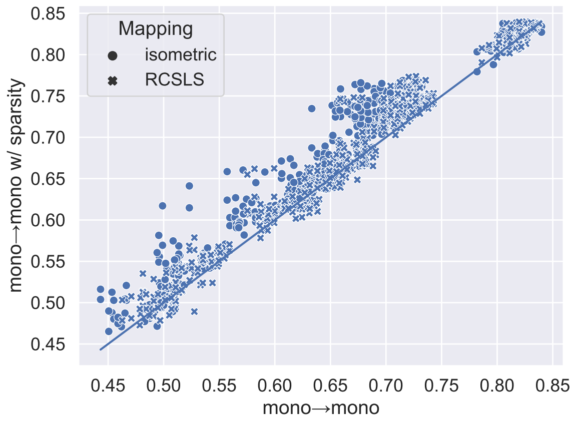

Figure 3: Comparison of the two best performing systems when the same hyperparameters were employed.

in 2 × 32 experiments all together. Our ablation study in Table 5 illustrates that this extra factor of 2 for the sparse experiments did not provided us an unfair advantage, i.e., when fixing the value of normalization in any way, the overall results did not differ substantially.

The difference in the average performance of our approach transforming sparse contextualized representations obtained by monolingual models is significant (using unpaired t-test[2], $p < 0.005$) compared to any other configuration. This suggests that the mono→mono approach has a robust advantage over alternative variants, and the improvements seen in Table 4 are *not* an effect of careful hyperparameter selection, but they generalize over a wide range of choices.

This effect is further corroborated in Figure 3, which offers a comparison between the two systems with the best average performance, i.e., mono→mono that operates with the dense vectors (results are along the x-axis) and the same model but with the enhancement of sparsification (results are along the y-axis). Each data point corresponds to a setting with the same hyperparameter choices, and points above the diagonal line with slope one demonstrate the benefits of sparsification.

We have demonstrated the improved utility of mapping language-specific sparse contextualized representations for conducting zero-shot WSD, requiring large pre-trained language-specific text encoders for the target languages. While such models are available for all languages in XL-WSD, a variety of the existing languages lack their dedicated language-specific pre-trained language model.

As such, an important question emerges whether it is possible to enjoy the benefits of mapping sparse contextualized representations for zero-shot WSD in the absence of a large pre-trained language model dedicated to the target language. To this end, we shall inspect the results of our multi→mono approach in Table 4, a series of mapping-based experiments in which we acted as if the monolingual language models (other than the one for English) did not exist. In these experiments, the sense embeddings were obtained with bert-large-cased (being specialized to English), and the mapping to the non-English target languages were performed towards their XLM-R representations during the evaluation. This way, we could simulate the effects of the absence of language-specific models.

The multi→mono approach provided a substantially better average performance compared to the mere utilization of a multilingual encoder in the case of dense contextualized representations as it can be seen in Table 4b. The average results of multi→mono are slightly inferior (albeit statistically insignificantly) to that of the multi approach for the application of sparse contextualized representations. However, when comparing the multi→multi results with that of multi→mono, we can see that by relying on a multilingual encoder alone, and allowing a mapping to be employed between its hidden representations pertaining to different languages, one can obtain the same (or even slightly better) performance as with the multi→mono approach. This highlights the importance of monolingual encoders for the target language, which seems to be more important than having access to a monolingual encoder for the source language.

5 Conclusions

In this paper we provided a systematic investigation of the benefits of using large monolingual pretrained language models in place of multilingual language models, such as XLM-R. We have shown that since monolingual neural language models are specifically tailored for a single (or at most a few related) languages, they can effectively mitigate the *curse of multilinguality* typical of multilingual models, and their application can significantly improve the F-scores in zero-shot WSD. We additionally showed that the benefits of sparse con-

[2] We used unpaired t-test as the number of experiments was not same in all cases, i.e., 4 experiments/language in the multi case, and either 32 or 64 experiments/language in the rest of the cases.

textualized word representations, obtained via a dictionary learning procedure, also convey to the cross-lingual setting, and that it provides complementary improvements to the usage of monolingual neural language models.

Acknowledgments

The research was supported by the Ministry of Innovation and Technology NRDI Office within the framework of the Artificial Intelligence National Laboratory Program. Additionally, we are thankful for the usage of ELKH Cloud (https://science-cloud.hu/) that helped us achieving the results published in this paper.
