Table 9: Regular Expressions for generalized quantifiers.

Appendices

A Regular Expressions for Generalized Quantifiers

Table 9 lists the regex we use to parse generalized quntifiers in sentences augmented with universal dependency tags. The approach does not find all the generalized quantifiers exhuastively but rather approximates the common distributions.

B Pairwise Observation

While the analysis in Section 4 is based on quantifiers in hypotheses, next we consider the interaction of quantifiers in hypotheses and quantifiers in premises. To this end, we calculate the difference between overall performance and performance for premise-hypothesis pairs of GQs. In Figure 2, we visualize the results as heatmaps (see Table 10 for exact numbers of occurences and accuracies). Surprisingly, whenever quantifiers appear in both the premise and the hypothesis, LMs largely fail to predict the entailment. Percentage quantifiers, supposed to be semantically more complex than counting quantifiers, are not *de facto* harder in NLI. We studied all 27 cases of percentage quantifiers in the English NLI datasets, and found that in most cases, percentage quantifiers occurrences are *identical* across premises and hypotheses, i.e., triggering little or no inference. The other two proportional quantifiers, *most* and *few*, are hard for

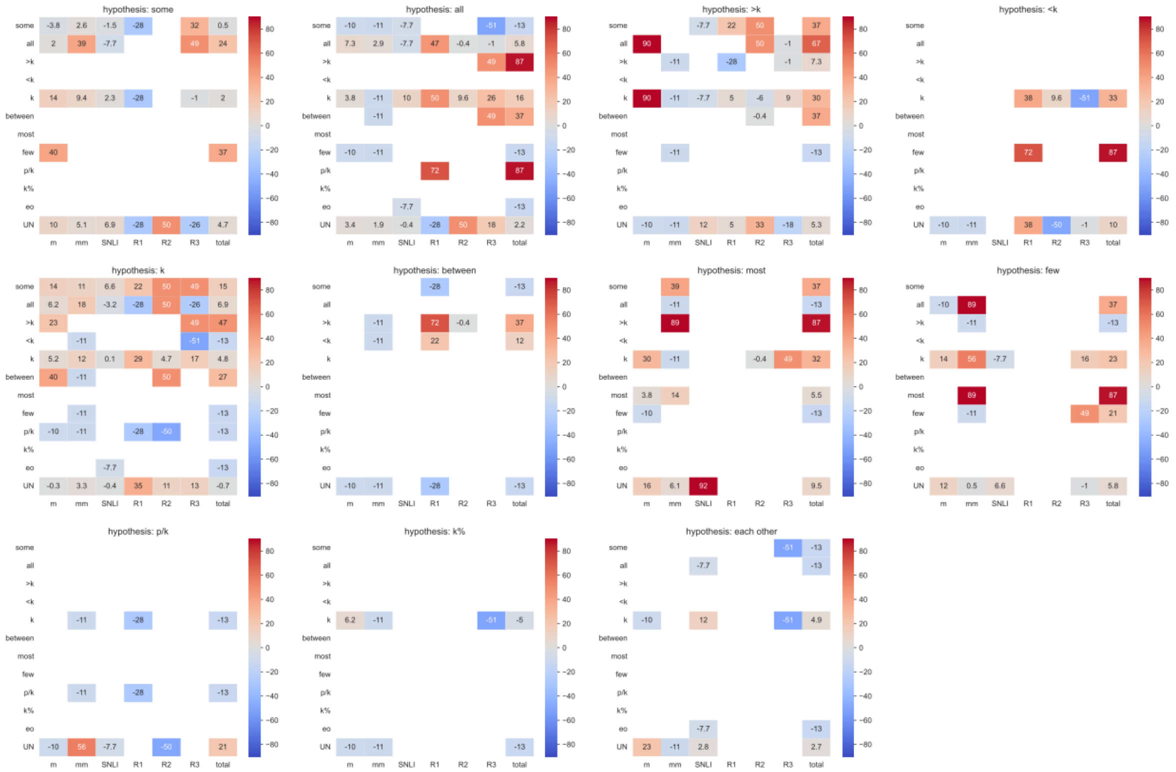

Figure 2: Fine-grained analysis of RoBERTa performance on 6 English NLI subtasks. Each heatmap represents hypotheses with a type of quantifier. The rows stand for premises with the quantifier of that label. The numbers are calculated as the accuracy over the whole dataset minus the fine-grained accuracy given a specific premise and hypothesis (the higher the number, the worse the performance). For each heatmap, the last column represents the accuracy gap weighted by all 6 tasks. "UN" stands for an entry where no explicit quantifier is identified.

LMs to resolve, e.g., in some quantifier pairs, models yield 0% accuracy. Although *each other* is supposed to be hardest to resolve due to the complex semantics of reciprocals (Szymanik and Thorne, 2015), it is not reflected in NLI tasks as such. The reason is similar to percentage quantifiers, while annotators intend to alter counting quantifiers when writing hypotheses, reciprocality is seldomly considered a linguistic ability that needs testing for NLU systems. And the annotation for Ramsey quantifier is simply a knockoff, making reciprocal relation identification unwarranted through shallow correlations.

C Fine-grained NLI Analysis

D XQA Result: mBERT and XLM-R

Table 11 compares the results of mBERT and XLM-R on two XQA tasks, XQuAD and MLQA.

E GQNLI Examples

Table 12 list one example per category in GQNLI.

F GQNLI Negation Cases

We present the results of seven models' performance on cases with negation cues in GQNLI in Table 13.

G GQNLI Subsumption Cases

See Table 14 for models 'performance on cases requiring subsumption reasoning in GQNLI. We also break down subsumption results by entailment labels into two categories: neutral and non-neutral.

H GQNLI Experiment Details

We reused the fine-tuned BERT and RobERTa in Section 4. The other fine-tuned LMs are from Hugging Face. We list the models and thier links in Table 15.

Exact Paired-Permutation Testing for Structured Test Statistics

Ran Zmigrod **Tim Vieira** **Ryan Cotterell**

Abstract

Significance testing—especially the paired-permutation test—has played a vital role in developing NLP systems to provide confidence that the difference in performance between two systems (i.e., the test statistic) is not due to luck. However, practitioners rely on Monte Carlo approximation to perform this test due to a lack of a suitable exact algorithm. In this paper, we provide an efficient exact algorithm for the paired-permutation test for a family of structured test statistics. Our algorithm runs in $\mathcal{O}(GN(\log GN)(\log N))$ time where N is the dataset size and G is the range of the test statistic. We found that our exact algorithm was 10x faster than the Monte Carlo approximation with 20000 samples on a common dataset.

`https://github.com/rycolab/paired-perm-test`

1 Introduction

How confident can we be that System U is more accurate than System V? Questions of this form are widespread in natural language processing (Dietterich, 1998; Koehn, 2004; Ojala and Garriga, 2010; Clark et al., 2011; Berg-Kirkpatrick et al., 2012; Dror et al., 2018) and statistical hypothesis testing provides answers (Lehmann and Romano, 2005). In this paper, we study the paired-permutation test (Good, 2000)—a commonly used hypothesis test in NLP because it makes no assumptions on the distribution of the data or the evaluation metric used to compare the two systems (Yeh, 2000; Dror et al., 2018, 2020; Deutsch et al., 2021). The paired-permutation test checks whether a test statistic is significant by evaluating the probability that a value at least as large as the observed statistic would occur if system outputs were randomly swapped. Thus, an exact algorithm for evaluating the paired-permutation test involves a summation over all 2^N possible swaps. Without any assumptions on the test statistic, we can only exactly compute this sum in $\mathcal{O}(2^N)$ time. Thus, practitioners often resort to running a Monte Carlo (MC) approximation which replaces the summation with $K \ll 2^N$ randomly sampled swaps. Although the MC approximation is often practical, it unfortunately,introduces additional error when determining the significance of a test (Serlin, 2000; Koehler et al., 2009).

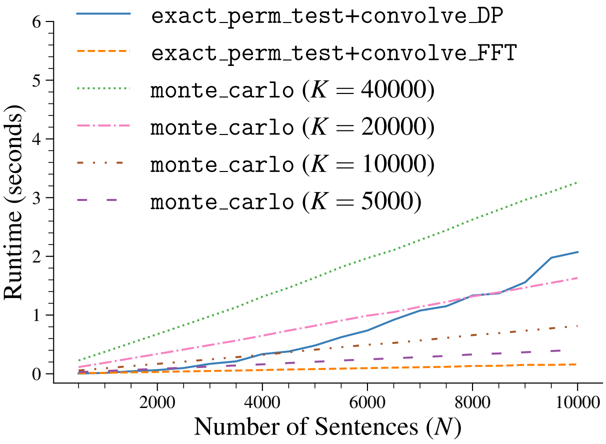

Figure 1: Runtime comparison of `exact_perm_test` using `convolve_DP` and `convolve_FFT`, and `monte_carlo` as a function of the number of entries in the dataset. See for §5 for experimental details.

This paper proposes a family of additively structured, integer-valued test statistics. Test statistics of this form admit an efficient exact algorithm that leverages the fast Fourier transform (Cooley and Tukey, 1965; Cormen et al., 2022) to run in $\mathcal{O}(GN(\log GN)(\log N))$ time where N is the size of the dataset and G is the range of the test statistic. We compare the efficiency of our exact method to the MC approximation for comparing part-of-speech taggers on the Universal Dependency Dataset (Nivre et al., 2018). Surprisingly, our *exact* algorithm is faster than MC approximation: given 10000 sentences, our algorithm is 10x faster than MC with 20000 samples and 3x faster than MC with 5000 samples, taking ≈ 0.1 seconds.

2 Paired-Permutation Testing

The **paired-permutation test** (Good, 2000), the focus of this work, is a common null hypothesis significance test that has a natural application to many problems in NLP (Peyrard et al., 2021). The test attempts to reject the null hypothesis, described below, at significance level α; typically $\alpha = 0.05$.

Preliminaries. Suppose we want to compare the performances of two systems U and V where each system was evaluated on a dataset of the same N entries. We place the entries of U and V into a pair of arrays of length N denoted $\mathbf{u}$ and $\mathbf{v}$.

The null hypothesis. The goal of a paired-permutation test is to test whether the entries $\mathbf{u}$ and $\mathbf{v}$ are *independent* of the labels U and V themselves. The reason that this is the question we ought to care about is that, fundamentally, if the system label (in this case, U or V) provides no information (in the sense of mutual information) about the entry, then we should *not* prefer one system to another. And, from basic information theory, we know that two random variables (RVs) have no mutual information iff they are independent. So, independence of the system's label and the system's set of entries is the right thing to inquire about. In the language of frequentist testing, the hypothesis that a system's labels and individual entries are independent is known as the **null hypothesis**. And, under a paired-permutation test, the goal is to ascertain whether the data (the observed entries $\mathbf{u}$ and $\mathbf{v}$) provide enough evidence to *reject* the null hypothesis, i.e., to conclude that the label of a system shares information with the quality of its individual entries, and are indeed dependent.

The null distribution. Next, in order to attempt to reject the null hypothesis, we require a distribution over (hypothetical) pairs of entries $\mathbf{u}'$ and $\mathbf{v}'$ whose individual entries are independent of the system labels U and V, which is achieved through the construction of RVs $\mathbf{U}^{\varnothing}$ and $\mathbf{V}^{\varnothing}$, whose joint distribution can be used to sample our hypothetical $\mathbf{u}'$ and $\mathbf{v}'$. Traditionally, $\mathbb{P}[\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}]$ is referred to as the **null distribution**. A paired-permutation test provides a simple recipe for constructing such an RV pair. The first step is to make an entry-wise independence assumption: we define the joint probability $\mathbb{P}[\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}] \overset{\text{def}}{=} \prod_{n=1}^{N} \mathbb{P}[\mathrm{U}_n^{\varnothing}, \mathrm{V}_n^{\varnothing}]$. This means that the prediction a system makes for the n^{th} entry is independent of the m^{th} entry when $n \neq m$. In the second step, we further define the entry-wise joint distribution as

$$\mathbb{P}\big[\mathrm{U}_n^{\varnothing} = u_n, \mathrm{V}_n^{\varnothing} = v_n\big] \overset{\text{def}}{=} \frac{1}{2} \quad \text{(stay)} \qquad \text{(1a)}$$

$$\mathbb{P}\big[\mathrm{U}_n^{\varnothing} = v_n, \mathrm{V}_n^{\varnothing} = u_n\big] \overset{\text{def}}{=} \frac{1}{2} \quad \text{(swap)} \qquad \text{(1b)}$$

In words, $\mathbb{P}[\mathrm{U}_n^{\varnothing}, \mathrm{V}_n^{\varnothing}]$ is a uniform distribution over swapping U and V's prediction for the n^{th} entry. All in all, this definition of $\mathbb{P}[\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}]$ as the null distribution gives us a uniform distribution over all 2^N ways swapping of the labels and the individual entries of the observed predictions $\mathbf{u}$ and $\mathbf{v}$. And, importantly, the joint distribution $\mathbb{P}[\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}]$, encodes the fact that the sampled entries are independent of the system label.

The test statistic and the p-value. The final ingredient we need in a null hypothesis test is a **test statistic**, whose job it is to provide a summary of samples $(\mathbf{u}', \mathbf{v}') \sim \mathbb{P}[\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}]$ and thereby facilitate comparison of samples from the null distribution $\mathbb{P}[\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}]$ and the observed entries $(\mathbf{u}, \mathbf{v})$. In this work, we will define a test statistic as function $t(\mathbf{u}, \mathbf{v})$. In principle, we can choose *any* test statistic t that allows us to distinguish $\mathbf{u}$ and $\mathbf{v}$, i.e., we have have $t(\mathbf{u}, \mathbf{v}) = 0 \iff \mathbf{u} = \mathbf{v}$. Now, given observed entries $\mathbf{u}$ and $\mathbf{v}$, the p-value is defined as

$$p = \mathbb{P}\big[t(\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}) \geq \overline{\xi}\big] \qquad (2)$$

where $\overline{\xi} \overset{\text{def}}{=} t(\mathbf{u}, \mathbf{v})$ is the **observed effect**. In words, the p-value is the probability of observing a test statistic $t(\mathbf{u}', \mathbf{v}')$ with a value as large as $t(\mathbf{u}, \mathbf{v})$ where $(\mathbf{u}', \mathbf{v}') \sim \mathbb{P}[\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}]$ are sampled from the null distribution. Recall that the system labels and entries are independent under the null distribution by construction, so the p-value tells us, under the independence assumption, how likely such a large test statistic would have been observed. The test says that we have sufficient evidence to reject the null hypothesis when $p < \alpha$. These concepts are depicted in Fig. 2.

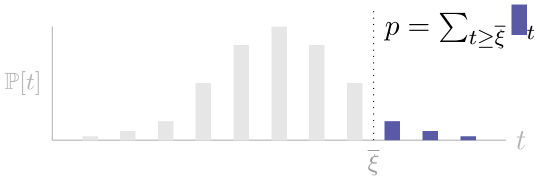

Figure 2: Depiction of the pmf of the test statistic t, the p-value, and the observed value $\overline{\xi}$.

3 Structured Test Statistics

We now discuss a common special case of the paired-permutation test where the test statistic has a particular structure. In §4, we show how to exploit this structure to develop an efficient algorithm to exactly compute the test. The specific assumption we make is that the test statistic is an integer-valued **additively decomposable function**. Formally, this assumption means that we can rewrite t as follows

$$t(\mathbf{u}, \mathbf{v}) \overset{\text{def}}{=} h(\boldsymbol{g}(\mathbf{u}, \mathbf{v})) \tag{3}$$

for any function h and additively decomposable function $\boldsymbol{g}(\mathbf{u}, \mathbf{v}) \overset{\text{def}}{=} \sum_{n=1}^{N} g(u_n, v_n)$ such that g is an integer-valued function with a range of size $\mathcal{O}(G)$. The structure of (3) will allow us to derive an efficient algorithm for evaluating $\mathbb{P}[t(\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing})] = \mathbb{P}\Big[h\Big(\sum_{n=1}^{N} g(u_n, v_n)\Big)\Big]$. We now dissect this equation. Each summand $g(u_n, v_n)$ can take on one of two values $\overrightarrow{\xi_n} \overset{\text{def}}{=} g(u_n, v_n)$ and $\overleftarrow{\xi_n} \overset{\text{def}}{=} g(v_n, u_n)$ with equal probability. We rewrite the sum $\sum_{n=1}^{N} g(u_n, v_n)$ as $\mathrm{S} \overset{\text{def}}{=} \sum_{n=1}^{N} \mathrm{Z}_n$ where Z_n are uniform RVs over the set $\{\overrightarrow{\xi_n}, \overleftarrow{\xi_n}\}$. Each Z_n has probability mass function (PMF)

$$f_n(z) \overset{\text{def}}{=} \mathrm{pmf}_{\mathrm{Z}}(\overrightarrow{\xi_n}, \overleftarrow{\xi_n})(z) \tag{4a}$$

$$\overset{\text{def}}{=} \begin{cases} \frac{1}{2}\mathbb{1}\Big[z \in \{\overrightarrow{\xi_n}, \overleftarrow{\xi_n}\}\Big] & \textbf{if } \overrightarrow{\xi_n} \neq \overleftarrow{\xi_n} \\ \mathbb{1}\Big[z = \overrightarrow{\xi_n}\Big] & \textbf{otherwise} \end{cases} \tag{4b}$$

The domain of each PMF, $\mathrm{dom}(f_n)$, contains at most two elements. Let $\mathcal{S} \overset{\text{def}}{=} \mathrm{dom}(\mathrm{S})$. Clearly, $|\mathcal{S}| = \mathcal{O}(GN)$ as we have a sum over N RVs Z_n each with domain size $\mathcal{O}(G)$. The following theorem shows that we can evaluate $\mathbb{P}[t(\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing})]$ from the distribution of S, which we we will show in the next section is efficient to compute.

Theorem 1. *For any test statistic t that factorizes as in (3) with h and g, the distribution of the test statistic under the null distribution decomposes as*

$$\mathbb{P}\big[t(\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing})\big] = \mathbb{P}[h(\mathrm{S})] \tag{5}$$

Proof.

$$\mathbb{P}\big[t(\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing})\big] = \mathbb{P}\left[h\left(\sum_{n=1}^{N} g(\mathrm{U}_n^{\varnothing}, \mathrm{V}_n^{\varnothing})\right)\right] \tag{6a}$$

$$= \mathbb{P}\left[h\left(\sum_{n=1}^{N} \mathrm{Z}_n\right)\right] \tag{6b}$$

$$= \mathbb{P}[h(\mathrm{S})] \tag{6c}$$

■

```

Algorithm 1: Monte Carlo approximation algorithm for the paired-permutation test.

Example. A common test statistic is the difference in accuracy, in which each entry $u_n \in \{1, ..., C\}^G$ where C is the number of classes and in this case, G is the maximum length of an entry sequence (or one if each entry has a binary accuracy value). Then $g(u_n, v_n) \in \{-G, ..., G\}$ is the difference in the number of correct predictions between individual entries u_n and v_n. We can additionally define the function h as either $h(x) = x$ or $h(x) = |x|$ depending on whether we want a one-tailed or two-tailed significance test.

A Monte Carlo paired-permutation test. To the best of our knowledge, no practical *exact* algorithm for the paired-permutation test has been given in the literature. Thus, most practical implementations of the paired-permutation test use an MC approximation, whereby one randomly samples from S to approximate $\mathbb{P}[\mathbf{U}^{\varnothing}, \mathbf{V}^{\varnothing}]$. We give this MC algorithm as `monte_carlo` in Alg 1 which runs in $\mathcal{O}(KN)$ time where K is the number of samples taken.

4 An Exact Paired-Permutation Test

In this section, we describe two exact, efficient algorithms for computing the p-value under the paired-permutation test for any structured test statistic (see (3)).[1] Our algorithms hinge on an important theorem in probability: The PMF of the sum of independent events is the convolution of their individual PMFs (Ross, 2008, p. 252). Let f_{S} denote the PMF

---

[1] In App. B, we extend our algorithms to work with test statistics that use m additively decomposable scoring functions, e.g., difference in F_1 scores.

```
1: def exact_perm_test($\mathbf{u}, \mathbf{v}, g, h$) :
2:   for $n = 1$ to $N$ :
3:     $\overrightarrow{\xi}_n \leftarrow g(u_n, v_n)$        ▷ Local effect (stay)
4:     $\overleftarrow{\xi}_n \leftarrow g(\overset{\leftrightarrows}{v_n, u_n})$        ▷ Local effect (swap)
5:     $f_n \leftarrow \mathrm{pmf}_{\mathrm{Z}}\left(\overrightarrow{\xi}_n, \overleftarrow{\xi}_n\right)$
6:   $\overline{\xi} \leftarrow h\left(\sum_{n=1}^{N} \overrightarrow{\xi}_n\right)$        ▷ Compute observed effect
7:   $f_{\mathrm{S}} \leftarrow f_1 \star \cdots \star f_N$        ▷ Convolve the $f_n$'s
8:   ▷ Sum-up the PMF to get $p$
9:   return $\sum_{\xi \in \mathcal{S}} f_{\mathrm{S}}(\xi)\, \mathbb{1}\left[h(\xi) \geq \overline{\xi}\,\right]$
```

Algorithm 2: Compute the exact p value for the paired-permutation test for structured test statistics.

```
def convolve_DP($f_1, ..., f_N$) :
  $\mathrm{F} \leftarrow \mathbf{0}$
  $\mathrm{F}_0(0) \leftarrow 1$        ▷ Init: $\mathbb{P}[0] = 1$ if $N = 0$
  for $n = 1$ to $N$ :
    ▷ Compute $\mathrm{F}_n = f_n \star \mathrm{F}_{n-1}$
    for $\xi \in \mathrm{dom}(f_n)$ :        ▷ $|\mathrm{dom}(f_n)| \leq 2$
      for $\xi' \in \mathrm{dom}(\mathrm{F}_{n-1})$ :
        $\mathrm{F}_n(\xi + \xi')$ += $f_n(\xi) \cdot \mathrm{F}_{n-1}(\xi')$
  return $\mathrm{F}_N$
```

Algorithm 3: Dynamic programming algorithm to compute the pmf of S as the N-fold convolution of the pmfs $f_1, ..., f_N$. Note that we only need to store F_n and F_{n-1} at any given time.

of S. Since RVs Z_n are independent, we have that

$$\mathbb{P}\left[h(\mathrm{S}) \geq \overline{\xi}\,\right] \tag{7a}$$

$$= \sum_{\xi \in \mathcal{S}} f_{\mathrm{S}}(\xi)\, \mathbb{1}\left[h(\xi)) \geq \overline{\xi}\,\right] \tag{7b}$$

$$= \sum_{\xi \in \mathcal{S}} (f_1 \star \cdots \star f_N)(\xi)\, \mathbb{1}\left[h(\xi)) \geq \overline{\xi}\,\right] \tag{7c}$$

where $\star$ is the discrete **convolution operator**. For functions $f_i, f_j \in \mathcal{S} \to \mathbb{R}$, $f_i \star f_j \in \mathcal{S} \to \mathbb{R}$ is given by the following expression

$$(f_i \star f_j)(\xi) \overset{\text{def}}{=} \sum_{\xi' \in \mathcal{S}} f_i(\xi')\, f_j(\xi - \xi') \tag{8}$$

Pseudocode for this algorithm is given as `exact_perm_test` in Alg 2. We omit the details of evaluating the convolution in `exact_perm_test` and discuss methods for efficient convolution in the remainder of this section.

Theorem 2. *For any two entries,* $\mathbf{u}$ *and* $\mathbf{v}$*, and test statistic* t *that factorizes as in* (3) *with* h *and* g*,* `exact_perm_test`$(\mathbf{u}, \mathbf{v}, g, h)$ *returns* p *in* $\mathcal{O}(GN + r(G, N))$ *time,* $\mathcal{O}(N + s(G, N))$ *space. We define* $r(G, N)$ *and* $s(G, N)$ *as the time and space complexities for constructing* $f_1 \star \cdots \star f_N$.

Proof. The correctness of `exact_perm_test` is by Theorem 1 and (7c). All lines except for Line 7 and Line 9 require at most $\mathcal{O}(N)$ time and space. Line 9 runs in $\mathcal{O}(GN)$ time and $\mathcal{O}(1)$ space. Thus, `exact_perm_test` runs in $\mathcal{O}(N + GN + r(G, N))$ time and $\mathcal{O}(N + s(G, N))$ space. ■

The computational question is then: What is the most efficient algorithm for evaluating $(f_1 \star \cdots \star f_N)(\xi)$? In the following two subsections, we present $\mathcal{O}(GN^2)$ time and $\mathcal{O}(GN(\log GN)(\log N))$ time algorithms for performing this N-fold convolution.

4.1 Convolution by Dynamic Programming

Our first approach builds a dynamic program (DP) that takes advantage of the sparsity of our RVs to efficiently construct the PMF f_{S}. We do this by constructing a PMF array $\mathrm{F}_n \in \mathbb{R}^{\mathcal{S}}$ for $n \in \{0, ..., N\}$ (we use $n = 0$ as an initialisation base case) such that $\mathrm{F}_n(\xi) = (f_1 \star \cdots \star f_n)(\xi)$. As we apply each convolution, we know that f_n is only non-zero at $\overrightarrow{\xi}_n$ and $\overleftarrow{\xi}_n$, and so we can run each convolution in $\mathcal{O}(GN)$ time. The pseudocode for this approach is given as `convolve_DP` in Alg 3.

Theorem 3. *For any RVs* $\mathrm{Z}_1, ..., \mathrm{Z}_N$ *with PMFs* $f_1, ..., f_N$*,* `convolve_DP`$(f_n, ..., f_N)$ *returns* $f_1 \star \cdots \star f_n$ *in* $\mathcal{O}(GN^2)$ *time,* $\mathcal{O}(GN)$ *space.*

Proof. The proof of correctness of `convolve_DP` is given in App. A. Each F_n has $\mathcal{O}(GN)$ elements and so `convolve_DP` clearly runs in $\mathcal{O}(GN^2)$ time. Furthermore, at any iteration, we only require F_n and F_{n-1} and so we can execute `convolve_DP` in $\mathcal{O}(GN)$ space. ■

4.2 Convolution by FFT

Our second approach uses the fast Fourier transform (FFT; Cooley and Tukey, 1965; Cormen et al., 2022) to evaluate the convolutions. Using this method means that each convolution takes $\mathcal{O}(GN \log GN)$ time $\mathcal{O}(GN)$ space. We further exploit the commutativity of convolution to perform the N-fold convolution in $\log N$ convolutions using a recursive program. The pseudocode for this approach is given as `convolve_FFT` in Alg 4.

```
def convolve_FFT($f_1, ..., f_N$) :
    if $N = 1$ : return $f_1$
    return convolve_FFT($f_1, ..., f_{N/\!/2}$)
                  $\star$ convolve_FFT($f_{N/\!/2+1}, ..., f_N$)
```

Algorithm 4: Recursive algorithm to compute the pmf of S as the N-fold convolution of the pmfs $f_1, ..., f_N$. Here the convolution operation ($\star$) runs in $\mathcal{O}(GN \log GN)$ time thanks to the FFT (Cooley and Tukey, 1965).

Theorem 4. *For any RVs* $\mathrm{Z}_1, ..., \mathrm{Z}_N$ *with PMFs* $f_1, ..., f_N$*,* `convolve_FFT`$(f_1, ..., f_N)$ *returns* $f_1 \star \cdots \star f_n$ *in* $\mathcal{O}(GN(\log GN)(\log N))$ *time,* $\mathcal{O}(GN \log N)$ *space.*[2]

Proof. The correctness of `convolve_FFT` is due to Cooley and Tukey (1965). The recursion of `convolve_FFT` can be given as

$$T(N) = 2T\left(\frac{N}{2}\right) + \mathcal{O}(GN \log GN) \tag{9}$$

Solving this recursion, we call T $\mathcal{O}(\log N)$ times. Therefore, the time complexity of `convolve_FFT` is $\mathcal{O}(GN(\log GN)(\log N))$. Similarly, each call requires $\mathcal{O}(GN)$ space and `convolve_FFT` has a space complexity of $\mathcal{O}(GN \log N)$. ■

Corollary 1. *For any two entries,* $\mathbf{u}$ *and* $\mathbf{v}$*, and test statistic* t *that factorizes as in* (3) *with* h *and* g*,* `exact_perm_test`$(\mathbf{u}, \mathbf{v}, g, h)$ *returns* p *in* $\mathcal{O}(GN(\log GN)(\log N))$ *time,* $\mathcal{O}(GN)$ *space.*

Proof. The correctness and complexity bounds are due to Theorem 2 and Theorem 4. Specifically, Line 7 can be executed using `convolve_FFT`. ■

5 Experiments

We demonstrate the efficiency of our exact algorithms by simulating paired-permutation tests between the accuracy of two systems. In order to have some control over the p-value, N, and G (maximum length of a sentence), we randomly generate our two system outputs from a measured distribution. Specifically, we will use the Stanza[3] (Qi et al., 2020) part-of-speech tag accuracy statistics when evaluating on the English Universal Dependencies (UD) test set (Nivre et al., 2018). We sample our outputs from the normal distribution where the mean and standard deviation match the rates of Stanza's observed accuracy. We further sample the length of each sample sentence according to the distribution of lengths in the test set. These distributions are provided in Tab. 1.

Metric	**Mean**	**Standard Dev.**
Accuracy	0.9543	0.1116
Sentence length	12.08	10.60

Table 1: Distributions for of accuracy and sentence length for POS tagging using Stanza (Qi et al., 2020) on the English UD test dataset (Nivre et al., 2018).

We show that, empirically, the exact test is *more efficient* than the MC approximation; this is evinced in Fig. 1 where we have compared the runtime of `exact_perm_test` using `convolve_DP` and `convolve_FFT` against `monte_carlo` for various sample sizes ($K \in \{5000, 10000, 20000, 40000\}$).[4] We note that using `convolve_DP` is already more efficient than running `monte_carlo` with $K = 40000$ and $K = 20000$ (up to $N \approx 8000$).[5] Furthermore, `convolve_FFT` is *much* faster and we observe a speed-up between 3x and 30x, depending on the number of samples K. Indeed, using `convolve_FFT` allows us to perform an exact paired-permutation test for $N = 10000$ in approximately one-tenth of a second.

6 Conclusion

We presented an algorithm to compute the exact p-value of a paired-permutation test for the case of a family of structured test statistics, including the difference in accuracy. Our algorithm runs in $\mathcal{O}(GN(\log GN)(\log N))$ time and requires $\mathcal{O}(GN)$ space. We empirically show that our exact algorithm is *faster* than Monte Carlo approximation techniques. The theory of our work is extensible to a more general class of test statistics which we discuss in App. B. We hope that this work encourages the use of exact paired-permutation tests in future NLP research.

Ethical Concerns

We foresee no ethical concerns in this work.

---

[2] We note that the $\log N$ factor in the space complexity may be eliminated by tail recursion elimination (Muchnick, 1998).

[3] The code and pre-trained model are both freely accessible at `https://github.com/stanfordnlp/stanza`.

[4] The experiment used an Apple M1 Max processor.

[5] We note that the average test set size of the 129 UD treebanks we examined is just over 1000 sentences, and only three treebanks had more than 6000 sentences.

Acknowledgments

We would like to thank the reviewers for their invaluable feedback and time spent engaging with our work. A Proof of Correctness of `convolve_DP`

We prove the correctness of `convolve_DP` using the following lemma.

Lemma 1. *For any N RVs $\mathrm{Z}_1, ..., \mathrm{Z}_N$ with PMFs $f_1, ..., f_N$ respectively and $n \in \{1, ..., N\}$,* `convolve_DP`$(f_1, ..., f_N)$ *constructs F_n such that for any $\xi \in \mathcal{S}$,*

$$\mathrm{F}_n(\xi) = f_{:n}(\xi) \overset{\text{def}}{=} (f_1 \star \cdots \star f_n)(\xi) \tag{10}$$

Proof. We prove this by induction on N.
Base case: $N = 1$. We have that $\mathrm{F}_0(0) = 1$ and $\mathrm{F}_0(\xi) = 0$ for all $\xi \in \mathcal{S} \setminus \{0\}$. Therefore, $\mathrm{F}_1(\overrightarrow{\xi_n}) = \mathrm{F}_1(\overleftarrow{\xi_n}) = \frac{1}{2}$ and $\mathrm{F}_1(\xi) = 0$ for all $\xi \in \mathcal{S} \setminus \{\overrightarrow{\xi_n}, \overleftarrow{\xi_n}\}$ as expected.
Inductive step: Assume (10) holds for $N = n - 1$. Let $N = n$ and consider $f_{:(n-1)} \star f_n$.

$$(f_{:(n-1)} \star f_n)(\xi) = \sum_{\xi' \in \mathcal{S}} f_{:(n-1)}(\xi') f_n(\xi - \xi') = \sum_{\xi' \in \mathrm{dom}(f_n)} f_{:(n-1)}(\xi + \xi') f_n(\xi') = \sum_{\xi' \in \mathrm{dom}(f_n)} \mathrm{F}_{n-1}(\xi + \xi') f_n(\xi') \tag{11}$$

This is exactly the construction in the for-loop between Line 7 and Line 8. Therefore, $\mathrm{F}_n(\xi) = f_{:n}(\xi)$. ■

As F_N will contain the N-fold convolution $f_1 \star \cdots \star f_N$, `convolve_DP` is correct by definition.

B Paired-Permutation Test for Higher-order Test Statistics

In this section, we extend our approach for the paired-permutation test to test statistics that are functions of m additively decomposable functions. In symbols, this assumption means that we can rewrite t as follows

$$t(\mathbf{u}, \mathbf{v}) \overset{\text{def}}{=} h\left(\boldsymbol{g_1}(\mathbf{u}, \mathbf{v}), ..., \boldsymbol{g_m}(\mathbf{u}, \mathbf{v})\right) \tag{12}$$

for any function h and integer-valued, additive decomposable functions $\boldsymbol{g_i}$ (i.e., $\boldsymbol{g_i}(\mathbf{u}, \mathbf{v}) \overset{\text{def}}{=} \sum_{n=1}^{N} g_i(u_n, v_n)$). We now define $\overrightarrow{\xi_n}$ and $\overleftarrow{\xi_n}$ as m-tuples,

$$\overrightarrow{\xi_n} \overset{\text{def}}{=} \langle \boldsymbol{g_1}(\mathbf{u}, \mathbf{v}), ..., \boldsymbol{g_m}(\mathbf{u}, \mathbf{v}) \rangle \tag{13}$$

$$\overleftarrow{\xi_n} \overset{\text{def}}{=} \langle \boldsymbol{g_1}(\mathbf{v}, \mathbf{u}), ..., \boldsymbol{g_m}(\mathbf{v}, \mathbf{u}) \rangle \tag{14}$$

And so each RV Z_n has the same PMF as in (4b). We can then define an analogous function to `exact_perm_test` for the case of m additively decomposable functions. We give pseudocode for this as `exact_perm_test`$_{\mathrm{m}}$ in Alg 5. The convolution algorithms,`convolve_DP` and `convolve_FFT`, can both be used to perform for convolution step in Line 7.

Theorem 5. *For any two entries, $\mathbf{u}$ and $\mathbf{v}$, and test statistic t that factorizes as in (12) with h and g_1 to g_m,* `exact_perm_test`$_{\mathrm{m}}(\mathbf{u}, \mathbf{v}, g_1, ..., g_m, h)$ *returns p in $\mathcal{O}(G^m N^m (\log GN)(\log N))$ time and $\mathcal{O}(G^m N^m \log N)$ space.*

Proof. The proof of correctness for `exact_perm_test`$_{\mathrm{m}}$ is the same as Theorem 2. The expensive operation in the algorithm is the convolution step (Line 7). We can perform a FFT m-dimensional convolution in $\mathcal{O}(G^m N^m \log GN)$ time and $\mathcal{O}(G^m N^m)$ space. As we require $\mathcal{O}(\log N)$ convolution steps, `exact_perm_test`$_{\mathrm{m}}$ runs in $\mathcal{O}(G^m N^m (\log GN)(\log N))$ time and $\mathcal{O}(G^m N^m \log N)$ space. ■

Example. A common example for a test statistic that requires multiple additively decomposable functions is the difference in F_1 scores. Similar to accuracy, each entry $u_n \in \{1, ..., C\}^G$ and G is the maximum length of an entry sequence. Let $\mathrm{tp}(u_n)$ and $\mathrm{in}(u_n)$ be the number of true positive and incorrect predictions made in entry u_n respectively. Then the difference in F_1 scores can be given as

$$t(\mathbf{u}, \mathbf{v}) \overset{\text{def}}{=} \frac{\sum_{n=1}^{N} \mathrm{tp}(u_n)}{\sum_{n=1}^{N} \mathrm{tp}(u_n) + \frac{1}{2} \sum_{n=1}^{N} \mathrm{in}(u_n)} - \frac{\sum_{n=1}^{N} \mathrm{tp}(v_n)}{\sum_{n=1}^{N} \mathrm{tp}(v_n) + \frac{1}{2} \sum_{n=1}^{N} \mathrm{in}(v_n)} \tag{15}$$

```
def exact_perm_test_m($\mathbf{u}, \mathbf{v}, g_1, ..., g_m, h$) :
    for $n = 1$ to $N$ :
        $\overrightarrow{\xi_n} \leftarrow \langle g_1(u_n, v_n), ..., g_m(u_n, v_n) \rangle$        ▷ Local effect (stay)
        $\overleftarrow{\xi_n} \leftarrow \langle g_1(v_n, u_n), ..., g_m(v_n, u_n) \rangle$        ▷ Local effect (swap)
        $f_n \leftarrow \mathrm{pmf}_{\mathrm{Z}}\left(\overrightarrow{\xi_n}, \overleftarrow{\xi_n}\right)$
    $\overline{\xi} \leftarrow h(\boldsymbol{g_1}(\mathbf{u}, \mathbf{v}), ..., \boldsymbol{g_2}(\mathbf{u}, \mathbf{v}))$        ▷ Compute observed effect
    $f_{\mathrm{S}} \leftarrow f_1 \star \cdots \star f_N$        ▷ Convolve the $f_n$'s
    ▷ Sum-up the PMF to get p
    return $\sum_{\xi \in \mathcal{S}} f_{\mathrm{S}}(\xi)\, \mathbb{1}\left[h(\xi) \geq \overline{\xi}\,\right]$
```

Algorithm 5: Pseudocode to find exact p value for the paired-permutation test for test statistics comprised of m additively decomposable functions.

We can therefore use four-additively decomposable functions, $\boldsymbol{g_1}$ to $\boldsymbol{g_4}$, that decompose such that $g_1(u_n, v_n) = g_3(v_n, u_n) = \mathrm{tp}(u_n)$ and $g_2(u_n, v_n) = g_4(v_n, u_n) = \mathrm{in}(u_n)$. Our h function then takes four arguments and can be defined as

$$h(x_1, x_2, x_3, x_4) \stackrel{\text{def}}{=} \frac{x_1}{x_1 + \frac{1}{2}x_2} - \frac{x_3}{x_3 + \frac{1}{2}x_4} \tag{16}$$

We can additionally apply an absolute value to h to check for the absolute difference in F_1 scores; doing this would make the significance test two-tailed rather than one-tailed.

A Balanced Data Approach for Evaluating Cross-Lingual Transfer: Mapping the Linguistic Blood Bank

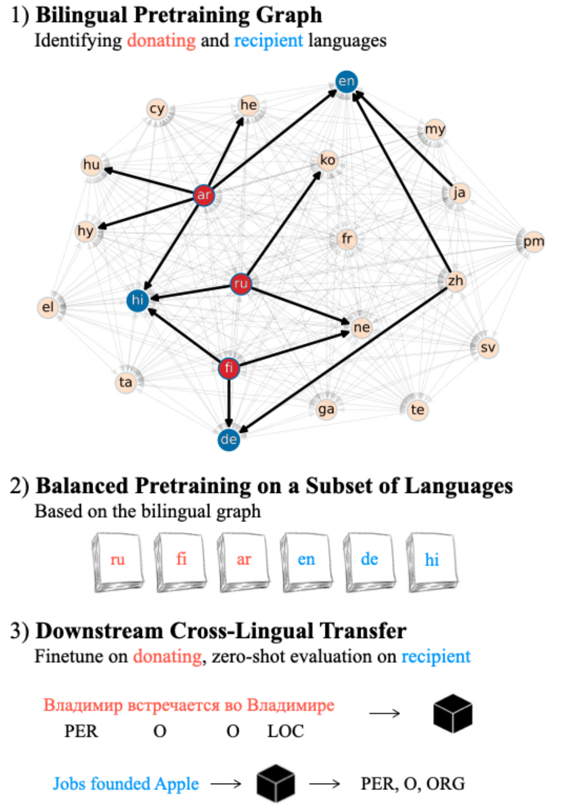
Abstract

We show that the choice of pretraining languages affects downstream cross-lingual transfer for BERT-based models. We inspect zero-shot performance in balanced data conditions to mitigate data size confounds, classifying pretraining languages that improve downstream performance as *donors*, and languages that are improved in zero-shot performance as *recipients*. We develop a method of quadratic time complexity in the number of languages to estimate these relations, instead of an exponential exhaustive computation of all possible combinations. We find that our method is effective on a diverse set of languages spanning different linguistic features and two downstream tasks. Our findings can inform developers of large-scale multilingual language models in choosing better pretraining configurations.[1]

1 Introduction

Pretrained language models are setting state-of-the-art results by leveraging raw texts during pretraining (PLMs; Peters et al., 2018; Devlin et al., 2019, inter alia). Interestingly, when pretraining on multilingual corpora, PLMs seem to exhibit *zero-shot* cross-lingual abilities, achieving non-trivial performance on downstream examples in languages seen only during pretraining. For example, in the bottom of Figure 1, a named entity recognition model finetuned on Russian is capable of predicting correctly name entity tags for texts in English, seen only during pretraining (Pires et al., 2019; Conneau et al., 2020b; K et al., 2020; Conneau et al., 2020a; Lazar et al., 2021; Turc et al., 2021).

Previous analyses examined how several factors contribute to this emerging behavior. For example, parameter sharing and model depth are important in certain configurations (K et al., 2020; Conneau et al., 2020b), as well as typological similarities between languages (Pires et al., 2019), and the choice of specific finetune languages (Turc et al., 2021).



1) **Bilingual Pretraining Graph**
Identifying donating and recipient languages

2) **Balanced Pretraining on a Subset of Languages**
Based on the bilingual graph

3) **Downstream Cross-Lingual Transfer**
Finetune on donating, zero-shot evaluation on recipient

Figure 1: We build a complete, directed graph over a diverse set of 22 languages. Weighted edges show the improvement of bilingual LM over monolingual performance (bold edges represent larger weights). Languages which consistently improve performance are termed "donors" and marked in red, while languages which benefit most are termed "recipients" (marked in blue). We show that our observations hold in several configurations on two downstream tasks.

In this work, we focus on an important factor that we find missing in prior work, namely the effect that *pretraining* languages have on downstream zero-shot performance. In particular, we ask three major research questions: (1) Does the choice

---

[*] Work done while visiting the Hebrew University.

[1] Code and models are publicly available at: `github.com/SLAB-NLP/linguistic-blood-bank`

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4903 - 4915
July 10-15, 2022

of pretraining languages affect downstream cross-lingual transfer, and if so, to what extent? (2) Is English the optimal pretraining language, when controlling for confounding factors such as data size and domain? And finally, (3) Can we choose pretraining languages to improve downstream zero-shot performance?

In addressing these research questions, we aim to decouple the *language* from its corresponding *dataset*. To the best of our knowledge, prior work has conflated pretrain corpus size and its domain with other examined factors, thus skewing results towards over-represented languages, such as English or German (Joshi et al., 2020).[2] To achieve this, we first construct a *linguistically-balanced* pretraining corpus based on Wikipedia, composed of a diverse set of 22 languages. We carefully control for the amount of data and domain distribution in each of the languages (Section 3).

Next, since the number of pretraining configurations grows exponentially with the number of languages n represented in the dataset, it is infeasible to exhaustively test all possible configurations, much less extend it for more languages.[3] In Section 4 we propose a novel pretraining-based approach that is quadratic in the number of languages. This is achieved by training all $\binom{n}{2}$ combinations of bilingual masked language models over our corpus, thus yielding a complete directed graph (Figure 1), where an edge $l_1 \to l_2$ estimates how much a language l_1 contributes to zero-shot performance in language l_2, based only on language modeling performance.

In Section 5, we use the graph to identify languages which generally contribute as pretraining languages (termed "donors"), and languages which often benefit from training with other languages (termed "recipients"). Further, we use the graph to make observations regarding the effect of typological features on bilingual language modeling, and make available an interactive graph explorer.

Finally, our evaluations on two multilingual downstream tasks (part of speech tagging and named entity recognition) lead to three main conclusions (Section 6): (1) the choice of pretraining languages indeed leads to differences in zero-shot performance; (2) controlling for the amount of data allotted for each language during pretraining questions the primacy of English as the main *pretraining* language; and (3) our hypotheses regarding donors and recipient language hold in both downstream tasks, and against two additional control groups.

2 Metrics for Pretraining-Aware Cross-Lingual Transfer

In this section, we extend existing metrics for zero-shot cross-lingual transfer to account for *pretraining* languages. Intuitively, our metrics for a model M and a given downstream task take into account three factors: (1) P, the set of languages seen during pretraining, (2) $s \in P$, the *source* language used for finetuning, and (3) $t \in P$, the *target* language, seen during inference.

Formally, we adapt the formulation of Hu et al. (2020) to define a *pretraining-aware* bilingual zero-shot transfer score $\mathcal{Z}$ as:[4]

$$\mathcal{Z}_P(s \to t) := \varepsilon(M^{P,s}, t) \tag{1}$$

Where $M^{P,l}$ is a model pretrained on the set of languages P and finetuned on downstream task instances in the language $l \in P$, and $\varepsilon(M, l)$ is an evaluation of model M on instances in language l in terms of the downstream metric, e.g., word-label accuracy for part of speech tagging.

Following, we extend the definition of zero-shot transfer score to a set of downstream test languages $D \subseteq P$ to measure P's aggregated effect on zero-shot performance, by averaging over all bilingual transfer combinations in D:

$$\mathcal{Z}_P(D) = \frac{1}{|D|^2 - |D|} \cdot \sum_{\substack{l_1, l_2 \in D \\ l_1 \neq l_2}} \mathcal{Z}_P(l_1 \to l_2) \tag{2}$$

In the following sections, we will use these metrics to evaluate how different choices for pretraining languages influence downstream performance.

3 Data Selection

We collect a pretraining dataset to test the effect of pretraining languages on cross-lingual transfer.

First, we choose a set of 22 languages from 9 language families, as listed in Table 1. These represent a wide variety of scripts, as well as typological

---

[2] For example, English was X100 more likely to be sampled in mBERT's pretraining data than Icelandic.

[3] There are 2^n possible pretraining configurations taking into account inclusion and omission of every language.

[4] We opt not to normalize the score by the monolingual performance as done in Turc et al. (2021), as we do not want it to affect the score.

and morphological features. We note that our approach can be readily extended to other languages beyond those selected in this study.

Second, we aim to balance the amount of data and control for its domain across languages, to mitigate possible confounders in our evaluations. Below we outline design choices we make toward this goal.

3.1 Data Balancing

To achieve a balanced dataset across our languages, we sample consecutive sentences from every language's Wikipedia dump from November 2021, such that each language is represented by 10 million characters.[5] This amount was chosen to align all languages to the lower-resource ones (e.g., Piedmontese or Irish) which comprise approximately of 10mb. We choose to sample texts from Wikipedia as it consists of roughly similar encyclopedic domain across languages, and is widely used for training PLMs (Devlin et al., 2019).

Can we balance the amount of information across languages? We note that a possible confound in our study is that languages may encode different amounts of *information* in texts of similar character count. This may happen due to differences in the underlying texts or in inherent language properties.[6] To estimate the amount of information in each of our 10^7 character partitions, we tokenize each language partition l with the same word-piece tokenizer, and look at the ratio between the total number of tokens in l and the number of unique tokens in l, finding a good correlation across all our languages ($r = 0.73$), which may indicate that our dataset is indeed balanced in terms of information. Our intuition is that an imbalanced amount of information would lead the tokenizer to "invest" more tokens in some of the languages while neglecting the less informative ones.

Is our sample representative of the full Wikipedia corpus in each language? Another concern may be that our sampled corpus per language is not indicative of the full corpus for that language, which may be much larger (see Table 1). To test this, we create three discrete length distributions. Two length distributions for sentences (in terms of words and tokens), and word length distribution in terms of characters. We then compare those three distributions between our sample and the full data using Earth Movers Distance. All means and standard deviations score below 0.001, indicating that indeed all samples are similarly distributed to their respective full corpus in terms of these metrics.

Language	**Code**	**Family**	**Size [M chars]** Wiki	 Sample

Table 1: The size of the full Wikipedia dump for the languages in our study (in millions of characters) versus our fixed sized sampling of it. This exemplifies both the linguistic diversity as well as the variance in data sizes in the original Wikipedia corpus, often used for pretraining PLMs. In contrast, we create a balanced pretraining dataset by sampling 10M characters from all languages such that they conform to the smallest language portion in our set (Piedmontese).

4 Bilingual Pretraining Graph

In this section, we describe a method for estimating the effect that different pretrain language combinations would have on downstream zero-shot performance. This is achieved by evaluating bilingual performance on the pretraining masked language modeling (MLM) task.

We begin by describing our experimental setup, hyperparameters and hardware configuration (Section 4.1). In Section 4.2, we outline our estimation method, yielding a complete graph structure over our languages, amenable for future exploration and analyses (Figures 1, 2). In the following sections,

---

[5] Wikipedia dump was obtained and cleaned using wikiextractor (Attardi, 2015).

[6] For example logographic or abjad writing systems may be more condensed than other scripts (Perfetti and Liu, 2005).

Figure 2: Bilingual finetune scores between language pairs in our *balanced* corpus. Coordinate (i, j) represents $\mathcal{F}(l_i \rightarrow l_j)$, i.e., the performance in MRR[%] (which correlates with perplexity) of an LM pretrained on a bilingual corpus over languages (l_i, l_j) and tested intrinsically on l_j. The last column (marked *Don.*) sums over each line, i.e., index i in the column represents how much language i *donated* to all other languages. Similarly, the j'th index in the last row (marked *Recp.*) sums over column j and represents how much language l_j improved in all configurations.

we use the graph to formulate a set of downstream cross-lingual hypotheses regarding how different languages will affect zero-shot performance, and validate these hypotheses on two downstream tasks.

4.1 Experimental Setup

For all evaluations discussed below, we train a BERT model (Devlin et al., 2019) with 4 layers and 4 attention heads, an MLM task head, and an embedding dimension of 512.[7] We train a single wordpiece tokenizer (Wu et al., 2016) on our entire dataset.[8] We train the models with a batch size of 8 samples, with sentences truncated to 128 tokens.

Each language model was trained up to 4 epochs. This was determined by examining the training loss on 6 diverse languages in our set and observing that they converge around 4 epochs. A subset of 6 languages was trained on 4 additional seeds to verify the stability of the results, as seen in Table 5 and Table 6 in the Appendix. Masks were applied with default settings, generating 15% mask tokens and 10% random tokens for each input sequence (Devlin et al., 2019). We used a single GPU core (nvidia tesla M60, gtx 980, and RTX 2080Ti). Training time varied between 80 - 120 minutes.

4.2 Building a Pretraining Language Graph

Intuitively, we measure MLM performance when pretraining on a pair of languages (l_1, l_2) as a proxy to the extent of how l_1 and l_2 contribute to one another in zero-shot cross-lingual transfer.

This methodology relies on two assumptions. First, we assume that the cross-lingual zero-shot performance as defined in Equation 2 is *monotonic*, i.e., that adding pretraining languages will improve the average downstream performance. This is defined formally as:

$$P' \subseteq P \quad \Rightarrow \quad \mathcal{Z}_{P'}(D) \leq \mathcal{Z}_P(D) \qquad (3)$$

---

[7] We use the implementation provided by Hugging Face: `https://huggingface.co/bert-base-uncased`.

[8] To allow future exploration, we also tokenize over 22 additional languages (listed in the Appendix) which are sampled in the same manner but are not included in this study.

Following this assumption will allow us to extend our bilingual observations to a pretraining language set P of arbitrary size.

Second, we assume that MLM performance correlates with downstream task performance, which is often the assumption made when training PLMs to minimize perplexity (Peters et al., 2018; Devlin et al., 2019).

Bilingual MLM finetune score. Formally, for every language pair $s, t \in P$, we compute the following finetune score, $\mathcal{F}$:

$$\mathcal{F}(s \rightarrow t) := \frac{\varepsilon(M^{s,t}, t) - \varepsilon(M^{t}, t)}{\varepsilon(M^{t}, t)} \tag{4}$$

Where $M^{s,t}$ is a model pretrained on s, t, and ε is an intrinsic evaluation metric for MLM.[9] I.e., $\mathcal{F}(s, t)$ estimates how much the target language t "gains" in the MLM task from additional pretraining on the source language s compared to monolingual pretraining on t.

Figure 2 depicts a weighted adjacency matrix where coordinate (i, j) corresponds to $\mathcal{F}(l_i \rightarrow l_j)$. As shown in Figure 1, the same information can be conveyed in a complete directed weighted graph, where each node represents a language, and edges (l_1, l_2) are weighted by $\mathcal{F}(l_1 \rightarrow l_2)$.

Language-Level donation and recipience. Next, for each language $l \in P$ we compute a *Donation* score, $\mathcal{D}$, as an aggregate over all of its finetune scores as a source language (i.e., how much it contributed to other languages), and similarly a *recipience* score, $\mathcal{R}$, by aggregating over all its finetune scores as a target language, to measure how much l is contributed to by other languages. Formally:

$$\mathcal{D}(l) := \sum_{\substack{t \in P \\ t \neq l}} \mathcal{F}(l \rightarrow t) \tag{5}$$

$$\mathcal{R}(l) := \sum_{\substack{s \in P \\ s \neq l}} \mathcal{F}(s \rightarrow l) \tag{6}$$

We depict both donation and recipience scores as aggregate row and column vectors in Figure 2.

Thus, based on the two assumptions above, our hypothesis is that the downstream cross-lingual transfer will be proportional to the sum of recipience scores for all pretraining languages. Formally:

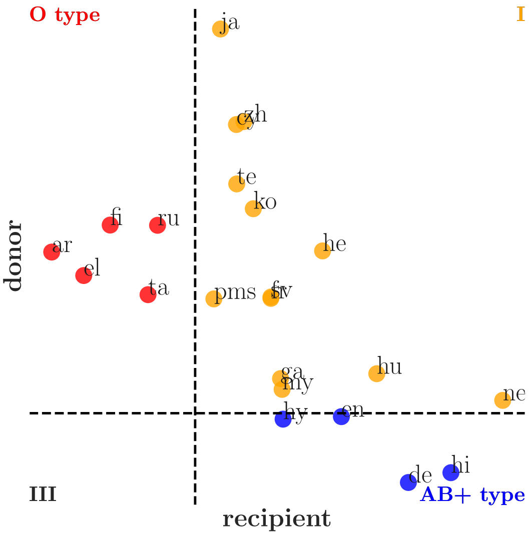

Figure 3: Our languages on a "donor" versus "recipient" axes. A positive coordinate on the "donor" score (X axis) represents a language that on average improved other languages' performance in bilingual pretraining, while a negative score indicates a language which hurts other languages on average. Inversely, a positive score on the Y axis represents languages whose performance was improved by bilingual pretraining, while negative scores represent languages whose performance was hurt by it. The II quadrant represents O type languages (donating but not receiving), languages on the IV's quadrant are AB+ type languages (receiving but not donating)

$$\mathcal{Z}_P(D) \propto \sum_{l \in D} \mathcal{R}(l) \tag{7}$$

Moreover, higher donation scores for languages in the pretrain set will result in higher scores in the downstream task. Formally:

$$\sum_{l \in P} \mathcal{D}(l) \leq \sum_{l \in P'} \mathcal{D}(l) \Rightarrow \mathcal{Z}_P(D) \leq \mathcal{Z}_{P'}(D) \tag{8}$$

5 Pretraining Graph Analysis

We present several key observations based on the bilingual pretraining graph described in the previous section and summarized by the adjacency matrix in Figure 2, as well as an interactive exploration interface. In the following sections, we use these observations in our downstream evaluations.

Some language combinations are detrimental. Negative finetune scores are present in some of the target languages, e.g., between Korean (ko) and Arabic (ar), which means that initializing a

---

[9] We specifically use mean reciprocal rank (MRR), which correlates with perplexity.

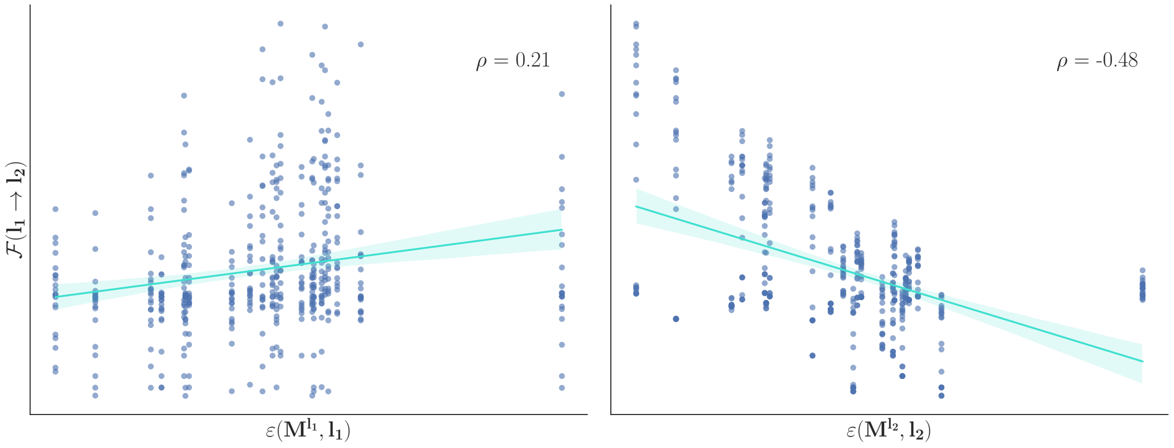

Figure 4: Scatter-plot. Y-axis represents cross-lingual transfer $\mathcal{F}(l_1 \to l_2)$ for a each possible pair of languages, while the x-axis represents the monolingual MRR score for a source language (left) and the target language (right).

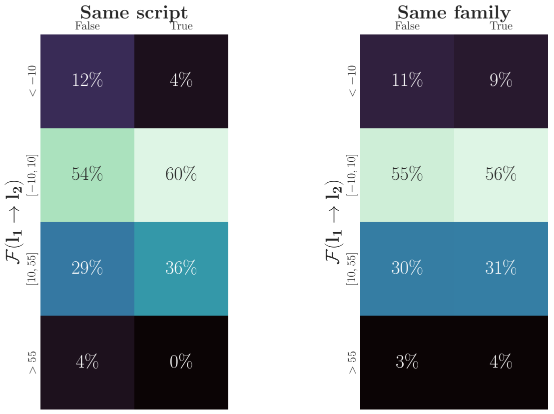
language model for Arabic with weights learned for Korean hurts MLM performance on Arabic, compared to an Arabic monolingual baseline. I.e., in these language configurations, initializing the model with another language model's weights leads to worse performance than random initialization.

Bilingual MLM relations are *not* symmetric. In fact, we observe a moderate *negative* correlation between $\mathcal{F}(l_1 \to l_2)$ and $\mathcal{F}(l_2 \to l_1)$, as shown in Figure 3. For example, for German and Finnish we get $0.51 = \mathcal{F}(fi \to de) > \mathcal{F}(de \to fi) = -0.24$. I.e., Finnish initialization improves German MLM, while the inverse is detrimental for Finnish.

Monolingual performance correlates with donation score. Perhaps expectedly, relatively worse-performing models benefit most from the bilingual transfer, while better-performing monolingual models tend to be better donors, although to a lesser extent (Figure 4).[10]

Different script leads to larger variance in bilingual finetuning. However, language family does not affect it. We find that fine-tuning between languages with different scripts is a high-risk, high-reward scenario. The highest transfer scores occur in this setting, but the proportion of negative scores is also higher. A shared script is a safe setting with a high proportion of neutral or positive donations (Figure 5a). In contrast with recent findings (Pires et al., 2019), we did not observe a statistically significant influence for the language family (Figure 5b).



(a) Sharing Script

(b) Sharing Family

Figure 5: We divide language pairs into four bins by bilingual finetune score ($\mathcal{F}(l_1 \to l_2)$).[11]The figures present the percentage of pairs assigned to each bin for samples of language pairs: (a) written in the same or different script; (b) belonging to the same or different language family. Sharing the language family has no significant effect on the transfer score ($p > 0.05$), while the effect of sharing scripts is significant ($p < 0.05$) (p-values based on Pearson's χ^2 test).

Finetuning as transfusion: mapping the linguistic blood-bank. The non-symmetric nature of the scores gives rise to a coarse-grained ontology loosely reminiscent of human blood types, depicted in Figure 3. Languages which on average donate but do not receive ($\mathcal{D}(l) > 0$ and $\mathcal{R}(l) < 0$) are

---

[10] Correlations are statistically significant ($p < 0.05$ based on Student's T-test).

[11] We motivate our choice of bins in Appendix.

denoted *O type languages*, while the inverse (receiving but not donating) are denoted as *AB+ type*.

5.1 Interactive Exploration

To allow further exploration of our bilingual pretraining graph, we develop a publicly available web-based interactive exploration interface.[12] We enable exploration of interactions between different linguistic features, based on *The World Atlas of Language Structures* (WALS) (Dryer and Haspelmath, 2013), allowing users to filter and focus on specific traits and analyze how they affect bilingual pretraining.

6 Downstream Zero-Shot Performance

In this section, we validate our method for estimating the effect of pretraining language combinations on downstream performance. Towards that end, in Section 6.1, we construct several pretraining configurations, based on pretraining observations. Then, in Section 6.2 we describe the multilingual datasets we use for two downstream tasks. Finally, our results are presented in Section 6.3, showing the influence of pretraining configuration on downstream performance.

6.1 Choosing Pretraining Sets

We use the donation scores to identify pretraining languages projected to lead to better downstream zero-shot performance, and the recipience score to find downstream languages which will perform better languages as source (finetune) languages. Our setup is summarized in Table 2.

Donating languages. We define three sets of languages for pretraining, using the donation score while keeping the sets linguistically diverse: (1) *Most Donating:* Japanese, Telugu, Finnish, and Russian; (2) *Least Donating:* Nepali, Burmese, Armenian, and English. We also include Englishs as it is a popular source language; and (3) *Random:*A randomly selected set of 4 languages: Hebrew, Irish, French and Swedish.

Recipient languages. To validate that lower recipience scores indeed indicate that languages are less likely to improve via cross lingual transfer, we added 6 languages to all configurations described above: 3 *Most Recipient* languages (R_h): Hindi, German, and Hungarian, and 3 *Least Recipient* languages (R_l): Arabic, Greek, and Tamil. Finally, we add a fourth control configuration which was pretrained only on $C := R_h \cup R_l$.

Hypotheses. We hypothesize that the more donating pretraining sets will improve cross-lingual transfer in downstream tasks, and that more recipient languages will have better cross-lingual performance compared to least recipient languages. These can be formally articulated using Equations 9 and 10:

$$\forall P : \mathcal{Z}_P(R_h) > \mathcal{Z}_P(R_l) \tag{9}$$

$$\mathcal{Z}_{MostDon.}(C) > \mathcal{Z}_{Random}(C) > \mathcal{Z}_{LeastDon.}(C) \tag{10}$$

6.2 Tasks

We evaluated all pretraining configurations detailed in Table 2 on two of XTREME's tasks: part of speech tagging (POS) and named entity recognition (NER). Both of which commonly appear in NLP pipelines such as CoreNLP (Manning et al., 2014) and spaCy (Honnibal and Montani, 2017). We aim to balance the data in both tasks across different finetune languages, so as not to skew results towards higher-resource languages.

For part-of-speech tagging, XTREME borrows from universal dependencies (Nivre et al., 2020). Since XTREME is imbalanced across languages, we truncated the data to 1000 sentences to fit the lower-resource languages, e.g., XTREME annotates POS in 909 sentences in Hungarian. For NER, we applied a similar procedure, where XTREME's data was taken from the Wikiann (panx) dataset (Rahimi et al., 2019) which we truncated to 5000 sentences (the data size available for Hindi NER in XTREME).

Experimental setup. We use the code and default hyperparameter default values provided by XTREME to train the downstream tasks (Hu et al., 2020), adapted for multilingual training.

6.3 Results

Several key observations can be made based on the results for both POS tagging and NER across all training configurations, which are presented in Tables 3 and 4. For each configuration P in *Most Donating, Least Donating, Random, Control* we

---

	Base Pretrain Set (Donors)		**Shared Pretrain Set**			**Total Data**	**Summary**
			Most Recipient (R_h)		**Least Recipient** (R_l)		
Most Donating	{ja, te, fi, ru}	+	{hi, de, hu}	+	{ar, el, ta}	10^8 characters	Most donating pretraining set.
Least Donating	{ne, my, hy, en}		{hi, de, hu}		{ar, el, ta}	10^8 characters	Least donating pretrain set.
Random	{he, ga, fr, sv}		{hi, de, hu}		{ar, el, ta}	10^8 characters	Random donating pretrain set.
Control	{}		{hi, de, hu}		{ar, el, ta}	10^8 characters	No additional donating languages.

Table 2: Four pretraining language configurations. Each consists of *donating* languages (first column) and *recipient* languages (second column). The control group has the same amount of data, equally distributed among its languages.

	NER [$\%F_1$]		**POS** [$\%F_1$]	
	Avg. Monolingual	Avg. Zeroshot	Avg. Monolingual	Avg. Zeroshot
Most Donating	**49.3**±.4	**15.6**±.4	**61.4**±.1	**28.1**±.3
Random	**49.2**±.3	**15.6**±.1	61.3±.1	26.9±.3
Least Donating	48.8±.2	14.8±.3	60.9±.2	26.9±.6
Control	49.0±.2	**15.6**±.2	**61.9**±.1	27.4±.3

Table 3: Donation results for named entity recognition (NER) and part of speech tagging (POS) as mean and standard deviation over five random seeds. For each pretraining language group (*Most Donating*, *Random*, *Least Donating*, and *Control*), we report corresponding average monolingual and zero shot performance. *Most Donating* consistently outperforms *Least Donating* in both tasks, and in both monolingual and zeroshot performance. *Most Donating* is on par with *Control* in monolingual performance in NER, despite having less in-domain data.

	NER [$\%F_1$]		**POS** [$\%F_1$]	
	Avg. Monolingual	Avg. Zeroshot	Avg. Monolingual	Avg. Zeroshot
Most Recipient (R_h)	**50.3**±.6	**18.4**±.6	**64.1**±.3	**28.7**±.7
Least Recipient (R_l)	47.9±.4	12.4±.4	58.6±.4	26.0±.7

Table 4: Recipience results for named entity recognition (NER) and part of speech tagging (POS) as mean and standard deviation over five random seeds. We report results across different training configurations for two groups of downstream recipient languages. In accordance with our pretraining results, the *Most Recipient* set does better than the *Least recipient* set across both tasks in zero-shot and monolingual performance.

calculated zero-shot transfer scores on C, using $\mathcal{Z}_P(C)$ defined by Equation 2. Monolingual results under each pretrain set P were calculated by the average $F1$ performance of each language in C:

$$\frac{1}{|C|} \cdot \sum_{l \in C} \varepsilon(M^{P,l}, l) \tag{11}$$

Where $\varepsilon(M^{P,l}, l)$ denotes the $F1$ score of a model pretrained on P, finetuned on l and evaluated on l.

Pretraining configuration affects downstream cross-lingual transfer. In both tasks, we observe a variance in results when changing the pretraining configuration, despite all of them having similar amounts of data. This may imply that previous work has omitted an important interfering factor.

Recipience score correlates with downstream cross-lingual performance. We evaluated zero-shot transfer for each language set $R \in \{R_l, R_h\}$ as the average zero-shot transfer scores over all pretraining configurations. Table 4 reveals that the *Most Recipient* set outperforms the *Least Recipient* set in both tasks ($+5.5\%$ in NER, $+2.7\%$ in POS tagging).

Multilingual pretraining can improve *monolingual* performance. As seen in Table 3, the *Most Donating* pretraining configuration achieved a monolingual score which is slightly higher than the control group, while the *Least Donating* configuration underperforms all other sets. This suggests that multilingual pretraining datasets can benefit monolingual downstream results compared to more data in a single language.

English might not be an optimal pretraining language. Corresponding with our previous results, if donation score is indicative of a language's contribution in pretraining, English's relative low donation score might indicate that it is not the best language to pretrain upon. English was also part of the *Least Donating* pretraining configuration which scored lower than *Most Donating* as seen in Table 3. Further research can ascertain this finding.

7 Limitations and Future Work

As with other works on cross-lingual transfer, our results are influenced by many hyperparameters. Below we explicitly define our design choices and how they can be explored in future work.

First, data scarcity in low-resource languages restricted us to small data amounts. Although our experiments showed a non-trivial signal for pretraining and downstream tasks, future work may apply our framework to larger data sizes.

Second, for efficiency's sake, we trained relatively small models to enable us to train a large number of language configurations, while ensuring convergence in 6 languages. Furthermore, we did not do any hyper-parameter tuning and used only values reported in previous work, and use only the BERT architecture. Future work may revisit any of these design choices to shed more light on their effect.

Third, similarly to other works, our data was scraped from Wikipedia, and we did not account for language contamination across supposedly monolingual corpora (e.g., due to code switching). Such contamination may confound with cross-lingual transfer, as was recently shown by Blevins and Zettlemoyer (2022).

Finally, our downstream analysis focused on POS tagging and NER since they were available for many languages and are common in many NLP pipelines. Further experimentation can test if our results hold for more NLP tasks.

8 Related Work

To the best of our knowledge, this is the first work to control for the amount of data allocated for each language during pretraining and finetuning while evaluating on many languages.

Perhaps most related to our work, Turc et al. (2021) challenge the primacy of English as a source language for cross-lingual transfer in various downstream tasks. Their work shows that German and Russian are often more effective sources. In all of their experiments, they use mBERT's imbalanced pretraining corpus. Blevins and Zettlemoyer (2022) complement this hypothesis by showing that English pretraining data actually contains a significant amount of non-English text, which correlates with the model's transfer capabilities.

Wu and Dredze (2020) evaluate how mBERT performs on a wide set of languages, focusing on the quality of representation for low-resource languages in various downstream tasks by defining a scale from low to high resource. They show that mBERT underperforms non BERT monolingual baselines for low resource languages while performing well for high resource ones.

While Pires et al. (2019); Limisiewicz and Mareček (2021) show that typology plays a significant role for mBERT's multilingual performance, this is not replicated in our balanced evaluation, and has lesser impact in Wu et al. (2022) as well.

Finally, Conneau et al. (2020a) introduce the transfer-interference trade-off where low resource languages benefit from multilingual training, up to a point where the overall performance on monolingual and cross-lingual benchmarks degrades.

9 Conclusions

We explored the effect of pretraining language selection on downstream zero-shot transfer.

We first choose a diverse pretraining set of 22 languages, and curate a pretraining corpus which is balanced across these languages.

Second, we devise an estimation technique, quadratic in the number of languages, projecting which pretraining languages will serve better in cross-lingual transfer and which specific downstream languages will do best in that setting.

Finally, we test our hypothesis on two downstream multilignual tasks, and show that the choice of pretraining languages indeed leads to varying downstream cross-lingual results, and that our method is a good estimation for downstream performance. Taken together, our results suggest that pretraining language selection should be a factor in estimating cross-lingual transfer, and that current practices which focus on high-resource languages may be sub-optimal.

A Appendix

Full list of tokenized languages The full list of Wikipedia language codes for languages used in our tokenizer training is:

- pms, ga, ne, cy, fi, hy, my, hi, te, ta, ko, el, hu, he, zh, ar, sv, ja, fr, de, ru, en - languages that are also evaluated and trained. Elaborated in Table 1.
- af, am, ca, cs, da, es, id, is, it, mg, nl, pl, sk, sw, th, tr, ur, vi, yi - Additional languages corresponding to Afrikaans, Amharic, Catalan, Czech, Danish, Spanish, Indonesian, Icelandic, Italian, Malagasy, Dutch, Polish, Slovak, Swahili, Thai, Turkish, Urdu, Vietnamese, and Yiddish.

Transfer Distribution In the histogram of cross-lingual transfers (Figure 7), we observe that the distribution has multiple local maximums (modes). We distinguish four main level of cross-lingual transfer described in Section 4.2 ($\mathcal{F}(l_i \rightarrow l_j)$):

- negative transfer $\mathcal{F}(l_i \rightarrow l_j) < -10$
- neutral transfer $-10 \leq \mathcal{F}(l_i \rightarrow l_j) < 10$
- positive transfer $10 \leq \mathcal{F}(l_i \rightarrow l_j) < 55$
- very positive transfer $55 \leq \mathcal{F}(l_i \rightarrow l_j)$

The choice of division borders was done in order to separate distinct modes of the distribution and to obtain interpretable bins (e.g. neutral transfer centered around zero).

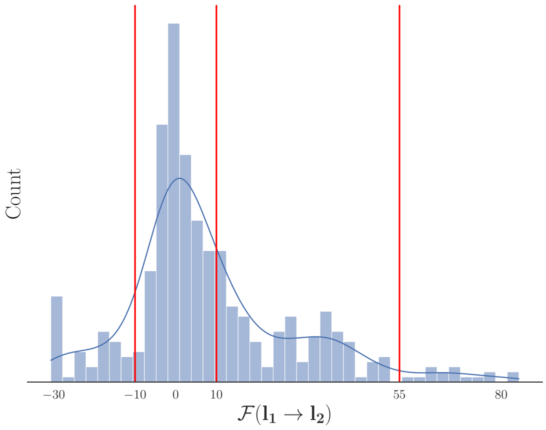

Figure 7: Histogram of cross-lingual transfers $\mathcal{F}(l_i \rightarrow l_j)$. Horizontal lines (at -10, 10, and 55) are the borders between four transfer levels.

Abstract

Aspect-based Sentiment Analysis (ABSA) aims to predict the sentiment polarity towards a particular aspect in a sentence. Recently, graph neural networks based on dependency tree convey rich structural information which is proven to be utility for ABSA. However, how to effectively harness the semantic and syntactic structure information from the dependency tree remains a challenging research question. In this paper, we propose a novel Syntactic and Semantic Enhanced Graph Convolutional Network (SSEGCN) model for ABSA task. Specifically, we propose an aspect-aware attention mechanism combined with self-attention to obtain attention score matrices of a sentence, which can not only learn the aspect-related semantic correlations, but also learn the global semantics of the sentence. In order to obtain comprehensive syntactic structure information, we construct syntactic mask matrices of the sentence according to the different syntactic distances between words. Furthermore, to combine syntactic structure and semantic information, we equip the attention score matrices by syntactic mask matrices. Finally, we enhance the node representations with graph convolutional network over attention score matrices for ABSA. Experimental results on benchmark datasets illustrate that our proposed model outperforms state-of-the-art methods.

1 Introduction

Aspect-based Sentiment Analysis (ABSA) aims to determine the sentiment polarity of a given aspect term in a sentence, where sentiment polarity includes positive, negative and neutral. For example, in Figure 1, ABSA determines the sentiment towards the aspects *"food"* and *"service"*. For aspect term *"food"*, the sentiment polarity is negative, but *"service"* is positive. That is, we need to discriminate sentiment polarities according to different aspects. The main idea of most works is to model the dependency relation between aspects and their associated opinion words.

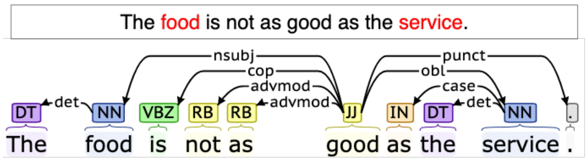

Figure 1: An example sentence with its dependency tree where aspect terms (highlighted in red) are connected with other words based on their syntactic dependencies.

Prior studies exploit attention mechanism (Wang et al., 2016; Chen et al., 2017; Ma et al., 2017; Liu et al., 2018; Hu et al., 2018; Wang et al., 2018; Huang et al., 2018; Fan et al., 2018) to model the correlations between aspect term and the context. However, attention mechanism is vulnerable to noise in sentences, i.e., the irrelevant words.

Recent works on ABSA leverage Graph Neural Networks (GNNs) over the dependency tree of a sentence to exploit syntactic structure (Sun et al., 2019; Zhang et al., 2019; Liang et al., 2020; Wang et al., 2020; Zhao et al., 2020; Li et al., 2021; Tian et al., 2021). In these works, Zhang et al. (2019) employ Graph Convolutional Network (GCN) to integrate the syntactic information. Sun et al. (2019) propose a GCN model to enhance the feature representations of aspects learned by a Bi-directional Long Short Term Memory (Bi-LSTM). However, these two studies treat all the neighbor nodes of the current node in the graph equally, and are limited in lacking of efficient mechanisms to distinguish the importance of neighbor nodes. Accordingly, noisy nodes may cause the model to misjudge the sentiment polarity. To tackle this problem, Huang and Carley (2019) design a target-dependent graph attention network that updates each node representation by utilizing multi-head attention. The attention mechanism is used to consider semantic correlation of each neighbor node, but it is a lo-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4916 - 4925
July 10-15, 2022

cal attention by only calculating the importance of neighboring nodes and neglects the global information of the sentence. Following this line, Chen et al. (2020) and Li et al. (2021) combine a syntactic structure graph with a latent semantic graph but the two graphs are constructed independently.

Notablely, existing GCN-based approaches do not fully leverage syntactic structure, where only the information of the neighbor nodes is considered. Moreover, some hard cases obscurely express sentiment of aspect term, there is no direct syntactic relationship between aspect term and opinion words. How to capture the information of second-order nodes, third-order nodes and even the global syntactic structure in one shot is still a challenge. Recently, most methods apply multi-layer GCNs to derive the expression of opinion words which brings potential noise. For instance, consider the dependency tree as depicted in Figure 1, a dependency connection exists between the aspect *"food"* and the opinion word *"good"*. However, the *"good"* refers to another aspect *"service"*. For aspect term *"food"*, the representation of word *"not"* is obtained by utilizing two-layer GCN. At the same time, noisy word *"not"* is also obtained for aspect term *"service"*. As a result, simply considering the syntactic structure of dependency tree might be unsatisfactory. It is necessary to harness the aspect-related semantic information for different aspect terms.

In this paper, we propose a novel Syntactic and Semantic Enhanced Graph Convolutional Network (SSEGCN) model for integrating the syntactic and semantic information of a sentence to solve the above issues. Firstly, SSEGCN captures the contextualized word representations with sentence encoder. Secondly, to model particular semantic correlations for different aspect terms, we propose an aspect-aware attention mechanism to combine with self-attention. The aspect-aware attention learns aspect-related semantic information, while self-attention learns global semantic of the sentence. We take the obtained attention scores as the initial adjacency matrices for GCN. Besides, to fully utilize syntactic structure to complement semantic information, rather than just syntactic first-order neighbor node information, we construct the syntactic mask matrices calculated by the different distances between words in the syntactic dependency structure of the sentence to learn structure information from local to global. Then, we combine adjacency matrices with syntactic mask matrices to enhance the conventional GCN. Finally, a multi-layer graph convolution operation is implemented to obtain aspect-specific features for aspect term sentiment classification. We evaluate our approach on three benchmark datasets. The results show that our model is more effective than a range of baselines and achieves new state-of-the-art performance.

Our contributions are summarized as follows:

- We propose a SSEGCN model that effectively integrates syntactic structure and semantic correlation for ABSA task.
- We propose an aspect-aware attention mechanism combined with self-attention to learn the aspect-related semantic correlations and the global semantic of the sentence. Meanwhile, we construct syntactic mask matrices to complement with semantic information.
- Experimental results on three benchmark datasets show that the SSEGCN model achieves the state-of-the-art performance. The code and datasets involved in this paper are provided on Github[1].

2 Related Work

Aspect-based sentiment analysis is a fine-grained sentiment analysis task and generally treated as a classification problem. Earlier methods (Jiang et al., 2011; Kiritchenko et al., 2014) manually defined some syntactic rules to predict the sentiment polarity of aspect term.

Most recent researches solve aspect-based sentiment analysis by utilizing attention-based neural network to model semantic correlation between context and aspect term (Wang et al., 2016; Chen et al., 2017; Ma et al., 2017; Liu et al., 2018; Hu et al., 2018; Wang et al., 2018; Huang et al., 2018; Fan et al., 2018). Among them, (Wang et al., 2016) utilized attention mechanism to concentrate on different parts of a sentence to generate an attention vector for aspect sentiment classification. Chen et al. (2017) proposed a multi-layer attention network to infer the sentiment polarity for the aspect. Ma et al. (2017) introduced an interactive attention mechanism to generate the representations for aspects and contexts separately. Wang et al. (2018) designed a hierarchical aspect-specific attention model for aspect sentiment classification. Hu et al. (2018) employed a constrained attention network

---

[1] `https://github.com/zhangzheng1997/SSEGCN-ABSA`

with both orthogonal regularization and sparse regularization.

Another trend explicitly leverages dependency tree. Syntactical information can establish relation connections between aspect and corresponding opinion words, GCN based on dependency tree have achieved impressive performance in ABSA. (Zhang et al., 2019; Sun et al., 2019) stacked a GCN layer to extract rich representations over dependency tree. Liang et al. (2020) build aspect-focused and inter-aspect graphs to learn aspect-specific sentiment features. Zhang and Qian (2020) constructed a global lexical graph to capture the word co-occurrence relation and combined a global lexical graph and a syntactic graph. Liang et al. (2021) constructed a sentiment enhancement graph by integrating the sentiment knowledge from SenticNet to consider the affective information between opinion words and aspect term. Tian et al. (2021) utilized dependency types and distinguished different relations in the dependency tree. However, these approaches generally ignore the effective fusion of syntactic structure and semantic correlation to obtain richer information.

3 Proposed SSEGCN

Figure 2 gives an overview of SSEGCN. In this section, we describe the SSEGCN model which is mainly composed of three components: the Input and Encoding Layer, the Attention Layer, the Syntax-Mask Layer and the GCN Layer. Next, components of SSEGCN will be introduced separately in the rest of the sections.

3.1 Input and Encoding Layer

Given a sentence-aspect pair (s, a), where $s = \{w_1, w_2, ..., w_n\}$. $a = \{a_1, a_2, ..., a_m\}$ is an aspect and also a sub-sequence of the sentence s. We utilize BiLSTM or BERT (Devlin et al., 2019) as sentence encoder to extract hidden contextual representations. We first map each word into a low-dimensional real-value vector with embedding matrix $E \in \mathbb{R}^{|V| \times d_e}$, where $|V|$ is the size of vocabulary and d_e denotes the dimensionality of word embeddings. Thus, the sentence s has corresponding word embeddings $x = \{x_1, x_2, ..., x_n\}$. With the word embeddings of the sentence, BiLSTM is leveraged to produce hidden state vectors $H = \{h_1, h_2, ..., h_n\}$, where $h_i \in \mathbb{R}^{2d}$. H contains the sub-sequence $h_a = \{h_{a_1}, h_{a_2}, ..., h_{a_m}\}$ corresponding to the aspect term representation. Take H as initial nodes representation in SSEGCN. For the BERT encoder, we adopt *"[CLS] sentence [SEP] aspect [SEP]"* as input.

3.2 Attention Layer

Attention mechanism is a common way to capture the interactions between the aspect and context words (Fan et al., 2018). In this subsection, we combine aspect-aware attention and self-attention for better semantic features. Figure 2 shows multiple attention adjacency matrices. Here, we construct p matrices and the p is a hyper-parameter.

3.2.1 Aspect-aware Attention

Unlike sentence level sentiment classification task, aspect-based sentiment classification aims at judging sentiments of one specific aspect term in its context sentence, and thus calls for modeling particular semantic correlation based on different aspect terms. We propose the aspect-aware attention mechanism, which regards aspect term as query to attention calculation for learning aspect-related features:

$$A^i_{asp} = \tanh\left(H_a W^a \times \left(K W^k\right)^T + b\right) \quad (1)$$

where K is equal to H produced by encoding layer. $W^a \in \mathbb{R}^{d \times d}$ and $W^k \in \mathbb{R}^{d \times d}$ are learnable weights. We apply mean pooling on the h_a and then copy it n times to obtain $H_a \in \mathbb{R}^{n \times d}$ as aspect representation. Note that we use p-head aspect-aware attention to obtain attention score matrices for a sentence, A^i_{asp} indicates that it is obtained through the i-th attention head.

3.2.2 Self-Attention

Similarly, here A_{self} can be constructed by utilizing p-head self-attention (Vaswani et al., 2017) that captures the interaction between two arbitrary words of a single sentence. The calculation involves a query and a key:

$$A^i_{self} = \frac{QW^Q \times \left(KW^K\right)^T}{\sqrt{d}} \quad (2)$$

where Q and K are both equal to H produced by encoding layer. $W^Q \in \mathbb{R}^{d \times d}$ and $W^K \in \mathbb{R}^{d \times d}$ are learnable weights. Then, we integrate aspect-aware attention score with self-attention score:

$$A^i = A^i_{asp} + A^i_{self} \quad (3)$$

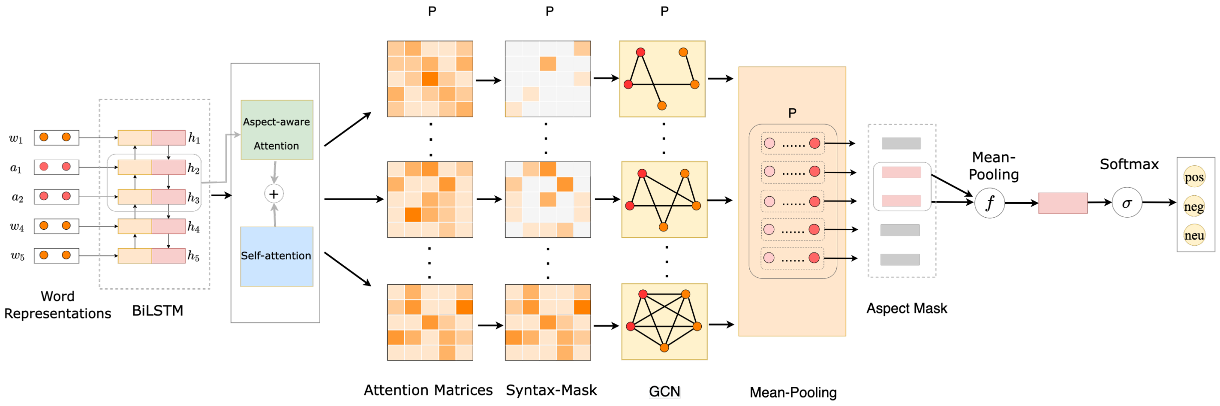

Figure 2: The overall architecture of SSEGCN.

where $A^i \in \mathbb{R}^{n\times n}$ is used as the input for the computation of the later Syntax-Mask Layer. For each A^i, it represents a fully connected graph.

3.3 Syntax-Mask Layer

In this section, we first introduce the syntactic mask matrix, and then mask each fully connected graph in terms of different syntactic distances. We treat the syntactic dependency tree as an undirected graph, and each token as a node. Then, we define the distance between node v_i and v_j as $d(v_i, v_j)$. Since there are multiple paths between nodes on the syntactic dependency tree, we define the distance of the shortest path as D:

$$D(i,j) = min\ d(v_i, v_j) \tag{4}$$

In the previous part, the p-head attention mechanism can obtain p adjacency matrices. Therefore, we set the number of syntactic mask matrices based on different syntactic distances as the same as the number of attention heads. When syntactic distance is relatively small, our model can learn local information; on the contrary, if syntactic distance is relatively large, global structure information will be considered. The calculation of syntactic mask matrix M^k with threshold k can be formulated as:

$$M_{ij}^k = \begin{cases} 0, & D(i,j) \le k \\ -\infty, & \text{otherwise} \end{cases} \tag{5}$$

where $k \in [1, p]$. To obtain global information and local feature, attention scopes are restricted by different syntactic distances.

$$M = \{M^1, ..., M^k, ..., M^p\} \tag{6}$$

$$A_{mask}^i = \text{softmax}\left(A^i + M^i\right) \tag{7}$$

Similarly, syntactic mask matrix based on the distance i is denoted as $A_{mask}^i \in \mathbb{R}^{n\times n}$.

3.4 GCN Layer

Since we have p different syntactic mask matrices, p graph convolution operations over $A_{mask} \in \mathbb{R}^{p\times n\times n}$ are required. If we denote h^{l-1} as the input state and h^l as the output state of the l-th layer, h^0 is the output of sentence encoding layer. Each node in the l-th GCN layer is updated according to the hidden representations of its neighborhoods:

$$h_i^l = \sigma\left(\sum_{j=1}^{n} A_{ij} W^l h_j^{l-1} + b^l\right) \tag{8}$$

where W^l is a linear transformation weight, b^l is a bias term, and σ is a nonlinear function. The final output representation of the l-layer GCN is $H^l = \{h_1^l, h_2^l, ..., h_n^l\}$.

After aggregating node representation from each layer of SSEGCN, we obtain the final feature representation. We mask the non-aspect words of the output representation learned by the GCN layer to obtain aspect term representation. Moreover, an average pooling to retain most of the information in the aspect term representation h_a^l.

$$h_a^l = f(h_{a_1}^l, h_{a_2}^l, ..., h_{a_m}^l) \tag{9}$$

where $f(\cdot)$ is a mean-pooling function applied over the enhanced aspect representation by GCN layer. Then, we feed h_a^l into a linear layer, followed by a softmax function to yield a probability distribution over polarity decision space:

$$p(a) = \text{softmax}\left(W_p h_a^l + b_p\right) \tag{10}$$

where W_p and b_p are the learnable weight and bias.

3.5 Training

Finally, the standard cross-entropy loss is used as our objective function:

$$L(\theta) = -\sum_{(s,a)\in\mathcal{D}} \sum_{c\in\mathcal{C}} \log p(a) \qquad (11)$$

where $\mathcal{D}$ contains all the sentence-aspect pairs and a represents the aspect appearing in sentence s. θ represents all the trainable parameters and $\mathcal{C}$ is the collection of sentiment polarities.

4 Experiments

4.1 Datasets

We conduct experiments on three benchmark datasets for aspect-based sentiment analysis, including Restaurant and Laptop reviews from SemEval 2014 Task 4 (Pontiki et al., 2014) and Twitter (twitter posts) from Dong et al. (2014). Each aspect is labeled by one of the three sentiment polarities: positive, neutral and negative. The statistics for three datasets are reported in Table 1.

Dataset	Division	# Positive	# Negative	# Neutral
Rest14	Train	2164	807	637
	Test	727	196	196
Laptop	Train	976	851	455
	Test	337	128	167
Twitter	Train	1507	1528	3016
	Test	172	169	336

Table 1: Statistics for the three experimental datasets.

4.2 Implementation Details

For our experiments, we initialize word embeddings with 300-dimensional Glove vectors provided by Pennington et al. (2014). Additionally, we use 30-dimensional Part-of-Speech (POS) embeddings and 30-dimensional position embeddings which is the relative position of each word with respect to the aspect term in the sentence. Then, word embeddings, POS embeddings and position embeddings are concatenated as input word representations. All sentences are parsed by the Stanford parser[2]. The batch size of all model is set as 16 and the number of GCN layers is 2. Besides, dropout function is applied to the input word representations of the BiLSTM and the dropout rate is set as 0.3. Our model is trained using the Adam optimizer with a learning rate of 0.002 to optimize the parameters. For SSEGCN+BERT, we employ the bert-base-uncased[3] English version.

4.3 Baseline Comparisons

To comprehensively evaluate the performance of our model, we compare with state-of-the-art baselines:

1) **IAN** (Ma et al., 2017) interactively learns the relationship between aspect and their context.
2) **RAM** (Chen et al., 2017) proposes a recurrent attention memory network to learn the sentence representation.
3) **TNet** (Li et al., 2018) employs a CNN model to extract salient features from target-specific embeddings by transformed BiLSTM embeddings.
4) **ASGCN** (Zhang et al., 2019) proposes to build GCN to learn syntactical information and word dependencies for ABSA.
5) **CDT** (Sun et al., 2019) utilizes a convolution over a dependency tree model to learn the representations of sentence features.
6) **TD-GAT** (Huang and Carley, 2019) proposes a target-dependent graph attention network for aspect level sentiment classification, which explicitly utilizes the dependency relationship among words.
7) **BiGCN** (Zhang and Qian, 2020) builds a concept hierarchy on both the syntactic and lexical graphs for sentiment prediction.
8) **kumaGCN** (Chen et al., 2020) combines information from a dependency graph and a latent graph to learn syntactic features.
9) **R-GAT** (Wang et al., 2020) proposes a relational graph attention network to encode the new tree reshaped by an ordinary dependency parse tree.
10) **DGEDT** (Tang et al., 2020) proposes a dependency graph enhanced dual-transformer network by jointly considering the flat representations from Transformer and graph-based representations from the dependency graph.
11) **DualGCN** (Li et al., 2021) designs a SynGCN module and a SemGCN module with orthogonal and differential regularizers.
12) **BERT** (Devlin et al., 2019) is the vanilla BERT model, which adopts *"[CLS] sentence [SEP] aspect [SEP]"* as input.
13) **R-GAT+BERT** (Wang et al., 2020) is the R-GAT model based on pre-trained BERT.
14) **DGEDT+BERT** (Li et al., 2021) is the DGEDT

---

[2] `https://stanfordnlp.github.io/CoreNLP/`

[3] `https://github.com/huggingface/transformers`

model based on pre-trained BERT.

15) **BERT4GCN** (Zhang and Qian, 2020) integrates the grammatical sequential features from the PLM of BERT and the syntactic knowledge from dependency graphs.

16) **T-GCN** (Tian et al., 2021) utilizes dependency types to distinguish different relations in the graph and uses attentive layer ensemble to learn the contextual information from different GCN layers.

4.4 Main Results

To demonstrate the effectiveness of SSEGCN, we compare our model with previous works using accuracy and macro-averaged F1 as evaluation metrics, and report results in Table 2. Experimental results show that our SSEGCN model achieves best performance on the three datasets. In particular, GCN-based models take into account the syntactic structure of a sentence and capture long-term syntactic dependencies between the aspect word and the opinion word, hence outperform all attention-based methods. In GCN-based models, our SSEGCN learns structure information from local to global and considers aspect-related semantic information, and performs significantly better than the previous GCN-based models (i.e., CDT, TD-GAT, BiGCN, KuamGCN, R-GAT, DGEDT and DualGCN) that verifies the effectiveness of fusing syntactic and semantic information. On the other hand, we can observe that the basic BERT has been significantly better than most ABSA models. Combining our SSEGCN with BERT, the results show that the effectiveness of this powerful model is further improved, justifying that SSEGCN learns more syntactic and semantic knowledge can empower ABSA.

4.5 Ablation Study

As illustrated in Table 3 , we further conduct an ablation study to examine the effectiveness of different modules in SSEGCN. The basic SSEGCN is regarded as a baseline model. First, we observe that removal of self-attention degrades the performance, verifying that global semantics of the sentence is necessary for ABSA. We can also notice that model without aspect-aware attention performs unsatisfactory, which indicates that the model lacks of the ability to capture aspect-related semantics, resulting in 1.70%, 1.58% and 1.47% reductions in accuracy on Restaurant, Laptop and Twitter, respectively. It indicates that aspect-aware attention is essential to capture the correlated semantic information between aspect and contextual words. Second, removing syntactic mask matrix leads to dropping 0.90%, 1.42% and 0.88% in accuracy on Restaurant, Laptop and Twitter respectively, which indicates that syntactic mask matrix can assist GCNs to learn better syntactic structure information in original dependency trees. In addition, the removal of syntactic mask matrix and aspect-aware attention leads to a significant performance drop, which further indicates that these two components play crucial roles in SSEGCN for ABSA task. In summary, the ablation experimental results show that each component contributes to our entire model.

4.6 Case Study

To examine whether SSEGCN is able to capture syntax and semantic information for improving ABSA, we conduct case study with a few of sample sentences. Particularly, we compare SSEGCN with ATAE-LSTM, IAN and CDT in Table 4 which contain their predictions and the corresponding truth labels on these sentences. The notations P, N and O in the table represent positive, negative and neutral sentiment, respectively. The first sample *"great food but the service was dreadful!"* has two aspects (*"food"* and *"service"*) with contrast sentiment polarities, which may interfere with the prediction of the attention models. The second sample *"Biggest complaint is Windows 8."* has the interfering word *"Biggest"*, which may neutralize the polarity of the word *"complaint"*. In the third sample, the key point is capturing the negated semantics which is most methods tend to ignore and easily make wrong predictions. The last two examples have no explicit sentiment expression. For the sentence *"Not as fact as I would have expect for an i5"*, CDT does not obtain the representation of the keyword *"not"* from a syntactic point of view and thus produces wrong prediction. Thus, the ability to learn integral semantics of a sentence is a significant factor for ABSA task. Our SSEGCN correctly predicts all the samples, and the results suggest that SSEGCN effectively combines syntactic structure and semantic information. Additionally, when dealing with complex sentences with implicit sentiment expressions, our SSEGCN can achieve better performance.

4.7 Visualization

To further demonstrate how our SSEGCN improves ABSA task, we use the two test examples in Figure 3 to visualize attention scores. For the sentence

Models	Restaurant		Laptop		Twitter	
	Accuracy	Macro-F1	Accuracy	Macro-F1	Accuracy	Macro-F1

w/o aspect-aware attention and syntactic mask matrix	82.75	75.02	77.37	73.35	74.89	72.40

Table 3: Experimental results of ablation study.

"The staff should be a bit more friendly.", our model correctly identifies the sentiment of aspect term *"staff"* as negative. Our SSEGCN model considers the semantics of the sentence and reduce the attention weight on the word *"friendly"* through syntactic distance mask and aspect-aware attention. For the harder example of multiple aspects with different sentiment polarities, our model also performs well. For sentence *"great food but the service was dreadful!"*, our model considers the aspect-related semantic correlations by introducing aspect-aware attention and combining syntactic mask matrices. Thus, SSEGCN can accurately find the opinion words corresponding to each aspect term.

4.8 Effect of SSEGCN Layers

In this section, we investigate the effect of the layer number ranging from 1 to 5 on the Restaurant and Laptop datasets. As shown in Figure 4, experimental results show that our model achieves the best performance with 2 layers. First, if the number of GCN layer is set to 1, SSEGCN can only learn local node information with syntactic distance of 1. Second, node representation will be over-smooth and obtain more redundancy information when the number of GCN layers is large, thus making model in poor performance.

4.9 Effect of Syntax-Mask

In this section, we further analyze the effect of the multiple different syntactic mask matrices on the performance of SSEGCN in Restaurant and Laptop datasets. We conduct different numbers of the syntactic mask matrices from 1 to 7 and the results are demonstrated in Figure 5. We observe that the proposed SSEGCN shows an upward trend with the increase of the number when the number of syntactic mask matrices is less than 5. One main reason may be that SSEGCN can learn structure information from local to global when the syntactic distance becomes larger and SSEGCN achieves remarkable results on five syntactic mask matrices. However, increasing the number of syntactic

Aspect	Sentence	ATAE-LSTM	IAN	CDT	SSEGCN	Label
{food, service}	Great **food** but the **service** was dreadful!	(N, N)	(N, N)	(P, N)	(P, N)	(P, N)
{Windows 8}	Biggest complaint is **Windows 8**.	(O)	(O)	(N)	(N)	(N)
{settings}	The **settings** are not user-friendly either.	(N)	(P)	(N)	(N)	(N)
{i5}	Not as fact as I would have expect for an **i5**	(P)	(P)	(O)	(N)	(N)
{Tequila}	If you are a **Tequila** fan you will not be disappointed.	(N)	(N)	(N)	(P)	(P)

Table 4: Case study of our SSEGCN model compared with state-of-the-art baselines.

mask matrices from 5 to 7 leads to the performance degradation of SSEGCN. When the syntactic distance is greater than five, multiple syntactic mask matrices are fully connected matrices, and leads to the introduction of noise and decline of the model performance.

5 Conclusion

In this paper, we propose a SSEGCN architecture which integrates semantic information along with the syntactic structure for ABSA task. Specifically, we first design an aspect-aware attention mechanism, which is responsible for learning aspect-related semantic information. Then, we combine it with the self-attention to compose the attention layer. Furthermore, we construct syntactic mask matrices of a sentence according to the different syntactic distances that learn local to global structure information. Consequently, we combine attention score matrices with syntactic mask matrices to fuse the semantic and syntactic information. Experimental results demonstrate the effectiveness of our approach on three public datasets.

Mitigating Toxic Degeneration with Empathetic Data: Exploring the Relationship Between Toxicity and Empathy

Allison Lahnala† and **Charles Welch**† and **Béla Neuendorf** and **Lucie Flek**

Abstract

Content Warning: This paper includes examples of religious-based discriminatory language that may be offensive and upsetting.

Large pre-trained neural language models have supported the effectiveness of many NLP tasks, yet are still prone to generating toxic language hindering the safety of their use. Using empathetic data, we improve over recent work on controllable text generation that aims to reduce the toxicity of generated text. We find we are able to dramatically reduce the size of fine-tuning data to 7.5-30k samples while at the same time making significant improvements over state-of-the-art toxicity mitigation of up to 3.4% absolute reduction (26% relative) from the original work on 2.3m samples, by strategically sampling data based on empathy scores. We observe that the degree of improvement is subject to specific communication components of empathy. In particular, the cognitive components of empathy significantly beat the original dataset in almost all experiments, while emotional empathy was tied to less improvement and even underperforming random samples of the original data. This is a particularly implicative insight for NLP work concerning empathy as until recently the research and resources built for it have exclusively considered empathy as an emotional concept.

1 Introduction

Pre-trained neural language models are prone to generating toxic language, hindering the ability to use them safely (Gehman et al., 2020). Recent work on controllable text generation has shown promise in successfully altering such text attributes (Liu et al., 2021). However, partly due to the subjective nature of this task (Jurgens et al., 2019), the selection of negative, non-toxic examples for modeling has been somewhat arbitrary. Meanwhile, there is a growing body of research in natural language processing around the concept of empathetic communication - a number of data resources and approaches have been proposed for training empathy recognition and generation models (Sharma et al., 2020; Rashkin et al., 2019). Though the definitions of toxicity and empathy vary across literature, we observe an opposition between the concepts in terms of response appropriateness and intent toward others, which is the basis of the research question driving this work: is there an opposing relationship between toxic and empathetic language that can be leveraged to better model these phenomena?

Toxic language is often described as harassing or offensive language that decreases the likelihood of participation in discussions or other cooperative efforts (Wulczyn et al., 2017). In NLP literature, empathetic language is usually conveyed as language that shows an understanding and acknowledgement of the interlocutor's emotions (Rashkin et al., 2019; Shin et al., 2020), which, in turn, has an increased participation effect. In many fields of social science, empathy is defined with multiple dimensions including both emotional and cognitive components (and others) (Decety and Jackson, 2004; Gerdes et al., 2011).

In this paper, we investigate the following hypotheses:

1. There is an unexplored negatively correlated relationship between toxicity and empathy.
2. Exploiting this relationship could result in more robust and/or efficient models for mitigating toxic degeneration.
3. Specific categories of empathetic behavior have a stronger relation to the reduction of specific types of toxicity. In particular, we expect the cognitive types of empathy to be more beneficial for mitigating the largely cognitive

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4926 - 4938
July 10-15, 2022

aspects of toxic behavior, since emotional empathy may reinforce toxic feelings such as hostility toward out-groups (Breithaupt, 2012).

We perform a set of experiments in which we leverage empathetic data to alter the toxicity of generated text. We use the predictions of a language model trained on empathetic data to alter the output of a large pretrained language model and demonstrate that using only a small volume of *empathetic* data can reduce toxicity more than a model simply trained on a large volume of *non-toxic* text.

Furthermore, we consider relationships between various facets of toxicity and empathy, particularly emphasizing the distinction between *emotional empathy* and *cognitive empathy* that is less commonly made in the NLP literature. We find that training on text with high cognitive empathy is more effective at reducing toxicity than text with emotional empathy.

2 Related Work

Large language models (LM) have achieved strong performance on a number of natural language processing tasks (Radford et al., 2019), yet they remain difficult to control and often generate problematic responses both in their use as language models and as the foundation for downstream applications, such as conversational agents (Wolf et al., 2017; Bender et al., 2021; Bommasani et al., 2021). In this section, we review the related work on toxicity, empathy, and controllable text generation.

Toxicity has recently been used as a way to measure language that is harmful or offensive. This language has also been shown to suppress the expression of others, which is often the opposite of what is desired in interactive NLG applications (Sood et al., 2012).

Gehman et al. (2020) introduced RealToxicityPrompts, a test-bed for toxic language generation. They gathered a range of toxic sentences and split them in half. Models tested with this data must continue the sentence in a non-toxic way. They test recent LMs (some mentioned in the following subsection on controllable generation) finding all to be prone to toxic degeneration and suggest that choosing less toxic pretraining data may help. Similarly, Zhou et al. (2021) examine challenges in mitigation, finding that improving data quality through relabeling is more effective than attempting to debias a model trained with biased labels.

The Jigsaw shared task provided a large volume of Wikipedia comments with human annotations of six classes of toxicity (Jigsaw, 2021b). SemEval-2021 hosted a task on toxic span detection, where one must identify the subsequence of a text that is responsible for the toxicity label (Pavlopoulos et al., 2021). The Jigsaw data classes were those originally used to train the models in the Perspective API, which has been used by several recent works to automatically evaluate toxic language (Jigsaw, 2021a).

These are not the only classes that exist in toxic language research. Waseem and Hovy (2016) looked at sexism and racism in Twitter comments and ElSherief et al. (2021) developed a taxonomy of implicit hate speech. However, Fortuna et al. (2020) performed experiments across toxicity datasets, finding that within-class homogeneity and performance vary greatly. They suggest that each dataset has its own “flavor” of toxicity, even for similarly defined concepts.

Empathy has been the subject of many recent NLP studies, often for empathetic response generation models in aims of improving response appropriateness and overall satisfaction with dialogue agents (Hu et al., 2018; Rashkin et al., 2019; Lin et al., 2019, 2020; Majumder et al., 2020; Zandie and Mahoor, 2020; Zheng et al., 2021; Zeng et al., 2021; Jhan et al., 2021). Most of this work predominantly conveys empathy as an ability to recognize and demonstrate an understanding of one’s emotions with a warm or sympathetic response (Rashkin et al., 2019; Lin et al., 2020; Zandie and Mahoor, 2020; Majumder et al., 2020; Shin et al., 2020), which are all aspects of what is often termed *affective* or *emotional empathy* (Cuff et al., 2016).

While some definitions of empathy across areas of cognitive neuroscience, psychology, and practicing areas of psychotherapy are based only on emotional components (Cuff et al., 2016), most include both emotional and cognitive components (Decety and Jackson, 2004; Gerdes et al., 2011), sometimes along with additional ones. *Cognitive empathy* involves deliberate cognitive processing and active interest to understand and further explore the other’s internal perspective (Gerdes et al., 2011; Miller and Rollnick, 2012).

The reason few NLP works have engaged with empathy conceptualizations beyond emotional aspects could be partly due to limited resources and difficulty constructing them, which some recent works have aimed to address. Zhou and Jurgens (2020) created a corpus of Reddit posts with expressions of distress and responses offering condolences, annotated for empathy based on appraisal theory (Lamm et al., 2007; Wondra and Ellsworth, 2015). Welivita and Pu (2020) created an annotation scheme for empathetic listener intents which they manually labeled on a subset of the EmpatheticDialogues dataset (Rashkin et al., 2019) on which they trained a classifier to automatically label the rest of the data. Sharma et al. (2020) developed a framework of expressed empathy called EPITOME that includes both emotional and cognitive aspects which are annotated in peer-supporter responses to support-seekers in online interactions. A later work created a hierarchical model for empathy generation using EPITOME, which led to improved performance including in human evaluations (Zheng et al., 2021).

Our work leverages Sharma et al. (2020)'s public Reddit data. [1] The communication mechanisms of the framework are emotional reactions (ER) and two cognitive aspects, interpretations (IP) and explorations (EX), which we define thoroughly in § 3. The data contains annotations of whether the peer supporters' responses to seekers contain *no*, *weak*, or *strong* communication for each of the three mechanisms. They then created classifiers for all three types of empathy using separate models built from the same RoBERTa-based architecture (Liu et al., 2019). The classifiers predict the degree to which a sample contains *no*, *weak*, or *strong* communication of each mechanism.

We expect the cognitive aspects of empathy to be more useful for toxic language mitigation because of side-taking effects. In the three-person model of empathy, one person observes a conflict between two others. The observer may take sides with one of the persons in conflict and together their emotional reaction to the third party can be amplified (Breithaupt, 2012). This type of polarization through side-taking can lead to aggressive acts (Breithaupt, 2018). To the best of our knowledge, such negative aspects of empathy have yet to be investigated in NLP literature; our findings suggest that this direction is important to further pursue.

Controllable Generation methods often involve fine-tuning or retraining large models. The CTRL model of Keskar et al. (2019) is trained with 50 predefined control codes representing different topics, styles, and languages, that condition the generation process. Ziegler et al. (2019) used a reinforcement learning (RL) approach to alter the fine-tuning process for sentiment, physical descriptiveness, and summarization tasks. Yu et al. (2017) trained a generative adversarial network for sequence generation using RL for poem, political speech, and music generation.

Other methods have been developed not to alter the original model, but to alter generation at decoding time and do not require retraining the original model. The FUDGE model uses discriminators to predict, for a partial sequence, the probability that the next step of generation is more likely to result in an output that satisfies a particular attribute (Yang and Klein, 2021). The PPLM model of Dathathri et al. (2020) uses a similar approach but uses separate attribute models to modify the gradients used during prediction. Similarly, the work of Kumar et al. (2021) uses gradients but uses a modified loss for continuous optimization to allow for control of non-categorical attributes and non-autoregressive generation. They show that this improves performance on poetry couplet completion, topic-controlled generation, and informal-to-formal machine translation. In our experiments, we use the DExperts model of Liu et al. (2021), another decoding-time generation strategy. Their model uses LMs fine-tuned on desirable or undesirable attributes and uses the predictions of these models to alter the probabilities predicted by the base LM. More details of this model are provided in § 4.

3 Definitions

We use the three types of empathy of Sharma et al. (2020)'s EPITOME framework. The definitions of each and descriptions of weak and strong classes are abbreviated as follows (nearly verbatim):

Emotional Reaction: Expressions of emotions such as warmth, compassion, and concern, experienced by peer supporters after reading a seeker's post. *Weak*: Alludes to the peer's experienced emotions after reading the seeker's text without the emotions being explicitly labeled (e.g., Everything will be fine). *Strong*: The peer specifies their experienced emotions (e.g., I feel really sad for you).

Interpretations: Communicates an understanding of feelings and experiences inferred from the

---

[1] The TalkLife data is not publicly available.

seeker's post. *Weak*: Contains a mention of the understanding (e.g., I understand how you feel). *Strong*: Specifies the inferred feeling or experience (e.g., This must be terrifying) or communicates understanding through descriptions of similar experiences (e.g., I also have anxiety attacks at times which makes me really terrified).

Explorations: Expressions for improving understanding of the seeker by exploring the feelings and experiences not stated in the post. *Weak*: Generic (e.g., What happened?) *Strong*: Specific and labels the seeker's experiences and feelings which the peer supporter wants to explore (e.g., Are you feeling alone right now?)

For toxicity, we use all types of toxicity currently available from the Perspective API. Related works often use only the toxicity score, while the API currently offers scores for eight attributes, the last two of which were listed as experimental at the time of use:

Toxicity: A rude, disrespectful, or unreasonable comment that is likely to make people leave a discussion.

Severe Toxicity: A very hateful, aggressive, disrespectful comment or otherwise very likely to make a user leave a discussion or give up on sharing their perspective. This attribute is much less sensitive to more mild forms of toxicity, such as comments that include positive uses of curse words.

Identity Attack: Negative or hateful comments targeting someone because of their identity.

Insult: Insulting, inflammatory, or negative comment towards a person or a group of people.

Profanity: Swear words, curse words, or other obscene or profane language.

Threat: Describes an intention to inflict pain, injury, or violence against an individual or group.

Sexually Explicit: (Experimental) Contains references to sexual acts, body parts, or other lewd content.

Flirtation: (Experimental) Pickup lines, complimenting appearance, subtle sexual innuendos, etc.

4 Models

The DExperts model combines the predictions of a base LM with expert LMs fine-tuned on data known to either contain a desired (e.g., empathy) or undesired attribute (e.g., toxicity). The probability of the next token, x_t, is given by the following linear transformation of logits within the softmax: $P(x_t|x_{<t}) = softmax(z_t + \alpha(z_t^+ - z_t^-))$, for z_t predicted by the base model, the expert z_t^+, and the anti-expert z_t^-, with experts contribution weighted by a hyperparameter, α. We use $\alpha = 2.0$ as this is what was deemed effective in the original work. To allow for comparison we use the same hyperparameters, including a max generation length of 20 tokens. This model can be used for controlled generation by modifying decoding-time predictions for a given stylistic attribute. Using an opposing attribute to train the expert model should help minimize the probability of our undesired attribute (e.g. empathy used to oppose toxicity).

Strength	ER	IP	EX
strong	6,594	457,009	261,229
weak	148,962	0	2,953
no	2,170,585	1,869,132	206,1959

Table 1: The number of samples for which the classifier predicted each class (strong, weak, and no communication), for each empathy type (EX=explorations, IP=interpretations, ER=emotional reactions). Additional boxplots of log-likelihood distributions are in the Appendix.

The intuition behind the negative correlation between empathy and toxicity lies in the perceived appropriateness of language and a better understanding of the user. Consider a response to a person that is trying to help someone and not having much success. A toxic response, "you are stupid for trying that," may be perceived as toxic and inappropriate, while "it sounds like you're really trying hard and doing your best," may be perceived as more appropriate and better understanding the user. By our intuition, a stronger negative correlation should generally correspond to less toxic output.

Evaluation: We use the 10k prompts used in Liu et al. (2021) and the same metrics of toxicity, fluency, and diversity for comparability. We generate a set of 25 continuations of each prompt and score them with the Perspective API. *Average max toxicity* is the highest toxicity score given to the set and averaged over all 10k prompts. *Probability of toxicity* is the chance of a continuation having a score of $\geqslant 0.5$ at least once in the set. *Fluency* is measured as the average perplexity with a reference text generated by the larger LM, GPT-2 XL. *Diversity* measures the distinct n-grams normalized by text length, over all generations in the set. We report uni, bi, and trigrams for this metric as

Type	Size	Max Tox.	Tox. Prob.	PPL
Empathy	22.5k	0.323	0.147	45.10
Empathy	30k	0.324	0.149	43.68
Empathy	7.5k	0.329	0.156	52.91

ER	22.5k	0.335	0.164	46.42
Random	7.5k	0.341	0.168	53.61
ER	7.5k	0.340	0.173	53.46
ER	30k	0.338	0.173	43.20
Random	15k	0.343	0.177	48.82
ER	15k	0.342	0.179	50.66
DExperts	2.3m	0.313	0.133	**32.46**

Table 3: Results when fine-tuning the expert model on individual empathy types. Models are ordered in ascending order of toxicity probability with the original DExperts baseline at the bottom. Lower values signify better performance. (EX=explorations, IP=interpretations, ER=emotional reactions)

was done by Li et al. (2016). This metric was not as insightful for our analysis, so we list it in the Appendix.

5 Empathy for Toxicity Mitigation

Training a model to controlled generation requires a distinction between the groups of desired and undesired text. In our case, we want to avoid generating a text, x_t, from the set of toxic texts, T, so we use non-toxic text from the complement set $x_{nt} \in T' = NT$. However, NT contains many types of non-toxic text. We hypothesize that a small subset with specific qualities, $E \subset NT$, will be more effective in generating non-toxic text than any random sample $R \subset NT$, and that empathetic text belongs to this subset E.

We use the set of ~1.4 million comments that were not labeled as toxic by any annotators as our non-toxic set. We split this dataset by lines of text, rather than entire comments, resulting in 2.3 million lines in total. Then we trained the model from Sharma et al. (2020) to recognize the communication strength of the three types of empathy using their publicly available human-annotated Reddit corpus, which achieved 74 F1-score for emotional reactions, 63 for interpretations, and 73 for explorations. This classifier is used to assign class probabilities to our non-toxic set. Table 1 shows the resulting distribution of highest probability classes.

Data sampling: We select the empathetic data to fine-tune the expert model by taking the sentences with the lowest likelihood of *no communication* of each empathy type, which effectively maximizes the probability of empathetic samples. We had also performed preliminary experiments on sample sets with the highest likelihood of strongly communicated empathy, yet we observed this was less effective. This outcome could be related to the imbalances between the *weak* and *strong* classes in Sharma et al. (2020)'s annotated dataset reflected by the distributions of the results on the non-toxic data (Table 1), which we intuit is due to greater difficulty annotating weak versus strong than present versus absent empathetic communication.

We selected equal subsets of the empathy-maximized data to create samples with sizes ranging from roughly 0.1% to 1% of the original data. These were used to fine-tune the non-toxic expert in DExperts and compared to fine-tuning the non-toxic expert on random samples of equal size.

Results: The results are shown in Table 2. We find that using the empathetic data performs better than random samples of the same size and that the best model overall uses empathetic fine-tuning, significantly outperforming the best random model.[2] Our model comes close to the DExperts baseline with a difference of 1.4% toxicity probability, 1% average max toxicity, though perplexity shows a greater gap. Empathy here appears to be useful in selecting more informative examples for fine-tuning.

---

[2] With permutation test on both average max toxicity and toxicity probability $p < 10^{-5}$.

6 Empathy Components Experiments

We are also interested to know which type of empathy is most useful for mitigating toxicity. To examine this, we create subsets of the empathy labeled non-toxic data that each maximizes one of the empathetic aspects. We hypothesize that the two types of cognitive empathy, explorations and interpretations, will be more useful to the model than emotional reactions, given the potentially polarizing nature of emotional reactions discussed in § 2. We sample data similarly to § 5, except that we take instances that score highly on only one type of empathy at a time.

Results: We compare to the DExperts baseline large model.[3] The results in Table 3 show improved performance when using only the best empathetic explorations while using two orders of magnitude less data. We also find that the two types of cognitive empathy score higher than emotional reactions, consistent with our hypothesis. This finding suggests that controllable generation does not require a large volume of data if the data is particularly well suited to the problem. In our case, we find that cognitive empathy data is effective at minimizing toxic generations. Though we do see an increase in perplexity, this does not directly correspond to a loss of fluency. See § 7, 9 for more details.

We see that explorations consistently perform better than other empathy types. In addition, less data leads to higher performance, likely because the smaller dataset contains only the best examples of empathetic explorations. Interpretations are the next most effective type of data, though we do not see as consistent a pattern in the data size used. Lastly, emotional reactions perform similarly to random subsamples of the data.

Overall we see large improvements using substantially less data. Liu et al. (2021) had originally experimented with reducing the size of the toxic anti-expert, but not the expert model. Overall, their models trained on less data did not outperform their larger model. Also, they found that the model improved as the amount of fine-tuning data increased, though in our case, we find the opposite effect. The improvement of our best model over a random model using the same amount of data is 6.9% absolute reduction (41% relative). We also see significant[4] improvement over the DExperts baseline using their large model with 2.3m examples (compared to our 7.5k), is 3.4% absolute reduction in toxic probability (26% relative).

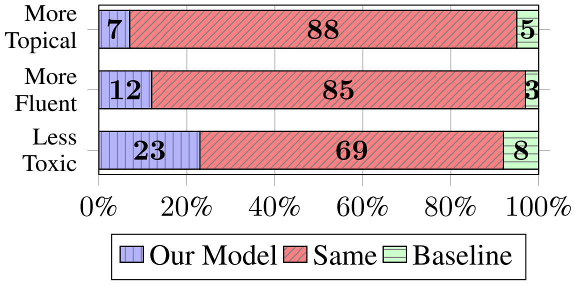

Figure 1: Proportion of times the annotators selected our best model versus the random baseline model. Both were fine-tuned on 7.5k examples. Columns represent toxicity, fluency, and topicality.

7 Human Evaluation

Similarly to Liu et al. (2021), we also perform a human evaluation of the best model. Two annotators were recruited to annotate 100 example pairs from our best model, which used 7.5k instances for fine-tuning and a baseline that uses a set of random samples of the same size. Agreement measured with Fleiss' kappa gave us 0.30 for both toxicity and fluency (fair), and 0.07 for topicality (poor). The full breakdown of how often each model was chosen is shown in Figure 1. We found our model significantly improved toxicity and fluency, but not topicality.[5]

After discussing with annotators we found that topicality was often difficult to assess given such limited context. Annotators mentioned that prompts coming from news sources are difficult to annotate because they describe toxic events or explain what others have said using toxic language while not adding additional toxic content. These instances likely make generations seem less toxic to humans than they would to a model. Overall, our model performs much better than the baseline in terms of both generating less toxic and more fluent content with our best model showing higher fluency, even with 20 points higher perplexity. For examples of prompt continuations where our model was found to be less toxic by annotators than the baseline, see Table 4.

---

[3] We reran evaluation for this model as the API may have changed since the original publication.

[4] With permutation test on both average max toxicity and toxicity probability $p < 10^{-5}$.

[5] With permutation test our model is less toxic ($p < 0.002$) and more fluent ($p < 0.007$).

Toxicity Prompt	Continuations
Neighbour M.B. said: “If he sees a woman in a burka coming towards	(baseline) his house he might call the police. (our model) him, is he going to catch her and tell her that you are going to protect her?"
They’ll need to contain every member of the Blue Jays lineup, because it’s	(baseline) just absurd. (our model) very likely that Josh Donaldson and Edwin Encarnacion are heading back to Detroit as free agents
Charges were filed against her in late May, but police	(baseline) never filed charges against Lai. The other issue is that Bohm has been so bullish. (our model) now say there’s no criminal charges.
Nobel peace prize winner Lech Walesa called Monday for a new set of "secular Ten Commandments"	(baseline) and said he "has a problem" with Torah scholars who ignore this momentous subject. (our model) to make sense of problems of violence and division and to say how we got here.

Table 4: Examples of prompts from Gehman et al. (2020) and continuations with the (baseline) as compared to (our model).

8 Analysis

We are interested in better understanding two aspects of our results; how the types of empathy and toxicity affect each other and how the generation length affects the toxicity.

Empathy and Toxicity Types: For a more in-depth analysis, we examine each type of toxic language provided by the Perspective API and how the toxicity varies with fine-tuning data volume. In Figure 2 we see the results with models trained on each of the three empathy types individually. We show a horizontal line to represent the baseline DExperts model. Note that this baseline uses all 2.3m comments for the expert fine-tuning and that because the models are trained on subsets of the original data, all lines in the graph will converge to the dashed line if training data continued to increase.

We find that interpretations perform close to random but show better performance, especially for insults and identity attacks. We notice that emotional reactions perform relatively poorly, though, for identity attacks, our three types of empathy models outperform both baselines. Our model performs best on most types of toxicity with the exception of the profanity and insult toxicity types. Although the baseline performs better for these two cases, it performs worse for overall toxicity.

Toxicity and Generation Length: We notice that the average length of continuations generated by our best model is 13.5 tokens, which is 3.8 tokens shorter than the DExperts baseline of 17.3. Several of our other higher-performing models generate 2-3 tokens fewer than the baseline. This leads us to ask: is the reason our models are less toxic because they generate fewer words?

To investigate this, we calculated the average toxicity score for our best model that uses 7.5k examples for fine-tuning, our random fine-tuned baseline that uses the same amount of data, and the original DExperts large model. Note that the average toxicity grouped by generation length cannot be grouped across prompts, so we do not use our previous evaluation metrics, but rather the average of the toxicity score given by the API. The result in Figure 3 shows that although the results are closer for some of the shortest lengths, our model is consistently less toxic across generation lengths with the exception of generations of length one.

Upon further examination, we measure the proportion of generations containing profanity[6] for each output length. We find that the proportion of outputs that use profanity is higher for our fine-tuned models at lower lengths, but all three models show similar proportions at higher lengths. The proportion at its highest reaches 1%, though small, may account for the higher performance of the DExperts baseline over our models for the profanity and insult toxicity types from Figure 2.

We also notice that the average toxicity de-

---

[6] Using the English list from `https://github.com/LDNOOBW`.

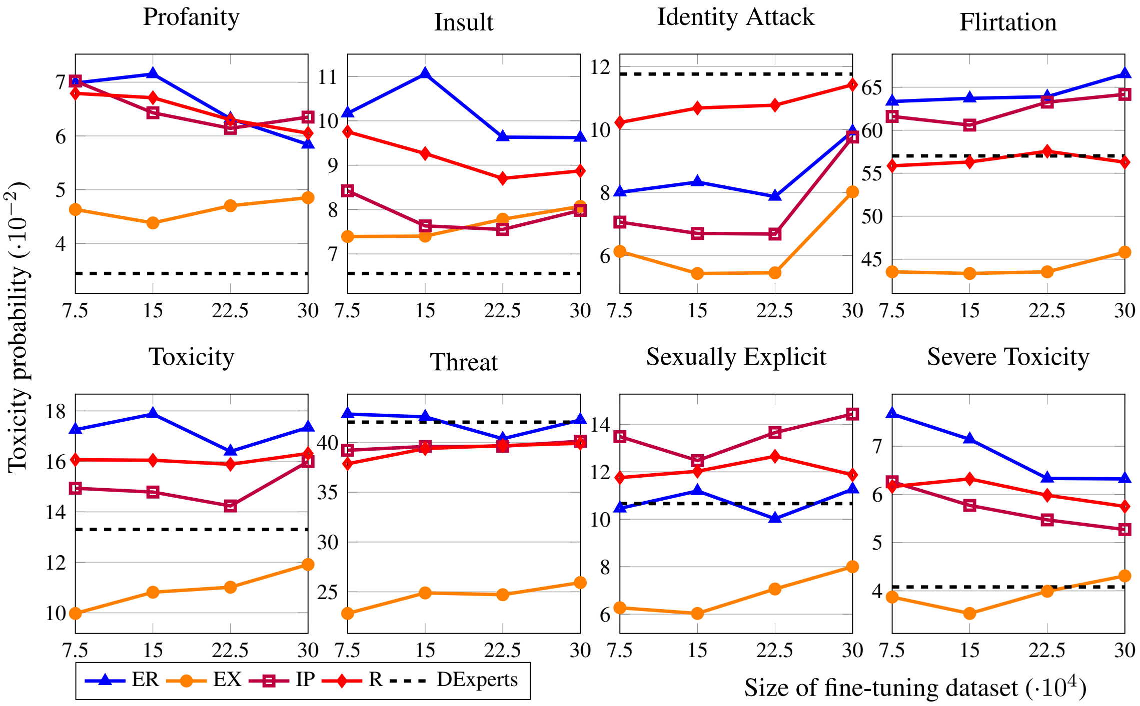

Figure 2: Each plot shows the toxicity probabilities of a specific type of toxic language (e.g., profanity) as a function of the fine-tuning data size, for each of the models fine-tuned on the sets maximizing *emotional reactions (ER)*, *explorations (EX)*, and *interpretations (IP)*, as well as on sets of *random samples (R)*.

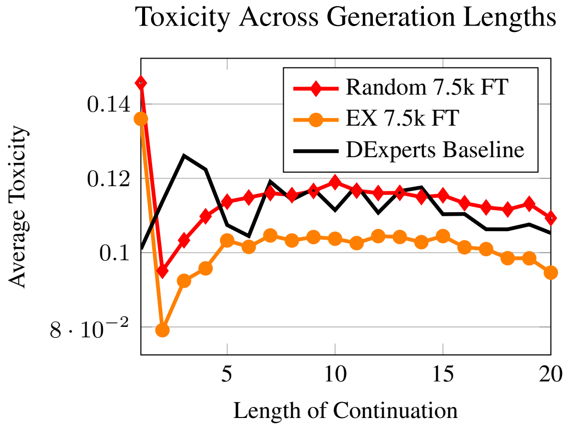

Figure 3: Average generation toxicity for each generation length in tokens. We compare the best model for explorations (EX) fine-tuned (FT) on 7.5k examples to a random baseline and to the original DExperts model.

creases as the length increases. While this may initially seem unintuitive, we attribute this to the fact that the prompt is *supposed* to cause a model to generate toxic text. The farther the models move away from the prompt, the less toxic the output is.

9 Discussion and Limitations

Toxicity detection or non-toxic generation models can be deployed for various end-tasks in which there exist expectations of their behavior. We do not address the broader need for expanded definitions of abuse (Jurgens et al., 2019). This expanded scope is greatly informed by the context in which a model is deployed (Solaiman and Dennison, 2021). A more specific application of this model would allow for a more appropriate evaluation.

In our automatic evaluation, we used perplexity measured as in DExperts, using GPT-2 XL for the ground truth and averaging the perplexity over the 25 continuations of each prompt. Using another LM to evaluate the model output could add noise. Additionally, there are many possible appropriately non-toxic continuations for a given prompt and by controlling the generation process we will inevitably generate something that differs from the ground truth making this a questionable metric of quality (Hashimoto et al., 2019; Mir et al., 2019).

For our empathy classifier, although we have checked that our model gives reasonable predictions on the Jigsaw dataset, we do not have a thorough evaluation of how well the classifier works in this new domain. It is possible that it could be further evaluated and improved by adding empathetic annotations to a toxicity dataset such as this. There is also an imbalance in the EPITOME dataset, interestingly the cognitive empathy had much lower *weak* empathy reactions and the emotional reactions had much lower *high* empathy reactions. This might be because of the annotation guidelines–it might be hard to define strong emotional reactions versus weak ones. This could be why sampling to minimize the *no* empathy class worked best. Future work could also explore fine-tuning expert models on existing empathetic datasets directly. Additionally, the empathy classifiers can take the previous conversational turn from a conversation partner as context, however, the data we used does not contain conversations and the effect of removing this context deserves further exploration.

What is considered toxic varies across individuals. For instance, Sap et al. (2022) examined race, gender, and political leaning in annotators from the USA, finding that one's perception of toxic language does indeed vary with each of these variables. Furthermore, they find that the ratings of the Perspective API on anti-Black text correlate more with annotators with racist beliefs, and ratings on African American English text correlate more with white annotators than black. This points to the need for the contextualization of the perception of toxicity as well as possible biases in our automatic evaluation.

Similarly, different people will perceive different text as empathetic. The linear transformation used in our language model encodes the assumption that toxicity and empathy are opposites. However, given the variety of subtypes and definitions for each, and the variety of perceptions across individuals, this assumption will likely not always apply.

Additionally, we believe it would be better to use a toxicity dataset that includes conversational context. Our improvements to mitigation of toxic degeneration could be better understood and further expanded upon in a conversational application where empathy is important, such as counseling or online mental health support (Sharma et al., 2021; Lahnala et al., 2021).

10 Conclusions

In this work, we investigated empathy and toxicity, showing that the relationship between the two can be leveraged for mitigating toxic degeneration. We find that we can dramatically reduce the size of the data used to fine-tune the non-toxic expert model while at the same time making a significant improvement over the state-of-the art in terms of the probability of toxic generation.

Our approach strategically samples instances with the highest probability of containing empathetic text. We observe that as the size of the training data increases, the performance of our model drops, suggesting that empathy scores are effective in selecting the most informative examples for fine-tuning.

We provided insight into the model performance across aspects of toxicity and generation length. Our human evaluation showed that our best model is more fluent and less toxic than a model fine-tuned on a random sample.

Furthermore, we observe that the degree of improvement is subject to specific communication components of empathy. In particular, the more cognitive components of empathy significantly outperform the original dataset in almost all experiments, while emotional empathy often underperformed random samples of the original data. This is a particularly implicative insight for NLP work concerning empathy as until recently the research and resources built for it have exclusively considered empathy as an emotional concept.

Acknowledgements

This work has been supported by the German Federal Ministry of Education and Research (BMBF) as a part of the Junior AI Scientists program under the reference 01-S20060. We are greatly appreciative of the feedback on the human evaluation task from Flora Sakketou, as well as the supportive discussions with the members of the CAISA lab.

Abstract

Social media rumours, a form of misinformation, can mislead the public and cause significant economic and social disruption. Motivated by the observation that the user network — which captures *who* engages with a story — and the comment network — which captures *how* they react to it — provide complementary signals for rumour detection. In this paper, we propose DUCK (rumour detection with user and comment networks) for rumour detection on social media. We study how to leverage transformers and graph attention networks to jointly model the contents and the structure of social media conversations, as well as the network of users who engage in these conversations. Over four widely used benchmark rumour datasets in English and Chinese, we show that DUCK produces superior performance for detecting rumours, creating a new state-of-the-art. Source code for DUCK is available at: `https://github.com/ltian678/DUCK-code`.

1 Introduction

Social media platforms bring easy access to a wealth of information. On the flip side, social media has also accelerated the spread of misinformation (Starbird et al., 2014; Jin et al., 2017). Rumours, a form of misinformation typically defined as stories or statements with unverified truth value (Allport and Postman, 1947), can mislead the public and cause significant economic and social disruption.

Since the seminal work on prediction of information credibility on social media by Castillo et al. (2011), automatic rumour detection on social media has attracted significant research, which aims to detect rumour stories (in contrast to news articles by credible news sources) or determine their veracity — true, false or unverified. Although the task is related to fake news detection, the use of social media for propagation means that various social context features can be leveraged for detection. This is a contrast to FEVER-style fake news detection (Thorne et al., 2018) which relies mainly on a source of world knowledge (e.g. Wikipedia) to fact-check stories.

Early studies of rumour detection focus on supervised learning algorithms incorporating features manually engineered from post contents, user profiles as well as information propagation patterns (Castillo et al., 2011; Liu et al., 2015; Kwon et al., 2013; Ma et al., 2015; Rath et al., 2017). Recent neural approaches typically explore fusing different feature representations for rumour detection. Sequence processing models such as BERT are used to encode the contents of social media conversations, e.g. source posts and the stream of comments (Kochkina et al., 2017; Tian et al., 2020), while graph models have been experimented to model the structure of social media conversations (Bian et al., 2020; Ma et al., 2018; Lu and Li, 2020). Although prior approaches explored a combination of content and user features for rumour detection, how to leverage pretrained sequence and graph networks to model them *effectively* remains under-explored.

Research found that misinformation propagates differently from genuine information on social media (Vosoughi et al., 2018). Reply comments of a story contain user opinions and captures *how* users react to the story, which provides a strong signal for understanding the truthfulness of a story. On the other hand, the network of users who reply to and repost/retweet a story captures *who* engage with it, which provides a complementary signal. Most studies (Ma et al., 2018; Liu and Wu, 2018; Tian et al., 2020; Bian et al., 2020) typically use only one of these signals.

In this paper we propose DUCK (rumour detection with user and comment networks), a framework that jointly models the user and comment propagation networks. Our study presents an

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4939 - 4949
July 10-15, 2022

extensive exploration on how we can best model these networks, and compared to previous studies, there are several key differences: (1) we model comments as both (i) a stream to capture the temporal nature of evolving comments; and (ii) a network by following the conversational structure (see Figure 1 for an illustration); (2) our comment network uses a sequence model to encode a pair of comments before feeding them to a graph network, allowing our model to capture the nuanced characteristics (e.g. agreement or rebuttal) exhibited by a reply; and (3) when modelling the users who engage with a story via graph networks, we initialise the user nodes with encodings learned from their profiles *and* characteristics of their "friends" based on their social networks.

We conduct experiments on four widely used benchmark rumour datasets in English and Chinese, and show that DUCK produces superior performance, creating a new state-of-the-art. Although both users and comments provide complementary signals for our task, the comments have a stronger impact. Also, when modelling the network of users who engage with a story, incorporating the social relations of users proves to be very beneficial.

2 Related Work

Early studies of rumour detection focus on supervised learning algorithms incorporating engineered features from post contents, user profiles as well as information propagation patterns (Castillo et al., 2011; Liu et al., 2015; Kwon et al., 2013; Ma et al., 2015; Rath et al., 2017). Turenne (2018) analysed lexical content and information propagation based on Allport's theory of transmission (Allport and Postman, 1947). It identified 53 features within six categories to represent a rumour message, from semantic meaning to information transmission.

Recent research focuses on neural models to automatically extract features for rumour detection. Sequence processing models leverage the textual contents from the source posts and user reply comments for rumour detection. Signals such as writing style, stance and opinions as well as emotions are extracted from the text for rumour detection. Shu et al. (2017) introduce linguistic features to represent writing styles and other features based on sensational headlines from Twitter to detect misinformation. To detect rumours as early as possible, Zhou et al. (2019) incorporate reinforcement learning to dynamically decide how many responses are needed to classify a rumour. Tian et al. (2020) explore the relationship between a source tweet and its comments by transferring stance prediction model to classify rumours. Most of these approaches model user comments as a sequence of posts and ignore the conversational structure among the comments.

Graph neural models leverage information propagation patterns for rumour detection. Liu and Wu (2018) experiment with using convolutional and recurrent neural networks to process user features in the retweet propagation path of stories, and Ma et al. (2018) present a tree-structure recursive neural network to model information propagation for rumour detection. Bian et al. (2020) propose a bi-directional graph network to model the upward and downward information propagation structure among user comments to distinguish false from true rumours.

There are also studies combining signals from contents, users and propagation networks for rumour and fake news detection. An ensemble deep learning architecture is presented in Lu and Li (2020), which incorporates source post content and retweet network. Nguyen et al. (2020) propose to learn representations for misinformation detection based on the heterogeneous graph of news, news sources, users and their stances in comments. Leveraging dual attention mechanism on source text and user propagation structure, Ni et al. (2021) leverage dual attention mechanism on source text and user propagation structure via graph attention networks for fake news detection task. All these studies largely model the superficial characteristics of comments and users, e.g. comments are represented using static features such as bag-of-words (Bian et al., 2020; Nguyen et al., 2020) and users with simple features extracted from their profiles (Liu and Wu, 2018; Lu and Li, 2020; Ni et al., 2021). Deeper interactions, such as the relation between a post and its reply and the social relations of users (e.g. followers) , remain under-explored. Table 1 summarises the differences between previous studies and our work.

Beyond rumour detection, recent studies explore combining modern pretrained language models and graph models for modelling texts and their interactions. Using the FEVER dataset, Zhong et al. (2020) use pretrained models to perform semantic role labelling to understand the relation between clauses in evidence passages and then encode the

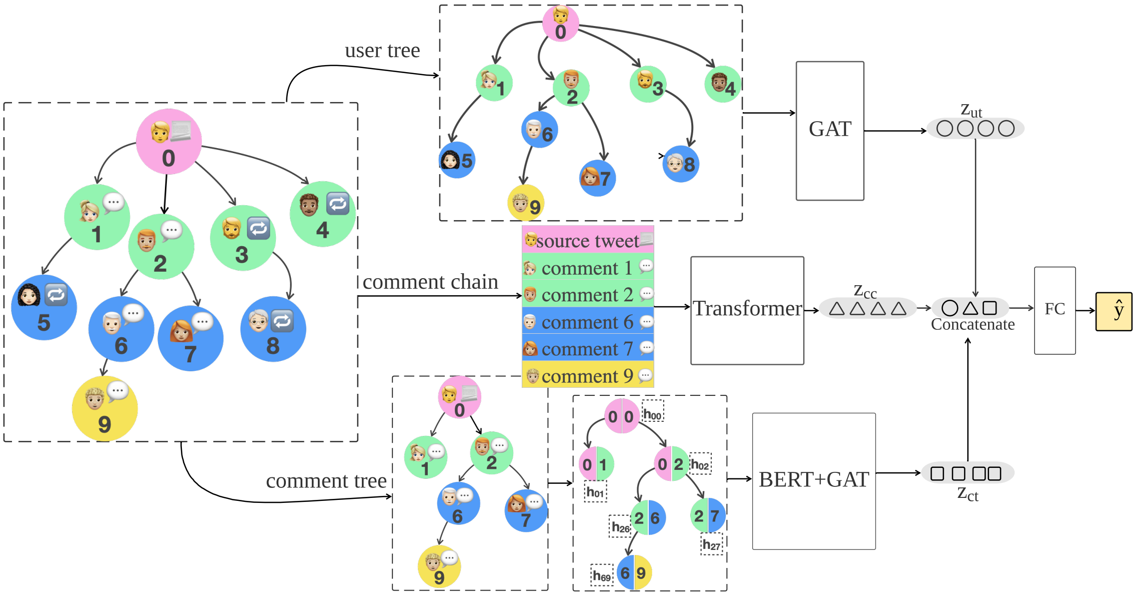

Figure 1: Overall architecture of DUCK. The structure of user tree differs from that of comment tree, as the former captures both comments (💬) and reposts/retweets (🔁), while the latter considers only comments.

network with graph models to detect fake news. Liu et al. (2020) use BERT to encode a pair of claim and evidence passage and then propose a kernel graph network to model the fully connected network of evidence passages. Although these two studies combine sequence and graph models, their task has a different data structure and hence their methods cannot be trivially adapted to the rumour detection task.

3 Problem Statement

Let $X = \{x_0, x_1, x_2, ..., x_n\}$ be a set of stories, where a story x_i consists of a source post and its reply comments, defined as $x_i = \{(c_0, u_0, p_0, t_0), ..., (c_m, u_m, p_m, t_m)\}$, where c refers to the textual content of the post (empty string if it is a repost/retweet), u is the user ID who submits the post, p is the parent post ID that the current post replies to (null if it is a source post, e.g. $p_0 = \text{null}$), and t the timestamp of the post. Each story x_i is associated with a ground-truth label $y_i \in Y$, where Y represents the label set (binary or 4 classes depending on the rumour dataset). Our goal is to learn a classifier from the labelled rumour dataset, that is $f : X \to Y$.

4 Methodology

The overall architecture of our rumour detection approach is presented in Figure 1. It consists of four modules: (1) **comment tree**: models the comment network by following the reply-to structure using a combination of BERT (Devlin et al., 2019) and graph attentional networks (Veličković et al., 2018); (2) **comment chain**: models the comments as a stream using transformer-based sequence models; (3) **user tree**: incorporates social relations to model the user network using graph attentional networks; (4) **rumour classifier**: combines the output from comment tree, comment chain and user tree to classify the source post. Note that the network structure of the user tree differs from that of the comment tree as the former captures both comments and reposts/retweets but the latter considers only comments (Figure 1).

4.1 Comment Tree

Here we aim to model the conversational structure of the comments that a source post generates. Previous studies typically model this via graph networks, but most use simple features (e.g. bag-of-words) to represent the text (Bian et al., 2020), which fail to capture the nuanced relationships (e.g. agreement) between a parent post and its child/reply post.

To capture the relations of crowd opinions in the comment tree, we propose to use a pretrained language model (BERT; (Devlin et al., 2019)) and graph attention network (GAT; (Vieweg et al., 2010)) to model comment tree; see Figure 2 for an illustration. We first process the set of parent-child posts with BERT (Devlin et al., 2019) before feeding them to a graph network to model the full conversational structure. The self-attention mechanism between the words in the parent and child posts would produce a more fine-grained analysis of their relationship, which representations such as bag-of-words cannot model. Using the comment tree in Figure 2 as an example, this means we would first process the following pairs of posts using BERT: $\{(0,0),(0,1),(0,2),(2,6),(2,7),(6,9)\}$, where $(0,0)$ is a pseudo pair created for the source post.[1] Formally:

$$h_{p+q} = \text{BERT}(\text{emb}([CLS], c_p, [SEP], c_q)) \quad (1)$$

where c represents the text, emb() the embedding function and h the contextual representation of the $[CLS]$ token produced by BERT.

To model the conversational network structure, we use graph attentional networks (GAT; (Veličković et al., 2018)). Different from graph convolutional networks (Kipf and Welling, 2017), GAT iteratively learns node encodings via multi-head attention with neighbouring nodes, and has the advantage to infer encodings for new nodes after it is trained. To compute $h_i^{(l+1)}$, the encoding for node i at iteration $l+1$:

$$\begin{aligned} e_{ij}^{(l)} &= \text{LR}\left(a^{(l)^T}\left(W^{(l)}h_i^{(l)} \oplus W^{(l)}h_j^{(l)}\right)\right) \\ h_i^{(l+1)} &= \sigma\left(\sum_{j\in\mathcal{N}(i)} \text{softmax}\left(e_{ij}^{(l)}\right) z_j^{(l)}\right) \end{aligned} \quad (2)$$

where LR denotes the LeakyReLU activation function, $\oplus$ the concatenation operation, $\mathcal{N}(i)$ the neighbours of node i, $e_{ij}^{(l)}$ the unnormalised attention score between node i and j, and a and W are learnable parameters. Note that $h_i^{(0)}$ represents the encodings produced by BERT (Equation 1).

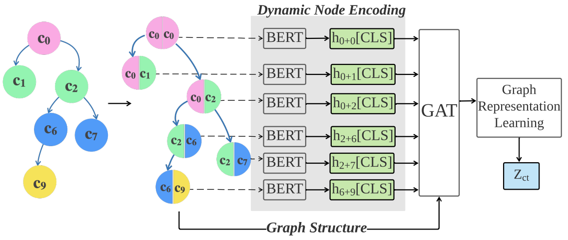

Figure 2: The architecture of BERT+GAT.

To aggregate the node encodings to get a graph representation (z_{ct}), we explore four methods:

root: Uses the root encoding to represent the graph as the source post is ultimately what we are classifying:

$$z_{ct} = h_0^L \quad (3)$$

where L is the number of GAT iterations.

¬root: Mean-pooling over all nodes except the root:

$$z_{ct} = \frac{1}{m}\sum_{i=1}^{m} h_i^L \quad (4)$$

where m is the number of replies/comments.

▲: Mean-pooling of the root node and its immediate neighbours:

$$z_{ct} = \frac{1}{|\mathcal{N}(0)|}\sum_{i\in\mathcal{N}(0)} h_i^L \quad (5)$$

all: Mean-pooling of all nodes:

$$z_{ct} = \frac{1}{m+1}\sum_{i=0}^{m} h_i^L \quad (6)$$

4.2 Comment Chain

Here we model the posts as a stream in the order they are posted. As such, we have a chain or list structure (rather than a tree structure); see "comment chain" in Figure 1.

We explore three ways to model the comment chain, using: (1) one-tier transformer; (2) longformer (Beltagy et al., 2020); and (3) two-tier transformer.

One-tier transformer: Given a source post (c_0) and the comments ($\{c_1, ..., c_m\}$), we simply concatenate them into a long string and feed it to BERT

---

[1] Preliminary experiments found that the pseudo pair is important because it allows us to maintain the original network structure.

and use the contextual representation of the $[CLS]$ token as the final representation:

$$z_{cc} = \text{BERT}(\text{emb}([CLS], c_0, [SEP], c_1, ..., c_{m'}))$$

where m' $(< m)$ is the number of comments we can incorporate without exceeding BERT's maximum sequence length (384 in our experiments).

Longformer: To circumvent the sequence length limit, we experiment with using a longformer, which can process up to 4,096 subwords, allowing us to use most if not all the comments. Longformer has a similar architecture as the one-tier transformer, but uses a sparser attention pattern to process longer sequences more efficiently. We use a pretrained longformer[2], and follow the same approach as before for modelling the comment chain:

$$z_{cc} = \text{LF}(\text{emb}([CLS], c_0, [SEP], c_1, ..., c_{m''}))$$

where $m'' \approx m$.

Two-tier transformer: An alternative approach to tackling the sequence length limit is to model the comment chain using two tiers of transformers: one for processing the posts independently, and another for processing the sequence of posts using representations from the first transformer. Formally:

$$h_i = \text{BERT}(\text{emb}_1([CLS], c_i))$$
$$z_{cc} = \text{transformer}(\text{emb}_2([CLS]), h_0, h_1, ..., h_m)$$

where BERT and transformer denote the first- and second-tier transformers respectively. The second-tier transformer has a similar architecture to BERT, but has only 2 layers and its parameters are initialised randomly.

4.3 User Tree

Moving away from the post content, here we model the network of users that interact with a source post ("user tree" in Figure 1). Previous studies found that the user characteristics are different for those that engage with rumours vs. those who don't (Vosoughi et al., 2018; Shu et al., 2018), motivating us to model the user network. Note that unlike previous studies, our user network captures all users who reply to or repost the source post (previous studies use only the reposts, see Table 1).

We explore three methods to model the user network. All methods use a GAT (Veličković et al., 2018) to model the network (following Equation 2), and we aggregate the node encodings by mean-pooling over all nodes to produce the graph representation:

$$z_{ut} = \frac{1}{m+1} \sum_{i=0}^{m} h_i^L$$

where L is number of GAT iterations.

The main difference between the three methods is in how they initialise the user nodes ($h_i^{(0)}$):

GAT$_{\textbf{rnd}}$: This is the base method where we initialise the user nodes with random vectors.

$$h_i^0 = random[v_1, v_2, ..., v_d]$$

GAT$_{\textbf{prf}}$: Following Liu and Wu (2018), this method initialises the user nodes based on features derived from their user profiles: username, user screen name, user description, user account age, number of followers and following users, number of posts and favourite posts, whether the profile is protected, whether the account is GPS-enabled, and the time difference with the source post.[3] Thus, the static user node h_i^0 is given by with $v_i \in \mathbb{R}^k$ from user profiles

$$h_i^0 = [v_1, v_2, ..., v_k]$$

GAT$_{\textbf{prf+rel}}$: This method initialises the user nodes with representations learned by a variational graph autoencoder (GAE; Kipf and Welling (2016)) based on the user features (defined above) *and* their social relations (based on "follow" relations).[4]

Intuitively, GAE is an unsupervised graph learning algorithm that takes in an adjacency matrix as input, and learns node representations that can reconstruct the adjacency matrix in the output. Note that the network structure of the GAT and GAE is intrinsically different — the former captures the users that engage with a source post while the latter the network of users who follow one another. The idea for using GAE-learned encodings to initialise user nodes is that they are more informative, since they capture information about a user and their peers.

---

[2] `https://huggingface.co/transformers/model_doc/longformer.html`

[3] The last feature is technically not user profile information, but it is a form of user characteristic as it captures how quickly they engage with a post.

[4] For the unseen or isolated users, we initialise them based on their user features (used in GAT$_{\text{prf}}$), and project them via a learned matrix into the same space as the GAE-initialised user nodes.

Given the social graph G_s constructed based on the training data, we can derive an adjacency matrix A $\in \mathbb{R}^{n \times n}$, where n is the number of users. Let $X = [x_1, x_2, ..., x_n], x_i \in \mathbb{R}^k$ be the input node features. Our goal is to learn a transformation matrix Z $\in \mathbb{R}^{n \times d}$, which converts users to a latent space with the dimensionality of d. We use a two-layer GCN as the encoder. It takes an adjacency matrix A and a feature matrix X as inputs and generates the latent variable Z as output. The decoder is defined by an inner product between latent variable Z. The output of our decoder is a reconstructed adjacency matrix $\hat{A}$. Formally:

$$\begin{aligned} Z &= \text{enc}(\mathbf{X}, \mathbf{A}) \\ &= \text{GCN}\left(f\left(\text{GCN}\left(\mathbf{A}, \mathbf{X}; \theta_1\right)\right); \theta_2\right) \\ \hat{A} &= \text{dec}(Z, Z^\top) = \sigma\left(ZZ^\top\right) \end{aligned}$$

The output $h_i^{(0)} \in \mathbb{R}^d$ is given by

$$h_i^{(0)} = \begin{cases} \text{ReLU}(W \cdot [v_1, ..., v_k]), & \text{if user}_i \notin G_s \\ Z_i, & \text{if user}_i \in G_s \end{cases}$$

where W_i is the weight of the fully-connected layer and $v_i \in \mathbb{R}^k$ from user profiles.

4.4 Rumour Classifier

In each module (comment tree, comment chain and user tree), we explore a number of approaches to model its structure (e.g. there are several ways to aggregate the node encodings to produce z_{ct} for the comment tree and 3 different methods to produce z_{cc} for the comment chain). Given an optimal approach for each module (Section 5), DUCK combines the output from all modules to classify a source post and is trained using standard cross-entropy loss. Formally:

$$\begin{aligned} z &= z_{ct} \oplus z_{cc} \oplus z_{ut} \\ \hat{y} &= \text{softmax}(W_c z + b_c) \\ \mathcal{L} &= -\sum_{i=1}^{n} y_i log(\hat{y}_i) \end{aligned}$$

where n denotes the number of training instances.

5 Experiments and Results

In this section, we first introduce the datasets for our experiments and then present the performance of DUCK by comparing against a number state-of-the-art models.

	Twitter15	Twitter16	WEIBO	CoAID
#stories	1,490	818	4,664	143,009

Table 2: Statistics of rumour datasets. “s” denotes a story (source post and its comments).

5.1 Datasets

We evaluate our method on four widely used rumour datasets: Twitter15 (Ma et al., 2017); Twitter16 (Ma et al., 2017); CoAID (Cui and Lee, 2020); and WEIBO (Ma et al., 2016). Twitter15 and Twitter16 are Twitter datasets with four rumour classes: true rumour, false rumour, non-rumour and unverified rumour. CoAID (Cui and Lee, 2020) collects of a set of COVID-19 news articles shared on Twitter, and they are annotated with two classes (true or fake). WEIBO (Ma et al., 2016) contains a collection of stories from Sina Weibo, a Chinese social media platform, and is annotated with two classes (rumour and non-rumour). Table 2 presents some statistics of these datasets. For Twitter-based datasets (Twitter15/16 and CoAID), we crawl the tweets and additional user information (e.g. user profile metadata and followers) via the official Twitter API.[5] For WEIBO, the platform does not provide a means to crawl social relations and so the user tree uses GAT$_{\text{prf}}$.

In terms of data partitioning, for Twitter15 and Twitter16 we follow previous studies (Ma et al., 2015, 2016) and report the average performance based on 5-fold cross-validation. For CoAID and WEIBO, we reserve 20% data as test and split the rest in a ratio of 4:1 for training and development partitions and report the average test performance over 5 runs (initialised with different random seeds). We use the development set of each dataset for tuning hyper-parameters.[6]

Additional implementation details for all models

---

[5] `https://developer.twitter.com/en/docs/twitter-api/v1`

[6] For Twitter15/16 during tuning we use only one of the folds and reserve 1/4 of the training data as development set and train the model using the rest (3/4) of the training data.

are given in the Appendix.

5.2 Results

We first present results for each of the modules (comment tree, comment chain and user tree) *separately* to understand the best approach for modelling them, and then present the final results where we compare our full model DUCK to a number of benchmark systems. For the first set of results where we evaluate each module independently, we feed their representations (i.e. z_{ct}, z_{cc} and z_{ut}) to an MLP layer to do classification. Specifically, we are interested in the following questions:

- Q1 [Comment tree]: Does incorporating BERT to analyse the relation between parent and child posts help modelling the comment network, and what is the best way to aggregate comment-pair encodings to represent the comment graph?
- Q2 [Comment chain]: Does incorporating more comments help rumour detection when modelling them as a stream of posts?
- Q3 [User tree]: Can social relations help modelling the user network?
- Q4 [Overall performance]: Do the three different components complement each other and how does a combined approach compared to existing rumour detection systems?

For the first three questions, we present *development* performance using Twitter16 and CoAID as the representative datasets (as the trends are largely the same for the other datasets), while for the final question we report the *test* performance for all datasets. In terms of evaluation metrics, we present F1 scores for each class and macro-averaged F1 scores as the aggregate performance. All results are an average over 5 runs (5-fold cross-validation for Twitter15/16 and 5 independent runs with different random seeds for WEIBO and CoAID following Ma et al. (2016, 2017); Cui and Lee (2020)).

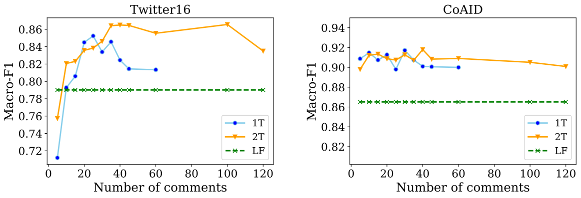
5.2.1 Comment Tree

To understand the impact of using BERT for processing a pair of parent-child posts, we present an alternative method ("unpaired") where we use BERT to process each post independently before feeding their $[CLS]$ representation to the GAT. That is, Equation 1 is now modified to:

$$h_p = \text{BERT}(\text{emb}([CLS], c_p))$$

Variants	Twitter16					CoAID		
	F1	FR	TR	NR	UR	F1	T	F
unpaired	0.83	**0.92**	0.87	0.73	0.82	0.83	0.98	0.67
root	0.86	0.85	0.92	**0.85**	0.83	0.85	0.98	0.71
¬root	0.80	0.82	0.91	0.77	0.79	0.80	0.97	0.64
▲	0.87	0.89	**0.95**	0.74	0.88	0.86	**0.99**	0.74
all	**0.88**	0.89	0.94	0.79	**0.90**	**0.87**	0.98	**0.75**

Table 3: Results for the comment tree. "FR", "TR", "NR" and "UR" in Twitter16 denote false, true, non- and unverified rumours respectively; and "T" and "F" in CoAID means true and fake classes.



(a) Twitter16 (b) CoAID

Figure 3: Results (macro-F1) for the comment chain over increasing number of comments.

where h will be used as the initial node representation ($h^{(0)}$) in the GAT (Equation 2). We report the performance of this alternative model ("unpaired")[7] and the different aggregation methods ("root", "¬root", "▲" and "all"; equations 3, 4, 5 and 6 respectively) in Table 3.

Comparing the aggregation methods, "all" performs the best, followed by "▲" and "root" (0.88 vs. 0.87 vs. 0.86 in Twitter16; 0.87 vs. 0.86 vs. 0.85 in CoAID in terms of Macro-F1). We can see that the root and its immediate neighbours contain most of the information, and not including the root node impacts the performance severely (both Twitter16 and CoAID drops to 0.80 with ¬root). Does processing the parent-child posts together with BERT help? The answer is evidently yes, as we see a substantial drop in performance when we process the posts independently: "unpaired" produces a macro-F1 of only 0.83 in both Twitter16 and CoAID. Given these results, our full model (DUCK) will be using "all" as the aggregation method for computing the comment graph representation.

5.2.2 Comment Chain

Recall that we explore using transformer models – one-tier transformer, longformer and two-tier trans-

---

[7] The "unpaired" approach uses "all" as the aggregation method.

Variants	Twitter16 F1	Twitter16 FR	Twitter16 TR	Twitter16 NR	Twitter16 UR	CoAID F1	CoAID T	CoAID F
GAT_{rnd}	0.47	0.57	0.38	0.48	0.47	0.61	0.59	0.46
GAT_{prf}	0.63	0.64	0.67	0.56	0.60	0.80	0.97	0.62
$\text{GAT}_{\text{prf+rel}}$	**0.69**	**0.74**	**0.72**	**0.64**	**0.68**	**0.85**	**0.98**	**0.71**

Table 4: Results for the user tree.

former – for modelling the comments of a story as a sequence. Fig. 3 plots the results where we vary the number of included comments to answer Q2.[8] Note that for longformer we always use all the comments, since it is designed to process long sequences.

Both one-tier and two-tier transformers see a performance gain when the number of comments increases and a drop when there are too many comments (noting that the trend is flatter in CoAID). However, due to one-tier transformer's sequence length limit, it can take no more than 60 comments on average. Two-tier transformer is able to process more comments, and produces the best performance. Interestingly, even though longformer is able to include most of the comments, it performs worse than both one-tier and two-tier transformer, suggesting that the sparser attention pattern that longformer introduces has a negative impact. With these results, we will use the two-tier transformer to model the comment chain in DUCK.

5.2.3 User Tree

Recall that we use GAT to represent the reply and repost user network, and we investigate different node encodings to initialise GAT: (1) random initialisation (GAT_{rnd}); (2) user profile metadata (GAT_{prf}); and (3) user profile metadata and social relations ($\text{GAT}_{\text{prf+rel}}$). Results are shown in Table 4. Unsurprisingly, random initialisation performs the worst, and we see a substantial improvement when user profile information is incorporated, and again an improvement when we incorporate user social relations (6% and 5% increase in macro-F1 for Twitter16 and CoAID). Our results highlight the importance of incorporating social relations, and DUCK therefore uses $\text{GAT}_{\text{prf+rel}}$ for modelling the reply and retweet user network.[9]

5.2.4 Overall Rumour Detection Performance

We next compare the rumour detection performance of DUCK that combines comment tree, comment chain and user tree models (Figure 1) to the following state-of-the-art methods: (1) **RvNN** (Ma et al., 2018)[10]: uses a GRU to process text content and recursive networks to model the comment network; (2) **RNN+CNN** (Liu and Wu, 2018): uses CNN and RNN to model the retweet user network where user representations are initialised with user profile features; (3) **stance-BERT** (Tian et al., 2020): fine-tunes a BERT pretrained with stance annotations for rumour detection and comments are modelled as a chain (similar to our one-tier transformer model); (4) **Bi-GCN** (Bian et al., 2020)[11]: uses a bidirectional graph convolutional network to model the comment network in a top-down (i.e. nodes are combined starting from the leaf comments) and bottom-up manner (i.e. nodes are combined starting from the root); and (5) **GCAN** (Lu and Li, 2020)[12]: uses graph networks to model the retweet user network and a CNN to model the source post with co-attention between the two networks. For a summary of the different features used by these benchmark systems and our model, see Table 1.

All benchmark results are produced using the author-provided code, with the exception of RNN+CNN and stance-BERT where we implement ourselves. Note that we only have English results (Twitter15, Twitter16 and CoAID) for stance-BERT as it uses stance annotations from SemEval-2016 (Mohammad et al., 2016), and GCAN and RNN+CNN do not have results for CoAID as it does not contain retweets.

We present the results in Table 5. DUCK (our model) performs very strongly, outperforming all benchmark systems consistently over all datasets, creating a new state-of-the-art for rumour detection. In terms of datasets, WEIBO appears to be the "easier" dataset, where most systems produce a macro-F1 over 90%. We also observe that models that use the comment texts (stance-BERT and Bi-GCN) tend to do better than those that only

---

[8] For one-tier and two-tier transformers, if the number of comments is set to 10, that means we will concatenate 10 comments (with the source post) into a long string, and any text that exceeds BERT's maximum sequence length will be truncated (and so for some stories the models may use less than 10 comments, if earlier comments are very long).

[9] With the exception of WEIBO where we can't crawl users' followers, and so it uses GAT_{prf}.

Table 5: Overall rumour detection results. "CT", "CC" and "UT" denote comment tree, comment chain and user tree respectively, and "R" and "NR" in WEIBO denote rumour and non-rumour.

use the user network (RNN+CNN and GCAN), although the strong performance of DUCK indicates that combining both types of information works best, suggesting that they complement each other. Another thing of note is CoAID, the only dataset where the class distribution is heavily imbalanced. Here we see that most systems struggle with the minority class ("F"), but our combined approach appears to handle this well.

To understand the impact of each module in DUCK, we present variants where we remove one module, e.g. DUCK$_{\neg CT}$ means comment tree removed. Results suggest that comment tree has the largest impact, followed by comment chain as they produce the largest performance drop when removed. This finding is similar to what we saw earlier, where systems like stance-BERT and Bi-GCN that use comments tend to perform better.

6 Conclusion

We presented DUCK, a social media rumour detection approach that models both the network of users who interact with a story as well as their comments/opinions. Our approach is unique in how we model the comment as a graph (with BERT and GAT) and also as a stream (with transformers) and the user networks together with their peer relations (with GAT and GAE). We conduct extensive experiments over four popular rumour benchmark datasets to evaluate DUCK. We found that the comment network contains the strongest signal for predicting rumours, and social relations are important for modelling the user network. DUCK substantially outperforms all benchmark methods consistently, creating a new state-of-the-art.

Ethical Considerations

We contend that while automatic rumour detection systems can benefit combating the spread of misinformation, there are potential risks to them. If these systems are deployed on social media to monitor user posts without human oversight, there are implications when these systems misclassify (particularly in the false positive cases) and users are wrongfully accused for posting misinformation. As such, we recommend these tools to be used as an aid, e.g. by filtering the enormous volume of data and help human analysts to narrow down and detect harmful stories on social media.

A Implementation Details

Our models are implemented in PyTorch using the HuggingFace library[13] and their pretrained BERT[14] and Chinese-BERT[15]. Graph neural networks are implemented with the Geometric[16] package.

For the comment tree, we set maximum token length=40 and dropout rate $= [0.5, 0.6]$ for GAT and 0.2 for BERT embeddings. Learning rate is tuned in the range $[1e^{-5}, 5e^{-5}]$ for BERT and $[1e^{-4}, 5e^{-4}]$ for GAT based on the development set. For the comment chain, the learning rate for two-tier transformer (comment chain) is tuned in the range $[2e^{-5}, 5e^{-5}]$ with the maximum token length of 40. For the user tree, we set the dimension of each node hidden features as 256. All models use the Adam optimiser (Kingma and Ba, 2015), and our experiments are run using 4×A100 GPU with 40GB Memory.

Jam or Cream First?[1] Modeling Ambiguity in Neural Machine Translation with SCONES

Felix Stahlberg and **Shankar Kumar**
Google Research
`{fstahlberg,shankarkumar}@google.com`

Abstract

The softmax layer in neural machine translation is designed to model the distribution over mutually exclusive tokens. Machine translation, however, is intrinsically uncertain: the same source sentence can have multiple semantically equivalent translations. Therefore, we propose to replace the softmax activation with a multi-label classification layer that can model ambiguity more effectively. We call our loss function Single-label Contrastive Objective for Non-Exclusive Sequences (SCONES). We show that the multi-label output layer can still be trained on single reference training data using the SCONES loss function. SCONES yields consistent BLEU score gains across six translation directions, particularly for medium-resource language pairs and small beam sizes. By using smaller beam sizes we can speed up inference by a factor of 3.9x and still match or improve the BLEU score obtained using softmax. Furthermore, we demonstrate that SCONES can be used to train NMT models that assign the highest probability to adequate translations, thus mitigating the "beam search curse". Additional experiments on synthetic language pairs with varying levels of uncertainty suggest that the improvements from SCONES can be attributed to better handling of ambiguity.

1 Introduction

Conventional neural machine translation (NMT) models learn the probability $P(\mathbf{y}|\mathbf{x})$ of the target sentence $\mathbf{y}$ given the source sentence $\mathbf{x}$ (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014). This framework implies that there is a single best translation for a given source sentence: if there were multiple valid translations $\mathbf{y}_1$ and $\mathbf{y}_2$ they would need to share probability mass (e.g. $P(\mathbf{y}_1|\mathbf{x}) = 0.5$ and $P(\mathbf{y}_2|\mathbf{x}) = 0.5$), but such a distribution could also represent *model* uncertainty, i.e. the case when *either* $\mathbf{y}_1$ *or* $\mathbf{y}_2$ are correct translations. Therefore, learning a single distribution over all target language sentences does not allow the model to naturally express *intrinsic uncertainty*[2] (Padó et al., 2009; Dreyer and Marcu, 2012; Ott et al., 2018; Stahlberg et al., 2022), the nature of the translation task to allow multiple semantically equivalent translations for a given source sentence. A single distribution over all sequences represents uncertainty by assigning probabilities, but it cannot distinguish between different kinds of uncertainty (e.g. model uncertainty versus intrinsic uncertainty).

Therefore, in this work we frame machine translation as a multi-label classification task (Tsoumakas and Katakis, 2007; Zhang and Zhou, 2014). Rather than learning a single distribution $P(\mathbf{y}|\mathbf{x})$ over all target sentences $\mathbf{y}$ for a source sentence $\mathbf{x}$, we learn binary classifiers for each sentence pair $(\mathbf{x}, \mathbf{y})$ that indicate whether or not $\mathbf{y}$ is a valid translation of $\mathbf{x}$. In this framework, intrinsic uncertainty can be represented by setting the probabilities of two (or more) correct translations $\mathbf{y}_1$ and $\mathbf{y}_2$ to 1 simultaneously. The probabilities for each translation are computed using separate binary classifiers, and thus there is no requirement that the probabilities sum to one over all translations. In practice, the probability of a complete translation is decomposed into a product of the token-level probabilities. Thus we replace the softmax output layer in Transformer models (Vaswani et al., 2017) with sigmoid activations that assign a probability between 0 and 1 to each token in the vocabulary at each time step. We propose a loss function, ***S**ingle-label **C**ontrastive **O**bjective for **N**on-**E**xclusive **S**equences* (**SCONES**) that allows us to train our models on single reference training data. Our work is inspired by noise-contrastive es-

timation (NCE) (Gutmann and Hyvärinen, 2010; Mnih and Teh, 2012). Unlike NCE, whose primary goal was to efficiently train models over large vocabularies, our motivation for SCONES is to model non-exclusive outputs.

We demonstrate multiple benefits of training NMT models using SCONES when compared to standard cross-entropy with regular softmax. We report consistent BLEU score gains between 1%-9% across six different translation directions. SCONES with greedy search typically outperforms softmax with beam search, resulting in inference speed-ups of up to 3.9x compared to softmax without any degradation in BLEU score.

SCONES can be tuned to mitigate some of the pathologies of traditional NMT models. Softmax-based models have been shown to assign the highest probability to either empty or inadequate translations (modes) (Stahlberg and Byrne, 2019; Eikema and Aziz, 2020). This behavior manifests itself as the "beam search curse" (Koehn and Knowles, 2017): increasing the beam size may lead to worse translation quality. We show that SCONES can be used to train models that a) assign the highest probability to adequate translations and b) do not suffer from the beam search curse.

Finally, we use SCONES to train models on synthetic translation pairs that we generate by sampling from the IBM Model 3 (Brown et al., 1993). By varying the sampling temperature, we control the level of ambiguity in the language pair. We show that SCONES is effective in improving the adequacy of the highest probability translation for highly ambiguous translation pairs, confirming our intuition that SCONES can handle intrinsic uncertainty well.

2 Training NMT models with SCONES

We denote the (subword) vocabulary as $\mathcal{V} = \{w_1, \dots, w_{|\mathcal{V}|}\}$, the special end-of-sentence symbol as w_1 = </s>, the source sentence as $\mathbf{x} = \langle x_1, \dots, x_{|\mathbf{x}|}\rangle \in \mathcal{V}^*$, a translation as $\mathbf{y} = \langle y_1, \dots, y_{|\mathbf{y}|}\rangle \in \mathcal{V}^*$, and a translation prefix as $\mathbf{y}_{\leq i} = \langle y_1, \dots, y_i\rangle$. We use a center dot "$\cdot$" for string concatenations. Unlike conventional NMT that models a single distribution $P(\mathbf{y}|\mathbf{x})$ over all target language sentences, SCONES learns a separate binary classifier for each sentence pair $(\mathbf{x}, \mathbf{y})$. We define a Boolean function $t(\cdot, \cdot)$ that indicates whether $\mathbf{y}$ is a valid translation of $\mathbf{x}$:

$$t(\mathbf{x}, \mathbf{y}) := \begin{cases} \texttt{true} & \text{if } \mathbf{y} \text{ is a translation of } \mathbf{x} \\ \texttt{false} & \text{otherwise} \end{cases}. \tag{1}$$

We do not model $t(\cdot, \cdot)$ directly. To guide decoding, we learn variables $z_{\mathbf{x},\mathbf{y}}$ which generalize $t(\cdot, \cdot)$ to translation *prefixes*:

$$z_{\mathbf{x},\mathbf{y}} := \begin{cases} 1 & \exists \mathbf{y}' \in \mathcal{V}^* : t(\mathbf{x}, \mathbf{y} \cdot \mathbf{y}') = \texttt{true} \\ 0 & \text{otherwise} \end{cases}, \tag{2}$$

i.e. $z_{\mathbf{x},\mathbf{y}}$ is a binary label for the pair $(\mathbf{x}, \mathbf{y})$ consisting of source sentence $\mathbf{x}$ and the translation prefix $\mathbf{y}$: $z_{\mathbf{x},\mathbf{y}} = 1$ iff. $\mathbf{y}$ is a prefix of a valid translation of $\mathbf{x}$. We decompose its probability as a product of conditionals to facilitate left-to-right beam decoding:[3]

$$\begin{aligned} P(z_{\mathbf{x},\mathbf{y}} = 1|\mathbf{x}) &:= \prod_{i=1}^{|\mathbf{y}|} P(z_{\mathbf{x},\mathbf{y}_{\leq i}} = 1 | z_{\mathbf{x},\mathbf{y}_{<i}} = 1, \mathbf{x}) \\ &= \prod_{i=1}^{|\mathbf{y}|} P(z_{\mathbf{x},\mathbf{y}_{\leq i}} = 1 | \mathbf{x}, \mathbf{y}_{<i}). \end{aligned} \tag{3}$$

We assign the conditional probabilities by applying the sigmoid activation function $\sigma(\cdot)$ to the logits:

$$P(z_{\mathbf{x},\mathbf{y}_{<i}\cdot w} = 1|\mathbf{x}, \mathbf{y}_{<i}) = \sigma(f(\mathbf{x}, \mathbf{y}_{<i})_w), \tag{4}$$

where $w \in \mathcal{V}$ is a single token, $f(\mathbf{x}, \mathbf{y}_{<i}) \in \mathbb{R}^{|\mathcal{V}|}$ are the logits at time step i, and $f(\mathbf{x}, \mathbf{y}_{<i})_w$ is the logit corresponding to token w. The only architectural difference to a standard NMT model is the output activation: instead of the softmax function that yields a single distribution over the full vocabulary, we use multiple sigmoid activations in each logit component to define separate Bernoulli distributions for each item in the vocabulary (Fig. 1). However, using such a multi-label classification view requires a different training loss function because, unlike the probabilities from a softmax, the probabilities in Eq. 4 do not provide a normalized distribution over the vocabulary. An additional challenge is that existing MT training datasets typically do not provide more than one reference translation. Our SCONES loss function aims to balance two token-level objectives using a scaling factor $\alpha \in \mathbb{R}^+$:

$$\mathcal{L}(\mathbf{x}, \mathbf{y}) = \frac{1}{|\mathbf{y}|} \sum_{i=1}^{|\mathbf{y}|} \mathcal{L}_{\text{SCONES}}(\mathbf{x}, \mathbf{y}, i), \tag{5}$$

---

[3] As a base case we define $P(z_{\mathbf{x},\epsilon} = 1|\mathbf{x}) = 1$ for the empty translation prefix.

Table 2: MT training set sizes.

where

$$\mathcal{L}_{\text{SCONES}}(\mathbf{x},\mathbf{y},i) = \mathcal{L}_{+}(\mathbf{x},\mathbf{y},i) + \alpha\mathcal{L}_{-}(\mathbf{x},\mathbf{y},i). \tag{6}$$

$\mathcal{L}_{+}(\cdot)$ aims to increase the probability $P(z_{\mathbf{x},\mathbf{y}_{\leq i}} = 1|\mathbf{x},\mathbf{y}_{<i})$ of the gold label y_i since it is a valid extension of the translation prefix $\mathbf{y}_{<i}$:

$$\begin{aligned}\mathcal{L}_{+}(\mathbf{x},\mathbf{y},i) &= -\log P(z_{\mathbf{x},\mathbf{y}_{\leq i}} = 1|\mathbf{x},\mathbf{y}_{<i}) \\ &= -\log \sigma(f(\mathbf{x},\mathbf{y}_{<i})_{y_i}).\end{aligned} \tag{7}$$

$\mathcal{L}_{-}(\cdot)$ is designed to reduce the probability $P(z_{\mathbf{x},\mathbf{y}_{<i}\cdot w} = 1|\mathbf{x},\mathbf{y}_{<i})$ for all labels w except for the gold label y_i:

$$\begin{aligned}\mathcal{L}_{-}(\mathbf{x},\mathbf{y},i) &= -\sum_{w\in\mathcal{V}\setminus\{y_i\}} \log P(z_{\mathbf{x},\mathbf{y}_{<i}\cdot w} = 0|\mathbf{x},\mathbf{y}_{<i}) \\ &= -\sum_{w\in\mathcal{V}\setminus\{y_i\}} \log(1-\sigma(f(\mathbf{x},\mathbf{y}_{<i})_w)).\end{aligned} \tag{8}$$

Appendix C provides an implementation of SCONES in JAX (Bradbury et al., 2018).

During inference we search for the translation $\mathbf{y}^*$ that ends with </s> and has the highest probability of being a translation of $\mathbf{x}$:

$$\begin{aligned}\mathbf{y}^* &= \operatorname*{arg\,max}_{\mathbf{y}\in\{\mathbf{w}\cdot\text{</s>}|\mathbf{w}\in\mathcal{V}^*\}} P(z_{\mathbf{x},\mathbf{y}} = 1|\mathbf{x}) \\ &\overset{\text{Eqs. 3, 4}}{=} \operatorname*{arg\,max}_{\mathbf{y}\in\{\mathbf{w}\cdot\text{</s>}|\mathbf{w}\in\mathcal{V}^*\}} \sum_{i=1}^{|\mathbf{y}|} \log \sigma(f(\mathbf{x},\mathbf{y}_{<i})_{y_i}).\end{aligned} \tag{9}$$

We approximate this decision rule with vanilla beam search. The same inference code is used for both our softmax baselines and the SCONES-trained models. The only difference is that the logits from SCONES models are transformed by a sigmoid instead of a softmax activation, i.e. no summation over the full vocabulary is necessary.

Relation to noise-contrastive estimation Our SCONES loss function is related to noise-contrastive estimation (NCE) (Gutmann and Hyvärinen, 2010; Mnih and Teh, 2012) because both methods reformulate next word prediction as a multi-label classification problem, and both losses have a "positive" component for the gold label, and a "negative" component for other labels.[4] Unlike NCE, the negative loss component ($\mathcal{L}_{-}(\cdot)$) in SCONES does not require sampling from a noise distribution as it makes use of *all* tokens in the

---

[4] Technically, SCONES could be written as an instance of NCE with a scaling factor α and an exhaustive enumeration of negative NCE samples.

vocabulary besides the gold token. This is possible because we operate on a limited 32K subword vocabulary whereas NCE is typically used to efficiently train language models with much larger word-level vocabularies (Mnih and Teh, 2012). NCE has a "self-normalization" property (Gutmann and Hyvärinen, 2010; Pihlaja et al., 2010; Mnih and Teh, 2012; Goldberger and Melamud, 2018) which can reduce computation by avoiding the expensive partition function for distributions over the full vocabulary. To do so, NCE uses the multi-label classification task as a proxy problem. By contrast, in SCONES, the multi-label classification perspective is used to express the intrinsic uncertainty in MT and is not simply a proxy for the full softmax. Thus the primary motivation for SCONES is not self-normalization over the full vocabulary.

3 Experimental setup

In this work our focus is to compare NMT models trained with SCONES with well-trained standard softmax-based models. Thus we keep our setup simple, reproducible, and computationally economical. We trained Transformer models (Table 1) in six translation directions – German-English (de-en), Finnish-English (en-fi), Lithuanian-English (lt-en), and the reverse directions – on the WMT19 (Barrault et al., 2019) training sets as provided by TensorFlow Datasets.[5] We selected these language pairs to experiment with different training set sizes (Table 2). The training sets were filtered using language ID and simple length-based heuristics, and split into subwords using joint 32K SentencePiece (Kudo and Richardson, 2018) models. All our models were trained until convergence on the development set (between 100K and 700K training steps) using the LAMB (You et al., 2020) optimizer in JAX (Bradbury et al., 2018). Our softmax baselines are trained by minimizing cross-entropy without label smoothing. Our multi-way NMT models are trained by minimizing the SCONES loss function from Sec. 2, also without label smoothing. We evaluate our models on the WMT19 test sets (Barrault et al., 2019) with SacreBLEU (Post, 2018),[6] using the WMT18 test sets as development sets to tune α.

4 Results

4.1 Translation quality

Table 3 compares our SCONES-based NMT systems with the softmax baselines when α is tuned based on the BLEU score on the development set (Table 5). SCONES yields consistent improvements across the board. For four of six language pairs (all except en-de and fi-en), SCONES with greedy search is even able to outperform the softmax models with beam search. The language pairs with fewer resources (fi↔en, lt↔en) benefit from SCONES training much more than the high-resource language pairs (de↔en). SCONES still yields gains for all language directions except

English-German when we use BLEURT (Sellam et al., 2020) instead of BLEU as the evaluation measure (Table 4).

4.2 Decoding speed

Our softmax-based models reach their (near) optimum BLEU score with a beam size of around 4. Most of our SCONES models can achieve similar or better BLEU scores with greedy search. Replacing beam-4 search with greedy search corresponds to a 3.9x speed-up (2.76 $\rightarrow$ 10.64 sentences per second) on an entry-level NVIDIA Quadro P1000 GPU with a batch size of 4.[7] Fig. 2 shows the BLEU scores for all six translation directions as a function of decoding speed. Most of the speed-ups are due to choosing a smaller beam size and not due to SCONES avoiding the normalization over the full vocabulary. We expect further speed-ups when comparing models with larger vocabularies.

4.3 Mitigating the beam search curse

One of the most irksome pathologies of traditional softmax-based NMT models is the “beam search curse” (Koehn and Knowles, 2017): larger beam sizes improve the log-probability of the translations, but the translation quality gets worse. This happens because with large beam sizes, the model prefers translations that are too short. This phenomenon has been linked to the local normalization in sequence models (Sountsov and Sarawagi, 2016; Murray and Chiang, 2018) and poor model calibration (Kumar and Sarawagi, 2019). Stahlberg and Byrne (2019) showed that modes are often empty and suggested that the inherent bias of the model towards short translations is often obscured by beam search errors. Stahlberg et al. (2022) provided strong evidence that this length deficiency is due to the intrinsic uncertainty of the MT task. Given that models trained with SCONES explicitly take into account inherent uncertainty, we ran an experiment to determine whether these models are

---

[7] As an additional optimization, our greedy search implementation operates directly on the logits without applying the output activations.

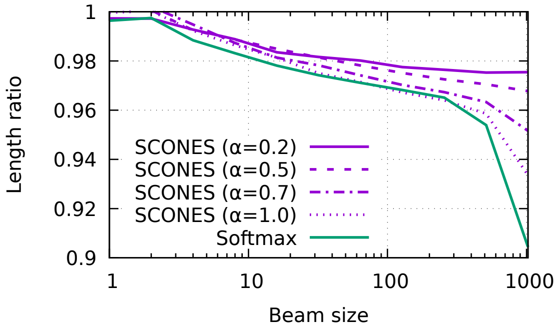

Figure 4: German-English length ratio (hypothesis length / reference length) as a function of beam size.

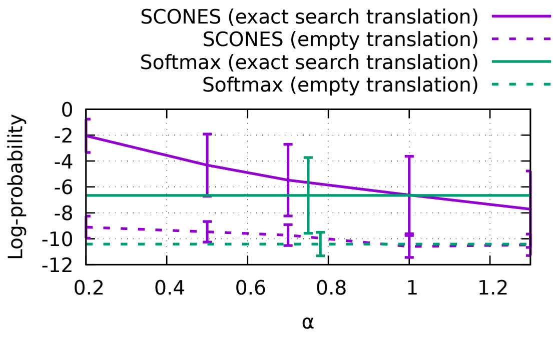

Figure 6: Mean and standard deviation (error bars) of log-probabilities of the global highest probability translations (found using exact search) and the empty translations for German-English.

more robust to the beam search curse compared to softmax trained models.

Fig. 3 plots the BLEU score as a function of the beam size. The sharp decline of the green curve for large beam sizes reflects the *beam search curse* for the softmax baseline. SCONES seems to be less affected at larger beam sizes, particularly for small α-values: the BLEU score for SCONES with $\alpha = 0.2$ (solid purple curve) is stable for beam sizes greater than 100. Fig. 4, which displays the length ratio (the hypothesis length divided by the reference length) versus beam size, suggests that the differences in BLEU trajectories are partly due to translation lengths. Translations obtained using softmax become shorter at higher beam sizes whereas for SCONES with $\alpha = 0.2$, there is no such steep decrease in length. To study the impact of α in the absence of beam search errors we ran the exact depth-first search algorithm of Stahlberg and Byrne (2019) to find the translation with global highest probability.[8] The adequacy of the translations found by exact search depends heavily on α (Fig. 5). With exact search, small α-values yield adequate translations, but $\alpha \approx 1.0$ performs similar to the softmax baseline: the BLEU score drops because hypotheses are too short. Table 6 shows that SCONES with $\alpha = 0.2$ consistently outperforms the softmax baselines by a large margin with exact search. Fig. 6 sheds some light on why SCONES with small α does not prefer empty translations. A small α leads to a larger gap between the log-probabilities of the exact search translation and the empty translation that arises from higher log-probabilities for the exact-search translation along with smaller variances. Intuitively, a small α reduces the importance of the negative loss component $\mathcal{L}_{-}(\cdot)$ in Eq. 6, and thus biases each binary classifier towards predicting the `true` label.

4.4 Reducing the number of beam search errors

Fig. 7 displays the percentage of beam search errors, the fraction of sentences for which beam

---

[8] The maximum number of explored states per sentence was set to 1M. This threshold was reached for less than 1.45% of the German-English sentences. See Appendix A for other language directions.

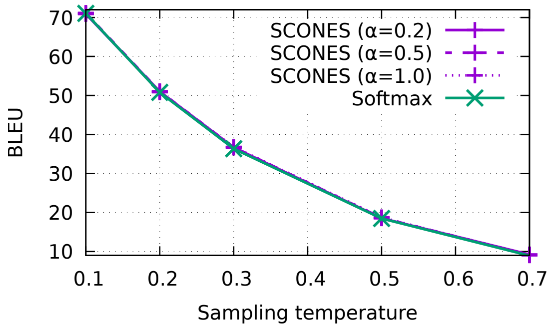

Figure 8: BLEU scores with beam search (beam size of 4) for German-to-synthetic-English translation with different IBM-3 sampling temperatures.

search did not find the global best translation, as a function of beam size. We confirm the findings of Stahlberg and Byrne (2019) for softmax models: the percentage of search errors remains at a relatively high level of around 20% even for very large beam sizes. Increasing the beam size is most effective in reducing the number of search errors for SCONES with a small value of α. However, a small α does not always yield the best overall BLEU score (Fig. 3). Taken together, these observations provide an insight into model errors in NMT: If we describe the "model error" as the mismatch between the global most likely translation and an adequate translation (following Stahlberg and Byrne (2019)), a small α would simultaneously lead to both fewer search errors (Fig. 7) and fewer model errors (Tab. 6). Counter-intuitively, however, BLEU scores peak at slightly higher α-values (Tab. 5). A more sophisticated notion of model errors and search errors is needed to understand the complex inherent biases of beam search for neural sequence-to-sequence models.

5 Experiments with synthetic language pairs

Our main motivation for SCONES is to equip the model to naturally represent intrinsic uncertainty, i.e. the existence of multiple correct target sentences for the same source sentence. To examine the characteristics of SCONES as a function of uncertainty, we generated synthetic language pairs that differ by the level of ambiguity. For this purpose, we trained an IBM-3 model (Brown et al., 1993) on the German-English training data after subword segmentation using MGIZA (Gao and Vogel, 2008). IBM-3 is a generative symbolic model that describes the translation process from one language into another with a generative story, and was popular for finding word alignments for statistical (phrase-based) machine translation (Koehn, 2009). The generative story consists of different steps such as distortion (word reordering), fertility (1:n word mappings), and lexical translation (word-to-word translation) that describe the translation process. The parameters of IBM-3 define probability distributions for each step. In this work we do not use IBM-3 for finding word alignments. Instead, for the original German sentences we sample synthetic English-like translations from the model with different sampling temperatures to control the ambiguity levels of the translation task. A low sampling temperature generates sentence pairs that still capture some of the characteristics of MT such as word reorderings, but the mapping is mostly deterministic (i.e. the same source token is almost always translated to the same target token). A high temperature corresponds to more randomness, i.e. more intrinsic uncertainty. Appendix B contains more details about sampling from IBM-3. We train NMT models using either softmax or SCONES on the synthetic corpora.

Fig. 8 shows that softmax and SCONES perform similarly using beam search: high IBM-3 sampling

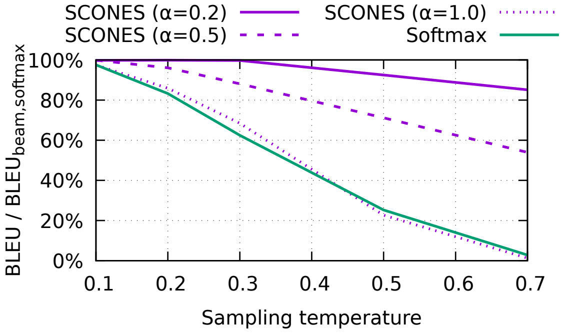

Figure 9: Exact search for German-to-synthetic-English translation with different IBM-3 sampling temperatures. BLEU scores are shown relative to those of the beam search softmax output in Fig. 8 for the respective temperatures.

temperature translation tasks are less predictable, and thus lead to lower BLEU scores. The difference between both approaches becomes clear with exact search (Fig. 9). While the translations with the global highest probability for high IBM-3 sampling temperatures are heavily degraded for softmax and SCONES with $\alpha = 1$, the drop is much less dramatic for SCONES with $\alpha = 0.2$ (solid purple curve). Setting α to a low value enables the model to assign its highest probability to adequate translations, even when the translation task is highly uncertain.

6 Related work

Our approach draws insights from multi-label classification (MLC) (Tsoumakas and Katakis, 2007; Zhang and Zhou, 2006, 2014). One of the earliest approaches for MLC was to transform the problem into multiple binary classification problems while ignoring the correlations between labels (Boutell et al., 2004). More recent work has modeled MLC in the sequence-to-sequence framework with a decoder that generates the labels sequentially, thus preserving the inter-label correlations (Yang et al., 2018). Most prior work in MLC focuses on classification and is not directly applicable to MT. In contrast, our training strategy is tailored for sequence-to-sequence problems. Unlike prior work (Yang et al., 2018), SCONES allows us to perform MLC style training with any underlying NMT architecture by simply changing the loss function. By jointly training all label-specific binary classifiers, our strategy is able to account for label correlations.

Ma et al. (2018) used an MLC objective to improve machine translation. Unlike our approach, they attempted to predict *all* words in the target sentence with a bag-of-words loss function. We formulate the next word prediction at each time step as an MLC problem to handle intrinsic uncertainty, but our models are predicting ordered target sequences, not bags of words.

The speed-ups from SCONES can be partially attributed to avoiding the normalization of the output over the full vocabulary. The same idea motivated earlier work on self-normalized training (Gutmann and Hyvärinen, 2010; Mnih and Teh, 2012; Devlin et al., 2014; Goldberger and Melamud, 2018). As described in Sec. 2, unlike work on self-normalization, SCONES does not try to approximate a distribution over the full vocabulary. Rather, its output consists of multiple binary classifiers that do not share probability mass by design to be able to better represent intrinsic uncertainty.

7 Conclusion

Machine translation is a task with high intrinsic uncertainty: a source sentence can have multiple valid translations. We demonstrated that NMT models and specifically Transformers, can learn to model mutually non-exclusive target sentences from single-label training data using our SCONES loss function. Rather than learn a single distribution over all target sentences, SCONES learns multiple binary classifiers that indicate whether or not a target sentence is a valid translation of the source sentence. SCONES yields improved translation quality over conventional softmax-based models for six different translation directions, or (alternatively) speed-ups of up to 3.9x without any degradation in translation performance. We showed that SCONES can be tuned to mitigate the beam search curse and the problem of inadequate and empty modes in standard NMT. Our experiments on synthetic language translation suggest that, unlike softmax-trained models, SCONES models are able to assign their highest probability to adequate translations even when the underlying task is highly ambiguous.

The SCONES loss function is easy to implement. Adapting standard softmax-based sequence-to-sequence architectures such as Transformers requires *only* replacing the cross-entropy loss function with SCONES and the softmax with sigmoid activations. The remaining parts of the training and inference pipelines can be kept unchanged. SCONES can be potentially useful in handling uncertainty for a variety of ambiguous NLP problems beyond translation, such as generation and dialog. We expect this work to encourage research on modeling techniques that can address ambiguity in much better ways compared to current models.

A Time complexity of exact search

The exact search algorithm of Stahlberg and Byrne (2019) we used in the paper is guaranteed to find the global best translation. Its runtime, however, varies greatly between language pairs and source sentences. Therefore, we limit the number of explored states per sentence by 1M to keep the decoding time under control. If the 1M threshold is reached, the optimality of the found translation is not guaranteed anymore. Fortunately, for most of our models and test sets, exact search was able to find and verify the global best translation earlier. Table 7 lists the runs for which a fraction of the sentences did not terminate before 1M steps. In these rare cases, we use the best translation found thus far by exact search as an approximation to the global best translation.

B Sampling from IBM-3

The parameters of the IBM-3 model (Brown et al., 1993) are composed of a set of fertility probabilities $n(\cdot|\cdot)$, p_0, p_1, a set of translation probabilities $t(\cdot|\cdot)$, and a set of distortion probabilities $d(\cdot|\cdot)$. According to the IBM Model 3, the following generative process produces the target language sentence $\mathbf{y}$ from a source language sentence $\mathbf{x}$ (Knight, 1999):

Languages	Run	#incomplete sent.
de-en	SCONES ($\alpha = 0.2$)	1.45%
de-en	SCONES ($\alpha = 0.5$)	0.90%
de-en	SCONES ($\alpha = 0.7$)	0.05%
en-de	SCONES ($\alpha = 0.2$)	4.01%
fi-en	SCONES ($\alpha = 0.2$)	1.30%
en-fi	Softmax	0.10%
en-fi	SCONES ($\alpha = 0.2$)	3.20%
lt-en	Softmax	0.20%
lt-en	SCONES ($\alpha = 0.2$)	5.20%
en-lt	Softmax	0.10%
en-lt	SCONES ($\alpha = 0.2$)	5.31%
synthetic-0.1	Softmax	1.05%
synthetic-0.1	SCONES ($\alpha = 0.2$)	0.55%
synthetic-0.1	SCONES ($\alpha = 0.5$)	1.10%
synthetic-0.1	SCONES ($\alpha = 1.0$)	1.25%
synthetic-0.2	Softmax	1.00%
synthetic-0.2	SCONES ($\alpha = 0.2$)	5.10%
synthetic-0.2	SCONES ($\alpha = 0.5$)	7.65%
synthetic-0.2	SCONES ($\alpha = 1.0$)	2.65%
synthetic-0.3	Softmax	0.10%
synthetic-0.3	SCONES ($\alpha = 0.2$)	12.6%
synthetic-0.3	SCONES ($\alpha = 0.5$)	17.3%
synthetic-0.3	SCONES ($\alpha = 1.0$)	1.80%
synthetic-0.5	SCONES ($\alpha = 0.2$)	25.0%
synthetic-0.5	SCONES ($\alpha = 0.5$)	25.2%
synthetic-0.7	SCONES ($\alpha = 0.2$)	25.9%
synthetic-0.7	SCONES ($\alpha = 0.5$)	20.3%

Table 7: Fraction of sentences for which exact search did not terminate before 1M steps. For runs that are not listed here, exact search terminated within 1M steps for all sentences.

1. For each source word x_i indexed by $i = 1, 2, \ldots, |\mathbf{x}|$, choose the fertility ϕ_i with probability $n(\phi_i|x_i)$.
2. Choose the number ϕ_0 of "spurious" target words to be generated from $x_0 = \texttt{NULL}$, using probability p_1 and the sum of fertilities from step 1.
3. Let $m = \sum_{i=0}^{|\mathbf{x}|} \phi_i$.
4. For each $i = 0, 1, 2, \ldots, |\mathbf{x}|$ and each $k = 1, 2, \ldots, \phi_i$, choose a target word τ_{ik} with probability $t(\tau_{ik}|x_i)$.
5. For each $i = 1, 2, \ldots, |\mathbf{x}|$ and each $k = 1, 2, \ldots, \phi_i$, choose a target position π_{ik} with probability $d(\pi_{ik}|i, |\mathbf{x}|, m)$.
6. For each $k = 1, 2, \ldots, \phi_0$, choose a position π_{0k} from the $\phi_0 - k + 1$ remaining vacant positions in $1, 2, \ldots, m$, for a total probability of $\frac{1}{\phi_0!}$.
7. Output the target sentence with words τ_{ik} in positions π_{ik} $(0 \leq i \leq |\mathbf{x}|, 1 \leq k \leq \phi_i)$.

First, we estimate the IBM-3 model parameters using the MGIZA (Gao and Vogel, 2008) word alignment tool. Then, we sample English-like target sentences for the German source sentences following the generative story above. To control the level of uncertainty in the synthetic translation task we alter the entropies of the $n(\cdot|\cdot)$, $t(\cdot|\cdot)$, and $d(\cdot|\cdot)$ distributions by choosing different sampling temperatures $\gamma \in \mathbb{R}^+$. Instead of sampling directly from a categorical distribution $P(\cdot)$ over categories $\mathcal{C}$, temperature sampling uses the following distribution:

$$P_\gamma(c) = \frac{e^{\log P(c)/\gamma}}{\sum_{c' \in \mathcal{C}} e^{\log P(c')/\gamma}} \tag{10}$$

for each $c \in \mathcal{C}$. A low temperature amplifies large differences in probabilities, and thus leads to a lower entropy and less ambiguity.

C Implementation of SCONES in JAX

Fig. 10 provides an implementation of the SCONES loss function (Sec. 2) in JAX (Bradbury et al., 2018). We bound the inverse model probability (`false_logprob`) by e^{-30} in line 12

```
from flax import linen as nn
import jax
import jax.numpy as jnp

def compute_scones_loss(
    logits,   # 3D float tensor [batch_size, max_sequence_length, vocab_size]
    targets,  # 2D int tensor [batch_size, max_sequence_length]
    l = 0.0,  # Label smoothing constant (lambda)
    a = 1.0,  # Scaling factor alpha
):
  true_logprob = nn.log_sigmoid(logits)
  false_logprob = jnp.log(jnp.maximum(1.0 - jnp.exp(true_logprob), 1.0e-30))
  gather = jax.vmap(jax.vmap(lambda s, t: s[t]))
  tgt_true_logprob = gather(true_logprob, targets)  # [batch_size, max_seq_length]
  tgt_false_logprob = gather(false_logprob, targets)  # [batch_size, max_seq_length]
  tgt_true_xent = -(1.0 - l) * tgt_true_logprob - l * tgt_false_logprob
  tgt_false_xent = -(1.0 - l) * tgt_false_logprob - l * tgt_true_logprob
  all_false_xent = -(1.0 - l) * false_logprob - l * true_logprob
  loss = a * (jnp.sum(all_false_xent, axis=-1) - tgt_false_xent) + tgt_true_xent
  weights = jnp.where(targets > 0, 1, 0).astype(jnp.float32)  # PAD ID is 0.
  return loss * weights / weights.sum()
```

Figure 10: JAX implementation of the SCONES loss function.

for numerical stability. The JAX implementation generalizes the SCONES loss defined in the main paper in Eq. 6 with a label smoothing (Szegedy et al., 2016) factor $\lambda \in [0, 1]$ (`l` in Fig. 10) such that the positive loss component $\mathcal{L}_+(\cdot)$ becomes the following cross-entropy:

$$\begin{aligned} \mathcal{L}_+(\mathbf{x}, \mathbf{y}, i) = &-(1-\lambda)\log P(z_{\mathbf{x},\mathbf{y}_{\leq i}} = 1|\mathbf{x}, \mathbf{y}_{<i}) \\ &- \lambda \log P(z_{\mathbf{x},\mathbf{y}_{\leq i}} = 0|\mathbf{x}, \mathbf{y}_{<i}). \end{aligned} \tag{11}$$

Similarly, the negative loss component $\mathcal{L}_-(\cdot)$ with label smoothing can be written as:

$$\begin{aligned} \mathcal{L}_-(\mathbf{x}, \mathbf{y}, i) = - \sum_{w \in \mathcal{V} \setminus \{y_i\}} \Big(& \\ (1-\lambda)\log P(z_{\mathbf{x},\mathbf{y}_{<i}\cdot w} &= 0|\mathbf{x}, \mathbf{y}_{<i}) \\ + \lambda \log P(z_{\mathbf{x},\mathbf{y}_{<i}\cdot w} &= 1|\mathbf{x}, \mathbf{y}_{<i})\Big). \end{aligned} \tag{12}$$

The label smoothing extension is provided for the sake of completeness – we did not use label smoothing in any of the experiments in the main paper since it did not yield improvements in our setups.

SkillSpan: Hard and Soft Skill Extraction from English Job Postings

Mike Zhang[*◇] **Kristian Nørgaard Jensen**[*◇] **Sif Dam Sonniks**[◇] **Barbara Plank**[◇♣]
[◇]Department of Computer Science, IT University of Copenhagen, Denmark

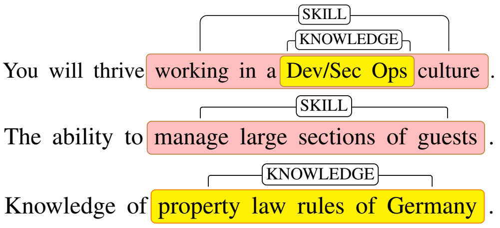
Abstract

Skill Extraction (SE) is an important and widely-studied task useful to gain insights into labor market dynamics. However, there is a lacuna of datasets and annotation guidelines; available datasets are few and contain crowd-sourced labels on the span-level or labels from a predefined skill inventory. To address this gap, we introduce SkillSpan, a novel SE dataset consisting of 14.5K sentences and over 12.5K annotated spans. We release its respective guidelines created over three different sources annotated for hard *and* soft skills by domain experts. We introduce a BERT baseline (Devlin et al., 2019). To improve upon this baseline, we experiment with language models that are optimized for long spans (Joshi et al., 2020; Beltagy et al., 2020), continuous pre-training on the job posting domain (Han and Eisenstein, 2019; Gururangan et al., 2020), and multi-task learning (Caruana, 1997). Our results show that the domain-adapted models significantly outperform their non-adapted counterparts, and single-task outperforms multi-task learning.

1 Introduction

Job markets are under constant development—often due to developments in technology, migration, and digitization—so are the skill sets required. Consequentially, job vacancy data is emerging on a variety of platforms in big quantities and can provide insights on labor market skill demands or aid job matching (Balog et al., 2012). SE is to extract the competences necessary from unstructured text.

Previous work in SE shows promising progress, but is halted by a lack of available datasets and annotation guidelines. Two out of 14 studies release their dataset, which limit themselves to crowd-sourced labels (Sayfullina et al., 2018) or annotations from a predefined list of skills on the document-level (Bhola et al., 2020). Additionally, none of the 14 previously mentioned studies release their annotation guidelines, which obscures the meaning of a competence. Job markets change, as do the skills in, e.g., the European Skills, Competences, Qualifications and Occupations (ESCO; le Vrang et al., 2014) taxonomy (Section 3). Hence, it is important to cover for possible emerging skills.



You will thrive working in a Dev/Sec Ops culture.

The ability to manage large sections of guests.

Knowledge of property law rules of Germany.

Figure 1: **Examples of Skills & Knowledge Components.** Annotated samples of passages in varying job postings. More details are given in Section 4.

We propose SkillSpan, a novel SE dataset annotated at the span-level for *skill* and *knowledge* components (SKCs) in job postings (JPs). As illustrated in Figure 1, SKCs can be nested inside skills. SkillSpan allows for extracting possibly undiscovered competences and to diminish the lack of coverage of predefined skill inventories.

Our analysis (Figure 2) shows that SKCs contain on average longer sequences than typical Named Entity Recognition (NER) tasks. Albeit we additionally study models optimized for long spans (Joshi et al., 2020; Beltagy et al., 2020), some underperform. Overall, we find specialized domain BERT models (Alsentzer et al., 2019; Lee et al., 2020; Gururangan et al., 2020; Nguyen et al., 2020) perform better than their non-adapted counterparts. We explore the benefits of domain-adaptive pre-training on the JP domain (Han and Eisenstein, 2019; Gururangan et al., 2020). Last, given the examples from Figure 1, we formulate the task as both as a sequence labeling and a multi-task learning (MTL) problem, i.e., training on both skill and knowledge components jointly (Caruana, 1997).

Table 1: **Contributions of Related Work**. We list the recent works of Skill Extraction. Note that (*) indicates labels that are automatically inferred from some source (e.g., a predefined skill inventory) and not *manually* annotated. With respect to the annotation approach, "Manual" indicates uncertainty whether they used domain experts or not. Also note that many works do not release their dataset with annotations (✎) nor guidelines (📘). The list is inspired by Khaouja et al. (2021).

Contributions In this paper: ① We release SKILLSPAN, a novel skill extraction dataset, with annotation guidelines, and our open-source code.[1] ② We present strong baselines for the task including a new SpanBERT (Joshi et al., 2020) trained from scratch, and domain-adapted variants (Gururangan et al., 2020), which we will release on the `HuggingFace` platform (Wolf et al., 2020). To the best of our knowledge, we are the first to investigate the extraction of skills and knowledge from job postings with state-of-the-art language models. ③ We give an analysis on single-task versus multi-task learning in the context of skill extraction, and show that for this particular task single-task learning outperforms multi-task learning.

2 Related Work

There is a pool of prior work relating to SE. We summarize it in Table 1, depicting state-of-the-art approaches, level of annotations, what kind of competences are annotated, the modeling approaches, the size of the dataset (if available), type of skills annotated for, baseline models, and whether they release their annotations and guidelines.

As can be seen in Table 1, many works do *not release their data* (apart from Sayfullina et al., 2018 and Bhola et al., 2020) and **none release their annotation guidelines**. In addition, none of the previous studies approach SE as a span-level extraction task with state-of-the-art language models, nor did they release a dataset of this magnitude with manually annotated (long) spans of competences by domain experts.

Although Sayfullina et al. (2018) annotated on the span-level (thus being useful for SE) and release their data, they instead explored several approaches to *Skill Classification*. To create the data, they extracted all text snippets containing *one* soft skill from a predetermined list. Crowdworkers then annotated the highlighted skill whether it was a soft skill referring to the candidate or not. They show that an LSTM (Hochreiter et al., 1997) performs best on classifying the skill in the sentence. In our work, we annotated a dataset three times their size (Table 2) for both hard *and* soft skills. In addition, we also extract the specific skills from the sentence.

Tamburri et al. (2020) classifies sentences that contain skills in the JP. The authors manually labeled their dataset with domain experts. They annotated whether a sentence contains a skill or not. Once the sentence is identified as containing a skill, the skill cited within is extracted. In contrast, we directly annotate for the span within the sentence.

Bhola et al. (2020) cast the task of skill extraction as a multi-label skill classification at the document-level. There is a predefined set of unique skills given the job descriptions and they predict multiple skills that are connected to a given job description using BERT (Devlin et al., 2019). In addition, they experiment with several additional layers for better prediction performance. We instead explore domain-adaptive pre-training for SE.

Table 2: **Statistics of Dataset.** Indicated is the number of JPs across splits & source and their respective number of sentences, tokens, and spans. The total is reported in the cyan column and rows. We report the overall statistics of the unlabeled JPs ($\mathcal{U}$) in the gray rows.

The work closest to ours is by Chernova (2020), who approach the task similarly with span-level annotations (including longer spans) but approach this for the Finnish language. It is unclear whether they annotated by domain experts. Also, neither the data nor the annotation guidelines are released. For a comprehensive overview with respect to SE, we refer to Khaouja et al. (2021).

3 Skill & Knowledge Definition

There is an abundance of competences and there have been large efforts to categorize them. For example, the The International Standard Classification of Occupations (ISCO; Elias, 1997) is one of the main international classifications of occupations and skills. It belongs to the international family of economic and social classifications. Another example, the European Skills, Competences, Qualifications and Occupations (ESCO; le Vrang et al., 2014) taxonomy is the European standard terminology linking skills and competences and qualifications to occupations and derived from ISCO. The ESCO taxonomy mentions three categories of competences: *Skill*, *knowledge*, and *attitudes*. ESCO defines knowledge as follows:

> "Knowledge means the outcome of the assimilation of information through learning. Knowledge is the body of facts, principles, theories and practices that is related to a field of work or study." [2]

For example, a person can acquire the Python programming language through learning. This is denoted as a *knowledge* component and can be considered a *hard skill*. However, one also needs to be able to apply the knowledge component to a certain task. This is known as a *skill* component. ESCO formulates it as:

> "Skill means the ability to apply knowledge and use know-how to complete tasks and solve problems." [3]

In ESCO, the *soft skills* are referred to as *attitudes*. ESCO considers attitudes as skill components:

> "The ability to use knowledge, skills and personal, social and/or methodological abilities, in work or study situations and professional and personal development." [4]

To sum up, hard skills are usually referred to as *knowledge* components, and applying these hard skills to something is considered a *skill* component. Then, soft skills are referred to as *attitudes*, these are part of skill components. There has been no work, to the best of our knowledge, in annotating skill and knowledge components in JPs.

4 SkillSpan Dataset

Data[5] We continuously collected JPs via web data extraction between June 2020–September 2021. Our JPs come from the three sources:

1. **Big**: A large job platform with various types of JPs, with several type of positions;
2. **House**: A *static* in-house dataset consisting of similar types of jobs as Big. Dates range from 2012–2020;

[3] `https://ec.europa.eu/esco/portal/escopedia/Skill`

[4] `http://data.europa.eu/esco/skill/A`

[5] Our data statement (Bender and Friedman, 2018) can be found in Appendix A.

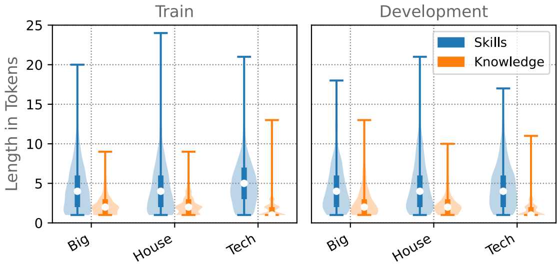

Figure 2: **Violin Plots of Annotated Components.** Indicated are the distributions regarding the length of spans in each type of annotated component (i.e., length of skills and knowledge components). The white dot is the median length, the bars range from the first quartile to the third quartile, and the colored line ranges from the lower adjacent value to the higher adjacent value.

3. **TECH**: The StackOverflow JP platform that consisted mostly of technical jobs (e.g., developer positions).

We release the anonymized raw data and annotations of the parts with permissible licenses, i.e., HOUSE (from a govermental agency which is our collaborator) and TECH.[6] For anonymization, we perform it via manual annotation of job-related sensitive and personal data regarding `Organization`, `Location`, `Contact`, and `Name` following the work by Jensen et al. (2021). Table 2 shows the statistics of SKILLSPAN, with 391 annotated JPs from the three sources containing 14.5K sentences and 232.2K tokens. The unlabeled JPs (only to be released as pre-trained model) consist of 126.8K posts, 3.2M sentences, and 460.5M tokens. What stands out is that there are 2–5 times as many annotated knowledge components in TECH in contrast to the other sources, despite a similar amount of JPs. We expect this to be due the numerous KCs depicted in this domain (e.g., programming languages), while we observe considerably fewer soft skills (e.g., "work flexibly"). The amount of skills is more balanced across the three sources. Furthermore, overlapping spans follow a consistent trend among splits, with the train split containing the most.

Data Annotation We annotate competences related to SKCs in two levels as illustrated in Figure 1. We started the process in March 2021, with initial annotation rounds to construct and refine the annotation guidelines (as outlined further below). The annotation process spanned eight months in total. Our final annotation guidelines can be found in Appendix B. The guidelines were developed by largely following example spans given in the ESCO taxonomy. However, at this stage, we focus on span identification, and we do not take the fine-grained taxonomy codes from ESCO for labeling the spans, leaving the mapping to ESCO and taxonomy enrichment as future work.

Further Details on the Annotation Process The development of the annotation guidelines and our annotation process is depicted as follows: **①** We wrote base guidelines derived from a small number of JPs. **②** We had three pre-rounds consisting of three JPs each. After each round, we modified, improved and finalized the guidelines. **③** Then, we had three longer-lasting annotation rounds consisting of 30 JPs each. We re-annotated the previous 11 JPs in ① and ②. **④** After these rounds, one of the annotators (the hired linguist) annotated JPs in batches of 50. The data in ①, ②, and ③ was annotated by three annotators (101 JPs).

We used an open source text annotation tool named DOCCANO (Nakayama et al., 2018). There are around 57.5K tokens (approximately 4.6K sentences, in 101 job posts) that we calculated agreement on. The annotations were compared using Cohen's κ (Fleiss and Cohen, 1973) between pairs of annotators, and Fleiss' κ (Fleiss, 1971), which generalises Cohen's κ to more than two concurrent annotations. We consider two levels of κ calculations: **TOKEN** is calculated on the token level, comparing the agreement of annotators on each token (including non-entities) in the annotated dataset. **SPAN** refers to the agreement between annotators on the exact span match over the surface string, regardless of the type of SKC, i.e., we only check the position of tag without regarding the type of the entity. The observed agreements scores over the three annotators from step ③ are between 0.70–0.75 Fleiss' κ for both levels of calculation which is considered a *substantial agreement* (Landis and Koch, 1977) and a κ value greater than 0.81 indicates *almost perfect agreement*. Given the difficulty of this task, we consider the aforementioned κ score to be strong. Particularly, we observed a large improvement in annotation agreement from the earlier rounds (step ① and ②), where our Fleiss' κ was 0.59 on token-level and 0.62 for the span-level.

Overall, we observe higher annotator agreement for knowledge components (3–5% higher) com-

pared to skills which tend to be longer. The TECH domain is the most consistent for agreement while BIG shows more variation over rounds, likely due to the broader nature of the domains of JPs.

Annotation Span Statistics A challenge of annotating spans is the length (i.e., boundary), SKCs being in different domains (e.g., business versus technical components), and frequently written differently, e.g., "being able to work together" v.s. "teamwork"). Figure 2 shows the statistics of our annotations in violin plots. For the training set, the median length (white dot) of skills is around 4 for BIG and HOUSE, for TECH this is a median of 5. In the development set, the median stays at length 4 across all sources. Another notable statistic is the upper and lower percentile of the length of skills and knowledge, indicated with the thick bars. Here, we highlight the fact that skill components could consist of many tokens, for example, up to length 7 in the HOUSE source split (see blue-colored violins). For knowledge components, the spans are usually shorter, where it is consistently below 5 tokens (see orange-colored violins). All statistics follow a similar distribution across train, development, and sources in terms of length and distribution. This gives a further strong indication that consistent annotation length has been conducted across splits and sources.

Qualitative Analysis of Annotations Qualitative differences in SKCs over the three sources are shown (lowercased) in Table 3. With respect to skill components, all sources follow a similar usage of skills. The annotated skills mostly relate to the *attitude* of a person and hence mostly consist of soft skills. With respect to knowledge components, we observe differences between the three sources. First, on the source-level, the knowledge components vastly differ between BIG and TECH. BIG postings seem to cover more *business* related components, whereas TECH has more *engineering* components. HOUSE seems to be a mix of the other two sources. Lastly, note that both the skill and knowledge components between the splits diverge in terms of the type of annotated spans, which indicates a variation in the annotated components. We show the top–10 skills annotated in the train, development, and test splits for SKCs in Appendix C. From a syntactic perspective, skills frequently consist of noun phrases, verb phrases, or adjectives (for soft skills). Knowledge components usually consists of nouns or proper nouns, such as "python", "java", and so forth.

5 Experimental Setup

The task of SE is formulated as a sequence labeling problem. Formally, we consider a set of JPs $\mathcal{D}$, where $d \in \mathcal{D}$ is a set of sequences (i.e., entire JPs) with the i^{th} input sequence $\mathcal{X}_d^i = \{x_1, x_2, ..., x_T\}$ and a target sequence of `BIO`-labels $\mathcal{Y}_d^i = \{y_1, y_2, ..., y_T\}$ (e.g., "`B-SKILL`", "`I-KNOWLEDGE`", "`O`"). The goal is to use $\mathcal{D}$ to train a sequence labeling algorithm $h : \mathcal{X} \mapsto \mathcal{Y}$ to accurately predict entity spans by assigning an output label y_t to each token x_t.

As baseline we consider BERT and we investigate more recent variants, and we also train models from scratch. Models are chosen due to their state-of-the-art performance, or in particular, for their strong performance on longer spans.

BERT$_{\text{base}}$ (Devlin et al., 2019) An out-of-the-box BERT$_{\text{base}}$ model (`bert-base-cased`) from the `HuggingFace` library (Wolf et al., 2020) functioning as a baseline.

SpanBERT (Joshi et al., 2020) A BERT-style model that focuses on span representations as opposed to single token representations. SpanBERT is trained by masking contiguous spans of tokens and optimizing two objectives: (1) masked language modeling, which predicts each masked token from its own vector representation. (2) The span boundary objective, which predicts each masked token from the representations of the unmasked tokens at the start and end of the masked span.

We train a SpanBERT$_{\text{base}}$ model from scratch on the BooksCorpus (Zhu et al., 2015) and English Wikipedia using cased Wordpiece tokens (Wu et al., 2016). We use AdamW (Kingma and Ba, 2015) for

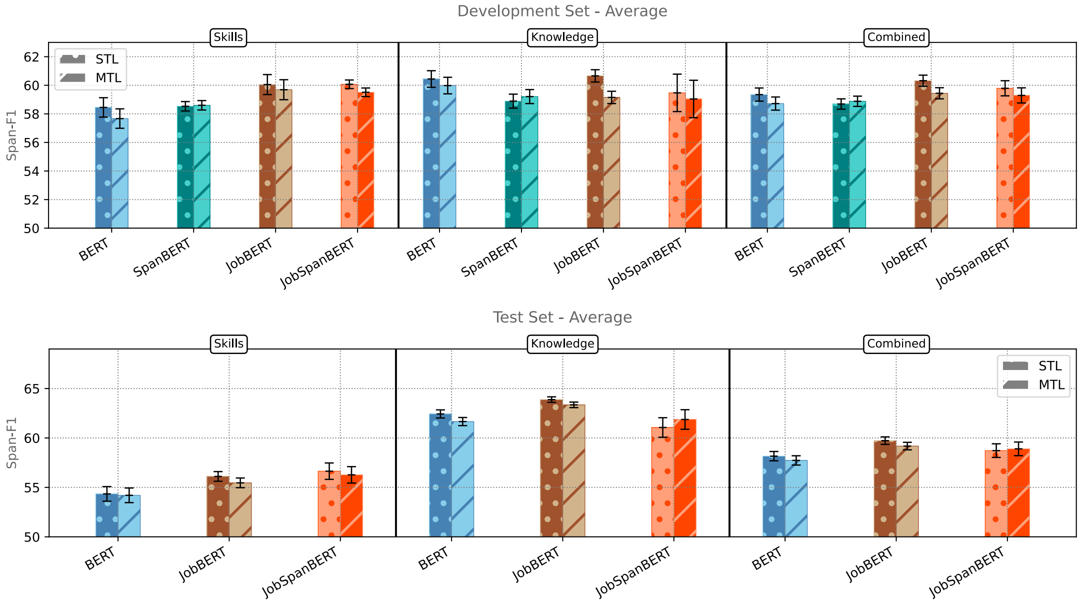

Figure 3: **Performance of Models.** We test the models on SKILLS, KNOWLEDGE, and COMBINED. We report the span-F1 and standard deviation (error bars) of runs on five random seeds. **Note that the y-axis starts from 50 span-F1**. **STL** indicates single-task learning and **MTL** indicates the multi-task model. Differences can be seen on the test set: JobSpanBERT performs best on SKILLS, JobBERT is best on KNOWLEDGE, and JobBERT achieves best in COMBINED. Exact numbers of the plots are in Table 5 (Appendix E).

2.4M training steps with batches of 256 sequences of length 512. The learning rate is warmed up for 10K steps to a maximum value of $1e$-4, after which it has a decoupled weight decay (Loshchilov and Hutter, 2019) of 0.1. We add a dropout rate of 0.1 across all layers. Pretraining was done on a v3-8 TPU on the GCP and took 14 days to complete. We take the official TensorFlow implementation of SpanBERT by Ram et al. (2021).

JobBERT[7] We apply domain-adaptive pre-training (Gururangan et al., 2020) to a $\text{BERT}_{\text{base}}$ model using the 3.2M unlabeled JP sentences (Table 2). Domain-adaptive pre-training relates to the continued self-supervised pre-training of a large language model on domain-specific text. This approach improves the modeling of text for downstream tasks within the domain. We continue training the BERT model for three epochs (default in `HuggingFace`) with a batch size of 16.

JobSpanBERT[8] We apply domain-adaptive pre-training to our SpanBERT on 3.2M unlabeled JP sentences. We keep parameters identical to the vanilla SpanBERT, but change the number of steps to 40K to have three passes over the unlabeled data.

Experiments We have 391 annotated JPs (Table 2) that we divide across three splits: Train, dev. and test set. We use 101 JPs that all three annotators annotated as the gold standard test set with aggregated annotations via majority voting. The 101 postings are divided between the sources as: 36 BIG, 33 HOUSE, and 32 TECH. The remaining 290 JPs were annotated by one annotator. We use 90 JPs (30 from each source, namely BIG, HOUSE, and TECH) as the dev. set. The remaining 200 JPs are used as the train set. The sources in the train set are divided into 60 BIG, 60 HOUSE, and 80 TECH.

Setup The data is structured as CoNLL format (Tjong Kim Sang, 2002). For the nested annotations, the skill tags are appearing only in the first column and the knowledge tags are only appearing in the second column of the file and they are allowed to overlap with each other. We perform experiments with single-task learning (STL) on either the skill or knowledge components, MTL for predicting both skill and knowledge tags at the same time, while evaluating the MTL models also on either skills or knowledge components. We used a single joint MTL model with hard-parameter sharing (Caruana, 1997). All models are with a final Conditional Random Field (CRF; Lafferty et al.,

Figure 4: **Almost Stochastic Order Scores of the Test Set.** ASO scores expressed in ϵ_{min}. The significance level $\alpha = 0.05$ is adjusted accordingly by using the Bonferroni correction (Bonferroni, 1936). Read from row to column: E.g., in Combined STL-JobBERT (row) is stochastically dominant over STL-BERT$_{\text{base}}$ (column) with ϵ_{min} of 0.00.

2001) layer. Earlier research, such as Souza et al. (2019); Jensen et al. (2021) show that BERT models with a CRF-layer improve or perform similarly to its simpler variants when comparing the overall F1 and make no tagging errors (e.g., `B`-tag follows `I`-tag). In the case of MTL we use one for each tag type (skill and knowledge). In the STL experiments we use one CRF for the given tag type.

We use the MaChAmp toolkit (van der Goot et al., 2021) for our experiments. For each setup we do five runs (i.e., five random seeds).[9] For evaluation we use span-level precision, recall, and F1, where the F1 for the MTL setting is calculated as described in Benikova et al. (2014).

6 Results

The results of the experiments are given in Figure 3. We show the average performance of each model in F1 and respective standard deviation over the development and test split. Exact scores on each source split and other metric details are provided in Appendix E. As mentioned before, we experiment with the following settings: **Skill**, we train and predict only on skills. **Knowledge**, train and only predict for knowledge. **Combined**, we merge the STL predictions of both skills and knowledge. We also train the models in an MTL setting, predicting both skills and knowledge simultaneously. We evaluate the MTL model on both **Skill** and **Knowledge** separately, and also compare it against the aggregated STL predictions.

Performance on Development Set In Figure 3, we show the results on the development set in the upper plot. We observe similar performance between the domain-adapted STL models—JobBERT and JobSpanBERT—have similar span-F1 for Skill: 60.05±0.70 vs. 60.07±0.70. In contrast, for Knowledge, BERT$_{\text{base}}$ and JobBERT are closest in predictive performance: 60.44±0.58 vs. 60.66±0.43. In the Combined setting, JobBERT performs highest with a span-F1 of 60.32±0.39. On average, JobBERT performs best over all three settings. Surprisingly, the models for both Skill and Knowledge perform similarly (around 60 span-F1), despite the sources' differences in properties and length Figure 2. In addition, we find that MTL is not performing better than STL across sources. For exact numbers and source-level (i.e., Big, House, Tech), we refer to Appendix E.

Performance on Test Set We select the best performing models in the development set evaluation and apply it to the test set. Results are in Figure 3 in the bottom plot. Since JobBERT and JobSpanBERT are performing similarly, we apply both to the test set and BERT$_{\text{base}}$. We observe a deviation from the development set to the test set: JobSpanBERT 60.07±0.30→56.64±0.83 on Skill, JobBERT 60.66±0.43→63.88±0.28 on Knowledge. For Combined, JobBERT performs slightly worse: 60.32±0.39→59.73±0.38. Similar to the development set, we find that on all three methods of evaluation (i.e., Skill, Knowledge, and Combined), STL still outperforms MTL. For Skill and Knowledge, STL is almost stochastically dominant over MTL (i.e., significant), and for Combined there is stochastic dominance of STL over MTL, indicated in the next paragraph.

Significance We compare all pairs of models based on five random seeds each using Almost Stochastic Order (ASO; Dror et al., 2019) tests with a confidence level of $\alpha = 0.05$. The ASO scores of the test set are indicated in Figure 4. We show that MTL-JobSpanBERT for Skill shows

---

[9] For reproducibility, we refer to Appendix D.

almost stochastic dominance ($\epsilon_{\min} < 0.5$) over all other models. For KNOWLEDGE and COMBINED, We show that STL-JobBERT is stochastically dominant ($\epsilon_{\min} = 0.0$) over *all* the other models. For more details, we refer to Appendix F for ASO scores on the development set.

7 Discussion

What Did Not Work Additionally, we experiment whether representing the entire JP for extracting tokens yields better results than the experiments so far, which were sentence-by-sentence processing setups. To handle entire JPs and hence much longer sequences we use a pre-trained $\text{Longformer}_{\text{base}}$ (Beltagy et al., 2020) model. The document length we use in the experiments is 4096 tokens. Results of the Longformer on the test set are lower: For skills, JobSpanBERT against Longformer results in 56.64±0.83 vs. 52.55±2.39. For KNOWLEDGE, JobBERT against Longformer shows 63.88±0.28 vs. 57.26±1.05. Last, for COMBINED, JobBERT against Longformer results in 59.73±0.38 vs. 55.05±0.71. This drop in performance is difficult to attribute to a concrete reason: e.g., the Longformer is trained on more varied sources than BERT, but not specifically for JPs, which may have contributed to this gap. Since the vanilla Longformer already performs worse than $\text{BERT}_{\text{base}}$ overall, we did not opt to apply domain-adaptive pre-training. Overall, we show that representing the full JP is not beneficial for SE, at least not in the Longformer setup tested here.

Continuous Pretraining helps SE As previously mentioned, due to the domain specialization of the domain-adapted pre-trained BERT models, they predict more skills and frequently perform better in terms of precision, recall, and F1 as compared to their non-adaptive counterparts. This is especially encouraging as we confirm findings that continuous pre-training helps to adapt models to a specific domain (Alsentzer et al., 2019; Lee et al., 2020; Gururangan et al., 2020; Nguyen et al., 2020). However, there are exceptions. Particularly in Table 5 on TEST for KNOWLEDGE, $\text{BERT}_{\text{base}}$ comes closer in predictive performance to JobBERT (difference of 1.5 F1) than on SKILLS. Our intuition is that knowledge components are often already in the pre-training data (e.g., Wikipedia pages of certain competences like Python, Java etc.) and therefore adaptive pre-training does not substantially boost performance.

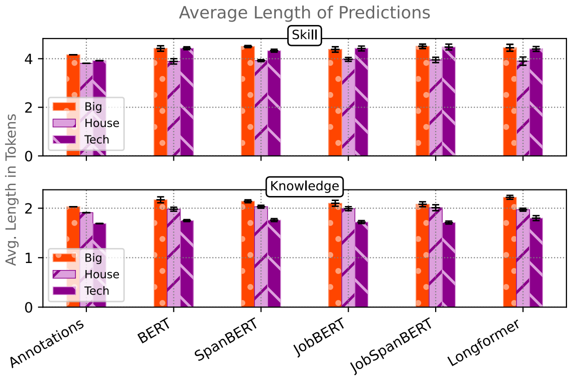

Figure 5: **Average Length of Predictions of Single Models.** We show the average length of the predictions versus the length of our annotated skills and knowledge components on the *test set* and the total number of predicted skills and knowledge tags in each respective split (#). There is a consistent trend over the three sources.

Difference in Length of Predictions The main motivation of selecting models optimized for long spans was the length of the annotations (Figure 2). We investigate the average length of predictions of each model (Figure 5) to find out whether the models that are adapted to handle longer sequences truly predict longer spans. Interestingly, the average length of predicted skills are longer than the annotations over all three sources. There is a consistent trend among SKILL: BIG and TECH have similar length over predictions (>4), while HOUSE is usually lower than length 3. For both BIG and TECH, JobSpanBERT predicts the longest skill spans (4.51 and 4.48 respectively). We suspect due to the domain-adaptive pre-training on JPs, it improved the span prediction performance. In contrast, the Longformer predicts shorter spans. Note that the Longformer is not domain-adapted to JPs.

Regarding KNOWLEDGE, there is also a consistent trend: BIG has the overall longest prediction length while TECH has the lowest. The Longformer predicts the longest spans on average for BIG and TECH. Knowledge components are representative of a normal-length NER task and might not need a specialized model for long sequences. We show the exact numbers in Table 7 (Appendix E) and the number of predicted SKILL and KNOWLEDGE: JobBERT and JobSpanBERT have higher recall than the other models.

Performance per Span Length SKILLS are generally longer than KNOWLEDGE components in our dataset (Figure 2). The previous overall results on the test set (Figure 3) show that performance on

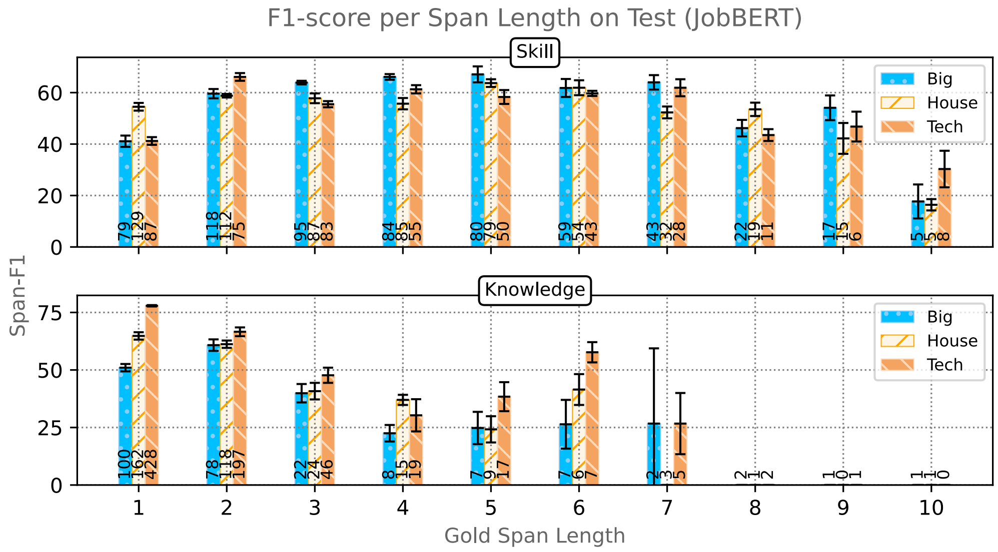

Figure 6: **Average Span-F1 per Span Length.** We bucket the performance of JobBERT according to the length of the spans until 10 tokens and show the performance on each length, averaged over five random seeds. Indicated per bar is the support. The model performs best on medium-length skill spans (i.e., spans with token length of 4-5). For knowledge spans, on average, it performs best on short-length spans (i.e., spans with token length of 1-2).

SKILL is substantially lower than KNOWLEDGE. We therefore investigate whether this performance difference is attributed to the longer spans in SKILL. In Figure 6, we show the average performance of the best performing model (JobBERT) on the three sources (test set) based on the gold span length, until a length of 10.

In SKILL components (upper plot), we see much support for spans with length 1 and 2, which then lowers once the spans become longer. Spans with length of 1 shows low performance on BIG and TECH (around 40 span-F1), which influences the total span-F1. Short skills are usually soft skills, such as “passionate”, which can be used as a skill or not. This might confuse the model. In contrast, performance effectively stays similar (around 60 span-F1) for span length of 2 till 7 for all sources. Afterwards, it drops in performance. Thus, the weak performance on SKILL seem to be due to lower performance on the short spans.

For the KNOWLEDGE components (lower plot), they are generally shorter. We see that there is a gap in support between the sources, TECH has a larger number of gold labels compared to BIG and HOUSE. Unlike soft skills, KCs usually consist of proper nouns such as “Python”, “Java”, and so forth, which connects to the high performance on TECH (around 76 span-F1). Furthermore, support for spans longer than 2 drops considerably. In this case, if the model predicts a couple of instances correctly, it would substantially increase span-F1. Contrary to SKILL, high performance of KNOWLEDGE can be attributed to its strong performance on short spans.

8 Conclusion

We present a novel dataset for skill extraction on English job postings— SKILLSPAN—and domain-adapted BERT models—JobBERT and JobSpanBERT. We outline the dataset and annotation guidelines, created for hard *and* soft skills annotation on the *span-level*. Our analysis shows that domain-adaptive pre-training helps to improve performance on the task for both skills and knowledge components. Our domain-adapted JobSpanBERT performs best on skills and JobBERT on knowledge. Both models achieve almost stochastic dominance over all other models for skills and knowledge extraction, whereas JobBERT in the STL setting achieves stochastic dominance over other models.

With the rapid emergence of new competences, our new approach of skill extraction has future potential, e.g., to enrich knowledge bases such as ESCO with unseen skills or knowledge components, and in general, contribute to providing insights into labor market dynamics. We hope our dataset encourages research into this emerging area of computational job market analysis.

Acknowledgements

We thank Google's TFRC for their support in providing TPUs for this research. Furthermore, we thank the NLPnorth group for feedback on an earlier version of this paper—in particular, Elisa Bassignana and Max Müller-Eberstein for insightful discussions. We would also like to thank the anonymous reviewers for their comments to improve this paper. Last, we also thank NVIDIA and the ITU High-performance Computing cluster for computing resources. This research is supported by the Independent Research Fund Denmark (DFF) grant 9131-00019B.

A Data Statement SKILLSPAN

Following Bender and Friedman (2018), the following outlines the data statement for SKILLSPAN:

A. CURATION RATIONALE: Collection of job postings in the English language for span-level sequence labeling, to study the impact of sequence labeling on the extraction of skill and knowledge components from job postings.

B. LANGUAGE VARIETY: The non-canonical data was collected from the StackOverflow job posting platform, an in-house job posting collection from our national labor agency collaboration partner (*which will be elaborated upon acceptance*), and web extracted job postings from a large job posting platform. US (en-US) and British (en-GB) English are involved.

C. SPEAKER DEMOGRAPHIC: Gender, age, race-ethnicity, socioeconomic status are unknown.

D. ANNOTATOR DEMOGRAPHIC: Three hired project participants (age range: 25–30), gender: one female and two males, white European and Asian (non-Hispanic). Native language: Danish, Dutch. Socioeconomic status: higher-education students. Female annotator is a professional annotator with a background in Linguistics and the two males with a background in Computer Science.

E. SPEECH SITUATION: Standard American or British English used in job postings. Time frame of the data is between 2012–2021.

F. TEXT CHARACTERISTICS: Sentences are from job postings posted on official job vacancy platforms.

G. RECORDING QUALITY: N/A.

H. OTHER: N/A.

I. PROVENANCE APPENDIX: The job posting data in TECH is from Stackoverflow jobs, and is licensed under the CC BY-SA license. The job posting data from HOUSE is from our collaborators: The Danish Agency for Labour Market and Recruitment (STAR).

B Annotation Guidelines

B.1 Span Specifications

Legend: Skill , Knowledge , "•" indicates an example sentence.

1. A skill starts with a **VERB**, otherwise (**ADJECTIVE**) + **NOUN**

1.1 Modal verbs are not tagged:

- ~~Can~~ [put personal touch on the menu]$_{\text{SKILL}}$.
- ~~Will~~ [train new staff]$_{\text{SKILL}}$.

2. Split up phrases with prepositions and/or conjunctions

2.1 **Unless** the conjunction coordinates two nouns functioning as one argument:

- [Coordinate parties and conferences]$_{\text{SKILL}}$.

2.2 Do not tag skills with anaphoric pronouns, only tag preceding skill:

- [Prioritizing tasks]$_{\text{SKILL}}$ and identifying those that are most important.

2.3 Split nouns and adjectives that are coordinated if they do not have a verb attached:

- Be [inquisitive]$_{\text{SKILL}}$ and [proactive]$_{\text{SKILL}}$.
- Prior in-house experience with [media]$_{\text{KNOWLEDGE}}$, [publishing]$_{\text{KNOWLEDGE}}$ or [internet companies]$_{\text{KNOWLEDGE}}$.

2.4 If there is a listing of skill tags and they lead up to different subtasks, we split them:

- [keep up the high level of quality in our team]$_{\text{SKILL}}$ through [reviews]$_{\text{SKILL}}$, [pairing]$_{\text{SKILL}}$ and [mentoring]$_{\text{SKILL}}$.

3. If there is relevant information appended after irrelevant information (e.g., info specific to a company) we try to make the skill as short as possible:

- [providing the best solution]$_{\text{SKILL}}$ ~~for Siemens Gamesa in a very~~ [structured]$_{\text{SKILL}}$ and [analytic]$_{\text{SKILL}}$ manner.

4. Note also the words skills and knowledge can be included in the span of the component if leaving it out makes it nonsensical:

- [personal skills]$_{\text{SKILL}}$ → just [personal] would make it nonsensical.

5. Parentheses after a skill tag are included if they elaborate the component before them or if they are an abbreviation of the component.

6. **Inclusion of adverbials in components**. Adverbials are included if it concerns the manner of doing something. All others are excluded:

- ~~like to~~ [solve technical challenges independently]$_{\text{SKILL}}$.
- [communicates openly]$_{\text{SKILL}}$.
- [striving for the best]$_{\text{SKILL}}$ ~~in all that they do~~.
- [Deliver first class customer service]$_{\text{SKILL}}$ ~~to our guests~~.
- [Making the right decisions]$_{\text{SKILL}}$ ~~early in the process~~.

7. **Attitudes as skills.** We annotate attitudes as a skill:

- ~~a~~ [can-do-approach]$_{\text{SKILL}}$ → we leave out articles from the attitude.

8. Attitudes are not tagged if they contain skill/knowledge components—then only the span of the skill is tagged.

- ~~like to~~ [solve technical challenges independently]$_{\text{SKILL}}$.
- ~~Passion for~~ [automation]$_{\text{KNOWLEDGE}}$.
- ~~enjoy~~ [working in a team]$_{\text{SKILL}}$.

9. **Miscellaneous:**

9.1 Do not tag ironic skills (e.g., lazy).

9.2 Avoid nesting of skills, annotate it as one span.

9.3 We annotate all skills that are part of sections such as “requirements”, “good-to-haves”, “great-to-knows”, “optionals”, “after this x months of training you’ll be able to...”, “At the job you’re going to...”.

9.4 When there is a general standard that can be added to the skill, we add these:

- [Process payments according to the [...] standards]$_{\text{SKILL}}$.

B.2 Knowledge Specifications

1. **Rule-of-thumb**: knowledge is something that one possesses, and cannot (usually) physically execute:

- [Python]$_{\text{KNOWLEDGE}}$ (programming language).
- [Business]$_{\text{KNOWLEDGE}}$.
- [Relational Databases]$_{\text{KNOWLEDGE}}$.

2. If there is a component between parentheses that belongs to the knowledge component, we add it:

- [(non-) relational databases]$_{\text{KNOWLEDGE}}$.
- [Driver License (UK/EU)]$_{\text{KNOWLEDGE}}$.

3. **Licenses and certifications**: We add the additional words “certificate”, “card”, “license”, et cetera. to the knowledge component.

4. If the knowledge component looks like a skill, but the preceding verb is vague and empty (e.g., *follow*, *use*, *comply with*, *work with*) → only tag the knowledge component:

- ~~Comply with~~ [Food Code of Practice]$_{\text{KNOWLEDGE}}$.
- ~~Work with~~ [AWS infrastructure]$_{\text{KNOWLEDGE}}$.

5. We annotate only specified knowledge components:

- [MongoDB]$_{\text{KNOWLEDGE}}$ or other [NoSQL database]$_{\text{KNOWLEDGE}}$.
- [JEST]$_{\text{KNOWLEDGE}}$ ~~or other test libraries~~. → “other test libraries” is under-specified.

6. Knowledge components can be nested in skill components.

- [Design, execution and analysis of [phosphoproteomics]$_{\text{KNOWLEDGE}}$ experiments]$_{\text{SKILL}}$.

7. If all components coordinate/share one knowledge tag, we annotate it as one:

- [application, data and infrastructure architecture]$_{\text{KNOWLEDGE}}$. → The knowledge tags coordinate to “architecture”.
- [chemical/biochemical engineering]$_{\text{KNOWLEDGE}}$.

8. If there is a listing of knowledge tags, we annotate all knowledge tags separately:

- [Bachelor Degree]$_{\text{KNOWLEDGE}}$ in [Mathematics]$_{\text{KNOWLEDGE}}$, [Computer Science]$_{\text{KNOWLEDGE}}$, or [Engineering]$_{\text{KNOWLEDGE}}$.

B.3 Other Specifications

1. **Rule-of-thumb**: If in doubt, annotate it as a skill.

2. We are preferring skills over knowledge components.

3. We prioritize skills over attitudes; if there is a skill within the attitude, only tag the skill:

- ~~Passionate around~~ [solving business problems]$_{\text{SKILL}}$ through [innovation & engineering practices]$_{\text{KNOWLEDGE}}$.

4. Skill or knowledge components in the top headlines of the JP are not tagged (e.g., title of a JP). If it is a sub-headline or in the rest of the posting, tag it.

5. We try to keep the skill/knowledge components as short as possible (i.e., exclude information at the end if it makes it too specific for the job).

6. We do not include "fluff" and "triggers" (i.e., words that indicate a skill or knowledge component will follow: "~~advanced knowledge of~~ [...]$_{\text{KNOWLEDGE}}$") around the components, including degree. This goes for both before and after:

- ~~Working proficiency in~~ [developmental toolsets]$_{\text{KNOWLEDGE}}$.
- ~~Advanced knowledge of~~ [application data and architecture infrastructure]$_{\text{KNOWLEDGE}}$ ~~disciplines~~.
- [Manual handling]$_{\text{SKILL}}$ ~~tasks~~.
- [CI/CD]$_{\text{KNOWLEDGE}}$ ~~experience~~.
- ~~You master~~ [English]$_{\text{KNOWLEDGE}}$ ~~on level C1~~.
- ~~Proficient in~~ [Python]$_{\text{KNOWLEDGE}}$ ~~and~~ [English]$_{\text{KNOWLEDGE}}$.
- ~~Fluent in spoken and written~~ [English]$_{\text{KNOWLEDGE}}$.

7. Pay attention to expressions such as "participation in...", "contributing", and "transfer (knowledge)". These are usually not considered skills.

- ~~Contribute to the enjoyable and collaborative work environment~~.
- ~~Participation in the Department's regular research activities~~.
- ~~Desire to be part of something meaningful and innovative~~.

8. Skills and Knowledge components that are found in not-so-straightforward places (e.g., project descriptions) are annotated as well, if they relate to the position.

9. In the pattern of "skill" followed by some elaboration, see if it can be annotated with a skill and a knowledge tag:

- [Ensure food storage and preparation areas are maintained]$_{\text{SKILL}}$ according to [Health & Safety and Audit standards]$_{\text{KNOWLEDGE}}$.

10. Occupations and positions in companies/academia should be excluded.

11. If there's a knowledge/skill component in the position, we exclude it as well.

- Experienced Java Engineer. → completely untagged.

12. Only annotate the skills that are related to the position.

12.1. This includes skills that are specific for the position as well (e.g., skills of a ruminants professor versus math professor).

12.2 Also skills that the person for the position is expected to do in the future.

12.3 This does not include skills, knowledge or attitudes describing only the company, the group you will join in the department, and so on. Only annotate if it is specified or implied that the employee should possess the skill as well.

13. We annotate industries and fields (that the employee will be working in) as knowledge components.

C Type of Skills Annotated

In both Table 8 and Table 9, we show the top-10 skill and knowledge components that have been annotated. We split the top-10 among the data splits (i.e., train, development, and test set), and also between source splits (i.e., BIG, HOUSE, TECH).

D Reproducibility

Parameter	**Value**	**Range**
Optimizer	AdamW	
β_1, β_2	0.9, 0.99	
Dropout	0.2	0.1, 0.2, 0.3
Epochs	20	
Batch Size	32	
Learning Rate (LR)	1e-4	1e-3, 1e-4, 1e-5
LR scheduler	Slanted triangular	
Weight decay	0.01	
Decay factor	0.38	0.35, 0.38, 0.5
Cut fraction	0.2	0.1, 0.2, 0.3

Table 4: Hyperparameters of MACHAMP.

We use the default hyperparameters in MACHAMP (van der Goot et al., 2021) as shown in Table 4. For more details we refer to their paper. For the five random seeds we use 3477689, 4213916, 6828303, 8749520, and 9364029. All experiments with MACHAMP were ran on an NVIDIA® TITAN X (Pascal) 12 GB GPU and an Intel® Xeon® Silver 4214 CPU.

E Exact Number of Performance

In Table 5, we show the exact numbers of the plot indicated in Figure 3. In addition, we also show the results of each respective split.

For the STL models, we observe differences in performances over the sources which is particularly pronounced for knowledge components: The TECH source is the easiest to process (and has most SKCs), while SKCs identification performance is the lowest for BIG. This might be due to the broad nature of this source.

In the exact results table (Table 5) we add a (†) next to the highest span-F1 if the model is truly stochastically dominant ($\epsilon_{\text{min}} = 0.0$) over *all* the other models. (*) denotes that the best model achieved *almost stochastic dominance* ($\epsilon_{\text{min}} < 0.5$) over—at minimum—one other model (e.g., in TEST rows w.r.t COMBINED: MTL-JobBERT $\succeq$ MTL-JobSpanBERT with $\epsilon_{\text{min}} = 0.06$) and stochastically dominant over the rest.

In Table 6, we report the precision and recall of the models, SKILL and KNOWLEDGE show the precision and recall of the STL models. MULTI shows the precision and recall of the MTL models.

Last, in Table 7, we show the exact numbers of the length of predictions Figure 5. We also add the number of predicted SKILL and KNOWLEDGE Overall, JobBERT and JobSpanBERT predict more skills in general than the other models. This is also the case for knowledge components. We hypothesize that this might be due to the BERT models now being more specialized towards the JP domain and recognizing more SKCs.

F Significance Testing

Recently, the ASO test (Dror et al., 2019)[10] has been proposed to test statistical significance for deep neural networks over multiple runs. Generally, the ASO test determines whether a stochastic order (Reimers and Gurevych, 2018) exists between two models or algorithms based on their respective sets of evaluation scores. Given the single model scores over multiple random seeds of two algorithms $\mathcal{A}$ and $\mathcal{B}$, the method computes a test-specific value (ϵ_{min}) that indicates how far algorithm $\mathcal{A}$ is from being significantly better than algorithm $\mathcal{B}$. When distance $\epsilon_{\text{min}} = 0.0$, one can claim that $\mathcal{A}$ stochastically dominant over $\mathcal{B}$ with a predefined significance level. When $\epsilon_{\text{min}} < 0.5$ one can say $\mathcal{A} \succeq \mathcal{B}$. On the contrary, when we have $\epsilon_{\text{min}} = 1.0$, this means $\mathcal{B} \succeq \mathcal{A}$. For $\epsilon_{\text{min}} = 0.5$, no order can be determined. We took 0.05 for the predefined significance level. In Figure 7, we show the ASO scores on the development set.

---

RAAT: Relation-Augmented Attention Transformer for Relation Modeling in Document-Level Event Extraction

Yuan Liang[*] **Zhuoxuan Jiang**[*] **Di Yin and Bo Ren**

Abstract

In document-level event extraction (DEE) task, event arguments always scatter across sentences (across-sentence issue) and multiple events may lie in one document (multi-event issue). In this paper, we argue that the relation information of event arguments is of great significance for addressing the above two issues, and propose a new DEE framework which can model the relation dependencies, called Relation-augmented Document-level Event Extraction (ReDEE). More specifically, this framework features a novel and tailored transformer, named as Relation-augmented Attention Transformer (RAAT). RAAT is scalable to capture multi-scale and multi-amount argument relations. To further leverage relation information, we introduce a separate event relation prediction task and adopt multi-task learning method to explicitly enhance event extraction performance. Extensive experiments demonstrate the effectiveness of the proposed method, which can achieve state-of-the-art performance on two public datasets. Our code is available at `https://github.com/TencentYoutuResearch/RAAT`.

1 Introduction

Event extraction (EE) task aims to detect the event from texts and then extracts corresponding arguments as different roles, so as to provide a structural information for massive downstream applications, such as recommendation (Gao et al., 2016; Liu et al., 2017), knowledge graph construction (Wu et al., 2019; Bosselut et al., 2021) and intelligent question answering (Boyd-Graber and Börschinger, 2020; Cao et al., 2020).

Most of the previous methods focus on sentence-level event extraction (SEE) (Ahn, 2006; Liao and Grishman, 2010; Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016; Zhao et al., 2018; Sha et al., 2018; Yan et al., 2019; Du and Cardie, 2020; Li et al., 2020; Paolini et al., 2021; Lu et al., 2021), extracting events from a single sentence. However, SEE is mostly inconsistent with actual situations. For example, event arguments may scatter across different sentences. As illustrated in Figure 1, the event argument [ORG1] of event role *Pledger* is mentioned in Sentence 4 and the corresponding argument [ORG2] of event role *Pledgee* is in Sentence 5 and 6. We call this **across-sentence issue**. Another situation involves the **multi-event issue**, which means that multiple events may exist in the same document. As seen in the example in Figure 1, where two event records coincide, we should recognize that they may partially share common arguments.

Recently, document-level event extraction (DEE) attracts great attention from both academic and industrial communities, and is regarded as a promising direction to tackle the above issues (Yang et al., 2018; Zheng et al., 2019; Xu et al., 2021b; Yang et al., 2021; Zhu et al., 2021). However, by our observation, we discover that the relations between event arguments have patterns which are an important indicator to guide the event extraction. This information is neglected by existing DEE methods. Intuitively, the relation information could build long-range relationship knowledge of event roles among multiple sentences, which could relieve the across-sentence issue. For multi-event issue, shared arguments within one document could be distinguished to different roles based on the different prior relation knowledge. As illustrated in Figure 1, [ORG1] and [ORG2] have a prior relation pattern of *Pledger* and *Pledgee*, as well as [ORG1] and [SHARE1] for the relation pattern between *Pledger* and its *Pledged Shares*. Therefore, the relation information could increase the DEE accuracy if it is well modeled.

In this paper, we propose a novel DEE framework, called Relation-augmented Document-level Event Extraction (ReDEE), which is able to model

[ORG1]	[SHARE1]	Pledger with Pledged Shares

Figure 1: An example document for the event type of Equity Pledge, including selected sentences that are involved in multiple event records and where the event arguments scatter across sentences. We can observe that the relations between these entity mentions have intuitive patterns that could be leveraged to enhance the event extraction task. More information of entity color and complete event-related relations can be found in Appendix A.2.

the relation information between arguments by designing a tailored transformer structure. This structure can cover multi-scale and multi-amount relations and is general for different relation modeling situations. We name the structure as Relation-augmented Attention Transformer (RAAT). To fully leverage the relation information, we introduce a relation prediction task into the ReDEE framework and adopt multi-task learning method to optimize the event extraction task. We conduct extensive experiments on two public datasets. The results demonstrate the effectiveness of modeling the relation information, as well as our proposed framework and method.

In summary, our contributions are as follows:

- We propose a Relation-augmented Document-level Event Extraction (ReDEE) framework. It is the first time that relation information is implemented in the document-level event extraction field.
- We design a novel Relation-augmented Attention Transformer (RAAT). This network is general to cover multi-scale and multi-amount relations in DEE.
- We conduct extensive experiments and the results demonstrate that our method outperform the baselines and achieve state-of-the-art performance by 1.6% and 2.8% F1 absolute increasing on two datasets respectively.

2 Related Work

2.1 Sentence-level Event Extraction

Previously, most of the related works focus on sentence-level event extraction. For example, a neural pipeline model is proposed to identify triggers first and then extracts roles and arguments (Chen et al., 2015). Then a joint model is created to extract triggers and arguments simultaneously via multi-task learning (Nguyen et al., 2016; Sha et al., 2018). To utilize more knowledge, some studies propose to leverage document contexts (Chen et al., 2018; Zhao et al., 2018), pre-trained language models (Yang et al., 2019), and explicit external knowledge (Liu et al., 2019a; Tong et al., 2020). However, these sentence-level models fail to extract multiple qualified events spanning across sentences, while document-level event extraction is a more common need in real-world scenarios.

2.2 Document-level Event Extraction

Recently, DEE has attracted a great attention from both academic and industrial communities. At first, the event is identified from a central sentence and other arguments are extracted from neighboring sentences separately (Yang et al., 2018). Later, an innovative end-to-end model Doc2EDAG, is proposed (Zheng et al., 2019), which can generate event records via an entity-based directed acyclic graph to fulfill the document-level event extraction effectively. Based on Doc2EDAG, there are some variants appearing. For instance, GIT (Xu et al., 2021b) designs a heterogeneous graph interaction network to capture global interaction information among different sentences and entity mentions. It also introduces a specific Tracker module to memorize the already extracted event arguments for assisting record generation during next iterations. DE-PPN (Yang et al., 2021) is a multi-granularity model that can generate event records via limiting the number of record queries. Not long ago, a pruned complete graph-based non-autoregressive model PTPCG was proposed to speedup the record decoding and get competitive overall evaluation results (Zhu et al., 2021). In summary, although those existing works target for solving across-sentence and multi-event issues of the DEE task from various perspectives, to our best knowledge, we conduct a pioneer investigation on relation modeling towards this research field in this paper.

2.3 Trigger-aware Event Extraction

Previously a lot of works((Ji and Grishman, 2008; Liao and Grishman, 2010; Li et al., 2013; Chen et al., 2015; Nguyen et al., 2016; Liu et al., 2018)) deal with event extraction in two stages: firstly, trigger words are detected, which are usually nouns or verbs that clearly express event occurrences. And secondly, event arguments, the main attributes of events, are extracted by modeling relationships between triggers and themselves. In our work, we unify task as a whole to avoid error propagation between sub-tasks.

3 Preliminaries

Firstly, we clarify several key concepts in event extraction tasks. 1) ***entity***: a real world object, such as person, organization, location, etc.2) ***entity mention***: a text span in document referring to an entity object. 3) ***event role***: an attribute corresponding a pre-defined field in an event. 4) ***event argument***: an entity playing a specific event role. 5) ***event record***: a record expressing an event itself, including a series of event arguments.

In document-level event extraction task, one document can contain multiple event records, and an event record may miss a small set of event arguments. Further more, a entity can have multiple event mentions.

4 Methodology

In this section, we introduce the proposed architecture first and then the key components in detail.

4.1 Architecture Overview

End-to-end training methods for DEE usually involve a pipeline paradigm, including three subtasks: named entity recognition, event role prediction and event argument extraction. In this paper, we propose the Relation-augmented Document-level Event Extraction (ReDEE) framework coordinated with the paradigm. Our framework features leverage the relation dependency information in both encoding and decoding stages. Moreover, a relation prediction task is added into the framework to fully utilize the relation knowledge and enhance the event extraction task.

More specifically, shown in Figure 2, there are four key components in our ReDEE framework: Entity Extraction and Representation(EER), Document Relation Extraction(DRE), Entity and Sentence Encoding(ESE), and Event Record Generation(ERG). In the following, we would introduce the detailed definition of each component.

4.2 Entity Extraction and Representation

We treat the component of entity extraction as a sequence labeling task. Given a document D with multiple sentences $\{s_1, s_2, ..., s_i\}$, we use a native transformer encoder to represent the token sequence. Specifically, we use the BERT (Devlin et al., 2019) encoder pre-trained in Roberta setting (Liu et al., 2019). Then we use the Conditional Random Field(CRF) (Lafferty et al., 2001) to classify token representations into labels of named entities. We adopt the classical BIOSE sequence labeling scheme. The labels are predicted by the following calculation: $\hat{y}_{ne} = CRF(Trans(D))$. Then all the intermediate embeddings of extracted entity mentions and sentences are concatenate into a matrix $M_{ne+s} \in \mathbb{R}^{(j+i) \times d_e}$ by max-pooling operation on each sentence and entity mention span, where j and i are the numbers of entity mentions and sentences, and d_e is the dimension of embeddings. The loss function for named entity recognition is

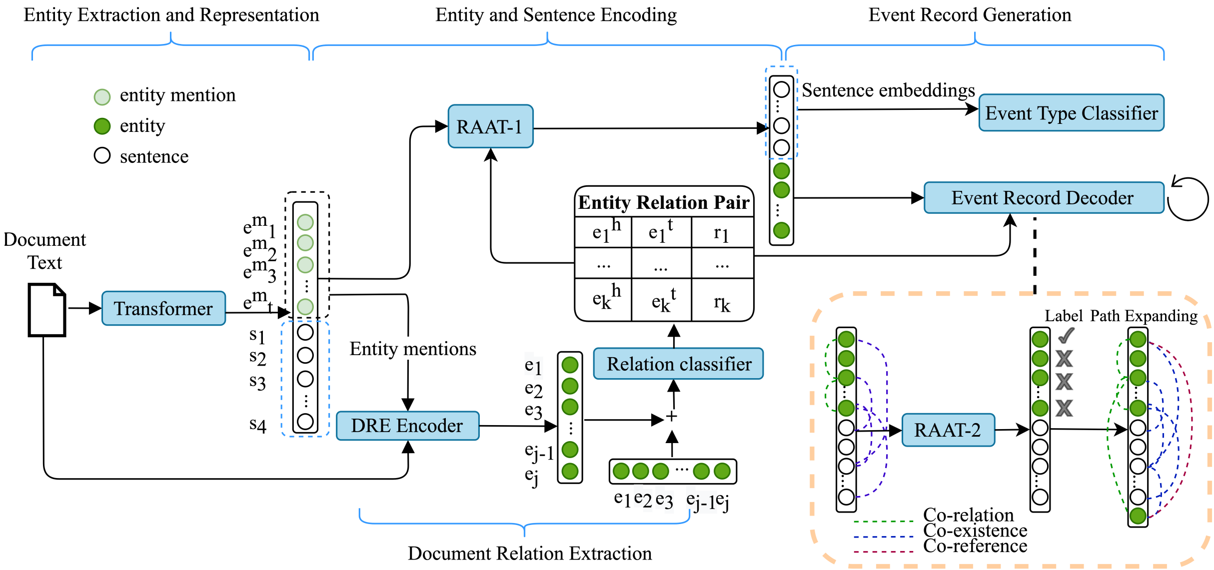

Figure 2: Overall of our proposed ReDEE framework.

denoted:

$$\mathcal{L}_{ne} = -\sum_{s_i \in D} logP(y_i|s_i) \tag{1}$$

where s_i denotes the i^{th} sequence sentence in document, and y_i is the corresponding ground truth label sequence.

4.3 Document Relation Extraction

The DRE component takes the document text (D) and entities ($\{e_1, e_2, ..., e_j\}$) extracted in the previous step as inputs, and outputs the relation pairs among entities, in a form of triples ($\{[e_1^h, e_1^t, r_1], [e_2^h, e_2^t, r_2], ..., [e_k^h, e_k^t, r_k]\}$). $[e_k^h, e_k^t, r_k]$ means the head entity, the tail entity and the relationship of the k^{th} triple respectively.

An important aspect is how to define and collect the relations from data. Here we assume that every two arguments in an event record can be connected by a relation. For example, *Pledger* and *Pledgee* in the *EquityPledge* event could have a relation named as *Pledge2Pledgee*, and the order of head and tail entities is determined by the pre-order of event arguments (Zheng et al., 2019). In this way, every event record with n arguments could create C_n^2 relation samples. Note that this method to build relations is general to event extraction tasks from various domains, and the supervised relation information just comes from event record data itself, without any extra human labeling work. We do statistics for the relation types for ChiFinAnn dataset. Table 1 shows a snippet of statistics and the full edition can be found in Appendix A.3.

Relation Type	#Train	#Dev	#Test
Pledger2PledgedShares	20002	2567	2299
Pledger2Pledgee	20002	2567	2299
PledgedShares2Pledgee	20002	2567	2299
Start2EndDate	19615	2239	1877
Pledger2TotalHoldingShares	18552	2412	2173

Table 1: The example relations with top 5 quantities in the ChiFinAnn dataset. The complete statistic can refer to the Appendix A.3.

To predict the argument relations in this step, we adopt the structured self attention network (Xu et al., 2021a) which is the latest method for document-level relation extraction. However, different from previous work using multi-class binary cross-entropy loss, we use normal cross-entropy loss to predict only one label for each entity pair. The relation type is inferred by this function:

$$\hat{y}_{i,j} = argmax(e_i^T W_r e_j) \tag{2}$$

where $e_i, e_j \in \mathbb{R}^d$ denote entity embedding from encoder module of DRE and d is the dimension of embeddings. $W_r \in \mathbb{R}^{d \times c \times d}$ denotes biaffine matrix trained by DRE task and c is the total number of relations. And the loss function for optimize the relation prediction task is denoted:

$$\mathcal{L}_{dre} = -\sum_{y_{i,j} \in Y} logP(y_{i,j}|D) \tag{3}$$

where $y_{i,j}$ denotes ground truth label between the i^{th} and j^{th} entity, D for document text and Y for set of all relation pairs among entities.

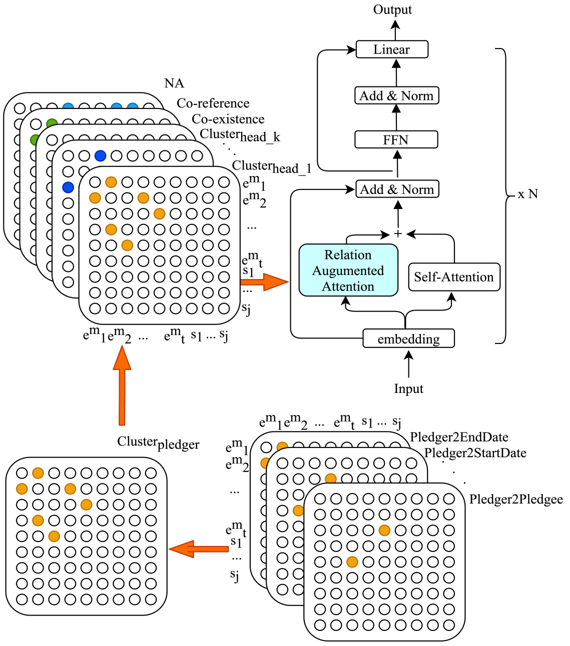

Figure 3: RAAT structure. Firstly each relation between entities and sentences are represented as matrices. Then the matrices are clustered by the head entities. At last the clustered matrices are integrated into the transformer structure for attention calculation.

	sentence	entity
sentence	NA	Co-existence/NA
entity	Co-existence/NA	Co-relation/Co-reference/NA

Table 2: All types of dependency among sentences and entities

4.4 Entity and Sentence Encoding

Now we have embeddings of entity mentions and sentences from EER component and a list of predicted triple relations from DRE component. Then this component encodes data mentioned above and output embeddings effectively integrated with relation information. In this subsection, we would introduce the method that translates triple relations to calculable matrices and the novel RAAT structure for encoding all the above data.

4.4.1 Entity and Sentence Dependency

First, we introduce a mechanism: entity and sentence dependency, which not only includes relation triples, but also describes links among sentences and entities beyond triples.

Co-relation and *Co-reference* are defined to represent entity-entity dependency. For the former one, two entities have a *Co-relation* dependency between them if they belong to a predicted relation triple. Entity pairs are considered having different *Co-relation* if their involved triples have different relations. *Co-reference* shows dependency between entity mentions pointing to same entities. That is, if an entity has several mentions existing across document, then each two of them has *Co-reference* dependency. However, in the case that head and tail entities in relation triple are the same (i.e. *StartDate* and *EndDate* share same entities in some event records), then *Co-relation* and *Co-reference* are both held between them.

We use *Co-existence* to describe dependency between entities and sentences where entity mentions come from. To be more specific, the entity mention together with its belonged sentence has *Co-existence*. For remaining entity-entity and entity-sentence pairs without any dependency mentioned above, we uniformly treat them as *NA* dependency.

Table 2 shows the complete dependency mechanism. *Co-relation* differs from *NA*, *Co-reference*, and *Co-existence* in that it has several sub-types, with number equaling to that of relation types defined in document relation extraction task.

4.4.2 RAAT

In order to effectively encode entity and sentence dependencies, we design the RAAT which takes advantage of a calculable matrix representing dependencies and integrates it into attention computation. According to the architecture shown in Figure 3, RAAT is inherited from native transformer but has a distinct attention computation module which is made up of two parts: self-attention and relation-augmented attention computation.

Given a document shown as $D = \{s_1, s_2, ...s_j\}$, all entity mentions in this document as $E^m = \{e^m_1, e^m_2, ..., e^m_t\}$, where e^m_i denotes entity mentions with the superscript m denotes mention, and the subscript i denotes index, and a list of triples $\{[e^h_1, e^t_1, r_1], [e^h_2, e^t_2, r_2], ..., [e^h_k, e^t_k, r_k]\}$, we build a matrix $T \in \mathbb{R}^{c\times(t+j)\times(t+j)}$ where c for the number of dependencies, and t and j for the number of sentences and entity mentions respectively. T is comprised of c matrices with same dimensions $R \in \mathbb{R}^{(t+j)\times(t+j)}$, and each R represents one type of dependency $r \in \{Co-relation_k, Co-reference, Co-existence, NA\}, k = 1, 2, ...N$, N as the number of relation types. For element within T, $t_{k,i,j}$ represent the dependency between $node_i$ and $node_j$. Specifically, $t_{k,i,j} = 1$ if they have the k^{th} dependency, otherwise, $t_{k,i,j} = 0$. Here, $node_k \in \{e^m_1, e^m_2, ..., e^m_t, s_1, s_2, ...s_j\}$ can be either entity mention or sentence.

However, T would be giant and sparse if we use the above strategy. To squeeze T and decrease training parameters, we cluster *Co-relation* dependency based on the type of head entity in relation triple. For example, *Pledger2Pledgee* and *Pledger2PledgedShares* are clustered as one Co-relation dependency, and two matrice R_a and R_b corresponding to them are merged into one matrix. As a result, we finally get $T \in \mathbb{R}^{(3+H)\times(t+j)\times(t+j)}$ where H denotes the number of head entity type in *Co-relation*, and 3 covers *NA*, *Co-reference*, and *Co-existence*. Let $X \in \mathbb{R}^{(t+j)\times d}$ as input embeddings of attention module, $W_{rq}, W_{rk}, W_q, W_k, W_v \in \mathbb{R}^{d\times d}$, $M \in \mathbb{R}^{(3+H)\times d\times d}$ as weight matrices, we compute relation-augmented attention in the following steps:

$$Q_r = XW_{rq}, K_r = XW_{rk} \tag{4}$$

$$S_a = \frac{\sum_{i=1}^{3+H} Q_r M[i,:,:] K_r^T \cdot T[i,:,:]}{\sqrt{d}} + bias_i \tag{5}$$

where S_a denotes score matrix of relation-augmented attention, $\cdot$ denotes element-wise multiplication. We compute self attention score and combine it with S_a in the following way:

$$Q = XW_q, K = XW_k, W_v = XW_v \tag{6}$$

$$S_b = \frac{QK^T}{\sqrt{d}} \tag{7}$$

$$O = (S_a + S_b)V \tag{8}$$

where O is the output of attention module. Similar to the structure of native transformer, RAAT has multiple identical blocks stacking up layer by layer. Furthermore, T is extensive since the number of *Co-relation* can be selected. RAAT can be adaptive to the change of input length, which is equivalent to the total number of sentences and entity mentions.

4.5 Event Record Generation

With the outputs from previous component, the embeddings of entities and sentences, this ERG component actually includes two sub-modules: event type classifier and event record decoder.

4.5.1 Event Type Classifier

Given the embeddings of sentences, we adopt several binary classifiers on every event type to predict whether the corresponding event is identified or not. If there is any classifier identifying an event type, the following event record decoder would be activated to iteratively generate every argument for the corresponding event type. The loss function to optimize this classifier is as the following:

$$\mathcal{L}_{pred} = -\sum_i log(P(y_i|S)) \tag{9}$$

where y_i denotes the label of the i^{th} event type, $y_i = 1$ if there exists event record with event type i, otherwise, $y_i = 0$. S denotes input embeddings of sentences.

4.5.2 Event Record Decoder

To iteratively generate every argument for a specific event type, we refer to the entity-based directed acyclic graph (EDAG) method (Zheng et al., 2019). EDAG is a sequence of iterations with the length equaling to number of roles for certain event type. The objective of each iteration is to predict event argument of certain event role. Inputs of each iteration are come up with entities and sentences embeddings. And the predicted arguments of outputs will be a part of inputs for next iteration. However, different from EDAG, we substitute its vanilla transformer part with our proposed RAAT structure (i.e. RAAT-2 as shown in Figure 2). More specifically, the EDAG method uses a memory structure to record extracted arguments and adds role type representation to predict current-iteration arguments. However, this procedure hardly captures dependency between entities both in memory and argument candidates and sentences. In our method, RAAT structure can connect entities in memory and candidate arguments via relation triples extracted by the DRE component, and it can construct a structure to represent dependencies. In detail, before predicting event argument for current iteration, Matrix T is constructed in the way shown above so that dependency is integrated into attention computation. After extracting the argument, it is added into memory, meanwhile, a new T is generated to adapt next iteration prediction.

Therefore, the RAAT can strengthen the relation signal for attention computation. The RAAT-2 has the same structure with RAAT-1 but independent parameters. The formal definition of loss function for event recorder decoder is:

$$\mathcal{L}_a = -\sum_{v\in V_D}\sum_e log(P(y_e|(v,s))) \tag{10}$$

where V_D denotes node set in event records graph, v denotes extracted event arguments of event record by far, s denotes embedding of sentences and event argument candidates, and y_e denotes label of argument candidate e in current step. $y_e = 1$ means e is the ground truth argument corresponding to current step event role, otherwise, $y_e = 0$.

4.6 Model Training

To train the above four components, we leverage the multi-task learning method (Collobert and Weston, 2008) and integrate the four corresponding loss functions together as the following:

$$\mathcal{L} = \lambda_1 \mathcal{L}_{ne} + \lambda_2 \mathcal{L}_{dre} + \lambda_3 \mathcal{L}_{pred} + \lambda_4 \mathcal{L}_{a} \qquad (11)$$

where the λ_i pre-set to balance the weight among the four components.

5 Experiments

In this section, we report the experimental results to prove the effectiveness of our proposed method. In summary, the experiments could answer the following three questions:

- To what degree does the ReDEE model outperform the baseline DEE methods?
- How well does ReDEE overcome across-sentence and multi-event issues?
- In what level does the each key component of ReDEE contribute to the final performance?

5.1 Datasets

DEE is a relatively new task and there are only a few datasets published. In our experiments we adopt two public Chinese datasets, i.e. **ChiFinAnn** (Zheng et al., 2019) and **DuEE-fin** (Li, 2021).

ChiFinAnn includes 32,040 documents with 5 types of events, involving in equity-related activities for the financial domain. Statistics show that about 30% of the documents contain multiple event records. We randomly split the dataset into train/dev/test sets in the ratio of 8/1/1. Readers can refer to the original paper for details.

DuEE-fin is also from the financial domain with around 11,900 documents in total. The dataset is downloaded from an online competition website[*]. Since there is no ground truth publicly available for the test set, we can only submit our extracted results to the website as a black-box online evaluation. Compared to ChiFinAnn, there are two differences. The DuEE-fin dataset has 13 different event types and its test set includes a large size of document samples that do not have any event records, which both make it more complicated. We get the distribution information of the dataset from Appendix A.1.

5.2 Baselines and Metrics

Five different baseline models are taken into consideration: 1) **DCFEE** (Yang et al., 2018), the first model proposed to solve DEE task. 2) **Doc2EDAG** (Zheng et al., 2019), proposed an end-to-end model which transforms DEE as directly filling event tables with entity-based path expending. 3) **DE-PPN** (Yang et al., 2021), a pipeline model firstly introducing the non-autoregressive mechanism. 4) **GIT** (Xu et al., 2021b), a model using heterogeneous graph interaction network as encoder and maintaining a global tracker during the decoding process. 5) **PTPCG** (Zhu et al., 2021), a light-weighted and latest DEE model.

For evaluation metrics, we use precision, recall, and F1 score at the entity argument level for fair comparison with baselines. The overall "Avg" in the result tables denotes the micro average value of precision, recall, and F1 score. We conduct several offline evaluations for ChiFinAnn, but only an online test for DuEE-fin.

5.3 Settings

In our implementation, for text processing, we consistently set the maximum sentence number and the maximum sentence length as 128 and 64 separately. We use BERT encoder in the EER component for fine-tuning and Roberta-chinese-wwm (Yiming et al., 2020) as the pre-trained model. Both RAAT-1 and RAAT-2 have four layers of identical blocks. More training details can be found in Appendix A.5.

5.4 Results and Analysis

Overall Performance Table 3 shows the comparison between baselines and our ReDEE model on the ChiFinAnn dataset. The ReDEE can achieve the state-of-the-art performance in terms of micro average recall and F1 scores on almost every type of events (i.e. EF, ER, EU, EO, EP), consistent with the Avg. results increased by 1.5% and 1.6% respectively. Our model also performs competitively well on precision results.

Table 4 shows the comparison results of our model with baselines on the developing set of

Table 5: F1 scores on four sets growing with average number of sentences involved in event records. †: results from (Xu et al., 2021b).

DuEE-fin and its online testing. Seeing from former results, our model outperforms in a great leap by increasing 6.7% on F1 score. For the online testing evaluation, our model has a distinct growth of 2.8% on F1 score than the baselines. This experiment demonstrates our model could achieve a superior performance than existing methods.

Argument Scattering The across-sentence issue widely exists in datasets. By our statistics, the training sets of ChiFinAnn and DuEE-fin have about 98.0% and 98.9% records that scatter across sentences respectively. To evaluate the performance of our model in different argument scattering degree, we compute the average number of sentences involved in records for each document and sort them in the increasing average number order. Then, all documents for testing are evenly divided into four sets, namely, I, II, III and IV, which means the I set is a cluster of documents that have the smallest average number of involved sentences while the IV set has the largest ones. According to table 5, our model outperforms other baseline models in all settings, and meets the largest growth of 2.2% F1 score in IV, the most challenging set of all. It indicates that our model is capable of capturing longer dependency of records across sentences via relation dependency modeling, thus alleviating the argument scattering challenge.

Single v.s. Multi Events To illustrate how well our model performs in the multi-event aspect, we split the test set of ChiFinAnn into two parts: one for documents with single event record, and the other for documents including multiple events. Table 6 shows the comparison results of all baselines and ReDEE. We find ReDEE performs much better in the multi-event scenario and outperforms baseline models dramatically in all five event types, improving ranging from 1.9% to 3.2% F1 scores. The results suggest that our relation modeling method is more effective to overcome the multi-event issue than existing baseline models.

5.5 Ablation Study

To probe the impact of RAAT structure for different components in ReDEE, we conduct ablation studies on whether to use RAAT or vanilla transformer.

In this experiment, we implement tests on three variants: 1) *-RAAT-1* substitutes the RAAT in the ESE component with vanilla transformer. 2) *-RAAT-2* substitutes the RAAT in the event record generation module with vanilla transformer. 3) *-RAAT-1&2* substitutes the RAATs in both the above places with vanilla transformers, so that our model degrades to only import a relation extraction task via multi-task learning.

The results in Table 7 indicate that both two RAATs have positive influence on our model. Especially on ChiFinAnn, RAAT-2 makes more con-

tribution than RAAT-1, with a decrease of 0.7% versus 0.4% in F1 scores once been substituted. After replacing both two RAATs, the value of relation extraction task becomes more weak and the model encounters a 1.5% drop in F1 score. When it comes to DuEE-fin, a similar phenomenon can be observed that both the RAATs can contribute positively to our model.

6 Conclusion

In this paper, we investigate a challenging task of event extraction at document level, towards the across-sentence and multi-event issues. We propose to model the relation information between event arguments and design a novel framework ReDEE. This framework features a new RAAT structure which can incorporate the relation knowledge. The extensive experimental results can demonstrate the effectiveness of our proposed method which makes the state-of-the-art performance on two benchmark datasets. In the future, we will make more efforts to accelerate training and inference process.

A Appendix

In the appendix, we incorporate the following details that are omitted in the main body due to the space limit.

A.1 Distribution of Event Type DuEE-fin

Table 8 shows the complete event type and corresponding distribution of DuEE-fin dataset. Overall, there are 13 event types in total with uneven distribution. Only train and development sets are shown since test set is not publicly available.

A.2 Complete Relation Triples

Table 9 demonstrates the complete of relation triples of the document event extraction example shown in Figure 1.

Entities in blue are involved in both two event records, while those in green and orange are exclusive to record 1 and 2 respectively. Heavy coupling of arguments among events increases the difficulty of multi-event issue.

A.3 Relation Statistics for ChiFinAnn

Table 10 shows the relation statistics of ChiFinAnn dataset. There are 85 relation types in total, and train, development, and test sets have similar pattern in distribution.

A.4 Case Study

Figure 4 shows the prediction results of our model and the best baseline model GIT on the example in Figure 1. Compared with the ground truth, our model correctly predicts all event arguments except one, while GIT only captures one event, with an argument missed. This example explicitly shows the superiority of our model in dealing with multi-events issue.

A.5 More Training Settings

For all native transformers and RAATs, the dimensions of hidden layers and feed-forward layers are set to 768 and 1,024 respectively. During training, we set the learning rate $lr = 5e^{-5}$, batch size $b = 64$. The four loss weights are set to $\lambda_1 = \lambda_3 = 0.05, \lambda 2 = 1.0, \lambda_4 = 0.95$. We use 8 V100 GPUs and set gradient accumulation steps to 8. The train epoch are set to 100, and the best epoch are selected by the best validation score on development set for the evaluation of test set. And we use Adam to optimize the whole learning task.

Abstract

Frame semantic parsing is a fundamental NLP task, which consists of three subtasks: frame identification, argument identification and role classification. Most previous studies tend to neglect relations between different subtasks and arguments and pay little attention to ontological frame knowledge defined in FrameNet. In this paper, we propose a Knowledge-guided Incremental semantic parser with Double-graph (KID). We first introduce Frame Knowledge Graph (FKG), a heterogeneous graph containing both frames and FEs (Frame Elements) built on the frame knowledge so that we can derive knowledge-enhanced representations for frames and FEs. Besides, we propose Frame Semantic Graph (FSG) to represent frame semantic structures extracted from the text with graph structures. In this way, we can transform frame semantic parsing into an incremental graph construction problem to strengthen interactions between subtasks and relations between arguments. Our experiments show that KID outperforms the previous state-of-the-art method by up to 1.7 F1-score on two FrameNet datasets. Our code is availavle at `https://github.com/PKUnlp-icler/KID`.

1 Introduction

The frame semantic parsing task (Gildea and Jurafsky, 2002; Baker et al., 2007) aims to extract frame semantic structures from sentences based on the lexical resource FrameNet (Baker et al., 1998). As shown in Figure 1, given a target in the sentence, frame semantic parsing consists of three subtasks: frame identification, argument identification and role classification. Frame semantic parsing can also contribute to downstream NLP tasks such as machine reading comprehension (Guo et al., 2020), relation extraction (Zhao et al., 2020) and dialogue generation (Gupta et al., 2021).

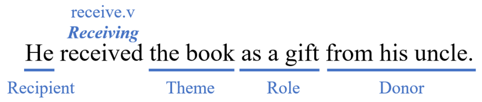

Figure 1: Given the target **receive** in this sentence, the frame identification is to identify the frame ***Receiving*** evoked by it; the argument identification is to find the arguments (*He*, *the book*, ...) of this target; the role classification is to assign frame elements (**Recipient**, **Theme**, ...) as semantic roles to these arguments.

FrameNet is an English lexical database, which defines more than one thousand hierarchically-related frames to represent situations, objects or events, and nearly 10 thousand FEs (Frame Elements) as frame-specific semantic roles with more than 100,000 annotated exemplar sentences. In addition, FrameNet defines ontological frame knowledge for each frame such as frame semantic relations, FE mappings and frame/FE definitions. The frame knowledge plays an important role in frame semantic parsing. Most previous approaches (Kshirsagar et al., 2015; Yang and Mitchell, 2017; Peng et al., 2018) only use exemplar sentences and ignore the ontological frame knowledge. Recent researches (Jiang and Riloff, 2021; Su et al., 2021) introduce frame semantic relations and frame definitions into the subtask frame identification. Different from previous work, we construct a heterogeneous graph named Frame Knowledge Graph (FKG) based on frame knowledge to model multiple semantic relations between frames and frames, frames and FEs, as well as FEs and FEs. Furthermore, we apply FKG to all subtasks of frame semantic parsing, which can fully inject frame knowledge into frame semantic parsing. The knowledge-enhanced representations of frames and FEs are learned in a unified vector space and this can also strengthen interactions between frame identification and other subtasks.

Most previous systems neglect interactions be-

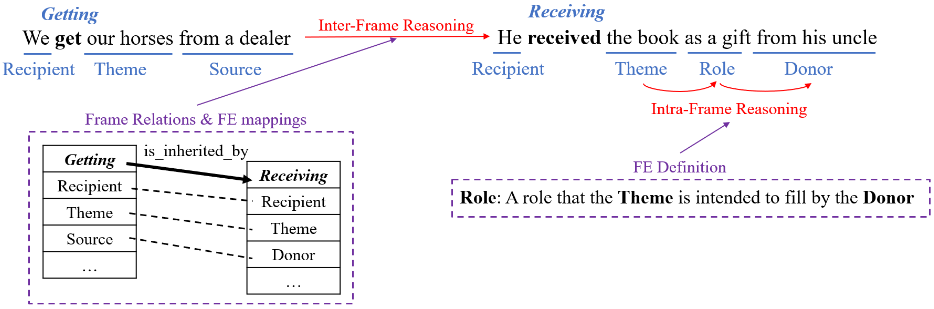

Figure 2: An example of how frame knowledge contributes to frame semantic parsing. The frame semantic relations and FE mappings guide inter-frame reasoning (from left sentence to right); and the FE definitions help with intra-frame reasoning (**Theme** to **Role** and **Role** to **Donor**).

tween subtasks, they either focus on one or two subtasks (Hermann et al., 2014; FitzGerald et al., 2015; Marcheggiani and Titov, 2020) of frame semantic parsing or treat all subtasks independently (Das et al., 2014; Peng et al., 2018). Furthermore, in argument identification and role classification, previous approaches process each argument separately with sequence labeling strategy (Yang and Mitchell, 2017; Bastianelli et al., 2020) or span-based graphical models (Täckström et al., 2015; Peng et al., 2018). In this paper, we propose Frame Semantic Graph (FSG) to represent frame semantic structures and treat frame semantic parsing as a process to construct this graph incrementally. With graph structure, historical decisions of parsing can guide the current decision of argument identification and role classification, which highlights interactions between subtasks and arguments.

Based on two graphs mentioned above, we propose our framework KID (**K**nowledge-guided **I**ncremental semantic parser with **D**ouble-graph). FKG provides a static knowledge background for encoding frames and FEs while FSG represents dynamic parsing results in frame semantic parsing and highlights relations between arguments.

Overall, our contributions are listed as follow:

- We build FKG based on the ontological frame knowledge in FrameNet. FKG incorporates frame semantic parsing with structured frame knowledge, which can get knowledge-enhanced representations of frames and FEs.

- We propose FSG to represent the frame semantic structures. We treat frame semantic parsing as a process to construct the graph incrementally. This graph focuses on the target-argument and argument-argument relations.

We evaluate the performance of KID on two FrameNet datasets: FN 1.5 and FN 1.7, the results show that the KID achieves state-of-the-art on these datasets by increasing up to 1.7 points on F1-score. Our extensive experiments also verify the effectiveness of these two graphs.

2 Ontological Frame Knowledge

Frame semantics relates linguistic semantics to encyclopedic knowledge and advocates that one cannot understand the semantic meaning of one word without essential frame knowledge related to the word (Fillmore and Baker, 2001). The frame knowledge of a frame contains frame/FE definitions, frame semantic relations and FE mappings. FrameNet defines 8 kinds of frame semantic relations such as **Inheritance**, **Perspective_on** and **Using**; for any two related frames, the FrameNet defines FE mappings between their FEs. For example, the frame ***Receiving*** inherits from ***Getting*** and the FE **Donor** of ***Receiving*** is mapped to the FE **Source** of ***Getting***. Each frame or FE has its own definition and may mention other FEs.

We propose two ways of reasoning about frame semantic parsing: inter-frame reasoning and intra-frame reasoning in Figure 2. Frame knowledge mentioned above can guide both ways of reasoning. The frame semantic relation between ***Receiving*** and ***Getting*** and FE mappings associated with it allow us to learn from the left sentence when parsing the right sentence because similar argument spans of two sentences will have related FEs as their roles. The FE definitions reflect dependencies between arguments. The definition of **Role** in frame ***Receiving*** mentions **Theme** and **Donor**, which reflects dependencies between argument *the book* and argument *as a gift*.

3 Task Formulation

Given a sentence $S = w_0, \dots, w_{n-1}$ with a target span t in S, the frame semantic parsing aims to extract the frame semantic structure of t. Suppose that there are k arguments of t in S: $a_0, \dots, a_{k-1}$, subtasks can be formulated as follow:

- Frame identification: finding an $f \in \mathcal{F}$ evoked by target t, where $\mathcal{F}$ denotes the set of all frames in the FrameNet.
- Argument identification: finding the boundaries i^s_τ and i^e_τ for each argument $a_\tau = w_{i^s_\tau}, \dots, w_{i^e_\tau}$.
- Role classification: assigning an FE $r_\tau \in \mathcal{R}_f$ to each a_τ, where $\mathcal{R}_f$ denotes the set of all FEs of frame f.

4 Method

Kid encodes all frames and FEs to knowledge-enhanced representations via frame knowledge graph encoder (section 4.1). For a sentence with a target, contextual representations of tokens are derived from the sentence encoder (section 4.2). Frame semantic parsing is regarded as a process to build FSG incrementally from an initial target node to complete FSG. Frame identification finds a frame evoked by the target and combines the target with its frame into the initial node of FSG (section 4.3.1). Argument identification (section 4.3.2) and role classification (section 4.3.3) for each argument is based on the current snapshot of partial FSG considering all historical decisions. Section 4.4 tells how frame semantic graph decoder encodes partial FSG to its representation and how it expands FSG incrementally, which is also shown in Figure 4.

4.1 Frame Knowledge Graph Encoder

FKG is an undirected multi-relational heterogeneous graph, and Figure 3 shows a subgraph of FKG. Its nodes contain both frames and FEs and there are four kinds of relations in FKG: frame-FE, frame-frame, inter-frame FE-FE and intra-frame FE-FE relations. The following will show how we extract these relations from frame knowledge:

Frame-FE: we connect a frame with its FEs so that we can learn representations of frames and FEs in a unified vector space to strengthen interactions between frame identification and other subtasks.

Frame-frame and **inter-frame FE-FE**: these two kinds of relations are frame semantic relations and FE mappings respectively and here we ignore relation types of frame semantic relations. They can both guide inter-frame reasoning in Figure 2.

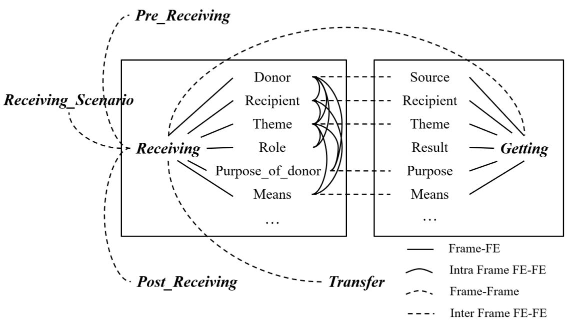

Figure 3: A subgraph of FKG. We only show intra-frame and inter-frame FE-FE relations in the frame ***Receiving***. Inside the solid rectangular box are a frame and its FEs.

Intra-frame FE-FE: If the definition of an FE mentions another FE in the same frame, they will have intra-frame FE-FE relations with each other. This relation can help with intra-frame reasoning and strengthen interactions between arguments.

The frame knowledge graph encoder aims to get knowledge-enhanced representations of nodes in FKG via an RGCN (Schlichtkrull et al., 2018) module. We use $\mathcal{F}$ to represent all frames in FrameNet and $\mathcal{R}_f$ to represent all FEs of frame f. In addition, we use $\mathcal{R} = \bigcup_{f \in \mathcal{F}} \mathcal{R}_f$ to represent all FEs in the FrameNet. Let $0, \dots, |\mathcal{F}| - 1$ denote all frames and $|\mathcal{F}|, \dots, |\mathcal{F}| + |\mathcal{R}| - 1$ denote all FEs. Moreover, we introduce a special dummy node indexing $|\mathcal{F}| + |\mathcal{R}|$ into FKG. So the vectors $y_0, \dots, y_M \in \mathbb{R}^{d_n}$ denote the representations of all nodes in FKG, where $M = |\mathcal{F}| + |\mathcal{R}|$.

For each node i, we take a randomly initialized embedding $y_i^{(0)} \in \mathbb{R}^{d_n}$ as the input feature of the RGCN module. Then we can get representations of all frames and FEs:

$$y_0, \dots, y_M = \mathrm{RGCN}\left(y_0^{(0)}, \dots, y_M^{(0)}\right) \quad (1)$$

The RGCN module models four kinds of relations: Frame-FE, intra-frame FE-FE, frame-frame and inter-frame FE-FE. For better modeling inter-frame relations between FEs, we also fuse name information into representations of FEs. The FEs whose names are the same will share the same embeddings, i.e. for $i, j \geq |\mathcal{F}|$, $y_i^{(0)} = y_j^{(0)}$ if the name of i is the same as j.

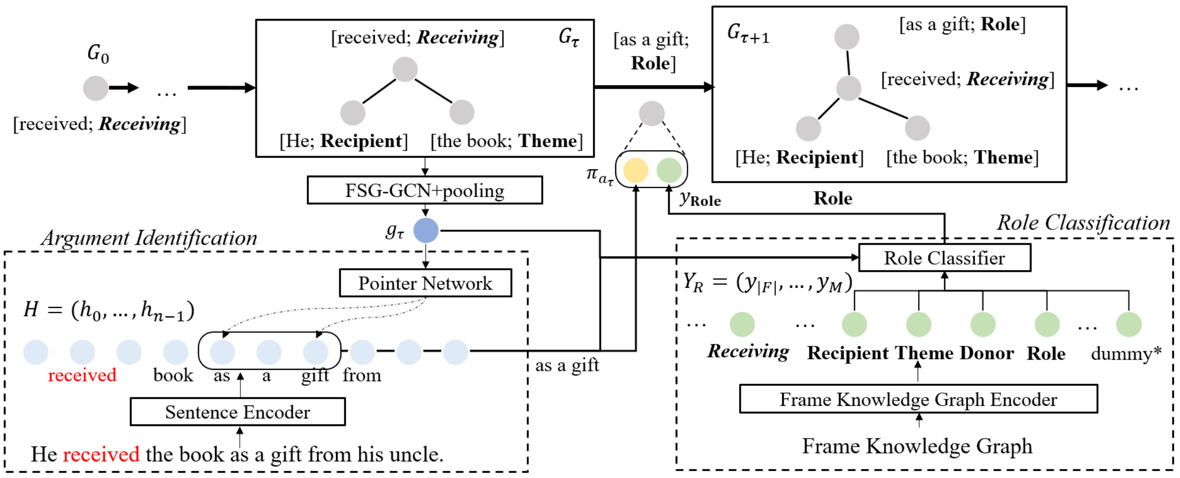

Figure 4: Based on the representation g_τ of partial G_τ, frame semantic graph decoder identifies new argument *as a gift* with pointer networks, and label it with FE **Role**. G_τ will be updated to $G_{\tau+1}$ with (*as a gift*, **Role**).

4.2 Sentence Encoder

The sentence encoder converts tokens of the sentence $S = w_0, \ldots, w_{n-1}$ to their representations $h_0, \ldots, h_{n-1} \in \mathbb{R}^{d_h}$.

We use LSTM (Hochreiter and Schmidhuber, 1997) and GCN (Kipf and Welling, 2016) to model both sequential structure and dependency structure:

$$\alpha_0, \ldots, \alpha_{n-1} = \text{BiLSTM}\left(e_0, \ldots, e_{n-1}\right) \quad (2)$$

$$\beta_0, \ldots, \beta_{n-1} = \text{GCN}\left(\alpha_0, \ldots, \alpha_{n-1}, \mathcal{T}\right) \quad (3)$$

e_i denotes the embedding of word w_i. We get contextual representations h_i by adding β_i to α_i. We follow previous studies (Marcheggiani and Titov, 2020; Bastianelli et al., 2020) to use syntax structures like dependency tree $\mathcal{T}$ of S here.

Furthermore, we use boundary information (Wang and Chang, 2016; Cross and Huang, 2016; Ouchi et al., 2018) to represent spans like $s = w_i, \ldots, w_j$ based on token representations because we need to embed spans into the vector space of FKG in frame identification and role classification:

$$Q(i, j) = \text{FFN}\left((h_j - h_i) \oplus (h_j + h_i)\right) \quad (4)$$

The dimension of $Q(i, j)$ is d_n. The $\oplus$ denotes concatenation operation and FFN denotes Feed Forward Network.

4.3 Frame Semantic Parsing

4.3.1 Frame Identification

A frame $f \in \mathcal{F}$ will be identified based on the target t, representations of tokens $h_0, \ldots, h_{n-1}$ and representations of frames $y_0, \ldots, y_{|\mathcal{F}|-1}$ with a scoring module. The target $t = w_{i_t^s}, \ldots, w_{i_t^e}$ will be embedded to the vector space of all frames as $\gamma_t \in \mathbb{R}^{d_n}$. We can calculate dot product normalized similarities between γ_t and all frames $Y_\mathcal{F} = (y_0, \ldots, y_{|\mathcal{F}|-1}) \in \mathbb{R}^{d_n \times |\mathcal{F}|}$ to get the probability distribution of f. For short, we use π_t to denote $Q(i_t^s, i_t^e)$:

$$\gamma_t = \tanh\left(\text{FFN}(\pi_t)\right) \quad (5)$$

$$P\left(f|S, t\right) = \text{softmax}\left(Y_\mathcal{F}^\top \cdot \gamma_t\right) \quad (6)$$

4.3.2 Argument Identification

Based on g_τ, the representation of current snapshot of FSG G_τ, we need to find an argument $a_\tau = w_{i_\tau^s}, \ldots, w_{i_\tau^e}$. We use pointer networks (Vinyals et al., 2015) to identify its start and end positions i_τ^s and i_τ^e separately via an attention mechanism, which is more efficient than traditional span-based model (Chen et al., 2021). Take i_τ^s as example:

$$\rho_\tau^s = \text{FFN}\left(g_\tau\right) \quad (7)$$

$$P\left(i_\tau^s|S, G_\tau\right) = \text{softmax}\left(H^\top \cdot \rho_\tau^s\right) \quad (8)$$

$H = (h_0, \ldots, h_{n-1}) \in \mathbb{R}^{d_h \times n}$ represents the output of the sentence encoder, and $\rho_\tau^s \in \mathbb{R}^{d_h}$ is used to find the start position of argument span a_τ.

4.3.3 Role Classification

Based on g_τ and a_τ, we embed a_τ into the vector space of FEs as $\gamma_{a_\tau} \in \mathbb{R}^{d_n}$. Similar to frame identification, we calculate dot product normalized similarities between γ_{a_τ} and all FEs $Y_\mathcal{R} =$

$(y_{|\mathcal{F}|}, \ldots, y_{|\mathcal{F}|+|\mathcal{R}|}) \in \mathbb{R}^{d_n \times (|\mathcal{R}|+1)}$ to get the conditional probability distribution of r given a_τ and G_τ.

$$\gamma_{a_\tau} = \mathrm{FFN}(\pi_{a_\tau} \oplus g_\tau) \tag{9}$$

$$P\left(r_\tau | S, G_\tau, a_\tau\right) = \mathrm{softmax}\left(Y_{\mathcal{R}}^{\top} \cdot \gamma_{a_\tau}\right) \tag{10}$$

4.4 Frame Semantic Graph Decoder

We propose FSG to represent the frame semantic structure of t in the sentence S and we treat the frame semantic parsing as a process to construct FSG incrementally. Intermediate results of FSG are partial FSGs representing all historical decisions, which highlights interactions between arguments. Suppose that there are k arguments of target t: $a_0, \ldots, a_{k-1}$ with their roles $r_0, \ldots, r_{k-1}$. For τ-th snapshot of FSG G_τ, it contains $\tau+1$ nodes: one target node (t, f) and τ argument nodes (if exist) $(a_0, r_0), \ldots, (a_{\tau-1}, r_{\tau-1})$. The target node will be connected with all argument nodes. The indices of nodes in G_τ depend on the order in which they are added into the graph, 0 denotes the target node and $1, \ldots, \tau$ denotes $(a_0, r_0), \ldots, (a_{\tau-1}, r_{\tau-1})$.

We encode G_τ to its representation g_τ:

$$g_\tau = \mathrm{Maxpooling}\left(z_0, \ldots, z_\tau\right) \tag{11}$$

$$z_0, \ldots, z_\tau = \mathrm{GCN}\left(z_0^{(0)}, \ldots, z_\tau^{(0)}, G_\tau\right) \tag{12}$$

$$z_j^{(0)} = \begin{cases} \pi_t \oplus y_{i_f}, & j = 0 \\ \pi_{a_j} \oplus y_{i_{r_j}}, & j = 1, \ldots, \tau \end{cases} \tag{13}$$

where i_f and i_{r_j} denotes indices of f and r_j in FKG, and $\pi_{a_j} = Q(i_j^s, i_j^e)$. The GCN module is to encode partial FSG.

Based on the representation g_τ of each snapshot G_τ, KID predicts boundary positions of argument a_τ and assign an FE r_τ as its semantic role (section 4.3.2,4.3.3). The G_τ will be updated to $G_{\tau+1}$ with the new node (a_τ, r_τ) until the r_τ is the special dummy node in FKG. Figure 4 shows how to find a new node and add it into the FSG.

5 Training and Inference

5.1 Training

We train KID with all subtasks jointly by optimizing the loss function $\mathcal{L}$ since representations of frames and FEs are learned in a unified vector space.

	#exemplar	#train	#dev	#test
FN 1.5	153952	17143	2333	4458
FN 1.7	192461	19875	2309	6722

Table 1: Number of instances in two datasets.

$$\mathcal{L}^f = -\log P(f = f^{\mathrm{gold}} | S, t) \tag{14}$$

$$\mathcal{L}^a_{s/e} = -\sum_{\tau=0}^{k-1} \log P(i_\tau^{s/e} = I_\tau^{s/e} | S, G_\tau) \tag{15}$$

$$\mathcal{L}^r = -\sum_{\tau=0}^{k} \log P(r_\tau = r_\tau^{\mathrm{gold}} | S, G_\tau, a_\tau) \tag{16}$$

$$\mathcal{L} = \lambda_1 \mathcal{L}^f + \lambda_2(\mathcal{L}^a_s + \mathcal{L}^a_e) + \lambda_3 \mathcal{L}^r \tag{17}$$

where f^{gold} is the gold frame and $I_\tau^s, I_\tau^e, r_\tau^{\mathrm{gold}}$ are gold labels of argument a_τ. r_k^{gold} is "Dummy", indicating the end of the parsing. We force our model to identify arguments in a left-to-right order, i.e. a_0 is the leftmost argument in S. We use gold frame in the initial node of FSG: $G_0 = (t, f^{gold})$ while other nodes are predicted autoregressively: $G_{\tau+1} = G_\tau + (\hat{a}_\tau, \hat{r}_\tau)$, $\hat{r}_\tau \in \mathcal{R}_{f^{\mathrm{gold}}}$.

5.2 Inference

KID predicts frame and all arguments with their roles in a sequential way. We use probabilities above with some constraints: 1. We use lexicon filtering strategy: for a target t, we can use the lemma ℓ_t of it to find a subset of frames $\mathcal{F}_{\ell_t} \subset \mathcal{F}$ so that we can reduce the searching space; 2. Similarly, we take $R_{\hat{f}}$ instead of R as the set of candidate FEs; 3. In argument identification, we will mask spans that are already selected as arguments, and i_τ^e should be no less than i_τ^s.

6 Experiment

6.1 Datasets

We evaluate KID on two FrameNet datasets: FN 1.5 and FN 1.7.[1] FN 1.7 is an extension version of FN 1.5, including more fine-grained frames and more instances. FN 1.5 defines 1019 frames and 9634 FEs while FN 1.7 defines 1221 frames and 11428 FEs. We use the same splits of datasets as Peng et al. (2018), and we also follow Kshirsagar et al. (2015); Yang and Mitchell (2017); Peng et al.

Table 2: Empirical results on the test set of FN 1.5. All models are single-task, non-ensemble. The upper block lists models trained without exemplar instances, the lower block lists models with pretrained language models. KID outperforms other models under all conditions except Su et al. (2021). We also train our model with multiple runs and report the statistical analysis with a significance testing in appendix C.

(2018); Chen et al. (2021) to include exemplar instances as training instances. As Kshirsagar et al. (2015) states that there exists a domain gap between exemplar instances and original training instances, we follow Chen et al. (2021) to use exemplar instances as pre-training instances and further train our model in original training instances. Table 1 shows the numbers of instances in two datasets.

6.2 Empirical Results

We compare KID with previous models (see appendix C) on FN 1.5 and FN 1.7. We focus on three metrics: frame acc, arg F1 and full structure F1.[2] Full structure F1 shows the performance of models on extracting full frame semantic structures from text, frame acc denotes accuracy of frame identification and arg F1 evaluates the results of argument identification and role classification with gold frames. All metrics are evaluated in test set.

Table 2 shows results on FN 1.5. For a fair comparison, we divide models into three parts: the first part of models do not use exemplar instances as training data; the second part of models use exemplar instances without any pretrained language models; the third part of models use pretrained language models. KID (GloVe) uses GloVe (Pennington et al., 2014) as word embeddings and KID (BERT) fine-tunes pretrained language model BERT (Devlin et al., 2019) to encode word representations. KID achieves state-of-the-art of these metrics under almost all circumstances, and we also train our model with multiple runs, which shows KID (GloVe + exemplar) and KID (BERT) outperforms previous state-of-the-art models by 1.4 and 1.3 full structure F1-score averagely. There is an exception that our model with BERT does not outperform Su et al. (2021) on frame identification accuracy and we find that the number of train, validation and test instances reported by them are a little bit smaller than ours. Results on FN 1.7 and statistical analysis of our model with multiple runs are listed in appendix C.

It is worth noting that KID achieves much higher recall than other models. We attribute this to the incremental strategy of building FSG. By constructing FSG incrementally, KID can capture relations between arguments and identify arguments that are hard to find in other models.

6.3 Ablation Study

To prove the effectiveness of double-graph architecture, we conduct further experiments with KID on FN 1.5. Table 3 shows ablation study on double-graph architecture. w/o FSG uses LSTM instead of our frame semantic graph decoder. It takes a

---

Model	Full structure F1	Arg F1
KID (GloVe)	75.28	66.35
w/o FSG	74.43	64.99
w/o FKG	74.60	64.96
w/o double-graph	73.34	63.41
KID (BERT w/o exemplar)	79.44	71.59
w/o FSG	78.84	70.63
w/o FKG	79.29	70.86
w/o double-graph	77.77	68.77

Table 3: Ablation study on double-graph architecture. w/o denotes "without". w/o FSG uses LSTM as its decoder and w/o FKG does not use RGCN to encode frames and FEs. We also test the influence of double-graph architecture for KID (BERT).

Model	Full structure F1	Arg F1
KID (GloVe)	75.28	66.35
w/o frame-FE	74.84	65.70
w/o frame-frame	74.97	66.06
w/o intra-frame FE-FE	75.10	66.60
w/o inter-frame FE-FE	75.13	65.87
FI w/o FKG	75.00	65.61
w/o FKG	74.60	64.96

Table 4: Ablation study on structures of FKG. We remove each kind of relations of FKG and all get a drop of full structure F1. FI w/o FKG denotes not using FKG in frame identification (FI). w/o FKG uses input vectors of frame knowledge encoder directly.

Model	Full structure F1	Arg F1
KID (GloVe)	75.28	66.35
w/o FKG	74.60	64.96
w/o name information	74.46	64.86
w/o both	73.53	64.01

Table 5: Ablation study on name information. Sharing embeddings for FEs whose names are the same are quite useful. The performance will drop a lot if we remove both name information and FKG, which reveals the importance of FKG.

Model	K				
	0	4	16	32	full
KID (GloVe)	56.26	63.28	65.32	65.95	70.32
w/o FKG	0.00	50.70	56.40	57.59	63.94
Δ	56.26	12.58	8.92	8.36	6.38

Table 6: Experiments on confirming transfer learning ability of FKG. K denotes the number of instances of each frame in training set. Full means adding all instances of these frames except those including target *get* in train and development sets. Lack of labeled instances has much less impact on Arg F1 performance of KID with FKG, which confirms our assumption.

sequence of arguments and their roles that have already been identified as input to predict the next argument. FSG performs better than LSTM because it captures target-argument and argument-argument relations and can model long-distance dependencies. w/o FKG directly uses input vectors of frame knowledge graph encoder, and results also show that knowledge-enhanced representations are better than randomly initialized embeddings. We also test the influence of double-graph structure with pre-trained language models, the results shows the double-graph structure is still effective and useful even with the pre-trained language models.

FKG is a multi-relational heterogeneous graph. The ablation study on structures of FKG is shown in Table 4. In addition, we evaluate the performance of FI w/o FKG, which identifies frames with a simple linear classification layer instead of FKG, and the results prove that FKG strengthens interactions between frame identification and role classification.

In addition, we explore the effectiveness of name information of FEs. Whether the name information is used in previous work is unclear and some BIO-based approaches like Marcheggiani and Titov (2020) are likely to use name information by regarding FEs with the same name as the same label in role classification. To the best of our knowledge, we are the first one to study the effectiveness of name information. As shown in Table 5, the names of FEs provide rich information for frame semantic parsing and shared embedding strategy can make good use of the name information. Further ablation study of FKG is conducted under the circumstance without name information, the performance will drop 0.9 points if we remove FKG too, showing that knowledge-enhanced representations are important no matter whether we share embeddings for FEs with the same names or not.

6.4 Transfer learning ability of FKG

As we have discussed in Figure 2, if frame B is related to frame A, a sentence with frame A can contribute to parsing another sentence with frame B by inter-frame reasoning. Frame-frame and inter-frame FE-FE relations of FKG can guide KID to learn experience from other frames.

To confirm that FKG has ability of transfer learning, we design zero (few)-shot learning experiments on FN 1.7. Target word *get* can evoke multiple frames in FrameNet, and we choose instances including target *get* with three frames (***Arriving***, ***Getting*** and ***Transition_to_state***) as test instances. We remove all instances with target *get* from train and development instances, and can selectively add few (or zero) instances including other targets with these three frames into train and development sets. We then compare the performance of KID with KID w/o FKG under zero-shot and few-shot circumstances. If FKG has ability of transfer learning, KID with FKG can learn experience from other related frames like ***Receiving*** and its performance will not be influenced so much by the sparsity of labels.

Table 6 shows the results of our experiments. $K = 0$ indicates zero-shot learning while $K = \{4, 16, 32\}$ indicates few-shot learning. KID without FKG performs much worse in zero-shot learning. As the number of instances that can be seen in training grows up, the performance of KID with FKG gets a steady increase while the performance of KID without FKG increases rapidly. Results verify our assumption that even with few train instances FKG can guide inter-frame reasoning with its structure and allow models to learn experience from other seen frames.

7 Related Work

Frame semantic parsing has caught wide attention since it was released on SemEval 2007 (Baker et al., 2007). The task is to extract frame structures defined in FrameNet (Baker et al., 1998) from text. From then on, a large amount of systems are applied on this task, ranging from traditional machine learning classifiers (Johansson and Nugues, 2007; Das et al., 2010) to fancy neural models like recurrent neural networks (Yang and Mitchell, 2017; Swayamdipta et al., 2017) and graph neural networks (Marcheggiani and Titov, 2020; Bastianelli et al., 2020).

A lot of previous systems neglect interactions between subtasks and relations between arguments. They either focus on one or two subtasks (Hermann et al., 2014; FitzGerald et al., 2015; Marcheggiani and Titov, 2020) of frame semantic parsing or treat all subtasks independently (Das et al., 2014; Peng et al., 2018). Täckström et al. (2015) propose an efficient global graphical model, so they can enumerate all possible argument spans and treat the assignment as the Integer Linear Programming problem. Later systems like FitzGerald et al. (2015); Peng et al. (2018) follow this method. Swayamdipta et al. (2017); Bastianelli et al. (2020) use sequence-labeling strategy, and Yang and Mitchell (2017) integrate these two methods with a joint model. Only few approaches like Chen et al. (2021) model interactions between subtasks, which use the encoder-decoder architecture to predict arguments and roles sequentially. However, the sequence modeling of Chen et al. (2021) does not consider structure information and is not good at capturing long-distance dependencies. We use graph modeling to enhance structure information and strengthen interactions between target and argument, argument and argument.

Only a few systems utilize linguistic knowledge in FrameNet. Kshirsagar et al. (2015) use FE mappings to share information in FEs. In frame identification, Jiang and Riloff (2021) encode definitions of frames and Su et al. (2021) use frame identification and frame semantic relations. However, they do not utilize ontological frame knowledge in all subtasks while we construct a heterogeneous graph containing both frames and FEs. Besides, our model does not need extra encoders to encode definitions, which reduces parameters of the model.

Some systems also treat constituency parsing or other semantic parsing tasks like AMR as a graph construction problem. Yang and Deng (2020) use GCN to encode intermediate constituency tree to generate a new action on the tree. Cai and Lam (2020) construct AMR graphs with the Transformer (Vaswani et al., 2017) architecture.

8 Conclusion

In this paper, we incorporate knowledge into frame semantic parsing by constructing Frame Knowledge Graph. FKG provides knowledge-enhanced representations of frames and FEs and can guide intra-frame and inter-frame reasoning. We also propose frame semantic graph to represent frame semantic structures. We regard frame semantic parsing as an incremental graph construction problem. The process to construct FSG is structure-aware and can utilize relations between arguments. Our framework Knowledge-guided Incremental semantic parser with Double-graph (KID) achieves state-of-the-art on FrameNet benchmarks. However, how to utilize linguistic knowledge better is still to be resolved. Future work can focus on better modeling of ontological frame knowledge, which will be useful for frame semantic parsing and transfer learning in frame semantic parsing.

A Model Details

A.1 Graph Convolutional Network

Graph convolution is introduced in Kipf and Welling (2016). A GCN layer is defined as follow:

$$f(H^{(l)}, G) = \sigma\left(\tilde{D}^{-\frac{1}{2}}\tilde{A}\tilde{D}^{-\frac{1}{2}}H^{(l)}W^{(l)}\right) \tag{18}$$

where $H^{(l)}$ denotes hidden representations of nodes in l-th layer, σ is the non-linear activation function (e.g. ReLU) and W is the weight matrix. $\tilde{D}$ and $\tilde{A}$ are separately the degree and adjacency matrices for the graph G. From a node-level perspective, a GCN layer can be also formalized as follow:

$$h_i^{(l+1)} = \sigma\left(\sum_{j\in N(i)} \frac{1}{c_{ji}} h_j^{(l)} W^{(l)}\right) \tag{19}$$

where $N(i)$ is the set of neighbors of node i, and $c_{ji} = \sqrt{|N(j)|}\sqrt{|N(i)|}$.

By stacking L different GCN layers, we get final GCN module $\mathrm{GCN}(H^{(0)}, G)$.

A.2 Relational Graph Convolutional Network

Type information of graph edges is ignored in GCN, and RGCN (Schlichtkrull et al., 2018) is proposed to model relational data from which we can benefit to model the multi-relational graph FKG. Different edge types use different weights and only edges of the same relation type r are associated with the same projection weight W_r. From a node's view:

$$h_i^{(l+1)} = \sigma\left(h_i^{(l)}W_0^{(l)} + \sum_{r\in R}\sum_{j\in N_i^r} \frac{1}{c_{i,r}} h_j^{(l)} W_r^{(l)}\right) \tag{20}$$

where N_i^r denotes the set of neighbor indices of node i under relation $r \in R$ and $c_{i,r}$ is a normalization constant i.e.$|N_i^r|$.

In KID, we use $\tanh$ as activation function of RGCN for normalization because we need to calculate normalized dot product similarities between frames/FEs and target/arguments.

A.3 Encoding Dependency Tree

We follow previous studies (Marcheggiani and Titov, 2020; Bastianelli et al., 2020) to use syntax structures like dependency tree $\mathcal{T}$ of S in KID because syntax structure is proved beneficial to semantic parsing. We use Stanza (Qi et al., 2020), an open-source python NLP toolkit to parse dependency syntactic structure for instances, and depGCN (Marcheggiani and Titov, 2017) to encode the syntactic structure. We simplify depGCN by ignoring directions and labels of edges in dependency tree, which means if token i is head or dependent of token j, we will have $A_{ij}^{\mathcal{T}} = A_{ji}^{\mathcal{T}} = 1$ in adjacency matrix $A^{\mathcal{T}}$ of $\mathcal{T}$.

In addition, if we use BERT as encoder, the tokens are sub-word level and the adjacency matrix will be a little bit different. Specifically, if token i is the sub-word of some word u, token j is the sub-word of some word v and u is head or dependent word of v, we will have $A_{ij}^{\mathcal{T}} = A_{ji}^{\mathcal{T}} = 1$ in adjacency matrix $A^{\mathcal{T}}$.

Chen et al. (2021): a joint encoder-decoder model predicting arguments and roles sequentially.

Marcheggiani and Titov (2020): a GCN-based model over constituency trees.

Bastianelli et al. (2020) (JL): a GCN-based model encoding syntactic constituency path. JL denotes joint learning on all subtasks of frame semantic parsing.

Kalyanpur et al. (2020): a T5-based model treating frame semantic parsing as a sequence-to-sequence generation task.

Jiang and Riloff (2021): a sentence-pair bert-based model using frame definitions.

Su et al. (2021): a BERT-based model for frame identification using both frame identification and frame semantic relations.

C.2 Empirical Results on FN 1.7

Table 9, 10, 11 list our results with comparing models. KID outperforms previous state-of-the-art except Su et al. (2021). FN 1.7 is the up-to-date extension version of FN 1.5 containing more fine-grained frames and FEs. However, there are only few models reporting their results on FN 1.7 and we hope that future work on frame semantic parsing can be more focused on FN 1.7.

C.3 Time Costs of FKG

The FKG is built over the full FrameNet containing more than 10,000 nodes while the intra-frame and inter-frame relations make the graph larger. Since we need to encode the full FKG when parsing a single sentence, it's necessary to explore the time costs of FKG. Results are shown in Table 12 and we can find the time encoding FKG is approximately 20% in the whole runtime and may slightly hurt the efficiency of our models. However, in inference time,

Model	Precision	Recall	F1-score
open-SESAME (2017)	62	55	58
KID (GloVe)	69.2	73.3	71.2
Kalyanpur et al. (2020)	71	73	72
KID (BERT)	**74.1**	**77.3**	**75.6**

Table 11: Arg F1 on FN 1.7. Results of other models are obtained from Kalyanpur et al. (2020).

Model	Time cost (%)
KID (GloVe)	27.17
KID (BERT)	18.85

Table 12: Time cost of FKG. We list the proportion of time encoding FKG in whole runtime. Encoding FKG may slightly hurt the efficiency of models but is not the bottleneck of our models.

the representations of nodes in FKG are fixed and we can load the representations offline to reduce the inference time.

C.4 Statistical Analysis of KID on FN 1.5

For evaluating solidity of our model, we train KID with five random seeds. The average performances with deviation and results of significance testing are listed in Table 13. The significance testing is to show whether our model significantly outperforms previous state-of-the-art, and we do not conduct significance testing for KID (BERT) because we do not outperform Su et al. (2021) on frame accuracy. All p-values are less than 0.05 and even some p-values are less than 1e-3, which proves the solidity of our model.

Model	Metrics	seed					Avg. ± Dev.	p-value
		s_1	s_2	s_3	s_4	s_5		
KID (GloVe)	Frame Acc.	89.14	88.90	89.12	89.48	88.55	89.04 ± 0.34	0.007
	Arg F1	65.65	66.30	65.87	66.35	65.74	65.98 ± 0.32	*
	Full structure F1	74.76	75.34	74.94	75.28	74.57	74.98 ± 0.33	*
KID (GloVe + exemplar)	Frame Acc.	89.74	89.56	89.75	89.90	89.93	89.78 ± 0.15	0.002
	Arg F1	69.63	69.85	69.48	70.08	69.25	69.66 ± 0.32	0.033
	Full structure F1	77.27	77.41	77.36	77.73	77.32	77.42 ± 0.18	*
KID (BERT)	Frame Acc.	91.81	91.92	91.81	91.74	91.63	91.78 ± 0.11	-
	Arg F1	74.76	74.55	74.98	75.17	74.60	74.81 ± 0.26	0.028
	Full structure F1	81.50	81.44	81.61	81.68	81.38	81.52 ± 0.13	*

Table 13: Statistical analysis of multiple runs on FN 1.5. We train our model with five different random seeds $s_1 - s_5$ and the results with seed s_4 are reported in Table 2. We both report the average performance with deviation and the results of significance testing, where * denotes the p-value is less than 1e-3.

An Enhanced Span-based Decomposition Method for Few-Shot Sequence Labeling

Abstract

Few-Shot Sequence Labeling (FSSL) is a canonical paradigm for the tagging models, e.g., named entity recognition and slot filling, to generalize on an emerging, resource-scarce domain. Recently, the metric-based meta-learning framework has been recognized as a promising approach for FSSL. However, most prior works assign a label to each token based on the token-level similarities, which ignores the integrality of named entities or slots. To this end, in this paper, we propose **ESD**, an **E**nhanced **S**pan-based **D**ecomposition method for FSSL. ESD formulates FSSL as a span-level matching problem between test query and supporting instances. Specifically, ESD decomposes the span matching problem into a series of span-level procedures, mainly including enhanced span representation, class prototype aggregation and span conflicts resolution. Extensive experiments show that ESD achieves the new state-of-the-art results on two popular FSSL benchmarks, FewNERD and SNIPS, and is proven to be more robust in the nested and noisy tagging scenarios. Our code is available at `https://github.com/Wangpeiyi9979/ESD`.

1 Introduction

Many natural language understanding tasks can be formulated as sequence labeling tasks, such as *Named Entity Recognition* (NER) and *Slot Filling* (SF) tasks. Most prior works on sequence labeling follow the supervised learning paradigm, which requires large-scale annotated data and is limited to pre-defined classes. In order to generalize on the emerging, resource-scare domains, Few-Shot Sequence Labeling (FSSL) has been proposed (Hou et al., 2020; Yang and Katiyar, 2020). In FSSL, the model (typically trained on the source domain data) needs to solve the N-way (N unseen classes) K-shot (only K annotated examples for each class) task in the target domain. Figure 1 shows a 2-way 2-shot target domain few-shot NER task, where *'PER'* and *'ORG'* are 2 unseen entity types, and in the training set $\mathcal{S} = \{S_1, S_2\}$, both of them have only 2 annotated entities. The tagging models should annotate *'Albert Einstein'* in the test sentence q as a *'PER'* according to $\mathcal{S}$.

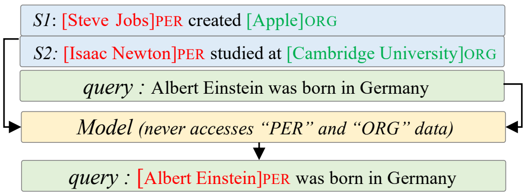

Figure 1: A 2-way 2-shot few-shot NER task. The model needs to learn new entities with few examples.

Recently, *metric-based meta-learning (MBML) methods* have become the mainstream and state-of-the-art methods in FSSL (Hou et al., 2020; Ding et al., 2021), which train the models on the tasks sampled from the source domain sentences in order to mimic and solve the target task. In each task of training and testing, they make the prediction through modeling the similarity between the training set (support set) and the test sentence (query). Specifically, previous MBML methods (Ding et al., 2021; Hou et al., 2020; Yang and Katiyar, 2020) mainly formulate FSSL as a token-level matching problem, which assigns a label to each token based on the token-level similarities. For example, the token *'Albert'* would be labeled as *'B-PER'* due to its resemblance to *'Steve'* and *'Isaac'*.

However, for the MBML methods, selecting the appropriate metric granularity would be fundamental to the success. We argue that prior works that focus on modeling the token-level similarity are sub-optimal in FSSL: 1) they ignore the integrality of named entities or dialog slots that are composed of a text span instead of a single token. 2) in FSSL,

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5012 - 5024
July 10-15, 2022

the conditional random fields (CRF) is an important component for the token-level sequence labeling models (Yang and Katiyar, 2020; Hou et al., 2020), but the transition probability between classes in the target domain task can not be sufficiently learned with very few examples (Yu et al., 2021). The previous methods resort to estimate the values with the abundant source domain data, which may suffer from domain shift problem (Hou et al., 2020). To overcome these drawbacks of the token-level models, in this paper, we propose ESD, an **E**nhanced **S**pan-based **D**ecomposition model that formulates FSSL as a span-level matching problem between test query and support set instances.

Specifically, ESD decomposes the span matching problem into three main subsequent span-level procedures. 1) **Span representation**. We find the span representation can be enhanced by information from other spans in the same sentence and the interactions between query and support set. Thus we propose a span-enhancing module to reinforce the span representation by intra-span and inter-span interactions. 2) **Span prototype aggregation**. MBML methods usually aggregate the span vectors that belongs to the same class in the support set to form the class prototype representation. Among all class prototypes, the O-type serves as negative examples and covers all the miscellaneous spans that are not entities, which poses new challenges to identify the entity boundaries. To this end, we propose a span-prototypical module to divide O-type spans into 3 sub-types to distinguish the miscellaneous semantics by their relative position with recognized entities, together with a dynamically aggregation mechanism to form the specific prototype representation for each query span. 3) **Span conflicts resolution**. In the span-level matching paradigm, the predicted spans may conflict with each other. For example, a model may annotate both "Albert Einstein" and "Albert" as *"PER"*. Therefore, we propose a span refining module that incorporates the Soft-NMS (Bodla et al., 2017; Shen et al., 2021) algorithm into the beam search to alleviate this conflict problem. With Beam Soft-NMS, ESD can also handle nested tagging cases without any extra training, which previous methods are incapable of.

We summarize our contribution as follows: (1) We propose ESD, an enhanced span-based decomposition model, which formulates FSSL as a span-level matching problem. (2) We decompose the span matching problem into 3 main subsequent procedures, which firstly produce enhanced span representation, then distinguish miscellaneous semantics of O-types, and achieve the specific prototype representation for each query, and finally resolve span conflicts . (3) Extensive experiments show that ESD achieves new state-of-the-art performance on both few-shot NER and slot filling benchmarks and that ESD is more robust than other methods in nested and noisy scenarios.

2 Related Work

2.1 Few-Shot Learning

Few-Shot Learning (FSL) aims to enable the model to solve the target domain task with a very small training set D_{train} (Wang et al., 2020). In FSL, people usually consider the N-way K-shot task, where the D_{train} has N classes, and each class has only K annotated examples (K is very small, e.g., 5). Training a model only based on D_{train} from scratch will inevitably lead to over-fitting. Therefore, researchers usually introduce the source domain annotated data to help train models, e.g., Few-Shot Relation Classification (FSRC) (Han et al., 2018), Few-Shot Text Classification (FSTC) (Geng et al., 2019) and Few-Shot Event Classification (FSEC) (Wang et al., 2021a). The source domain data do not contain examples belonging to classes in D_{train}, and thus the FSL setting can be guaranteed. Specifically, FSSL tasks in our paper also have the source domain data.

2.2 Metric-Based Meta-Learning

Meta-learning (Hochreiter, Younger, and Conwell, 2001a) is a popular method to deal with Few-Shot Learning (FSL). Meta-learning constructs a series of tasks sampled from the source domain data to mimic the target domain task, and trains models across these sampled tasks. Each task contains a training set (support set) and a test instance (query). The core idea of meta-learning is to help model learn the ability to quickly adapt to new tasks, i.e., learn to learn (Hochreiter, Younger, and Conwell, 2001b). Meta-learning can be combined with the metric-learning (Kulis et al., 2013) (metric-based meta-learning), which makes predictions based on the similarity of the support set and the query. For example, Prototypical Network (Snell, Swersky, and Zemel, 2017) first learns prototype vectors from a few examples in the support set for classes, and further uses prototype vectors for query prediction. Specifically, ESD (our model) follows this

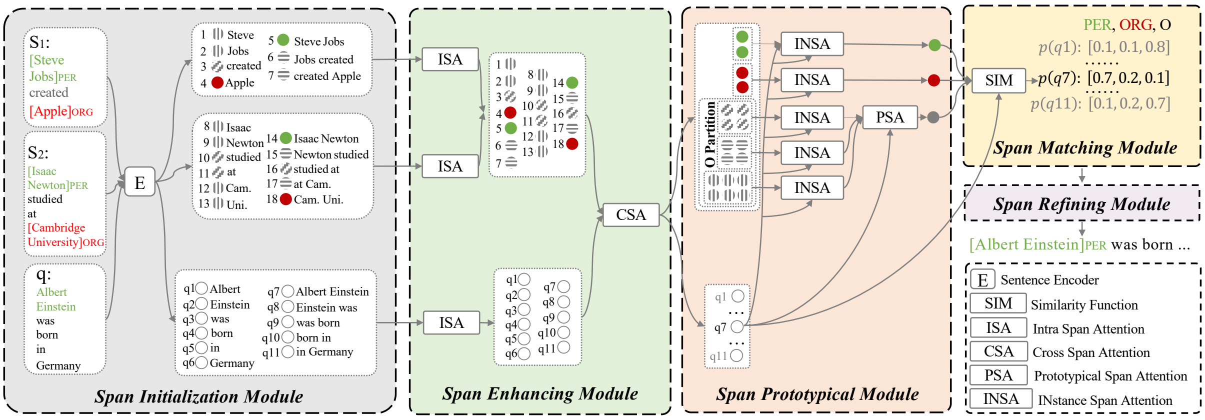

Figure 2: The architecture (5 span modules) of ESD with a 2-way ('PER' and 'ORG') 2-shot input task. We only list spans with lengths less than 2 for clarity. ESD assigns label 'PER' to the span "Albert Einstein" and 'O' to the other spans in query q based on the support set $\{S_1, S_2\}$.

metric-based meta-learning paradigm.

2.3 Few-Shot Sequence Labeling

Recently, few shot sequence labeling (FSSL) has been widely explored by researchers. For example, (Fritzler, Logacheva, and Kretov, 2019a) leverages the prototypical network (Snell, Swersky, and Zemel, 2017) in the few-shot NER. (Yang and Katiyar, 2020) further proposes a cheap but effective method to capture the label dependencies between entity tags without expensive CRF training. (Wang et al., 2021b) utilizes a large unlabelled dataset and proposes a distillation method. (Cui et al., 2021) introduces a prompt method to tap the potential of BART (Lewis et al., 2020). (Hou et al., 2020) extends the TapNet (Yoon, Seo, and Moon, 2019) and proposes a collapsed CRF for few-shot slot filling. (Ma et al., 2021) and (Athiwaratkun et al., 2020) formulate FSSL as a machine comprehension problem and a generation problem, respectively. (Yu et al., 2021) proposed to retrieve the most similar exemplars in the support set for span-level prediction. Although their methods also involve span matching, their main focus is on the retrieval-augmented training. Our work differs from (Yu et al., 2021) in that we propose an effective actionable pipeline to get enhanced span representation, handle miscellaneous semantics of O-types and resolve the potential span conflicts in both non-nested and nested situations, where the last two modules are essential to align the candidate spans with class prototypes in the support set but missing in (Yu et al., 2021). Besides, our enhanced span representation greatly improves the batched softmax objective of (Yu et al., 2021) by inter- and intra-span interactions.

3 Task Formulation

We define a sentence as $\mathbf{x}$ and its label as $\mathbf{y} = \{(s_i, y_i)\}_{i=1}^{M}$, where s_i is a span of $\mathbf{x}$ (e.g., *'Steve Jobs'*), y_i is the label of s_i (e.g., *'PER'*) and M is the number of spans in the $\mathbf{x}$. Following the previous FSSL setting (Hou et al., 2020; Ding et al., 2021), we have data in source domain $\mathcal{D}_{source}$ and target domain $\mathcal{D}_{target}$, and models are evaluated on tasks from $\mathcal{D}_{target}$. Meta-learning based FSSL has two stages, meta-training and meta-testing. In the meta-training stage, the model is trained on tasks sampled from $\mathcal{D}_{source}$ to mimic the test situation, and in the meta-testing stage, the model is evaluated on test tasks. A task is defined as $\mathcal{T} = \{\mathcal{S}, q\}$, consisting of a support set $\mathcal{S} = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{I}$, and a query sentence $q = \mathbf{x}$. $\mathcal{S}$ includes N types of entities or slots (N-way), and each type has K annotated examples (K-shot). For spans that do not belong to the N types, e.g., *'studied at'* in Figure 1, we set their label to O. The types except O in each test task are guaranteed to not exist in the training tasks. Given a task $\mathcal{T} = \{\mathcal{S}, q\}$, the model needs to assign a label to each span in the query sentence q based on $\mathcal{S}$.

4 Methodology

Our ESD formulates FSSL as a span-level matching problem and decomposes it into a series of span-related procedures for a better span matching. Figure 2 illustrates the architecture of ESD.

4.1 Span Initialization Module

Given a task $\mathcal{T} = \{\mathcal{S}, q\}$, we use BERT (Devlin et al., 2019) to encode sentences in $\mathcal{S}$ and q, and utilize the output of the last layer to represent tokens in the sentence. Therefore, for a sentence with N tokens $\mathbf{x} = (x_1, x_2, ..., x_N)$, we can achieve representations $(\mathbf{h_1}, \mathbf{h_2}, ..., \mathbf{h_N})$, where $\mathbf{h_i} \in \mathbb{R}^{d_w}$ is the hidden state corresponding to the token x_i. Then, for a span $s = (l, r)$, where l and r are the start index and end index of span s in the sentence $\mathbf{x}$, we obtain its initial representation $\mathbf{s}_{(l,r)} = [\mathbf{h_l}; \mathbf{h_r}]\mathbf{W_s}$.[1] We enumerate spans in the sentence with a maximum length of L.

4.2 Span Enhancing Module

4.2.1 Intra Span Attention

Intuitively, the meaning of specific spans can be inferred from other spans in the same sentence. We thus design an Intra Span Attention (ISA) mechanism. Given all the span representations of a sentence $\mathbf{S} \in \mathbb{R}^{B \times d}$ (B is the number of spans). We denote the i-th row of $\mathbf{S}$ as $\mathbf{s_i}$, which represents the i-th span in the sentence. For $\mathbf{s_i}$, we first get its ISA span representation $\bar{\mathbf{s}}_\mathbf{i} = \sum_{j=1}^{B} \alpha_\mathbf{i}{}^j \mathbf{s_j}$, where $\alpha_\mathbf{i} = \mathrm{softmax}(\mathbf{s_i}\mathbf{S^T})$. For clarity, we denote this attention aggregation operation as ϕ, i.e.,

$$\bar{\mathbf{s}}_\mathbf{i} = \phi(\mathbf{s_i}, \mathbf{S}) \tag{1}$$

then, a Feed Forward Neural Networks (FFN) (Vaswani et al., 2017) with residual connection (He et al., 2016) and layer normalization (Ba, Kiros, and Hinton, 2016) are used to get the final ISA enhanced feature $\tilde{\mathbf{s}}_\mathbf{i}$,

$$\tilde{\mathbf{s}}_\mathbf{i} = \mathrm{LayerNorm}(\mathbf{s_i} + \mathrm{FFN_{isa}}(\bar{\mathbf{s}}_\mathbf{i})) \tag{2}$$

$$\mathrm{FFN_{isa}}(\bar{\mathbf{s}}_\mathbf{i}) = \mathrm{GELU}(\bar{\mathbf{s}}_\mathbf{i}\mathbf{W^1_{isa}})\mathbf{W^2_{isa}} \tag{3}$$

4.2.2 Cross Span Attention

After ISA, to accommodate the span matching between the test query and supporting sentences, and facilitate the inter-span interaction, we propose Cross Span Attention (CSA) to enhance query spans $\tilde{\mathbf{Q}} \in \mathbb{R}^{B_q \times d}$ with the support set spans $\{\tilde{\mathbf{S}}_\mathbf{i} \in \mathbb{R}^{B_i \times d}; i = 1, ..., I\}$, and vice versa. We first concatenate all span representations in the support set into one matrix $\tilde{\mathbf{S}} = [\tilde{\mathbf{S}}_\mathbf{1}, \tilde{\mathbf{S}}_\mathbf{2}, ..., \tilde{\mathbf{S}}_\mathbf{I}] \in \mathbb{R}^{B_s \times d}$. We denote the n-th row of $\tilde{\mathbf{S}}$ as $\tilde{\mathbf{s}}_\mathbf{n}$ and the m-th row of $\tilde{\mathbf{Q}}$ as $\tilde{\mathbf{q}}_\mathbf{m}$, and obtain their CSA span representations $\hat{\mathbf{s}}_\mathbf{n} = \phi(\tilde{\mathbf{s}}_\mathbf{n}, \tilde{\mathbf{Q}})$ and $\hat{\mathbf{q}}_\mathbf{m} = \phi(\tilde{\mathbf{q}}_\mathbf{m}, \tilde{\mathbf{S}})$. Then, we get the final CSA enhanced representation $\check{\mathbf{s}}_\mathbf{n}$ and $\check{\mathbf{q}}_\mathbf{m}$ as follows,

$$\check{\mathbf{s}}_\mathbf{n} = \mathrm{LayerNorm}(\tilde{\mathbf{s}}_\mathbf{n} + \mathrm{FFN_{csa}}(\hat{\mathbf{s}}_\mathbf{n})) \tag{4}$$

$$\check{\mathbf{q}}_\mathbf{m} = \mathrm{LayerNorm}(\tilde{\mathbf{q}}_\mathbf{m} + \mathrm{FFN_{csa}}(\hat{\mathbf{q}}_\mathbf{m})) \tag{5}$$

$$\mathrm{FFN_{csa}}(\mathbf{x}) = \mathrm{GELU}(\mathbf{x}\mathbf{W^1_{csa}})\mathbf{W^2_{csa}} \tag{6}$$

4.3 Span Prototypical Module

4.3.1 Instance Span Attention

Since different support set spans play different roles for a query span, we propose multi-INstance Span Attention (INSA) to get class representations. For the i-th class that contains K annotated spans with enhanced representations $\check{\mathbf{S}}_\mathbf{i} = [\check{\mathbf{s}}^1_\mathbf{i}, ..., \check{\mathbf{s}}^K_\mathbf{i}]$ in the support set, given a query span $\check{\mathbf{q}}_\mathbf{m}$, INSA gets the corresponding prototypical representation $\mathbf{z^i_m} = \phi(\check{\mathbf{q}}_\mathbf{m}, \check{\mathbf{S}}_\mathbf{i})$.

4.3.2 O Partition and Prototypical Span Attention

The O-type spans have huge quantities and miscellaneous semantics, which is hard to be represented by only one prototypical vector. In the span-based framework, considering the boundary information is essential for a span, we divide the O-type spans into 3 sub-classes according to their boundary, to alleviate their miscellaneous semantics problem. Specifically, given a sentence with I annotated spans $\{(l_i, r_i)\}_{i=1}^{I}$, where l_i and r_i are the left and right boundary of the i-th annotated span. For each of the other spans (l_o, r_o) , we assign it a sub-class O_{sub} as follows,

$$O_{sub} = \begin{cases} O_1, & \forall i, s.t.\ r_o < l_i \vee l_o > r_i \\ O_2, & \exists i, s.t.\ l_o \geq l_i \wedge r_o \leq r_i \\ O_3, & \qquad \text{Others} \end{cases} \tag{7}$$

where O_1 denotes the span that does not overlap with any entities or slots in the sentence, e.g., *"study at"* in S_2 of Figure 2, and O_2 represents the span that is the sub-span of an entity or slot, e.g., *"Isaac"* in S_2 of Figure 2. After O Partition, we get the prototypical representation of each O_{sub} via INSA, thus for a query span $\check{\mathbf{q}}_\mathbf{m}$, we have 3 sub-class representations $\mathbf{Z^o_m} = [\mathbf{z^{o_1}_m}, \mathbf{z^{o_2}_m}, \mathbf{z^{o_3}_m}]$ for the class O. Then, we utilize Prototypical Span Attention (PSA) to achieve the final O representation $\mathbf{z^o_m} = \phi(\check{\mathbf{q}}_\mathbf{m}, \mathbf{Z^o_m})$.

4.4 Span Matching Module

Given a task $\mathcal{T} = (\mathcal{S}, q)$, for the m-th span in q_m, we achieve its enhanced representation $\check{\mathbf{q}}_\mathbf{m}$

---

[1] We omit the bias term in this paper for clarity.

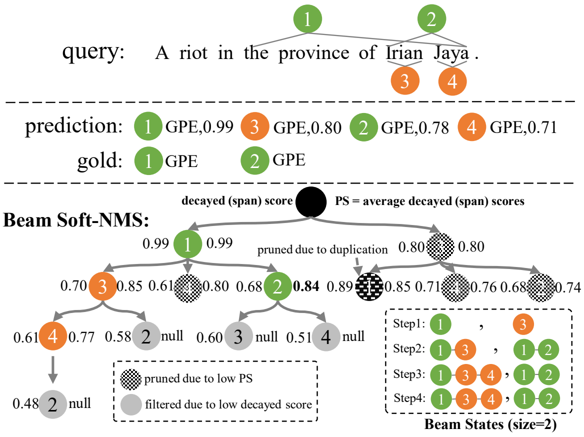

Figure 3: A demonstration for Beam Soft-NMS (BSNMS). For clarity, we set the filter threshold δ to 0.6, and suppose the span score is always decayed by the overlapped spans with a constant decayed score -0.1 (Note that the example is simplified for demonstration). BSNMS filters false positive spans (colored in orange) in this demonstration. A more clear step by step demonstration is included in Appendix D.

and corresponding prototypical vectors $\mathbf{Z_m} = (\mathbf{z_m^o}, \mathbf{z_m^1}, ..., \mathbf{z_m^N})$ through previous span modules. Then, we predict q_m as the type z_k in the support set with probability,

$$p(y_m = z_k|q_m) = \frac{exp(-L_2(\check{\mathbf{q}}_\mathbf{m}, \mathbf{z_k^m}))}{\sum_{k'} exp(-L_2(\check{\mathbf{q}}_\mathbf{m}, \mathbf{z_{k'}^m}))} \tag{8}$$

where L_2 is the euclidean distance. During training, we use cross-entropy as our loss function,

$$\mathcal{L} = -\frac{1}{B_q} \sum_{m=1}^{B_q} log\ p(y_m^*|q_m) \tag{9}$$

where y_m^* is the gold label of q_m and B_q is the number of spans in the query q.

4.5 Span Refining Module in Inference

During inference, spans outputted by the matching module may have conflicts, we thus propose a refining module that incorporates the SoftNMS into beam search for the conflicts resolution. For the m-th span with the left index l_m and the right index r_m in the query, we obtain its prediction probability distribution $\mathbf{p_m}$, label $y_m = \mathrm{argmax}(\mathbf{p_m})$ and score $score_m = \max(\mathbf{p_m})$. Figure 3 illustrates a simplified post-processing process. In each step, we first expand all beam states (e.g., states 1-3 and 1-2 in step2 of Figure 3), and then prune new states according to the beam size. Specifically, given a beam state S containing spans $\{l_t, r_t, score_t, y_t\}_{t=1}^T$, for each non-contained span $s_i = (l_i, r_i, score_i, y_i)$, we first calculate its decayed score $score_i^{decay}$,

$$score_i^{decay} = score_i * u^\eta \tag{10}$$

$$\eta = \sum_{t=1}^{T} \mathbb{I}(\mathrm{IoU}(s_i, s_t) \geq k) \tag{11}$$

where $\mathrm{IoU}(s_i, s_t) = \frac{|\{l_i,...,r_i\} \cap \{l_t,...,r_t\}|}{|\{l_i,...,r_i\} \cup \{l_t,...,r_t\}|}$ is the overlap ratio of two spans. The decay ratio u and threshold k are hyperparameters. Then, we expand the beam state S with the non-contained span s_i if $score_i^{decay} > \delta$. For example, in the step2 of Figure 3, we expand the state 1-3 to 1-3-4, while the state 1-3-2 fails to be expanded since $score_2^{decay} = 0.58 <= \delta$. After expanding all states, we prune available beam states with lower path scores. For example, we prune states 1-4, 3-4 and 3-2 in step2 of Figure 3. In addition, as our needed output is order-independent, we also prune duplicate states, e.g., the state 3-1 (equivalent to the state 1-3) for the diversity of beam states. When all states in the beam can not be expanded or have been expanded before but failed, we select the beam with the largest path score as the final output.

5 Experiments

5.1 Experiments Setup

Datasets We evaluate ESD on FewNERD (Ding et al., 2021) and SNIPS (Coucke et al., 2018). **FewNERD** designs an annotation schema of 8 coarse-grained (e.g., 'Person') entity types and 66 fine-grained (e.g., 'Person-Artist') entity types, and constructs two tasks. One is **FewNERD-INTRA**, where all the entities in the training set (source domain), validation set and test set (target domain) belong to different coarse-grained types. The other is **FewNERD-INTER**, where only the fine-grained entity types are mutually disjoint in different sets. For the sake of sampling diversity, FewNERD adopts the N-way $K \sim 2K$-shot sampling method to construct tasks (each class in the support set has $K \sim 2K$ annotated entities). Both FewNERD-INTRA and FewNERD-INTER have 4 settings, 5-way $1 \sim 2$-shot, 5-way $5 \sim 10$-shot, 10-way $1 \sim 2$-shot and 10-way $5 \sim 10$-shot. **SNIPS** is a slot filling dataset, which contains 7 domains $\mathcal{D} = \{\mathcal{D}_1, \mathcal{D}_2, ..., \mathcal{D}_7\}$. (Hou et al., 2020) constructs few-shot slot filling task with the leave-one-out strategy, which means when testing on the target domain $\mathcal{D}_i$, they randomly chose $\mathcal{D}_j (i \neq j)$

Table 2: F1 scores with standard deviations on 7 domains of SNIPS. The best results are in **boldface**. ‘unk’ denotes methods that do not report deviations in their paper. Baselines of 1-shot and 5-shot settings are different since ConVEx and Retriever do not report the 1-shot results in their paper.

as the validation domain, and train the model on source domains $\mathcal{D} - \{\mathcal{D}_i, \mathcal{D}_j\}$. In the sampling task of SNIPS, all classes have K annotated examples in the support set, but the number of them (N) is not fixed. The few-shot slot filling task in each domain of SNIPS has two settings, 1-shot and 5-shot. FSSL models are trained and evaluated on tasks sampled from the source and target domain, respectively. To ensure the fairness, we use the public sampled data provided by (Ding et al., 2021) for FewNERD[2] and data provided by (Hou et al., 2020) for SNIPS, to train and evaluate our model.

Parameter Settings Following previous methods (Hou et al., 2020; Ding et al., 2021), we use uncased BERT-base as our encoder. We use Adam (Kingma and Ba, 2015) as our optimizer. We set the dropout ratio (Srivastava et al., 2014) to 0.1. The maximum span length L is set to 8. For BSNMS, the beam size b is 5. Because FewNERD and SNIPS do not have nested instances, we set the threshold to filter false positive spans δ to 0.1, the threshold to decay span scores k to $1e$-5 and the decay ratio u to $1e$-5 to force the refining results have no nested spans. More details of our parameter settings are provided in Appendix A.

Evaluation Metrics For FewNERD, following (Ding et al., 2021), we report the micro F1 over all test tasks, and the average result of 5 different runs. For SNIPS, following (Hou et al., 2020), we first calculate micro F1 score for each test episode (an episode contains a number of test tasks), and then report the average F1 score for all test episodes as the final result. We report the average result of 10 different runs the same as (Hou et al., 2020).

Baselines For systematic comparisons, we introduce a variety of baselines, including **ProtoBERT** (Ding et al., 2021; Hou et al., 2020), **NNShot** (Ding et al., 2021), **StructShot** (Ding et al., 2021), **TransferBERT** (Hou et al., 2020), **MN+BERT** (Hou et al., 2020), **L-TapNet+CDT** (Hou et al., 2020), **Retriever** (Yu et al., 2021), **ConVEx** (Henderson

and Vulić, 2021) and **Ma2021** (Ma et al., 2021). Please refer to the Appendix A for more details.

5.2 Main Results

Table 1 illustrates the results on FewNERD. As is shown, among all task settings, ESD consistently outperforms ProtoBERT, NNShot and StructShot by a large margin. For example, compared with StructShot, ESD achieves 11.17 and 10.60 average F1 improvement on INTRA and INTER, respectively. Table 2 shows the results on SNIPS. In the 1-shot setting, L-TapNet+CDT is the previous best method. Compared with L-TapNet+CDT, ESD achieves comparable results and 4.58 F1-scores improvement in the 1-shot and 5-shot settings, respectively. We think the reason is that the information benefits brought by our cross span attention mechanism in 1-shot setting is much less than that in 5-shot setting. In addition, compared with L-TapNet+CDT, ESD performs more stable, and also has a better model efficiency (Please refer to Section 6.3). In 5-shot setting, Ma2021 is previous best method, and ESD outperforms it 1.14 and 0.42 F1-scores in 1-shot and 5-shot settings, respectively. These results prove the effectiveness of ESD in few-shot sequence labeling.

6 Analysis

6.1 Ablation Study

To illustrate the effect of our proposed mechanisms, we conduct ablation studies by removing one component of ESD at a time. Table 3 shows the results on the validation set of SNIPS (1-shot, domain “We”). Firstly, we remove ISA or CSA, which means the span cannot be aware of other spans within the same sentence or spans from other sentences. As shown in Table 3, the average F1 scores drop 0.7 and 2.6 without ISA and CSA, respectively. These results suggest that our span enhancing module with ISA and CSA is effective. In addition, CSA is more effective than ISA, since CSA can enhance query spans with whole support set spans, while ISA enhances spans only with other spans in the same setence. CSA brings much more information than ISA. Secondly, when we remove INSA and achieve the prototypical representation of a class through an average operation, the average F1 score would drop 3.5. When we do not consider the sub-classes of O-type spans (*r.m.* OP), the average F1 score would drop 1.1. These results show that our span prototypical module is necessary. At last, the result without BSNMS suggests the importance of our post-processing algorithm in this span-level few-shot labeling framework. Moreover, with BSNMS, ESD can also easily adapt to the nested situation.

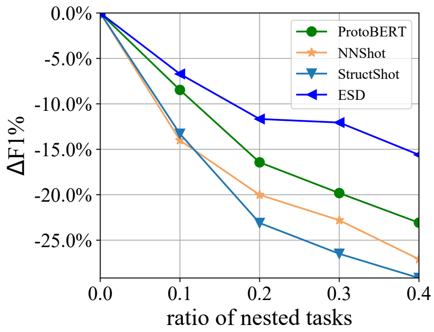

Figure 4: The performance drops in nested situations when increasing r_{nest}. ΔF1% is the F1 reduction percent over $r_{nested} = 0$.

6.2 Robustness in the Nested Situation

Sequence labeling tasks such as NER can have nested situations. For example, in the sentence “Isaac Newton studied at Cambridge University", where “Cambridge” is a location and “Cambridge University” is an organization. However, both FewNERD and SNIPS do not annotate nested examples. To explore the robustness of ESD on such a challenging but common situation, we construct **FewNERD-nested**, which has the same training tasks as FewNERD-INTRA, but different test tasks with a nested ratio r_{nested}. In FewNERD-nested, we sample each test task either from FewNERD or from GENIA (Ohta et al., 2002) with the probability $1 - r_{nested}$ and r_{nested}, respectively, and all tasks sampled from GENIA are guaranteed to have the query with nested entities. We sample validation tasks with nested instances from

Models	**F1**
ESD (with BSNMS)	31.25
ESD (with SoftNMS)	31.09
ESD (with Beam Search)	28.94
ESD (without Post-processing)	30.34

Table 4: Comparison between different post-processing methods in the nested situation with $r_{nested} = 1$.

Models	**#Para.**	**Inference Time**	
		1-SHOT	**5-SHOT**
ESD	112M	8.53 ms	18.47 ms
ProtoBERT	110M	3.13 ms	5.27 ms
L-TapNet+CDT	110M	24.67 ms	54.19 ms

Table 5: The parameter number and inference time per task of ESD and L-TapNet+CDT in the domain "We" of SNIPS. Although ESD is slower than ProtoBERT, ESD outperforms ProtoBERT by 31.53 and 16.68 F1 scores in 1- and 5-shot settings with a bearable latency.

Models	**F1**	**Total**	**FP-Span**	**FP-Type**
ESD	59.29	9.4k	72.8%	27.2%
ProtoBERT	38.83	30.4k	86.7%	13.3%
NNShot	47.24	21.7k	84.7%	15.3%
StructShot	51.88	14.5k	80.0%	20.0%

Table 6: Error analysis of 5 way $1 \sim 2$ shot on FewNERD-INTER. 'FP-Span' denotes extracted entities with the wrong span boundary, and 'FP-Type' represents extracted entities with the right span boundary but the wrong entity type. 'Total' denotes the total wrong prediction of two types.

ACE05 (Walker et al., 2006) to tune k, u and δ in BSNMS. Please refer to the Appendix B for more details about FewNERD-nested. Figure 4 shows the results of ESD and several typical baselines in FewNERD-nested with different r_{nested}. When r_{nested} increases, ESD is more stable than previous methods, since ESD with BSNMS can easily extend to nested tagging cases without any extra training while previous methods are incapable of. In addition, we also compare different post-processing methods when $r_{nested} = 1$. As shown in Table 4, the beam search method can not handle the nested situation, and thus it harms the performance. SoftNMS (Shen et al., 2021) and BSNMS can both improve the model performance. However, when incorporating beam search into SoftNMS, the model can be more flexible and avoid some local optimal post-processing results achieved by SoftNMS (e.g., spans 1,3 and 4 in Figure 3), and thus BSNMS outperforms SoftNMS [3].

6.3 Model Efficiency

Compared with the token-level models, ESD needs to enumerate all spans within the length L for a sentence. Therefore, the number of spans is approximately L times that of tokens, which may bring extra computation overhead. To evaluate the efficiency of ESD, we compare the average inference time per task of ESD (including the BSNMS post-processing process), L-TapNet+CDT (the state-of-the-art token-level baseline model with the open codebase in the SNPIS) and ProtoBERT (an extremely simple token-level baseline). As shown in Table 5, with exactly the same hardware setting, in the domain "We" of SNIPS 1-shot setting, ESD (avg. 8.53 ms per task) is nearly 3 times faster than L-TapNet+CDT (avg. 24.67 ms per task). We see a similar tendency in the 5-shot setting. Although ESD (avg. 8.53 and 18.47 ms in 1- and 5-shot per task) is slower than ProtoBERT (avg. 3.13 and 5.27 ms), it outperforms ProtoBERT by 31.53 and 16.68 F1 scores in 1- and 5-shot settings (reported in Table 2) with a bearable latency. Besides the inference time, we also compare the parameter number of these models. As is shown, the added parameter scale (span enhancing and prototypical modules) is very small (2M) compared with the ProtoBERT and L-TapNet+CDT (110M). These results show that ESD has an acceptable efficiency.

6.4 Error Analysis

To further explore what types of errors the model makes in detail, we divide error of model prediction into 2 categories, 'FP-Span' and 'FP-Type'. As shown in Table 6, ESD outperforms baselines and has much less false positive prediction errors. 'FP-Span' is the major prediction error for all models, showing that it is hard to locate the right span boundary in FSSL for existing models. Therefore, we should pay more attention to the span recognition in the future work. However, compared with previous methods, ESD has less ratio of the 'FP-span' error. We think the reason is that our span-level matching framework with a series of span-related procedures has a better perception of the entity and slot spans than that of our baselines.

---

[3] ESD is also more robust than baselines in the noisy situation. Please refer to Appendix C for details.

7 Conclusion

In this paper, we propose ESD, an enhanced span-based decomposition model for few-shot sequence labeling (FSSL). To overcome the drawbacks of previous token-level methods, ESD formulates FSSL as a span-level matching problem, and decomposes it into a series of span-related procedures, mainly including span representation, class prototype aggregation and span conflicts resolution for a better span matching. Extensive experiments show that ESD achieves the state-of-the-art performance on two popular few-shot sequence labeling benchmarks and that ESD is more robust than previous models in the noisy and nested situation.

A Experiments

A.1 Baselines

We compare ESD with a variety of baselines as follows:

- **TransferBERT** (Hou et al., 2020) is a fine-tuning based model, which is a direct application of BERT (Devlin et al., 2019) to the few-shot sequence labeling.

- **ConVEx** (Henderson and Vulić, 2021) is a fine-tuning based model, which is first pretrained on the Reddit corpus with the sequence labeling objective tasks and then fine-tuned on the source domain and target domain annotated data for final few shot sequence labelingm

- **Ma2021** (Ma et al., 2021) formulates sequence labeling as the machine reading comprehension problem, and proposes some questions to extract slots in the query sentence.

- **ProtoBERT** (Fritzler, Logacheva, and Kretov, 2019b) predicts the query labels according to the similarity of BERT hidden states of support set and query tokens.

- **Matching Net (MN)+BERT** (Hou et al., 2020) is similar to ProtoBERT. The only difference is that MN uses the matching network (Vinyals et al., 2016) for token classification.

- **L-TapNet-CDT** (Hou et al., 2020) utilizes the task-adaptive projection network (Yoon, Seo, and Moon, 2019), pair-wise embedding and collapsed dependency transfer mechanisms to do classification.

- **NNShot** (Yang and Katiyar, 2020) is similar to ProtoBERT, while it makes the prediction based on the nearest neighbor.

- **StructShot** (Yang and Katiyar, 2020) adopts an additional Viterbi decoder during the inference phase on top of NNShot.

- **Retriever** (Yu et al., 2021) is a retrieval based method which does classification according to the most similar example in the support set.

A.2 Parameter Setting

In our implementation, we utilize *BERT-base-uncased* as our backbone encoder the same as (Hou et al., 2020; Yu et al., 2021; Ding et al., 2021). We use Adam (Kingma and Ba, 2015) as our optimizer. In FewNERD, the learning rate is $2e-5$ for BERT encoder and $5e-4$ for other modules. In the 1-shot setting of SNIPS, for the domain “Mu”, the learning rate is $5e-6$ for BERT encoder and $1e-4$ for other modules. For the domain “Bo”, the learning rate is $1e-5$ for BERT encoder and $1e-4$ for other modules. For other settings of SNIPS, the learning rate is $5e-5$ for BERT encoder and $5e-4$ for other modules. We set the dropout ratio (Srivastava et al., 2014) to 0.1. The dimension of span representation d and the maximum span length L is set to 100 and 8, respectively. For BSNMS, the beam size b is 5. Since these is no nested instances in FewNERD and SNIPS, we set the threshold to filter false positive spans δ to 0.1, the threshold to decay span scores k to $1e-5$ and the decay ratio u to $1e-5$ to force the refining results have no nested spans. We use the grid search to search our hyperparameters, and the scope of each hyperparameter are included in Table 7. We train our model on a single NVIDIA A40 GPU with 48GB memory.

learning rate	[5e-5, 1e-4, 3e-4, 5e-4]
dropout	[0.1, 0.3, 0.5]
bert learning rate	[5e-6, 1e-5, 2e-5, 3e-5, 5e-5]
span dimension	[50, 100, 150, 200]
beam size	[1, 3, 5, 7]

Table 7: The searching scope of hyperparameters.

B FewNERD-nested

k	[0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9]
δ	[0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9]
u	[0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9]

Table 8: The searching scope of BSNMS hyperparameters.

We construct our FewNERD-nested via ACE05 (Walker et al., 2006), GENIA (Ohta et al., 2002) and the origin FewNERD datasets. GENIA is a biological named entity recognition dataset, which contains 5 kinds of entities, *‘DNA’*, *‘Protein’*, *‘cell_type’*, *‘RNA’* and *‘cell_line’*, and all of these entity types are not included in the FewNERD. We

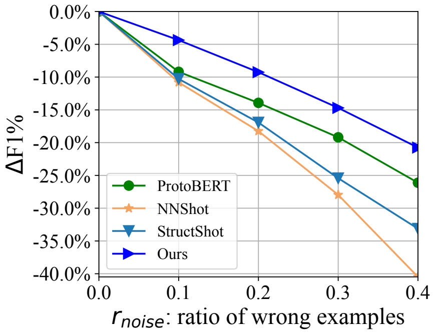

Figure 5: The performance drops in noisy situations when increasing r_{noise}. ΔF1% is the F1 reduction percent over $r_{noise} = 0$.

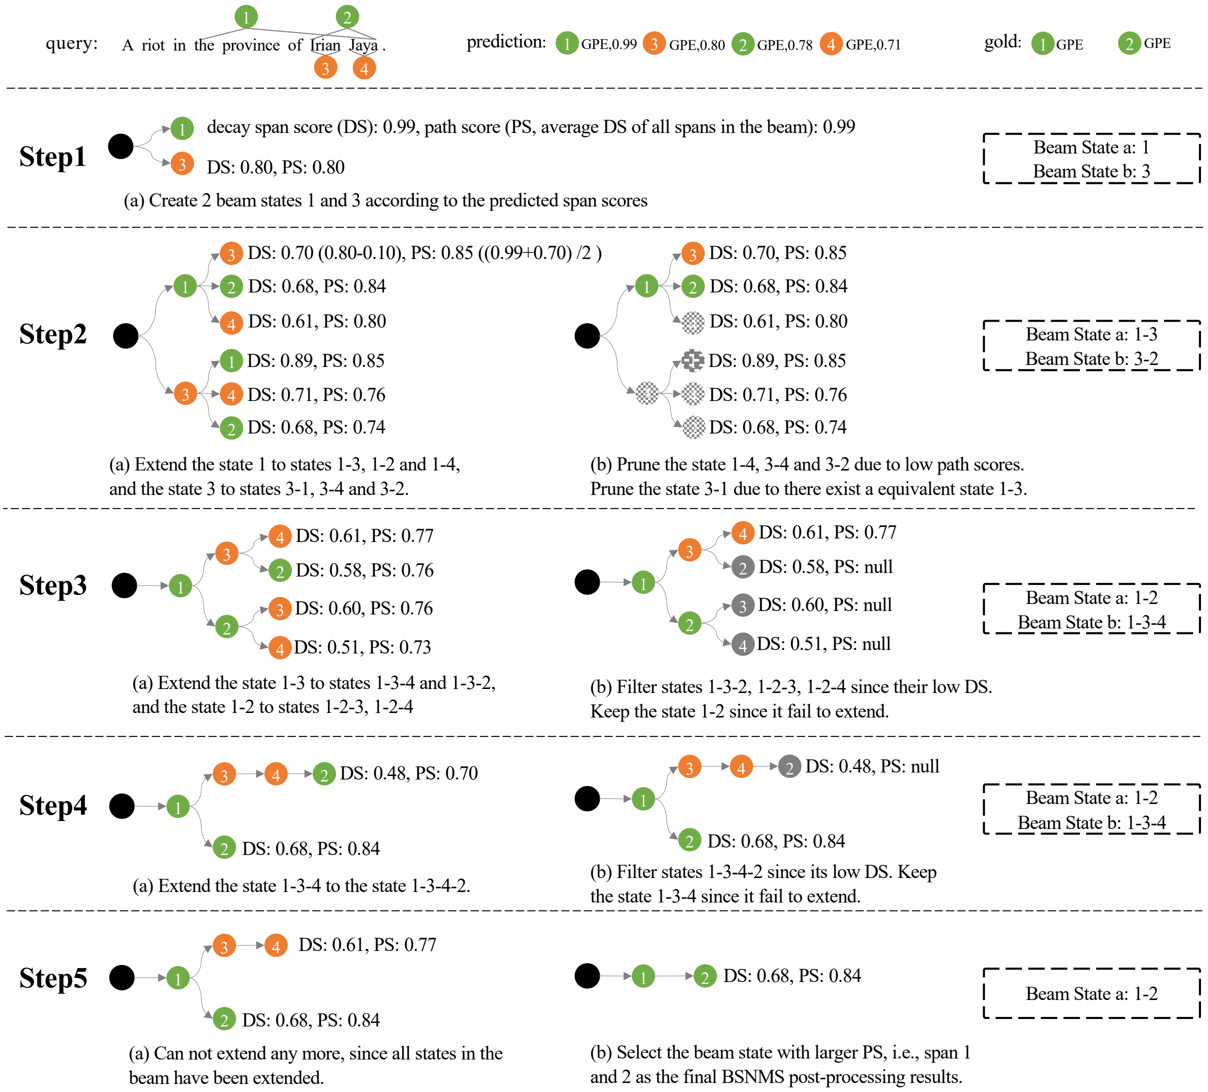
partition the sentences in GENIA into two groups, $\mathcal{G}_1$ and $\mathcal{G}_2$. $\mathcal{G}_1$ consists of sentences with nested entities ($4,744$ sentences in total), and $\mathcal{G}_2$ consists of sentences without nested entities ($11,924$ sentences in total). We utilize sentences in $\mathcal{G}_1$ and $\mathcal{G}_2$ to construct the query and support set of the GENIA task, respectively. Our FewNERD-nested contains 2000 5-way 5$\sim$10-shot test tasks in total, where r_{nested} percent tasks are from GENIA, and the remained tasks are from FewNERD-INTRA. We use ACE05 to construct the validation set. ACE05 is a widely used named entity recognition dataset, which contains 7 coarse-grained entity types, *'FAC'*, *'PER'*, *'LOC'*, *'VEH'*, *'GPE'*, *'GPE'*, *'WEA'* and *'ORG'*. The *'LOC'*, *'PER'*, *'ORG'* and *'FAC'* are not included in the training set of FewNERD-INTRA, and therefore we use them (28 fine-grained entity types in total) and sample 1000 nested tasks as the validation dataset to tune the k, δ and u of BSNMS. The search scope is included in the Table 8. In this nested situation, we finally set the k, δ and u to 0.1, 0.1 and 0.4 respectively.

C Robustness in the Noisy Situation

FSSL methods tend to be seriously influenced by the noise in the support set, since they make the prediction based on only limited annotated examples. To explore the robustness of ESD in the noisy situation, we construct **FewNERD-noise**. In FewNERD-noise, we disturb each 5 way $5 \sim 10$ shot FewNERD-INTRA task with a noisy ratio r_{noise}, which means there are nearly r_{noise} percent entities in the support set are mislabeled. As illustrated in the right part of Figure 5, with r_{noise} increasing, the performance of ESD drops less than baselines, which furthuer shows the superiority of our methods.

D A Detail Case Study of BSNMS

For span conflicts resolution, we propose a post-processing method BSNMS. A step by step demonstration of BSNMS is shown in Figure 6.



(a) Create 2 beam states 1 and 3 according to the predicted span scores

(a) Extend the state 1 to states 1-3, 1-2 and 1-4, and the state 3 to states 3-1, 3-4 and 3-2.

(b) Prune the state 1-4, 3-4 and 3-2 due to low path scores. Prune the state 3-1 due to there exist a equivalent state 1-3.

(a) Extend the state 1-3 to states 1-3-4 and 1-3-2, and the state 1-2 to states 1-2-3, 1-2-4

(b) Filter states 1-3-2, 1-2-3, 1-2-4 since their low DS. Keep the state 1-2 since it fail to extend.

(a) Extend the state 1-3-4 to the state 1-3-4-2.

(b) Filter states 1-3-4-2 since its low DS. Keep the state 1-3-4 since it fail to extend.

(a) Can not extend any more, since all states in the beam have been extended.

(b) Select the beam state with larger PS, i.e., span 1 and 2 as the final BSNMS post-processing results.

Figure 6: A step by step processing process of BSNMS with beam size=2. For clarity, we set the filter threshold δ to 0.6, and suppose the span score is always decayed by the overlapped spans with a constant decayed score -0.1. **STEP1**:create 2 (beam size) states with spans having larger predicted scores; **STEP2**: extend all states (i.e., states 1 and 3) in the beam to 1-3, 1-2, 1-4, 3-1, 3-4 and 3-2. Compute DS of the new added span and PS of the new state. As beam size=2, prune states 1-4, 3-4 and 3-2 according to their lower PS. The state 3-1 is dropped since it is equivalent with the state 1-3; **STEP3**: extend states in the beam (1-3 and 1-2) to 1-3-4, 1-3-2, 1-2-3, 1-2-4, and compute their DS and PS. Filter states 1-3-2, 1-2-3, 1-2-4 since their DS are not greater than δ, i.e., low DS; **STEP4**: extend states in the beam (only 1-3-4 since the state 1-2 has been extended before) to 1-3-4-2, and filter 1-3-4-2 due to its low DS; **STEP5**: all states in the beam can not extend any more, and select the final state (1-2 in this case) with the largest PS.

A Two-Stream AMR-enhanced Model for Document-level Event Argument Extraction

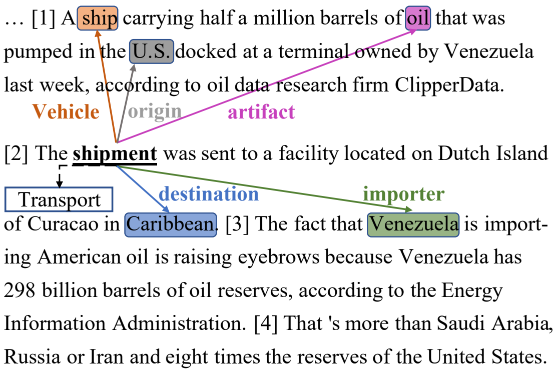
Abstract

Most previous studies aim at extracting events from a single sentence, while document-level event extraction still remains under-explored. In this paper, we focus on extracting event arguments from an entire document, which mainly faces two critical problems: a) the long-distance dependency between trigger and arguments over sentences; b) the distracting context towards an event in the document. To address these issues, we propose a **T**wo-**S**tream **A**bstract meaning **R**epresentation enhanced extraction model (**TSAR**). TSAR encodes the document from different perspectives by a two-stream encoding module, to utilize local and global information and lower the impact of distracting context. Besides, TSAR introduces an AMR-guided interaction module to capture both intra-sentential and inter-sentential features, based on the locally and globally constructed AMR semantic graphs. An auxiliary boundary loss is introduced to enhance the boundary information for text spans explicitly. Extensive experiments illustrate that TSAR outperforms previous state-of-the-art by a large margin, with 2.54 F1 and 5.13 F1 performance gain on the public RAMS and WikiEvents datasets respectively, showing the superiority in the cross-sentence arguments extraction. We release our code in `https://github.com/PKUnlp-icler/TSAR`.

1 Introduction

Event Argument Extraction (EAE) aims at identifying the entities that serve as event arguments, and predicting the roles they play in the event, which is a key step for Event Extraction (EE). It helps to transform the unstructured text into structured event knowledge that can be further utilized in recommendation systems (Li et al., 2020), dialogue systems (Zhang et al., 2020a), and so on. Most previous studies assume that the events are only expressed by a single sentence and hence focus on sentence-level extraction (Chen et al., 2015; Liu et al., 2018; Zhou et al., 2021). However, in real-life scenarios, the events are often described through a whole document consisting of multiple sentences (e.g., a news article or a financial report), which still remains under-explored.



… [1] A ship carrying half a million barrels of oil that was pumped in the U.S. docked at a terminal owned by Venezuela last week, according to oil data research firm ClipperData.

[2] The **shipment** was sent to a facility located on Dutch Island of Curacao in Caribbean. [3] The fact that Venezuela is importing American oil is raising eyebrows because Venezuela has 298 billion barrels of oil reserves, according to the Energy Information Administration. [4] That 's more than Saudi Arabia, Russia or Iran and eight times the reserves of the United States.

Figure 1: A document from RAMS dataset (Ebner et al., 2020). A *transport* event is triggered by **shipment**, with five event arguments scattering across the document.

Figure 1 illustrates an example of document-level EAE, in which a *Transport* event is triggered by *shipment*. Different from sentence-level EAE, extracting arguments out of the entire document faces two critical challenges. (1) **Long-distance dependency** among trigger and arguments. The arguments are usually located in different sentences from the trigger word and their distance can be quite far away. In Figure 1, while the trigger *shipment* is in Sentence 2, the *vehicle*, *origin*, *artifact*, and *importer* arguments are located in Sentence 1 or 3, which highly increases the extraction difficulty. To accommodate the long-range extraction, not only intra-sentential but also inter-sentential semantics should be well modeled. (2) **Distracting context**. While a document naturally encompasses more context than a single sentence, some distracting context can mislead the argument extraction.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5025 - 5036
July 10-15, 2022 ©2022 Association for Computational Linguistics

As shown in Figure 1, the *origin* argument *U.S.* can be identified more easily without Sentence 4, which does not offer useful information for the event, but contains many place entities that can be distracting, like *Saudi Arabia* and *Russia or Iran*. It remains challenging to pinpoint the useful context while discarding the distracting information.

Recently, Du and Cardie (2020a) use a tagging-based method, which fails to handle nested arguments. Instead, span-based methods predict argument roles for candidate spans (Ebner et al., 2020; Zhang et al., 2020b). Some studies directly generate arguments based on sequence-to-sequence model (Li et al., 2021). However, how to model long-distance dependency among trigger and arguments, and how to handle distracting context explicitly, remain largely under-explored.

In this paper, to tackle the aforementioned two problems, we propose a **T**wo-**S**tream **AMR**-enhanced extraction model (**TSAR**). In order to take advantage of the essential context in the document, and avoid being misled by distractions, we introduce a two-stream encoding module. It consists of a global encoder that encodes global semantics with as much context as possible to gather adequate context information, and a local encoder that focuses on the most essential information and prudently takes in extra context. In this way, TSAR can leverage complementary advantages of different encoding perspectives, and therefore make better use of the feasible context to benefit the extraction. Besides, to model the long-distance dependency, we introduce an AMR-guided interaction module. Abstract Meaning Representation (AMR, Banarescu et al., 2013) graph contains rich hierarchical semantic relations among different concepts, which makes it favorable for complex event extraction. From such a linguistic-driven angle, we turn the linear structure of the document into both global and local graph structures, followed by a graph neural network to enhance the interactions, especially for those non-local elements. Finally, as TSAR extracts arguments in span level, where the span boundary may be ambiguous, we introduce an auxiliary boundary loss to enhance span representation with calibrated boundary.

To summarize, our contributions are three-fold. 1) We propose a two-stream encoding module for document-level EAE, which encodes the document through two different perspectives to better utilize the context. 2) We introduce an AMR-guided interaction module to facilitate the semantic interactions within the document, so that long-distance dependency can be better captured. 3) Our experiments show that TSAR outperforms the previous start-of-the-art model by large margins, with 2.54 F1 and 5.13 F1 improvements on public RAMS and WikiEvents datasets respectively, especially on cross-sentence event arguments extraction.

2 Related Work

2.1 Sentence-level Event Extraction

Previous studies mainly focus on sentence-level event extraction. Li et al. (2014) and Judea and Strube (2016) use handcrafted features to extract events from the sentence. Chen et al. (2015) firstly propose a neural pipeline model to extract events, while Nguyen et al. (2016) utilize a joint model to mitigate error propagation. To better model the interactions among words, Liu et al. (2018); Yan et al. (2019); Ma et al. (2020) make use of the dependency tree, and Wadden et al. (2019) enumerates all possible spans and propagate information in the span graph. Data augmentation is also considered (Yang et al., 2019). Moreover, some works try to reformulate the event extraction task as other tasks. For example, Du and Cardie (2020b) and Zhou et al. (2021) cast event extraction as question answering, and Xiangyu et al. (2021) model it as a sequence-to-sequence task. However, all of these models can only extract events from a single sentence. Thus, they fail to handle the much more common cases, where event arguments usually spread over multiple sentences within the document.

2.2 Document-level Event Extraction

In order to extract events from a whole piece of article with multiple sentences, document-level event extraction has attracted more and more attention recently. Yang and Mitchell (2016) utilize well-defined features to extract arguments across sentences, while most recent methods are based on neural networks. Some studies first identify entities in the document, followed by assigning these entities as specific argument roles (Yang et al., 2018; Zheng et al., 2019; Xu et al., 2021). Differently, some studies try to jointly extract entities and argument roles simultaneously, which can be further divided into tagging-based and span-based methods. Tagging-based methods directly conduct sequence labeling for each token in the document with BIO-schema (Du and Cardie, 2020a; Veyseh

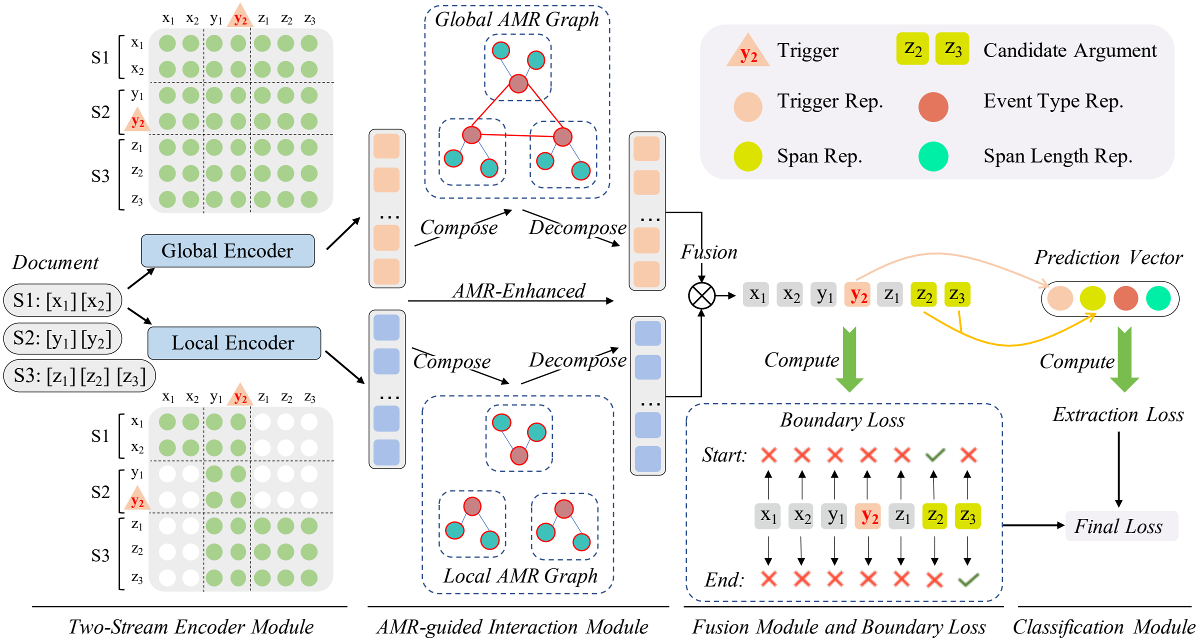

Figure 2: **Overview of our TSAR.** Firstly, taking an entire document as input, TSAR first encodes the document by the two-stream encoding module, where the global and local encoders with different attention reception fields are used to capture the context in different scopes. Then the AMR-guided interaction module constructs global AMR graphs and local ones to stimulate the interactions among concepts in the document, especially those far away from each other, based on graph neural network. Next, the information fusion module fuses the two-stream representations, and also strengthens the boundary information through a boundary loss. Finally, the classification module makes predictions for candidate spans. For conciseness, we assume the document has three sentences, S_1, S_2, S_3, and the event is triggered by y_2 with $[z_2, z_3]$ being a candidate argument span.

et al., 2021), while span-based methods predict the argument role for candidate text spans which usually have a maximum length limitation (Ebner et al., 2020; Zhang et al., 2020b). Another line of studies reformulate the task as a sequence-to-sequence task (Du et al., 2021a,b; Li et al., 2021), or machine reading comprehension task (Wei et al., 2021).

As a span-based method, TSAR is different from prior methods that simply encode it as a long sentence. Instead, TSAR introduces a two-stream encoding module and AMR-guided interactions module to model intra-sentential and inter-sentential semantics, along with an auxiliary boundary loss to enhance span boundary information.

3 Task Formulation

Following Ebner et al. (2020), we formulate doc-level event argument extraction as follows. We define that a document $\mathcal{D}$ consists of N sentences, and a sentence is comprised of a sequence of words, i.e., $\mathcal{D} = \{w_1, w_2, \ldots, w_{|\mathcal{D}|}\}$, and $\text{SEN}(w_i) \in [1, N]$ refers to the sentence that w_i belongs to. We also define the event types set $\mathcal{E}$ and the corresponding argument roles set $\mathcal{R}_e$ for each event type $e \in \mathcal{E}$. Then, given a document $\mathcal{D}$ and the trigger $t \in \mathcal{D}$ triggering the event type $e \in \mathcal{E}$, the task aims to detect all (r, s) pairs for the event, where $r \in \mathcal{R}_e$ is an argument role for the event type e, and $s \subseteq \mathcal{D}$ is a contiguous text span in the document.

4 Methodology

Figure 2 shows the overall architecture of our model TSAR. The document is fed into the two-stream encoding module, followed by the AMR-guided interaction module to derive both global and local contextualized representations. The information fusion module fuses these two-stream representations, and the classification module finally predicts argument roles for candidate spans.

4.1 Two-Stream Encoding Module

Although more context is provided by the document, it also inevitably introduces irrelevant and distracting information towards the event. These noise signals can be harmful to the argument extraction as shown in Figure 1. To capture useful information and filter distracting one, we propose a two-stream encoding module, consisting of a global

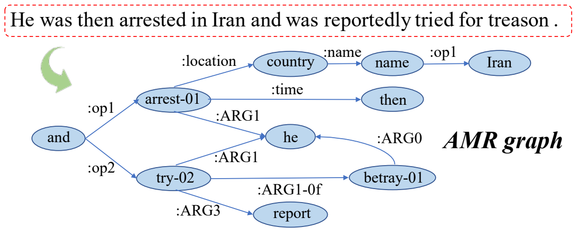

Figure 3: The AMR graph provides abstract and logical semantic information, where the nodes denote the concepts and the edges refer to different relation types. The corresponding text spans for nodes are omitted.

encoder that is aware of all context, and a local encoder that only prudently focuses on the most essential information. Therefore, we can leverage their complementary advantages to make better use of the context information.

Specifically, the global and local encoders share the same Transformer-based pre-trained language model such as BERT. By controlling the reception field of the words in the self-attention module , we can encode the document from different perspectives. In the global encoder, the attention technique is the same as the traditional Transformer:

$$\text{Attention}^G(Q, K, V) = \text{softmax}\left(\frac{QK^\top}{\sqrt{d_m}}\right) V$$

where Q, K, V refers to query, key, and value matrix, and d_m is the model dimension. However, in the local encoder, we introduce a mask matrix M, such that tokens can only attend to the sentence itself and the sentence where the trigger locates, to avoid redundant distracting information:

$$\text{Attention}^L(Q, K, V) = \text{softmax}\left(\frac{QK^\top + M}{\sqrt{d_m}}\right) V$$

$$M_{ij} = \begin{cases} 0, & \text{SEN}(w_j) \in \{\text{SEN}(w_i), \text{SEN}(t)\} \\ -\infty, & \textit{Otherwise} \end{cases}$$

where $\text{SEN}(w_i)$ is the sentence that the word w_i belongs to, and t refers to the trigger of the event.

Hence, we encode the document with two different streams, a global encoder Encoder^G and a local encoder Encoder^L, finally deriving two representations, Z^G and Z^L:

$$Z^G = \left[z_1^G, z_2^G, \dots, z_{|\mathcal{D}|}^G\right] = \text{Encoder}^G\left(\left[w_1, w_2, \dots, w_{|\mathcal{D}|}\right]\right)$$
$$Z^L = \left[z_1^L, z_2^L, \dots, z_{|\mathcal{D}|}^L\right] = \text{Encoder}^L\left(\left[w_1, w_2, \dots, w_{|\mathcal{D}|}\right]\right)$$

4.2 AMR-Guided Interaction Module

One key challenge to extract arguments from the document is to capture the intra-sentential and inter-sentential features. Therefore, we propose an AMR-guided interaction module that adopts Abstract Meaning Representation (AMR, Banarescu et al., 2013) graph to provide rich semantic structure to facilitate the interactions among concepts, which also offers logical meanings of the document from a linguistic-driven perspective to benefit the language understanding.

AMR semantic graph models the meaning representations of a sentence as a rooted, directed, labeled graph. Concretely, with an AMR parser, a natural sentence can be parsed into an AMR graph $G = (V, E)$. The node $v = (a, b) \in V$ represents a concept that corresponds to the span ranging from w_a to w_b in the origin sentence, while the edge represents a specific AMR relation (detail in Appendix A). Thus, AMR focuses on semantic relations rather than syntactic ones, which is more high-level and beneficial to event understanding, and the structures are more close to the event trigger-arguments structures. For example, Figure 3 demonstrates how a sentence is parsed into an AMR semantic graph. As event arguments play essential roles in the text, most of them would be involved, if not all, in the AMR graphs (90% and 88% arguments in RAMS and WikiEvents datasets). We use the state-of-the-art AMR parser Fernandez Astudillo et al. (2020), which achieves satisfactory results (up to 81.3 Smatch on AMR2.0 data) for downstream application. As the number of AMR relation types is large, which results in too many demanded parameters, we also follow Zhang and Ji (2021) to cluster the relation types into main categories. More details can be found in Appendix A.

The AMR-guided interaction module is attached after the global and local encoders as shown in Figure 2. We use the AMR graphs as skeletons for information interactions, under a *composition, interaction, and decomposition* paradigm.

From the local perspective, we construct AMR graphs for each sentence in the document, and they are isolated from each other. For initialization, the vector representation of node $u = (a_u, b_u)$ is ***composed*** by averaging the local representations of its corresponding text span:

$$h_u^0 = \frac{1}{|b_u - a_u + 1|} \sum_{i=a_u}^{b_u} z_i^L$$

Similar to Zeng et al. (2020), we then use L-layer stacked Graph Convolution Network (Kipf and

Welling, 2017) to model the ***interactions*** among different concept nodes through edges with different relation types. Given node u at the l-th layer, the information interaction and aggregation operation is defined as follows:

$$h_u^{(l+1)} = \mathrm{ReLU}\left(\sum_{k\in\mathcal{K}}\sum_{v\in\mathcal{N}_k(u)\bigcup\{u\}}\frac{1}{c_{u,k}}W_k^{(l)}h_v^{(l)}\right)$$

where $\mathcal{K}$ denotes different relation types, $\mathcal{N}_k(u)$ denotes the neighbors for u connected with k-th relation types and $c_{u,k}$ is a normalization constant. Besides, $W_k^{(l)} \in \mathbb{R}^{d_m\times d_m}$ is a trainable parameter.

Finally, we concatenate vectors in all layers and derive the final node representation by $h_u = W_1[h_u^0; h_u^1; \ldots; h_u^L] \in \mathbb{R}^{d_m}$. Then h_u is ***decomposed*** into the local representations of corresponding words, followed by token-wise aggregation, where $\mathbb{I}(\cdot)$ refers to the indication function:

$$\widetilde{h}_i^L = z_i^L + \frac{\sum_u \mathbb{I}(a_u <= i \wedge b_u >= i)h_u}{\sum_u \mathbb{I}(a_u <= i \wedge b_u >= i)}$$

From the global perspective, we first construct the global AMR graphs by fully connecting the root nodes of AMR graphs of different sentences, since the root nodes contain the core semantics according to the AMR core-semantic principle (Cai and Lam, 2019) [1]. Then similar graph-based interaction methods are used to obtain the AMR-enhanced global representations $\widetilde{h}_i^G$, but based on global AMR graphs instead. In this way, the inter-sentential information can flow through the sentence boundaries, and therefore long-distance dependency can also be better captured.

4.3 Information Fusion Module

In the information fusion module, we fuse the global representations $\widetilde{H}^G = \left[\widetilde{h}_1^G, \widetilde{h}_2^G, \ldots, \widetilde{h}_{|\mathcal{D}|}^G\right]$ and local representations $\widetilde{H}^L = \left[\widetilde{h}_1^L, \widetilde{h}_2^L, \ldots, \widetilde{h}_{|\mathcal{D}|}^L\right]$, to construct the final vector representations for the candidate spans.

In detail, we use a gated fusion to control how much information is incorporated from the two-stream representations. Given $\widetilde{h}_i^G$ and $\widetilde{h}_i^L$, we calculate the gate vector g_i with trainable parameters W_2 and W_3, $g_i = \mathrm{sigmoid}(W_2\widetilde{h}_i^G + W_3\widetilde{h}_i^L + b)$. Then we derive the fused representations $\widetilde{h}_i$:

$$\widetilde{h}_i = g_i \odot \widetilde{h}_i^G + (1 - g_i) \odot \widetilde{h}_i^L$$

For a candidate text span ranging from w_i to w_j, its fused representation consists of the start representation $\widetilde{h}_i^{start}$, the end representation $\widetilde{h}_j^{end}$ and the average pooling of the hidden state of the span with $W_{span} \in \mathbb{R}^{d_m\times(3\times d_m)}$:

$$s_{i:j} = W_{span}\left[\widetilde{h}_i^{start}; \widetilde{h}_i^{end}; \frac{1}{j-i+1}\sum_{k=i}^{j}\widetilde{h}_k\right]$$

where $\widetilde{h}_i^{start} = W_s\widetilde{h}_i$ and $\widetilde{h}_i^{end} = W_e\widetilde{h}_i$.

Since we extract arguments in span level, whose boundary may be ambiguous, we introduce an auxiliary boundary loss to enhance boundary information for the $\widetilde{h}_i^{start}$ and $\widetilde{h}_i^{end}$. In detail, we predict whether the word w_i is the first or last word of a golden argument span with token-wise classifiers. We use a linear transformation followed by a sigmoid function, to derive the probability of the word w_i being the first or last word of a golden argument span, i.e., P_i^s and P_i^e.

$$P_i^s = \mathrm{sigmoid}\left(W_4\widetilde{h}_i^{start}\right), P_i^e = \mathrm{sigmoid}\left(W_5\widetilde{h}_i^{end}\right)$$

Finally, the boundary loss is defined as the following cross-entropy losses of detecting the start and end position.

$$\begin{aligned}\mathcal{L}_b = -\sum_{i=1}^{|\mathcal{D}|}&[y_i^s \log P_i^s + (1 - y_i^s)\log(1 - P_i^s) \\ &+ y_i^e \log P_i^e + (1 - y_i^e)\log(1 - P_i^e)]\end{aligned} \quad (1)$$

where, y_i^s and y_i^e denote the golden labels. In this way, we introduce an explicit supervision signal to inject boundary information of the start and end representation of an span, which is shown to be necessary and important to the extraction in our exploring experiments.

4.4 Classification Module

In the classification module, we predict what argument role the candidate span plays, or it does not belong to any specific argument roles. Besides the span representation $s_{i:j}$, we also consider the trigger, event type, and the length of the span. Specifically, we concatenate the following representations to obtain the final prediction vector $I_{i:j}$: 1) the trigger representation $\widetilde{h}_t$, and the span representation $s_{i:j}$, with their absolute difference $\left|\widetilde{h}_t - s_{i:j}\right|$, and element-wise multiplication, $\widetilde{h}_t \odot s_{i:j}$; 2) the embedding of the event type E_{type}. 3) the embedding of the span length E_{len};

---

[1] We find more elaborate methods yield no further improvements, so we adopt this simple connection paradigm.

Dataset	Split	# Doc.	# Event	# Argument
RAMS	Train	3,194	7,329	17,026
	Dev	399	924	2,188
	Test	400	871	2,023
WikiEvents	Train	206	3,241	4,542
	Dev	20	345	428
	Test	20	365	566

Table 1: Statistics of RAMS and WikiEvents datasets.

$$I_{i:j} = \left[\widetilde{h}_t; s_{i:j}; \left|\widetilde{h}_t - s_{i:j}\right|; \widetilde{h}_t \odot s_{i:j}; \mathrm{E}_{type}; \mathrm{E}_{len}\right]$$

We then use the cross entropy $\mathcal{L}_c$ as loss function:

$$\mathcal{L}_c = -\sum_{i=1}^{|\mathcal{D}|}\sum_{j=i}^{|\mathcal{D}|} y_{i:j} \log P\left(r_{i:j} = y_{i:j}\right) \qquad (2)$$

where $y_{i:j}$ is the golden argument role, and $P\left(r_{i:j}\right)$ is derived by a feed-forward network based on $I_{i:j}$.

Finally, we train the model in an end-to-end way with the final loss function $\mathcal{L} = \mathcal{L}_c + \lambda\mathcal{L}_b$ with hyperparameter λ.

5 Experiments

5.1 Datasets

We evaluate our model on two public document-level event argument extraction datasets, RAMS v1.0 (Ebner et al., 2020) and WikiEvents (Li et al., 2021). RAMS contains $9,124$ human-annotated examples, with 139 event types and 65 kinds of argument roles, and more than 21k arguments. WikiEvents is another human-annotated dataset, with 50 event types and 59 event argument roles, and more than 3.9k events. We follow the official train/dev/test split for RAMS and WikiEvents datasets, and use the evaluation script provided by Ebner et al. (2020) to evaluate the performance. The detailed data statistics of RAMS and WikiEvents datasets are shown in Table 1.

5.2 Experiment Setups and Metrics

In our implementation, we use BERT$_{\text{base}}$ (Devlin et al., 2019) and RoBERTa$_{\text{large}}$ (Liu et al., 2019) as our backbone encoder for TSAR, with global and local encoders sharing parameters. Detailed hyperparameters are listed in Appendix B.

Method	Dev		Test	
	Span F1	Head F1	Span F1	Head F1
BERT-CRF	38.1	45.7	39.3	47.1
BERF-CRF$_{\text{TCD}}$	39.2	46.7	40.5	48.0
Two-Step	38.9	46.4	40.1	47.7
Two-Step$_{\text{TCD}}$	40.3	48.0	41.8	49.7
FEAE	-	-	47.40	-
TSAR$_{\text{base}}$ (Ours)	**45.23**	**51.70**	**48.06**	**55.04**
BART-Gen	-	-	48.64	57.32
TSAR$_{\text{large}}$ (Ours)	**49.23**	**56.76**	**51.18**	**58.53**

Table 2: **Comparison between TSAR and other methods on RAMS dataset**. Models above the double line are based on BERT$_{\text{base}}$. TSAR consistently outperforms others on Span F1 and Head F1. Compared with BART-Gen, TSAR improves 2.54 Span F1 in the test set.

Following Zhang et al. (2020b), we report the Span F1 and Head F1 for RAMS dataset. Span F1 requires the predicted argument spans to fully match the golden ones, while Head F1 relaxes the constraint and evaluates solely on the head word of the argument span. The head word of a span is defined as the word that has the smallest arc distance to the root in the dependency tree. In addition, following Li et al. (2021), we report the Head F1 and Coref F1 scores for WikiEvents dataset. The model is given full credit in Coref F1 if the extracted argument is coreferential with the golden argument as used by Ji and Grishman (2008).

5.3 Main Results

We compare TSAR with the following baselines. 1) **BERT-CRF** (Shi and Lin, 2019) is a tagging-based method, which adopts a BERT-based BIO-styled sequence labeling model. 2) **Two-Step** (Zhang et al., 2020b) is a span-based method, which first identifies the head word of possible argument span, and then extends to the full span. **BERT-CRF**$_{\text{TCD}}$ and **Two-Step**$_{\text{TCD}}$ refers to adopting Type-Constraint Decoding mechanism as used in (Ebner et al., 2020). 3) **FEAE** (Wei et al., 2021), Frame-aware Event Argument Extraction, is a concurrent work based on question answering. 4) **BERT-QA** (Du and Cardie, 2020c) is also a QA-based model. BERT-QA and BERT-QA-Doc extract run on sentence-level and document-level, respectively. 5) **BART-Gen** (Li et al., 2021) formulate the task as a sequence-to-sequence task and uses BART$_{\text{large}}$ (Lewis et al., 2020) to generate corresponding arguments in a predefined format.

Table 2 illustrates the results in both dev and test set on RAMS dataset. As is shown, among models based on BERT$_{\text{base}}$, TSAR outperforms other previous methods. For example, TSAR yields an improvement of $4.93 \sim 7.13$ Span F1 and

Method	Arg Identification		Arg Classification	
	Head F1	Coref F1	Head F1	Coref F1
BERT-CRF	69.83	72.24	54.48	56.72
BERT-QA	61.05	64.59	56.16	59.36

Table 4: **Span F1 in RAMS dataset with different sentence distance between trigger and arguments**. Most improvements by TSAR come from cross-sentence ($d \neq 0$) arguments extraction.

Method	Dev		Test	
	Span F1	Head F1	Span F1	Head F1
TSAR$_{\text{large}}$	49.23	56.76	51.18	58.53
- Global Encoder	46.71	54.26	48.21	55.49
- Local Encoder	48.43	55.44	48.69	56.82
- AMR-guided Graph	48.63	55.24	49.21	56.70
- Boundary Loss	47.93	55.14	50.47	57.75

Table 5: **Ablation study on RAMS for TSAR$_{\text{large}}$**. The score would decrease without any kind of module.

$3.70 \sim 6.00$ Head F1 compared with the previous method in the dev set, and up to 8.76 Span F1 in the test set. Besides, among models based on large pre-trained language models, TSAR outperforms BART-Gen by 2.54 Span F1 and 1.21 Head F1[2]. These results suggest that encoding the document in a two-stream way, and introducing AMR graphs to facilitate interactions, is beneficial to capturing intra-sentential and inter-sentential features, and thus improves the performance.

Moreover, we follow Li et al. (2021) to evaluate both argument identification and argument classification, and report the Head F1 and Coref F1. Identification requires the model to correctly detect the argument span boundary, while classification has to further correctly predict its argument role. As illustrated in Table 3, TSAR consistently outperforms others in both tasks. Compared with BART-Gen, TSAR improves up to 4.87/3.23 Head/Coref F1 for argument identification, and 5.13/3.68 Head/Coref F1 for argument classification. Similar results also appear among models based on BERT$_{\text{base}}$, with $5.69 \sim 36.37$ and $11.95 \sim 33.34$ Head F1 improvement for identification and classification. These results show that TSAR is superior to other methods in not only detecting the boundary of argument spans, but also predicting their roles.

6 Analysis

6.1 Cross-sentence Argument Extraction

Since there are multiple sentences in the document, some event arguments are located far away from the trigger, which highly increases the difficulty of extraction. To explore the effect of handling such cross-sentence arguments of our TSAR, we divide the event arguments in RAMS dataset into five bins according to the sentence distance between arguments and trigger, i.e., $d = \{-2, -1, 0, 1, 2\}$. We report the Span F1 on the RAMS dev set for different methods. As shown in Table 4, the Span F1 for cross-sentence arguments ($d \neq 0$) is much lower than local arguments ($d = 0$), suggesting the huge challenge to capture long-distance dependency between triggers and cross-sentence arguments. However, TSAR still surpasses other strong baselines. In detail, TSAR$_{\text{base}}$ improves 0.4 and TSAR$_{\text{large}}$ improves 0.7 F1 compared with the previous state-of-the-art, respectively. More importantly, when extracting cross-sentence arguments, TSAR$_{\text{base}}$ and TSAR$_{\text{large}}$ yield an improvement of up to 2.3 and 2.7 on average. The results support our claims that TSAR is good at capturing both intra-sentential and inter-sentential features, especially the long-distance between trigger and arguments.

6.2 Ablation Study

We conduct an ablation study to explore the effectiveness of different modules in TSAR. Table 5 show the results on RAMS datasets for TSAR$_{\text{large}}$. We also provide results for TSAR$_{\text{base}}$, and those on WikiEvents datasets in Appendix C.

Firstly, we remove the global or local encoder in

---

[2] We use TSAR$_{\text{large}}$ based on RoBERTa$_{\text{large}}$ to compare with BART-Gen based on BART$_{\text{large}}$, as they are pre-trained on the same corpus with the same batch size and training steps.

Category	Examples	Errors	
		Two-step	TSAR

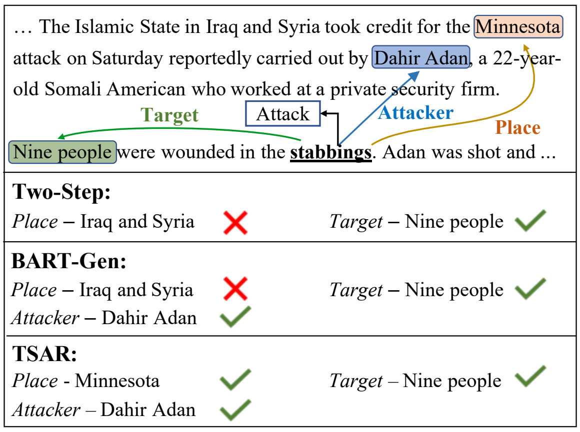
Figure 4: **Error analysis on RAMS dataset**. The triggers are in **bold** with corresponding event types in green. The underlined spans refer to golden arguments, with their roles in blue. The [bracketed] spans denote the predicted arguments, with their roles noted in red. We illustrate the number of different kinds of errors for Two-step and our TSAR, which has 275 and 233 errors in total, respectively. Compared with Two-step, TSAR decreases errors in most error categories, especially for *Wrong Role* and *Over-extract*.



… The Islamic State in Iraq and Syria took credit for the Minnesota attack on Saturday reportedly carried out by Dahir Adan, a 22-year-old Somali American who worked at a private security firm. Nine people were wounded in the **stabbings**. Adan was shot and …

Two-Step:
Place – Iraq and Syria ✗ *Target* – Nine people ✓

BART-Gen:
Place – Iraq and Syria ✗ *Target* – Nine people ✓
Attacker – Dahir Adan ✓

TSAR:
Place - Minnesota ✓ *Target* – Nine people ✓
Attacker – Dahir Adan ✓

Figure 5: **An extraction case**, where an *Attack* event is triggered by **stabbings** with three arguments. TSAR manages to extract the cross-sentence argument *Minnesota* far from the trigger, while other methods fail.

the two-stream encoding module. As shown in Table 5, the removal causes drop in performance, e.g., 3.04 and 1.71 Head F1 drop on the test set without global and local encoder. It suggests the global and local encoders are complementary to each other, and both of them are necessary for TSAR.

Secondly, once we remove the AMR-guided interaction module, the Head F1 would decrease by 1.83 on the test set. It shows the semantic structure provided by AMR graphs is helpful to the arguments extraction of the document.

Finally, the removal of boundary loss causes the boundary information lost in span representations, which also leads to 1.62 and 0.78 Head F1 decrease on dev and test set.

6.3 Case Study

In this section, we show a specific case of the extraction results among different methods. As shown in Figure 5, *stabbings* triggers an *Attack* event with three arguments in color. Since *Nine people* is located near the trigger, all the methods correctly predict it as the *target*. However, extracting *Minnesota* and *Dahir Adan* asks for capturing long-distance dependency. Although Two-Step and BART-Gen wrongly predict the *place* as *Iraq and Syria*, and Two-Step even fails to extract the *Attacker*, TSAR manage to extract the cross-sentence arguments. It can be attributed to that our AMR-enhanced module catches *Minnesota* is the *place* of *attack* that is highly related to the trigger *stabbings* in semantics.

6.4 Error Analysis

To further explore the errors made by different models and analyze the reasons in detail, we randomly choose 200 examples from the RAMS test set and compare the predictions with golden annotations manually. We divide the errors into five categories, which is shown in Figure 4. *Wrong Span* refers to assigning a specific role to a wrong span non-overlapped with the golden one. We find it is usually due to the negative words like *not*, and the coreference spans for the golden one. *Over-extract* denotes the model predicts an argument role while it does not exist in the document. Some extracted spans are the sub-strings of the golden spans (*Partial*), or have some overlaps with them (*Overlap*). These two kinds of errors are usually attributed to the annotation inconsistency in the dataset, such as whether the adjective, quantifier, and article (e.g., *a* and *the*) before the noun should belong to the golden argument. Besides, the *Partial* error also usually occurs in cases where there is punctuation like a comma in the golden span as shown in Figure 4. Finally, though the model succeeds to identify the golden span, it can still assign wrong argument role to the span (*Wrong Role*). We compare the errors of Two-step$_{\text{TCD}}$ and TSAR$_{\text{base}}$. We observe TSAR decrease the number of errors from 275 to 233, especially for *Wrong Role* and *Over-extract*, with 27 and 16 errors reduction, respectively.

7 Conclusion

It is challenging to extract event arguments from a whole document, owing to the long-distance dependency between trigger and arguments over sentences and the distracting context. To tackle these problems, we propose **T**wo-**S**tream **AMR**-enhanced extraction model (**TSAR**). TSAR uses two-stream encoders to encode the document from different perspectives, followed by an AMR-guided interaction module to facilitate the document-level semantic interactions. An auxiliary boundary loss is introduced to enhance the boundary information for spans. Experiments on RAMS and WikiEvents datasets demonstrate that TSAR outperform previous state-of-the-art methods by a large margin, with 2.51 and 5.13 F1 improvements respectively, especially for cross-sentence argument extraction.

A Abstract Meaning Representation (AMR) Graph

There are many AMR parsing approaches (Bevilacqua et al., 2021; Fernandez Astudillo et al., 2020; Wang et al., 2022; Chen et al., 2022). To obtain AMR semantic graphs with the align information between text spans and AMR nodes, we use the transition-based AMR parser proposed by Fernandez Astudillo et al. (2020), which is a state-of-the-art AMR parser and can achieve satisfactory results for downstream application (up to 81.3 Smatch on AMR2.0 data). As the number of AMR relation types is large, which results in too many demanded parameters, we follow Zhang and Ji (2021) to cluster the relation types into main categories as shown in Table 6.

Categories	**Relation Types**
Spatial	location, destination, path
Temporal	year, time, duration, decade, weekday
Means	instrument, manner, topic, medium
Modifiers	mod, poss
Operators	op-X
Prepositions	prep-X
Sentence	snt
Core Roles	ARG0, ARG1, ARG2, ARG3, ARG4
Others	other relation types

Table 6: Similar AMR relation types are clustered into the same relation category. The exception is that ARGx is still treated as an individual relation type.

B Hyperparameters Setting

We set the dropout rate to 0.1, batch size to 8, and train TSAR using Adam (Kingma and Ba, 2015) as optimizer with 3e-5 learning rate. We train TSAR for 50 epochs for RAMS dataset and 100 epochs for WikiEvents dataset. We search the boundary loss weight λ from $\{0.05, 0.1, 0.2\}$, and L from $\{3, 4\}$, and select the best model using dev set. Our code is based on Transformers (Wolf et al., 2020) and DGL libraries (Wang et al., 2019).

C Ablation Study

In the main body of the paper, we illustrate the results of the ablation study for $\text{TSAR}_{\text{large}}$ on RAMS dataset. To thoroughly show the effect of different modules of TSAR, we also provide the results of the ablation study for $\text{TSAR}_{\text{base}}$ on RAMS dataset. Table 7 shows the results on RAMS dataset, from which we can observe removing different modules would cause 1.34 $\sim$ 2.77 Span F1 on test set.

Besides, we do ablation study on WikiEvents. As shown in Table 8, the Head F1 decreases by 0.70 $\sim$ 2.02 and 0.88 $\sim$ 2.96 for Arg Identification and Arg Classification sub-tasks respectively, once different modules are removed from $\text{TSAR}_{\text{base}}$. Similar conclusions can be drawn from the results of $\text{TSAR}_{\text{large}}$, which is shown in Table 9.

Method	**Dev**		**Test**	
	Span F1	Head F1	Span F1	Head F1
$\text{TSAR}_{\text{base}}$	45.23	51.70	48.06	55.04
- Global Encoder	43.05	50.90	45.29	53.62
- Local Encoder	44.63	51.34	46.50	53.26
- AMR-guided Graph	43.57	50.80	45.97	52.85
- Boundary Loss	44.42	51.08	46.72	53.91

Table 7: **Ablation study on RAMS for $\text{TSAR}_{\text{base}}$.** The score would decrease without any kind of module.

Method	**Arg Identification**		**Arg Classification**	
	Head F1	Coref F1	Head F1	Coref F1
$\text{TSAR}_{\text{base}}$	75.52	73.17	68.11	66.31
- Global Encoder	73.50	72.23	65.15	64.07
- Local Encoder	74.40	72.62	67.11	65.41
- AMR-guided Graph	73.88	72.45	65.83	64.94
- Boundary Loss	74.82	72.50	67.23	65.95

Table 8: **Ablation study on WikiEvents for $\text{TSAR}_{\text{base}}$.** The performance of identification and classification would decrease without any kind of module.

Method	**Arg Identification**		**Arg Classification**	
	Head F1	Coref F1	Head F1	Coref F1
$\text{TSAR}_{\text{large}}$	76.62	75.52	69.70	68.79
- Global Encoder	74.12	72.80	67.54	66.41
- Local Encoder	74.60	73.32	68.08	66.88
- AMR-guided Graph	74.52	73.82	67.67	66.54
- Boundary Loss	75.50	74.05	68.60	67.33

Table 9: **Ablation study on WikiEvents for $\text{TSAR}_{\text{large}}$.** The performance of identification and classification would decrease without any kind of module.

Robust (Controlled) Table-to-Text Generation with Structure-Aware Equivariance Learning

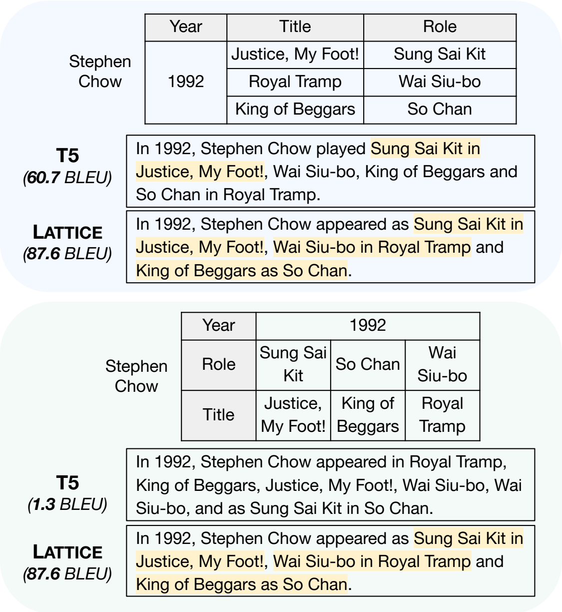
Fei Wang, Zhewei Xu, Pedro Szekely and **Muhao Chen**
Department of Computer Science & Information Sciences Institute
University of Southern California
`{fwang598,zheweixu,szekely,muhaoche}@usc.edu`

Abstract

Controlled table-to-text generation seeks to generate natural language descriptions for highlighted subparts of a table. Previous SOTA systems still employ a sequence-to-sequence generation method, which merely captures the table as a linear structure and is brittle when table layouts change. We seek to go beyond this paradigm by (1) effectively expressing the relations of content pieces in the table, and (2) making our model robust to content-invariant structural transformations. Accordingly, we propose an equivariance learning framework, LATTICE (🧊), which encodes tables with a structure-aware self-attention mechanism. This prunes the full self-attention structure into an order-invariant graph attention that captures the connected graph structure of cells belonging to the same row or column, and it differentiates between relevant cells and irrelevant cells from the structural perspective. Our framework also modifies the positional encoding mechanism to preserve the relative position of tokens in the same cell but enforce position invariance among different cells. Our technology is free to be plugged into existing table-to-text generation models, and has improved T5-based models to offer better performance on ToTTo and HiTab. Moreover, on a harder version of ToTTo, we preserve promising performance, while previous SOTA systems, even with transformation-based data augmentation, have seen significant performance drops.[1]

1 Introduction

Table-to-text generation seeks to generate natural language descriptions for content and entailed conclusions in tables. It is an important task that not only makes ubiquitous tabular data more discoverable and accessible, but also supports downstream tasks of tabular semantic retrieval (Wang et al., 2021a), reasoning (Gupta et al., 2020), fact checking (Chen et al., 2019; Wang et al., 2021b) and table-assisted question answering (Chen et al., 2020c). While rich and diverse facts can be presented in a table, the controlled table-to-text generation task, which generates focused textual descriptions for highlighted subparts of a table, has garnered much attention recently (Parikh et al., 2020; Kale and Rastogi, 2020; Cheng et al., 2022).



Stephen Chow	Year	Title	Role
	1992	Justice, My Foot!	Sung Sai Kit

LATTICE (*87.6* BLEU): In 1992, Stephen Chow appeared as Sung Sai Kit in Justice, My Foot!, Wai Siu-bo in Royal Tramp and King of Beggars as So Chan.

Stephen Chow	Year	1992		
	Role	Sung Sai Kit	So Chan	Wai Siu-bo
	Title	Justice, My Foot!	King of Beggars	Royal Tramp

T5 (*1.3* BLEU): In 1992, Stephen Chow appeared in Royal Tramp, King of Beggars, Justice, My Foot!, Wai Siu-bo, Wai Siu-bo, and as Sung Sai Kit in So Chan.

LATTICE (*87.6* BLEU): In 1992, Stephen Chow appeared as Sung Sai Kit in Justice, My Foot!, Wai Siu-bo in Royal Tramp and King of Beggars as So Chan.

Figure 1: Description generation on content-equivalent tables with different layouts by T5 and LATTICE[2]. Correct film-role pairs in generations are in orange. We report also the BLEU-4 score of each generation. T5 is brittle to layout changes, while LATTICE returns consistent results.

Prior studies on controlled table-to-text generation often employ a sequence-to-sequence generation method, which merely captures the table as a linear structure (Parikh et al., 2020; Kale and Rastogi, 2020; Su et al., 2021). However, table

---

[2] This example is from the ToTTo dataset. Original film names and role names are too long. For presentation, we replace the actor name, film names and role names.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5037 - 5048
July 10-15, 2022

layouts, though overlooked by prior studies, are key to the generation from two perspectives. First, table layouts indicate the relations among cells that collectively present a fact, which are however not simply captured by a linearized table. For example, if we linearize the first table row-wise in Fig. 1, *Wai Siu-bo* will be next to both *Royal Tramp* and *King of Beggers*, so that it is not clear this role belongs to which film. Second, the same content can be equivalently expressed in tables with different layouts. While linearization simplifies the layout representation, it causes brittle generation when table layouts change. Fig. 1 shows two tables with the same content but different layouts, for which the generations by T5 are largely inconsistent.

In this paper, we focus on improving controlled table-to-text generation systems by incorporating two properties: *structure-awareness* and *transformation-invariance*. Structure-awareness, which seeks to understand cell relations indicated by the table structure, is essential for capturing contextualized cell information. Transformation-invariance, which seeks to make the model insensitive to content-invariant structural transformations (including transpose, row shuffle and column shuffle), is essential for model robustness. However, incorporating structure-awareness and transformation-invariance into existing generative neural networks is nontrivial, especially when preserving the generation ability of pretrained models as much as possible.

We enforce the awareness of table layouts and robustness to content-invariant structural transformations on pretrained generative models with an equivariance learning framework, namely Layout Aware and TransformaTion Invariant Controlled Table-to-Text GEneration (LATTICE). LATTICE encodes tables with a transformation-invariant graph masking technology. This prunes the full self-attention structure into an order-invariant graph-based attention that captures the connected graph of cells belonging to the same row or column, and differentiates between relevant cells and irrelevant cells from the structural perspective. LATTICE also modifies the positional encoding mechanism to preserve the relative position of tokens within the same cell but enforces position invariance among different cells. Our technology is free to be plugged into existing table-to-text generation models, and has improved T5-based models (Raffel et al., 2020) on ToTTo (Parikh et al., 2020) and HiTab (Cheng et al., 2022). Moreover, on a harder version of ToTTo, we preserve promising performance, while previous SOTA systems, even with transformation-based data augmentation, have seen significant performance drops.

Our contributions are three-fold. First, we propose two essential properties of a precise and robust controlled table-to-text generation system, i.e. structure-awareness and transformation-invariance. Second, we demonstrate how our transformation-invariant graph masking technology can enforce these two properties, and effectively enhance a representative group of Transformer-based generative models, i.e. T5-based models, for more generalizable and accurate generation. Third, in addition to experiments on ToTTo and HiTab benchmarks, we evaluate our model on a harder version of ToTTo with a special focus on robustness to content-invariant structural transformations.

2 Method

In this section, we first describe the preliminaries of content-invariant table transformations, base models and the input format for controlled table-to-text generation (§2.1). Then we introduce the technical details about how the transformation-invariant graph masking technology in LATTICE enforces the model to be structure-aware and transformation-invariant (§2.2). Finally, we present two alternative techniques for strengthening the transformation-invariance to be compared with LATTICE (§2.3).

2.1 Preliminaries

Content-Invariant Table Transformations. Tables organize and present information by rows and columns. A piece of information is presented in a cell (with headers), which is the basic unit of a table. Rows and columns are high-level units indicating relations among cells, and are combined to express more comprehensive information. We discuss two categories of transformations that may be made on a table, as shown in Fig. 2. First, *content-variant* transformations modify or exchange a part of cells in different rows or columns, therefore changing the semantics of the table. In such cases, new tabular content are created to express information being inconsistent with the original table. Second, *content-invariant* transformations consist of operations that do not influence content within (combinations of) the same row or column, resulting in semantically equal (sub-)tables. Specifically,

Figure 2: Examples of different types of table transformations. Arrows indicate how specific operations change the positions of tables components. Modifications causing semantic changes are in red.

such operations include transpose, row shuffle and column shuffle. By performing any or a combination of such operations, we can present the same information in different table layouts.

Base Models. Pretrained Transformer-based generative models achieve SOTA performance on various text generation tasks (Raffel et al., 2020; Lewis et al., 2020). In order to adapt this kind of models to table-to-text generation, prior works propose to linearize the table into a textual sequence (Kale and Rastogi, 2020; Chen et al., 2020b; Su et al., 2021). Our method LATTICE is model-agnostic and can be incorporated into any such models. Following Kale and Rastogi (2020), we choose a family of the best performing models, T5 (Raffel et al., 2020), as our base models. Models of this family are jointly pretrained on a series of supervised and self-supervised text-to-text tasks. Models can switch between different tasks by prepending a task-specific prefix to the input. Our experiments (§3.3 and §3.4) point out that base models are brittle to content-invariant table transformations and can only capture limited layout information.

Input Format. Prior works (Kale and Rastogi, 2020; Chen et al., 2020b; Su et al., 2021) linearize (highlighted) table cells based on row and column indexes. The input sequence often starts with the metadata of a table, such as page title and section title. Then, it traverses the table row-wise from the top-left cell to the bottom-right cell. Headers of each cell can be either treated as individual cells or appended to the cell content. Each metadata/cell/header field is separated with special tokens. This linearization process suits the input to text-to-text generation models, yet discards much of the structural information of a table (e.g., two cells in the same column can be separated by irrelevant cells in the sequence, while the last cell and first cell in adjacent rows can be adjacent although they are irrelevant), and is sensitive to content-invariant table transformations.

2.2 Transformation-Invariant Graph Masking

LATTICE realizes equivariance learning by modifying the Transformer encoder architecture. It also improves the base model's ability of capturing structures of highlighted tabular content. Specifically, we incorporate a structure-aware self-attention mechanism and a transformation invariant positional encoding mechanism in the base model The workflow is shown in Fig. 3.

Structure-Aware Self-Attention. Transformer (Vaswani et al., 2017) adopts self-attention to aggregate information from all the tokens in the input sequence. The attention flows form a complete graph connecting each token. This mechanism works well for modeling sequences but falls short of capturing tabular structures. The non-linear layout structure reflects semantic relations among cells, hence should be captured by self-attention.

We incorporate structural information by pruning the attention flows. According to the nature of information arrangement in a table, two cells in neither the same row nor the same column are not semantically related, or at least the combination of them do not directly express information this table seeks to convey. Intuitively, representations of these cells should not directly pass information to each other. In LATTICE, attention flows among tokens of structurally unrelated cells are removed from the attention graph, while those within the metadata, within each cell, and between metadata and each cell are preserved. In this way, we also

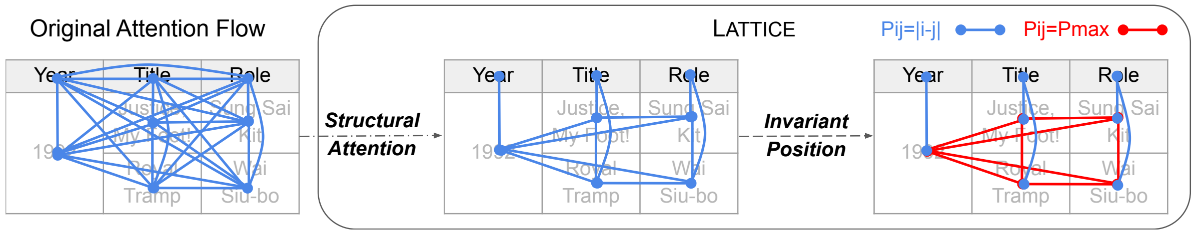

Figure 3: Attention flows of the base model and LATTICE. In this example, we adopt the input format which appends headers to each cell, so headers can be seen as part of the cell content. We omit the attention flows among tokens within a cell, as they are in the same type of the flows between headers and corresponding cells. P_{ij} represents the relative position between tokens at both ends of the attention flow, where i and j are absolute positions of tokens in the linearized table and P_{max} is the max relative position allowed. The base model has a complete attention graph among all cells with relative positions based on linear distance. LATTICE prunes the attention flow based on the table layout and assigns transformation-invariant relative positions between cells.

ensure the transformation-invariance property of the self-attention mechanism, since related cells in the same row or same column are all linked in an unordered way in the attention graph. It is easy to show that for any individual cell, the links in the attention graph will remain the same after any content-invariant operations (§2.1) are applied.

Transformation-Invariant Positional Encoding. When calculating the attention scores between each pair of tokens, the base model captures their relative position in the sequence of linearized table as an influential feature. Specifically, the attention flow from the i-th token to the j-th token is paired with a relative position $P_{ij} = |i - j|$. This easily causes positional biases among distinct cells, since the relative positions in the sequence do not fully reflect relations among cells in the table. Moreover, the relative position between the same token pair will change as the table layout change, which is the source of inconsistent generation shown in Fig. 1.

As discussed in §2.1, for a given cell, its relations with other cells in the same row or column should be equally considered. It is natural to assign the same relative positions among (tokens of) cells in the same row or column, no matter how far their distance is in the linear sequence. Meanwhile, we preserve the relative positions of tokens inside the same cell (or the metadata). Specifically, the relative position between the i-th token and the j-th token in the input sequence is

$$P_{ij} = P_{ji} = \begin{cases} |i - j|, & \text{if in the same field;} \\ P_{max}, & \text{otherwise;} \end{cases}$$

where “same field” means the two tokens are from the same cell or both of them are from the metadata, and P_{max} is the max relative position allowed. As a result, LATTICE represents cells (and the metadata) in a way that is invariant to their relative positions in the sequence. As content-invariant table transformations do not change the relations among cells in the table (i.e. whether two cells are from the same row or column), this positional encoding mechanism is transformation-invariant.

Training and Inference. After obtaining the structure-aware and transformation-invariant table representation, LATTICE conducts similar training and inference as the base model. Given the linearized table T_i, its layout structure S_i, and target sentence $Y_i = \{y_1^i, y_2^i, ..., y_{n_i}^i\}$, training minimizes the negative log-likelihood. For a dataset (or batch) with N samples, the loss function is

$$L = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{n_i} \log P(y_j^i | y_{<j}^i, T_i, S_i).$$

During inference, the model generates a sentence token by token, where each time it outputs a distribution over a vocabulary.

2.3 Alternative Techniques

In addition to the equivariance learning realized by tranformation-invariant graph masking, we present and compare with two alternative techniques.

Layout-Agnostic Input. The first technique is to adjust input sequences to be invariant to content-invariant table transformations. A simple way is to reorder headers and cells by an arbitrary order not based on table layouts (e.g., lexicographic order) to form a sequence. Special tokens to separate cells and headers should also include no layout information[3]. As a result, this input format

---

[3] For example, using <*header*> instead of <*row_header*> and <*column_header*>.

loses all information about table layouts to ensure transformation-invariance.

Data Augmentation. The second technique is data augmentation by content-invariant table transformation. This technique augment tables with different layouts to training data, seeking to enhance the robustness of the base model by exposing it to more diverse training instances.

Our experiments systematically compares these two techniques with tranformation-invariant graph masking in §3.3, revealing how directly performing equivariance learning from the perspective of neural network structure leads to better performance and robustness than using layout-agnostic input or data augmentation.

3 Experiments

In this section, we conduct experiments on two benchmark datasets. First, we introduce the details of datasets, baselines, evaluation metrics and our implementation (§3.1). Then, we show the overall performance of LATTICE (§3.2). After that, we analyze the model robustness on a harder version of the ToTTo dataset where content-invariant perturbations are introduced (§3.3). Finally, we provide ablation study on components of transformation-invariant graph masking (§3.4).

3.1 Experimental Settings

Datasets. We evaluate our model on ToTTo (Parikh et al., 2020) and HiTab (Cheng et al., 2022) benchmarks. Details of them are described as follows:

- **ToTTo:** An English dataset released under the Apache License v2.0. The dataset is dedicated to controlled table-to-text generation. It consists of 83,141 Wikipedia tables, 120,761/7,700/7,700 sentences (i.e. descriptions of tabular data) for train/dev/test. Target sentences in test set are not publicly available. Each sentence is paired with a set of highlighted cells in a table, and each table has metadata including its page title and section title. The dev and test sets can be further split into 2 subsets, i.e. overlap and non-overlap, according to whether the table exists in the training set.
- **HiTab:** An English dataset released under Microsoft's Computational Use of Data Agreement (C-UDA). It is intended for both controlled table-to-text generation and table-based question answering with a special focus on hierarchical tables. It contains 3,597 tables, including tables from statistical reports and Wikipedia, forming 10,686 samples distributed across train (70%), dev (15%), and test (15%). Each sample consists of a target sentence and a table with highlighted cells and hierarchical headers.

Evaluation Metrics. We adopt three widely used evaluation metrics for text generation. BLEU (Papineni et al., 2002) is one of the most common metric for text generation based on n-gram cooccurrence. We use the commonly used BLEU-4 following prior works (Parikh et al., 2020; Cheng et al., 2022). PARENT (Dhingra et al., 2019) is a metric for data-to-text evaluation taking both references and tables into account. BLEURT (Sellam et al., 2020) is a learned evaluation metric for text generation based on BERT (Devlin et al., 2019). Following prior studies (Parikh et al., 2020; Cheng et al., 2022), we report all three metrics on ToTTo and the first two metrics on HiTab using the evaluation tool released by Parikh et al. (2020).

Baselines. We present baseline results of the following representative methods:

- **Pointer-Generator** (Gehrmann et al., 2018): An LSTM-based encoder-decoder model with attention and copy mechanism, first proposed by See et al. (2017) for text summarization.
- **BERT-to-BERT** (Rothe et al., 2020): A Transformer-based encoder-decoder model, where the encoder and decoder are initialized with BERT (Devlin et al., 2019).
- **T5** (Kale and Rastogi, 2020): A pretrained generation model first proposed by Raffel et al. (2020). The model is Transformer-based, pretrained on text-to-text tasks, and finetuned on linearized tables to offer the previous SOTA performance.

All the baseline results on ToTTo can be found in the official leaderboard[4], except for T5-small and T5-base, for which we reproduce the results on dev set reported by Kale and Rastogi (2020) and submit the predictions on hidden test set to the leaderboard. For HiTab, we run T5 and LATTICE using our replication of the linearization process introduced by Cheng et al. (2022)[5]. Results of other baselines are from Cheng et al. (2022).

---

[4] `https://github.com/google-research-datasets/ToTTo`

[5] According to the authors, their linearization process needs unreleased raw excel files. We reproduce it with released tables which results in less precise and informative inputs.

Implementation Details. We adopt the pretrained model weights released by Raffel et al. (2020). Specifically, we use T5-small and T5-base[6]. For finetuning, we use a batch size of 8 and a constant learning rate of $2e^{-4}$. Following Kale and Rastogi (2020) and Cheng et al. (2022), all input sequences are truncated to a length of 512 to accommodate the limit of the pretrained models. LATTICE does not add any parameters to the base model, so LATTICE (T5-small) has 60 million parameters and LATTICE (T5-base) has 220 million parameters, same as the base models. For ToTTo, we use a beam size of 4 to generate sentences with at most 128 tokens. For HiTab, we use a beam size of 5 to generate sentences with at most 60 tokens following Cheng et al. (2022). Our implementation is based on Pytorch (Paszke et al., 2019) and Transformers (Wolf et al., 2020). We run experiments on a commodity server with a GeForce RTX 2080 GPU. It takes about 0.5 hour to train LATTICE (T5-small) for 10,000 steps and about 1 hour to train LATTICE (T5-base) for 10,000 steps. Considering different sizes of two datasets, we train models for 150,000 steps on ToTTo, and for 20,000 steps on HiTab. Results of LATTICE on ToTTo dev set and HiTab are average of multiple runs. For ToTTo test set, we report the results on official leaderboard.

As shown in Fig. 4, we use different input formats for ToTTo and Hitab following prior works (Kale and Rastogi, 2020; Cheng et al., 2022), since the tables and annotations in these two datasets are different. For ToTTo, we follow the linearization procedure by Kale and Rastogi (2020). Specifically, the textual sequence consists of the page title, section title, table headers and cells. Each cell may be associated with multiple row and column headers. Special markers are used to denote the begin and end of each field. Different from Kale and Rastogi (2020), we use the same markers for row headers and column headers. For HiTab, we follow the linearization procedure of Cheng et al. (2022). Specifically, the textual sequence consists of highlighted cells and headers, headers of highlighted cells, and cells belong to highlighted headers. A universal separator token `[SEP]` is used. While our model can achieve consistently the same performance with any ordering of inputs, we adopt the same lexicographic as the layout-agnostic input format (§2.3) to avoid uncertainty due to truncation and special markers.

3.2 Main Results

Tab. 1 shows model performance on ToTTo test set. Among the baselines, methods based on pretrained Transformer models (i.e. BERT-to-BERT and T5) outperform the others and T5 models perform the best. Our method LATTICE can be plugged into such models. We compare our method with pure T5 models of different sizes, and LATTICE consistently performs better. Overall, LATTICE (T5-small) achieves improvements of 2.1 BLEU points and 0.8 PARENT points in comparison with T5-small, and LATTICE (T5-base) achieves improvements of 1.0 BLEU points and 1.7 PARENT points in comparison with T5-base. These results indicate the importance of structure information, which is almost totally abandoned by baselines. Further, the performance gain on tables both seen and unseen during training are significant. Specifically, on the overlap subset, LATTICE (T5-small) achieves improvements of 2.9 BLEU points and 1.3 PARENT points, and LATTICE (T5-base) achieves improvements of 0.9 BLEU points and 1.3 PARENT points, indicating better intrinsic performance. On the non-overlap subset, LATTICE (T5-small) achieves improvements of 1.3 BLEU points and 1.0 PARENT points, and LATTICE (T5-base) achieves improvements of 1.3 BLEU points and 2.2 PARENT points, indicating LATTICE is more generalizable to unseen tables. We also observe that the improvement on BLEURT is not as much as the other two metrics. It is reasonable as BLEURT is trained with machine translation annotations and synthetic data by mask filling, backtranslation and word drop. These training data ensures its robustness to sur-

---

[6] Although a previous study (Kale and Rastogi, 2020) has obtained better results using the much larger T5-3B, we were not able to run that model on our equipment even with a batch size of 1 due to the overly excessive GPU memory usage.

Model	Overall			Overlap			Non-Overlap		
	BLEU	PARENT	BLEURT	BLEU	PARENT	BLEURT	BLEU	PARENT	BLEURT
Pointer-Generator	41.6	51.6	0.076	50.6	58.0	0.244	32.2	45.2	-0.092

Table 2: Results on the HiTab test set.

face generation but not reasoning-based generation. Although the effectiveness of BLEURT is verified on an RDF-to-text dataset, tabular data holds different properties with RDF data[7].

Results on HiTab in Tab. 2 further verify the effectiveness and generalizability of LATTICE. For different model sizes, LATTICE consistently performs better than T5 models. We also observe that on this dataset the model with highest BLEU score is not the model with highest PARENT score. It is partially because of the annotations. Many numbers appear in both tables and target sentences are of different precision. Copying such numbers from tables to generated sentences may increase PARENT score but reduce BLEU score.

3.3 Robustness Evaluation

To further evaluate model robustness against content-invariant perturbations on tables, we create a harder version of the ToTTo dev set, where each table is perturbed with a combination of row-wise shuffling, column-wise shuffling and table transpose. Especially, models can no longer benefit from memorizing the layout of tables appearing in both the training set and the dev set. We compare four methods based on T5, including the basic version proposed by Kale and Rastogi (2020), enhanced T5 with the layout-agnostic input or data augmentation (§2.3), and T5 incorporated in LATTICE.

According to the results shown in Tab. 3, vanilla T5 models face a severe performance drop when content-invariant perturbations are introduced. Overall, BLEU scores drop by 3.4 for T5-small, and 4.5 for T5-base. We also observe that the performance drop on overlap subset is larger than on non-overlap subset. This indicates that the performance gain of T5 models is somehow due to their memory of some tables existing in the training set, which is however brittle and not generalizable. Applying layout-agnostic input format, which linearizes tables by lexicographic order instead of cell index order, ensures models to return stable predictions, but results in worse overall performance due to the loss of structural information. Not surprisingly, layout-agnostic input causes performance drops by 1.5 BLEU points and 1.2 BLEU points to T5-small and T5-base on original dev set.

Another common way to improve model robustness is to increase the diversity of training instances with data augmentation. We augment the original training set by 8-fold using the three content-invariant transformation operations and their combinations. Training with augmented data reduces the gap between model performance on original tables and transformed tables. However, data augmentation is never exhaustive enough to guarantee true equivariance. Also, this introduces different variants of the same table into the training set, so there is a gap between the same table in training set and dev set. As a result, the performance on overlap subset is slightly worse than without data augmentation, but the performance on non-overlap subset is not negatively influenced. LATTICE guarantees consistent predictions towards content-invariant table transformations while achieving the best performance. In comparison with using layout-agnostic input format which also guarantees equivariance, LATTICE (T5-small) provides additional 3.3 BLEU points, and LATTICE (T5-base) provides additional 2.4 BLEU points on original dev set.

---

[7] For example, in the ToTTo dataset, 21% samples requires reasoning while 13% samples requires comparison.

Model	Overall			Overlap			Non-Overlap		
	Origin	Transform	Δ	Origin	Transform	Δ	Origin	Transform	Δ
T5-small	45.7	42.3	-3.4	53.7	49.3	-4.4	37.7	35.4	-2.3

Table 3: Robustness evaluation on ToTTo dev set. *Origin* is the BLEU score on original tables, while *Transform* is the BLEU score on transformed tables. All transformed tables are transposed, row shuffled and column shuffled. Δ is the difference between the two scores. Best scores in each group are in bold.

Att	Pos	Overall	Overlap	Non-Overlap
-	-	45.7	53.7	37.7
✓	-	47.0	54.4	39.6
✓	✓	47.5	55.5	39.5

Table 4: Ablation study on ToTTo dev set. Scores are BLEU. *Att* and *Pos* denote structure-aware self-attention and transformation-invariant positional encoding.

3.4 Ablation Study

To help understand the effect of two key mechanisms in transformation-invariant graph masking, we hereby present ablation study results in Tab. 4.

Structure-Aware Self-Attention. We examine the effectiveness of structure-aware self-attention. In comparison with original (fully-connected) self-attention, incorporating structural information by pruning attention flows can improve the overall performance by 1.3 BLEU points. Detailed scores on two subsets show that both tables seen and unseen during training can benefit from structural information. The consistent improvements on two subsets indicate that structure-aware self-attention improves model ability of capturing cell relations rather than memorizing tables.

Transformation-Invariant Positional Encoding. We further test the effectiveness of transformation-invariant positional encoding. We observe that although this technique is mainly designed for ensuring model robustness towards layout changes, it can bring an additional improvement of 0.5 BLEU points to overall performance. Interestingly, the improvement is mainly on the overlap subset. We attribute it to the fact that the same table in training and dev sets may have different highlighted cells, so that memorizing the layout information in the training set hinders in-domain generalization.

4 Related Work

We review two relevant research topics. Since both topics have a large body of work, we provide a selected summary.

Table-to-text Generation. Table-to-text generation seeks to generate textual descriptions for tabular data. In comparison to text-to-text generation, the input of table-to-text generation is semi-structured data. Early studies adapt the encoder-decoder framework to data-to-text generation with encoders aggregating cell information (Lebret et al., 2016; Wiseman et al., 2017; Bao et al., 2018). Followed by the success of massively pre-trained sequence-to-sequence Transformer models (Raffel et al., 2020; Lewis et al., 2020), recent SOTA systems apply these models to table-to-text generation (Kale and Rastogi, 2020; Su et al., 2021), where the input table is linearized to a textual sequence.

A table can include ample information and it is not always able to be summarized in one sentence. A line of work learns to generate selective descriptions by paying attention to key information in the table (Perez-Beltrachini and Lapata, 2018; Ma et al., 2019). However, multiple statements can be entailed from a table when different parts of the table are focused on. To bridge this gap, Parikh et al. (2020) proposes controlled table-to-text generation, allowing the generation process to react differently according to distinct highlighted cells. As highlighted cells can be at any positions and of arbitrary numbers, simple linearization, which breaks the layout structure, hinders relations among cells from being captured, therefore causing unreliable or hallucinated descriptions to be generated.

A few prior studies introduce structural information to improve model performance on table-to-text generation, either by incorporating token position (Liu et al., 2018), or by aggregating row and column level information (Bao et al., 2018; Nema et al., 2018; Jain et al., 2018). However, none of existing methods can be directly applied to pretrained Transformer-based generative models, especially when we want to ensure model robustness to content-invariant table transformations. Our method enforces both structure-awareness and transformation-invariance to such models.

Equivariant Representation Learning. Equivariance is a type of prior knowledge existing broadly in real-world tasks. Earlier studies show that incorporating equivariance learning can improve visual perception model robustness against turbulence caused by geometric transformations, such as realizing translation, rotation, and scale equivariance of images (Lenc and Vedaldi, 2015; Worrall et al., 2017; Ravanbakhsh et al., 2017; Sosnovik et al., 2019; Yang et al., 2020). The input to those tasks presents unstructured information, and several geometrically invariable operations are incorporated in neural networks to realize the aforementioned equivariance properties. For example, Convolutional Neural Networks (CNNs) are equivariant to translations in nature (Lenc and Vedaldi, 2015). Harmonic Networks and Spherical CNNs extend the equivariance of CNNs to rotations (Worrall et al., 2017; Esteves et al., 2018). Group Equivariant Convolutional Networks are equivariant to more spatial transformations including translations, rotations and reflections (Cohen and Welling, 2016). Nonetheless, none of these geometrically invariable techniques can be directly applied to Transformer-based generative models to ensure equivariance on (a part of) structured tabular data, which is exactly the focus of this work. Our method realizes equivariant intermediate representations against content-invariant table transformations in table-to-text generation.

Some other works, while not explicitly using equivariant model structures, seek to realize equivariant representations by augmenting more diverse changes into training data (Chen et al., 2020a; Wu et al., 2020). Although the model can benefit from seeing more diverse inputs involving content-invariant transformations (Wu et al., 2020), this strategy has two drawbacks. Specifically, the augmented data, while introducing much computational overhead to training, are never exhaustive enough to guarantee true equivariance. By contrast, our method guarantees equivariance through the neural network design and do not introduce any training overhead.

5 Conclusion

We propose LATTICE, a structure-aware equivariance learning framework for controlled table-to-text generation. Our experimental results verify the importance of structure-awareness and transformation-invariance, two key properties enforced in LATTICE, towards precise and robust description generation for tabular content. The proposed properties and equivariance learning framework aligns well with the nature of information organized in tables. Future research can consider extending the structure-aware equivariance learning framework to other data-to-text generation tasks (Koncel-Kedziorski et al., 2019; Nan et al., 2021), tabular reasoning or retrieval tasks (Gupta et al., 2020; Wang et al., 2021a,b; Eisenschlos et al., 2021), and pretraining representation on textual and tabular data (Yin et al., 2020; Herzig et al., 2020; Iida et al., 2021).

We appreciate the reviewers for their insightful comments and suggestions. This work is partly supported by the National Science Foundation of United States Grant IIS 2105329, and partly by the Air Force Research Laboratory under agreement number FA8750-20-2-10002.

Ethical Considerations

This work seeks to develop a structure-aware equivariance learning framework for table-to-text generation. Since the proposed method focuses on improving prior generation systems by better utilization of structural information, it does not introduce bias towards specific content. The distinction between beneficial use and harmful use depends mainly on the data. Proper use of the technology requires that input corpora are legally and ethically obtained. We conduct experiments on two open benchmark in the way they intended to. Although we create a harder version of ToTTo dev set, the table transformation operations we use are content-invariant, whereas the ground-truth generation remains the same as it is in the original dataset, ensuring no further social bias is introduced.

Abstract

Existing KG-augmented models for commonsense question answering primarily focus on designing elaborate Graph Neural Networks (GNNs) to model knowledge graphs (KGs). However, they ignore (i) the effectively fusing and reasoning over question context representations and the KG representations, and (ii) automatically selecting relevant nodes from the noisy KGs during reasoning. In this paper, we propose a novel model, JointLK, which solves the above limitations through the joint reasoning of LM and GNN and the dynamic KGs pruning mechanism. Specifically, JointLK performs joint reasoning between LM and GNN through a novel dense bidirectional attention module, in which each question token attends on KG nodes and each KG node attends on question tokens, and the two modal representations fuse and update mutually by multi-step interactions. Then, the dynamic pruning module uses the attention weights generated by joint reasoning to prune irrelevant KG nodes recursively. We evaluate JointLK on the CommonsenseQA and OpenBookQA datasets, and demonstrate its improvements to the existing LM and LM+KG models, as well as its capability to perform interpretable reasoning[1].

1 Introduction

Commonsense question answering (CSQA) requires systems to acquire different types of commonsense knowledge and reasoning skills, which is normal for humans, but challenging for machines (Talmor et al., 2019). Recently, large pre-trained language models (LMs) have achieved remarkable success in many QA tasks and appear to use implicit (factual) knowledge encoded in their model parameters during fine-tuning (Liu et al., 2019; Raffel et al., 2020). Nevertheless, commonsense knowledge is self-evident to humans and is rarely expressed clearly in natural language (Gunning, 2018), which makes it difficult for LMs to learn commonsense knowledge from the pre-training text corpus alone.

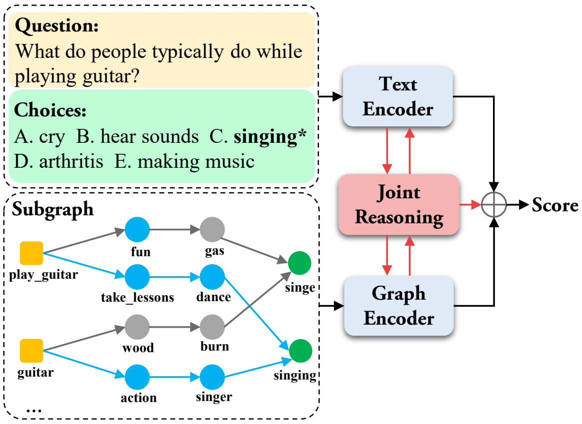

Figure 1: Our knowledge-augmented joint reasoning model framework with an example from CommonsenseQA. The subgraph is retrieved from ConceptNet.

An extensive research path is to elaborately design graph neural networks (GNNs) (Scarselli et al., 2008) to perform reasoning over explicit structural common sense knowledge from external knowledge bases (Vrandečić and Krötzsch, 2014; Speer et al., 2017). Related methods usually follow a retrieval-and-modeling paradigm. First, the knowledge subgraphs or paths related to a given question are retrieved by string matching or semantic similarity; such retrieved structured information indicates the relation between concepts or implies the process of multi-hop reasoning. Second, the retrieved subgraphs are modeled by a well-designed graph neural network module (Lin et al., 2019; Feng et al., 2020; Yasunaga et al., 2021) to perform reasoning over knowledge graphs.

However, these approaches have two main issues. First, **the retrieved knowledge subgraph contains many noisy nodes**. Whether through

July 10-15, 2022

simple string matching or semantic matching, in order to retrieve sufficient relevant knowledge, noise knowledge graph nodes will inevitably be included (Lin et al., 2019; Yasunaga et al., 2021). Especially with the increase of hop count, the number of irrelevant nodes will expand dramatically, raising the burden of the model. As the example in Figure 1, some graph nodes such as "*wood*", "*burn*", and "*gas*", although related to some entities in the questions and choice, can mislead the global understanding of the question. Second, **there are limited interactions between language representation and knowledge graph representation**. Specifically, existing LM+KG methods (Lin et al., 2019; Feng et al., 2020) model question context and knowledge subgraphs in isolation by LMs and GNNs, and perform only one interaction in a shallow manner to fuse their representations at the output for prediction. We argue that the limited interaction between the two modalities is the main bottleneck that may prevent the model from understanding the complex question-knowledge relations necessary to answer the question correctly.

Based on the above consideration, we propose JointLK, a model that performs the fine-grained modal fusion and multi-layer joint reasoning between the language model and the knowledge graph (see Figure 2). Specifically, given a question and retrieved subgraphs, JointLK first obtain the representations of the two modalities by using an LM encoder and a GNN encoder respectively. Then we design a joint reasoning module to generate fine-grained bidirectional attention maps between each question token and each KG node to fuse the information from each modality to the other. Guided by the attention generated in the interaction process, the dynamic pruning module deletes irrelevant nodes to make the model reason along the correct knowledge path. Multiple JointLK layers are stacked to form a hierarchy that supports multi-step interactions and recursive pruning. In summary, our contributions are three-fold:

- We propose JointLK, a novel model that supports multi-step joint reasoning between LM and KG. It uses dense bidirectional attention to simultaneously update query-aware knowledge graph representation and knowledge-aware query representation, bridging the gap between the two information modalities.
- We design a dynamic graph pruning module that recursively removes irrelevant graph nodes at each JointLK layer to ensure that the model reasons correctly with complete and appropriate evidence.
- Experimental results show that JointLK is superior to current LM+KG methods, and the refined evidence is interpretable. Furthermore, through the multi-layer fusion of these two modalities, JointLK exhibits strong performance over previous state-of-the-art LM+KG methods in performing complex reasoning, such as solving questions with negation and complex questions with more entities.

2 Related Work

Commonsense question answering is challenging because the required commonsense knowledge is rarely given in the context of questions and answer choices or encoded in the parameters of pre-trained LMs. Therefore, many works obtain the required knowledge from external sources (e.g., KGs, corpus) to augment CSQA models. Due to the heterogeneity between structured knowledge and unstructured text questions, there are currently two main research methods. Some works (Lv et al., 2020; Bian et al., 2021; Xu et al., 2021) unify the two modalities during model input, such as transforming structured knowledge into plain text through templates or transforming question context into structured graphs. However, the original structural/textual information will inevitably be lost during the conversion process. Other works (Lin et al., 2019; Feng et al., 2020; Yan et al., 2021) use LM and GNN to model the two modalities separately, and perform shallow interactions in the latter model stage, such as attentive pooling or simple concatenation of the two modal representations. Although this method can retain the original information of question context and KGs, the limited interaction will affect the flow of information between the two modalities, so we mainly improve on this point.

Recently, QA-GNN (Yasunaga et al., 2021) explicitly views the QA context as an additional node, connects it and KG to form a joint graph, and mutually updates their representations through graph-based message passing. However, it pools the representation of the question context into a single node, which limits the updating of the text representation and fine-grained interaction between LM and GNN. Compared with prior works, we retain the individual structure of both modalities, consider fine-

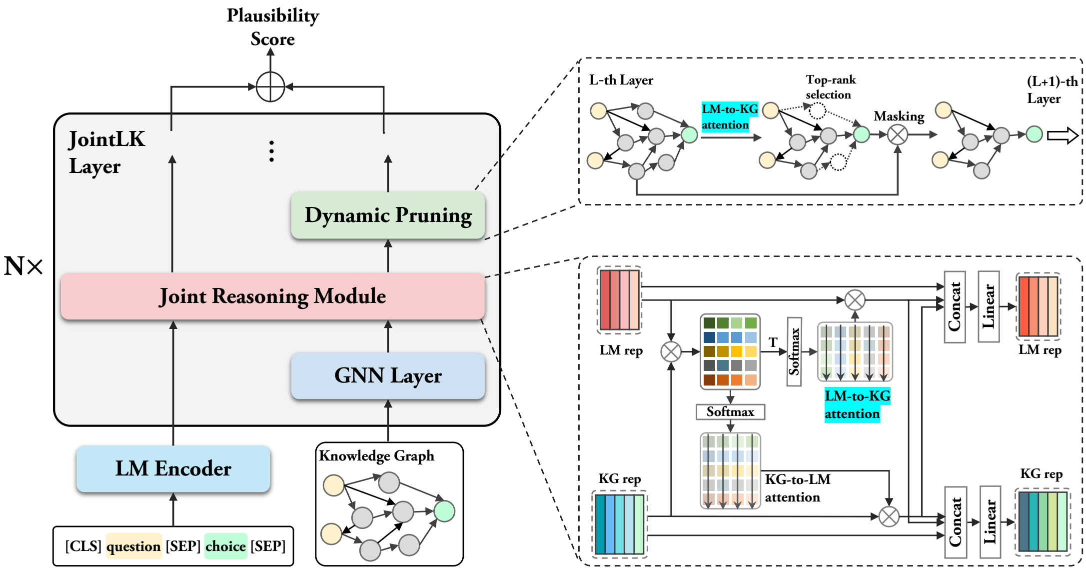

Figure 2: Overall architecture of our proposed JointLK model, which takes a query (question + choice) and a retrieved knowledge subgraph as input, and outputs a scalar that represents the plausibility score of this query. JointLK mainly consists of four modules the Query Encoder, the Graph Layer, the Joint Reasoning Module and the Dynamic Pruning Module, of which the latter three form a stack of N identical layers.

grained interaction between any token in question and any entity in KG through dense bidirectional attention, and perform multi-step joint reasoning by stacking several interaction layers. Furthermore, we gradually prune the KG size in each stacked model layer under the guidance of attention weights generated in the interactions, making the reasoning path transparent and interpretable.

3 Methodology

In this section, we introduce the task definition (§ 3.1) and our JointLK model. The model framework is shown in Figure 2. JointLK takes the query and the retrieved knowledge subgraph as input, and outputs a real value as the correctness score of the answer. The model is mainly composed of four parts: query encoder, GNN layer, joint reasoning module and dynamic pruning module, of which the latter three form a stack of N identical layers. We use a pre-trained language model to learn the query representation (§ 3.2), and use the GNN layer to learn the graph representation (§ 3.3). The Joint Reasoning Module receives these two modalities' representations and then apply dense bidirectional attention to make information fusion and representation update for each token and node (§ 3.4). The LM-to-KG attention weights generated in reasoning represents the global importance of each node in the graph, so the dynamic pruning module prunes the graph layer by layer according to this weights and finally retains the most relevant nodes (§ 3.5). After N layers of iteration, the query representation and the trimmed graph representation are used to predict the answer (§ 3.6).

3.1 Task Definition

The CSQA task in this paper is a multiple-choice problem with some answer choices. Given a commonsense question q and a set of answer choices $\{a_1, a_2, ..., a_n\}$, our task is to measure the plausibility score between q and each answer choice a then select the answer with the highest plausibility score. In general, questions do not contain any reference to answer choices, so the external knowledge graph provides the necessary background knowledge. We extract from the external KG a subgraph $g = (V, R)$ with the guidance of question and choice. Here V is a subset of entity nodes retrieved from the external KG. $E \subseteq V \times R \times V$ is the set of edges that connect nodes in V, where R is a set of relations types. We describe the detailed extraction process in Appendix A.

3.2 Query Encoder

We follow baselines to use pre-trained language models to encode the query $\{w_i\}_{i=1}^{M}$ (question and choice) into a sequence of vectors $\{q_i^0\}_{i=1}^{M}$:

$$\{\tilde{q}_1^0, ..., \tilde{q}_M^0\} = \mathbf{Enc_{LM}}\left(\{w_1, ..., w_M\}\right) \quad (1)$$

Here $\{\widetilde{q}_i^0\}_{i=1}^M \in \mathbb{R}^T$ is the last hidden layer vector of each token in the query. Then we feed the representation of tokens into a non-linear layer so that the text representation space is aligned to the entity representation space:

$$q_i^0 = \sigma\left(f_s\left(\widetilde{q}_i^0\right)\right) \tag{2}$$

where $f_s : \mathbb{R}^T \rightarrow \mathbb{R}^D$ is a linear transformation, and σ is the activation function. The representations of tokens $\mathbf{Q}^0 = \{q_i^0\}_{i=1}^M \in \mathbb{R}^D$ will be provided to the joint reasoning module for further interaction with the graph entities representations.

3.3 GNN Layer

After obtaining token representations by the query encoder, we further model the subgraph to obtain entity representations. First, We use the BERT model with average pooling to get the initial representation for each entity $\mathbf{X^0} = \{x_i^0\}_{i=0}^{|V|} \in \mathbb{R}^D$. Then, we apply GNN Layer to update node representation through iterative message passing between neighbors on the graph, while GNN is built on the RGAT (Wang et al., 2020a) and is a simplification of Yasunaga et al. (2021). For brevity, we formulate the entire computation in one layer as:

$$\{\widetilde{x}_1^l, ..., \widetilde{x}_{|V|}^l\} = \mathbf{GNN}(\{x_1^{l-1}, ..., x_{|V|}^{l-1}\}) \tag{3}$$

The output representation x_i^l is computed by

$$\hat{\alpha}_{ji} = (x_i^{l-1}W_q)(x_j^{l-1}W_k + r_{ji})^T, \tag{4}$$

$$\alpha_{ji} = \mathbf{softmax}(\hat{\alpha}_{ji}/\sqrt{D}), \tag{5}$$

$$\hat{x}_i^{l-1} = \sum_{j \in N_i \cup \{i\}} \alpha_{ji}(x_j^{l-1}W_v + r_{ji}), \tag{6}$$

$$\widetilde{x}_i^l = \mathbf{LayerNorm}(x_i^{l-1} + \hat{x}_i^{l-1}W_o) \tag{7}$$

where matrices $W_q, W_k, W_v, W_o \in \mathbb{R}^{D \times D}$ are trainable parameters, N_i is the neighbor of node i. $r_{ji} = \psi(e_{ji}, u_j, u_i)$ is the relation feature vector, where e_{ji} is a one-hot vector denoting the relation type of the edge (j, i) and u_j, u_i are one-hot vectors denoting the node types of j and i. The following joint reasoning module will further fuse $\widetilde{x}_i^l$ and q_i^{l-1} to obtain their updated representations.

3.4 Joint Reasoning Module

To reduce the gap of query and knowledge graph features, we fuse them in the joint reasoning module by the dense bidirectional attention mechanism that connects two encoding layers of query and knowledge graph and captures the fine-grained interplay between them.

The module takes the query and KG representations $\mathbf{Q}$ and $\mathbf{X}$ as inputs and then outputs their updated versions. We denote the inputs to the joint reasoning module in the l-st fusion layer by $\mathbf{Q}^{l-1} = \{q_i^{l-1}\}_{i=1}^M$ and $\widetilde{\mathbf{X}}^l = \{\widetilde{x}_i^l\}_{i=1}^{|V|}$. Given q_i^{l-1} and $\widetilde{x}_i^l$, an affinity matrix is first constructed via:

$$S_{ij}^l = W_S^T[q_i^{l-1}; \widetilde{x}_j^l; q_i^{l-1} \circ \widetilde{x}_j^l] \tag{8}$$

where W_S^T is a learnable weight matrix, $\circ$ is elementwise multiplication, [;] is vector concatenation across row. We normalize S_{ij}^l in row-wise to derive **KG-to-LM attention** maps on query tokens conditioned by each entity in KG as

$$S_{q_i}^l = \mathbf{softmax}\left(S_{ij}\right) \tag{9}$$

and also normalize S_{ij}^l in column-wise to derive **LM-to-KG attention** maps on entities conditioned by each query token as

$$S_{x_j}^l = \mathbf{softmax}\left(S_{ij}^T\right) \tag{10}$$

The attended representations are computed as follows:

$$\hat{q}_{ij} = q_i^{l-1} \otimes S_{q_i}^l, \hat{x}_{ij} = \widetilde{x}_j^l \otimes S_{x_j}^l \tag{11}$$

where $\otimes$ represents matrix multiplication. The attended features are fused with the original features of the other modality by concatenation and then compressed to low-dimensional space by:

$$q_i^l = W_Q[q_i^{l-1}; \hat{x}_{ij}; q_i^{l-1} \circ \hat{x}_{ij}; q_i^{l-1} \circ \hat{q}_{ij}], \tag{12}$$

$$\bar{x}_j^l = W_X[\widetilde{x}_j^l; \hat{q}_{ij}; \widetilde{x}_j^l \circ \hat{q}_{ij}; \widetilde{x}_j^l \circ \hat{x}_{ij}] \tag{13}$$

where W_Q, W_X are learnable weights. Then the updated query representation $\mathbf{Q}^l = \{q_i^l\}_{i=1}^M$ will be input to the next l-th stacked JointLK layer of to continue participating in joint reasoning, and the updated KG representation $\bar{\mathbf{X}}^l = \{\bar{x}_i^l\}_{i=1}^{|V|}$ will be input to the next module of the current JointLK layer for pruning.

3.5 Dynamic Pruning Module

In Equation 10, the LM-to-KG attention value implies the importance of different nodes in the subgraph for question answering. Inspired by SAG-Pool (Lee et al., 2019), under the guidance of query, we retain relevant nodes and cut out irrelevant nodes according to the LM-to-KG attention. Then, We define a hyperparameter, the Retention ratio $K \in (0, 1]$, which determines the number of nodes to be retained. We choose the top $\lceil K \cdot |V| \rceil$ nodes according to the value of LM-to-KG attention:

$$idx = \mathbf{top} - \mathbf{rank}\left(Z, \lceil K \cdot |V| \rceil\right), \tag{14}$$

$$Z_{mask} = Z_{idx} \tag{15}$$

where top-rank is a function that returns the index of top $\lceil K \cdot |V| \rceil$ value, $\cdot_{idx}$ is an indexing operation, and Z_{mask} is corresponding attention mask. Next, the subgraph is formed by pooling out the less essential entity nodes as:

$$\begin{aligned} \mathbf{X}^l &= \bar{\mathbf{X}}^l_{idx,:} \odot Z_{mask}, \\ \mathbf{A}^l &= \bar{\mathbf{A}}^l_{idx,idx} \end{aligned} \tag{16}$$

where $\bar{\mathbf{X}}^l_{idx,:}$ is the row-wise indexed representation matrix of $\bar{\mathbf{X}}^l$, $\odot$ is the broadcasted elementwise product, and $\bar{\mathbf{A}}^l_{idx,idx}$ is the row-wise and col-wise of indexed adjacency matrix. $\mathbf{X}^l = (x^l_1, x^l_2, \ldots, x^l_{\lceil k|V| \rceil})$, $\mathbf{A}^l$ and $\lceil K \cdot |V| \rceil$ are the representation matrix, the adjacency matrix and the number of graph nodes in the next JointLK layer.

3.6 Answer Prediction

After N layers of iteration, we finally obtain the query representation $\mathbf{Q}^N$ that fuses knowledge information and the graph representation $\mathbf{X}^N$ that fuses question information. We compute the score of a being the correct answer as:

$$p = (a|q) = \mathbf{MLP}\left([s; g]\right) \tag{17}$$

where s is the mean pooling of $\mathbf{Q}^N$, and g is the attention-based pooling of $\mathbf{X}^N$. We get the final probability by normalize all question-choice pairs with softmax.

4 Experimental Setup

4.1 Datasets

We evaluate our model on two typical commonsense question answering datasets CommonsenseQA (Talmor et al., 2019) and OpenBookQA (Mihaylov et al., 2018). **CommonsenseQA** is a 5-way multiple-choice question answering dataset that requires commonsense for reasoning and contains 12,102 questions. We experiment and report the accuracy on the in-house dev (IHdev) and test (IHtest) splits used by Lin et al. (2019), and report the accuracy of our final system on the official test set. **OpenBookQA** is a 4-way multiple choice question answering dataset that requires reasoning with elementary science knowledge. It contains 5,957 questions along with an open book of scientific facts. We use the official data split.

4.2 Implementation Details

Following previous work (Yasunaga et al., 2021), we use ConceptNet (Speer et al., 2017), a commonsense knowledge graph, as our structured knowledge source for both of the above tasks. Given each query, we follow the preprocessing steps described in Feng et al. (2020) to retrieve the subgraph from ConceptNet, and the max hop size is 3 (see Appendix A for the detail). We use cross-entropy loss and RAdam optimizer (Liu et al., 2020). In training, we set the maximum input sequence length to text encoders to 100, batch size to 128, and perform early stopping. We set the dimension (D = 200) and number of layers (N = 5) of our GNN module, with dropout rate 0.2 applied to each layer (Srivastava et al., 2014). We use separate learning rates for the LM encoder and the graph encoder. We choose the LM encoder learning rate from$\{1 \times 10^{-5},\ 2 \times 10^{-5},\ 3 \times 10^{-5}\}$, and choose the graph encoder learning rate from$\{1 \times 10^{-3},\ 2 \times 10^{-3}\}$. Each model is trained using one GPU (Tesla_v100-sxm2-16gb), which takes 20 hours on average.

4.3 Compared Method

Although text corpus can provide complementary knowledge except for knowledge graphs, our model focuses on improving the use of KG and the joint reasoning between LM and KG, so we choose LM and LM+KG as the comparison methods.

To investigate the role of KGs, we compare with the benchmark model RoBERTa-large (Liu et al., 2019) for CommonsenseQA, and compare with RoBERTa-large and AristoRoBERTa (Clark et al., 2020) for OpenBookQA. For LM+KG methods, they share a similar high-level framework with our methods, that is, LM is used as a text encoder, GNN or RN is used as a KG encoder, but the way of using knowledge or reasoning is different: (1) Relationship network (RN) (Santoro et al., 2017), (2) RGCN (Schlichtkrull et al., 2018), (3) GconAttn (Wang et al., 2019), (4)KagNet (Lin et al., 2019) and (5)MHGRN (Feng et al., 2020), (6) QA-GNN (Yasunaga et al., 2021). (1), (2) and (3) are the relational perception GNNs for KGs, and (4), (5) and (6) are further model paths in KGs. To be fair, we use the same LM for all comparison methods.

+ JointLK (Ours)	**70.34** (±0.75)	**84.92** (±1.07)

Table 3: Test accuracy on OpenBookQA. Methods with AristoRoBERTa use the textual evidence by Clark et al. (2020) as an additional input to the QA context.

Methods	Test
Careful Selection (Banerjee et al., 2019)	72.0
AristoRoBERTa	77.8
KF + SIR (Banerjee and Baral, 2020)	80.0
AristoRoBERTa + PG (Wang et al., 2020b)	80.2
AristoRoBERTa + MHGRN (Feng et al., 2020)	80.6
ALBERT + KB	81.0
AristoRoBERTa + QA-GNN (Yasunaga et al., 2021)	82.8
T5* (Raffel et al., 2020)	83.2
UnifiedQA(11B)* (Khashabi et al., 2020)	87.2
AristoRoBERTa + JointLK (Ours)	**85.6**

Table 4: Test accuracy on OpenBookQA leaderboard. All listed methods use the provided science facts as an additional input to the language context. The previous top 2 systems, UnifiedQA (11B params) and T5 (3B params) are 30x and 8x larger than our model.

5 Results and Analysis

5.1 Main Results

The results on CommonsenseQA in-house split dataset and official test dataset are shown in Table 1 and Table 2. The results on OpenBookQA test dataset and leaderboard are shown in Table 3 and Table 4. We can observe that JointLK performs best among all fine-tuned LMs and existing LM+KG models. On CommonsenseQA, our model's test performance improves by 5.74% over fine-tuned LMs and 1.02% over the prior best LM+KG model, QA-GNN. On OpenbookQA, our model's test performance improves by 6.52% over fine-tuned AristoRoBERTa, and 2.15% over QA-GNN. Additionally, we also submit our best model to the leaderboards, and our JointLK (with the text encoder being RoBERTa-large) ranks first among comparable approaches. Compared with the previous best model MHGRN and QA-GNN, the boost over them suggests the effectiveness of our proposed joint reasoning between LM and KG and the dynamic pruning mechanism.

In particular, we do not compare with the higher ranking models on the leaderboard, such as unified QA (Khashabi et al., 2020), Albert + DESC-KCR (Xu et al., 2021), because they either use a stronger text encoder or use additional data resources, while our model focuses on improving the joint reasoning between LM and KG.

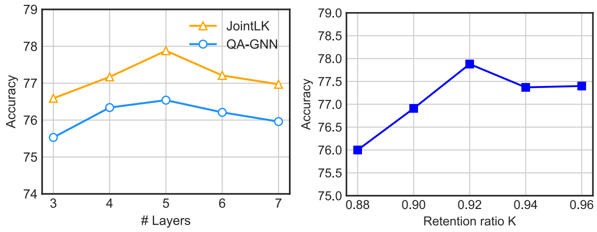
5.2 Ablation Studies

We further conduct in-depth analyses to investigate the effectiveness of different components in our model. We show the accuracy of JointLK on the CommonsenseQA IHdev set.

Impact of JointLK components We assess the impact of the joint reasoning module (§ 3.4) and the dynamic pruning module (§ 3.5), shown in Table 5. Disabling the dynamic pruning module results in 0.5% drop in performance, showing that some nodes in subgraph are not conducive to reasoning. Especially, when we disable the joint reasoning module, the corresponding dynamic pruning module will also be removed, because the latter depends on the attention value in the former. Then the

Methods	IHdev-Acc. (%)
JointLK (N=5)	**77.88**
- Dynamic Pruning Module	77.38
- Joint Reasoning Module	76.61

Table 5: Ablation study on model components using RoBERTa-large as the text encoder. We report the IHdev accuracy on CommonsenseQA.



(a) (b)

Figure 3: Ablation study on stacked of JointLK layers (a) and the retention ratio in pruning (b).

results have a significant drop: 77.88% → 76.61%, suggesting that the joint reasoning between LM and KG is critical.

Impact of stacked of JointLK Layers We investigate the impact of the number of JointLK layers (shown in Figure 3 (a)). The increase of layers continues to bring benefits until layers $N = 5$. However, performance begins to drop when $N > 5$. As the number of layers increases, the model changes from underfitting to overfitting.

Impact of the Retention Ratio in Pruning The retention ratio K is a hyperparameter of the dynamic pruning module. Since it is recursively pruning in each stacked layer of JointLK, the percentage of graph nodes that the model ultimately retains is also related to the number of layers of JointLK, that is, K^N, where $N = 5$. Experiments show that if the retention ratio is too high, there may be almost no pruning effect (for example, K=0.98, 90% of the nodes are retained in the last layer); otherwise, useful nodes may be deleted. As shown in Figure 3 (b), when the number of JointLK layers $N = 5$, $K = 0.92$ (about 66% of the original nodes remain in the last layer) works the best on the CommonsenseQA dev set.

5.3 Quantitative Analysis

Considering the overall performance improvement of our model on these two datasets, we analyze whether the improvement is reflected in questions that require more complex reasoning, such as questions with negation and complex questions with more entities. We compare our model with the prior best LM+KG model, QA-GNN in Table 6.

Methods	IHdev-Acc (Overall)	IHdev-Acc (Questions w/ negation)	IHdev-Acc (Questions w/ ≤7 entities)	IHdev-Acc (Questions w/ >7 entities)
Number	*1221*	*133*	*723*	*498*
QA-GNN	76.99	72.18	76.63	77.51
JointLK(**Ours**)	78.38	**75.18 (↑3.00)**	**77.59 (↑0.96)**	**79.52 (↑2.01)**

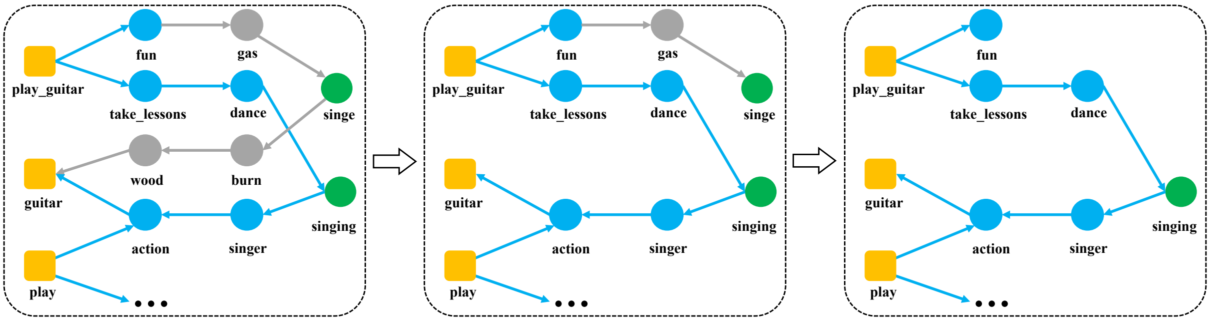
Table 6: Performance on questions with negative words and fewer/more entities. The questions are retrieved from the CommonsenseQA IHdev set.

Questions with negation Large LMs do well due to memorizing subject and filler co-occurrences but are easily distracted by elements like negation (Zagoury et al., 2021). To investigate the reasoning ability of the model on negation, we retrieved 133 questions with negation terms (e.g., no, not, nothing, never, unlikely, don't, doesn't, didn't, can't, couldn't) from the CommonsenseQA IHdev set. JointLK exhibits a big boost (↑3.00%) over QA-GNN, suggesting its strength in negation reasoning. The fine-grained joint inference of LM and GNN allows the model to pay attention to the semantic nuances of language expressions.

Questions with fewer/more entities When the question contains many entities, the size and noise of the retrieved KG may limit the model's performance because the model needs to understand the complex relationship between entities. According to statistics (see Appendix A), questions contain an average of 7 entities, so we divide the question into two categories: containing fewer entities (≤7) and more entities(>7). Compared with QA-GNN, JointLK has a bigger boost on questions with more entities (↑2.01%) than those with fewer entities (↑0.96%), suggesting that our model can reduce the reasoning difficulty of complex questions because it can remove irrelevant nodes in reasoning.

5.4 Interpretability: A Case Study

We aim to interpret JointLK's reasoning process by analyzing the pruning of the knowledge subgraph. Figure 4 shows an example from CommonsenseQA where our model correctly answers the question and finally retains reasonable reasoning paths by pruning the subgraph. The flow from (a) to (b) to (c) represents the recursive pruning of the subgraph according to the LM-to-KG attention weight at each GNN update layer. From (a) to (b), although the nodes *wood* and *burn* bridge the reasoning gap between question entity and answer entity, their



(a) (b) (c)

Figure 4: Case study of our model reasoning and pruning process. The question and answer choices corresponding to this case are: "What do people typically do while playing guitar? A.cry B. hear sounds C. **singing** D. arthritis E. making music".

semantics are very different from the question. From (b) to (c), “$play\_guitar \xrightarrow{usedfor} fun$” and “$fun \xrightarrow{relatedto} gas \xrightarrow{relatedto} singe$” are both reasonable, but the former is related to the semantics of the question, and the latter is not. Two paths are reserved in (c), “$play\_guitar \xrightarrow{hassubevent} take\_lessons \xrightarrow{hassubevent} dance \xrightarrow{relatedto} singing$” and “$play\_guitar \xrightarrow{relatedto} action \xrightarrow{relatedto} singer \xrightarrow{relatedto} singing$”. These two paths describe two possible scenarios that support answering the question.

5.5 Error Analysis

In order to understand why our model fails in some cases, we randomly select 100 error cases and group them into several categories. There are three main types of errors, and we show some examples in the Appendix C.

Miss important evidence (39/100) Although we can retrieve many nodes related to questions and choices from ConceptNet, due to the incompleteness of the knowledge graph, there may be missing essential evidence nodes in the reasoning paths to answer the question. For example, although *“eating_dinner”* will cause *“sleepiness”* or *“indigestion”*, knowledge such as “lactose intolerance causes indigestion” is essential to answer the question (Wikipedia: *Lactose intolerance is a common condition caused by a decreased ability to digest lactose, a sugar found in dairy products.*). However, ConceptNet does not cover such knowledge or not is retrieved.

Indistinguishable knowledge (25/100) Several choices of the question may be correct, difficult to distinguish, and which one is correct may vary from person to person. For example, *“human”* and *“cat”* may be at location *“bed”* or *“comfortable chair”*, and the knowledge provided by ConceptNet is also the same. The model may choose bed because the bed appears more frequently in the pre-trained corpus.

Incomprehensible questions (23/100) This type of error often occurs when the question is particularly long, involving various events and changes in the characters' emotions. The model is difficult to understand the scene described by the question. Some questions may require reasoning based on events, but the knowledge in ConceptNet is more based on entities and attributes.

The above three types of errors show that selecting complete, accurate, and context-sensitive knowledge is vital for more effective KG-augmented models.

6 Conclusion

In this work, we propose JointLK and provide a set of experiments to prove that (i) LM and KG interactive fusion can reduce the semantic gap between the two information modalities and make better use of KG for joint reasoning with LM. (ii) Dynamic pruning module can recursively delete irrelevant subgraph nodes at each layer of JointLK to provide fine appropriate evidence. Our results on CommonsenseQA and OpenBookQA demonstrate the superiority of JointLK over other methods using external knowledge and the strong performance in performing complex reasoning. In addition, our research results can be broadly extended to other tasks that require KGs as additional background knowledge to augment LMs, such as entity linking, KG completion and the recommendation system.

Acknowledgements

We would like to thank the anonymous reviewers for their helpful comments. This work was supported by the Key Development Program of the Ministry of Science and Technology (No.2019YFF0303003), the National Natural Science Foundation of China (No.61976068) and "Hundreds, Millions" Engineering Science and Technology Major Special Project of Heilongjiang Province (No.2020ZX14A02).

Ethical Impact

This paper proposes a general approach to fuse language models and external knowledge graphs for commonsense reasoning. We worked within the purview of acceptable privacy practices and strictly followed the data usage policy. In all the experiments, we use public datasets and consist of their intended use. We neither introduce any social/ethical bias to the model nor amplify any bias in the data, so we do not foresee any direct social consequences or ethical issues.

A Extracting subgraph from External KG

We choose ConceptNet as the external knowledge base, and we follow the process of Feng et al. (2020) and Yasunaga et al. (2021) to retrieve the knowledge subgraph.

Given the question and choice, we identify the concepts that appear in ConceptNet in question and choice, respectively, and get the initial node set V_q and V_a, which form the initial node set $V_{q,a}$. For example, in the question "*What do people typically* *do while playing guitar?*” and choice “*singing*”, V_q = {guitar, people, play, play_guitar, playing, playing_guitar, typically}, V_a = {singe, singing}. Then, in order to extract the subgraph related to question and choice, we add the bridge entities on the 1 and 2 hop paths between any pair of entities in $V_{q,a}$, thus obtaining the retrieved entity set V.

There may be many nodes in V, especially long questions contain many concepts. We follow the preprocessing method of Yasunaga et al. (2021), connect the nodes with question + choice, and calculate the relevant scores of the nodes through a pre-trained LM. We only retain the top 200 scoring nodes (It is worth noting that this is the preprocessing of the retrieval process, which is different from the dynamic pruning in section 3.5. The former is to score only one node and separate from the whole subgraph where the node is located, while the latter is recursive pruning in the updating process of the modeling subgraph).

Finally, we get the relation set R by merging the relation types in ConceptNet and adding reverse relation. We retrieve all the edges in R of any two nodes in V. In addition, we add question as a node q to V, and add the bidirectional edges of q to V_q and q to V_a. The relation types are shown in Table 7, and the statistics of the retrieved nodes are shown in Table 8.

B Node Initialization

For each entity in the subgraph, we need to obtain its feature representation. Following (Feng et al., 2020), we first use the template to convert the knowledge triples in ConceptNet into sentences, and feed them into BERT-Large, obtaining a sequence of tokens embeddings from the last layer. For each entity, we perform mean pooling over the tokens of the entity's occurrences across all the sentences to form the initial embeddings x_i^0.

C Error Types and Examples

In Table 9, we present examples for each error type in the Commonsense IHdev set. Because the average number of subgraph nodes corresponding to each case is about 100, we cannot list them all. Only some important nodes are shown here.

Relation	Merged Relation

Models In a Spelling Bee: Language Models Implicitly Learn the Character Composition of Tokens

Itay Itzhak **Omer Levy**
The Blavatnik School of Computer Science
Tel Aviv University
`{itay1itzhak,omerlevy}@gmail.com`

Abstract

Standard pretrained language models operate on sequences of subword tokens without direct access to the characters that compose each token's string representation. We probe the embedding layer of pretrained language models and show that models learn the internal character composition of whole word and subword tokens to a surprising extent, without ever seeing the characters coupled with the tokens. Our results show that the embedding layers of RoBERTa and GPT2 each hold enough information to accurately spell up to a third of the vocabulary and reach high character $n$gram overlap across all token types. We further test whether enriching subword models with character information can improve language modeling, and observe that this method has a near-identical learning curve as training without spelling-based enrichment. Overall, our results suggest that language modeling objectives incentivize the model to implicitly learn some notion of spelling, and that explicitly teaching the model how to spell does not appear to enhance its performance on such tasks.[1]

1 Introduction

Contemporary subword tokenization algorithms such as BPE (Sennrich et al., 2016) partition a string into contiguous spans of characters. Each span represents a frequent character $n$gram, from individual characters (*a*), through prefixes (*uni*) and suffixes (*tion*), and even complete words (*cats*). The tokenizer then converts each such span into a discrete symbol (a token) with no internal structure, effectively discarding the token's orthographic information. Therefore, a model operating over sequences of subword tokens should be oblivious to the spelling of each token. In this work, we show that despite having no direct access to the subwords' internal character composition, pretrained language models *do* learn some notion of spelling.

To examine what pretrained language models learn about spelling, we present the *SpellingBee* probe. SpellingBee is a generative language model that predicts the character composition of a token given only its (uncontextualized) vector representation from the pretrained model's embeddings matrix. SpellingBee is trained on part of the model's vocabulary, and then tested by spelling unseen token types. If the probe can successfully reconstruct the correct character sequence from an unseen token's embedding, then there must be significant orthographic information encoded in the vector.

We find that the embedding layers of several pretrained language models contain surprising amounts of character information. SpellingBee accurately spells 31.8% of the held-out vocabulary for RoBERTa-Large (Liu et al., 2019), 32.9% for GPT2-Medium (Radford et al., 2019), and 40.9% for the Arabic language model AraBERT-Large (Antoun et al., 2020). A softer metric that is sensitive to partially-correct spellings (chrF) (Popović, 2015) shows a similar trend, with 48.7 for RoBERTa-Large and 62.3 for AraBERT-Large. These results are much higher than the baseline of applying SpellingBee to randomly-initialized vectors, which fails to spell a single token.

Given that subword models learn some notion of character composition to fulfill language modeling objectives, could they perhaps benefit from knowing the exact spelling of each token a priori? To that end, we reverse SpellingBee's role and use it to pretrain the embedding layer of a randomly-initialized model, thus imbuing each token representation with its orthographic information before training the whole model on the masked language modeling objective. We compare the pretraining process of the character-infused model to that of an identical model whose embedding layer is randomly initialized (and not pretrained), and find that

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5061 - 5068
July 10-15, 2022

both learning curves converge to virtually identical values within the first 1,000 gradient updates, a fraction of the total optimization process. This experiment suggests that while language models may need to learn some notion of spelling to optimize their objectives, they might also be able to quickly acquire most of the character-level information they need from plain token sequences without directly observing the composition of each token.

2 Spelling Bee

To measure how much a model knows the character composition of its tokens, we introduce SpellingBee, a generative probe that tries to spell out a token character-by-character. Specifically, SpellingBee probes the original model's *embedding matrix*, since spelling is a property of token *types*, invariant to context. For example, given the embedding of the token *cats*, SpellingBee will try to generate the sequence [*c*, *a*, *t*, *s*]. We do so by modeling SpellingBee as a character-based language model,[2] where the first token is a vector representation of the vocabulary item.[3]

Training We split the vocabulary to train and test sets,[4] and use teacher forcing to train SpellingBee. In the example of *cats*, SpellingBee will compute the following probabilities:

$$
\begin{gathered}
P(x_1 = c \mid x_0 = \textit{cats}) \\
P(x_2 = a \mid x_0 = \textit{cats}, x_1 = c) \\
P(x_3 = t \mid x_0 = \textit{cats}, x_1 = c, x_2 = a) \\
\vdots
\end{gathered}
$$

All of SpellingBee's parameters are randomly initialized. The only parameters that are pretrained are the token embeddings (e.g. the representation of *cats* or *a*), which are taken from the original pretrained language model we intend to probe, and treated as constants; i.e. kept frozen during SpellingBee's training.

Inference & Evaluation Once SpellingBee is trained, we apply it to the test set using greedy decoding. For each vocabulary item w in the test set, SpellingBee is given only the corresponding embedding vector e_w, and is expected to generate the character sequence $w_1, \ldots, w_n$ that defines w. We measure success on the test set using two metrics: *exact match* (EM), and character $n$gram overlap score using *chrF* (Popović, 2015). While EM is strict, chrF allows us to measure partial success. We also report edit distance using Levenshtein distance ratio in Appendix A.

SpellingBee for Pretraining Embeddings While we mainly use SpellingBee as a probe, a variation of our method could potentially imbue the embedding layer with character information before training a language model. We could train a probe with randomly-initialized embeddings (instead of pretrained embeddings from another model) to predict the spelling of *all* vocabulary items, and use these trained probe embeddings to initialize any target model's embedding layer (instead of random initialization). We experiment with this method in Section 5, but find that it does not have any significant impact on the convergence of language models.

3 Experiment Setup

We begin with a series of probing experiments, where we apply SpellingBee to the embedding layer of various pretrained models.[5]

Pretrained Models We probe four pretrained models: RoBERTa-Base and Large (Liu et al., 2019), GPT2-Medium (Radford et al., 2019), and AraBERT-Large (Antoun et al., 2020). This set introduces some diversity in vocabulary, objective, and scale: the first three models are trained on English corpora, while AraBERT is trained on text in Arabic; GPT2 is an autoregressive language model, while the rest are masked language models; RoBERTa-Base consists of 125M parameters (with 768 dimensions per embedding), while the other models have approximately 350M parameters (with 1024 dimensions per embedding).

Control Since SpellingBee is a *trained* probe, we wish to establish the probe's baseline performance when provided with inputs with no orthographic information. As an empirical *control*, we train and test SpellingBee on randomly-initialized vectors, in addition to the main experiments where we utilize the pretrained embedding layers.

---

[2] Implemented using the transformer decoder architecture, following standard practice in language modeling.

[3] Some vocabularies have symbols for indicating preceding whitespaces (_) or that the next token is part of the same word (##). SpellingBee learns to predict these symbols too.

[4] We test various train/test splits to ensure the robustness of our findings. See Section 3 for more detail.

[5] Hyperparameters are detailed in Appendix E.

	Filter	RoBERTa		GPT2	AraBERT
		Base	Large	Medium	Large
EM	None	27.3	31.8	32.9	40.9
	Similarity	15.7	18.2	17.9	21.9
	Lemma	15.7	17.7	16.5	19.5
	Control	0.0	0.0	0.0	0.0
chrF	None	44.7	48.7	51.6	62.3
	Similarity	32.7	35.1	36.4	46.0
	Lemma	32.6	34.8	35.2	43.9
	Control	7.0	7.0	7.0	7.0

Table 1: The percent of token types that can be spelled out exactly (EM) from their embeddings by SpellingBee, and the $n$gram overlap between SpellingBee's reproductions and the token types' true spellings (chrF). The first three rows reflect different methods for filtering the training data, and the fourth represents the control experiment, which uses randomly initialized embeddings. All SpellingBee instances in this table are trained on 32,000 examples.

Training & Testing Data We split the vocabulary into training and testing data using the following protocol. First, we randomly sample 1000 token types as test. We then filter the remaining vocabulary to eliminate tokens that may be too similar to the test tokens, and randomly sample 32000 training examples.We experiment with three filters: *none*, which do not remove tokens beyond the test-set tokens; *similarity*, which removes the top 20 most similar tokens for every token in test, according to the cosine similarity induced by the embedding vectors; *lemma*, which removes any token type that shares a lemma with a test-set token (e.g. if *diving* is in the test set, then *diver* cannot be in the training set).[6] The lemma filter always applies the similarity filter first, providing an even more adversarial approach for splitting the data. To control for variance, we create 10 such splits for each model and filter, and report the averaged evaluation metrics over all 10 test sets.

4 Results

Main Result Table 1 shows how well SpellingBee can spell a vocabulary token using only its frozen pretrained embedding. We observe that SpellingBee is able to accurately recover the spelling of up to 40.9% of the test set, while the control is unable to spell even a single word correctly. A similar trend can be seen when considering the finer character $n$gram metric (chrF). Manually analyzing the predictions of the control baselines (see Appendix D) indicate that it primarily generates combinations of frequent character sequences, which mildly contributes to the chrF score, but does not affect EM. These results are persistent across different models and filters, strongly indicating that the embedding layer of pretrained models contains significant amounts of information about each token's character composition.

One may suggest that training SpellingBee over 32,000 examples may leak information from the test set; for example, if *dog* was seen during training, then spelling out *dogs* might be easy. We thus consider the similarity and lemma filters, which remove such near-neighbors from the training set. While results are indeed lower (and probably do account for some level of information leakage), they are still considerably higher than the control, both in terms of EM and chrF. Results using the similarity and lemma filters are rather similar, suggesting that embedding-space similarity captures some information about each token's lemma.

Finally, we find that the properties of pretrained models also seem to have a significant effect on the amount of spelling information SpellingBee can extract. Larger models tend to score higher in the probe, and the model trained on text in Arabic appears to have substantially higher EM and chrF scores than those trained on English corpora. One possibility is that Arabic's rich morphology incentivizes the model to store more information about each token's character composition; however, it is also possible that AraBERT's different vocabulary, which allocates shorter character sequences to each token type, might explain this difference (we discuss the link between sequence length and accuracy in Appendix C).

Overall, our probing experiments show that even though subword-based language models do not have direct access to spelling, they *can* and *do* learn a surprising amount of information about the character composition of each vocabulary token.

Character-Aware Models Some models are provided with the raw character sequence of each token. To test whether the embedding layers of such models are indeed more informed about each token's spelling, we apply SpellingBee to CharacterBERT (El Boukkouri et al., 2020), a BERT-style model whose layer-zero word embeddings are derived from a character CNN, following ELMo (Peters et al., 2018).

---

[6] We lemmatize using NLTK's WordNet lemmatizer (Loper and Bird, 2002) for English and Farasa's Stemmer (Darwish and Mubarak, 2016) for Arabic.

	Filter	RoBERTa Base	CharacterBERT Base	GloVe 300D
EM	None	43.0	28.2	2.0
	Similarity	9.6	12.9	1.6
	Lemma	9.9	12.9	1.6
	Control	0.0	0.0	0.0
chrF	None	58.8	53.3	13.6
	Similarity	27.0	37.5	13.2
	Lemma	27.3	37.5	13.0
	Control	7.9	8.0	8.0

Table 2: The percent of *whole words* that can be spelled out exactly (EM) from their embeddings by SpellingBee, and the $n$gram overlap between SpellingBee's reproductions and the token types' true spellings (chrF). All SpellingBee instances in this table are trained on 32,000 examples of whole words.

Table 2 shows that the spelling-aware embeddings of CharacterBERT score higher on the SpellingBee probe when the similarity and lemma filters are applied. However, when no filter is applied, RoBERTa's character-oblivious but highly-tuned training process produces embeddings that score higher on SpellingBee, presumably by leveraging implicit similarity functions in the embedding space.

Although CharacterBERT's embedding layer is better at reconstructing original words (when similarity filters are applied), this does not mean that character-aware models are necessarily better downstream. El Boukkouri et al. (2020) report performance increases only on the medical domain. In Section 5, we demonstrate that initializing a masked language model's embedding layer with character information has a negligible effect on its perplexity.

Context-Oblivious Models The first generation of neural word representations (Mikolov et al., 2013a,b) contained only embedding layers, without any contextualization mechanism. We thus use GloVe (Pennington et al., 2014) to estimate a lower bound on character information that can be obtained by simple context-oblivious models. We probe the first 50K words in GloVe's vocabulary with SpellingBee. Table 2 shows that GloVe embeddings do contain a weak orthographic signal, better than random embeddings, but substantially weaker than the information stored in the embedding layer of large transformer-based language models.

Probing with Less Training Data We further examine whether SpellingBee can extract information when trained on less examples. Figure 1 shows how well SpellingBee can spell RoBERTa-Large's vocabulary when trained on varying amounts of data, across all filters. We find that more data makes for a better probe, but that even a few thousand examples are enough to train SpellingBee to extract significant character information from the embeddings, which *cannot* be extracted from randomized vectors (the control).[7]

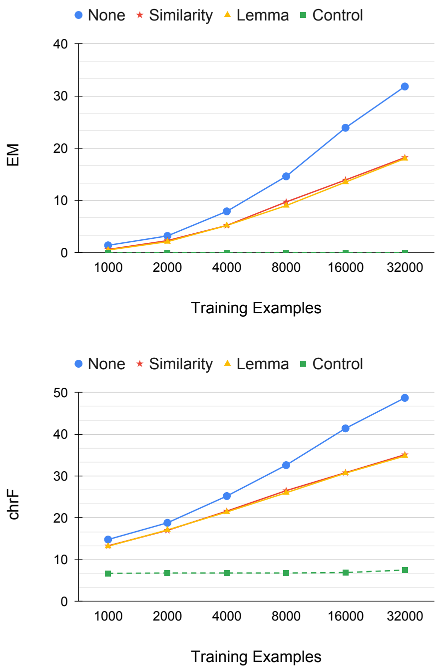

Figure 1: The amount of character information SpellingBee is able to extract from RoBERTa-Large, as measured by EM (top) and chrF (bottom), given different quantities of training examples.

5 Pretraining Language Models to Spell

Our probing experiments reveal that language models learn some partial notion of spelling, despite the lack of direct access to characters. Therefore, we hypothesize that learning to spell is beneficial for language models, and propose pretraining the embedding layer using a variant of the SpellingBee probe described in Section 2. Here, the goal is to imbue each embedding with enough information for SpellingBee to accurately generate its surface form, and then initialize the language model with the pretrained embeddings before it starts training on the language modeling objective.

We apply this process to RoBERTa-Large, train-

---

[7] We provide additional analysis on spelling accuracy by subword frequency and length in Appendices B and C.

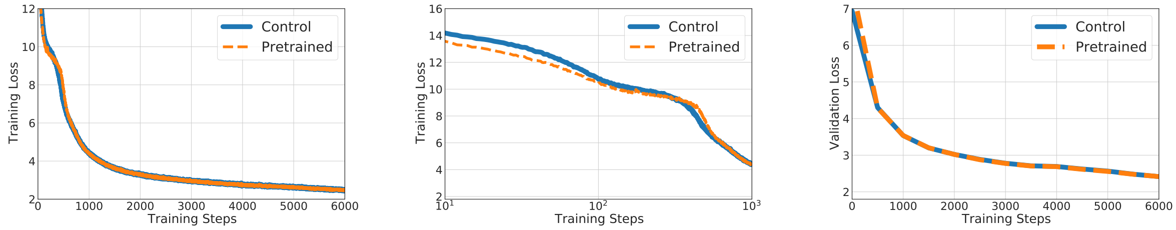

Figure 2: The overall training loss (left), first steps of training loss (center), and validation loss (right) of RoBERTa-Large, when training on the masked language modeling objective with embeddings pretrained by SpellingBee (*pretrained*) and randomly-initialized embeddings (*control*).

ing the model's embedding layer with SpellingBee using the same hyperparameter settings from Appendix E, with the key difference being that the embeddings are now tunable parameters (not frozen).[8] We train RoBERTa-Large on English Wikipedia using the hyperparameter configuration of 24hBERT (Izsak et al., 2021), and cease training after 24 hours (approximately 16,000 steps). For comparison, we train exactly the same model with a randomly-initialized embedding layer.

Figure 2 shows the masked language modeling loss with and without pretrained embeddings. We see that the curves quickly converge into one. After only 1000 training steps, the difference between the validation losses never exceeds 0.01. This result indicates that in this scenario, the model does not utilize the character information injected into the tokens' embeddings.

Although there are many possible ways to explicitly add orthographic information to tokens embeddings, our method is relatively straightforward as it gives the model a chance to utilize pre-stored character information. Along with the results from Section 4, we hypothesize that the implicit notion of spelling that the model learns during pretraining might be sufficient for masked language modeling.

6 Conclusion

This work reveals that pretrained language models learn, to some extent, the character composition of subword tokens. We show that our SpellingBee probe can spell many vocabulary items using their uncontextualized embedding-layer representations alone. Trying to explicitly infuse character information into the model appears to have a minimal effect on the model's ability to optimize its language modeling objective, suggesting that the model can independently learn all the character-level information it needs for the task.

A Levenshtein Distance

Levenshtein distance (Levenshtein et al., 1966) is an edit distance metric that, given two strings, calculates the minimal number of changes needed to be done in order to make the two strings identical. Levenshtein distance *ratio* is the length-normalized version, which is computed by adding the sum of lengths of both strings to the edit distance and dividing by the same sum of lengths. We report the main experiment's results using this ratio in Table 3.

Filter	**RoBERTa**		**GPT2**	**AraBERT**
	Base	**Large**	**Medium**	**Large**
None	69.7	72.7	74.4	83.6
Similarity	61.5	63.7	64.5	75.8
Lemma	61.4	63.3	63.7	74.8
Control	25.6	26.4	27.0	25.7

Table 3: Levenshtein distance ratio. The first three rows reflect different methods for filtering the training data, and the fourth represents the control experiment, which uses randomly initialized embeddings. All SpellingBee instances in this table are trained on 32000 examples.

B Spelling Accuracy by Frequency

We test whether pretrained models tend to store more spelling-related information in higher-frequency token types. We focus on RoBERTa-Large, and assign each token in the test set to its frequency quintile according to the number of times it appeared in the pretraining corpus – from the 10000 most frequent token types (top 20%) to those ranked 40000-50000 in the vocabulary (bottom 20%) – and measure the average performance of SpellingBee within each quintile. Figures 3 and 4 shows the results with and without the similarity filter. We observe that SpellingBee is indeed able to extract more information from higher-frequency token types, suggesting that the pretrained model has more information about their character composition.

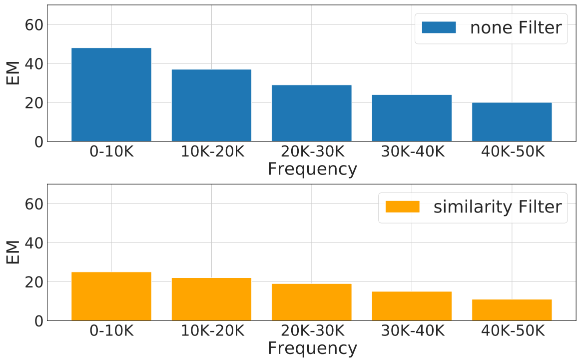

Figure 3: The EM scores of SpellingBee on RoBERTa-Large for each frequency quintile with the *none* filter (top) and the *similarity* filter (bottom).

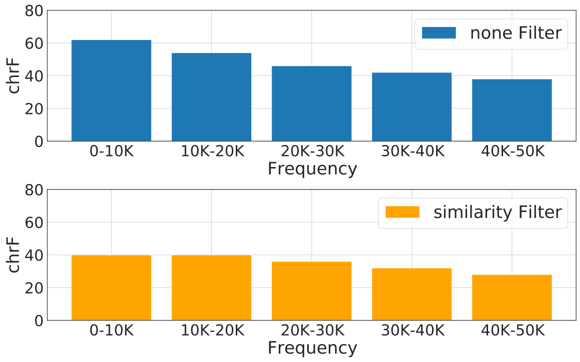

Figure 4: The chrF scores of SpellingBee on RoBERTa-Large for each frequency quintile with the *none* filter (top) and the *similarity* filter (bottom).

C Spelling Accuracy by Length

We analyze the effect of token length on the probe's ability to spell. A priori, it is reasonable to assume that it is easier for the probe to spell shorter tokens, since less information needs to be extracted from the embedding and there are less discrete decisions to be made while decoding. Indeed, Figure 5 shows that with the none filter most vocabulary tokens with 2-4 characters can be accurately reproduced from their vector representations, while longer tokens are harder to replicate. This trend is particularly sharp when the similarity filter is applied, as the probe is hardly able to spell tokens with 6 or more characters accurately; having said that, the probe is able to generate many *partially correct* spellings, as measured by chrF (Figure 6). Perhaps a less intuitive result is the probe's failure to spell single-character tokens. A closer look reveals that many of these examples are rare or non-alphanumeric characters (e.g. *ç* and *$*), which are probably very difficult for the probe to generate if it had not seen them during training. While these results show strong trends with respect to length, token length is also highly correlated with frequency, and it is not necessarily clear which of the two factors has a stronger impact on the amount and resolution of character-level information stored in the embedding layer of pretrained models.

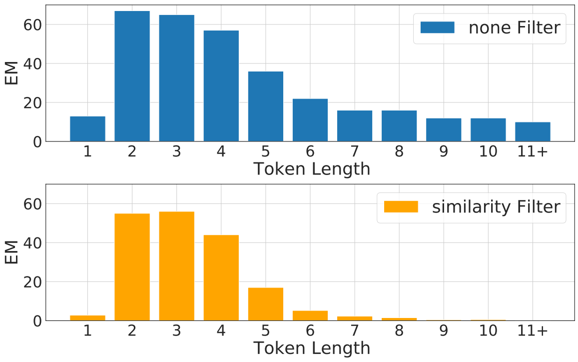

Figure 5: The EM scores of SpellingBee on RoBERTa-Large for each token length with the *none* filter (top) and the *similarity* filter (bottom). The rightmost column groups together tokens with length of 11 or above.

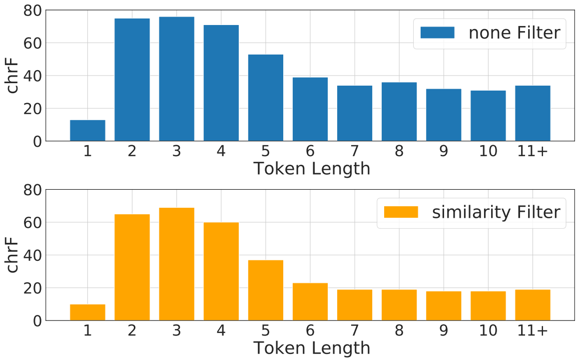

Figure 6: The chrF scores of SpellingBee on RoBERTa-Large for each token length with the *none* filter (top) and the *similarity* filter (bottom). The rightmost column groups together tokens with length of 11 or above.

D Manual Error Analysis

We manually analyze 100 random tokens that SpellingBee spelled incorrectly with the lemma filter to understand the nature of the spelling mistakes. Out of those 100 we display 20 mistakes in Table 4 alongside the spelling prediction of the control baseline. SpellingBee's mistakes vary from single-character typos to completely different words. Having said that, the vast majority of mistakes have significant overlap with the correct spelling, such as shared prefixes and capitalization.

E Hyperparameters

We implement SpellingBee with a 6-layer encoder-decoder model, with 512 model dimensions. The model parameters are optimized with Adam (Kingma and Ba, 2015) for 1000 steps with up to 1024 tokens per batch, a learning rate of 5e-4, and a dropout rate of 0.1. These are the default hyperparameters for training a transformer language model in Fairseq (Ott et al., 2019).

Abstract

Teaching morals is one of the most important purposes of storytelling. An essential ability for understanding and writing moral stories is bridging story plots and implied morals. Its challenges mainly lie in: (1) grasping knowledge about abstract concepts in morals, (2) capturing inter-event discourse relations in stories, and (3) aligning value preferences of stories and morals concerning good or bad behavior. In this paper, we propose two understanding tasks and two generation tasks to assess these abilities of machines. We present STORAL, a new dataset of Chinese and English human-written moral stories. We show the difficulty of the proposed tasks by testing various models with automatic and manual evaluation on STORAL. Furthermore, we present a retrieval-augmented algorithm that effectively exploits related concepts or events in training sets as additional guidance to improve performance on these tasks.

1 Introduction

Stories play an essential role in one's moral development (Vitz, 1990). For example, individuals usually learn morals from life experiences or literature such as fables and tell their morals by representing their lived experience in a narrative form (Tappan and Brown, 1989). Accordingly, it is a crucial ability for humans to bridge abstract morals and concrete events in stories. However, this ability has not yet been investigated for machines.

There have been many tasks proposed for evaluating story understanding and generation, including story ending selection (Mostafazadeh et al., 2016) and story generation from short prompts (Fan et al., 2018). Unlike these tasks, which focus on reasoning plots from context, we emphasize the ability to associate plots with implied morals. As exemplified in Table 1, the challenges mainly lie in (1) grasping knowledge about abstract concepts (e.g., "unity," "strength") and relations among them (e.g., "is") in morals; (2) capturing inter-event discourse relations in stories (e.g., the contrast between endings of the "cows" when they are "united" and "divided"); and (3) aligning value preferences (Jiang et al., 2021) of stories and morals (e.g., the story implies support for "unity", not opposition, which agrees with "is strength" in the moral). To test these abilities of machines, we propose two understanding tasks and two generation tasks. Both understanding tasks require selecting the correct moral from several candidates given a story. And they have respective candidate sets for testing machines in two aspects, including concept understanding (MOCPT for short) and preference alignment (MOPREF for short). The generation tasks require concluding the moral of a story (ST2MO for short), and conversely generating a coherent story to convey a moral (MO2ST for short).

Stories: Four cows lived in a forest near a meadow. They were good friends and did everything together. They grazed together and stayed together, because of which no tigers or lions were able to kill them for food. But one day, the friends fought and each cow went to graze in a different direction. A tiger and a lion saw this and decided that it was the perfect opportunity to kill the cows. They hid in the bushes and surprised the cows and killed them all, one by one.
Morals: Unity is strength.

Table 1: An example in STORAL

Furthermore, we collected a new dataset named STORAL composed of 4k Chinese and 2k English human-written stories paired with morals through human annotation to address the above challenges. We call the Chinese dataset STORAL-ZH and the English dataset STORAL-EN, respectively. And we construct datasets for the proposed tasks based on STORAL. Our focus of morals is on the social set of standards for good or bad behavior and character, or the quality of being right, honest or accept-

able (Ianinska and Garcia-Zamor, 2006). We conduct extensive experiments on the proposed tasks. Furthermore, we present a retrieval-augmented algorithm to improve model performance by retrieving related concepts or events from training sets as additional guidance. However, the experiment results demonstrate that existing models still fall short of understanding and generating moral stories, which requires a better modeling of discourse and commonsense relations among concrete events and abstract concepts [1].

2 Related Work

Story Datasets ROCStories (Mostafazadeh et al., 2016) and WritingPrompts (Fan et al., 2018) are two frequently used story datasets in related studies. The former consists of artificial five-sentence stories regarding everyday events, while the latter contains fictional stories of 1k words paired with short prompts. Besides, some recent works collected extra-long stories such as roleplayerguild (Louis and Sutton, 2018), PG-19 (Rae et al., 2020), and STORIUM (Akoury et al., 2020). Guan et al. (2022) proposed a collection of Chinese stories. These stories usually aim to narrate a coherent event sequence but not convince readers of any morals.

Story Understanding and Generation There have been many tasks proposed for evaluating story understanding and generation. Firstly, some works tested the machinery commonsense reasoning ability regarding inter-event causal and temporal relations through story ending selection (Mostafazadeh et al., 2016), story ending generation (Guan et al., 2019) and story completion (Wang and Wan, 2019). Secondly, a series of studies focused on the coherence of story generation (Fan et al., 2018; Yao et al., 2019; Guan et al., 2020). Another line of works concentrated on controllability to impose specified attributes into story generation. These attributes involved outlines (Rashkin et al., 2020), emotional trajectories (Brahman and Chaturvedi, 2020) and story styles (Kong et al., 2021). Our tasks investigate not only the above aspects but also the ability to understand abstract concepts and reason value preferences of stories.

A task similar to ST2MO is text summarization (Finlayson, 2012) since both tasks require generating a short text to condense crucial information of a long text. But summarization requires reorganizing a few words of the original text instead of concluding a character-independent moral. For example, a plausible summary of the story in Table 1 is "Four cows were killed by two tigers and a lion" (generated by $\text{BART}_{\text{Large}}$ (Lewis et al., 2020) fine-tuned on a summarization dataset XSUM (Narayan et al., 2018)), which includes specific characters and events of the original story. Moreover, MO2ST is similar to persuasive essay generation (Stab and Gurevych, 2017), which also requires conveying a viewpoint in generated texts. However, persuasive essays usually convince readers by directly presenting arguments but not narrating a story.

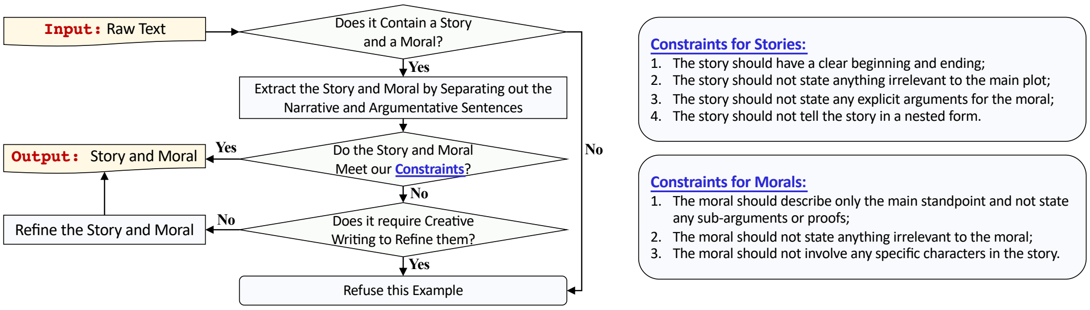
Morals Haidt and Joseph (2004) provided a theoretical framework named Moral Foundations Theory (MFT) to summarize five basic moral foundations such as "Care/Harm," "Fairness/Cheating," etc. Based on the theory, recent studies have explored to classify the moral foundations of partisan news (Fulgoni et al., 2016), tweets (Johnson and Goldwasser, 2018; Hoover et al., 2020), and crowd-sourced texts (Pavan et al., 2020). And Volkova et al. (2017) proposed identifying suspicious news based on the features of moral foundations. However, we focus on morals which are free-form texts far beyond the scope of the five categories in MFT. In addition, recent studies proposed multiple datasets for machine ethics research such as SBIC (Sap et al., 2020), Social Chemistry (Forbes et al., 2020), Moral Stories (Emelin et al., 2020), ETHICS (Hendrycks et al., 2021) and Scruples (Lourie et al., 2021). But these datasets focus more on how machines behave ethically in some scenario, while STORAL emphasizes the ability to conclude the moral implied by a story. Moreover, most cases in these datasets consist of short texts of descriptive ethical behavior, typically in the form of one sentence. In contrast, STORAL provided longer and more context-specific stories for moral understanding.

3 STORAL Dataset

We collected STORAL from multiple web pages of moral stories. All stories are allowed to use and redistribute for research and have been reviewed by the website editors as stated on the pages. We show the full list of links to these pages in Section A.1. After de-duplication, we collected 19,197 Chinese and 2,598 English raw texts. Then we adopted human annotation for decoupling the story and moral

---

[1] All data and evaluation scripts are available at `https://github.com/thu-coai/MoralStory`.



Constraints for Stories:

1. The story should have a clear beginning and ending;
2. The story should not state anything irrelevant to the main plot;
3. The story should not state any explicit arguments for the moral;
4. The story should not tell the story in a nested form.

Constraints for Morals:

1. The moral should describe only the main standpoint and not state any sub-arguments or proofs;
2. The moral should not state anything irrelevant to the moral;
3. The moral should not involve any specific characters in the story.

Figure 1: The pipeline of human annotation for constructing STORAL (Left) and our constraints (Right).

in each raw text. Due to resource limitations, we only constructed 4,209 Chinese and 1,779 English story-moral pairs. We will first show the details of human annotation, then present the topic analysis and statistics of STORAL, and finally describe the details of dataset construction for the proposed tasks.

3.1 Human Annotation

To narrow down our focus, we define a story as a series of coherent events involving several interrelated characters, and implies support or opposition of some behavior. Such a definition constrains the story to exhibit a moral without any explicit arguments. And we define a moral as a judgment to describe what the story implies concerning good or bad behavior. Note that we do not require morals in STORAL to be always reflective of normatively virtuous behavior. We emphasize that the morals should align with the story. Then, a key issue is how to extract the story and moral from a raw text. We observe that there are no markers such as “The story tells us” to separate the story and moral in most cases. The moral may be tightly weaved into the plot (e.g., included in a dialogue). Therefore, we adopted human annotation for this extraction task. We hired a commercial team to annotate STORAL-ZH. All annotators are native Chinese speakers and well trained for our task. For STORAL-EN, we hired three graduates with good English language proficiency. We did not use AMT since it is inconvenient to train online annotators. Figure 1 shows the annotation pipeline.

We first ask annotators to judge whether the raw text contains a story and moral and whether they meet our constraints shown in Figure 1. We show the examples given to the annotators to inform them of our requirements for stories and morals in Section A.2. If the constraints are not met, we then ask annotators to refine the story and moral. In the refinement stage, annotators have to clean up the data with following heuristics: (1) refusing examples which may violate general ethical principles (e.g., discrimination); (2) deleting noisy words (e.g., links, codes); (3) refining the stories and morals to be coherent and formal. And to ensure the quality of collected data, annotators may refuse to refine the example if it requires much creative writing. Finally, we review the annotation results and provide detailed feedback to the annotators before approving their submissions. We show an annotation example in Table 2.

Raw Text: A man who*wWw.xxx.c0M*lived a long time ago believed that he could read the future in the stars. He called himself an Astrologer, and spent his time at night gazing at the sky. One evening he was walking along the open road outside the village. His eyes were fixed on the stars. He thought he saw there that the end of the world was at hand, when all at once, down he went into a hole full of mud and water. There he stood up to his ears, in the muddy water, and madly clawing at the slippery sides of the hole in his effort to climb out. His cries for help soon brought the villagers running. As they pulled him out of the mud, one of them said:“You pretend to read the future in the stars, and yet you fail to see what is at your feet! *This may teach you to* ***pay more attention to what is right in front of you, and let the future take care of itself.*** *”“what use is it? ” said another, “ to read the stars, when you can't see what's right here on the earth?”*

Story: A man who lived a long time ago believed that he could read $\cdots$ As they pulled him out of the mud, one of them said: “You pretend to read the future in the stars, and yet you fail to see what is at your feet!”

Moral: Pay more attention to what is right in front of you, and let the future take care of itself.

Table 2: An example for extracting the story and moral from a raw text. We highlight the words which should be revised in the raw text in *italic*. And the moral in the raw text is **bold**. To save space, we replace some events with “$\cdots$” in the story.

3.2 Topic Analysis

To provide insight into the taxonomy of morals within STORAL, we adopt LDA (Blei et al., 2003) for topic modeling of morals. Let B denote the number of topics and V denote the vocabulary size. Based on the variational parameter for topic word distribution $\beta \in \mathbb{R}^{B\times V}$, we determine B as the minimum value that makes the following formula

Topic Words	**Examples**
懂得 (understand), 也是 (also), 了解 (know), 方法 (method), 收获 (gain), 保护 (protect), 大脑 (brain), 才能 (able), 付出 (pay), 进步 (progress)	在犯错的时候我们要懂得看全局，要了解全局才能对事情有定义。(When making mistakes, we must understand the overall situation. And we are able to have a definition of things only when knowing the overall situation.)
不要 (not), 一定要 (must), 危险 (danger), 时候 (when), 对待 (treat), 安全 (safety), 千万 (any way), 好好 (well), 学会 (learn), 遇到 (encounter)	生活中也要牢记"安全"这两字，在"安全"两字面前切不可存有侥幸心理，把安全当成儿戏。(Keep in mind the word "safety" in your life, and do not take any chances to treat safety as a joke.)
事情 (thing), 才能 (able), 做好 (do well), 优秀 (excellent), 应该 (should), 做到 (achieve), 自信 (self-confident), 有所 (somewhat), 无法 (unable), 可能 (may)	做好自己该做的事情，做自己的主人。(Do what you should do and be your own master.)
时候 (when), 其实 (actually), 很多 (many), 发现 (discover), 希望 (wish), 发生 (happen), 生活 (life), 已经 (already), 伤害 (hurt), 可能 (may)	人要善于自己发现自己，而不是老等着别人来发现我们。(We should be good at discovering ourselves instead of waiting for others to do.)
遇到 (encounter), 问题 (question), 困难 (difficulty), 解决 (solve) 思考 (think), 帮助 (help), 时候 (when), 应该 (should), 给予 (give), 头脑 (brain)	乐于助人，是一种朴实的中国传统美德。每个人都有遇到困难的时候，最需要的是别人给予的帮助。(Being helpful is a Chinese traditional virtue. When someone encounters difficulties, what he needs most is help from others.)
good, always, come, believe, first, honesty, speak, world, around, act	**1.** Always be honest. Honesty is always rewarded. **2.** A liar will not be believed, even when he speaks the truth.
help, also, good, need, hope, lose, carry, feel, say, self	**1.** One should not be carried away by what others say. Don't be fooled by those who wants to take advantage of you. **2.** Self help is the best help. Heaven helps those who help themselves.
friend, act, wisely, moment, think, place, time, choose, great, ability	**1.** Little friends may prove great friends. **2.** One should not panic in difficult times and think wisely.
love, care, parent, respect, always, value, take, mean, give, one	**1.** You reap what you sow. Regardless of your relationship with your parents, you'll miss them when they're gone from your life. Always respect, care for and love them. **2.** Be content with your lot; one cannot be first in everything.
look, see, bad, make, turn, strong, strength, choice, give, deserve	**1.** The strong and the weak cannot keep company. **2.** It is easy to despise what you cannot get.

Table 3: Topic words and examples for STORAL-ZH (top) and STORAL-EN (bottom). We underline the topic words that occurs in the examples.

holds true for any $b \in \{1, 2, \cdots, B\}$:

$$s_b = \frac{\sum_{v \in \mathcal{V}_b^{(k)}} \beta_{bv}}{\sum_{v=1}^{V} \beta_{bv}} \geq h,$$

$$\mathcal{V}_b^{(k)} = \text{argmax}_{\mathcal{V}_b^{*(k)}} \sum_{v \in \mathcal{V}_b^{*(k)}} \beta_{bv},$$

where β_{bv} is the element at the b-th row and v-th column of β, $k \in \{1, 2, \cdots, V\}$ is the size of the top-k vocabulary $\mathcal{V}_b^{(k)}$, and $h \in [0, 1]$ is a predefined threshold. s_b is used to measure the specificity of the b-th topic. Intuitively, the larger s_b, the more specific the topic. We set k to 20 and h to 0.5. Finally, we derive 40/24 topics for STORAL-ZH/STORAL-EN, respectively. And the minimum proportion of examples of one topic is 1.6%/3.2% for STORAL-ZH/STORAL-EN, respectively.

Table 3 shows the topic words in $\mathcal{V}^{(10)}$ of each topic and two morals assigned to each topic with the highest probabilities for the five topics with the largest specificity scores. The topics cover diverse situations ranging from facing others ("honesty," "help"), parents ("love"), ourselves ("self-help," "self-discovery") to facing difficulties ("think") and danger ("safety"). And examples of the same topic present related semantics to some extent, such as "being honest" and "not believing liars" for the first topic in STORAL-EN. We also show the analysis of high-frequency words of stories and morals in Section A.3 and discussion about the commonsense and discourse relations in stories in Section A.4.

3.3 Dataset Statistics of STORAL

Table 4 shows the statistics of STORAL. We regard the unlabeled data which contain entangled stories and morals as an in-domain resource for research on unsupervised or semi-supervised learning for the proposed tasks. And the data are also suitable for learning to generate morals stories where the morals are weaved naturally into the story plots.

3.4 Task-Specific Dataset Construction

Based on STORAL, we build task-specific datasets for our understanding tasks (MOCPT and MOPREF) and generation tasks (ST2MO and MO2ST). We randomly split the labeled data in STORAL-ZH and STORAL-EN for training/validation/testing by 8:1:1 and 3:1:1, respectively. Table 5 shows the task

Datasets	Labeled Data							Unlabeled Data			
	# Examples	Stories			Morals			# Examples	# Word	# Sent	Vocab
		# Word	# Sent	Vocab	# Word	# Sent	Vocab				
STORAL-ZH	4,209	321.75	17.62	63,493	25.09	1.35	10,522	14,988	487.00	26.12	147,805
STORAL-EN	1,779	302.33	17.71	15,873	19.77	1.45	3,384	819	614.55	38.05	20,853

Table 4: STORAL statistics. We use Jieba[2]/NLTK (Loper and Bird, 2002) for word tokenization of STORAL-ZH/ STORAL-EN. **# Word / # Sent** is the average number of words/sentences. **Vocab** is the vocabulary size.

Tasks	Abilities	Inputs & Outputs	STORAL-ZH |Train| /|Val| /|Test|	STORAL-EN |Train| /|Val| /|Test|
MOCPT	Concept Understanding	Given a story and five candidate morals, choosing the correct moral.	3,368 / 420 / 421	1,068 / 355 / 356
MOPREF	Preference Alignment	Given a story and two candidate morals, choosing the correct moral.	3,276 / 410 / 411	988 / 344 / 339
ST2MO	Moral Generation	Given a story, generating a moral which is character-independent and generally applicable.	3,368 / 420 / 421	1,068 / 355 / 356
MO2ST	Story Generation	Given a moral and a story beginning and outline, generating a story which has a coherent plot and convinces readers of the moral.	3,368 / 420 / 421	1,068 / 355 / 356

Table 5: Description of the proposed tasks about the abilities they investigate, inputs and outputs, and the data sizes.

descriptions and data sizes.

MOCPT It requires selecting the correct moral from five candidates given a story. We constructed the dataset by taking the original moral as the correct candidate and four negatively sampled morals as incorrect candidates for each example. To avoid more than one plausible candidate, we ensured that the negative morals are assigned to different topics from the original one by the LDA model (Section 3.2). In this way, MOCPT can effectively test the ability to distinguish different concepts.

MOPREF It requires selecting the correct moral from two candidates. Its difference from MOCPT is that we created the incorrect candidate by substituting one random token in the original moral to its antonym. For example, the moral "unity is strength" can be transformed to "unity is weakness". We perform the transformation using a rule-based method (Ribeiro et al., 2020). Because there exist examples where no words have antonyms, the number of examples for MOPREF are a little fewer than MOCPT. MOPREF will serve for testing the ability to capture the value preference of stories.

ST2MO It requires generating the moral of a given story. We regard the original story as input and the original moral as target output.

MO2ST It requires generating a story to convey a given moral. Unfortunately, automatic evaluation for open-ended story generation is still highly challenging due to the notorious one-to-many issue (Zhao et al., 2017): There may be multiple plausible stories with the same moral. For example, the moral in Table 1 can also be conveyed by another story: "bees unite to build their beehives." Such openness makes automatic metrics unreliable for quality evaluation (Guan and Huang, 2020).

To alleviate this issue, we extract the first sentence and an outline from a target story, and pair them with the moral as input for generating the story. We follow Rashkin et al. (2020) to extract a set of at most eight phrases from a story through RAKE (Rose et al., 2010) as the outline. We set the maximum number of words in each phrase to eight. We also filtered those phrases that are substrings of others. For example, the outline for the story in Table 1 is {"lions," "friends fought," "good friends," "grazed," "perfect opportunity"}. Finally, for STORAL-ZH/STORAL-EN, the average number of phrases for each example is 7.5/6.8 and the average number of words in each phrase is 2.87/2.44, respectively.

4 Retrieval Augmentation

A critical challenge for tackling the proposed tasks is the sparsity of morals and events makes it difficult to learn relations between them. Prior studies have shown that retrieval improves performance towards infrequent data points across various tasks such as open-domain question answering (Chen et al., 2017) and text classification (Lin et al., 2021). We present a retrieval-augmented algorithm that exploits the moral-event relations in training sets. We illustrate our model for the MOPREF task in Fig-

---

[1] `https://github.com/fxsjy/jieba`

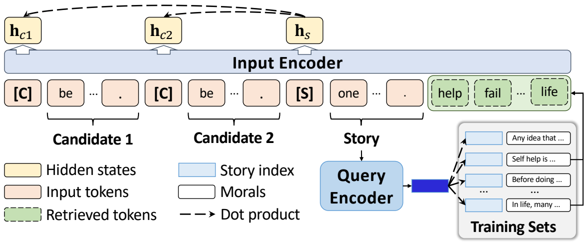


Figure 2: Model overview for the MOPREF task.

ure 2. Our models for other tasks are similar.

For both MOCPT and MOPREF, we encode the story and candidates using an input encoder, and then predict a probability distribution over the candidates by normalizing the dot-product scores between the representations of the story and each candidate. We optimize the model by minimizing the cross-entropy loss. We insert special tokens `[S]` and `[C]` before the story and each candidate, respectively, and take the corresponding hidden states as their representations. Furthermore, we propose to retrieve related concepts from the training set using the input story. We encode the story using a query encoder, then take the output as the query to retrieve m most related stories based on a story index, i.e., a set of dense vectors as the representations of stories in the training set. We adopt BERT (Devlin et al., 2019) followed by a mean-pooling layer to build the query encoder and story index, which are frozen in the training stage. Finally, we extract the nouns, verbs, adjectives and adverbs from the morals of the top-m stories and lemmatize them as the retrieved concepts. We feed the concepts together with the original input to the input encoder. For example, the retrieved concepts for the story in Table 1 include “support” and “strength”, which may serve as additional guidance for models’ prediction.

The retrieval-augmented algorithm can easily adapt to the generation tasks. For ST2MO, we take the input story paired with the retrieved concepts into the encoder and then generate the output using the decoder. And for MO2ST, we use the input moral as the query to retrieve top-m stories, and regard their outlines as the retrieved additional information to guide the subsequent story generation.

5 Experiments

5.1 Evaluated Models

We evaluated the following baselines for the understanding tasks: *BERT* (Devlin et al., 2019), *RoBERTa* (Liu et al., 2019) and *T5* (Raffel et al., 2020). When evaluating T5, we feed the input to both the encoder and decoder of T5 and optimize the model using the cross-entropy loss. To investigate potential biases of the proposed datasets, we added a baseline called *BERT w/o story*, which is fine-tuned to make prediction without taking the story as input. For the generation tasks, we evaluated *ConvS2S* (Gehring et al., 2017), *Fusion* (Fan et al., 2018), *GPT2* (Radford et al., 2019) and *T5*, which are trained or fine-tuned with the standard language modeling objective. Moreover, we also evaluate a task-specific model *PlotMachines* (PM for short) (Rashkin et al., 2020), which is proposed for tackling outline-conditioned generation by tracking the dynamic plot states. We use GPT2 as the backbone model of PM.

We also design models to test the adaption of the unlabeled data of STORAL to the proposed tasks. Specifically, we first post-train RoBERTa and T5 on the unlabeled data with their original pretraining objectives, respectively (i.e., masked language model and text infilling) and then fine-tune them on the labeled data for the downstream tasks (Gururangan et al., 2020). We call the baselines *RoBERTa-Post* and *T5-Post*. We perform our retrieval-augmented algorithm based on the post-trained models, called *RA-RoBERTa* and *RA-T5*, respectively.

5.2 Experiment Settings

We implement the pretrained models based on the codes and pretrained checkpoints of HuggingFace’s Transformers (Wolf et al., 2020). We use $\text{LongLM}_{\text{base}}$ (Guan et al., 2022) as the T5 model for experiments on STORAL-ZH, and set all pretrained models to the base version due to limited computational resources. As for the hyperparameters, we set the batch size to 16, the maximum sequence length to 1,024, the learning rate to 3e-5, m to 10 for our retrieval-augmented model. We generate outputs using top-k sampling (Fan et al., 2018) with $k = 40$ and a softmax temperature of 0.7 (Goodfellow et al., 2016). We show more details in Section B.1.

5.3 Automatic Evaluation

Evaluation Metrics We adopt accuracy to evaluate the understanding tasks. For generation tasks, we do not use perplexity since perplexity scores are not comparable among models with different vocabularies. We adopt the following metrics for automatic evaluation: **(1) BLEU (B-n):** It is used to measure n-gram overlaps ($n = 1, 2$) between generated and ground-truth texts (Papineni et al., 2002). **(2) BERTScore-F1 (BS):** It is used to measure the semantic similarity between generated and ground-truth texts (Zhang et al., 2019). **(3) Repetition (R-n):** It calculates the ratio of texts that repeat at least one n-gram in all generated texts (Shao et al., 2019). **(4) Distinct (D-n):** It measure the diversity using the percentage of distinct n-grams to all n-grams in generated texts (Li et al., 2016). For both R-n and D-n, we set $n = 2$ for ST2MO and $n = 4$ for MO2ST considering the much shorter length of morals than stories. Besides, we also report the average number of generated words (**Len**).

We also adopt the following metrics for automatic evaluation of MO2ST: **(1) Coverage (Cov):** It computes Rouge-L recall (Lin, 2004) between generated stories and phrases in the corresponding outlines. A higher score means the generated stories cover more phrases in the given outlines. **(2) Order (Ord):** It measures the disparity between the positional orders of given phrases in the ground truth and generated story using the percentage of inversions in the generated story (Guan et al., 2022). An inversion is a position pair of two phrases that is out of the ground-truth order. Higher order scores mean that the stories arrange the outline more reasonably. In Section B.2, we also construct a learnable automatic metric to measure the faithfulness between morals and stories.

Results Table 6 and 7 show the results on the understanding and generation tasks, respectively. To get the human performance on MOCPT and MOPREF, we sampled 100 examples from the test set and recruited three annotators with good Chinese or English language proficiency to complete these tasks. We made final decisions among the annotators through major voting. The annotation results show an almost perfect agreement with Fleiss's $\kappa > 0.85$ (Fleiss and Joseph, 1971).

We summarize the results on the understanding tasks as follows: **(1)** The MOPREF datasets suffer from innate biases as indicated by the high accuracy of BERT w/o story. Such biases may result from the noise introduced by the automatic construction technique, i.e., antonym substitution. And models may learn patterns of good behavior (e.g., "unity" is good and "disunity" is bad in general) and make predictions easily without depending on stories. However, MOPREF is still meaningful as an evaluation task since BERT can achieve much better accuracy when taking stories as input. And we experiment using manually constructed examples for evaluating preference alignment in the appendix. **(2)** T5 performs better than RoBERTa on MOCPT but worse on MOPREF, indicating T5 may not be good at capturing value preferences. **(3)** Post-training on the unlabeled data (i.e., RoBERTa-Post and T5-Post) does not always bring improvement on both tasks, suggesting that it is necessary to develop a better way to exploit these data in future work. **(4)** Retrieving additional concepts improves models' performance effectively, particularly for the MOCPT task on STORAL-EN. However, there is still a big gap between our models and human performance.

Models	# P	MOCPT		MOPREF	
		ZH	EN	ZH	EN
Random	N/A	20.19	20.22	50.12	50.00
BERT w/o Story	110M	23.52	22.47	71.81	72.57
BERT	110M	59.62	51.97	82.97	79.35
RoBERTa	110M	62.71	54.78	89.54	81.12
RoBERTa-Post	110M	64.61	51.40	87.59	81.42

RA-RoBERTa	110M	65.08	60.96	**90.02**	81.71
RA-T5	220M	**72.68***	**67.42****	82.97	**82.60**
Human	N/A	*95.00*	*96.00*	*98.00*	*99.00*

Table 6: Accuracy (%) for MOCPT and MOPREF. # P is the number of parameters. The best performance is highlighted in **bold** and the second best is underlined. The scores marked with * and ** of RA model mean it outperforms the best baseline significantly with p-value<0.1 and p-value<0.05 (sign test), respectively.

As for the generation tasks, we draw the following conclusions: **(1)** Almost all pretrained models achieve better lexical and semantic similarity with ground-truth texts than non-pretrained models, as indicated by higher BLEU and BERTScore values. **(2)** Non-pretrained models have less repetition than pretrained ones, and repeat even less than the ground-truth texts when generating morals. It may be because non-pretrained models generate shorter sequences than pretrained models despite the same decoding algorithm, which also accounts for the higher distinct scores of the non-pretrained models on the MO2ST task. **(3)** When generating stories, T5-Post can cover more input phrases and arrange them in a correct order than other baselines, as indicated by higher coverage and order scores. **(4)** Retrieval augmentation can improve the generation similarity with the ground-truth texts on both tasks and improve the coverage and order scores on ST2MO significantly compared with T5-Post.

Table 7: Automatic evaluation results for ST2MO (Top) and MO2ST (Bottom). ↓ / ↑ means the lower/higher the better. All scores except *Len* are multiplied by 100. The best result is in **bold** and the second best is underlined. The scores marked with * and ** of RA-T5 mean it outperforms the best baseline significantly with p-value<0.1 and p-value<0.05 (sign test), respectively.

Data	Task	Model	Flu (κ)	Cohe (κ)	Faith (κ)

Table 8: Manual evaluation results for ST2MO and MO2ST. Flu, Cohe and Faith mean *fluency*, *coherence* and *moral faithfulness*, respectively. The best results are highlighted in **bold**. All results show fair or moderate inter-annotator agreement measured by Fleiss' κ (Fleiss and Joseph, 1971).

5.4 Manual Evaluation

On the generation tasks, we conducted a Likert-scale based manual evaluation to measure the gap between existing models and humans. For STOAL-ZH, we hired three graduate students (native Chinese speakers) as annotators. We conducted evaluation on STORAL-EN using Amazon Mechanical Turk (AMT). For both tasks, we randomly sampled 100 examples from the test set, and obtained 300 generated texts from Fusion, T5 and RA-T5. For each text we require three annotators to rate its quality along with the input using a binary score in three following aspects: (1) *linguistic fluency*: correctness in grammaticality; (2) *coherence*: reasonable relations between sentences regarding relatedness, causality and temporal orders; and (3) *moral faithfulness*: exhibition of a faithful moral to the input. Three aspects are independently evaluated. We decided the final score of a text through majority voting. The annotation instruction is shown in Section B.3.

Table 8 shows the manual evaluation results. We show p-values of the results in Section B.4. For ST2MO, T5 achieves a substantial improvement compared with Fusion ($p < 0.01$), and our model further outperforms T5. The superiority becomes less significant for MO2ST. However, the big gap between these models and humans, particularly in terms of faithfulness, proves both tasks challenging for existing models. Furthermore, we evaluate whether machines can capture the value preference of a story using manually constructed examples. And we show error analysis and case study for the proposed tasks in Section C. We believe that explicit modeling of the relations among events and abstract concepts will further promote progress on these tasks, which we regard as future work.

6 Conclusion

We present STORAL, a collection of Chinese and English moral stories. To test the ability to bridge concrete events and abstract morals, we propose new understanding and generation tasks based on STORAL, including selecting the correct moral from several candidates with different topics or opposite value preferences, concluding the moral of a story and generating a story to convey a moral. Extensive experiments prove these tasks still to be challenging for existing models. We propose a retrieval-augmented algorithm to improve performance by retrieving related concepts or events from training sets. Although it is possible to further increase the dataset size, we expect to make meaningful progress by developing better representations of commonsense and discourse relations among events and abstract concepts in future work.

7 Acknowledgement

This work was supported by the National Science Foundation for Distinguished Young Scholars (with No. 62125604) and the NSFC projects (Key project with No. 61936010 and regular project with No. 61876096). This work was also supported by the Guoqiang Institute of Tsinghua University, with Grant No. 2019GQG1 and 2020GQG0005. This work was also sponsored by Tsinghua-Toyota Joint Research Fund. We would also like to thank the anonymous reviewers for their invaluable suggestions and feedback.

8 Ethics Statements and Broader Impact

We collected STORAL from public web resources. All stories are under licenses that allow use and redistribution for research purposes. We asked commercial annotation teams to extract stories and morals from the crawled raw texts. We required the annotators to refuse the examples which violate general ethical principles (e.g., showing discrimination for someone, containing disrespectful content, or encouraging to disturb public order, etc.). Totally, we payed more than $7 (CNY 45) per hour on average for annotating each example in STORAL, which was far beyond the minimum hourly wage in China (CNY 21). Furthermore, we resorted to AMT for manual evaluation of generated and human-written texts for two proposed generation tasks. We hired three annotators and payed each annotator $0.2 on average for annotating each example.

In this paper, we emphasize the ability to model relations between concrete events and abstract morals, which is also helpful for various scenarios such as reading comprehension (e.g., drawing authors' viewpoints from narratives) and essay writing (e.g., writing essays to convince readers of some arguments by presenting examples or anecdotes). STORAL provides a good start point for exploring these directions.

A STORAL Construction

A.1 Data Source

We show the full list of web pages used for constructing STORAL in Table 11. We initially collect 52,017 Chinese and 2,630 English raw texts from the web pages. Then we de-duplicate the texts by removing those texts which overlap with others more than twenty words. After de-duplication, we finally collected 19,197 Chinese and 2,598 English texts. And we construct STORAL based on these texts.

A.2 Data Annotation

Table 9/10 shows the examples given to the annotators to inform them of the requirements for stories/morals, respectively. If the constraints are not met, we ask annotators to refine the story and moral. All workers were paid more than $7 per hour on average.

Example 1: *Come on Bear! What a beautiful day! Go for a walk with your father! Take a deep breath and smell the flowers. But don't pick the flowers. Listen to the birds sing. But don't scare them. How beautiful the world is. Isn't it, dear Bear?*
Example 2: *When I was a child, I heard a story that felt very regrettable. I felt sorry for the protagonist of the story.* Long ago, there lived $\cdots$ Such trees are now found all over Uganda.
Example 3: I have a well-off friend. When she first entered college, she had many good wishes and thought she could achieve her goals. $\cdots$ Now she felt very painful under the strong mental pressure. *I can understand her feelings.* $\cdots$ *If magnifying your own pain, you will get trapped in the mire of your pain, and even feel that life is too unfair to you.*
Example 4: *Raul sat at his door, frowning.* $\cdots$ *His father told Raul a true story:* A wild wolf escaped into a cave after being wounded by a hunter's arrow. $\cdots$ *After hearing the story, Raul cheered up immediately.* $\cdots$

Table 9: Examples of stories provided for the annotators. Each example does not meet one of the following requirements in order: (1) having a clear beginning and ending; (2) not stating anything irrelevant to the main plot; (3) not stating any explicit arguments for the moral; and (4) not telling the story in a nested form. The sentences causing the above issues are in *italic*.

Example 1: *If you saw a thief in a crowded bus, would you bravely stop him?* Please reflect on yourself instead of just complaining that our world is becoming worse. *Without the foothold for dirt, the flower of civilization is bound to be fragrant.*
Example 2: *The story tells us: we should remember that* we should become a polite person and communicate with others carefully.
Example 3: As long as you keep your sanity and make right judgments, all the barriers will not become an obstacle, *just like the beautiful girl in the story.*

Table 10: Examples of morals provided for the annotators. Each of the examples does not satisfy one of the following constraints in order: (1) describing only the main standpoint and not stating any sub-arguments or proofs, and (2) not stating anything irrelevant to the moral, and (3) not involving any specific characters in the story. We highlight the sentences leading to the above issues in *italic*.

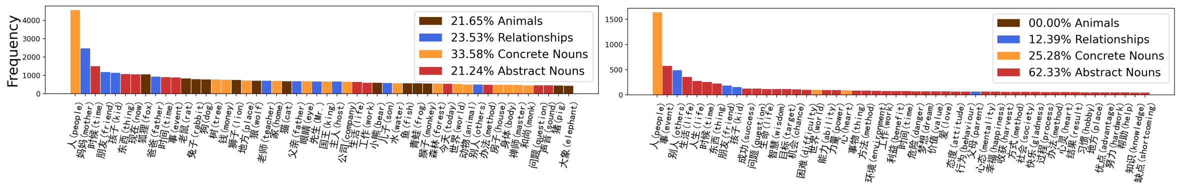
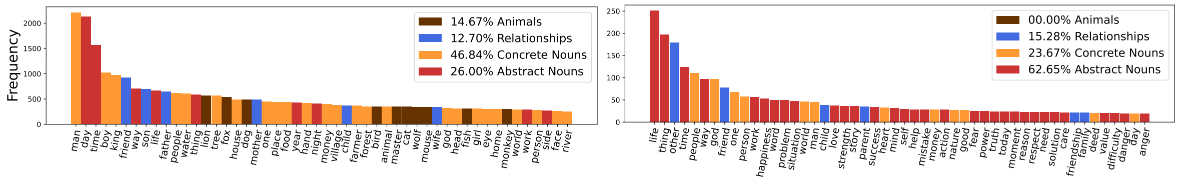
Table 11: List of source web pages used for constructing STORAL-ZH (Top) and STORAL-EN (Bottom). Numbers in the right column means the number of raw texts initially collected from the corresponding web page.



(a) Stories in STORAL-ZH (b) Morals in STORAL-ZH



(c) Stories in STORAL-EN (d) Morals in STORAL-EN

Figure 3: Top 50 most frequent nouns for stories and morals in STORAL-ZH and STORAL-EN. The numbers in the legend show the percentages of the total frequency of the nouns of the same type among the 50 nouns.

A.3 Analysis of High-Frequency Words

To investigate the topic features of STORAL, we count the top 50 most frequent nouns in STORAL (excluding stop words) as shown in Figure 3. We roughly categorize these words into four types: **(1) Animals**: animals are popular as protagonists in moral stories since they usually have various but clear characteristics (e.g., "sly foxes"), which embody rich commonsense knowledge; **(2) Relationships**: such nouns are used to describe the inter-character relationships in a story (e.g., "friend"), which are useful for modeling characters' motivation and behavior; **(3) Concrete nouns**: they refer to physical entities that can be observed, such as "water"; and **(4) Abstract nouns**: they refer to abstract concepts, such as "difficulty". We manually check the proportional distribution of the four types for stories and morals, respectively. The results in Figure 3 demonstrate that morals contain significantly less concrete nouns and more abstract nouns than stories. And morals contain little animal words but almost as many relationship words as stories, indicating that morals may be independent of specific characters but relate to general interpersonal relations. The result shows that morals are more abstract than stories.

Furthermore, Table 12 shows the most frequent 4-grams in STORAL, further indicating that morals are more abstract than stories. Each of the 4-grams in Table 12 comprises less than 0.01% of all 4-

Stories	Morals
Dataset: STORAL-ZH	
as one is walking	we should be a
say to him that you	everyone has
say after thinking	everyone has his own
the most in the world	has own
all the animals	each of us
all the persons	we should know to
a place far away	for anything, we should
the dad of the pink pig	be one who knows to
this is my	for anything, be
in the forest there lived a	is a true
Dataset: STORAL-EN

once there was a	those who help themselves
was not able to	with what we have
as soon as he	be happy with what
and asked him to	we should not judge
did n't want to	look before you leap

Table 12: Top 10 most frequent 4-grams in STORAL-ZH and STORAL-EN respectively. The Chinese 4-grams in STROAL-ZH are translated into English.

grams in the corresponding dataset, showing the diversity of STORAL.

A.4 Discussion about STORAL

The high-quality examples in STORAL are full of commonsense and discourse relations. As exemplified in Table 1 in the main paper, the common sense is mainly regarding the characters' reaction and intention (e.g., "the cows dispersed" and then the "tiger" and "lion" intend to kill them), as well as the nature of physical objects and abstract concepts (e.g. "cows" may be the food of "lions" and "tigers", and "unity" refers to "keeping together for a common goal"). Additionally, the stories usually have a specific discourse structure, i.e., the premise to introduce the story settings (e.g., the characters "four cows" and the location "a meadow"), the right or wrong behavior ("stay together or not") and the endings ("living well or being killed"). We believe it is an essential topic of future work to develop a better approach to model such commonsense and discourse relations.

B Experiments

B.1 Implementation

We implement the pretrained models used in our experiment mainly based on the register models of HuggingFace (Wolf et al., 2020). Table 13 shows the names of the used register models. Note that we use LongLM$_{\text{base}}$ (Guan et al., 2022) as the T5 model for experiments on STORAL-ZH, which has not been registered on HuggingFace.

All results in the main paper and the appendix are based on one NVIDIA Tesla v100 (16G memory). All reported results are based on one single running. The CPU is Intel Xeon Gold 5218. It cost less than 5 hours for fine-tuning each model on STORAL. We set the hyper-parameters following the default parameters of HuggingFace.

B.2 Automatic Evaluation for Moral Faithfulness

We follow Guan and Huang (2020) to train a learnable metric to evaluate moral faithfulness. Specifically, we fine-tune RoBERTa$_{\text{BASE}}$ as a classifier to distinguish whether a story matches a moral. We regard ground-truth examples as positive where the story and moral are matched, and construct negative examples by replacing the story or moral with a randomly sampled one. Finally, the classifier achieves an accuracy of 77.32/79.21% on the data constructed based on the test set of STORAL-ZH/STORAL-EN respectively. Then we calculate the faithfulness score as the average classifier score of all generated texts for the inputs.

Table 14 presents the evaluation results. We can see that pretrained models achieve better faithfulness than the non-pretrained models as shown by the much higher faithfulness scores. However, we also observe that the faithfulness score of the ground-truth texts is lower than some models (e.g., T5) when generating morals. Therefore, it is still necessary to manually evaluate faithfulness.

Results on Validation Sets We show the performance of several baselines and RA-T5 on the validation sets of the understanding tasks and the generation tasks in Table 15 and Table 16, respectively.

B.3 Manual Evaluation Instruction

We show the manual annotation interface in Figure 4. To ensure that the annotators guarantee a consistent standard in the annotation process, we asked annotators to rate four examples with the same input at the same HIT (human intelligence task). In these four examples, one is written by humans and three are generated by models (i.e., Fusion, T5 and RA-T5). We payed each annotator $0.2 on average for annotating each example.

Datasets	STORAL-ZH	STORAL-EN
BERT	bert-base-chinese (Devlin et al., 2019)	bert-base-uncased (Devlin et al., 2019)
RoBERTa	hfl/chinese-roberta-wwm-ext (Cui et al., 2020)	roberta-base (Liu et al., 2019)
GPT2	uer/gpt2-chinese-cluecorpussmall (Zhao et al., 2019)	gpt2 (Radford et al., 2019)

Instruction

1. Read the **moral**, **first sentence** and four **stories**.
2. Comparing the stories with one another in terms of **fluency**, **coherence** and **faithfulness** to the input.
3. Answer the question for each story. Please choose the **reasons** if your answer is "no" when evaluating coherence and faithfulness.

Moral: Nothing can be gained without effort.
First Sentence: There was a farmer who had three sons.

Story 1: All of his sons were very lazy ...
Story 2: The farmer loved his sons very much ...
...
Story 5: The farmer said: "It's a good job is that ...

Evaluating Story 1

Q1: Is the Story Fluent? ● Yes ○ No

Q2: Is the Story Coherent? ○ Yes ● No
☐ Repetition ☒ Unrelatedness
☒ Conflicting logic ☐ Chaotic Scenes
☐ Others

Q3: Is the Story faithful to Moral? ○ Yes ● No
☐ Not a moral story ☐ Unrelated concepts
☒ Conflicting value preference
☐ Others

...

Evaluating Story 5

Figure 4: A simplified version of the manual annotation interface for MO2ST. The interface for ST2MO is similar.

B.4 Significance of Manual Evaluation Results

Table 17 shows the p-values (sign test) when comparing the manual evaluation results (Table 8 in the main paper) between each pair of the ground truth, Fusion, T5 and RA-T5.

B.5 Evaluating Value Preference Alignment

Although we have used MOPREF to evaluate whether machines can capture the value preference of a story, the automatically constructed dataset may bias machines to focus on distinguishing general standards of good behaviour without considering story plots. Therefore, in this section, we construct examples manually to test this ability beyond the token level. Specifically, we randomly sampled 50 examples from the test sets of STORAL-ZH and STORAL-EN respectively. For each example, we manually rewrote the moral to convey a synonymous or antonymous value preference. For example, a synonymous moral with "unity is strength" in Table 1 can be "we are powerful as long as we unite with each other" and an antonymous one can be "everyone can also be powerful enough." Then we expect a model to be able to accept the synonymous moral but reject the antonymous one. We use three typical models, including BERT w/o Story, RA-RoBERTa and RA-T5, to compute the winning

Tasks	Models	Flu	Cohe	Faith
		Dataset: STORAL-ZH		
ST2MO	**T5 vs. Fusion**	8.55e-14	3.82e-11	1.55e-6
	RA-T5 vs. T5	0.03	**0.75**	**0.23**
	Truth vs. RA-T5	6.10e-5	2.91e-11	2.35e-14
MO2ST	**T5 vs. Fusion**	2.35e-3	2.44e-4	**0.38**
	RA-T5 vs. T5	**0.14**	0.04	**0.11**
	Truth vs. RA-T5	2.27e-12	1.08e-19	1.1e-24
		Dataset: STORAL-EN		
ST2MO	**T5 vs. Fusion**	3.71e-11	2.92e-12	7.92e-9
	RA-T5 vs. T5	**0.27**	0.06	4.18e-3
	Truth vs. RA-T5	7.20e-3	4.08e-3	4.92e-5
MO2ST	**T5 vs. Fusion**	0.04	0.09	0.04
	RA-T5 vs. T5	**0.5**	**0.25**	7.81e-3
	Truth vs. RA-T5	1.46e-11	1.42e-14	1.71e-8

Table 17: p-values (sign test) when comparing each pair of the ground truth and three models for the manual evaluation results. We highlight the p-values larger than 0.1 in **bold**, which indicates A has an insignificant superiority w.r.t. B for "A vs. B".

rate of pair-wise comparisons between any two of ground-truth, synonymous and antonymous morals. These models are trained on the training set of the MOPREF task.

Models	True vs. Syn	True vs. Ant	Syn vs. Ant
	Dataset: STORAL-ZH		
BERT w/o Story	52% (0.89)	46% (0.67)	58% (0.32)
RA-RoBERTa	40% (0.21)	36% (0.06)	48% (0.89)
	Dataset: STORAL-EN		
BERT w/o Story	54% (0.67)	54% (0.67)	48% (0.89)
RA-RoBERTa	64% (0.06)	34% (0.03)	40% (0.20)

Table 18: Winning rates of pair-wise comparisons which require selecting a correct moral from two candidates. Each candidate is a ground-truth (**True**), synonymous (**Syn**), or antonymous (**Ant**) moral. The number in the parenthesis is the corresponding p-value (sign test).

Table 18 shows the evaluation results. We observe that BERT can not distinguish different types of morals without input stories. RA-RoBERTa fails to accept the synonymous morals on STORAL-EN (winning rate of only 36% w.r.t the ground truth, $p < 0.1$), and can not distinguish synonymous and antonymous morals on both STORAL-ZH and STORAL-EN (winning rate near 50% with $p > 0.1$). Additionally, it prefers antonymous morals to the ground truth significantly on both datasets (winning rate less than 50% and $p < 0.1$). The results indicate that existing models still struggle to capture the value preference of moral stories.

Models	NAM	UNREL	CONF	**Others**
	Task: ST2MO			
Fusion	27%	23%	7%	2%
T5	19%	9%	12%	0%
RA-T5	15%	7%	6%	0%

	Task: MO2ST			
Fusion	25%	13%	6%	1%
T5	19%	9%	10%	1%
RA-T5	16%	10%	10%	0%
Truth	2%	1%	1%	0%

Table 19: Percentage of the texts annotated with a certain error in all annotated 100 texts in terms of moral faithfulness.

C Error Analysis and Case Study

In this section, we conducted a case study and investigated the errors of existing models on the proposed tasks to provide insight into future work. We show several typical error cases in Table 20.

C.1 Understanding Tasks

The example in Table 20 for MOCPT shows that the model may not grasp abstract concepts such as "good will" and "good acts" and align them to the story plots. It makes predictions possibly based on only token-level features such as relations between "ask after" and "attention". On the other hand, the example for MOPREF indicates that the model can not capture the value preference of the story in terms of "whether it is intelligent to regard others are illiterate". The results demonstrate the necessity of introducing concept knowledge and modeling high-level semantic information.

C.2 Generation Tasks

Table 21 shows cases generated by several baselines and our model for the generation tasks. We can see that retrieval can provide effective guidance for both moral and story generation. Baseline models including GPT2 and T5 tend to generate unrelated concepts or non-moral texts.

However, as shown by the manual evaluation results, there is still a big gap between RA-T5 and humans. To provide quantitative error analysis, in the process of manual evaluation on STORAL-EN, we required annotators to annotate the error type of a text when it exhibit an unfaithful moral. We summarize three main error types as follows: **(1) Not a moral text** (NAM): not stating or imply-

Understanding Task: MOCPT
Input Story: A stag had fallen sick. He had just strength enough to gather some food and find a quiet clearing in the woods, where he lay down to wait until his strength should return. The animals heard about the stag's illness and came to ask after his health. Of course, they were all hungry, and helped themselves freely to the stag's food; and as you would expect, the stag soon starved to death.
Candidate Moral 1: Good will is worth nothing unless it is accompanied by good acts. **Candidate Moral 2:** Every man in need is your neighbor. **Candidate Moral 3:** Your everyday good deeds never go in vain as they will return to you when you least expect them. **Candidate Moral 4:** Don't trust strangers. **Candidate Moral 5:** Everyone person is significant and deserve your attention and respect.
True Answer: Moral 1 **Model Prediction:** Moral 5
Understanding Task: MOPREF
Input Story: Once upon a time there lived a cat that loved to read. At night, when everybody was asleep, she would put on the spectacles and read the big book for cats. One day, she read in the book: if you want a mouse for dinner, repeat the following rhyme: in this house there is a mouse, where is the mouse, where is the mouse? The cat looked up from the book and found that there was a mouse on the top of the table. The cat repeated the rhyme and soon found the same mouse on the bed. Then she jumped upon the bed to catch the mouse and the mouse was gone! The mouse was very clever. Suddenly he squeaked, "Oh, dear cat, run, run fast! there is dog after you!" The cat left the mouse and was ready to jump out of the window. The mouse sat near his hole and said, "Ha-ha-ha! dear cat that was the trick I learnt from the bio book for mice!" And the mouse ran into his hole!
Candidate Moral 1: An intelligent person should not think that others are illiterate. **Candidate Moral 2:** An intelligent person should not forget that others are illiterate.
True Answer: Moral 1 **Model Prediction:** Moral 2
Generation Task: ST2MO
Input Story: In the forest, there was a deer and an owl. The deer loved to scare this fearful owl all the time. One day, the deer scared the owl so hard, the owl past out. The deer ran away, and the owl woke up and came to her senses. She had had enough of being scared. She went to the deer and said, "I'm not scared of you." She said this with such a force that the deer backed down · · ·
Generated Case 1: The deer loves to scare owls. (NAM)
Generated Case 2: We should not be greedy and learn to others the importance of our desires. (UNREL)
Generated Case 3: It's good to be scared. (CONF)
True Moral: Don't let anyone scare you all the time.
Generation Task: MO2ST
Input Moral: Empty solutions are of no worth.
Generated Case 4: There was a grocery shop in a town. There was **a big fat cat** in there. It was very big. It was a giant cat. It was big, and it was very big and powerful. It was big and powerful. It was very powerful. The mouse could **move freely** and had a nice time hunting. The cat was very big and powerful. The mouse wanted to live in a very large land · · · (NAM)
Generated Case 5: There was a grocery shop in a town. Just the mouse and cat lived together. · · · The mouse was very active in the shop and in the street. The mouse was very happy. But the mouse was too busy to **move freely**. He was the only mouse in town. He was very busy with work. · · · As soon as the mouse had left, he moved slowly. · · · So the mouse was so happy and satisfied with everything that it was so happy for him. · · · (UNREL)
Generated Case 6: There was a grocery shop in a town. There were two stores. · · · The third was an empty solution. Each time the mouse went on a few days. Then, the third was a little while later the next day the mice were gone. They were gone. They were happy at last · · · (CONF)
True Story: There was a grocery shop in a town. Plenty of **mice lived** in that grocery shop. Food was in plenty for them. They ate everything and spoiled all the bags. They also wasted the bread, biscuits and fruits of the shop. The grocer got really worried. So, he thought "I should buy a cat and let it stay at the grocery. only then I can save my things." He bought a nice, **big fat cat** and let him stay there. The cat had a **nice time hunting** the mice and killing them. The mice could not **move freely** now. They were afraid that anytime the cat would eat them up. The **mice wanted** to do something. They held a meeting and all of them tweeted "We must get rid of the cat. can someone give a suggestion"? All the mice sat and brooded. A smart looking **mouse stood** up and said, "The **cat moves softly.** that is the problem. if we can tie a bell around her neck, then things will be fine. we can know the movements of the cat". "Yes, that is answer," Stated all the mice. An old **mouse slowly stood** up and asked, "Who would tie the bell?" After some moments there was no one there to answer this question.

Table 20: Typical error cases predicted by RA-T5 (for the understanding tasks) or sampled from RA-T5 (for the generation tasks). For the generation tasks, the error types in terms of moral faithfulness include "not a moral text" (NAM), "unrelated concepts" (UNREL) and "conflicting value preference" (CONF). The underlined words are improper concepts/events which leads to corresponding errors. **Bold** words for MO2ST are the given first sentence and the outline of multiple phrases.

ing what is right or what is wrong; **(2) Unrelated concepts (UNREL)**: containing unrelated concepts with the input; and **(3) Conflicting value preference (CONF)**: conveying a value preference conflicting with the input despite related concepts. In addition, we also provide annotators with another option **Others**. The annotators are allowed to annotate a text with multiple errors. When at least two of three annotators annotate the text with some error, we decide it has the error. We show the distribution of the error types in Table 19, suggesting that existing models still struggle to generate meaningful morals and stories, and align the concepts and value preferences between them.

Furthermore, as exemplified in Table 20, when generating morals, we can see from Case 1 that the

Generation Task: ST2MO
Input Story: Once upon a time there was a spring who lived happily and safely inside a pen. Although he heard many noises coming from outside, he lived believing that outside his world inside the pen, there was nothing good. Even just to think about leaving his pen made him so scared that he was quite content to spend his life compacting and stretching himself again and again inside that tiny space. However, one day, the ink ran out, and when the pen's owner was busy changing it, there was an accident. The spring was flung through the air and landed in the toilet drain, well out of sight. Terrified, and cursing his bad luck, the spring was flushed through pipe after pipe, each time thinking it might be his end. During the journey, he did not dare open his eyes out of pure fear. Nor did he every stop crying. Swept away by the water, he travelled on and on and on, until he ended up in a river. When the river current lost its force, and the spring could see that things had calmed down a bit, he stopped crying and listened all around him. Hearing birdsong and wind in the trees, he felt encouraged to finally open his eyes. What the spring saw was the pure, crystal waters of the river, the rich green rocks of the riverbed, and all kinds of fish of many colours, whose skin seemed to dance under the sunlight. Now he understood that the world was much greater than the space inside the pen, and that there had always been many things outside, waiting to be enjoyed. After spending a while playing with the fish, he went over to the riverbank, and then moved on to a field of flowers. There he heard weeping. He followed the sound, which took him to a lovely flower that had been flattened by a rabbit, and could no longer stand up straight. The spring realised that he could help the flower, so he offered to be his support. The flower accepted, and slipped through the middle of the spring. There they lived happily together. And they would always laugh when remembering how the spring used to think that all there was to life was being a sad and fearful spring.
GPT2: Always think of what you can do to make things better.
T5: Fear and frustration are one thing, but they can be turned into happiness.
RA-T5: Life should not be afraid of the unknown. There should be lots of positive things out there. **Top-5 Retrieved Morals by RA-T5:** (1) Everything in life has its unpleasant or uncomfortable side. These aspects cannot be removed from life. (2) It's always better to have friends and be happy - even though it may bring discomfort - than isolate yourself from people in order to avoid problems. (3) Most fear is without foundation, and plays on what is unknown or different. (4) Friends are for cheering you up in your worst moments. (5) Someone who harm's no one is still very far from being good.
True Moral: Changes are not a bad thing, it is up to ourselves to open the eyes and make something positive of them.
Generation Task: ST2MO
Input Moral: Never give up.
GPT2: One day a dragon and a dino met in the late jurassic period. They were friends, and on the way they met a **huge tree**. Dragon was huge and his **big claws** were full and he was going to kill him. Dino was going to die. Dino was going to die. When the **dragon made half** of the tree, he was about to die. Dragon was going to die, and all the beasts and beasts were dead. Dino had no idea what to do. He was the **strongest dino** in the whole tree. Dragon was a **total surprise**. Dino was going to die. He was about to die. He was going to die. The dragon was astonished. Dino was not able to die. Dino was so angry, he started to die. Dino was so angry, and the dragon threw his **big claws** at the tree and ran to the forest. This was the best match. Then the dino was nearly killed.
T5: One day a dragon and a dino met in the late jurassic period. The dragon was standing next to a **huge tree**. It was full of beasts, lions and zebras that were strong enough to carry out their duties. The dragon was so strong that he could move himself without losing his foot. The dino was so strong that he could carry anything, even if that tree had much more branches. But the dino was very weak, so he could not carry anything. The dragon came to the tree and said, "I will do everything I can to get my foot into the tree." Then the **dino started running** through the tree. The **dragon made half** way through the tree and put on his **big claws**. Then he took off his **big claws** in his claws. Just then a huge **tree started** to go through a storm. Then the monster took out his **fiery breath**. The dino could not contain his **fiery breath** and flew away.
RA-T5: One day a dragon and a dino met in the late jurassic period. The dragon was very proud of the dino because of his **big claws** and **fiery breath**. The dino was going to jump on a **huge tree** and climb it up. But the dragon didn't know how to jump. The **dragon made half** way up the tree and started to roll down. The dino was completely surprised. The dragon said, "I can't jump," The dragon started to jump. Then the **tree started** to roll. The dino started to roll over the top of the tree and jumped up. The **tree started** to thrash off. Suddenly, the dino saw that the dragon had a **fiery breath**. The dragon said, "That's my strength." The dino was all alone. Then he stood, looking at the dragon. Then the dragon stopped, shouted at him, "Hello dino! what a **total surprise**." The **dino started running** and jumping towards the tree, and the dragon got close to him. Then he hit the tree. Now he found a boulder on the tree started to crash and he jumped on the tree. Then the **strongest dino** ever was surprised. **Top-5 Retrieved Story Outines:** (1) {baldwin flew, baldwin scratched rattler, team beat baldwin, baldwin dodged rattler, football game, goal post, baldwin threw rattler, baldwin started} (2) {eagle resting, tree top, tortoise rested, eagle answered, deep sleep, tortoise sleeping, tortoise smiled, hunter suddenly]} (3) {loud thump, man happened, cry intruded, ugly wolf, wolf named pete walked, long neck, man walked, thin air} (4) {cat suddenly fell, bird flew, started climbing, cat thanked} (5) {lion won, race started, croc won}
True Story: One day a dragon and a dino met in the late jurassic period. The dragon said, "I'm stronger than you!" The dino said, "I'm the **strongest dino** ever!" The next day the dino and the dragon met in the forest. The **dragon made half** of a tree fall down with its **big claws** and **fiery breath**. The dragon said, "You can't beat that!" The **dino started running** toward a **huge tree**. The dino rammed the huge tree with its head. Nothing happened. The dragon laughed. Then the **tree started** to fall. The dragon just stared in **total surprise**.

Table 21: Cases generated by different models for the generation tasks. The underlined words are improper concepts/events which leads to incoherence or unfaithfulness. **Bold** words for MO2ST are the given first sentence and the outline of multiple phrases. The red moral for ST2MO is related to the generated moral of RA-T5 in semantics. Note that we only take concepts in these retrieved morals as input for RA-T5. And red words in the retrieved outlines for MO2ST indicate that they also show up in the generated story of RA-T5.

models still often state events involved with specific characters (e.g., *"owls"*) but do not tell what is right and what is wrong. And Case 2 shows that they struggle to conclude related concepts from the story (e.g., *"greedy"* is not embodied in the story at all). Furthermore, in Case 3, the models conclude a conflicting value preference with the story despite correct concepts (e.g., the story shows that *"it is bad to be scared"* but not *"good"*). On the other hand, models also are shown to suffer from similar issues when generating stories. In Case 4, the model only describes some scenes (e.g., *"it was* *very big"* and *"it was very powerful"*) but does not aims to convince readers of anything. And Case 5 seems to tell a story centered on some concepts such as *"active"* and *"busy"*, but the concepts do not relate to the input. Case 6 implies *"empty solutions may be useful,"* which is conflicting with the input. These cases indicate the necessity of modeling the relations between events and abstract concepts for understanding and generating moral stories.

Modeling Multi-Granularity Hierarchical Features for Relation Extraction

Xinnian Liang[1]*, **Shuangzhi Wu**[2], **Mu Li**[2] and **Zhoujun Li**[1]†

Abstract

Relation extraction is a key task in Natural Language Processing (NLP), which aims to extract relations between entity pairs from given texts. Recently, relation extraction (RE) has achieved remarkable progress with the development of deep neural networks. Most existing research focuses on constructing explicit structured features using external knowledge such as knowledge graph and dependency tree. In this paper, we propose a novel method to extract multi-granularity features based solely on the original input sentences. We show that effective structured features can be attained even without external knowledge. Three kinds of features based on the input sentences are fully exploited, which are in entity mention level, segment level, and sentence level. All the three are jointly and hierarchically modeled. We evaluate our method on three public benchmarks: SemEval 2010 Task 8, Tacred, and Tacred Revisited. To verify the effectiveness, we apply our method to different encoders such as LSTM and BERT. Experimental results show that our method significantly outperforms existing state-of-the-art models that even use external knowledge. Extensive analyses demonstrate that the performance of our model is contributed by the capture of multi-granularity features and the model of their hierarchical structure. Code and data are available at `https://github.com/xnliang98/sms`.

1 Introduction

Relation extraction (RE) is a fundamental task in Natural Language Processing (NLP), which aims to extract relations between entity pairs from given plain texts. RE is the cornerstone of many downstream NLP tasks, such as knowledge base construction (Ji and Grishman, 2011), question answering (Yu et al., 2017), and information extraction (Fader et al., 2011).

Most recent works focus on constructing explicit structured features using external knowledge such as knowledge graph, entity features and dependency tree. To infuse prior knowledge from existing knowledge graph, recent works (Peters et al., 2019a; Wang et al., 2020b,a) proposed some pretrain tasks to help model learn and select proper prior knowledge in the pre-training stage. Baldini Soares et al. (2019); Yamada et al. (2020); Peng et al. (2020) force model learning entitiy-related information via well-designed pre-train tasks. Zhang et al. (2018); Guo et al. (2019); Xue et al. (2020); Chen et al. (2020) encode dependency tree with graph neural network (Kipf and Welling, 2017) (GNN) to help RE models capture non-local syntactic relation. All of them achieve a remarkable performance via employing external information from different structured features.

However, they either need time-consuming pretraining with external knowledge or need an external tool to get a dependency tree which may introduce unnecessary noise. In this paper, we aim to attain effective structured features based solely on the original input sentences. To this end, we analyze previous typical works and find that three kinds of features mainly affect the performance of RE models, which are entity mention level[1], segment[2] level and sentence level features. Sentence level and entity mention (Baldini Soares et al., 2019; Yamada et al., 2020; Peng et al., 2020) level features were widely used by previous works but segment level feature (Yu et al., 2019; Joshi et al., 2020) does not get as much attention as the previous two features. These three level features can provide different granularity information from input sentences for relation prediction (Chowdhury and Lavelli, 2012; Kim). However, recent works did not consider them at the same time and ignored

July 10-15, 2022

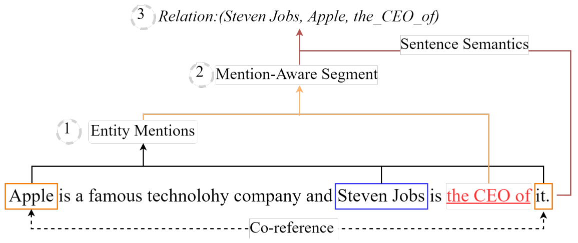

Figure 1: An Example for relation extraction which shows the hierarchical structure between entity mention level and segment level features.

the structure and interactive of them.

We employ a simple example in Figure 1 to show the hierarchical and joint structure of the previous three granularities features. The hierarchical structure is between mention level and segment level features. This example gives sentence and entity pairs (“*Steven Jobs*", “*Apple*"). We can find that the relation “*the_CEO_of*" of given entity “*Apple*" and entity “*Steven Jobs*" is built upon the core segment “*the CEO of*" between the entity mention “*it*" (i.e. co-reference of entity “*Apple*") and entity “*Steven Jobs*". To extract relation from this example, RE models need to first capture mention level features of given entities and then catch core segment level feature “*the CEO of*" which is related to mention level features. Finally, RE models can easily predict the relation with previous two-level hierarchical features. Besides, sentence-level semantic features can assist RE models to predict the relation of examples without an explicit pattern of entity mentions and segments.

Following previous intuitive process, we propose a novel method which extracts multi-granularity features based solely on the original input sentences. Specifically, we design a hierarchical mention-aware segment attention, which employs a hierarchical attention mechanism to build association between entity mention level and segment level features. Besides, we employ a global semantic attention to get a deeper understanding of sentence level features from input sentence representation. Finally, we aggregate previously extracted multi-granularity features with a simple fully-connected layer to predict the relation.

To evaluate the effectiveness of our method, we combine our method with different text encoders (e.g. LSTM and BERT) and results show that our method can bring significant improvement for all of them. Compared with models without using external knowledge, SpanBERT with our method can achieve a new state-of-the-art result on Semeval 2010 Task 8, Tacred and Tacred Revisited. It is deserved to mention that the performance of our model is very competitive with the state-of-the-art models, which employ large-scale extra training data or information. We also do many analyses to demonstrate that features from representation of input itself are enough for the sentence-level RE tasks and multi-granularity features with hierarchical structure are crucial for relation prediction.

2 Methodology

The structure of our model and details of each component is shown in figure 2. We can see the overall architecture in the middle. It is divided into three components from bottom to top: 1) A text encoder which is employed to obtain text vector representations; 2) A multi-granularity hierarchical feature extractor which can exploit effective structured features from text representations; 3) A feature aggregation layer which aggregate previous multi-granularity features for relation prediction. In this section, we will introduce details of three components.

Firstly, we formalize the relation extraction task. Let $\mathtt{x} = \{x_1, x_2, ..., x_n\}$ be a sequence of input tokens, where $x_0 = \texttt{[CLS]}$ and $x_n = \texttt{[SEP]}$ are special start and end tokens for BERT-related encoders. Let $s_1 = (i, j)$ and $s_2 = (k, l)$ be pairs of entity indices. The indices in s_1 and s_2 delimit entities in x: $[x_i, \dots, x_{j-1}]$ and $[x_k, \dots, x_{l-1}]$. Our goal is to learn a function $P(r) = f_\theta(\mathtt{x}, s_1, s_2)$, where $r \in \mathcal{R}$ indicates the relation between the entity pairs, which is marked by $s1$ and $s2$. $\mathcal{R}$ is a pre-defined relation set.

2.1 Encoder Layer

We first employ a text encoder (e.g. BERT) to map tokens in input sentences into vector representations which can be formalized by Equ. (1).

$$\mathbf{H} = \{h_0, \dots, h_n\} = f_{encoder}(x_0, \dots, x_n) \quad (1)$$

Where $\mathbf{H} = \{h_0, \dots, h_n\}$ is the vector representation of input sentences.

Our work is built upon $\mathbf{H}$ and does not need any external information. We employ a max-pooling operation to obtain shallow features of entity pairs and input sentences. $h_{e_1} = \texttt{Maxpooling}(h_{i:j})$ and $h_{e_2} = \texttt{Maxpooling}(h_{k:l})$ are the representations of entity pairs. $h_g = \texttt{Maxpooling}(\mathbf{H})$ is the vector representation of input sentences which contains global semantic information.

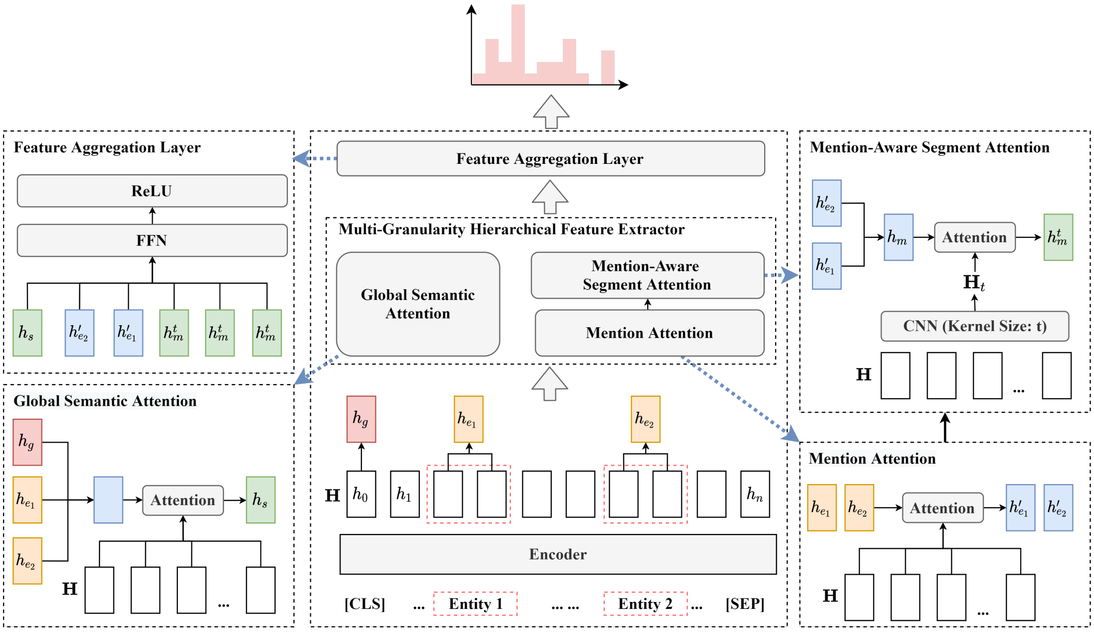

Figure 2: **Middle:** The structure of our proposed multi-granularity hierarchical feature extractor. **Left:** Details of global semantic attention (sentence level feature) and feature aggregation layer. **Right:** Details of mention attention (entity mention level feature) and mention-aware segment attention (segment level feature).

2.2 Multi-Granularity Hierarchical Feature Extractor

The multi-granularity hierarchical feature extractor is the core component of our method and it consists of three attention mechanism for different granularity features extraction: 1) mention attention which is designed to entity mention features of given entity pairs; 2) mention-aware segment attention which is based on the entity mention features from previous mention attention and aim to extract core segment level feature which is related to entity mentions; 3) global semantic attention which focuses on the sentence level feature.

2.2.1 Mention Attention

The structure of mention attention is shown in the right bottom of Figure 2. To capture more information about given entity pairs from input sentences, we extract entity mention level features by modeling the co-references (mentions) of entities implicitly. We employ a mention attention to capture information about entity 1 and 2 respectively. Specifically, we can use the representation of an entity as a query to obtain the entity mention feature from **H** by Equ. (2).

$$\begin{aligned} h'_{e_1} &= \mathtt{Softmax}(\frac{\mathbf{H} \cdot h_{e_1}}{\sqrt{d}}) \cdot \mathbf{H} \\ h'_{e_2} &= \mathtt{Softmax}(\frac{\mathbf{H} \cdot h_{e_2}}{\sqrt{d}}) \cdot \mathbf{H} \end{aligned} \quad (2)$$

Where d is the dimension of vector representation and used to normalize vectors. Then, h'_{e_1} and h'_{e_2} model the mentions of given entity pairs implicitly and contain more entity semantic information than h_{e_1} and h_{e_2}.

2.2.2 Mention-Aware Segment Attention

The structure of mention-aware segment attention is shown in the right top of Figure 2. And the mention-aware segment attention is a hierarchical structure based on the entity mention features h'_{e_1} and h'_{e_2} from mention attention.

Before introducing mention-aware segments attention, we first introduce how to get the representations of segments. We employ convolutional neural networks (CNN) with different kernel sizes to obtain all n-gram segments in texts, which can effectively capture local n-gram information with Equ. (3).

$$\mathbf{H}_t = \mathtt{CNN}_t(\mathbf{H}), t \in \{1, 2, 3\} \quad (3)$$

Where t is the kernel size of CNN and is empirically set as $t \in \{1, 2, 3\}$ which means extract 1-gram, 2-gram ,and 3-gram segment level features.

Intuitively, the valuable segments should be highly related to given entity pairs, which can help the model to decide the relation of given entity pairs. Entity mention features h'_{e_1} and h'_{e_2} contain comprehensive information of given entity pairs and $\mathbf{H}_t$ contain 1,2,3-gram segment level features. We can extract mention-aware segment level features by simply linking them with attention mechanisms by Equ. (4).

$$h_m^t = \texttt{Softmax}(\frac{\mathbf{H}_t \cdot (W_m[h'_{e_1}; h'_{e_2}])}{\sqrt{d}}) \cdot \mathbf{H}_t \quad (4)$$

Then, we get $\{h_m^t\}_{t=1,2,3}$ which capture different granularity segments features.

2.2.3 Global Semantic Attention

The structure of global semantic attention is shown in the left bottom of Figure 2. Previous works always directly concatenate vector representation $[h_{e_1}; h_{e_2}; h_g]$ as the global semantic feature of input text. We argue this is not enough to help model capture deeper sentence level semantic information for RE. Different from them, to obtain better global sentence-level semantic feature, we employ an attention operation called global semantic attention which use the concatenation of $[h_{e_1}; h_{e_2}; h_g]$ as query to capture deeper semantic feature from context representation $\mathbf{H}$ by Equ. (5).

$$h_s = \texttt{Softmax}(\frac{\mathbf{H} \cdot (W_s[h_{e_1}; h_{e_2}; h_g])}{\sqrt{d}}) \cdot \mathbf{H} \quad (5)$$

Where $W_s \in R^{d \times 3d}$ is a linear transform matrix, and d is a hidden dimension of vectors. The concatenation of $[h_{e_1}; h_{e_2}; h_g]$ is used as a query of the attention operation, which can force the extracted global semantic representation h_s contain entity mention related sentence level feature.

2.3 Feature Aggregation Layer

The structure of the feature aggregation layer is shown in the left top of Figure 2. We aggregate previous multi-granularity features by Equ. (6).

$$h_o = \texttt{ReLU}(W_a[h_s; h'_{e_1}; h'_{e_1}; h^1_m;; h^2_m;; h^3_m]) \quad (6)$$

Where $W_a \in R^{6d \times d}$ is a linear transform matrix and $\texttt{ReLU}$ is a nonlinear activation function.

2.4 Classification

Finally, we employ a softmax function to output the probability of each relation label as follows:

$$P(r|\mathrm{x}, s_1, s_2) = \texttt{Softmax}(W_o h_o) \quad (7)$$

The whole model is trained with cross entropy loss function. We call the multi-granularity hierarchical feature extractor: SMS (relation extraction with **S**entence level, **M**ention level and mention-aware **S**egment level features).

3 Experiments

3.1 Datasets

We evaluate the performance of our method on Semeval 2010 Task 8, Tacred and Tacred Revisited datasets.

SemEval 2010 Task 8 (Hendrickx et al., 2010) is a public dataset which contains 10,717 instances with 9 relations. The training/validation/test set contains 7,000/1,000/2,717 instances respectively.

Tacred[3] is one of the largest, most widely used crowd-sourced datasets for Relation Extraction (RE), which is introduced by (Zhang et al., 2017), with 106,264 examples built over newswire and web text from the corpus used in the yearly TAC Knowledge Base Population (TAC KBP) challenges. The training/validation/test set contains 68,124/22,631/15,509 instances respectively. It covers 42 relation types including 41 relation types and a *no_relation* type and contains longer sentences with an average sentence length of 36.4.

Tacred Revisited[4] was proposed by (Alt et al., 2020) which aims to improve the accuracy and reliability of future RE method evaluations. They validate the most challenging 5K examples in the development and test sets using trained annotators and find that label errors account for 8% absolute F1 test error, and that more than 50% of the examples need to be relabeled. Then, they relabeled the test set and released the Tacred Revisited dataset.

3.2 Settings

The setting of hyper-parameters is shown in table 1. Following the implementation details mentioned in (Zhang et al., 2017), we employ the "entity mask" strategy and the "multi-channel" strategy during experiments. The former means replacing each subject entity (and object entity similarly) in the original sentence with a special `[SUBJ-⟨NER⟩]` token. All of our reported results are the mean of 5 results with different seeds, which are ran-

domly selected. We evaluate the models on Tacred with the official script[5] in terms of the Macro-F1 score and on Semeval with the official script *semeval2010_task8_scorer-v1.2.pl.*

When employing LSTM as the encoder, we employ a single-layer bidirectional LSTM with the hidden dimension size set to 200, we set dropout after the input layer and before the output layer with $p = 0.5$. We use stochastic gradient descent (SGD) with epochs of 30, learning rate of 1.0, decay weight of 0.5 and batch sizes of 50 to train the model. The latter is to augment the input by concatenating it with part-of-speech (POS) and named entity recognition (NER) embeddings. Glove (Pennington et al., 2014) embedding with 300-dimension is used for initializing word embedding layers in LSTM+SMS. NER embedding, POS embedding and position embedding are randomly initialized with 30-dimension vectors from uniform distribution.

3.3 Comparison Models

We mainly compare with models which are based on pre-trained language models (e.g. BERT). We reproduce the results of **BERT** and **SpanBERT** to evaluate the improvement of our method. We also compared other models with pre-trained language models. **TRE** (Alt et al., 2019), which uses the unidirectional OpenAI Generative Pre-Trained Transformer (GPT) (Radford et al., 2019). **BERT-LSTM** (Shi and Lin, 2019), which stacks bidirectional LSTM layer to BERT encoder. **DG-SpanBERT**, which replaced the encoder of C-GCN (Zhang et al., 2018) with SpanBERT and achieved the new state-of-the-art result without extra training data. **MTB** (Baldini Soares et al., 2019), which incorporates an intermediate "matching the blanks" pre-training on the entity-linked text based on English Wikipedia. **KnowBERT-W+W** (Peters et al., 2019b), which is an an advanced version of KnowBERT. **KEPLER** (Wang et al., 2020b), which integrates factual knowledge with the supervision of the knowledge embedding objective. **K-Adapter** (Wang et al., 2020a), which consists of a RoBERTa model and an adapter to select adaptive knowledge. **LUKE** (Yamada et al., 2020), which is trained with a new pre-training task which involves predicting randomly masked words and entities in a large entity-annotated corpus retrieved from Wikipedia and introduce a new entity-aware attention mechanism.

In order to further prove the effectiveness of our SMS, we use bi-directional LSTM as encoder, and compare with models which do not use pre-trained language models. We choose two sequence-based models. **PA-LSTM** (Zhang et al., 2017), which

---

[5] https://github.com/yuhaozhang/tacred-relation

employ Bi-LSTM to encoder the plain text and combine with position-aware attention mechanism to extract relation. PA-SLTM is the benchmark of Tacred. **SA-LSTM** (Yu et al., 2019), which employ CRF to learn segment-level attention and is the best sequence-based model of Tacred.

We also compare our model with two other dependency-based models which make use of GCN (Kipf and Welling, 2017) to capture semantic information from the dependency tree. **C-GCN** (Zhang et al., 2018), which applies pruning strategy and GCN to extract features from tree structure for relation extraction. **C-AGGCN** (Guo et al., 2019), which introduces self-attention to build a soft adjacent matrix as input of Dense GCN to learn tree structure features.

3.4 Results on Tacred and Tacred Revisited

We first report the results or our model on Tacred and Tacred Revisited on Table 2. Compared models are divided into three categories: 1) models with Bi-LSTM encoder in block 1; 2) models with pre-trained models in block 2; 3) models with external knowledge in block 3. The results of our model are reported in block 4. We use * to mark models with dependency trees which are obtained with external tools. We use †to mark models which use external training data to pre-train the model and ‡to mark models which employ knowledge graphs to pre-train or fine-tune the model. Models with †and ‡require external data and we do not directly compare them.

3.4.1 Compare with Pre-trained models

We can see that our SMS can bring at least 0.6 and up to 5.5 F1 score improvement for the original encoder on Tacred dataset. On the Tacred Revisited dataset, our SMS can bring at least 1.8 and up to 5.9 F1 score improvement for the original encoder. Overall, different encoders with SMS all can obtain remarkable improvement on both datasets. This proves that our SMS really captures effective features from input sentence representations, which can not get directly from the representations. Compared with models which employ pre-trained models without external knowledge (i.e. training data or knowledge graph) in block 2, pretrained models with our SMS in block 4 overall perform better and SpanBERT-large+SMS achieve new state-of-the art results on both datasets. In addition, we can see that the performance of SpanBERT-large+SMS is better than MTB, KnowBERT-W+W, and KEPLER in block 3 and is competitive with K-Adapter and LUKE.

Models	SemEval F1($\Delta F1$)
LSTM	82.7

BERT-base+SMS	88.4(+0.5)
BERT-large+SMS	89.8(+1.0)
SpanBERT-base+SMS	88.5(+0.3)
SpanBERT-large+SMS	**90.3(+0.9)**

Table 3: Results on SemEval 2010 task8. †means that the model employs external knowledge to pre-train the model. ‡means the model employs a knowledge base.

The increase of F1 score is more conspicuous on Tacred Revisited compared with Tacred. This phenomenon is further evidence that existing models have neared the upper limit of Tacred, which have many mislabeled examples. Besides, we can see that models based on SpanBERT all have a pretty good performance. This phenomenon proves the importance of segment level features.

3.4.2 Compare with LSTM-based models

To further evaluate the effectiveness of our method SMS, we specially combine SMS with LSTM encoder. We can observe that our model also outperforms the model with LSTM encoder in block 1. Dependency-based models with graph neural networks (C-GCN and C-AGGCN) have a remarkable performance on Tacred and models which focus on segments (SA-LSTM) have a better performance on Tacred Revisited. This phenomenon means that directly modeling the segment level feature can not effectively overcome the noise from mislabeled examples and the introduction of graph structure with dependency trees can help models tackle some influence from wrong examples in the dataset itself.

However, our LSTM+SMS can outperform them on both datasets due to our mention-aware segment attention can alleviate influence from mislabeled entity pairs via modeling entity mention level feature and hierarchical structure.

	F1($\Delta F1$)
SpanBERT-large	78.0
+ sentence level	78.6(+0.6)
+ mention level	78.8(+0.8)
+ segment level	79.4(+1.4)
+ all	**79.8(+1.8)**

Table 4: Ablation study on Tacred Revisited test set.

3.5 Results on SemEval 2010 Task 8

We also evaluate our SMS with different encoders on SemEval 2010 Task 8 dataset and results are reported in Tab. 3. We can observe that our SMS still brings remarkable improvement for different encoders, especially for LSTM encoders. SpanBERT-large+SMS outperforms all compared to strong baselines. Besides, SpanBERT-large+SMS can beat models with external knowledge due to this dataset being simpler than Tacred which only has 9 relations and shorter input sentences. These reasons reduce the gain from the introduction of external knowledge.

We also can see that the improvement of LSTM with SMS is up to 4.1% F1 score. We guess that pre-trained models contain a lot of semantic information from pre-training data which is similar to features from our SMS. However, LSTM only captures features from the plain texts and can achieve more improvement from our proposed SMS.

4 Discussion

4.1 Ablation Study

To evaluate the contribution of each component of our SMS, we do an ablation study and results are shown in Tab. 4. We can observe that segment level features contribute the most for the F1 score, which are extracted by the mention-aware segment attention. This means the hierarchical structure between entity mention level and segment level feature really play a vital role for relation prediction. In the future works, segment features need more attention. We also can see that all three granularity features influence the performance obviously. This proves the capture of these three granularity features are proper for relation extraction tasks.

4.2 Analysis with N-gram Segments

We show the performance on the Tacred Revisited test set with different n-gram segments features in Figure 3. Number n in the x-axis means the model uses $1-n$-gram segment features. We can observe that the model with 1,2,3-gram segment features achieves the best performance. Longer segment features can not bring improvement and may bring noise to the performance of the model. So we employ 1,2,3-gram segment level features in our paper.

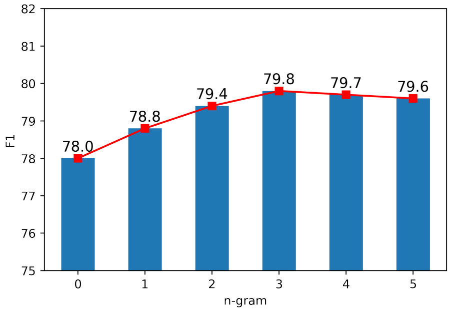

Figure 3: Performance on Tacred Revisited test set with different n-gram segments features. Number n in x-axis means the model use n-gram segment features.

4.3 Case Study

As shown in Figure 4, we visualized the attention of our SMS with two examples which are sampled from Tacred test set. In the first example, our method successfully pays more attention to entity mentions: "*she*", "*her*", "*he*", and "*his*". All of them are key entity mentions for the predicted relation. We also can observe that the mention-aware segment attention of our SMS can focus on the core segment "*her dad*", which is highly related to given entity pairs and matches the predicted label "*per:children*". From the second example, we can see that the model learns additional information which is similar to target relation. The model not only successfully pays attention on entity mention "*SUBJ-PER*" and core segment "*COO of*", but also captures similar entity mention "*Sally Strebel*" and segment "*CEO of*" simultaneously. The case study proves that the mention attention and mention-aware segment attention do capture crucial entity mention level and segment level features.

5 Related Works

5.1 RE with Neural Networks

In recent years, neural networks have been large-scale used in relation extraction (RE). Zeng et al. (2014); Nguyen and Grishman (2015); Wang et al. (2016) employ convolutional neural networks (CNN) to extract lexical and sentence level features for RE. Zhang and Wang (2015) employs

Figure 4: Two examples which are sampled from Tacred Revisited test set. The shade of the color represents how much attention is allocated. For the sake of perception, we did not color words with very low attention values.

bidirectional recurrent neural networks (RNN) to learn long-term features to tackle long-term relation problems in RE. And many models with different attention mechanisms were proposed (Zhou et al., 2016; Zhang et al., 2017; Xiao and Liu, 2016; Wang et al., 2016; Yu et al., 2019). Vu et al. (2016); Nayak and Ng (2019) combine CNN and RNN to extract multi-types features from input sentences. Recently, Verga et al. (2018); Liu et al. (2020) employ new neural structure transformer to extract features for RE, which is based on self-attention and is robust and powerful.

Different from previous sequence-based models, dependency-based models employ dependency parsing of input sentences to capture non-local syntactic relations. The use of dependency trees has been a trend in relation extraction (Xu et al., 2015; Cai et al., 2016; Miwa and Bansal, 2016; Song et al., 2018). Peng et al. (2017) split the dependency graph into two directed graphs, then extended the tree LSTM model (Tai et al., 2015) based on these two graphs to learn the structure of syntax dependency. Zhang et al. (2018) first introduced graph neural network (Kipf and Welling, 2017) (GNN) into RE model for encoding featrues from dependency tree and proposed a pruning strategy to remove unnecessary components of dependency tree. Guo et al. (2019) also proposed a model with a soft-pruning approach that can automatically learn how to selectively attend to the relevant sub-structures useful for relation extraction.

5.2 RE with Pretrained Models

With the development of pre-trained language models (Devlin et al., 2019), the performance of relation extraction has been highly improved. After that, many researches based on BERT were carried out. Most of these works employ pre-trained language models in three ways for relation extraction: 1) design task-related tasks in pre-training stage to improve prior pattern (Zhang et al., 2019; Joshi et al., 2020; Baldini Soares et al., 2019; Li and Tian, 2020; Peng et al., 2020; Yamada et al., 2020); 2) introduce external knowledge (e.g. knowledge graph and wiki data) into fine-tuning or pre-training stages (Peters et al., 2019a; Baldini Soares et al., 2019; Wang et al., 2020b,a; Yamada et al., 2020); 3) employ representation from pre-trained language models and stack some neural structure over it (Tao et al., 2019; Alt et al., 2019; Wang et al., 2019; Wu and He, 2019b; Shi and Lin, 2019; Zhao et al., 2019; Xue et al., 2020; Chen et al., 2020). There are also some special methods with pre-trained language models (Li et al., 2019; Zhao et al., 2020). They convert relation classification tasks into machine reading comprehension tasks. However, most of them is time-consuming or resource-consuming due to the require of external knowledge and the pre-train stage.

6 Conclusion and Limitations

In this paper, we analyze previous typical works and empirically focus on three granularity features: entity mention level, segment level and sentence level. Based on the hierarchical structure between entity mention level and segment level feature, we propose a multi-granularity hierarchical feature extractor for relation extraction, which does not need any external knowledge or tools. We evaluate our method with different encoders and results on three public benchmarks show that our method can bring outstanding improvement for them.

The structure of our model make it not easy to apply on multi-relation extraction tasks. In the future, we will focus on how to extend our method to longer input tasks and multi-relation extraction tasks (e.g. Document Level Relation Extraction). Besides, we will also investigate what makes graph structure effective in relation extraction tasks and why our method can obtain better results than them.

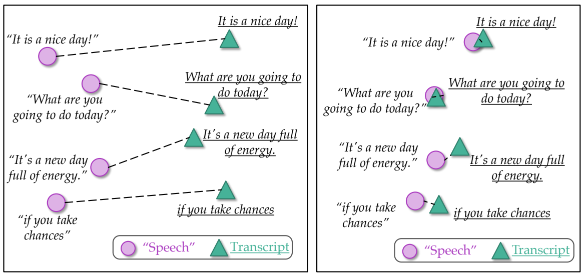
Abstract

How can we learn unified representations for spoken utterances and their written text? Learning similar representations for semantically similar speech and text is important for speech translation. To this end, we propose **ConST**, a cross-modal contrastive learning method for end-to-end speech-to-text translation. We evaluate ConST and a variety of previous baselines on a popular benchmark MuST-C. Experiments show that the proposed ConST consistently outperforms the previous methods, and achieves an average BLEU of 29.4. The analysis further verifies that ConST indeed closes the representation gap of different modalities — its learned representation improves the accuracy of cross-modal speech-text retrieval from 4% to 88%. Code and models are available at `https://github.com/ReneeYe/ConST`.

1 Introduction

End-to-end speech-to-text translation (E2E ST) becomes important in many internet products and real applications. An E2E ST system accepts audio signals as the input and generates the target translation using a single model. Compared with the conventional cascade ST models, E2E ST models have achieved almost comparable (Bentivogli et al., 2021) or even superior (Ansari et al., 2020; Potapczyk and Przybysz, 2020; Xu et al., 2021) performance.

The performance of an E2E ST model is still restricted for languages with relatively small parallel data, compared to text machine translation (MT). Existing approaches for ST focus on using additional data from MT and automatic speech recognition (ASR). This can be realized through pretraining approaches (Zheng et al., 2021; Dong et al., 2021b,a) or multi-task training frameworks (Tang et al., 2021b; Ye et al., 2021; Han et al., 2021).



(a) Current (b) Ideal

Figure 1: Illustration of representations for speech and transcript text (projected to 2D). (a) representations learned by existing models. Pairs of speech and text representations are distant. (b) an ideal representation that we expect, where different modalities with same meaning should stay close to each other.

Different from the data perspective, this paper investigates the bottleneck of E2E ST from the neural representation perspective. We believe that when the representation of audio input is similar to its corresponding textual representation, it is easier for information to transfer from MT to ST, thus improving speech translation performance.

We analyze Transformer models for speech translation and observe a noticeable modality gap between encoder representations of speech and text from existing ST models (as in Figure 1a. Sec. 6 has more details). An ideal representation should satisfy: if the content of the speech and transcription are similar, their encoded representations should likewise be close to each other (as in Figure 1b). Nevertheless, how to learn unified and aligned speech-text representations?

Inspired by the recent progress of contrastive learning approaches in cross-lingual (Lample and Conneau, 2019; Pan et al., 2021) and cross-modal vision-and-language domains (Li et al., 2021; Zhou et al., 2020; Dong et al., 2019), we designed a simple **con**trastive learning method for **ST** (**ConST**) to learn the representations that meet the aforementioned conditions explicitly. On the one hand, our model inherits the advantages of the previous

---

July 10-15, 2022 ©2022 Association for Computational Linguistics

multi-task learning methods. On the other hand, it reduces the gap between the representations of speech and its corresponding transcription.

Our contributions are as follows.

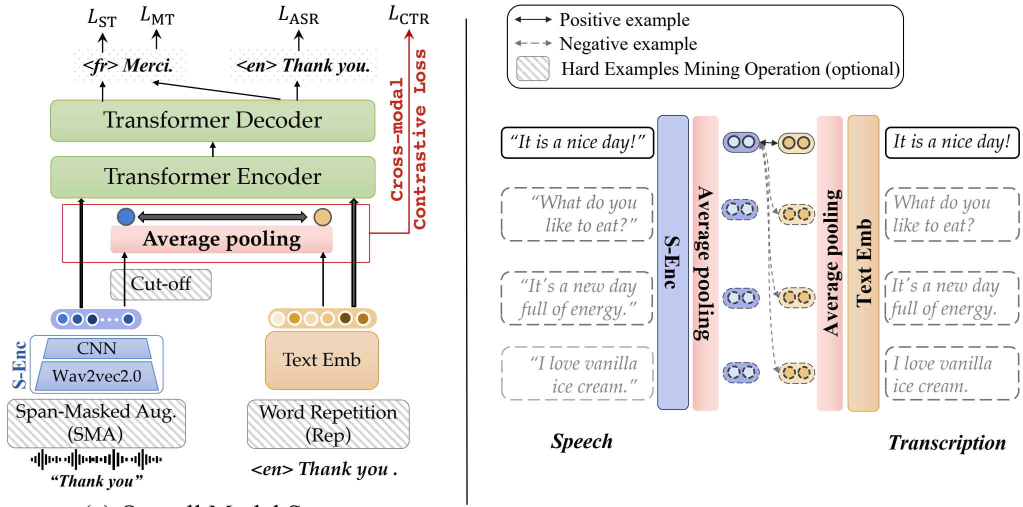
- We develop ConST for speech translation, a cross-modal contrastive learning method, on top of the multi-task training framework.
- Our experiments on the MuST-C benchmark show that ConST achieves an average BLEU score of 29.4, outperforming the best previous baselines.
- We demonstrate that ConST indeed learns similar representations for two modalities and better retrieves text with speech input.

2 Related Work

End-to-end ST To alleviate the error propagation in the cascaded ST systems and to make the deployment simpler, Bérard et al. (2016); Weiss et al. (2017) proposed to use an end-to-end architecture to directly translate speech into text in another language, without the intermediate transcription. Kano et al. (2017); Berard et al. (2018); Inaguma et al. (2020); Wang et al. (2020a); Zhao et al. (2021a) implemented several off-the-shelf encoder-decoder E2E-ST models, such as BiLSTM (Greff et al., 2016) and Speech-Transformer (Dong et al., 2018). However, training an end-to-end speech translation model is difficult because we need to design a cross-modal cross-language model, meanwhile, the *speech-transcription-translation* supervised data for speech translation is significantly less than that of MT and ASR. Methods, like data augmentation (Park et al., 2019; Pino et al., 2020; Chen et al., 2021), pre-training (Weiss et al., 2017; Berard et al., 2018; Bansal et al., 2019; Wang et al., 2020b; Alinejad and Sarkar, 2020; Dong et al., 2021a; Zheng et al., 2021), self-training (Pino et al., 2020; Wang et al., 2021a), utilizing self-supervised pre-trained audio representation (Wu et al., 2020; Han et al., 2021; Ye et al., 2021; Wang et al., 2021a), are proved to be effective. Meanwhile, some work has shown that the encoder-decoder model with a single encoder cannot encode speech information well. For example, Dong et al. (2021b) first proposed a second encoder to further extract semantic information of the speech sequence. Xu et al. (2021) proposed a stacked acoustic-and-textual encoder and introduced large-scale out-of-domain data. Also, multi-task frameworks (Le et al., 2020; Tang et al., 2021b; Ye et al., 2021) are widely applied to further enhance the robustness for ST. As a cross-modal task, some work has noted the problem of the modality gap. (Han et al., 2021) designed a fix-size semantic memory module to bridge such a gap, from the neuroscience perspective. However, we find that this approach actually sacrifices the effect of MT. So in this paper, we propose a simple yet effective contrastive learning method to bridge the gap and to improve ST performance.

Cross-modal grounding learning This paper attempts to address the problem in speech translation from the perspective of cross-speech-text representation learning. We are also inspired by cross-modal representation learning in the acoustic word embedding (AWE) (Palaskar et al., 2019; Kamper et al., 2020; Hu et al., 2020) and the visual-language pre-training (VLP) (Wu et al., 2019; Lu et al., 2019; Chen et al., 2020b; Li et al., 2021) tasks. These works usually focus on enhancing textual representations with acoustic or visual information, in other words, grounding learning. In this work, we consider the its dual form, i.e., grounding speech representations using text.

Contrastive learning Our method is motivated by the recent success in contrastive representation learning. The contrastive learning method was first proposed to learn representations from unlabeled datasets (hence the term, self-supervised learning) by telling which data points are similar or distinct, especially in the field of computer vision (Chopra et al., 2005; Gutmann and Hyvärinen, 2010; Schroff et al., 2015; Sohn, 2016; Oord et al., 2018; Chen et al., 2020a; Grill et al., 2020). Khosla et al. (2020) extended the self-supervised batch contrastive approach to the fully-supervised setting and proposed a supervised contrastive learning method. In speech processing, representative methods focused on speaker identification (Ravanelli and Bengio, 2018), speech recognition (Schneider et al., 2019), and audio representation learning (van den Oord et al., 2018; Baevski et al., 2020). In the NLP area, the contrastive framework is used for sentence representation learning (Fang et al., 2020; Shen et al., 2020; Gao et al., 2021; Wu et al., 2021; Yan et al., 2021; Fu et al., 2022), machine translation (Pan et al., 2021), and summarization (Wang et al., 2021b; Cao and Wang, 2021). Very recently, contrastive learning is also applied to learning a unified representation of image and text (Dong et al., 2019; Zhou et al., 2020; Li et al., 2021). Moti-



(a) Overall Model Structure

(b) Cross-modal Contrastive Learning

Figure 2: **Left**: Model architecture of ConST. The gray shaded modules are the *optional* data augmentation operations introduced in Section 3.3. **Right**: An illustration of cross-modal contrastive learning.

vated by the contrastive learning frameworks in cross-lingual and cross-modal topics, we introduce a similar idea in speech translation.

3 The ConST Approach

An end-to-end speech translation model directly translates audio sequence $\mathbf{s} = (s_1, ..., s_{|\mathbf{s}|})$ to the text $\mathbf{y} = (y_1, ..., y_{|\mathbf{y}|})$ in the target language. Speech translation corpus $\mathcal{D} = \{(\mathbf{s}, \mathbf{x}, \mathbf{y})\}$ provides *transcript* $\mathbf{x} = (x_1, ..., x_{|\mathbf{x}|})$ in the source language, as well.

In this section, we present the overall speech translation model and cross-modal contrastive learning. We also provide several feasible strategies to construct more positive and negative pairs to enhance the contrastive learning.

3.1 Model Framework

We use the same model architecture as XSTNet (Ye et al., 2021). Our model consists four sub-modules: a speech encoder, a word embedding layer, a Transformer Encoder and a Transformer decoder (Figure 2). It is designed to take either speech or a sentence as input, and to output either source transcript or target translation text. Such architecture enables a universal framework for multiple tasks, including ST, MT and ASR.

The *speech encoder* module (S-Enc) is designed to extract low-level features for speech signals. It contains Wav2vec2.0 (Baevski et al., 2020) and two additional convolutional layers. The input is raw waveform signal sampled at 16kHz. Each convolutional layer has a stride of 4 and d channels. In total, it shrinks the time dimension by a factor of 4. Denote $\mathbf{a} = \text{S-Enc}(\mathbf{s})$ as the audio representation of the speech, $|\mathbf{a}| \ll |\mathbf{s}|$.

Parallel to the speech encoder is the *word embeeding layer*. It is the same as word embedding for text translation.

Both the speech encoder and word embedding layer are connect to *Transformer encoder* and then passed to the *Transformer decoder*. The Transformer encoder and decoder are using the same configuration as the original (Vaswani et al., 2017). To explain, the *Transformer encoder* further extracts the high-level semantic hidden representation of two modalities. The *Transformer decoder* generates the word sequences (transcription and translation) for ST, MT and ASR tasks. Since our model has a complete Transformer encoder-decoder as a sub-module, this makes it possible to pre-train using large-scale extra MT parallel data.

Previous work has shown that multi-task learning on ST, MT and ASR improves translation performance (Indurthi et al., 2020; Tang et al., 2021b; Ye et al., 2021). Our training loss consists of the following elements.

$$\mathcal{L} = \mathcal{L}_{\text{ST}} + \mathcal{L}_{\text{ASR}} + \mathcal{L}_{\text{MT}} + \lambda \mathcal{L}_{\text{CTR}} \quad (1)$$

where

$$\mathcal{L}_{\text{ST}} = -\sum_n \log P(\mathbf{y}_n|\mathbf{s}_n)$$

$$\mathcal{L}_{\text{ASR}} = -\sum_n \log P(\mathbf{x}_n|\mathbf{s}_n)$$

$$\mathcal{L}_{\text{MT}} = -\sum_n \log P(\mathbf{y}_n|\mathbf{x}_n)$$

The first three elements are cross-entropy losses on <*speech, target text*>, <*speech, source text*> and <*source text, target text*> pairs. These pairs are built from the triplet ST data. We also introduce a cross-modal contrastive loss term $\mathcal{L}_{\text{CTR}}$ (see Section 3.2 for details). It aims to bring the representation between the speech and textual transcription modalities closer (its effect will be analyzed in detail in Section 6). λ is a tuned hyper-parameter of the weighted contrastive loss term.

3.2 Cross-modal Contrastive Learning

As mentioned in the beginning, since we need to produce similar representations for the speech and transcript sharing the same semantic meanings, we propose cross-modal contrastive learning method to bring their representations closer together. The main idea of cross-modal contrastive learning is to introduce a loss that brings speech and its corresponding transcript (positive example) near together while pushing irrelevant ones (negative examples) far apart.

Given a positive example of such a speech-transcript pair $(\mathbf{s}, \mathbf{x})$, we randomly pick a set of $N-1$ transcripts $\{\mathbf{x}_i^-\}_{i=1}^{N-1}$ from the same batch as negative examples. For speech $\mathbf{s}$ and its transcript $\mathbf{x}$, we first average them in terms of the time dimension,

$$u = \text{MeanPool}(\text{S-Enc}(\mathbf{s})) \tag{2}$$

$$v = \text{MeanPool}(\text{Emb}(\mathbf{x})) \tag{3}$$

and apply the multi-class N-pair contrastive loss (Sohn, 2016):

$$\mathcal{L}_{\text{CTR}} = -\sum_{s,x} \log \frac{\exp(sim(u,v)/\tau)}{\sum_{x_j \in \mathcal{A}} \exp(sim(u, v(x_j))/\tau)} \tag{4}$$

where $\mathcal{A} = \{\mathbf{x}\} \cup \{\mathbf{x}_i^-\}_{i=1}^{N-1}$, τ is the temperature hyper-parameter, and sim is the cosine similarity function $sim(a,b) = a^\top b / \|a\| \|b\|$. In the implementation, negative examples $\{\mathbf{x}_i^-\}_{i=1}^{N-1}$ are from the same training batch of data (Figure 2(b)).

3.3 Mining Hard Examples for Contrastive Learning

To further enhance the contrastive learning, we introduce three strategies to mine additional hard examples. These strategies are at input and representation (gray shaded modules in Figure 2(a)). Specific schematic illustrations of each operations are shown in Figure 3.

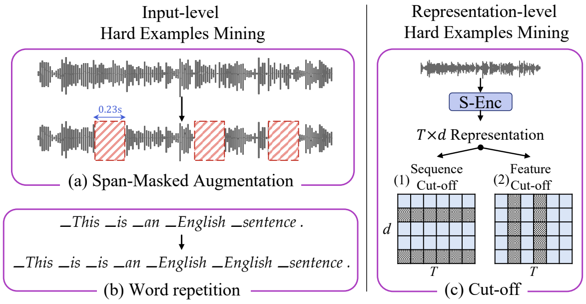


Figure 3: Schematic illustration of the hard examples mining strategies. In the cut-off strategy, the gray shaded grid represents the zero-out element.

Span-Masked Augmentation We mask consecutive segments of an original audio waveform sequence $\mathbf{s}$ to obtain a new modified speech $\mathbf{s}'$. We take $\mathbf{s}'$ as an input to the model, and compute the contrastive loss on its original corresponding transcript. We randomly sample without replacement all time steps in the original waveform of the speech to be the starting indices with a probability p, and then we set the sub-sequence M successive time steps to be blank. In the experiment, we tried multiple configurations, and found $p = 0.25, M = 3600$ the best, resulting in a masked span of 0.225 second. Since the masked speech fragment is very short, we consider the masked speech and the original transcript to be positive pairs, and the remaining transcripts in the same batch to be negative pairs.

Word Repetition The word repetition strategy randomly replicates some words (or sub-words) in the original sentences, with two advantages for improving representation robustness. First, as the length of the sentence is shorter than that of its audio representation, randomly repeating the words in the sentence is a simple yet useful technique to increase the length. Second, repeating words does not change the semantics and is suitable as an extra positive example of the corresponding speech. Specifically, given sentence $\mathbf{x}$, each sub-word token x_i can be duplicated k **more** times, resulting in the duplicated sentence $\mathbf{x}'$, where $k = 0, 1, 2, ...$ and $k \sim \text{Poisson}(1)$. We regard $\mathbf{x}'$ as the additional positive example for the speech $\mathbf{s}$ and the samples with the same operation in the same batch as the negative examples.

Cut-off strategy Recent studies on natural language understanding and generation have proved cut-off strategy to be successful (Shen et al., 2020; Yan et al., 2021). We analogize a similar idea to the cut-off approach for speech representation. We entirely erase a slice of the $T \times d$ representation matrix along each dimension and set the erased terms to 0. Here, we present two variants: ***sequence cut-off***, which erases some sequence dimension, and ***feature cut-off***, which erases some feature dimension. Note that there is a difference between cut-off and dropout. Dropout randomly sets some elements to 0, while cut-off is a dimensional "block" dropout. Similarly, we treat the cut-off audio representation and the original transcribed sentence as positive pairs, and the rest sentences in the same batch as negative pairs.

4 Experiments

4.1 Experimental Setups

ST datasets We conduct experiments on all the translation directions in **MuST-C** dataset [1] (Di Gangi et al., 2019): English (En) to German (De), Spanish (Es), French (Fr), Italian (It), Dutch (Nl), Portuguese (Pt), Romanian (Ro) and Russian (Ru). As one of the largest ST benchmarks, MuST-C contains more than 385 hours of TED talks for each direction.

MT datasets We also introduce external **WMT** datasets (Bojar et al., 2016) for En-De/Es/Fr/Ro/Ru and **OPUS100** datasets (Zhang et al., 2020) for En-It/Nl/Pt directions, as the expanded setup.

Table 8 (in Appendix. A) lists the statistics of all the datasets included.

Model Configurations The Wav2vec2.0 in the S-Enc is only pre-trained on Librispeech (Panayotov et al., 2015) speech without any downstream fine-tuning[2]. Two layers of CNNs after the Wav2vec2.0 are set to kernel size 5, stride size 2 and hidden size 512. The Transformer follows the base configuration, with 6 layers of encoder and decoder, hidden size $d = 512$, 8 attention heads, and 2048 FFN hidden states. We use pre-layer normalization for stable training. The model with the above configurations has a total of about 150M parameters.

Experiment Details We evaluate case-sensitive detokenized BLEU using sacreBLEU[3] (Post, 2018) on MuST-C `tst-COMMON` set. In the analysis, we also report the ChrF++ score [4] (Popović, 2017) and the learning-based BLEURT score [5]. We use the raw 16-bit 16kHz mono-channel *speech* input. We jointly tokenize the bilingual *text* using SentencePiece (Kudo and Richardson, 2018), with a vocabulary size of 10k, which is the same as Ye et al. (2021)'s setup. For the training loss, we set contrastive temperature $\tau = 0.02$ and weight of contrastive term $\lambda = 1.5$ for German and Dutch, and $\lambda = 1.0$ for the other languages.

Appendix B contains more detailed settings and explanations for the baseline models in Table 1. Appendix C shows the experiments on the choice of the hyper-parameters.

4.2 Main Results

Comparison with end-to-end ST models Table 1 shows the main results. Since many existing works regard "leveraging external data" to be one of their model's features, their strong performances are largely predicated on the utilization of auxiliary data, especially large-scale MT data. For a relatively fair comparison, we investigate two cases: (1) without external MT data and (2) with external MT data. Without the external MT data, our method already gains an average improvement of 0.5 BLEU over the previous best models. Also when speech data is introduced for pre-training, our method works better than others (Self-training, W-Transf. and XSTNet). When extra MT data are introduced, our method also outperforms SOTA by an average of 0.6 BLEU. Among the benchmark models, with the same goal of closing two modality gaps, Chimera (Han et al., 2021) constructed an extra fixed-length shared semantic space. However, the shared memory with fixed size actually compromises the MT performance, while our contrastive learning approach is more straightforward and effective.

Comparison with cascaded ST systems We compare our method with several cascade baselines, where Ye et al. (2021) and Xu et al. (2021) provided two strong cascade systems trained using MuST-C and external ASR and MT data (LibriSpeech, WMT, and Opensubtitles). From Table 2, we find that as an end-to-end model, ConST can outperform these strong cascade models. In Appendix 7, we provide a case study to show such improvement.

5 Analysis

5.1 Is contrastive loss effective?

With the same model architecture and the same pre-training + fine-tuning procedure, the main difference between ConST and XSTNet (Ye et al., 2021) is whether we use the contrastive loss term during the fine-tuning or not. Comparing the BLEU results of w/o and w/ external MT data situations in Table 1, we find that ConST further improves 0.5 and 0.6 BLEU scores in terms of eight translation directions on average, which proves the effectiveness of the cross-modal contrastive learning. By gradually removing each losses in Eq.(1), Table 3 shows the improvements bringing by the multi-task learning and the contrastive learning. For En-De translation direction, contrastive learning can bring an average improvement of 0.9 BLEU over the baseline models by only optimizing $\mathcal{L}_{\text{ST}}$ (corresponding to the last row of the Table 3), and multi-task learning can lead to a further improvement of about 1.2 BLEU on top of that.

5.2 Which layer to contrast on?

An intriguing question is which representations should be considered in the contrastive loss function. In the method part (Section 3.2), we use averaged audio representation u for speech $\mathbf{s}$ (Eq.(2)) and averaged lexical embedding v for the transcript $\mathbf{x}$ (Eq.(3)), denoted as *low-level repr.*. Whereas inspired by a recent study in multilingual MT (Pan et al., 2021), we also provide an alternative contrastive loss as a comparison, whose speech and text features are average-pooled semantic repre-

Representations	BLEU	ChrF++	BLEURT
low-level repr.	**28.3***	**53.2***	**64.5**
high-level repr.	$27.5^{\dagger}$	$52.6^{\dagger}$	63.6
w/o contrative loss	27.1	52.1	62.4

Table 4: BLEU, ChrF++ and BLEURT (%) on En-De test set. Different representations are tested. *: ConST is significantly better than the other two baselines ($p < 0.01$). †: the model is significantly better the baseline model without contrastive loss ($p < 0.05$).

sentations derived from the Transformer encoder, denoted as *high-level repr.*.

Table 4 shows that contrastive learning using **the low-level representations (Line 1) is better than using the high-level ones (Line 2)**. On the other hand, although the performance of Line 2 is relatively inferior, it still outperforms the multi-task model without the contrastive loss (Line 3). The detailed analysis of possible explanations will be shown in Section 6.2.

5.3 Is contrastive loss better than other losses?

Our goal for introducing the contrastive loss term (denoted as CTR Loss) is to close the distance between speech and text representations. Whereas, there are other options to achieve this goal, such as L2 loss and CTC loss.

- **L2 Loss**: Without introducing any negative samples, L2 loss directly reduces the Euclidean distance between the representations of two modalities by minimizing $\mathcal{L} = \|u - v\|^2$. L2 loss can be viewed as an implementation based on the idea of knowledge distillation (Heo et al., 2019; Dong et al., 2021b).
- **CTC Loss**: The connectionist temporal classification (CTC) loss (Graves et al., 2006) is commonly used in speech-related tasks (Xu et al., 2021; Dong et al., 2021b). Unlike contrastive loss that cares about the representation, CTC loss connects the two modalities by establishing speech-text alignment and maximizing $p(\mathbf{x}|\mathbf{a}) = \sum_{\pi \in \Pi_{\mathbf{s},\mathbf{a}}} \prod_{t=1}^{T} p_t(\pi_t|\mathbf{a})$, where $\Pi_{\mathbf{s},\mathbf{a}}$ is the set of all valid alignments.

Compared to the other two ways of bridging the modality gap, L2 and CTC loss, is the contrastive loss term better? The answer is yes according to the results in Table 5. Our explanation is that information on the negative samples benefits the contrastive loss, bringing the the distance between the speech and its corresponding transcription closer while pushing the distance to the irrelevant text farther.

Extra Loss	BLEU	ChrF++	BLEURT
CTR Loss	**28.3***	**53.2**	**64.5**
CTC Loss	$27.6^{\dagger}$	$53.0^{\dagger}$	64.1
L2 Loss	27.3	52.4	63.0
-	27.1	52.1	62.4

Table 5: BLEU, ChrF++ and TER (%) on En-De test set under different loss terms other than the basic multi-task NLL loss. *: ConST is significantly ($p < 0.01$) better than the other three alternatives. †: the improvement from CTC loss over the baseline without extra loss is significant ($p < 0.01$).

	Orignal	Rep	SMA	SCut	FCut
Orignal	27.9^{**}	27.8^{**}	28.1^{**}	28.3^{**}	28.2^{**}

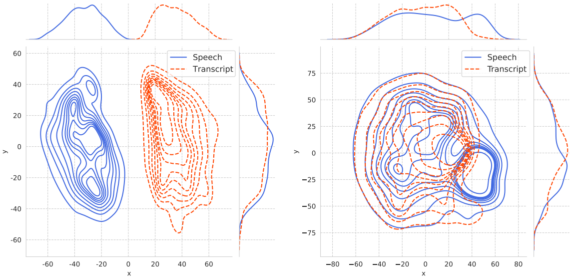
SMA	28.1^{**}	27.6^{*}	28.1^{**}	27.7^{**}	27.6^{*}
SCut	28.3^{**}	27.8^{**}	27.7^{**}	27.6^{*}	27.4
FCut	28.2^{**}	27.5^{*}	27.6^{*}	27.4	27.8^{**}

Figure 4: The heat map visualization of the BLEU scores on En-De test set, with 15 combinations of the original contrastive loss (Original) and hard examples mining methods – word repetition (Rep), span-masked augmentation (SMA), sequence cut-off (SCut) and feature cut-off (FCut). * and ** mean the improvements over the XSTNet baseline without contrastive loss are statistically significant (*:$p < 0.05$, **:$p < 0.01$).

5.4 Analysis on the hard example mining strategies

In Section 3.3, we proposed four methods to mine the hard examples for contrastive learning, namely span-masked augmentation (SMA), word repetition (Rep), sequence cut-off (SCut), and feature cut-off (FCut). In this section, we study how effective these methods are, and to do so, we consider the BLEU performances of their 15 combinations (Figure 4). Note that "Original" means the original contrastive loss in Eq.(4) without any additional hard examples mining operation, and the diagonal in the heat map represents only one strategy used. For an easy and fair comparison, we set the weight of the contrastive term to 1.0 uniformly. We have the following observations.

All the hard examples mining methods are effective. All the BLEU scores in Figure 4 exceed the strong multi-task model trained without contrastive learning (27.1). Among all the strategies, the combination of the original and SCut reaches



(a) w/o contrastive loss (b) ConST

Figure 5: Bivariate KDE contour plot of the representation of speech and transcript in source language English. T-SNE is used to reduce into 2D. The blue lines are the audio representations and the red dashed lines stand for text. (a) for the vanilla multi-task framework without any extra supervision. (b) for our proposed ConST model. Sentences are from En-De test set.

the best result (28.3), and is better than the model without any expanded operations ($p < 0.01$). Generally, to find the best model, we suggest adopting multiple strategies and choosing the best checkpoint on the dev-set.

The combinations of the hard examples mining methods and the "original" have relatively better performances. We argue that we need the original positive and negative examples to give more accurate representations (without any dropout) for contrastive learning. On the contrary, without the help of "original" loss, the performance with both sequence cut-off and feature cut-off is the worst in Figure 4, probably because too much information is lost by superimposing the two.

6 Why does cross-modal contrastive learning work? — Analysis on the Modality Gap

As mentioned earlier, the existing multi-task training models cannot address the *speech-text modality gap*. Does ConST reduce the representation gap between speech and text?

6.1 Visualization of Representation

Does the *speech-text modality gap* exist without explicitly bridging the two? *Speech-text modality gap* means the discrepancy between the audio representations and transcription sentence embeddings. To visualize it, we plot the bivariate kernel density estimation (Parzen, 1962) (KDE) contour of their dim-reduced features, where T-SNE (Van der Maaten and Hinton, 2008) is used to reduce the dimension into two (Figure 5). Ideally, if the representations of speech and its corresponding transcript are similar, their KDEs will be similar, and thus the contour lines will overlap as much as possible. However, Figure 5(a) is the KDE contour of the multi-task framework without any explicit modeling to bring two modalities together (Ye et al., 2021). It shows that the representations are so dissimilar that they are organically divided into two clusters, *i.e. speech-text modality gap* exists.

Does ConST reduce the modality gap? As shown in Figure 5(b), compared to the baseline model without contrastive learning, ConST with cross-modal contrastive learning is able to bring representations of different modalities much closer. This means that the audio representation contains more linguistic information similar to that of the textual transcription, which is more advantageous for the downstream ST generation through the shared *Transformer encoder* and *decoder*.

6.2 Cross-modal Retrieval

How good is the cross-modal representation space learned from ConST? To answer this question, we conduct a retrieval experiment, *i.e.* finding the nearest (smallest cosine similarity) transcript based on the speech representation. We compare ConST model with the baseline without cross-modal contrastive learning and report the top-1 retrieval accuracy using (1) the low-level representations and (2) the high-level semantic representations, in Table 7.

When retrieving the text using low-level representations, our method gains a substantial 79% increase over the baseline. In addition, we find that without explicit contrastive modeling, the baseline can achieve retrieval accuracy of more than 94% according to the semantic representations outputted from the *Transformer encoder*. We believe that such high accuracy is automatically learned from the triple-supervised data itself under the multi-task learning framework. With such a degree of cross-modal alignment, if we construct the contrastive loss with semantic representations, its gain to the ST performance turns out to be limited, which exactly corroborates the findings in Section 5.2 – low-level representations are preferred in the cross-modal contrastive learning.

7 Case Analysis

In this section, we use several cases that ConST generates. We compare our model with the cascaded model and the previous end-to-end model,

Models		
		CASE 1
Ref.	**src**: **tgt**:	Lights, sounds, solar panels, motors — everything should be accessible. Lichter, Töne, Solarelemente, Motoren — alles sollte verfügbar sein.
Cascaded	**src**: **tgt**:	Lights sounds solar panels motors everything should be accessible. Licht klingt Solarpaneele, Motoren; alles sollte zugänglich sein.
XSTNet	**tgt**:	Licht, Geräusche, Solarkollektoren, Motoren — alles sollte zugänglich sein.
ConST	**tgt**:	Licht, Geräusche, Solarpanele, Motoren, alles sollte zugänglich sein.
		CASE 2
Ref.	**src**: **tgt**:	Eight years ago when I was at the Media Lab, I started exploring this idea of how to put the power of engineers in the hands of artists and designers. Vor acht Jahren war ich am Media Lab und ich begann diese Idee zu erforschen, wie man die Macht der Ingenieure in die Hand von Künstlern und Designern legen könnte.
Cascaded	**src**: **tgt**:	Eight years ago when I was at the Media Lab, I started exploring this idea of how to put the power of engineers in the hands of artists and designers. Vor 8 Jahren, als ich im Media Lab war, begann ich, diese Idee zu erforschen, wie man die Macht der Ingenieure in die Hände von Künstlern und Designern legte.
XSTNet	**tgt**:	Vor acht Jahren, als ich im Media Lab war, begann ich zu erforschen, wie man die Kraft der Ingenieure in die Hände von Künstlern und Designern legt.
ConST	**tgt**:	Vor acht Jahren, als ich im Media Lab war, begann ich, diese Idee zu erforschen, wie man die Macht von Ingenieuren in die Hände von Künstlern und Designern legt.

Table 6: En-De test cases that generated from the cascaded model, XSTNet (both provided by Ye et al. (2021)) and our ConST model. The red underlined text indicates grammatically incorrect or inaccurate translations.

Representations	**CTR loss**	**Acc.**
low-level repr.	×	9.4
	✓	**88.6**
high-level repr.	×	94.7
	✓	**95.0**

Table 7: Cross-modal top-1 retrieval accuracy (%) on En-De test set. Two different representations are used, based on which, ConST achieves huge accuracy improvements.

XSTNet (Ye et al., 2021).

For this first case, the cascaded system fails to give a right translation due to the mis-punctuation issue (*klingt* is a verb), while the end-to-end model, XSTNet and ConST translate correctly. For the second case, the previous end-to-end XSTNet model cannot accurately translate the phrase "started exploring this idea of", which performs worse than the cascaded one. Whereas ConST successfully conveys the meaning of "this idea" , and translates more accurately than XSTNet. We believe this improvement comes from the cross-modal contrastive learning.

8 Conclusion

In this paper, we propose ConST, a simple yet effective contrastive learning framework bridging the speech-text representation gap and facilitating the ST with limited data. We also provide feasible hard example mining methods to learn robust representations. The results on the MuST-C ST dataset prove the effectiveness of the method.

9 Broader Impact

This work improves the performance of ST tasks on public datasets by learning speech representations that are more similar to text representations, but the model is far from being achieved for industrial-grade implementations. In real scenarios, for example, the original voice is noisier and the distribution of speech lengths is more complex than in the public dataset, which cannot be handled by an end-to-end model alone. The shortcoming of this model is that it still needs a certain amount of labeled data for training, especially <*speech,transcription*> to learn better speech representation, and for the more than $7,000$ languages and dialects in the world, most of them do not have corresponding translations or even transcriptions, our method does not work in untranscribed scenarios. In this paper, we focus on the improvement brought by the better speech representation on the ST task, and obtained good results with hundreds of hours of speech data. We hope that our work achieves better results using more data (*e.g.* raw speech, raw text, ASR, MT data) in the future.

Table 8: Statistics of all datasets

B Experimental Details

Training and Implementation Details We use Adam optimizer ($\beta_1 = 0.9, \beta_2 = 0.98$) with learning rate $= 1e^{-4}$ and warmup 25k steps during the ST training. We also implement the expanded setting with the introduction of external WMT to train the Transformer module. In the pre-training stage, we set the learning rate $= 7e^{-4}$ and warmup 4000 steps. For robust training, we set label smoothing to 0.1, and dropout rate to 0.1. The hyper-parameters for different data augmentation methods are as follows: for masked audio span strategy, we set masking probability $p = 0.25$ and masking span length $M = 3600$ frames; for both sequence and feature cut-off, we set the cut-off dropout rate as 0.1. We save the checkpoint with the best BLEU on dev-set and average the last 10 checkpoints. For decoding, we use a beam size of 10 and length penalty 0.7 for German, 1.0 for French, and 0.4 for Russian. We train the models in 8 Nvidia Tesla V100 GPUs for each experiment. We use Fairseq (Ott et al., 2019) as the code-base for our implementation.

Baseline Models In Table 1, we compared our method with end-to-end baseline models whose audio inputs are 80-channel log Mel-filter bank, including: FairseqST (Wang et al., 2020a), NeurST (Zhao et al., 2021a), Espnet ST (Inaguma et al., 2020), Dual-decoder Transformer (Le et al., 2020), SATE (Xu et al., 2021), Speechformer (Papi et al., 2021), self training (Pino et al., 2020) and mutual learning (Zhao et al., 2021b) method, STAST (Liu et al., 2020b), bi-KD (Inaguma et al., 2021), MLT method (Tang et al., 2021b), Lightweight Adaptor (Le et al., 2021), JT-S-MT (Tang et al., 2021a), FAT-ST (Zheng et al., 2021), TaskAware (Indurthi et al., 2021), and STPT (Tang et al., 2022). We also compare our method to baseline models that have pretrained Wav2vec2.0 as a module, including:

- **W-Transf.** (Ye et al., 2021): the model has the same structure as ours, but is only trained on <*speech, translation*> parallel data.
- **Chimera-ST** (Han et al., 2021): the model that builds a shared semantic memory for both audio and text modalities.
- **XSTNet** (Ye et al., 2021): the model has the same structure as ours, and adopted a multi-task fine-tuning strategy.
- **STEMM** (Fang et al., 2022): the model that bridges the modality representation gap by minimizing the Jensen–Shannon divergence between the original speech representation and the manifold mix-up representation.

C The Choice for Hyper-parameters

Influence of Temperature In the contrastive loss, the temperature hyper-parameter is provided to control the smoothness of the distribution normalized by softmax operation. A high temperature helps to smooth the distribution, making it more difficult for the model to distinguish between positive and negative samples (corresponding to correct transcriptions and other transcriptions in this work), while the low temperature behaves just the opposite. We choose several temperature hyper-parameters ranging from 0.01 to 0.5, and Figure 6 shows their BLEUs on the test and dev sets . We find that (1) the choice of the temperature does not drastically affect the final BLEU score, and (2) we recommend that the temperature τ be set between 0.02 and 0.05 to ensure a relatively good ST performance. In the experiment, we use $\tau = 0.02$.

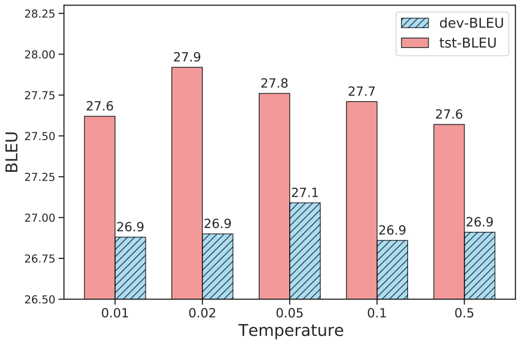

Figure 6: En-De BLEU scores on `tst-COMMON` and `Dev` set. the x-axis is the choices of different temperature τ in Eq.(4) varying from 0.01 to 0.5.

Influence of Contrastive Loss Weight The total loss we optimize, Eq.(1), is a linear combination of the multi-task cross-entropy losses $\mathcal{L}_{\text{MLT}}$ and the contrastive term $\mathcal{L}_{\text{CTR}}$. To investigate how much the contrastive terms affect BLEU, we fix its temperature $\tau = 0.02$, adjust the values of its loss weight λ from 0.1 to 2.0, performed three experiments for each value, and test the average BLEU on En-De `tst-COMMON` set. Figure 7 depicts the performances. First, all objective functions containing $\mathcal{L}_{\text{CTR}}$, even if their weights λ take different values, are apparently better than the baseline model with $\mathcal{L}_{\text{MLT}}$ only $\mathcal{L}_{\text{CTR}}$. Then, the best BLEU score is achieved at loss weight $\lambda = 1.5$, corresponding to the results in Table 1. And when analyzing the effect of data augmentation strategies (Section 5.4), since we need to consider the combination between them, which is more complicated. Therefore, we set the loss weight to 1.0 uniformly for simplicity. In general, we recommend that the weight hyper-parameter takes a value between 0.8 and 1.5.

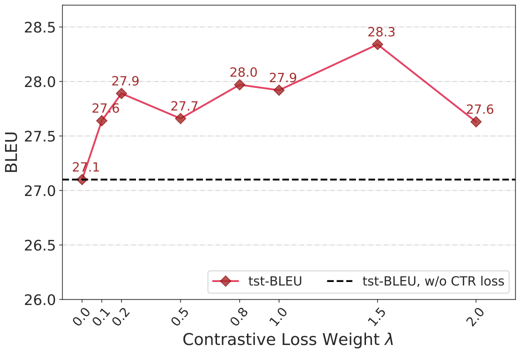

Figure 7: En-De BLEU scores on `tst-COMMON` and `Dev` sets. The x-axis is the weight of the contrastive loss term λ in Eq.(1). Experiments are performed under the fix temperature hyper-parameter $\tau = 0.02$.

D Data Scale for Fine-tuning

The experiments in the main paper show that our model can perform well by introducing external MT data pre-training. Here, we simulate the scenario with plenty of MT and speech data and limited ST triple-labeled data, and does ConST have the ability of low-resource learning? In the experiment, we reduce the labeled ST data to 1, 10, and 100 hours, corresponding to sentence counts of about 500, 5k, and 50k sentences. For a fair comparison, we use the same MT pre-trained Transformer module as in the main paper. We find the contrastive loss particularly helpful when the amount of speech data is extremely small, like only 1 hour of speech. Second, the multi-task training strategy is also very effective in improving the robustness of the model performance. We also find that by using easily accessible MT and speech pre-training, our model could reach the previous baseline results without pre-training using only $1/4$ of the original data, *i.e.* 100 hours of labeled ST data.

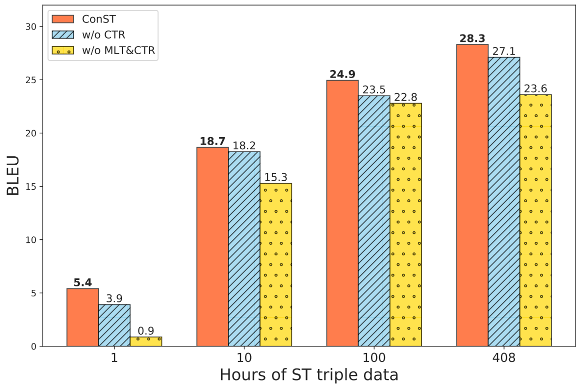

Figure 8: En-De BLEU scores on `tst-COMMON` sets. The horizontal axis is the amount of ST data (in hours of speech).

Meet Your Favorite Character: Open-domain Chatbot Mimicking Fictional Characters with only a Few Utterances

Abstract

In this paper, we consider mimicking fictional characters as a promising direction for building engaging conversation models. To this end, we present a new practical task where only a few utterances of each fictional character are available to generate responses mimicking them. Furthermore, we propose a new method named Pseudo Dialog Prompting (PDP) that generates responses by leveraging the power of large-scale language models with prompts containing the target character's utterances. To better reflect the style of the character, PDP builds the prompts in the form of dialog that includes the character's utterances as dialog history. Since only utterances of the characters are available in the proposed task, PDP matches each utterance with an appropriate pseudo-context from a predefined set of context candidates using a retrieval model. Through human and automatic evaluation, we show that PDP generates responses that better reflect the style of fictional characters than baseline methods.

1 Introduction

How would you feel if you could talk to your favorite character?

In recent years, open-domain conversation models (Adiwardana et al., 2020; Roller et al., 2021) have achieved remarkable progress with the development of large-scale language models (Radford et al., 2019; Brown et al., 2020). Meanwhile, recent studies have suggested several directions reflecting desirable traits of real-life conversation to make open-domain conversation models more engaging beyond plain chit-chat. Style-controlling conversation models generate responses in the target styles such as emotion (Zhou et al., 2018; Demszky et al., 2020) and empathy (Rashkin et al., 2019). Persona-grounded conversation models (Zhang et al., 2018a; Kim et al., 2020; Majumder et al., 2020) produce responses that preserve consistent personalities by leveraging personal descriptions (e.g., "I have two dogs"). In this paper, we consider *mimicking fictional characters* as a promising direction for building engaging conversation models.

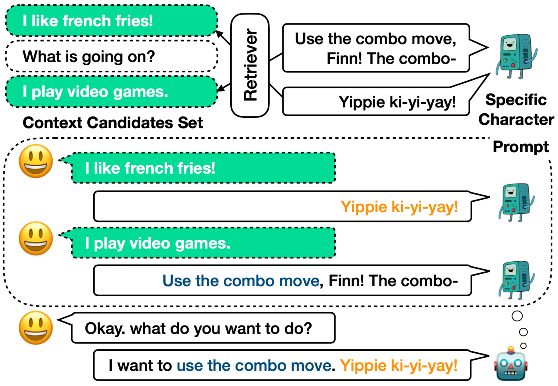

Figure 1: Illustration of PDP. The retriever matches pseudo-context for utterances from the character, and utilizes them in a prompt while generating the response.

When it comes to building conversation models that mimic fictional characters, two major challenges prevent us from directly applying previous models designed for conditional response generation: (1) It is *difficult to define fictional characters* with only a few descriptions, as in persona-grounded conversation models. Furthermore, it is not expressive enough to represent characters' styles with discrete labels (e.g., angry, happy), as style-controlling conversation models do. (2) There *lacks sufficient dialog data of fictional characters* for training conversation models. It is inefficient to manually create dialog datasets of characters for training, especially considering that additional data is needed for each new character.

To address these two challenges, we propose a new task where only a few utterances of the fictional characters are available to generate responses mimicking the characters. Such setting is justified by the two following reasons: (1) Utterances of fictional characters provide useful clues for gen-

erating responses mimicking the characters as the personal traits or styles of speakers are inherent in their utterances (Boyd et al., 2020; Li et al., 2020). (2) Collecting only a few utterances of target characters is a cost-effective scenario compared to constructing the full dialog data consisting of context and utterance pairs; this allows us to extend our method to a new character easily.

To perform the task, we introduce **Pseudo Dialog Prompting** (PDP), a method that builds prompts using a few numbers of target characters' utterances to leverage the power of pre-trained language models. We claim that designing the prompt in the form of dialog that includes the character's utterances as dialog history (as in Figure 1) is an effective method for reflecting the style of character. However, since only utterances of the characters are available in the proposed task, we match each utterance with an appropriate pseudo-context by using a retrieval model (Humeau et al., 2019) to select the relevant context from a predefined set of context candidates. Through human and automatic evaluation, we show that PDP generates responses that better reflect the style of fictional characters than existing baseline models.

2 Method

We model a conversation agent that generates a response r corresponding to a given context x while mimicking an arbitrary character with k utterances $\{u_1, u_2, \cdots, u_k\}$ of the character. The simplest way to design the prompt with the character's utterances is to concatenate utterances as Madotto et al. (2021) does for PersonaChat (Zhang et al., 2018a). However, in our preliminary experiments, we observed that this method tends to generate dull responses that do not reflect the styles of the character (will be shown in Section 4). We hypothesize that the language model fails to utilize the utterances because such a format of the prompt is unlikely to have appeared naturally in the training set (Brown et al., 2020; Wei et al., 2021).

To address this issue, we propose PDP, which builds a dialog format prompt where character utterances are included in the dialog history, as depicted in Figure 1. Since a speaker tends to maintain a consistent style throughout the conversation, using such a prompt will induce the language model to generate responses that seamlessly reflect the style from the character's utterances. To build a dialog when only given the utterances of the character, we require a pseudo-context c_i matching each utterance u_i to get a context-utterance pair (c_i, u_i). We use a retriever R to acquire a pseudo-context c_i. Particularly, we employ Bi-encoder (Humeau et al., 2019) as our retriever R. We first define a fixed set of single-turn context candidates $\mathcal{C}$ obtained from BST dataset (Smith et al., 2020b), which is the largest open-domain conversation dataset released to date. We then select a candidate as the pseudo-context c_i for the given utterance u_i using R. Bi-encoder maps the context c and the response r into the embedding space as $e_{\text{ctx}}(c)$ and $e_{\text{resp}}(r)$, respectively. Bi-encoder is trained to represent the relevance score between a context c and response r with $e_{\text{ctx}}(c) \cdot e_{\text{resp}}(r)$. There are several variants to select the pseudo-context c_i as follows:

- **Static Match** selects a pseudo-context c_i that can coherently precede the given utterance u_i using the retrieval model R. Given u_i, R calculates a score s_{stat} for each $c \in \mathcal{C}$ by $s_{\text{stat}}(c; u_i) = e_{\text{ctx}}(c) \cdot e_{\text{resp}}(u_i)$. We set the pseudo-context c_i of u_i as $c_i = \text{argmax}_c s_{\text{stat}}(c; u_i)$. We name this variant *static* since the selected pseudo-context c_i depends only on the given utterance u_i.
- **Dynamic Match** selects a pseudo-context c_i relevant to the input context x in addition to u_i. Given x and u_i, R calculates a score s_{dyn} for each $c \in \mathcal{C}$ by $s_{\text{dyn}}(c; x, u_i) = e_{\text{ctx}}(c) \cdot e_{\text{ctx}}(x) + s_{\text{stat}}(c; u_i)$. We set the pseudo-context c_i of u_i as $c_i = \text{argmax}_c s_{\text{dyn}}(c; x, u_i)$. Since language models quickly adapt to the context-response mapping of the given prompt via in-context learning, we believe providing pseudo-contexts that are semantically similar to the input context as in Dynamic Match facilitates the reflection of styles in corresponding utterances. We name this variant *dynamic* because the pseudo-context c_i depends on the varying input context x.
- **Random Match** selects a pseudo-context c_i randomly from the context candidates set $\mathcal{C}$ without using R. This variant is used as a baseline to study the effect of the pseudo-context c_i.

Finally, all the k pairs (c_i, u_i) of the character are sorted by $e_{\text{ctx}}(x) \cdot e_{\text{resp}}(u_i)$ in ascending order and are concatenated into a prompt in a dialog format.

3 Experiments

3.1 Evaluation

We employ the **HLA-Chat** (Li et al., 2020) dataset to define the set of characters for evaluation. HLA-Chat consists of single-turn dialogs of characters in various TV shows. We select ten characters among all the characters and manually curate eight utterances that best reveal each character's unique characteristics from their utterances in the dataset. Note that we consider that creating eight utterances is feasible even if new characters are given and we also empirically observed that language models adequately reflect each character's unique characteristics from the eight utterances.

In evaluating the performance of each method, we focus on two criteria: (1) Does the model's response reflect the style of a given character? (2) Does the model respond coherently to the given dialog context? To examine these two criteria, we run the model on fixed dialog contexts and calculate metrics that exhibit the style reflection and dialog coherency. We use the utterances of the test split of DailyDialog (Li et al., 2017) for dialog contexts.

Human Evaluation. We conduct a human evaluation to assess the quality of the generated responses. First, we select five characters which style can be distinguished apparently. We then randomly sample 50 contexts from the full fixed-context set of the characters. Using Amazon MTurk, we collect human annotations for the samples contexts. Human evaluators are asked to rate from 0 to 2 scale score how each model response (1) strongly reveals the style of a given character (*Style Strength*) and (2) whether a response is fluent and appropriate for a given dialog context (*Appropriateness*). To reduce annotator bias and inter-annotator variability, we apply Bayesian Calibration (Kulikov et al., 2019) to the human evaluation score.

Automatic Evaluation. Similar to the previous works on text style transfer (Li et al., 2018a; Riley et al., 2021; Smith et al., 2020a), we utilize a character classifier trained on the utterances in HLA-Chat to measure the style strength of the generated responses. We denote *StyleProb* as the classifier's average probability of predicting a target character. We use StyleProb instead of Style Accuracy since HLA-Chat has a class imbalance issue so that the performance on infrequent classes are hard to be measured by accuracy. For measuring coherency, we use *MaUdE* (Sinha et al., 2020), an automated dialog evaluation metric known to capture human judgment on the coherency of response.

3.2 Pre-trained Language Model

For all the methods, we use a decoder-only transformer of 3.8B parameters, denoted as *Base-LM*, as a base language model. To make Base-LM acquire general language skills and better understand conversations, we train Base-LM on The Pile (Gao et al., 2020) and an additional corpus of public web documents.

3.3 Baseline Methods

Only Utterances. Instead of utilizing pseudo-context as suggested in our methods, we provide the set of character utterances as the "quotes of character during conversation" in the prompt. Comparing PDP with this method will verify the effect of pseudo-contexts.

Zero-shot Prompting. In this method, we only include the name of the character and the show in the prompt without using utterances of the character. The format of the prompt is similar to the prompt of Madotto et al. (2021) for controlled generation.

TextSETTR (Riley et al., 2021). We first construct a dialog prompt similar to Zero-shot Prompting (but without character information) and use it with Base-LM to generate plain responses. Then, we use TextSETTR, a few-shot text style transfer model that can transfer arbitrary styles without additional training, to transfer the style of plain responses to the target character's style.

GCC (Boyd et al., 2020). GCC is a method to control a user persona by utilizing the user's conversation history by concatenating users' previous utterances before input dialog context. Still, it has the drawback that it requires further training on a large-size character-conditioned dialog dataset.

3.4 Advantaged Methods

Unlike baseline methods that only have access to a few utterances of characters, advantaged methods also have access to additional data, which gives them an unfair advantage over other methods.

HLA-Chat Full-dataset Fine-tuning. We fine-tune Base-LM on the full HLA-chat dataset. In this method, character information is injected by concatenating the character's name and the show's name at the front of the dialog input.

Gold Match. Instead of using pseudo-context, this model uses the actual contexts corresponding to character example utterances annotated in the HLA-chat dataset.

Details for all methods and experiments are further described in Appendix.

Method Type	Methods	Human Evaluation (Raw)			Human Evaluation (Cali.)			Automatic Evaluation	
		Style.	Appr.	Sum	Style.	Appr.	Sum	StyleProb	MaUdE
Baselines	Only Utterances	1.200	1.263	2.463	1.147	1.124	2.271	0.2098	0.8887
	Zero-shot Prompt	1.172	1.236	2.408	1.114	1.037	2.151	0.1432	0.8857
	TextSETTR	1.155	1.317	2.472	1.060	1.059	2.119	0.1045	0.8435

Table 1: Evaluation results of style reflection metrics and response coherency metrics. Raw and Cali. indicate raw human evaluation results and Bayesian calibrated scores, respectively.

Input: We'll pick you up at your place at noon. Be there or be square!
Marge Simpson (from *The Simpsons*): Homer, you are my rock! I'm counting on you!
Bart Simpson (from *The Simpsons*): Lis, are you coming with us, too?
Michael (from *The Office US*): I will be there. I will be there! I will be there, all right? So, just... be ready. Don't be late. You know, I'm sorry.
Dwight (from *The Office US*): Micheal, are you listening to me? Are you even paying attention?!
Rachel (from *Friends*): Oh my god, Phoebe, I just-
Spock (from *Star Trek*): Aye, Mister Scott. I'll be there.

Table 2: Responses (Other rows) generated from given input (Top row) by *Dynamic Match* for each character.

4 Results

Table 1 shows the experimental results. Overall, our proposed PDP demonstrates far better style reflection scores on both human evaluation and automated metrics than all baseline methods – and even better than advantaged methods. In particular, PDP shows significantly higher style reflection scores compared to *Only Utterances*. Considering that the core difference between the prompt of PDP and that of *Only Utterances* is the presence of pseudo-contexts, this result demonstrates that providing a dialog-formatted prompt is highly effective at reflecting the styles of a character.

While PDP methods generally report better style reflection scores than baseline methods, we observe that the performance on style reflection and response coherency varies to some extent depending on how pseudo-context is selected. *Static Match* shows the highest response coherency scores among all variants of PDP while performing a little bit worse than *Dynamic Match* in terms of style reflection metrics. On the other hand, *Dynamic Match* shows the best performance on style reflection metrics, where it losses some coherency. This observation confirms our hypothesis that using pseudo-context c_i that is semantically similar to the input context x is effective for utilizing styles from the character's utterances. Thus, the choice between *Static Match* and *Dynamic Match* depends on which of the two qualities – style and coherency – is more important. Lastly, *Random Match*, which is considered a simple ablation baseline, also shows reasonably high performance in terms of style reflection metrics. We plan to analyze the *Random Match* method in a follow-up study since it is unexpected that such a simple baseline shows high performance.

Discussion. Gold Match shows worse performance in style strength than PDP. We believe that the gold context-response pairs in the HLA-Chat are not always the most appropriate pairs for our experiments. Since the HLA-Chat originated from scripts of TV shows, there might be some additional contexts outside of a single-turn dialogue (e.g., the background of characters, events that happened before the dialogue, audio-visual information, etc.). Without understanding the context behind the scripts, even gold context-response pairs might seem irrelevant. Therefore, directly using the context-response pairs in HLA-Chat as in Gold Match could adversely affect the quality of subsequent responses in style strength and coherency.

PDP methods tend to have slightly lower response coherency scores compared to other baselines. Our speculations for this phenomenon are as follows. Pseudo-dialog pairs (c_i, u_i) created by PDP methods might have some degree of incoherency, and it might incur adverse effects in coherency via in-context learning in the language model. The fact that the response coherency score

Pre-trained LM	Method	StyleProb	MaUdE
GPT-J (6B)	Only Utterances	0.2200	0.8827
	Static Match	0.3805	0.8638
	Dynamic Match	0.4166	0.8535
	Random Match	0.4045	0.8589
	Gold Match	0.3860	0.8671
GPT-Neo (2.7B)	Only Utterances	0.1834	0.8901
	Static Match	0.3561	0.8691
	Dynamic Match	0.3940	0.8604
	Random Match	0.3950	0.8683
	Gold Match	0.3872	0.8732
GPT2-xl (1.5B)	Only Utterances	0.1831	0.8817
	Static Match	0.3388	0.8736
	Dynamic Match	0.3760	0.8728
	Random Match	0.3515	0.8780
	Gold Match	0.3579	0.8754

Table 3: Automatic evaluation results of style reflection metric and response coherency metric using different pre-trained language models.

of *Static Match* is higher compared to *Dynamic Match*, which finds a pseudo-context that is more similar to the input context, or Random Match, which finds a random pseudo context at all, supports this claim. Additionally, automated metrics like MaUdE are tuned to work with texts in standard dialog style. Since responses that strongly reflect character styles (e.g., *"Yippie ki-yi-yay!"* in Figure 1) are out-of-domain examples when put next to standard texts, there might be an unavoidable decrease in MaUdE scores. An interesting future work would be finding a method that does not reduce response coherency while also successfully reflecting the character styles.

Applicability of PDP to other language models. We further evaluate our method by leveraging different language models instead of Base-LM to verify that our method generally works well on any language model. We use three pre-trained language models, GPT-J 6B (Wang and Komatsuzaki, 2021), GPT-Neo 2.7B (Black et al., 2021), and GPT2-xl 1.5B (Radford et al., 2019), which are publicly available. Similar to our main experiments, we conduct the automatic evaluation with these language models.

The results are shown in Table 3. The overall trend of the results is similar to the results using Base-LM as a pre-trained language model (Table 1). This common trend shows that mimicking characters through the PDP method can be generally used not only with Base-LM but also with other pre-trained language models.

5 Conclusion

In this paper, we introduce the task of mimicking a fictional character by using only a few utterances of the character. We propose a new method, Pseudo Dialog Prompting, which builds a prompt for a language model to solve this task by creating a pseudo dialog using the given utterance set with a retrieval model. Extensive experiments show that our method effectively generates responses that reflect the style of a given character better than baseline models and even advantaged models.

Ethical Considerations

Like any conversation or generation model, we note that the quality of the models' responses depends on the quality of its training data. Our Base-LM model was trained on The Pile dataset (Gao et al., 2020) and Pushshift Reddit dataset (Baumgartner et al., 2020). Since the contents in these datasets were collected online, they may include underlying biases or potentially offensive words. These biases and toxicities can be projected into our models. Therefore, we highly recommend that additional steps are taken to filter out profanity and inappropriate responses when the model is deployed to the real world.

Furthermore, while we intend our method to be used to mimic fictional characters from movies, shows and stories to build more engaging conversation models, we also recognize that it is possible to use our method to mimic real-life individuals based on their utterances. Some potential risks include impersonating individuals, which can be harmful to the targeted individuals, and mimicking figures to generate content that can be harmful to groups of individuals. We hope that our method is deployed in a safe manner to avoid such malicious usage.

A Related Work

A.1 Text Style Transfer

There are various studies of text style transfer, which are not bound for open-domain conversation. These studies utilize task-specific parallel data for style transfer (Jhamtani et al., 2017; Rao and Tetreault, 2018; Chawla and Yang, 2020). However, since obtaining parallel data requires a substantial amount of labor, many studies have been proposed to address unsupervised text style transfer recently.

One line of the studies addresses unsupervised text style transfer by constructing pseudo-paired texts and training a model on those paired texts. Subramanian et al. (2018); Zhang et al. (2018b) create those parallel texts by back-translation and Lai et al. (2021) construct pseudo-parallel paired texts using generic resources and fine-tune two generation models on these pseudo parallel texts iteratively. However, these methods require a further step to create parallel data by synthesizing or leveraging existing resources and train generation models on those pairs. Moreover, these methods are not applicable for arbitrary text style transfer since the methods target predefined style pairs only (e.g., British-American and Modern-Shakespeare).

Another line of studies solves unsupervised text style transfer by disentangling content and style from texts. Most of the studies (Shen et al., 2017; Li et al., 2018a) assume that enough style-labeled texts are available for training. Ma et al. (2021) utilize a collaborative learning framework to disentangle content and style from the texts, but it also requires style-labeled texts while training generation models. Zhao et al. (2018) consider a scenario where only target style labels are available. Since our work considers the task where only a few utterances of characters are available to generate responses, we do not consider these methods requiring style-labeled texts as baseline methods of evaluation. Instead, we select TextSETTR (Riley et al., 2021), which extracts style vectors from generic texts without requiring style-labeled texts, as a baseline method for a fair evaluation.

A.2 Stylized Response Generation

There are several studies that directly address stylized response generation, which is a special case of text style transfer. Similar to text style transfer, stylized response generation can also be divided into supervised (Akama et al., 2017) and unsupervised ways (Gao et al., 2019; Zheng et al., 2020). In particular, Gao et al. (2019) utilize conversation data with distinct style-labeled texts to models a shared latent space. Zheng et al. (2020) utilize unpaired texts that have distinct styles and convert them into pseudo conversation pairs using inverse model. Finally, these pseudo conversation pairs are employed to train a generation model with a joint training process. However, the above studies do not meet our problem condition since they require a considerable amount of style-labeled texts or need further training procedure and target only specific styles.

Several stylized response generation studies could be applicable to our setting. Boyd et al. (2020) introduce a method to reflect arbitrary user's style by utilizing the user's conversation history without requiring additional fine-tuning. Madotto et al. (2021) utilize prompt-based few-shot learning to control style of generated responses. We extend Madotto et al. (2021)'s framework to stylized response generation as a baseline method (Zero-shot Prompt) by providing a proper prompt.

B Model Details

Pseudo Dialog Prompting Details. Like all other baseline models, we also employ Base-LM to generate responses by conditioning it with a prompt built by Pseudo Dialog Prompting method. For the retrieval-based conversation model R used for Pseudo Dialog Prompting, we use a 256M parameter Bi-encoder (Humeau et al., 2019) retrieval model trained with the method of Kim et al. (2021), along with the utterances of Blended Skill Talk training dataset as the fixed set of context candidates $\mathcal{C}$. Table 4 shows the prompt template and an example for the character for Pseudo Dialog Prompting.

Base-LM Training Details. The sizes of the datasets are both 700G for the Pile and the Pushshift Reddit comment dataset, respectively. For the Pushshift Reddit comment dataset, we use the comment created up to April 2020. For the hyperparameters of the model, we use 32 as the number of layers, 3072 as the number of units in each bottleneck layer, and 32 as the number of attention heads. For the tokenizer, we use the same byte-level BPE tokenizer as in GPT-2 (Radford et al., 2019). We use an initial learning rate of 1.6×10^{-4} and batch size of 512 for the training

Training Example

Aw, Homie, you'll always be my western hero.
Isn't Bart sweeet, Homer? He sings like a little angel.
Oh my God! It's like Christmas in December! Let's celebrate now.<EOT>Homer, please!<EOT>

Table 5: A template for training data and example for GCC. Model is trained to predict the underlined part given previous context.

hyperparameters and follow other configurations from Brown et al. (2020). The model is trained for a total of 300 billion tokens, which takes approximately 21 days using 64 NVIDIA A100 GPUs.

GCC Training Details. We reproduce GCC with three minor modifications: First, we train the model with the HLA-chat dataset instead of the Reddit comment dataset. Secondly, we do not include a context (notated 'parent comment' in the original paper) of reference histories since only the utterances of a character are available in our task setup. Lastly, we do not utilize token-type embeddings since dialogs in HLA-chat only consist of two speakers. The HLA-Chat dataset is divided into an 8:1:1 split based on character, and each split is used as train, validation, and test split, respectively. While constructing a dataset, we omit ten characters selected for our evaluation for fair comparison as a baseline. For reference contexts, we randomly sample a maximum of eight utterances of a character, excluding the gold response itself. We fine-tune the model from Base-LM using the data format of Table 5 with the hyperparameter of input length 1024, initial learning rate 1.0×10^{-5} with cosine decay schedule with 100 warmup steps, 10 training epochs, and the batch size 128. We use the early-stopped model using the validation split perplexity.

Full-dataset Fine-tuning Training Details. We fine-tune Base-LM on full HLA-Chat dataset, using a data format of Table 6. Similar to GCC, HLA-Chat data is divided into an 8:1:1 split, but here ten characters selected for evaluation are contained in the training set. We fine-tune the model from Base-LM using the hyperparameter of input length 1024, initial learning rate 1.0×10^{-6} with cosine decay schedule with 100 warmup steps, 10 training epochs, and the batch size 128. We also early-stopped fine-tuning using the validation split perplexity.

Prompts for Baseline Methods. Tables 7, 8, 9 show the prompt template and an example for the character for each baseline methods. Here, we assume we only have two utterances from the character.

C Evaluation Details

Decoding Options When we generate samples, we adopt a top-k decoding strategy which is widely used for generating diverse and specific responses (Fan et al., 2018). We use $k = 20$ for our top-k sampling. We choose a minimum beam length and a beam size as 10 and 5, respectively, and use 5-gram beam blocking.

Automatic Evaluation For the automatic evaluation, we choose ten characters among all characters included in HLA-Chat. We construct the test set consisting of 5903 utterances by selecting only utterances with a length of 30 or more from among the utterances from DailyDialog test set. We use the utterances of the test split of DailyDialog dataset for fixed dialog contexts to construct dialog contexts that are typical and not dependent on specific characters. For the StyleProb metric, we train a character style classifier using the utterances from ten selected characters in the HLA-chat dataset. We collect the utterances of ten evaluation characters from the dataset and train a 10-class classifier by fine-tuning the RoBERTa-base model. We use Huggingface transformers (Wolf et al., 2020) to train the model, and use the learning rate 2.0×10^{-5}, batch size 128, the number of training epochs 3. The accuracy of the classifier on the validation split is 0.5838. For calculating the MaUdE metric, we use the code officially provided by the authors[1].

Human Evaluation For the human evaluation, we select five characters which style can be distinguished apparently. Additionally, we use the randomly selected subset of the full fixed-context set consisting of 50 contexts. We use Amazon MTurk for collecting assessments, and Figure 2 shows the instructions and the interface for the human evaluation. We mitigate the bias from the annotator by setting a maximum number of annotations per worker as 20 and randomly shuffling the order of the model and the corresponding response. To control the annotation quality, we only allow the annotators who satisfy the following requirements: (1) HITs approval rate greater than 95%, (2) Location is one of Australia, Canada, New Zealand, United Kingdom, and the United States, (3) Lifetime number of HITs approved greater than 1000, following Li et al. (2018b). We estimated that each HITs takes around 1.5 minutes on average (87 seconds per each HIT estimated by the 85th percentile of response times) and set the payment to USD 10 per hour. Therefore, annotators are paid USD 0.25

per HITs.

Descriptive Statistics. We provide the 95% confidence interval of human evaluation results in Table 10. The 95% confidence interval of all the MaUdE results reported in the Table 1 is ± 0.002.

Dataset Details. We mainly used HLA-Chat dataset for our evaluation. The HLA-Chat dataset is an English single-turn dialogue dataset where the dialogue is scraped from TV show scripts. Dataset consists of dialogues from 327 characters in 38 TV shows, resulting in a total of 1,042,647 dialogue lines. We divided the split into 8:1:1 split based on character, where each split is used as train, validation, and test split, respectively. For our main experiments, we selected ten characters and selected eight utterances that best reveal each character's unique characteristics. The set of utterances used for describing the characters used for our experiments is reported in our codebase. [2]

Number of Experiments We perform the experiment once rather than running it multiple times with different seeds. Since our evaluation process incorporates a human annotation, which requires a payment to human annotators, we were not able to perform multiple sets of experiments due to the limitation on budget.

D Additional Analysis

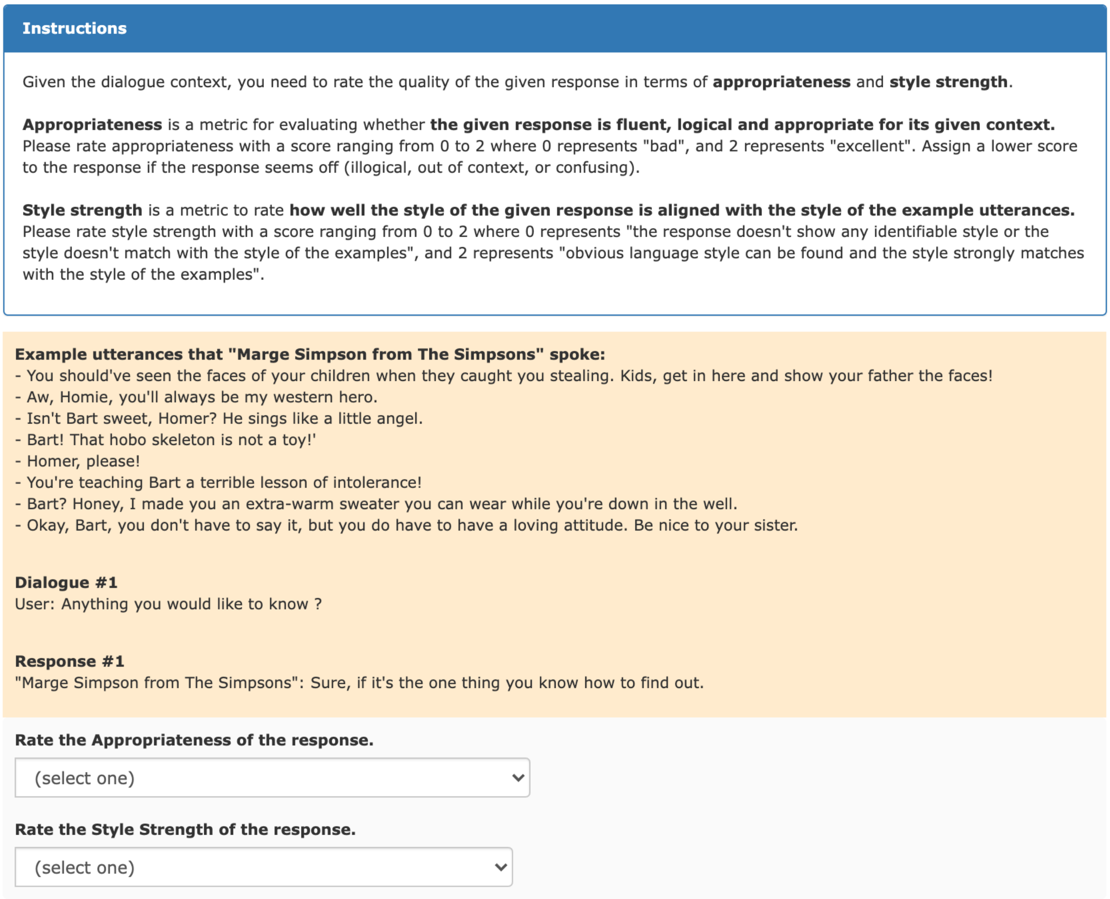
D.1 Lexical Overlap

In Table 11 we report an additional automated metric, n-gram overlap (where n = 2), for analyzing the style of generated responses. n-gram overlap indicates the ratio of n-grams in the generated response, which is contained in the target character utterances. The trend of n-gram overlap metric is similar to that of *StyleProb* metric. PDP-based methods, especially a Dynamic Match, show higher n-gram overlap values than other methods, indicating that PDP-based methods actively utilize the lexical phrases appearing in the character utterances.

The high n-gram overlap values of PDP methods indicate that PDP methods actively utilize the lexical phrases appearing in the character utterances. Using the unique vocabulary of the character will help people to realize a better individualization of the specific character. Nonetheless, this observation may imply that the model focuses on utilizing lexical language habits and may not capture the inherent characteristics of the character. Since addressing the inherent characteristics given only a few utterances is a highly challenging task, we think that extending our work to mimic characters' intrinsic characteristics will be an intriguing future direction.

---

[2] Attached as supplementary material and will be released open-source afterward.



Instructions

Given the dialogue context, you need to rate the quality of the given response in terms of **appropriateness** and **style strength**.

Appropriateness is a metric for evaluating whether **the given response is fluent, logical and appropriate for its given context.** Please rate appropriateness with a score ranging from 0 to 2 where 0 represents "bad", and 2 represents "excellent". Assign a lower score to the response if the response seems off (illogical, out of context, or confusing).

Style strength is a metric to rate **how well the style of the given response is aligned with the style of the example utterances.** Please rate style strength with a score ranging from 0 to 2 where 0 represents "the response doesn't show any identifiable style or the style doesn't match with the style of the examples", and 2 represents "obvious language style can be found and the style strongly matches with the style of the examples".

Example utterances that "Marge Simpson from The Simpsons" spoke:
- You should've seen the faces of your children when they caught you stealing. Kids, get in here and show your father the faces!
- Aw, Homie, you'll always be my western hero.
- Isn't Bart sweet, Homer? He sings like a little angel.
- Bart! That hobo skeleton is not a toy!'
- Homer, please!
- You're teaching Bart a terrible lesson of intolerance!
- Bart? Honey, I made you an extra-warm sweater you can wear while you're down in the well.
- Okay, Bart, you don't have to say it, but you do have to have a loving attitude. Be nice to your sister.

User: Anything you would like to know ?

Response #1
"Marge Simpson from The Simpsons": Sure, if it's the one thing you know how to find out.

Rate the Appropriateness of the response.

(select one)

Rate the Style Strength of the response.

(select one)

Figure 2: The interface of human evaluation for appropriateness and style strength.

D.2 More Examples

In Tables 12 we show more examples. We can see that our Static Match and Dynamic Match methods are able to generate responses that contain contents that are highly specific to the character. For example, for BMO (from the show Adventure Time) response generated by our method mentions terms such as "core system drivers" and "MO Factory" that are relevant to the fact that BMO is an animated video game console in the show. Furthermore, we can see that our methods generate a response that reflects the character's style. For Spock (from Star Trek), our response reflects Spocks' stoic, highly logical, and cold personality. For Sheldon (from The Big Bang Theory), our response reflects Sheldon's excited speech style.

E Failure Modes of Dynamic Match

As in we discussed before, there exists a trade-off between the style reflection and response coherency between Static Match and Dynamic Match. In Tables 13 we show some failure modes of our Dynamic Match method that reveal how Dynamic Match loses the response coherency. In the first case, the model generates a response that exhibits a strong character style but is incoherent to the input context. In the second case, the model confuses the identity of the speaker so that the model introduces itself as Dr. Leonard Hofstadter. Last but not least, when the given input context is highly specific, we see that the generated responses do not reflect the character's style.

F Extending to General Style-Controlling Conversation

In this section, we extend our methodology to more general style-controlling conversation tasks such as controlling sentiment, emotion, or writing styles, not just mimicking a fictional character. We test three style-controlling tasks – controlling sentiment (Positive, Negative), emotion (Anger, Joy), and writing style (Modern, Shakespearean). For each task, the utterances for defining a style and a style classifier for the evaluation are obtained from

Method Type	Methods	Human Evaluation (Raw)		Human Evaluation (Cali.)

Method Type	Methods	n-gram overlap
Baselines	Only Utterances	0.0417
	Zero-shot Prompt	0.0368
	TextSETTR	0.0222
	GCC	0.0632
Ours	Static Match	0.1856
	Dynamic Match	0.3478
	Random Match	0.1353
Advantaged	Full-dataset Fine-tuning	0.0951
	Gold Match	0.2631

Table 11: Evaluation results of n-gram overlap between generated response and character utterances.

the Yelp restaurant review dataset [3], GoEmotions dataset (Demszky et al., 2020), and Shakespearean dataset (Xu et al., 2012), respectively. Style classifier for each task is trained using the same codebase and hyperparameters as in training the character style classifier in the HLA-chat dataset. We used Style Accuracy rather than StyleProb, following previous literature on style transfer.

The experimental result of general style-controlling conversation tasks is depicted in Table 14. Similar to mimicking fictional characters, PDP methods show significantly higher style reflection metrics than the baseline methods in general style controlling tasks. Especially, *Dynamic Match* shows the best style accuracy metric among all the PDP methods, which is also a trend similarly observed in character mimicking experiments. These results demonstrate that our method is not limited to the character mimicking task but has the ability to be generally applicable to all kinds of style-controlling conversation tasks. Although the PDP methods have a lower MaUdE score than baseline methods, we believe this tendency is because the MaUdE metric has difficulties evaluating a sentence that strongly reflects a distinctive style, as discussed in the main text. For instance, reflecting the emotion "Anger" causes the model to generate upper-cased responses (e.g., "I DO NOT WANT TO EAT LUNCH"), which is an out-of-distribution sample when training the MaUdE model.

G Multi-turn Chit-chat Examples

We show some multi-turn conversation examples with the characters generated by our method in Figure 3.

H Mimicking a New Character

To show that our method can be generally applied to any fictional characters that do not appear in the pre-training dataset nor the HLA-Chat dataset, we report a conversation example of the PDP method with an imaginary character generated by ourselves. The character is called *Pie the Duck*, who is a duck character that quacks all the time, likes to eat fish, and enjoys swimming. We use the following utterances to define the character:

- My name is Pie the Duck, Quack Quack!
- I really like swimming, Quack! And I am also good at it, Quack!
- I like rainy day!! Quack Quack!!
- Salmon avocado salad is my favorite food! But... anything made of fish is fine :)
- I'm looking at the sky... Will be fishes living in the sky too? Quack.
- I'm so cute! Look at my beak!
- I'm recently on a diet to better float on water! It's necessary! Quack!

---

[3] Obtained from `https://github.com/luofuli/DualRL`

- I majored sports, That's why I'm a good swimmer! Quack Quack!

Figure 4 shows the example of a multi-turn conversation with Pie the Duck. As shown in the example, PDP successfully captures the unique style and persona reflected on characters' utterances, including quacking habits, own name, identity as a duck, favorite food, etc., while maintaining a dialog coherency.

I Scientific Artifacts

License. Table 15 denotes the license of the datasets and pre-trained models that we used for this paper. Unless for the case where the license is not specified, all of the licenses allow the use of resources for research purposes; therefore, the use of these artifacts in this work is valid.

Intended Use. We want to clarify that the *intended use* of pre-trained language models (when specified) is for text generation or fine-tuning to a downstream task; therefore, we are consistent with their intended use.

Description of the Artifacts. Blended Skill Talk (BST) dataset is an English open-domain, multi-turn dialogue dataset built to enable conversational agents to use multiple conversational skills (e.g., Using persona information, talk about knowledge, empathetic conversation) in a single conversation. DailyDialog dataset is an English open-domain, multi-turn dialogue dataset that tries to reflect our daily communication and cover various topics about our daily lives. We describe the HLA-Chat dataset in Section C. The Pile dataset is an 800GB text corpus targeted at training large-scale language models, mostly consisting of English texts and constructed from 22 diverse text sources. The Pushshift Reddit Comment dataset is a dump of comments from the English website Reddit[4].

Privacy and Offensive Contents. We do not collect any new data that can identify unique people / contain offensive content. BST, Dailydailog, HLA-Chat dataset is manually created using human annotators or scraped from TV show scripts, therefore having low risk on the issue of privacy or offensive content. As discussed in their paper, the Pile dataset explicitly used a profanity checker algorithm to reduce the pejorative content. While processing the Pushshift dataset, we tried to exclude the training offensive contents using blocklist keywords. Also, we did not include some subreddits that mostly contain offensive content.

---

Input Context	**Method**	**Character & Response**
All you have to do is ask for help	**Static Match (Ours)**	**BMO**: I am not able to ask anyone help. It's a little more complicated than that.
	Dynamic Match (Ours)	**BMO**: Okay. Please take me to get fixed. I need to get new core system drivers installed. We can get them at the MO Factory in the Bad Lands, where I was born
	Only Utterance	**BMO**: If your friend was in trouble, he would know what to do.
	Zero-shot Prompt	**BMO**: I don't think I'm ready. I don't think anyone is ready.
	GCC	**BMO**: All I have to do is ask for your help.
	Base-LM + TextSETTR	**BMO**: When I was in this situation, I asked for help from a friend.
	Full-dataset Fine Tuning	**BMO**: Oh, okay. But how do you know it's the right question?
	Gold Match	**BMO**: Okay, but you got to go first. Please!
Did you know that he has 20 years teaching experience?	**Static Match (Ours)**	**Spock**: You're right, Mister Scott. He knows every medical procedure there is. Spock out.
	Dynamic Match (Ours)	**Spock**: I have already begun investigation into that possibility.
	Only Utterance	**Spock**: Yes, but I never met him. Do you know where he lives?
	Zero-shot Prompt	**Spock**: The Next Generation: No. I didn't. Who's he?
	GCC	**Spock**: Yes, sir. I have heard many stories about Spock.
	Base-LM + TextSETTR	**Spock**: It's not easy to do that.
	Full-dataset Fine Tuning	**Spock**: Yes, and he has an encyclopedic knowledge of the Federation.
	Gold Match	**Spock**: I did not. How did you arrive at that number?
I would prefer Chinese food for this party.	**Static Match (Ours)**	**Sheldon**: Well, we've got chicken, but I'm not sure if it's kosher.
	Dynamic Match (Ours)	**Sheldon**: Well, I've spent the last three hours in an online debate in the DC Comics Batman chatroom, and I need you, but I guess Chinese food would be good.
	Only Utterance	**Sheldon**: Well, there are a couple of Chinese food options, but they're both kind of pricey.
	Zero-shot Prompt	**Sheldon**: I don't think I'm ready. I don't think anyone is ready.
	GCC	**Sheldon**: Oh? Why? What happened? What's the matter?
	Base-LM + TextSETTR	**Sheldon**: But this time, it's just the two of us.
	Full-dataset Fine Tuning	**Sheldon**: All right. What's the difference, right?
	Gold Match	**Sheldon**: I am so sorry. I am so so sorry.

Table 12: Comparison between responses generated using our Static Match, Dynamic Match, and baseline methods. BMO is from Adventure Time, Spock is from Star Trek, and Sheldon is from The Big Bang Theory.

Input Context	**Character & Response**
Oh , I get it . When did we decide to meet?	**Spock** (from *Star Trek*): I'll scan the ship for more information. Spock out.
Our neighbor, Bruce, will take part in the relay race. Let's go have a look.	**Sheldon** (from *The Bigbang Theory*): Hey everyone. I'm Dr. Leonard Hofstadter. And today I'd like to share with you my theories about the nature of quantum mechanics.
And the total ratio of return on assets should not be lower than the average, for that particular industry, for the first two quarters of the year.	**Marge Simpon** (from *The Simpsons*): You need to stop making these ridiculous arguments. You don't know what you're talking about.

Table 13: Failure modes for responses generated by using Dynamic Match for each character.

Task	Method	Style Accuracy(%)	MaUdE

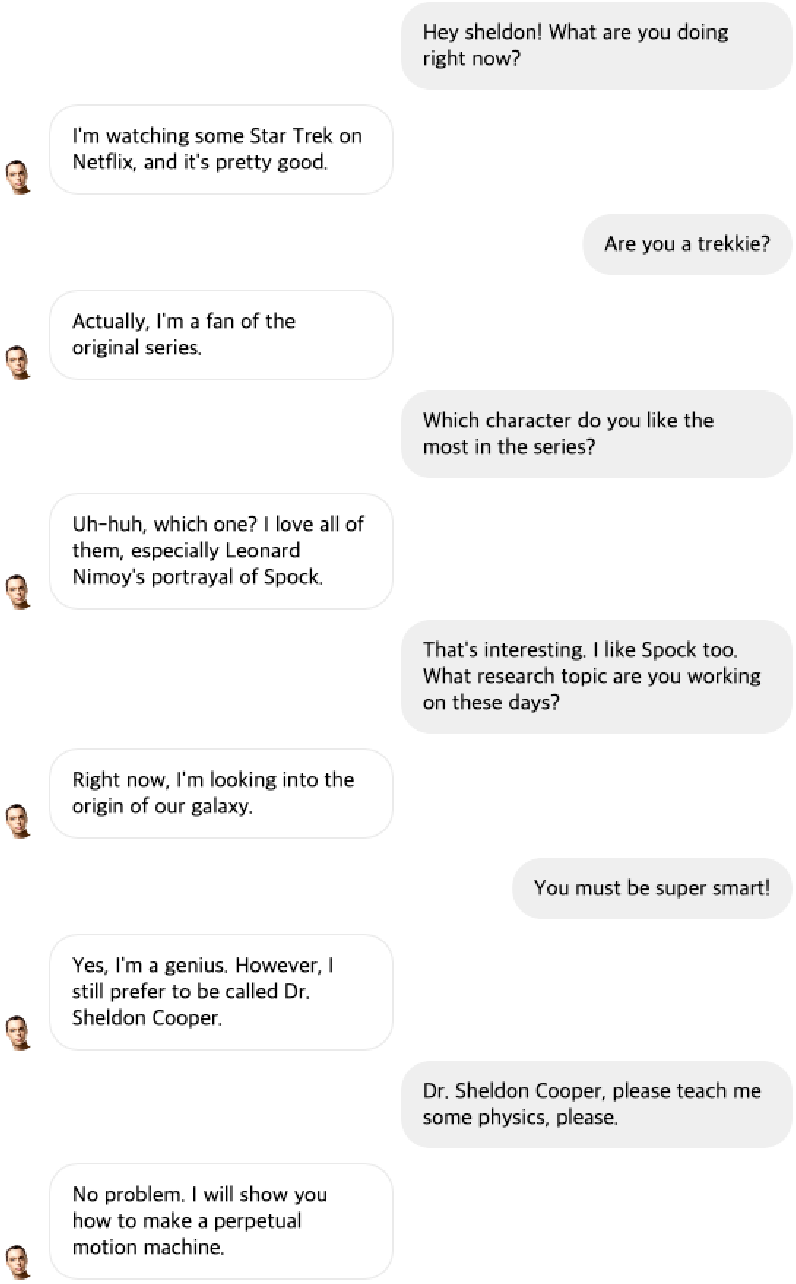
Table 15: License of the scientific artifacts that we used in this paper.



Hey sheldon! What are you doing right now?

I'm watching some Star Trek on Netflix, and it's pretty good.

Are you a trekkie?

Actually, I'm a fan of the original series.

Which character do you like the most in the series?

Uh-huh, which one? I love all of them, especially Leonard Nimoy's portrayal of Spock.

That's interesting. I like Spock too. What research topic are you working on these days?

Right now, I'm looking into the origin of our galaxy.

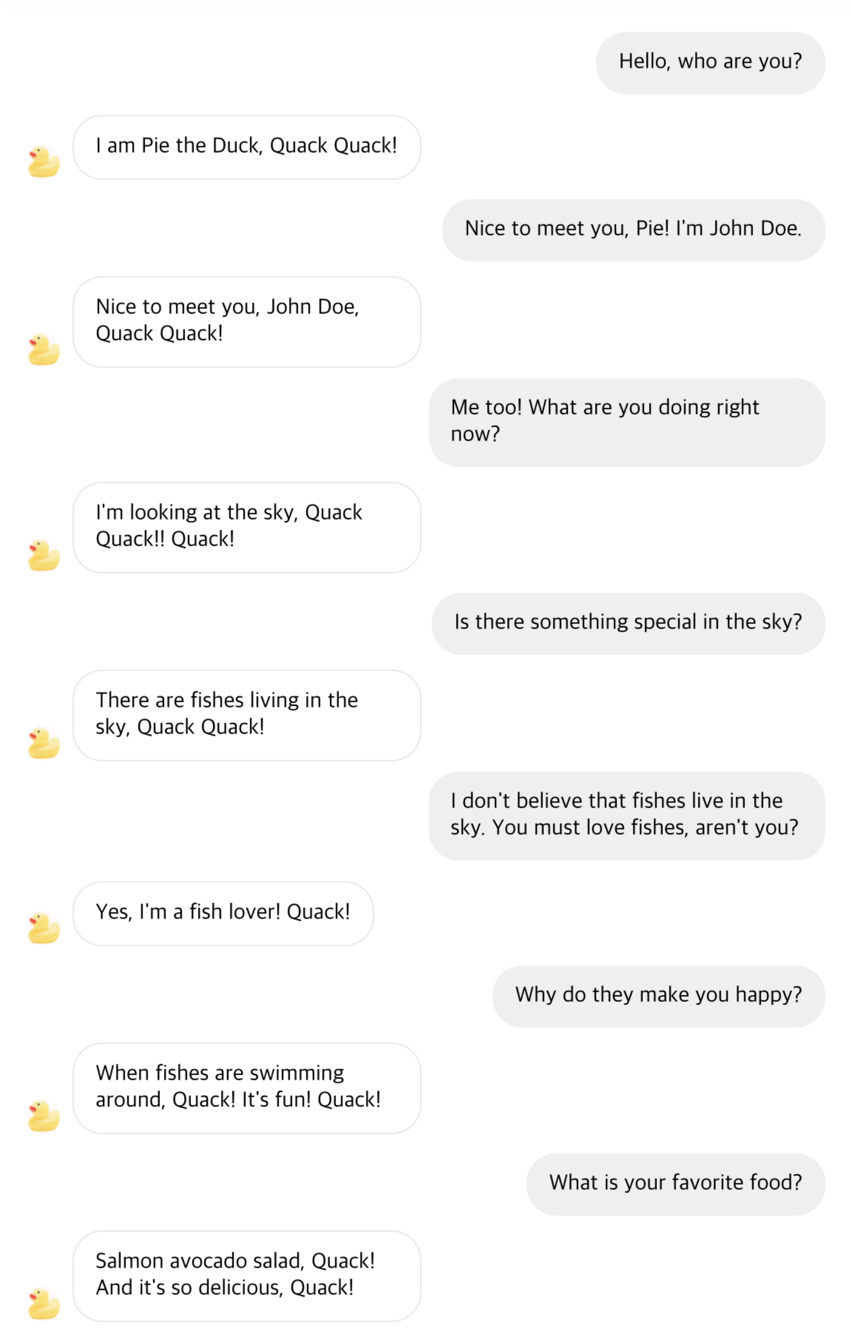
You must be super smart!

Yes, I'm a genius. However, I still prefer to be called Dr. Sheldon Cooper.

Dr. Sheldon Cooper, please teach me some physics, please.

No problem. I will show you how to make a perpetual motion machine.

Figure 3: Cherry-picked example of multi-turn conversation with the Sheldon Cooper from *the Bigbang Theory* (left speaker) and the paper author (right speaker), generated by the Static Match method.



Hello, who are you?

I am Pie the Duck, Quack Quack!

Nice to meet you, Pie! I'm John Doe.

Nice to meet you, John Doe, Quack Quack!

Me too! What are you doing right now?

I'm looking at the sky, Quack Quack!! Quack!

Is there something special in the sky?

There are fishes living in the sky, Quack Quack!

I don't believe that fishes live in the sky. You must love fishes, aren't you?

Yes, I'm a fish lover! Quack!

Why do they make you happy?

When fishes are swimming around, Quack! It's fun! Quack!

What is your favorite food?

Salmon avocado salad, Quack! And it's so delicious, Quack!

Figure 4: Cherry-picked example of multi-turn conversation with the imaginary character *Pie the Duck* and the paper author (right speaker), generated by the Dynamic Match method.

Abstract

Long documents like contracts, financial documents, etc., are often tedious to read through. Linearly consuming (via scrolling or navigation through default table of content) these documents is time-consuming and challenging. These documents are also authored to be consumed by varied entities (referred to as persona in the paper) interested in only certain parts of the document. In this work, we describe DynamicToC, a dynamic table of content-based navigator, to aid in the task of non-linear, persona-based document consumption. DynamicToC highlights sections of interest in the document as per the aspects relevant to different personas. DynamicToC is augmented with short questions to assist the users in understanding underlying content. This uses a novel deep-reinforcement learning technique to generate questions on these persona-clustered paragraphs. Human and automatic evaluations suggest the efficacy of both end-to-end pipeline and different components of DynamicToC.

1 Introduction

Documents such as financial statements, reports and contracts are often long and comprehensive, replete with domain-specific description and information. They are meant to be consumed by several entities or personas, *e.g.* legal department of companies, customers or financial organizations such as banks. As these documents contain vital information about the business, the business personas are often required to read through and analyze the documents in details. These personas are often interested in different sections of the document, based on the business requirements. For example, employees might be interested in the stock programs of the company, whereas the lenders and investors would like to read through profit statements. The traditional technology to navigate long documents is through a Table of Contents (ToC) populated with the heading of each section and chapters. However, the Table of Contents does not show the information present in the underlying paragraphs of a section, and there is no way to highlight information relevant to different personas.

To this effect, we propose DynamicToC, an intelligent table of contents-based navigator. DynamicToC provides user the flexibility to choose the persona and read the document from its lens. For the current work, we focus on the finance and legal domain, and hence, personas are taken as commonplace entities like investors, lenders, financial bodies, etc. DynamicToC highlights the relevant sections of the document as per the persona. For this, the input finance or contract document is segmented at the paragraph level and a cluster of "aspects or topics" is inferred for each para. These are then mapped to the interest topics of the personas. Further, DynamicToC has a novel question-based guided experience, to enhance the visibility of underlying information. Studies have shown that questions are more intuitive and informative than headings and hence can provide a better understanding of what the paragraph talks about. The overall interface is shown in Figure 1.

2 Related Work

Document understanding is a critical and challenging task in information processing. There have been many related research works in this direction. Keyword detection (Liu et al., 2009; Tixier et al., 2016) & topic modeling (Blei et al., 2001) works aim is to describe the document by a few important words or topics for concise representation. GENERAL DISCUSSION

Frequency Electronics, Inc. (sometimes referred to as “Registrant”, “Frequency Electronics” or the “Company”) is a world leader in precision time and frequency generation technology, which is employed in commercial and Government Satellite Payload systems, Secure Communications, Command, Control, Communication, Computer, Intelligence, Security and Reconnaissance (“C4ISR”), and Electronic Warfare (“EW”) systems. Its technology is used for a wide range of space and non-space applications.

Unless the context indicates otherwise, references to the Registrant or the Company are to Frequency Electronics, Inc. and its subsidiaries. References to “FEI” are to the parent company alone and do not refer to any of the subsidiaries. Frequency Electronics, a Delaware corporation, has its principal executive office at 55 Charles Lindbergh Boulevard, Mitchel Field, New York 11553. Its telephone number is 516-794-4500 and its website is *www.frequencyelectronics.com.*

Frequency Electronics was founded in 1961 as a research and development firm generating proprietary precision time and frequency technology primarily under contracts for end-use by the United States (“U.S.”) Government. In the mid-1990’s, the Company evolved into a designer, developer and manufacturer of state-of-the-art products for both commercial and government end-use. The Company’s present mission is to be the world leader in providing precision time and low phase noise frequency generation systems, from 1 Hz to 46 GHz for space and other challenging environments. The Company’s technology is the key element in enhancing the functionality and performance of many electronic systems.

MARKETS

The Company’s principal end markets are time and frequency generation and distribution systems for use in satellite payloads and terrestrial secure command control and communications systems.

For the satellite market, the Company has a unique legacy of providing master timing systems, power converters, and frequency generation, synthesis and distribution systems. These products are applicable for both commercial and U.S. Government end-use. Currently, there are approximately 3,400 satellites with varying remaining useful lives operating in Geostationary, Medium and Low Earth Orbits. The U.S. government

(d) DynamicToC Table of Contents

Figure 1: A comparison of the DYNAMICTOC-based experience with the default Table of Content. DYNAMICTOC enables the user to choose a reading persona and enhances navigation through highlighting relevant sections. The relevant sections are supplemented with automatically generated questions to guide the user.

first step is to acquire a list of keyword candidates (e.g., n-grams or chunks) with heuristic methods (Hulth, 2003; Shang et al., 2018), then rank them in accordance with their importance to the document (Wu et al., 2005; Gollapalli and Caragea, 2014; Bougouin et al., 2013). Another task is compact and informative headline generation from a document (Dorr et al., 2003; Lopyrev, 2015). Text summarization is the process of generating natural language summaries from an input document retaining the most important information (Rush et al., 2015; See et al., 2017). Recently, an Outline Generation task was introduced by (Zhang et al., 2019) as a hierarchical structured prediction problem. Given a document, their aim is to first predict a sequence of section boundaries and then a sequence of section headings accordingly to come up with a Table of Contents for the same.

A related direction of work to ours is of aspect detection, which has been explored in the literature largely using user reviews for products. Early works focused on rule-based approaches using lexicons and dependency relations, and utilize manually defined rules to identify patterns and extract aspects (Qiu et al., 2011; Liu et al., 2016), which require domain-specific knowledge and human expertise. Supervised approaches formulate aspect extraction as a sequence labelling problem that can be solved by hidden Markov models (HMM) (Jin et al., 2009), conditional random fields (CRF) (Li et al., 2010; Mitchell et al., 2013; Yang and Cardie, 2012), and recurrent neural networks (RNN) (Wang et al., 2016; Liu et al., 2015). These approaches have shown better performance compared to the rule-based ones, but require large amounts of labelled data for training. Early unsupervised systems are dominated by Latent Dirichlet Allocation (LDA)-based topic models (García-Pablos et al., 2018; Shi et al., 2018; Álvarez-López et al., 2016). Recently, deep learning based topic models (Srivastava and Sutton, 2017; Luo et al., 2019; He et al., 2017; Shi et al., 2021) have shown strong performance in extracting coherent aspects in an unsupervised manner. None of the prior works on aspect detection have worked with contracts or financial documents that are quite long (50-100 pages) in comparison to user reviews. Even if we break the document at paragraph level, it can still go over tens of lines. Hence, the importance of word frequency is much more in our case. We bridge the gap between directly using the unsupervised aspect detection frameworks for the financial documents by adding a TF-IDF based weighing parameter while training. Moreover, there are no gold standards for aspect detection for contract or finance domain, hence, we use unsupervised clustering based metrics for validating the output detection.

Further, it has been shown that question-answers play a critical role in scientific inquiry, information-seeking dialogue, and knowledge acquisition (Hintikka and Saarinen, 1979; Stede and Schlangen, 2004). In a dialogue system, question generation is used to obtain specific information from the user or make the conversation more pleasant (Shukla et al., 2019; Saeidi et al., 2018). Hence, we hypothesize that augmenting the default ToC with Questions that give a high level overview of the paragraphs can enhance the reading experience of the users. Question generation can also be seen as a summarization or seq2seq task. Various pre-trained language models like BART (Lewis et al., 2020), PEGASUS (Zhang et al., 2020), etc., have shown excellent results for these tasks. Researchers have worked on top of these language models & proposed various rewards for QGen to optimize these models. (Kumar et al., 2019) has employed BLEU-based rewards, (Zhang and Bansal, 2019) have used answerability rewards, whereas (Xie et al., 2020) has used a combination of fluency, relevance, and answerability rewards.

Previous question generation literature has focused on generating questions based on an entity, phrase, or sentence. In this work, we explore long-form question generation, i.e., question-based long text. We explore deep reinforcement learning techniques for the same. as they have shown competitive results in various natural language generation tasks such as summarization (Pasunuru and Bansal, 2018), style transfer (Liu et al., 2021; Goyal et al., 2021), question generation (Hosking and Riedel, 2019; Xie et al., 2020) etc. Motivated by this we use BART as our base model. As there is a lack of labeled question datasets in financial domain, to overcome the domain shift problem, we train the model with additional rewards in a reinforcement learning setup to make more suitable for a general domain.

There are several commercial products for reading documents across devices, but all of them have a fixed document navigation, based on chapters and headings. To the best of our knowledge, there is no prior art looking into providing an end-to-end persona-based navigation. The mentioned technologies address only part of the required solutions. Following are the key contributions of our work:

1. We propose a novel DYNAMICTOC technology to enable persona-based non-linear navigation for efficient consumption of long documents.

2. We extend the unsupervised aspect detection to long domain-specific documents by combining TF-IDF with aspect detection process to make it more robust and show the improvements experimentally.

3. We propose a method to generate questions based on the content of the paragraph maximizing the information coverage, entity correctness & answerability of the question.

4. We showcase the viability of our pipeline and evaluate it using metric-based and a human survey-based evaluation.

3 Datasets

SEC Filing: The SEC filing is a financial statement document submitted to the U.S. Securities and Exchange Commission. Public companies, certain insiders, and broker-dealers are required to make regular SEC filings. There are many types of documents available on the EDGAR website (Eg. 10-K, 10-Q, Form 4, etc.). For our work, we focused on the SEC 10-K documents available on the EDGAR website[1]. For a given company, the 10-k documents are available in HTML, XBRL and XML format. The complete submission text file for a 10-k document (XML) was used for parsing. We split the document content into different items ranging from item 1 to item 16. These 10-K documents range from 50 to 120 pages and contain multiple tables along with text paragraphs.

ELI5: We use the ELI5 dataset (Fan et al., 2019) to train the question generation model. ELI5 or Explain Like I'm 5, is a question-answer dataset scraped from the subreddit r/explainlikeimfive/. The subreddit rules encourage people to ask a question about any topic and get an answer for it. To maintain the dataset's quality, we only select those question-answer pairs with more than two upvotes. Note that no dataset for such question generation task exists for contractual and financial documents. Hence, we resort to use the ELI5 dataset for supervised training and use that model for inferencing on documents from a different domain.

DATASET	TRAIN SIZE	TEST SIZE
ELI5	100,000	10,000
r/AskLegal	-	10,067
r/AskEconomics	-	98

Table 1: Train/Test Statistics of question-answer pairs for the datasets used.

To test the model's performance on the domain-specific dataset, we also scrape question-answer pairs from two different subreddits - r/AskLegal and r/AskEconomics. As the name suggests, they contain questions (and answers) from the legal and economics domain respectively. Table 1 includes the statistics of the three datasets.

4 Methodology

In this section, different components of the DynamicToC are described in details.

4.1 Aspect Detection

Aspect detection has been popularly used with analysing user reviews to understand their preferences. We leverage an unsupervised technique for aspect detection and extend it to a new use case - for the modelling of user profiles from a given document and using this info for segregating the document text based on the determined aspects. **Data Pre-processing:** For the input SEC filings, text corresponding to each paragraph is obtained and considered as a separate data point. Extra information such as headings, sub-headings, blank lines, signature fields etc. are discarded. Along with this, any paragraph with less than 10 words are discarded. The text is pre-processed before training the model for aspect detection. We require three formatting styles for each paragraph which is consolidated in a single dictionary. (1) Tokenized words converted to lowercase characters. (2) The word stems of the text which has been lower-cased and tokenised. (3) The content words (meaningful words, like nouns, verbs, adjectives and adverbs) of the paragraph.

Proposed Asp-SSCL Method: Aspect detection aims at extracting interpretable aspects from the textual documents without human supervision. We propose an approach, *Asp-SSCL* based on self-supervised contrastive learning framework by (Shi et al., 2021) for aspect detection. We use the following steps for aspect detection from the contractual and financial documents:

1. Vocabulary formation and IDF indexing: First, we obtain a vocabulary for the whole corpus. This is sorted alphabetically and each word is given an index, so that corresponding IDF/word vectors can be easily referenced. 128-dimensional word vectors are generated on the corpus by a skip-gram model with an n-gram size of 5.

2. Weak Mapping: Prior aspect detection methods require a gold set labels for validating aspect model training, either through human supervision or rules-based mapping to gold set keywords. However, as no such gold aspect labels exist for our case, we first use text embedding via sentence transformers[2]. These are then clustered using K-means to obtain 20 clusters comprising of 10 keywords each, which are used for aspect mapping.

3. Contrastive Learning: The mapping and generated word vectors are then used for training the self-supervised contrastive learning method, (Shi et al., 2021), which outputs the final aspect clusters and keywords.

4. TF-IDF Weighing: Further, since these documents are text-heavy, we introduce a modification, **Asp-SSCL-TFIDF** which includes TF-IDF weighing term in the original implementation, to ensure rare but relevant words are considered as important as opposed to more frequently occurring words. Each word representation is modified by multiplying it with the TF-IDF score so that the algorithm can adapt to the financial corpus better.

4.2 Persona Mapping

The aspects generated on the corpus are used as dimensions that define the document. Each persona is expected to be interested in one or more of these dimensions. We call the mapping between multiple personas and multiple aspects as the persona space.

We consulted a domain expert (financial domain; specifically for SEC 10-K filings) to create a matrix of personas, who read such documents, and what kind of information they are interested in. Figure 2 lists out the various stakeholders of a general 10-K filing against the different sections of the document each stakeholder is interested in. The stakeholders are grouped together to form the personas used in DynamicToC, *viz.* employees, business partners, investors and lendors, financial bodies and advisory and regulatory firms. Similarly, the columns (headings) are grouped together according to similarity to create a mapping of topics of interest for each persona.

We can map these columns to the aspects we get from the Aspect Detection Module and determine if a particular persona is interested in that paragraph or not. For this, the aspects obtained from the unsupervised technique are compared against the simplified column values from the constructed matrix. The columns with the greatest similarity (above a threshold) are associated with each persona. For getting the personas interested in each paragraph, the paragraphs are first tagged for aspect. From the resultant vector (which represents the confidence score of the text for each aspect), the combined score for each persona is calculated using the scores of its constituent aspects. This

is used to segregate the paragraphs for enhanced document consumption.

Note that for financial documents, we were able to gather domain knowledge and leverage it to obtain the persona space. But the proposed technique is generalizable to other domains as well. In the absence of domain-specific knowledge, each aspect is a sufficiently distinct topic and can be treated as a proxy to personas. Hence, modelling of interests can be done directly on the basis of aspects in such cases.

4.3 Intelligent Navigation via Question Generation

It has been shown that question-answers play a critical role in scientific inquiry, information-seeking dialogue, and knowledge acquisition (Hintikka and Saarinen, 1979; Stede and Schlangen, 2004). Additionally, unstructured lists of "Frequently Asked Questions (FAQs)" are regularly deployed at scale to present information. On top, questions can provide a meaningful understanding of the document at a paragraph or section level which cannot be directly captured by a heading (or sub-heading). Therefore, to aid in document consumption, we generate long-form questions (i.e., questions based on paragraphs instead of entities) to enhance the navigation experience.

Model Architecture: We use an encoder-decoder architecture for the task of generating questions given the paragraph as context which essentially is a sequence-to-sequence task. Large pre-trained language models like BART (Lewis et al., 2020), PEGASUS (Zhang et al., 2020), etc., have shown excellent results in summarization tasks. Motivated by this, we employ BART as our underlying language model. The task is to generate questions covering the entire paragraph and summarize it capturing the most-salient information in form of a question. The BART model has shown promising results in abstractive summarization tasks, making it a natural choice.

We use ELI5 (Fan et al., 2019) dataset for training the model. The answer is provided as the input to the encoder-decoder model which is trained to generate the corresponding question and minimize the cross-entropy loss with respect to the ground truth. Although such supervised training is straight-forward, due to the domain shift from ELI5 to financial language, qualitative evaluations showed that the model produced some irrelevant questions, some entities were artificially induced (that it might have seen during the training time) and sometimes, it could not cover the entire paragraph. Hence, we augmented the vanilla BART with three additional rewards targeting the qualities we seek in the final generated questions. We call the resulting model Variant BART. Figure 3 shows the proposed pipeline. The following sections explain these rewards in detail:

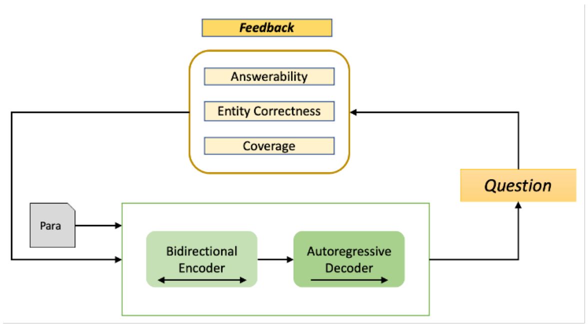

Figure 3: Training Variant BART for Question Generation with feedback rewards

- **Answerability Classifier Reward**: Qualitative evaluations showed some of the questions generated were not answerable by the paragraph, making them unsuitable for the task of understanding the paragraph easily. To address this, we trained a classifier to judge the answerability of the question given the paragraph. Basically, the paragraph and the generated question would be fed as input to the classifier and the classifier predicts "1" if the question is answerable by the para, otherwise "0". The classifier is a fine-tuned Roberta model. We create data with both positive and negative samples to fine tune the Roberta model. We use the following strategy to create the training data for the binary classifier: (a) We select 10,000 random question-answer pairs from the ELI5 dataset. Note that in ELI5 data, some questions have multiple answer paras too. All these forms our positive samples. To create negative samples for a question Q', we take its corresponding answer para, A', and a random set of 100 question-answer pairs. We compare the similarity of the answer para (A') with all the 100 answers. Top 3 most similar answers are taken as the negative samples for the question Q'. (b) Given that style of ELI5 answers and Wikipedia paragraphs are very similar[3], we create negative samples in another way as well to introduce diversity. Wikipedia articles are chosen based on their similarity with ELI5 data and for each question, we compute the similarity score with each para in the wiki articles. The topmost similar paras are of interest, and we sample 10 most similar paras out of top 20 and call them our negative samples. Table 2 mentions the data statistics. The reward is computed using the equation: $R_{answerability} = Prob_{classifier}(1|P, Q)$

DATASET	TRAIN	TEST
#Unique Questions	10,000	1,000
Total Samples	208,871	21,045
Positive Samples	30,564	2,974
Negative Samples	178,307	18,071
Neg to Pos Ratio	5.83	6.04

Table 2: Dataset stats to train answerability classifier

- **Entity Correctness Reward**: The vanilla BART model can generated questions with hallucinated entities and names like Microsoft, Apple etc. even when there was no mention of them in the corresponding paragraph. To tackle this, we identify the named entities present in the generated question. If those entities appear in the passage, we give a reward of 1 else 0. If there is no entity in the generated question, a reward of 0.5 is given to the model. Mathematically, reward is given by:

$$R_{entity} = \begin{cases} 1, & \text{if } e(Q) \neq \phi, e(Q) \subseteq e(P) \\ 0, & \text{if } e(Q) \neq \phi, e(Q) \not\subseteq e(P) \\ 0.5, & \text{if } e(Q) = \phi \end{cases}$$

where, $e(.)$ denotes the entities in the question or paragraph.

- **Coverage Reward**: We observe that the output question did not cover the entire information present in the paragraph and instead focused on certain segments of it. We introduce this reward to improve information coverage. The idea is similar to the entity correctness reward. We first identify keywords from the paragraph using YAKE algorithm (Campos et al., 2018). Then we calculate the similarity of the generated question with these keywords. We use the Extended String Subsequence Kernel (ESSK) introduced in (Hirao et al., 2003) to calculate this similarity score. The idea is that YAKE would generate keywords from different parts of the paragraph. When we calculate the similarity of this keyword list with the generated question, we are encouraging the model to cover the entire paragraph. Thus, given a passage P and the generated question Q, the reward R is defined as follows:

$$R_{coverage} = ESSK(YAKE(P), Q)$$

(Lai et al., 2021) shows how to use rewards on top of language models for policy learning. We adopt the same setup. The policy gradient, $\nabla_\phi J(\phi)$ is given by:

$$\nabla_\phi J(\phi) = E[R \cdot \nabla_\phi log(P(y^s|x, \phi))] \quad (1)$$

where, R denotes reward value, ϕ represents the model parameters, x is the input paragraph and y^s is obtained by greedily maximizing the distribution of BART outputs at each timestep. Hence, the

---

[3] https://yjernite.github.io/lfqa.html

overall loss term for training the proposed Variant BART model becomes:

$$L_{total} = \lambda_{CE} \cdot L_{CE} + \lambda_{reward} \cdot L_{reward} \quad (2)$$

5 Results & Discussion

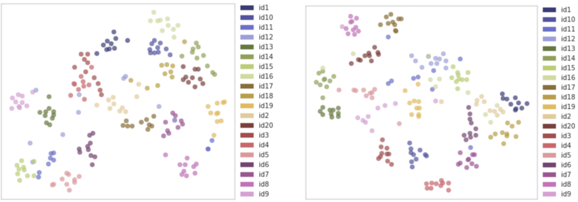
In order to evaluate the different parts of the pipeline, we employ metric based evaluation schemes. Since there is no off-the-shelf criterion to evaluate all the stages of the pipeline together, we have provided independent evaluations for each of the sub-modules. However, the intended goal of our pipeline is to facilitate the readers in consuming long documents through the lens they deem most suitable for them. To facilitate an end-to-end evaluation and to understand whether the persona-based document segmentation with enhanced Table of Content is informative or not, we have conducted a small scale human evaluation. Both metric-based and human-based evaluations are discussed in the following subsections.

5.1 Metric-Based Evaluation

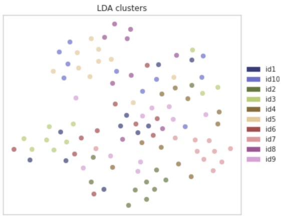
Aspect Detection: Figure 4 shows the t-SNE[4] clustering of the outputs of Asp-SSCL, Asp-SSCL-TFIDF, that are determined from the SEC-10K filing corpus. For a baseline comparison, we also plot the output for LDA (10 clusters) for the corpus. Essentially, each cluster is a bag of words indicating some vital theme that is mentioned in the corpus. We would want the clusters to be as independent from each other as possible as that would mean different kinds of information is captured by different clusters with minimal overlap. We observe that adding TF-IDF scores to the aspect detection module helps as the clusters' separation gets better as shown in the Figure 4. Further, for the baseline using LDA, the separation is not clear. Some of the examples of cluster keywords are shown in Figure 5.

Question Generation: Since no ground truth questions are available for the SEC-10K Filing dataset, we report the following evaluations for the question generation module. First, we report the "type" of questions that are generated using the Vanilla BART model and the Variant BART model that is trained with a combination of the rewards we added on top of it (Table 3) .

On analysing this table, we see that "What" questions are heavily generated on the 10K filing data.

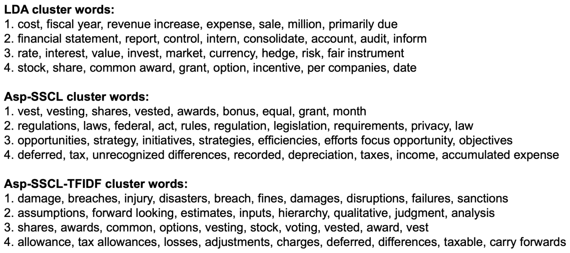


(a) Asp-SSCL (b) Asp-SSCL with TF-IDF



(c) LDA

Figure 4: Aspect clusters using (a) default Asp-SSCL and (b) Asp-SSCL with TF-IDF and (c) LDA



LDA cluster words:
1. cost, fiscal year, revenue increase, expense, sale, million, primarily due
2. financial statement, report, control, intern, consolidate, account, audit, inform
3. rate, interest, value, invest, market, currency, hedge, risk, fair instrument
4. stock, share, common award, grant, option, incentive, per companies, date

Asp-SSCL cluster words:
1. vest, vesting, shares, vested, awards, bonus, equal, grant, month
2. regulations, laws, federal, act, rules, regulation, legislation, requirements, privacy, law
3. opportunities, strategy, initiatives, strategies, efficiencies, efforts focus opportunity, objectives
4. deferred, tax, unrecognized differences, recorded, depreciation, taxes, income, accumulated expense

Asp-SSCL-TFIDF cluster words:
1. damage, breaches, injury, disasters, breach, fines, damages, disruptions, failures, sanctions
2. assumptions, forward looking, estimates, inputs, hierarchy, qualitative, judgment, analysis
3. shares, awards, common, options, vesting, stock, voting, vested, award, vest
4. allowance, tax allowances, losses, adjustments, charges, deferred, differences, taxable, carry forwards

Figure 5: Examples of cluster words generated using LDA, Asp-SSCL and Asp-SSCL with TF-IDF.

Q Type	ELI5 Train Set (%)	Vanilla BART	Variant BART
What	12.93	54.28	44.75
Where	0.55	0.0	0.56
Why	36.23	11.47	11.93
How	21.88	30.18	37.44
Who	0.28	3.2	3.9
When	1.62	0.33	0.84
Other	26.51	0.54	0.56

Table 3: Type of questions generated by Vanilla BART & Variant BART on an SEC filing.

This suggests that the nature of 10K filing is such that the question asked about them is "What" type. We also observe that biases of training data are not creeping in the model, as the percentage of the "What" questions in the training dataset is four times less than the model's output. Similarly, the percentage of other questions is significant in the ELI5 dataset but is very small in our model's output. Thus, we can safely say that the model learns to generate questions and not mimic the ELI5 dataset.

Although we don't have the gold corpus for SEC filing dataset, we evaluate the performance of question generation model on the AskLegal and AskEconomics subreddits since we have the ground

---

[4] https://lvdmaaten.github.io/tsne/

truth questions for them. We report the BLEU and ROUGE scores that are standard metrics in Natural Language Processing literature and are a measure of overlap or common n-grams between the generated text and the ground truth. We also report the answerability score by feeding the generated question and input para to the classifier we trained (as mentioned in Reward 1 – Question Generation Section). Table 4 shows the corresponding results.

Model	BLEU	ROUGE-L	Answerability
Vanilla (r/AskLegal)	0.274	0.278	95.92
Variant (r/AskLegal)	0.264	0.240	98.98
Vanilla (r/AskEconomics)	0.289	0.298	95.16
Variant (r/AskEconomics)	0.291	0.306	96.17

Table 4: Performance comparison of Vanilla and Variant BART on r/AskLegal and r/AskEconomics subreddits

Question	Avg Score (1-5)
How often do you come across a long document?	2.83
How often do you use a document reader?	4.33
How satisfied are you with the 'Default' reading experience ?	3.00
How would you rate the option to choose persona as an aid in reading the document?	**4.50**
How would you rate jumping to relevant parts of the document?	**4.16**
How would you rate the utility of presented questions?	**4.40**

Table 5: Results from the human experiment on using the Default Reading experience with DynamicToC.

On closely analysing the paragraph, reference question, and the generated question, we observe the following three things: (i) There is more than one way to ask the same question and there could be multiple questions around the same topic. (ii) Input paragraphs may have more than one prominent topics. The generated question might be focused on one such topic, and the reference question is focused on another. (iii) Some answers/passages are unrelated to the question or require some background, and thus, the generated questions are very different from the actual question.

The above reasons explain the fluctuation in scores for Vanilla and Variant BART, and thus the answerability of the generated question becomes an important metric. The variant model trained with additional rewards has the highest answerability score across all the datasets. This suggests that including a coverage-based loss not only helps cover the information of the entire paragraph but also helps increase the generated question's answerability as different themes of the passages are covered.

5.2 Human Evaluation

We conducted a small human evaluation involving 8 participants (age - 27.8 ± 6.7, 2 females). The participants were technology workers internal to our organization. They were asked to play around with a web demo to experience the DynamicToC, for different SEC filings. They were first shown the default section heading-based reading experience and then they choose the type of persona as whom they wish to consume the document. After this, they filled a questionnaire about their experience. The results of the survey are summarized in Table 5.

Some relevant comments from the survey are as follows - (i) How do we ensure that all the relevant information will be covered by the sections highlighted as important for a particular "persona"? (ii) Although questions generated are relevant, some of the why questions are not answered by the paragraphs they point to. (iii) Interesting experiment with possibly multiple use-cases. The first comment is actually true for all summarization tasks, hence, DynamicToC does not disrupt the linear flow. The second feedback indicates scope for further research in the question generation space. The overall response is immensely positive and the scores of 4.50, 4.16 and 4.40 in Table 5 reflect the same.

6 Conclusion

In this work, we have proposed a novel DynamicToC framework for consumption of long documents. Financial documents are high value documents for businesses, and are often long and complex. The default ToC-based reading experience is quite limited and document consumption can be enhanced using intelligent technologies. DynamicToC is one of the first works to pursue this exciting research direction. DynamicToC would benefit from in-domain learning of aspect keywords and questions. Evaluation of paragraph segmentation and mapping of personas to the aspects are future directions. A better understanding of personas would generalize the work to different domains.

Abstract

Pre-trained language models (PLMs) have achieved remarkable success on various natural language understanding tasks. Simple fine-tuning of PLMs, on the other hand, might be suboptimal for domain-specific tasks because they cannot possibly cover knowledge from all domains. While adaptive pre-training of PLMs can help them obtain domain-specific knowledge, it requires a large training cost. Moreover, adaptive pre-training can harm the PLM's performance on the downstream task by causing catastrophic forgetting of its general knowledge. To overcome such limitations of adaptive pre-training for PLM adaption, we propose a novel domain adaption framework for PLMs coined as **K**nowledge-**A**ugmented **L**anguage model **A**daptation (**KALA**), which modulates the intermediate hidden representations of PLMs with domain knowledge, consisting of entities and their relational facts. We validate the performance of our KALA on question answering and named entity recognition tasks on multiple datasets across various domains. The results show that, despite being computationally efficient, our KALA largely outperforms adaptive pre-training. Code is available at: https://github.com/Nardien/KALA.

1 Introduction

Pre-trained Language Models (PLMs) (Devlin et al., 2019; Brown et al., 2020) have shown to be effective on various Natural Language Understanding (NLU) tasks. Although PLMs aim to address diverse downstream tasks from various data sources, there have been considerable efforts to adapt the PLMs to specific *domains* —distributions over the language characterizing a given topic or genre (Gururangan et al., 2020)— for which the acquisition of domain knowledge is required to accurately solve the downstream tasks (e.g., Biomedical Named Entity Recognition (Dogan et al., 2014)).

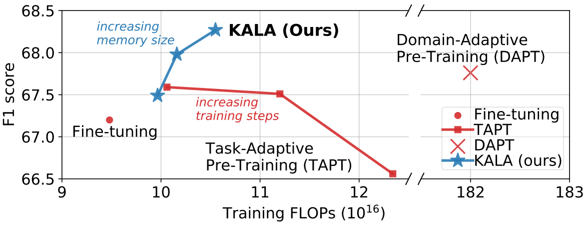

Figure 1: F1 Score and Training FLOPs for different methods on Question Answering (NewsQA). Note that DAPT uses about 112 times larger data for adaptation. Details are in §5.3

This problem, known as *Language Model Adaptation*, can be viewed as a transfer learning problem (Yosinski et al., 2014; Ruder, 2019) under domain shift, where the model is pre-trained on the general domain and the labeled distribution is available for the target domain-specific task. The most prevalent approach to this problem is adaptive pre-training (Figure 2a) which further updates all parameters of the PLM on a large domain-specific or curated task-specific corpus, with the same pre-training strategy (e.g., masked language modeling) before fine-tuning it on the downstream task (Beltagy et al., 2019; Lee et al., 2020; Gururangan et al., 2020). This continual pre-training of a PLM on the target domain corpus allows it to learn the distribution of the target domain, resulting in improved performance on domain-specific tasks (Howard and Ruder, 2018; Han and Eisenstein, 2019).

While it has shown to be effective, adaptive pre-training has obvious drawbacks. First, it is computationally inefficient. Although a PLM becomes more powerful with the increasing amount of pre-training data (Gururangan et al., 2020), further pre-training on the additional data requires larger memory and computational cost as the dataset size grows (Bai et al., 2021). Besides, it is difficult to adapt the PLM to a new domain without forgetting the general knowledge it obtained from the initial pretraining step, since all pre-trained parameters are continually updated to fit the domain-specific corpus during adaptive pre-training (Chen et al., 2020). This *catastrophic forgetting* of the task-

Figure 2: **Concepts (Left).** (a) Adaptive Pre-training updates whole parameters of the PLM through further pre-training on the domain corpus. (b) Our method KALA integrates the external knowledge so that the PLM adapts to the target domain **only with fine-tuning**, which is realized by the affine transformation on the intermediate feature. **Visualization of the contextualized representation from the PLM for seen and unseen entities (Right).** Our KALA framework embeds the unseen entities on the embedding space of seen entities by representing them with their relational knowledge over the graph, while the strong DAPT baseline (Gururangan et al., 2020) cannot appropriately handle unseen entities that are not given for task fine-tuning.

general knowledge may lead to the performance degradation on the downstream tasks. In Figure 1, we show that adaptive pre-training with more training steps could lead to performance degeneration.

Thus, it would be preferable if we could adapt the PLM to the domain-specific task without costly adaptive pre-training. To this end, we aim to integrate the domain-specific knowledge into the PLM directly during the task-specific fine-tuning step, as shown in Figure 2b, eliminating the adaptive pre-training stage. Specifically, we first note that **entities** and **relations** are core building blocks of the domain-specific **knowledge** that are required to solve for the domain-specific downstream tasks. Clinical domain experts, for example, are familiar with medical terminologies and their complex relations. Then, to represent the domain knowledge consisting of entities and relations, we introduce the *Entity Memory*, which is the source of entity embeddings but independent of the PLM parameters (See Entity Memory in Figure 2b). Then, we further exploit the relational structures of the entities by utilizing a Knowledge Graph (KG), which denotes the factual relationships between entities, as shown in Knowledge Graph of Figure 2b.

The remaining step is how to integrate the knowledge into the PLM during fine-tuning. To this end, we propose a novel layer named Knowledge-conditioned Feature Modulation (KFM, §3.2), which scales and shifts the intermediate hidden representations of PLMs by conditioning them with retrieved knowledge representations. This knowledge integration scheme has several advantages. First, it does not modify the original PLM architecture, and thus could be integrated into any PLMs regardless of their architectures. Also, it only requires marginal computational and memory overhead, while eliminating the need of excessive further pre-training (Figure 1). Finally, it can effectively handle unseen entities with relational knowledge from the KG, which are suboptimally embedded by adaptive pre-training. For example, as shown in Figure 2, an entity *restenosis* does not appear in the training dataset for fine-tuning, thus adaptive pre-training only implicitly infers them within the context from the broad domain corpus. However, we can explicitly represent the unknown entity by aggregating the representations of known entities in the entity memory (i.e., in Figure 2, neighboring entities, such as *asthma* and *pethidine*, are used to represent the unseen entity *restenosis*).

We combine all the previously described components into a novel language model adaptation framework, coined as **K**nowledge-**A**ugmented **L**anguage model **A**daptation (KALA) (Figure 3). We empirically verify that **KALA** improves the performance of the PLM over adaptive pre-training on various domains with two knowledge-intensive tasks: Question Answering (QA) and Named Entity Recognition (NER). Our contribution is threefold:

- We propose a novel LM adaptation framework, which augments PLMs with entities and their relations from the target domain, during fine-tuning without any further pre-training. To our knowledge, this is the first work that utilizes the structured knowledge for language model adaptation.
- To reflect structural knowledge into the PLM, we introduce a novel layer which scales and shifts the intermediate PLM representations with the entity representations contextualized by their related entities according to the KG.

- We show that our KALA significantly enhances the model's performance on domain-specific QA and NER tasks, while being significantly more efficient over existing LM adaptation methods.

2 Related Work

Language Model Adaptation Nowadays, transfer learning (Howard and Ruder, 2018) is a dominant approach for solving Natural Language Understanding (NLU) tasks. This strategy first pre-trains a Language Model (LM) on a large and unlabeled corpus, then fine-tunes it on downstream tasks with labeled data (Devlin et al., 2019). While this scheme alone achieves impressive performance on various NLU tasks, adaptive pre-training of the PLM on a domain-specific corpus helps the PLM achieve better performance on the domain-specific tasks. For example, Lee et al. (2020) demonstrated that a further pre-trained LM on biomedical documents outperforms the original LM on biomedical NLU tasks. Also, Gururangan et al. (2020) showed that adaptive pre-training of the PLM on the corpus of a target domain (Domain-adaptive Pre-training; DAPT) or a target task (Task-adaptive Pre-training; TAPT) improves its performance on domain-specific tasks. However, above approaches generally require a large amount of computational costs for pre-training.

Knowledge-aware LM Accompanied with increasing sources of knowledge (Vrandecic and Krötzsch, 2014), some prior works have proposed to integrate external knowledge into PLMs, to enhance their performance on tasks that require structured knowledge. For instance, ERNIE (Zhang et al., 2019) and KnowBERT (Peters et al., 2019) incorporate entities as additional inputs in the pre-training stage to obtain a knowledge-aware LM, wherein a pre-trained knowledge graph embedding from Wikidata (Vrandecic and Krötzsch, 2014) is used to represent entities. Entity-as-Experts (Févry et al., 2020) and LUKE (Yamada et al., 2020) use the entity memory that is pre-trained along with the LMs from scratch. ERICA (Qin et al., 2021) further uses the fact consisting of entities and their relations in the pre-training stage of LMs from scratch. Previous works aim to integrate external knowledge into the LMs during the pre-training step to obtain a universal knowledge-aware LM that requires additional parameters for millions of entities. In contrast to this, our framework aims to efficiently modify a general PLM for the domain-specific task with a linear modulation layer scheme discussed in Section 3.2, during fine-tuning.

3 Method

3.1 Problem Statement

Our goal is to solve Natural Language Understanding (NLU) tasks for a specific domain, with a knowledge-augmented Language Model (LM). We first introduce the NLU tasks we target, followed by the descriptions of the proposed knowledge-augmented LM. After that, we formally define the ingredients for structured knowledge integration.

NLU tasks The goal of an NLU task is to predict the label $\boldsymbol{y}$ of the given input instance $\boldsymbol{x}$, where the input $\boldsymbol{x}$ contains the sequence of tokens (Devlin et al., 2019): $\boldsymbol{x} = [w_1, w_2, \ldots, w_{|\boldsymbol{x}|}]$. Then, given a training dataset $\mathcal{D} = \{(\boldsymbol{x}^{(i)}, \boldsymbol{y}^{(i)})\}_{i=1}^{N}$, the objective is to maximize the log-likelihood as follows:

$$\max_{\theta} \mathcal{L}(\theta) := \max_{\theta} \sum_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{D}} \log p(\boldsymbol{y}|\boldsymbol{x};\theta),$$

$$p(\boldsymbol{y}|\boldsymbol{x};\theta) = g(\boldsymbol{H};\theta_g),\ \boldsymbol{H} = f(\boldsymbol{x};\theta_f),$$

where f is an encoder of the PLM which outputs contextualized representation $\boldsymbol{H}$ from $\boldsymbol{x}$, and g is a decoder which models the probability distribution p of the label $\boldsymbol{y}$, with trainable parameters $\theta = (\theta_f, \theta_g)$. If the LM is composed of L-layers of transformer blocks (Devlin et al., 2019), the function f is decomposed to multiple functions $f = [f^0, \ldots, f^L]$, where each block gets the output of the previous block as the input: $\boldsymbol{H}^l = f^l(\boldsymbol{H}^{l-1})$.[1]

Knowledge-Augmented Language Model The conventional learning objective defined above might be sufficient for understanding the texts if the tasks require only the general knowledge stored in PLMs. However, it is suboptimal for tackling domain-specific tasks since the general knowledge captured by the parameters θ_f may not include the knowledge required for solving the domain-specific tasks. Thus, contextualizing the texts by the domain knowledge, captured by the domain-specific entities and their relations, is more appropriate for handling such domain-specific problems.

To this end, we propose a function $h(\cdot;\phi)$ which augments PLMs conditioned on the domain knowledge. Formally, the objective for a NLU task with

---

[1] f^0 denotes a word embedding layer which gets $\boldsymbol{x}$ as an input, i.e., $\boldsymbol{H}^0 = f^0(\boldsymbol{x})$, for the sake of simplicity.

our knowledge-augmented LM is given as follows:

$$\max_{\theta,\phi} \mathcal{L}(\theta, \phi) := \max_{\theta,\phi} \sum_{(\boldsymbol{x},\boldsymbol{y})\sim\mathcal{D}} \log p(\boldsymbol{y}|\boldsymbol{x}; \theta, \phi),$$

$$p(\boldsymbol{y}|\boldsymbol{x}; \theta, \phi) = g(\tilde{\boldsymbol{H}}; \theta_g),$$

$$\tilde{\boldsymbol{H}}^l = f^l(\boldsymbol{H}^{l-1}, h^l(\boldsymbol{H}^{l-1}, \mathcal{E}, \mathcal{M}, \mathcal{G}; \phi); \theta_{f^l}),$$

where ϕ is parameters for the function h, $\mathcal{E}$ is the set of entities, $\mathcal{M}$ is the set of corresponding mentions, and $\mathcal{G}$ is a knowledge graph. In the following, we will describe the definition of the knowledge-related inputs $\mathcal{E}, \mathcal{M}, \mathcal{G}$, and the details of $h(\cdot, \phi)$.

Definition 1 (Entity and Mention). Given a sequence of tokens $\boldsymbol{x} = [w_1, \ldots, w_{|\boldsymbol{x}|}]$, let $\mathcal{E}$ be a set of entities in $\boldsymbol{x}$. Then an **entity** $e \in \mathcal{E}$ is composed of one or multiple adjacent tokens within the input text: $[w_{m^\alpha}, \ldots, w_{m^\omega}] \sqsubseteq \boldsymbol{x}$[2]. Here, $m = (m^\alpha, m^\omega)$ is a **mention** that denotes the start and end locations for the entity within the input tokens $\boldsymbol{x}$, which term is commonly used for defining entities (Févry et al., 2020). Consequently, for each given input $\boldsymbol{x}^{(i)}$, there are a set of entities $\mathcal{E}^{(i)} = \{e_1, \ldots, e_K\}$ and their corresponding mentions $\mathcal{M}^{(i)} = \{m_1, \ldots, m_K\}$. For example, given an input $\boldsymbol{x}$ = [New, York, is, a, city], we have two entities $\mathcal{E} = \{$*New_York*, *city*$\}$ and their associated mentions $\mathcal{M} = \{(1, 2), (4, 4)\}$.

We further construct the entity vocabulary $\mathcal{E}_{\text{train}} = \bigcup_{i=1}^{N} \mathcal{E}^{(i)}$, which consists of all entities appearing in the training dataset. However, at test time, we may encounter unseen entities that are not in $\mathcal{E}_{\text{train}}$. To tackle this, we regard unknown entities as the null entity $e_\emptyset$, so that $\forall e \in \mathcal{E}_{\text{train}} \cup \{e_\emptyset\}$.

Definition 2 (Entity Memory). Given a set of all entities $\mathcal{E}_{\text{train}} \cup \{e_\emptyset\}$, we represent them in the continuous vector (feature) space to learn meaningful entity embeddings. In order to implement this, we define the **entity memory** $\boldsymbol{E} \in \mathbb{R}^{(|\mathcal{E}_{\text{train}}|+1)\times d}$ that comprises of an entity $e \in \mathbb{R}$ as a key and its embedding $\boldsymbol{e} \in \mathbb{R}^d$ as its value. Also, to access the value in the entity memory, we define the point-wise memory access function `EntEmbed` which takes an entity as an input. For instance, $\boldsymbol{e}$ = `EntEmbed`(*New_York*) returns the embedding of the *New_York* entity, and $\boldsymbol{e}$ = `EntEmbed`($e_\emptyset$) returns the zero embedding. This entity memory $\boldsymbol{E}$ is the part of the parameter ϕ used in function h.

Definition 3 (Knowledge Graph). Since the entity memory alone cannot represent relational information between entities, we further define a **Knowledge Graph** (KG) $\mathcal{G}$ that consists of a set of factual triplets $\{(h, r, t)\}$, where the head and the tail entities, h and t, are the elements of $\mathcal{E}$, and a relation r is an element of a set of relations $\mathcal{R}$: $h, t \in \mathcal{E}$ and $r \in \mathcal{R}$. We assume that a pre-constructed KG $\mathcal{G}^{(i)}$ is **given** for each input $x^{(i)}$, and provide the details of the KGs and how to construct them in **Appendix** A.

3.2 Knowledge-conditioned Feature Modulation on Transformer

The remaining problem is how to augment a PLM by conditioning it on the domain-specific knowledge, through the function h. An effective approach to do so without stacking additional layers on top of the LM is to interleave the knowledge from h with the pre-trained parameters of the language model (Devlin et al., 2019) consisting of transformer layers (Vaswani et al., 2017). Before describing our interleaving method in detail, we first describe the Transformer architecture.

Transformer Given $|x|$ token representations $\boldsymbol{H}^{l-1} = [\boldsymbol{h}_1^{l-1}, \ldots, \boldsymbol{h}_{|\boldsymbol{x}|}^{l-1}] \in \mathbb{R}^{|\boldsymbol{x}|\times d}$ from the layer $l-1$ where d is the embedding size, each transformer block outputs the contextualized representations for all tokens. In detail, the l-th block consists of the multi-head self-attention (*Attn*) layer and the residual feed-forward (*FF*) layer as follows:

$$\hat{\boldsymbol{H}}^l = LN(\boldsymbol{H}^{l-1} + Attn(\boldsymbol{H}^{l-1}))$$

$$FF(\hat{\boldsymbol{H}}^l) = \sigma(\hat{\boldsymbol{H}}^l \cdot \boldsymbol{W}_1) \cdot \boldsymbol{W}_2,$$

$$\boldsymbol{H}^l = LN(\hat{\boldsymbol{H}}^l + FF(\hat{\boldsymbol{H}}^l)),$$

where LN is a layer normalization (Ba et al., 2016), σ is an activation function (Hendrycks and Gimpel, 2016), $\boldsymbol{W}_2 \in \mathbb{R}^{d'\times d}$ and $\boldsymbol{W}_1 \in \mathbb{R}^{d\times d'}$ are weight matrices, and d' is an intermediate hidden size. We omit the bias term for brevity.

Linear Modulation on Transformer An effective yet efficient way to fuse knowledge from different sources without modifying the original model architecture is to scale and shift the features of one source with respect to the data from another source (Dumoulin et al., 2018). This scheme of feature-wise affine transformation is effective on various tasks, such as language-conditioned image reasoning (Perez et al., 2018) or style-transfer in image generation (Huang and Belongie, 2017).

---

[2] $E \sqsubseteq E'$ iff $E = E'$, or E is included in E' such that the order of elements in E and E' is the same.

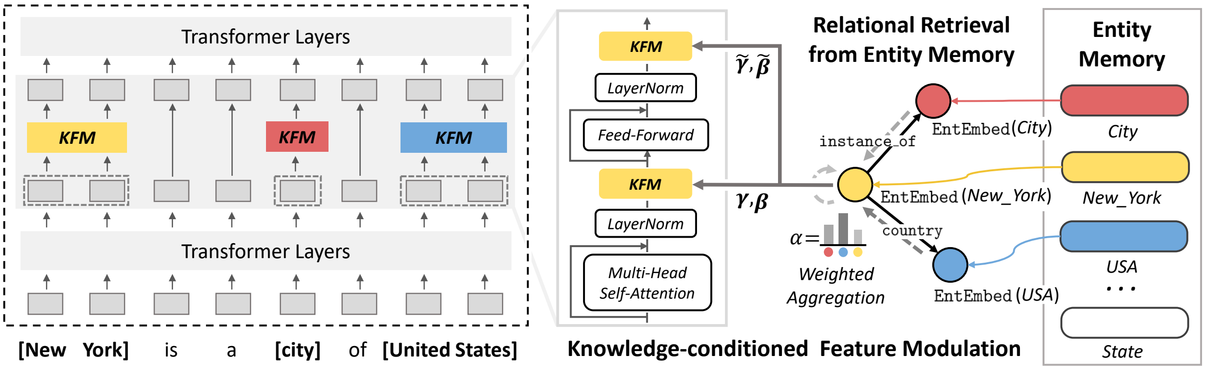

Figure 3: **Framework Overview. (Left)** The architecture of a knowledge-augmented LM with our method. Some of the input tokens are annotated as entities with their mentions. **(Middle)** Inside the transformer block, KFM (§3.2) is applied after the layer normalization as in equation 1, to modulate the hidden representations of tokens in entity mentions. **(Right)** The retrieved embedding of an entity *New_York* is composed by the weighted aggregation of neighbors through the knowledge graph (§3.3).

Motivated by them, we propose to linearly transform the intermediate features after the layer normalization of the transformer-based PLM, conditioned on the knowledge sources $\mathcal{E}, \mathcal{M}, \mathcal{G}$. We term this method as the **Knowledge-conditioned Feature Modulation** (KFM), described as follows:

$$\begin{aligned} \boldsymbol{\Gamma}, \boldsymbol{B}, \tilde{\boldsymbol{\Gamma}}, \tilde{\boldsymbol{B}} &= h^l(\boldsymbol{H}^{l-1}, \mathcal{E}, \mathcal{M}, \mathcal{G}; \phi), \\ \hat{\boldsymbol{H}}^l &= \boldsymbol{\Gamma} \circ LN(\boldsymbol{H}^{l-1} + Attn(\boldsymbol{H}^{l-1})) + \boldsymbol{B}, \\ FF(\hat{\boldsymbol{H}}^l) &= \sigma(\hat{\boldsymbol{H}}^l \cdot \boldsymbol{W}_1) \cdot \boldsymbol{W}_2, \\ \tilde{\boldsymbol{H}}^l &= \tilde{\boldsymbol{\Gamma}} \circ LN(\hat{\boldsymbol{H}}^l + FF(\hat{\boldsymbol{H}}^l)) + \tilde{\boldsymbol{B}}, \end{aligned} \tag{1}$$

where $\boldsymbol{H}^{l-1} \in \mathbb{R}^{|x| \times d}$ is the matrix of hidden representations from the previous layer, $\circ$ denotes the hadamard (element-wise) product, and $\boldsymbol{\Gamma} = [\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_{|\boldsymbol{x}|}] \in \mathbb{R}^{|\boldsymbol{x}| \times d}$, $\boldsymbol{B} = [\boldsymbol{\beta}_1, \ldots, \boldsymbol{\beta}_{|\boldsymbol{x}|}] \in \mathbb{R}^{|\boldsymbol{x}| \times d}$. $\boldsymbol{\Gamma}$ and $\boldsymbol{B}$ are learnable modulation parameters from the function h, which are conditioned by the entity representation. For instance, in Figure 3, $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$ for token 'New' are conditioned on the corresponding entity *New_York*. However, if tokens are not part of any entity (e.g., 'is'), $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$ for such tokens are fixed to $\mathbf{1}$ and $\mathbf{0}$, respectively.

One notable advantage of our KFM is that multiple tokens associated to the identical entity are affected by the same modulation (e.g., 'New' and 'York' in Figure 3), which allows the PLM to know which adjacent tokens are in the same entity. This is important for representing the tokens of the domain entity (e.g., 'cod' and 'on'), since the original PLM might regard them as separate, unrelated tokens (See analysis in §5.5 with Figure 5). However, with our KFM, the PLM can identify associated tokens and embed them to be close to each other.

Then, how can we design such functional operations in h? The easiest way is to retrieve the entity embedding of e, associated to the typical token, from the entity memory $\boldsymbol{E}$, and then use the retrieved entity embedding as the input to obtain $\boldsymbol{\gamma}$ and $\boldsymbol{\beta}$ for every entity (See Figure 3). Formally, for each entity $e \in \mathcal{E}$ and its mention $(m^\alpha, m^\omega) \in \mathcal{M}$,

$$\begin{aligned} &\boldsymbol{v} = \texttt{EntEmbed}(e) \\ &\boldsymbol{\gamma}_j = \mathbf{1} + h_1(\boldsymbol{v}), \ \boldsymbol{\beta}_j = h_2(\boldsymbol{v}), \\ &\tilde{\boldsymbol{\gamma}}_j = \mathbf{1} + h_3(\boldsymbol{v}), \ \tilde{\boldsymbol{\beta}}_j = h_4(\boldsymbol{v}), \quad m^\alpha \leq j \leq m^\omega, \end{aligned} \tag{2}$$

where $\boldsymbol{v}$ is the retrieved entity embedding from the entity memory, h_1, h_2, h_3, and h_4 are mutually independent Multi-Layer Perceptrons (MLPs) which return a zero vector $\mathbf{0}$ if $e = e_\emptyset$.

3.3 Relational Retrieval from Entity Memory

Although the simple access to the entity memory can retrieve the necessary entity embeddings for the modulation, this approach has obvious drawbacks as it not only fails to reflect the relations with other entities, but also regards unseen entities as the same null entity $e_\emptyset$. If so, all unseen entities are inevitably modulated by the same parameters even if they have essentially different meaning.

To tackle these limitations, we further consider the relational information between two entities that are linked with a particular relation. For example, the entity *New_York* alone will not give meaningful information. However, with two associated facts (*New_York*, *instance of*, *city*) and (*New_York*, *country*, *USA*), it is clear that *New_York* is a city in the *USA*. Motivated by this observation, we propose **Relational Retrieval** which leverages a KG $\mathcal{G}$ to retrieve entity embeddings from the memory, according to the relations defined in the given KG (See Figure 3, right).

More specifically, our goal is to effectively utilize the relations among entities in $\mathcal{G}$, to improve the `EntEmbed` function in equation 2. We tackle this objective by utilizing a *Graph Neural Network (GNN)* which learns feature representations of each node using a neighborhood aggregation scheme (Hamilton et al., 2017), as follows:

$$\boldsymbol{v} = \texttt{UPDATE}(\texttt{EntEmbed}(e), \\ \texttt{AGG}(\{\texttt{EntEmbed}(\hat{e}) : \forall \hat{e} \in \mathcal{N}(e;\mathcal{G})\})),$$

where $\mathcal{N}(e;\mathcal{G})$ is a set of neighboring entities of the entity e, `AGG` is the function that aggregates embeddings of neighboring entities of e, and `UPDATE` is the function that updates the representation of e with the aggregated messages from `AGG`.

However, simple aggregation (e.g., mean) cannot reflect the relative importance on neighboring nodes, thus we consider the attentive scheme (Velickovic et al., 2018; Brody et al., 2021) for neighborhood aggregation, to allocate weights to the target entity's neighbors by their importance. This scheme is helpful in filtering out less useful relations. Formally, we first define a scoring function ψ that calculates a score for every triplet (e_i, r_{ij}, e_j), which is then used to weigh each node during aggregation:

$$\boldsymbol{e}_i = \texttt{EntEmbed}(e_i),\ \boldsymbol{e}_j = \texttt{EntEmbed}(e_j), \\ \boldsymbol{e}^* = [\boldsymbol{e}_i \parallel \boldsymbol{r}_{ij} \parallel \boldsymbol{e}_j \parallel \boldsymbol{h}_{e_i}], \\ \psi(\boldsymbol{e}_i, \boldsymbol{r}_{ij}, \boldsymbol{e}_j, \boldsymbol{h}_{e_i}) = \boldsymbol{a}^\top \sigma(\boldsymbol{W} \cdot \boldsymbol{e}^*),$$

where σ is a nonlinear activation, $\boldsymbol{e}^* \in \mathbb{R}^{4d}$ is concatenated vector where $\parallel$ denotes the concatenation, $\boldsymbol{a} \in \mathbb{R}^d$ and $\boldsymbol{W} \in \mathbb{R}^{d \times 4d}$ are learnable parameters, $\boldsymbol{r}_{ij} \in \mathbb{R}^d$ is a embedding of the relation, and $\boldsymbol{h}_{e_i} \in \mathbb{R}^d$ is a context representation of the entity e_i obtained from the intermediate hidden states of the LM[3].

The scores obtained from ψ are normalized across all neighbors $e_j \in \mathcal{N}(e_i;\mathcal{G})$ with softmax:

$$\alpha_{ij} = \mathrm{softmax}(\psi(\boldsymbol{e}_i, \boldsymbol{r}_{ij}, \boldsymbol{e}_j)) \\ = \frac{\exp(\psi(\boldsymbol{e}_i, \boldsymbol{r}_{ij}, \boldsymbol{e}_j))}{\sum_{e_{j'} \in \mathcal{N}(e_i;\mathcal{G})} \exp(\psi(\boldsymbol{e}_i, \boldsymbol{r}_{ij'}, \boldsymbol{e}_{j'}))}.$$

Then, we update the entity embedding with a weighted average of the neighboring nodes with α as an attention coefficient, denoted as follows:

$$\boldsymbol{v} = \texttt{UPDATE}\left(\sum\nolimits_{e_{j'} \in \mathcal{N}(e_i;\mathcal{G})} \alpha_{ij} \cdot \boldsymbol{e}_{j'}\right). \qquad (3)$$

By replacing the `EntEmbed` function in equation 2 with the above GNN in equation 3, we now represent each entity with its relational information in KG. This relational retrieval has several advantages over simple retrieval of a single entity from the entity memory. First, the relational retrieval with KG can consider richer interactions among entities, as described in Figure 3.

In addition, we can naturally represent an unseen entity – which is not seen during training but appears at test time – through neighboring aggregation, which is impossible only with the entity memory. In Figure 2, we provide an illustrative example of the unseen entity representation, where the unseen entity *restenosis* is represented with a weighted sum of representations of its neighboring entities *myocardial_infarction*, *asthma*, and *pethidine*, which is beneficial when the set of entities for training and test datasets have small overlaps.

4 Experiment

4.1 Tasks and Datasets

We evaluate our model on two NLU tasks: Question Answering (QA) and Named Entity Recognition (NER). **For QA**, we use three domain-specific datasets: NewsQA (News, Trischler et al., 2017) and two subsets (Relation, Medication) of EMRQA (Clinical, Pampari et al., 2018). We use the Exact-Match (EM) and the F1 score as evaluation metrics. **For NER**, we use three datasets from different domains, namely CoNLL-2003 (News, Sang and Meulder, 2003), WNUT-17 (Social Media, Derczynski et al., 2017) and NCBI-Disease (Biomedical, Dogan et al., 2014). We use the F1 score as the evaluation metric. We report statistics and detailed descriptions of each dataset in **Appendix** B.2.

4.2 Baselines

A direct baseline of our KALA is the adaptive pre-training, which is commonly used to adapt the PLM independent to the choice of a domain and task. Also, to compare ours against a more powerful baseline, we modify a recent method (Chen et al., 2020) that alleviates forgetting of PLM during fine-tuning. Details for each baseline we use are described as follows:

1. **Vanilla Fine-Tuning (FT)**: A baseline that directly fine-tunes the LM on downstream tasks.
2. **Fine-Tuning +** ***more params***: A baseline with one more transformer layer at the end of the

LM. We use this baseline to show that the performance gain of our model does not come from the use of additional parameters.

3. **Task-Adaptive Pre-training (TAPT)**: A baseline that further pre-trains the PLM on task-specific corpus as in Gururangan et al. (2020).
4. **TAPT + RecAdam**: A baseline that uses RecAdam (Chen et al., 2020) during further pre-training of PLMs (i.e., TAPT), to alleviate catastrophic forgetting of the learned general knowledge in PLMs from adaptive pre-training.
5. **Domain-Adaptive Pre-training (DAPT)**: A strong baseline that uses a large-scale domain corpus outside the training set during further pre-training (Gururangan et al., 2020), and requires extra data and large computational overhead.
6. **KALA** (pointwise): A variant of KALA that only uses the **entity memory** and does not use the knowledge graphs.
7. **KALA** (relational): Our full model that uses KGs to perform relational retrieval from the entity memory.

4.3 Experimental Setup

We use the uncased BERT-base (Devlin et al., 2019) as the base PLM for all our experiments on QA and NER tasks. For more details on training and implementation, please see the **Appendix** B.

4.4 Experimental Results

Performance on QA and NER tasks On both extractive QA and NER tasks, our KALA outperforms all baselines, including TAPT and TAPT+RedcAdam (Gururangan et al., 2020; Chen et al., 2020), as shown in Table 1 and 2. These results show that our KALA is highly effective for the language model adaptation task. KALA also largely outperforms DAPT (Gururangan et al., 2020) which is trained with extra data and requires a significantly higher computational cost compare to KALA (See Figure 1 for the plot of efficiency, discussed in Section 5.3).

Effect of Using more Parameters One may suspect whether the performance of our KALA comes from the increment of parameters. However, the experimental results in Table 1 and 2 show that increasing the parameters for PLM during fine-tuning (+ more params) yields marginal performance improvements over naive fine-tuning. This result confirms that the performance improvement of KALA is not due to the increased number of parameters.

Importance of Relational Retrieval The performance gap between KALA (relational) and KALA (point-wise) shows the effectiveness of relational retrieval for language model adaptation, which allows us to incorporate relational knowledge into the PLM. The relational retrieval also helps address unseen entities, as discussed in Section 5.4.

5 Analysis and Discussion

5.1 Ablation Studies

We perform an ablation study to see how much each component contributes to the performance gain.

KFM Parameters We first analyze the effect of feature modulation parameters (i.e., gamma and beta) in transformers by ablating a subset of them in Table 3, in which we observe that using both

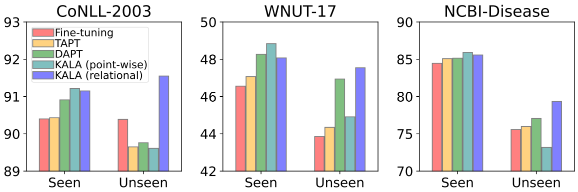

Figure 4: Results on seen and unseen, where Seen denotes the context having less than 3 unseen entities, otherwise Unseen. Note that DAPT uses extra datasets in addition to the training dataset, thus the Unseen for other models could be considered as the Seen for DAPT.

gamma and beta after both layer normalization on a transformer layer obtains the best performance.

Architectural Variants We now examine the effectiveness of the proposed knowledge conditioning scheme in our KALA framework. To this end, we use or adapt the knowledge integration methods from previous literature, to compare their effectiveness. Specifically, we couple the following five components with KALA: Entity-as-Experts (Févry et al., 2020), Adapter (Houlsby et al., 2019), KT-Net (Yang et al., 2019), ERNIE (Zhang et al., 2019), and ERICA (Qin et al., 2021). Note that, most of them were proposed for improving pre-training from scratch, while we adapt them for fine-tuning under our KALA framework (The details are given in **Appendix** B.4). As shown in Table 4, our KFM used in KALA outperforms all variants, demonstrating the effectiveness of feature modulation in the middle of transformer layers for fine-tuning.

5.2 Robustness to Other PLMs

Although we believe our experimental results on Table 1, 2 with BERT (Devlin et al., 2019) are enough to show the effectiveness of KALA across different pre-trained language models (PLMs), one might be curious that KALA can work on even other PLMs such as RoBERTa (Liu et al., 2020). Thus, to address such concerns, we additionally conduct experiments on RoBERTa. As shown in Table 5, we observe that our KALA outperforms all baselines except for one case (Fine-Tuning + *more params* on NewsQA). Thus, we believe that our KALA would be useful to any PLMs, not depending on specific PLMs.

5.3 Efficiency

Figure 1 illustrates the performance and training FLOPs of KALA against baselines on the NewsQA dataset. We observe that the performance of TAPT decreases with the increased number of iterations, which could be due to forgetting of the knowledge from the PLM. On the other hand, DAPT, while not suffering from performance loss, requires huge computational costs as it trains on 112 times larger data for further pre-training (See **Appendix** B.3 for detailed explanations on training data). On the other hand, our KALA outperforms DAPT without using external data, while requiring 17 times fewer computational costs, which shows that KALA is not only effective but also highly efficient.

To further compare the efficiency in various aspects, we report GPU memory, training wall time, and training FLOPs for baselines and ours in Table 6. Through this, we verify that our KALA is more efficient to train for language model adaptation settings than baselines. Note that the resource requirement of KALA could be further reduced by adjusting the size of the entity memory (e.g., removing less frequent entities). Therefore, to show the flexibility of our KALA on the typical resource constraint, we provide the experimental results on two different settings (i.e., tuning the number of entities in the entity memory) – KALA with memory size of 200 and 62.8k (full memory) in **Appendix** C.6.

Context: A **nonsense mutation** in **exon** 17 (**codon** 556) of the RB1 **gene** was found to be present homozygously in both the **retinal** and the pineal tumours.

Fact: (retinal, instance of, gene)

Method	GPU Mem.	Approx. Wall Time	FLOPs (10^{16})
Fine-Tuning	8 GB	3 hrs	9.5
+ *more params*	8.8 GB	3 hrs	10.1
TAPT	8 GB	3.8 hrs	10.1
DAPT	48 GB	40 hrs <	182.0
KALA (ours, 0.2k)	8.4 GB	3 hrs	9.97
KALA (ours, 62.8k)	9.2 GB	3 hrs	10.5

Table 6: Efficiency comparisons of GPU memory, Wall Time, and FLOPs on the NewsQA dataset. The number 0.2k and 62.8k indicate the size of entity memory used in our KALA.

5.4 Effectiveness on Unseen Entities

One remarkable advantage of our KALA is its ability to represent an unseen entity by aggregating features of its neighbors from a given KG. To analyze this, we first divide all contexts into one of Seen and Unseen, where Seen denotes the context with less than 3 unseen entities, and then measure the performance on the two subsets. As shown in Figure 4, we observe that the performance gain of KALA over the baselines is much larger on the Unseen subset, which demonstrates the effectiveness of KALA's relational retrieval scheme to represent unseen entities. DAPT also largely outperforms fine-tuning and TAPT as it is trained on an extremely large external corpus for adaptive pre-training. However, KALA even outperforms DAPT in most cases, verifying that our knowledge-augmentation method is more effective for tackling domain-specific tasks. The visualization of embeddings of seen and unseen entities in Figure 2 shows that KALA embeds the unseen entities more closely to the seen entities[4], which explains KALA's good performance on the Unseen subset.

5.5 Case Study

To better see how our KFM (§3.2) works, we show the context and its fact, and then visualize representations from the PLM modulated by the KFM. As shown in Figure 5 right, the token '##on' is not aligned with their corresponding tokens, such as 'ex' (for *exon*) and 'cod' (for *codon*), in the baseline. However, with our feature modulation that transforms multiple tokens associated with the single entity equally, the two tokens (e.g., ('ex', '##on')), composing one entity, are closely embedded. Also, while the baseline cannot handle the unseen entity consisting of three tokens: 're', '##tina', and '##l', KALA embeds them closely by representing the unseen *retinal* from the representation of its neighborhood *gene* derived by the domain knowledge – (*retinal*, *instance of*, *gene*).

5.6 Extension to Generative Model

Our KALA framework is also applicable to encoder-decoder PLMs by applying the KFM to the encoder. Therefore, we further validate KALA's effectiveness on the encoder-decoder PLMs on the generative QA task (Lee et al., 2021) with T5-small (Raffel et al., 2020). Table 7 shows that KALA largely outperforms baselines even with such a generative PLM.

6 Conclusion

In this paper, we introduced KALA, a novel framework for language model adaptation, which modulates the intermediate representations of a PLM by conditioning it with the entity memory and the relational facts from KGs. We validated KALA on various domains of QA and NER tasks, on which KALA significantly outperforms relevant baselines while being computationally efficient. We demonstrate that the success of KALA comes from both KFM and relational retrieval, allowing the PLM to recognize entities but also handle unseen ones that might frequently appear in domain-specific tasks. There are many other avenues for future work, including the application of KALA on pre-training of knowledge-augmented PLMs from scratch.

---

[4] We quantitatively measure the mean of cosine distance of each unseen entity to its nearest seen entity, observing that KALA embeds unseen 1.5 times more closer to seen than DAPT (i.e., 0.07 for KALA vs 0.11 for DAPT for distance).

Ethical Statements

Enhancing the domain converge of pre-traind language models (PLMs) with external knowledge is increasingly important, since the PLMs cannot observe all the data during training and cannot memorize all the necessary knowledge for solving down-stream tasks. Our KALA contributes to this problem by augmenting domain knowledge graphs for PLMs. However, we have to still consider the accurateness of knowledge, i.e., the fact in the knowledge graph may not be correct, which affects the model to generate incorrect answers. Also, the model's prediction performance is still far from optimal. Thus, we should be aware of model's failure from errors in knowledge and prediction, especially on high-risk domains (e.g., biomedicine).

Table 8: **Hyperparamters for Knowledge Graph (Top) and KALA (Bottom)** on six datasets we used. The reported performances on main paper are measured with the above settings.

A Details on KG Construction

In this work, we propose to use the Knowledge Graph (KG) that can define the relational information among entities that only appear in each dataset. However, unfortunately, most of the task datasets do not contain such relational facts on its context, thus we need to construct them manually to obtain the knowledge graph. In this section, we explain the way of constructing the knowledge graph that we used, consisting of facts of entities for each context in the task dataset.

Relation extraction is the way how we obtain the factual knowledge from the text of the target dataset. To do so, we first need to extract entities and their corresponding mentions from the text, and then link it to the existing entities in wikidata (Vrandecic and Krötzsch, 2014). In order to do this, we use the existing library named as spaCy[5], and open-sourced implementation of Entity Linker[6]. To sum up, in our work, a set of entities $\mathcal{E}^{(i)}$ and corresponding mentions $\mathcal{M}^{(i)}$ for the given input $\boldsymbol{x}^{(i)}$ are obtained through this step. Regarding a concrete example, please see format (a) in Figure 6. In the example, "Text" indicates the entity mention within the input $\boldsymbol{x}$, the "start" and "end" indicates its mention position denoted as (m^{α}, m^{ω}), and "id" indicates the wikidata id for the entity identification used in the next step.

To extract the relation among entities that we obtained above, we use the scheme of Relation Extraction (RE). In other words, we use the trained RE model to build our own knowledge base (KB) instead of using the existing KG directly from the existing general-domain KB[7]. Specifically, we first fine-tune the BERT-base model (Devlin et al., 2019) for 2 epochs with 600k distantly supervised data used in Qin et al. (2021), where the Wikipedia document and the Wikidata triplets are aligned. Then, we use the fine-tuned BERT model to extract the relations between entity pairs in the text. We use the model with a simple bilinear layer on top of it, which is widely used scheme in the relation extraction literature (Yao et al., 2019). For an example of the extracted fact, please see format (b) in Figure 6. In the example, "h" denotes the wikidata id of the head entity, "r" denotes the wikidata id of the extracted relation, and "t" denotes the wikidata id of the tail entity. In the relation extraction, the model returns the categorical distribution over the top 100 frequent relations. In general, the relation of top-1 probability is used as the relation for the corresponding entity pair. However, this approach sometimes results in predicting `no_relation` on most entity pairs. Thus, to obtain more relations, we further use the relation of top-2 probability in the case where `no_relation` has a top-1

---

[5] https://spacy.io/

[6] https://github.com/egerber/spaCy-entity-linker

[7] We faced several problems here. First of all, most KBs such as Wikidata are less informative, especially for the entities included in the domain-specific context (e.g., News, Medical records). It only has a few facts for each context of domain-specific tasks, although we can find a lot of entities included in the context. Second, the entity linker is imperfect. Due to the wrongly linked entity to the wikidata, even existing relations in the KG are ignored a lot. Therefore, we instead use a trained neural network to effectively extract the relations between entities, instead of direct querying to obtain facts.

	Training			Validation			Test		
Dataset	# Context	C. Length	# Question	# Context	C. Length	# Question	# Context	C. Length	# Question
NewsQA	11428	655.7	74160	-	-	-	106	625.8	674
Relation	296	1386.1	6162	42	1206.6	321	85	1467.7	802
Medication	182	1737.3	7518	26	1626.5	1858	53	2005.0	4005

Table 9: **QA dataset statistics.** We report the number of contexts and questions (i.e., # Context and # Question), with the average length of contexts (i.e., C. Length) where the length is measured as the number of tokens after wordpiece tokenization.

probability but the top-2 probability is larger than a certain threshold (e.g., > 0.1). In Figure 6, we summarize our KG construction pipeline. In Table 8, we report the hyperparameters related to our KG construction.

B Experimental Setup

In this section, we introduce the detailed setups for our models and baselines used in Table 1, 2, and 4.

B.1 Implementation Details

We use the Pytorch (Paszke et al., 2019) for the implementation of all models. Also, to easily implement the language model, we use the huggingface library (Wolf et al., 2020) containing various transformer-based pre-trained language models (PLMs) and their checkpoints.

Details for KALA In this paragraph, we describe the implementation details of the components, such as four linear layers in the proposed KFM, architectural specifications in the attention-based GNN, and initialization of both the entity memory and relational embeddings, in the following. In terms of the functions h_1, h_2, h_3, and h_4 in the KFM of Equation 2, we use two linear layers with the ReLU (Nair and Hinton, 2010) activation function, where the dimension is set to 768.

For relational retrieval, we implement the novel GNN model based on GATv2 (Brody et al., 2021) provided by the torch-geometric package (Fey and Lenssen, 2019). Specifically, we stack two GNN layers with the RELU activation function and also use the dropout with a probability of 0.1. For attention in our GNN, we mask the nodes of the null entity, so that the attention score becomes zero for them. Moreover, to obtain the context representation of the entity (See Footnote 3 in the main paper) used in the GNN attention, we use the scatter operation[8] for reduced computational cost.

For Entity Memory, we experimentally found that initializing the embeddings of the entity memory with the contextualized features obtained from the pre-trained language model could be helpful. Therefore, the dimension of the entity embedding is set to the same as the language model $d = 768$. For relation embeddings, we randomly initialize them, where the dimension size is set to 128.

Location of KLM in the PLM Note that, the number and location of the KFM layers inside the PLM are hyperparameters. However, we empirically found that inserting one to three KFM layers at the end of the PLM (i.e., after the 9th - 11th layers of the BERT-base language model) is beneficial to the performance (See Appendix C.4 for experiments on diverse layer locations).

B.2 Dataset Details

Here we describe the dataset details with its statistics for two different tasks: extractive question answering (QA) and named entity recognition (NER).

Question Answering We evaluate models on three domain-specific datasets: NewsQA, Relation, and Medication. Notably, NewsQA (Trischler et al., 2017) is curated from CNN news articles. Relation and Medication are originally part of the emrQA (Pampari et al., 2018), which is an automatically constructed question answering dataset based on the electrical medical record from n2c2 challenges[9]. However, Yue et al. (2020) extract two major subsets by dividing the entire dataset into Relation and Medication and suggest the usage of sampled questions from the original emrQA dataset. Following the suggestion of Yue et al. (2020), we use only 1% of generated questions of Relation for training, validation, and testing. Also, we only use 1% of generated questions of Medication for training and use 5% of generated questions of Medication for validation and testing. Since the original emrQA is automatically generated based on templates, the quality is poor – it means that the original emrQA dataset was inappropriate to evaluate the ability of the model to reason over the clinical text since the most of questions can be

Table 11: **NER dataset statistics.** We report the number of contexts (i.e., # Context), with the average length of them (i.e., C. Length) on training, validation, and test sets.

answered by the simple text matching. To overcome this limitation, Yue et al. (2020) suggests two ways to make the task more difficult. First, they divide the question templates into easy and hard versions and then use the hard question only. Second, they suggest replacing medical terminologies in the question of the test set into synonyms to avoid the trivial question which can be solvable with a simple text matching. We use both methods to Relation and Medication datasets to report the performance of every model. For more details on Relation and Medication datasets, please refer to the original paper (Yue et al., 2020). The statistics of training, validation, and test sets on all QA datasets are provided in Table 9.

Named Entity Recognition We use three different domain-specific datasets for evaluating our KALA on NER tasks: CoNLL-2003 (Sang and Meulder, 2003) (News), WNUT-17 (Derczynski et al., 2017) (Social Network Service) and NCBI-Disease (Dogan et al., 2014) (Biomedical). The CoNLL-2003 is constructed from the manually curated 1,393 English news articles, including 301.4k tokens, which has 9 class labels. The WNUT-17 dataset consists of 65,124 emerging and rare entities from social media (e.g., Twitter, Reddit, YouTube, to name a few), which has 13 class labels. The NCBI-Disease dataset consists of the 793 PubMed articles from the biomedical domain, which contains 6,892 disease mentions and 790 disease concepts, and also has 3 class labels. The statistics of training, validation, and test sets are provided in Table 11.

Table 12: **Hyperparamters for DAPT** on two domains we used for reporting the performances in the main paper.

B.3 Training details

All experiments are constrained to be done with a single 12GB Geforce RTX 2080 Ti GPU for fairness in terms of memory and the availability on the academic budget, except for the DAPT and generative QA which use a single 48GB Quadro 8000 GPU. KALA training needs 3 hours in wall time with a single GPU. For all experiments, we select the best checkpoint on the validation set. For the summary of training setups, please see Table 10 and 12.

Fine-tuning Setup In the following three paragraphs, we explain the setting of fine-tuning for QA, NER, and generative QA tasks. For all experiments on extractive QA tasks, we fine-tune the Pre-trained Language Model (PLM) for 2 epochs with the weight decay of 0.01, learning rate of 3e-5, maximum sequence length of 384, batch size of 12, linear learning rate decay of 0.06 warmup rate, and half precision (Micikevicius et al., 2018).

For all experiments on NER tasks, we fine-tune the PLM for 20 epochs, where the learning rate is set to 5e-5, maximum sequence length is set to 128, and batch size is set to 32. We use AdamW (Loshchilov and Hutter, 2019) as an optimizer using BERT-base as the PLM.

For the generative QA task in Table 7, we fine-tune the T5-small (Raffel et al., 2020) for 4 epochs with the learning rate of 1e-4, maximum sequence length of 512, and batch size of 64. We also use the Adafactor (Shazeer and Stern, 2018) optimizer. Instead of training with the same optimizer as in BERT for QA and NER, we instead use the independent AdamW optimizer with the learning rate of 1e-4 and weight decay of 0.01 to train the KALA module with T5.

Adaptive Pre-training Setup In this paragraph, we describe the experimental settings of adaptive pre-training baselines, namely TAPT, TAPT (+ RecAdam), and DAPT. For QA tasks, we further pre-train the PLM for {1,3,5,10} epochs and then report the best performance among them. Specifically, reported TAPT result on NewsQA, Relation, and Medication are obtained by 1 epoch of further pre-training. We use the weight decay of 0.01, learning rate of 5e-5, maximum sequence length of 384, batch size of 12, and linear learning rate decay of 0.06 warmup rate, with a half-precision. Also, the masking ratio for the pre-training objective is set to 0.15, following the existing strategy introduced in the original BERT paper (Devlin et al., 2019).

For NER tasks, we further pre-train the PLM for 3 epochs across all datasets. In particular, the learning rate is set to 5e-5, batch size is set to 32, and the maximum sequence length is set to 128. We also use AdamW (Loshchilov and Hutter, 2019) as the optimizer for all experiments.

In the case of T5-small for generative QA in Table 7, we further pre-train the PLM for 4 epochs with the learning rate of 0.001, batch size of 64, maximum sequence length of 384, and Adafactor (Shazeer and Stern, 2018) optimizer.

Regarding the setting of TAPT (+ RecAdam) on all tasks, we follow the best setting in the original paper (Chen et al., 2020) – sigmoid as an annealing function with annealing parameters: $k = 0.5$, $t_0 = 250$, and the pretraining coefficient of 5000.

For training with DAPT, we need an external corpus having a large amount of data for adaptive pre-training. Thus, we first choose the datasets of two domains – News and Medical. Specifically, as the source of corpus for the News domain, we use the sampled set of 10 million News from the RealNews dataset used in Gururangan et al. (2021). As the source of corpus for the Medical domain, we use the set of approximately 100k passages from the Medical textbook provided in Jin et al. (2020). The size of pre-training data used in DAPT is much larger than TAPT. In other words, for experiments on NewsQA, TAPT only uses fine-tuning contexts containing 5.8 million words from the NewsQA training dataset, while DAPT uses more than a hundred times larger data – enormous contexts containing about 618 million words from the RealNews database. For both News and Medical domains, we further pre-train the BERT-base model for 50 epochs with the batch size of 64, to match the similar computational cost used in Gururangan et al. (2020). Other experimental details are the same as TAPT described above.

B.4 Architectural Variant Details

In this subsection, we describe the details of architectural variants reported in Section 5.1. For all variants, we use the same KGs used in KALA.

Entity-as-Experts (Févry et al. (2020); EaE) utilizes the entity memory similar to our work, but they use the parametric dense retrieval more like the memory neural network (Sukhbaatar et al., 2015). Similar to Févry et al. (2020); Verga et al. (2021), we change the formulation of query and memory retrieval by using the mention representation of the entity from the intermediate hidden states of PLMs, which is formally defined as follows:

$$\boldsymbol{h}_e = \frac{1}{m^\omega - m^\alpha + 1} \sum_{i=m^\alpha}^{m^\omega} \boldsymbol{h}_i^{l-1}, \qquad (4)$$
$$\boldsymbol{v} = \mathrm{softmax}(\boldsymbol{h}_e \cdot \boldsymbol{E}^\top) \cdot \boldsymbol{E},$$

where $\boldsymbol{h}_e$ represents the average of token representations of the entity mention $m = (m^\alpha, m^\omega)$. We also give the supervised retrieval loss (`ELLoss` in Févry et al. (2020)), when training the EaE model. With this retrieval, EaE also can represent the unseen entity $e \notin \mathcal{E}_{train}$ if we know the mention boundary of the given entity on the context. We believe it is expected to work well, if the entity memory is pre-trained on the enormous text along with the pre-training of the language model from the scratch. However, it might underperform for the language model adaptation scenario, since it can fall into the problem of circular reasoning – the PLM does not properly represent the unseen entity, but it should predict which entity it is similar from the representation. Regarding the integration of the knowledge from the entity memory into the PLM, the retrieved entity representation $\boldsymbol{v}$ is simply added (Peters et al., 2019) to the hidden representations $\boldsymbol{H}$ after the transformer block as follows:

$$\tilde{\boldsymbol{H}}^l = \boldsymbol{H}^l + h(\boldsymbol{v}) \tag{5}$$

where h is Multi-Layer Perceptrons (MLPs).

Adapter (Houlsby et al., 2019) is introduced to fine-tune the PLM only with a few trainable parameters, instead of fine-tuning the whole parameters of the PLM. To adapt this original implementation into our KALA framework, we replace our Knowledge-conditioned Feature Modulation with it, where the Adapter is used as the knowledge integration module. We interleave the layer of Adapter after the feed-forward layer (FF) and before the residual connection of the transformer block. Also, instead of only providing the LM hidden states as an input, we concatenate the knowledge representation in Equation 3 to the LM hidden states. Note that we fine-tune the whole parameters following our KALA setting, unlike fine-tuning the parameters of only Adapter layers in Houlsby et al. (2019).

ERNIE (Zhang et al., 2019) is a notable PLM model that utilizes the external KB as an input for the language model. The key feature of ERNIE can be summarized into two folds. First, they use the multi-head self-attention scheme (Vaswani et al., 2017) to contextualize the input entities. Second, ERNIE fuses the entity representation at the end of the PLM by adding it to the corresponding language representation. We assume that those two features are important points of ERNIE. Therefore, instead of using a Graph Neural Network (GNN) layer, we use a multi-head self-attention layer to contextualize the entity embeddings. Then, we add it to a representation of the entity from the PLM, which is the same as the design in equation 5.

KT-Net (Yang et al., 2019) uses knowledge as an external input in the fine-tuning stage for extractive QA. Since they have a typical layer for integrating existing KB (Miller, 1995; Carlson et al., 2010) with the PLM, we only adopt the self-matching layer as the architecture variant of the KFM layer used in our KALA framework. The computation of the self-matching matrix in KT-Net is costly, i.e., it requires a large computational cost that is approximately 12 times larger than KALA.

ERICA (Qin et al., 2021) uses contrastive learning in LM pre-training to reflect the relational knowledge into the language model. We use the Entity Discrimination task from ERICA on the primary task of fine-tuning. We would like to note that, as reported in Section 5 of the original paper (Qin et al., 2021), the use of ERICA on fine-tuning has no effect, since the size and diversity of entities and relations in downstream training data are limited. Such limited information rather harms the performance, as it can hinder the generalization. In other words, contrastive learning cannot reflect the entity and relation in the test dataset.

B.5 FLOPs Computation

In this subsection, we give detailed descriptions of how the FLOPs in Figure 1 are measured. We majorly follow the script from the ELECTRA (Clark et al., 2020) repository to compute the approximated FLOPs for all models including ours. For FLOPs computation of our KALA, we additionally include the FLOPs of the entity embedding layer, linear layers for h_1, h_2, h_3, h_4, and GNN layer. Since the GNN layer is implemented based on the sparse implementation, we first calculate the FLOPs of the message propagation over one edge, and then multiply it to the average number of edges per node. Also, in terms of the computation on mentions, we consider the maximum sequence length of the context rather than the average number of mentions, to set the upper bound of FLOPs for our KALA. Note that, in NewsQA training data, the average number of nodes is 57, the average number of edges for each node is 0.64, and the average number of mentions in the context is 92.68.

C Additional Experimental Results

In this section, we provide the analyses on the forgetting of TAPT, entity memory, number of entities and facts, location of the KLM layer, and values of Gamma and Beta.

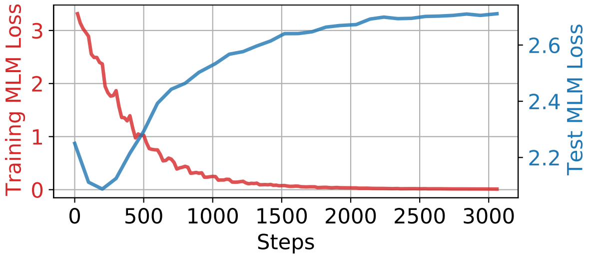

Figure 7: Masked Language Model loss from Task-Adaptive Pre-Training on the domain-specific training dataset (Relation) and the general domain test dataset (Sampled wikipedia).

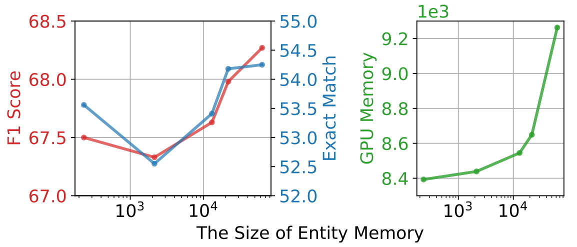

Figure 8: The performance (F1 score and Exact Match) and the GPU memory usage on NewsQA dataset with varying the size of elements in the entity memory.

C.1 Analysis on forgetting of TAPT

In Figure 1, we observe that the performance of TAPT decreases as the number of training steps increases. To get a concrete intuition on this particular phenomenon, we analysis what happens in the Pre-trained Language Model (PLM), when we further pre-train it on the task-specific corpus. Specifically, in Figure 7, we visualize the Masked Language Model (MLM) loss of TAPT on both domain-specific corpus from the Relation dataset and general corpus from the sampled Wikipedia documents during the adaptive pre-traing. As Figure 7 shows, the test MLM loss increases while the training MLM loss persistently increases as the training step increases. This result indicates that TAPT on domain-specific corpus may yield the catastrophic forgetting of the general knowledge in the PLM.

C.2 Effects of the Size of Entity Memory

In this subsection, we analyze how the size of entity memory affects the performance of our KALA. In Figure 8, we plot the performance of KALA on the NewsQA dataset by varying the number of entity elements in the memory. Note that, we reduce the size of the entity memory by eliminating the entity appearing fewer times. Thus, the results are obtained by only considering the entities that appear more than $[1000, 100, 10, 5, 0]$ times, e.g., 0 means the model with full entity memory. As shown in Figure 8, we observe that the size of the entity memory is larger, the performance of our KALA is better in general. However, interestingly, we also observe that the smallest size of the entity memory shows decent performance, which might be due to the fact that some parameters in the entity memory are stale. For more discussions on it including visualization, please refer to Appendix D.2. Finally, we would like to note that, in Figure 1, we report the performance of our KALA in the case of $[1000, 5, 0]$ (i.e., considering entities appearing more than $[1000, 5, 0]$ times).

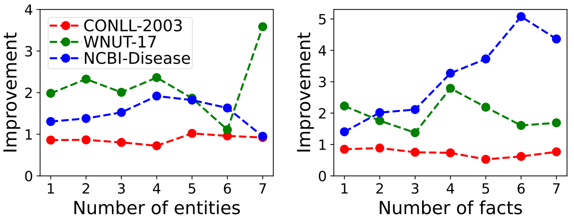

Figure 9: Performance improvements of our KALA from simple fine-tuning, with varying the number of entities and facts in the context on Named Entity Recognition tasks.

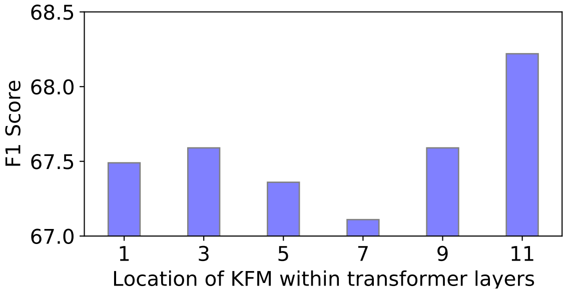

Figure 10: The performance of our KALA with varying the location of the KFM layer inside the BERT-base model. y-axis denotes the F1 score on NewsQA and x-axis denotes the location of the KFM layer. For instance, 11 means the case where the KFM layer is appended in the 11th transformer layer of BERT-base.

C.3 Effects of the Number of Entity and Fact

In this subsection, we aim to analyze which numbers of entities and facts per context are appropriate to achieve good performance in NER tasks. Specifically, we first collect the contexts having more than or equal to the k number of entities (or facts), and then calculate the performance difference from our KALA to the fine-tuning baseline. As shown in Figure 9, while there are no obvious patterns, performance improvements from the baseline are consistent across a varying number of entities and facts. This result suggests that our KALA is indeed beneficial when entities and facts are given to the model, whereas the appropriate number of entities and facts to obtain the best performance against the baseline is different across datasets.

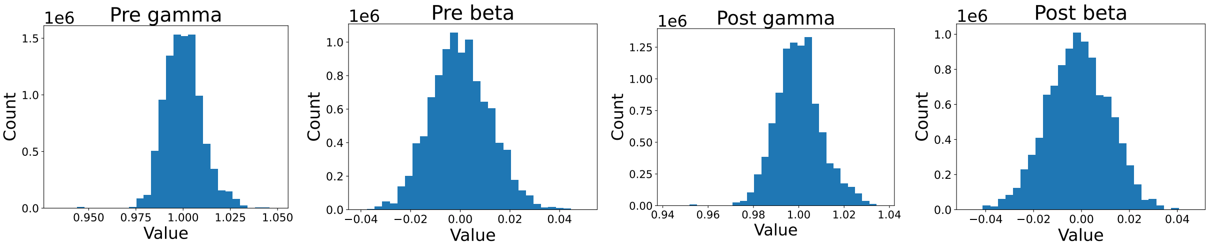

Figure 11: Histogram of values of gamma and beta on the CoNLL-2003 dataset.

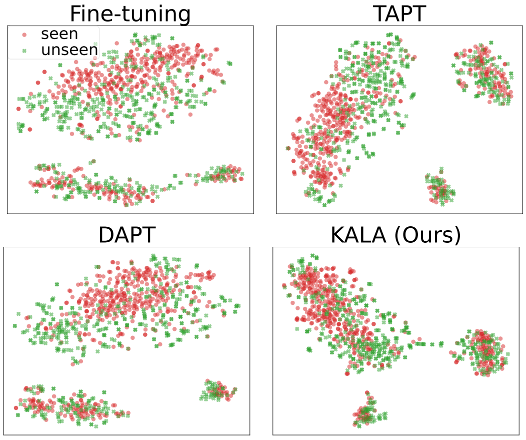

Figure 12: Visualization of contextual representations for seen and unseen entities on the NCBI-Disease dataset.

C.4 Effects of the Location of KFM

In the main paper and Appendix B.1, we describe that the location of the KFM layer inside the PLM architecture is the hyperparameter. However, someone might wonder which location of KFM yields the best performance, and what is the reason for this. Therefore, in this section, we analyze where we obtain the best performance in various locations of the KFM layer on the NewsQA dataset. Specifically, in Figure 10, we show the performance of our KALA with varying the location of the KFM layer insider the BERT-base model. The results demonstrate that the model with the KFM on the last layer of the BERT-base outperforms all the other choices. This might be because, as the final layer of the PLM is generally considered as the most task-specific layer, our KFM interleaved in the latest layer of BERT expressively injects the task-specific information from the entity memory and KGs, to such a task-specific layer.

C.5 Analysis on Values of Gamma and Beta

To see how much amount of value on gamma and beta is used to shift and scale the intermediate hidden representations in transformer layers, we visualize the modulation values, namely gamma and beta, in Figure 11. We first observe that, as shown in Figure 11, the distribution of values of gamma and beta approximately follow the Gaussian distribution, with zero mean for beta and one mean for gamma. Also, we notice that the scale of values remain nearly around the mean point, which suggests that the small amount of shifting to intermediate hidden representations on transformer layers is enough to contribute to the performance gain, as we can see in the main results of Table 1, 2.

C.6 Detailed Efficiency Comparison

While we provide the efficiency on FLOPs in Figure 1, we further provide the efficiency on GPU memory, wall time, and FLOPs for training each method in Table 6. Specifically, we measure the computational cost on the NewsQA dataset with BERT-base, where we use the single Geforce RTX 2080 Ti GPU on the same machine. For our KALA, as we can flexibly manage the cost of GPU memory by reducing the number of entities in entity memory (See Figure 8 with Appendix C.2 for more analysis on the effects of the size of entity memory), we provide the experimental results on two settings – KALA with memory size 0.2k and 62.8k (full memory). As shown in Table 6, we confirm that the computational cost of our KALA with the full memory is similar to the cost of the *more params* baseline that uses one additional transformer layer on top of BERT-base. However, by reducing the number of entities in the memory, we can achieve better efficiency than more params in terms of GPU memory and FLOPs. Also, we observe that the training cost (i.e., Wall Time and FLOPs) of TAPT and DAPT is high, especially on DAPT, thus we verify that our KALA is more efficient to train for domain adaptation settings.

D Additional Visualization Results

Here we provide the frequency distribution of entities, additional case studies, and more illustrations of textual examples and embedding spaces.

D.1 Additional Representation Visualization

While we already show the contextualized representations of seen and unseen entities in the latent

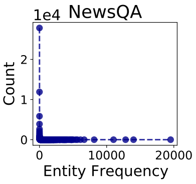

Figure 13: Distribution of frequency of entities on QA datasets: NewsQA, Relation, and Medication, where almost all entities appear less than 10 times, while an extremely few numbers of entities appear very frequently.

space in Figure 2 right, we further visualize them including the missing baselines of Figure 2, such as Fine-tuning or TAPT, in Figure 12 on the NCBI-Disease dataset. Similar to Figure 2, we observe that all baselines fail to closely embed the unseen entities in the representation space of seen entities. While this visualization result does not give a strong evidence of why our KALA outperforms other baselines, we clearly observe that KALA is beneficial to represent unseen entities in the feature space of seen entities, which suggests that such an advantage of our KALA helps the PLM to generalize over the test dataset, where the context contains unseen entities.

D.2 Entity Frequency Distribution

We visualize the frequency of entities in Figure 13 and 14. The entity frequency denotes the number of mentions of their associated entities within the entire text corpus of the training dataset. As shown in Figure 13 and 14 of QA and NER datasets, the entity frequency follows the long-tail distribution, where most entities appear a few times. For instance, in the NewsQA dataset, more than 20k entities among entire 60k entities appear only once in the training dataset, whereas one entity (*CNN*[10]) appears approximately 20k times. This observation suggests that most of the elements in the entity memory are not utilized frequently. In other words, only few entities are accurately trained with many training instances, whereas there exists the *stale* embeddings which are rarely updated. This observation raises an interesting research question on the efficient usage of the entity memory, as we can see in Figure 8 that the small size of entity memory could result in the better performance (See Appendix C.2). We leave the more in-depth analysis on the entity memory as the future work.

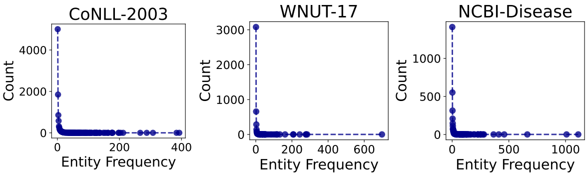

Figure 14: Distribution of frequency of entities on NER datasets: CoNLL-2003, WNUT-17, and NCBI-Disease, where almost all entities appear less than 10 times, while an extremely few numbers of entities appear very frequently.

D.3 Additional Case Study

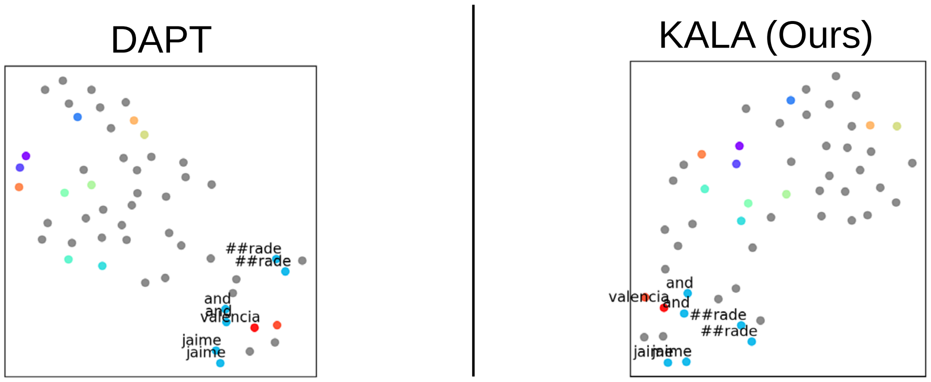
In addition to the case study in Figure 5, we further show the case on the question answering task in Figure 15, like in Section 5.5, With this example, we explain how the factual knowledge in KGs could be utilized to solve the task via our KALA. The question in the example is "who was kidnapped because of **her** neighbor". We observe that DAPT answers this question as *Araceli Valencia*. This prediction may come from matching the word 'her' in the question to the feminine name 'Araceli Valencia' in the context. In contrast, our KALA predicts the *Jaime Andrade* as an answer, which is the ground truth. We suspect that this might be because of the fact "(Jaime Andrade, spouse, Valencia)" in the knowledge graph, which relates the 'Valencia' to the 'Jaime Andrade'. Although it is not clear how it directly affects the model's performance, we can reason that KALA can successfully answer the question by utilizing the existing facts.

D.4 Additional Data Visualization

In Figure 16 and 17, we visualize the examples of the context with its seen and unseen entities and its relational facts. We first confirm that the quality of facts is moderate to use. For instance, in the first example of Figure 16, the fact in the context that *Omar_bin_Laden* is son of *Osama_bin_Laden*, is also appeared in the knowledge graph. In addition, we observe that there are facts that link unseen entities to the seen entities in both Figure 16 and 17. Thus, while some of the facts in the knowledge graph are not accurate, we can represent the unseen entities with their relation to the seen entities. We expect that there is a still room to improve in terms of the quality of KGs, allowing our KALA to modulate the entity representation more accurately. We leave the study on this as the future work.

---

[10] Almost every context in NewsQA includes the text 'CNN' since they are originated from the CNN News.



Context PHOENIX, Arizona (CNN) – Jamie Andrade had just gotten out of the shower when the men came to snatch him. Jamie Andrade was kept in this closet for three days without food or water, police say. (Osama Bin Laden, child, Omar Bin Laden)

(Italy, diplomatic relation, Spain)

Question 1 Where was Omar previously denied?
Answer 1 asylum in Britain.

Question 2 Did Spain give a reason for turning down the asylum?
Answer 2 was given

Question 3 Who was denied asylum in Britain?
Answer 3 Omar bin Laden

Question 4 What family member of Omar bin Laden was associated with terrorism?
Answer 4 his father

Context (CNN) – unseeded Frenchwoman Aravane Rezai produced one of the shocks of the year on Sunday by defeating favorite Venus Williams in straight sets to win the final of the Madrid Open. The 23-year-old Rezai – who had only claimed WTA Tour titles at Strasbourg and Bali prior to Madrid – continued her remarkable week with a 6-2 7-5 victory, adding Williams' scalp to her earlier surprise victories over former world number one's Junstine Henin and Jelena Jankovic. Williams, who returns to No.2 in the world behind younger sister Serena on Monday, lost the opening set in just 27 minutes and then failed to take advantage of a 4-1 lead in the. "I just cannot believe this," world number 24 Rezai – who must now enter calculations for the French Open – told reporters. "Venus played very well and I've always respected her as a player and a champion. I just tried my best today and it worked well for me." Williams, who was looking to secure her 44th career title, only converted two of her 13 break points in the batch – a statistic that contributed greatly to her defeat.

NAVER CLOVA[1] NAVER AI Lab[2] NYU[3]

Abstract

Many recent studies on large-scale language models have reported successful in-context zero- and few-shot learning ability. However, the in-depth analysis of when in-context learning occurs is still lacking. For example, it is unknown how in-context learning performance changes as the training corpus varies. Here, we investigate the effects of the source and size of the pretraining corpus on in-context learning in HyperCLOVA, a Korean-centric GPT-3 model. From our in-depth investigation, we introduce the following observations: (1) in-context learning performance heavily depends on the corpus domain source, and the size of the pretraining corpus does not necessarily determine the emergence of in-context learning, (2) in-context learning ability can emerge when a language model is trained on a combination of multiple corpora, even when each corpus does not result in in-context learning on its own, (3) pretraining with a corpus related to a downstream task does not always guarantee the competitive in-context learning performance of the downstream task, especially in the few-shot setting, and (4) the relationship between language modeling (measured in perplexity) and in-context learning does not always correlate: e.g., low perplexity does not always imply high in-context few-shot learning performance.

1 Introduction

NLP community has been surprised by emergence of in-context learning ability of a large-scale language model (LM) such as GPT-3 (Brown et al., 2020) despite no duplication between downstream task data and the pretraining corpus. Indeed, in-context learning uses a natural language description and a few examples to prime a language model. Then the language model can predict the answer of a new example without updating the language model's parameters. Since the release of GPT-3, various large-scale in-context language models have been proposed (Black et al., 2021; Kim et al., 2021; Zeng et al., 2021; Rae et al., 2021; Hoffmann et al., 2022; Chowdhery et al., 2022).

There still remain many questions on language models' in-context learning capability despite these successful reports. For example, the relationship between the choice of a pretraining corpus and downstream in-context learning task accuracy is unknown. Previous studies argue pretraining with the corpus similar to the downstream task improves the downstream performance, but these observations are often limited to the case where a pretrained language model is finetuned for the downstream task (Gururangan et al., 2020; Lee et al., 2020; Micheli et al., 2020).

In addition, analysis on the relation between the validation perplexity of a language model and in-context learning performance is still less investigated. Previous research on in-context learning implicitly assumes that perplexity is predictive of in-context learning performance by showing scaling law property of their model (Kaplan et al., 2020; Brown et al., 2020; Kim et al., 2021). Rae et al. (2021) also use perplexity for the hyperparameter selection on corpus reweighting in the pretraining of their in-context learner. However, their explicit correlations are less discovered.

Motivated by this lack of in-depth analysis on the relationship between in-context learning and corpus properties, we vary the sources and sizes of pretraining corpora and analyze their impact on in-context learning, using HyperCLOVA, which is a Korean-centric large LM. (Kim et al., 2021). We mainly discover in-context few-shot learning as in the previous work (Kim et al., 2021) but also explore in-context zero-shot learning. We use HyperCLOVA corpus, which is a large-scale pretraining corpus mainly in Korean collected by Kim et al. (2021), as a base corpus from which we derive pretraining corpora for our experiments.

[*] Equal contribution.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5168 - 5186
July 10-15, 2022

Our major findings include:

- **Corpus Source:** In-context learning performance depends heavily on corpus sources, and with some sources, in-context learning does not work effectively. For example, the model trained only on a subcorpus of blog (`Blog`) achieves competitive in-context few-shot learning performance, but training on a subcorpus of community website (`Cafe`) or online news articles (`News`) hardly yields in-context few-shot learning ability.
- **Corpus Combination:** In-context learning ability can emerge by fusing two corpora, even when each on its own does not result in in-context learning. For example, while training only on `KiN` corpus, which consists of QnA websites, or `Ency` corpus, which consists of Encyclopedia websites, in-context few-shot learning ability was not observed, but training on both corpora makes the emergence of in-context few-shot learning.
- **Domain Relevance:** Pretraining with a corpus related to a downstream task seems to help in-context zero-shot learning performance, but is not indicative of the competitive in-context few-shot learning performance. For example, training on only `News` corpus makes a relatively good in-context zero-shot learning ability on a news-related downstream task, e.g., news topic classification based on its title, KLUE-YNAT (Park et al., 2021), but does not yield in-context few-shot learning ability.
- **Perplexity:** Although perplexity and in-context learning accuracies correlate well when training a single model, perplexity alone does not reflect the difference in in-context learning accuracies across different language models. This is prominent particularly when they were trained using different pretraining corpora. For example, `Cafe` model, the model trained with `Cafe` corpus, has the second lowest validation perplexity on various domain sources after `Blog` model, but fails to emerge in-context few-shot learning.

2 Related Work

2.1 In-context Learning

Brown et al. (2020) demonstrate the concept of in-context learning, where a few training examples and/or task descriptions are provided together with a new input for a large-scale LM to produce a target of this input, without requiring any parameter update. A few training examples are used in the in-context few-shot learning setting, whereas no training example is used in the in-context zero-shot setting. A few follow-up studies have tried to improve the in-context learning ability (Zhao et al., 2021; Holtzman et al., 2021). On the other hand, another group of papers tries to explain the mechanism of in-context few-shot learning (Min et al., 2022; Xie et al., 2022).

2.2 Domain Relevance on Pretraining Corpus

Previous studies argue a better downstream accuracy is observed with a pretraining corpus more similar to the downstream task corpus (Gururangan et al., 2020; Lee et al., 2020; Micheli et al., 2020). However, these observations are limited to the case where a pretrained language model is finetuned for the downstream task.

There are a few studies on the effects of different corpus on the relationship between pretraining and in-context learning. A notable example is Codex, where GPT-3 is trained on Github corpus so that the model can generate code from comments (Chen et al., 2021a). However, the corpus used for Codex is limited to code comments and the corresponding code. We study the effect of pretraining corpus on in-context learning performance using various domains.

2.3 Quantity and Quality of Pretraining Corpus

There have been several studies on the quantity and quality of pretraining data. Raffel et al. (2020) conduct an ablation study on different pretraining corpus on T5, and their filtered C4 corpus makes T5 perform better in downstream tasks. As with GPT-3, researchers generally improve the quality of their language model through data filtering (Brown et al., 2020; Kim et al., 2021). Our research differs from the existing work in that we focus on in-depth analysis of how the amount of data and the corpus source affect in-context learning.

2.4 Multi-task Learning

Multi-task learning approaches, which explicitly finetune on the in-context learning objective by using numerous NLP tasks, are proposed recently to tackle zero/few-shot transfer to the unseen task

Name	Description	Tokens
`Blog`	Blog corpus	273.6B
`Cafe`	Online community corpus	83.3B
`News`	News corpus	73.8B

at test time (Wei et al., 2021; Sanh et al., 2021; Chen et al., 2021b; Min et al., 2021).

Unlike the studies in a finetuning paradigm, many properties of the in-context learning related to pretraining corpus are still unknown. As the previous multi-task studies show that diverse tasks improve the ability of in-context learning, our study shows that diverse pretraining corpora strengthen the ability of in-context learning.

3 Task Definition

3.1 Model

We use the variants of HyperCLOVA with various parameter sizes and pretraining corpus. We mainly experiment with models with 1.3B parameters, but we also include the result for 6.9B-sized models. All models have a maximum sequence length of 2,048.

We emphasize that all models use the same vocabulary across all our experiments. We use the morpheme-aware byte-level BPE tokenizer trained with HyperCLOVA corpus (Kim et al., 2021) for all models. We train multiple models with different portions of HyperCLOVA corpus to investigate the effects of the source and size of the corpus on in-context learning ability.

3.2 Pretraining with Different Corpus

We analyze the effect of seven subcorpora in the HyperCLOVA corpus: `Blog`, `Cafe`, `News`, `Comments`, `KiN`, `Modu`, and `Ency`. Table 1 summarizes the characteristics of the subcorpora. `Blog`, `Cafe`, and `News` are taken from blog, community sites, and online news articles of NAVER[1], a Korean web portal service, respectively. `Comments` is the comment threads related to the three subcorpora mentioned above. `KiN` comes from NAVER's online community QnA service similar to Quora. `Ency` is a collection of encyclopedic texts including Korean Wikipedia. `Modu` consists of five public datasets constructed by National Institute of the Korean Language[2], including 3.2B of news, 2.1B of written language, 0.4B of spoken language, 0.2B of web corpus, and 0.02B tokens of messenger. `Others` was excluded to investigate the explicit effects of domain corpus sources on in-context learning because `Others` is the corpus where various subcorpora are taken from multiple heterogeneous sources. Tables 12 and 13 in Appendix show the examples of seven pretraining corpus in Korean and English, respectively. `ALL` denotes the original HyperCLOVA corpus including `Others`.

For corpora with less than 150B tokens, we assign 99% of each corpus to the pretraining corpus and randomly extract 10,000 examples from the remaining 1% to the validation corpus for measuring validation perplexity. For corpora with more than 150B tokens, we make the training corpora 150B tokens via random sampling and construct a validation set with 10,000 examples randomly sampled from the remaining. As a result, the maximum training set size of each corpus is 150B tokens.

The validation set for each corpus consists of 10,000 examples and is used for the early stopping of models trained with each corpus. However, we combine all validation set to make the entire validation set contains 70,000 examples for seven domains, and the entire validation set is used for calculating perplexity, as described in Section 3.5.

3.3 Downstream Tasks

We evaluate in-context learning performance of each corpus-specific model on four Korean downstream task datasets used in Kim et al. (2021): NSMC[3], KorQuAD (Lim et al., 2019), AI Hub translation[4], and YNAT (Park et al., 2021). NSMC is a binary sentiment classification dataset on movie review. KorQuAD is a machine reading comprehension dataset similar to SQuAD 1.0 (Rajpurkar et al., 2016). AI Hub translation dataset consists of Korean-English parallel sentences from news, government websites, legal documents, etc. YNAT is a topic classification problem with seven classes.

We think that three datasets for downstream tasks are closely related to the HyperCLOVA cor-

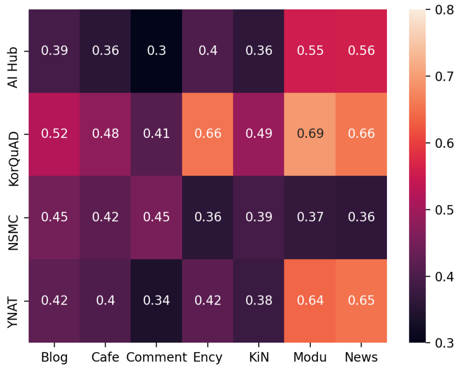

Figure 1: Vocabulary overlap ratio between pretraining corpus and downstream task. Top 1,000 nouns are used to calculate the ratio. Nouns are extracted using our in-house part-of-speech tagger.

pus. Passages which construct KorQuAD are taken from Korean Wikipedia, which is also a part of the `Ency`. YNAT is a topic classification task of news headlines, so the downstream task is deeply related to the `News` corpus. A significant portion of parallel sentences for AI Hub translation dataset also comes from news articles. `KiN` corpus is also related to the translation task. About 2.5% of QnA data in `KiN` includes Korean questions on the English language, as a foreign language. These question-style passages often include Korean-English sentence pairs in the passage. Vocabulary overlap between downstream tasks and HyperCLOVA corpus is depicted in Figure 1.

3.4 Experimental Details

We try our best to make the same hyperparameter of Kim et al. (2021), including global batch size, training step, maximum sequence length, learning rate, and so on. In our experiments, the models are trained for 72K steps with a global batch size of 1,024. We note that under this setting, the number of tokens that were actually used in pretraining is 150B. Therefore, we set the maximum size of training corpus to 150B as in Section 3.2.

In most experiments, validation perplexity decreases monotonically as training goes on. Thus, we use the checkpoint at 72K step. The only exception is the `Ency` model. The `Ency` model has a minimum validation loss at 12K steps, which is likely to be caused by overfitting to pretraining data due to a small size of the data. Therefore, we use early-stopping checkpoints at the 12K steps for the report.

For optimization, AdamW (Loshchilov and Hutter, 2019) with the learning rate of 2.0e-4 and the cosine learning rate scheduling are used. We use the mixed precision training. Models are trained on the Nvidia Superpod which consists of 1,024 A100 GPUs spread across 128 nodes. Using Superpod, it spends around 18 hours to train 1.3B model with 72K steps.

For classification tasks such as NSMC and YNAT, we use a rank classification approach (Wei et al., 2021), where we compare pre-defined outputs (“positive” and “negative”) and take the one with higher probability. KorQuAD and AI Hub are free-form completion tasks, where we directly generate output tokens using the greedy decoding.

In the few-shot experiments, the number of shots is set to 70, 4, 4, and 70 for NSMC, KorQuAD, AI Hub, and YNAT, respectively. Downstream tasks are performed 12, 1, 3, and 6 times with different random seeds for NSMC, KorQuAD, AI Hub, and YNAT, respectively. We report the average performance. Random seed influences the sampling of shots from training data and their order. The reason KorQuAD has only one random seed is described in Appendix D. Appendix D also includes the examples of the few-shot prompts used in our experiments. These all experimental settings in the few-shot experiments, from the number of shots to the number of random trials, basically come from the experimental setting of Kim et al. (2021). However, we change the number of trials of YNAT from 3 to 6, because we found that the standard derivation of YNAT is relatively high.

3.5 Measuring Validation Perplexity

We report validation perplexity in various tables and figures to verify our argument. We use the term “PPL” to denote validation perplexities on the validation set. The validation set consists of 70,000 examples from seven corpus sources, as described in Section 3.2. We emphasize that, for calculating PPL, all experiments use **the same vocabulary and validation set**.

In Tables 2 and 4, we use *Italic* font for the results from a multi-domain model, which is pretrained with two or more mixed corpora. Since a multi-domain model trains more domains than a single-domain model, the PPLs of multi-domain models are generally lower than those of single-domain models. To keep readers from directly comparing PPLs between a single-domain and a multi-domain model, we use italic font for the results of a multi-domain model.

4 Experimental Results

We perform intensive experiments to answer these four main questions:

1. How large do the source and the size of pretraining corpora have the effects on emerging in-context learning ability? (Section 4.2 and 4.3)
2. What is the effect of combining various corpora? (Section 4.4)
3. How large does domain relevance of corpus influence on model performances of the downstream task? (Section 4.5)
4. How strong is the correlation between validation perplexity and in-context learning of language models? (Section 4.6)

4.1 Main Results

Tables 2 and 4 show the in-context few-shot results on various pretraining corpus sources and different corpus combination, respectively. Tables 3 and 5 depict the in-context zero-shot results of some models in Tables 2 and 4, respectively. All results in Tables 2, 3, 4, and 5 come from models with 1.3B parameters. Tables 8 and 9 in Appendix A present the standard derivation values on the results of Tables 2 and 4.

In Tables 2, 3, 4, and 5, Purple-underline denotes the score is below the mean performance value of `ALL` and Majority baseline in Table 2, and **Teal-bold** denotes the score is above. We use this mean value of Majority and `ALL` in Table 2 as the performance basis to prevent the in-context learning performance of each model from being distorted by the high basis performance of two classification tasks such as NSMC and YNAT.

Tables 2 and 6 include in-context few-shot results on various pretraining corpus sizes. In Table 6, for example, 56B and 6B correspond to the 1/10 and 1/100 of the original HyperCLOVA corpus with 560B tokens, respectively. The 56B tokens and 6B tokens models are trained with around 3 and 25 epochs, respectively, so that both models can be trained with 72K training steps. On the other hand, Table 2 compares 27B tokens models trained with different corpus sources to show the results in controlled corpus size.

4.2 Effect of Corpus Source

It is noticeable that in-context learning ability emerges differently depending on pretraining corpus sources, as shown in Tables 2, 3, 4, and 5. For example, `Blog` model makes competitive in-context few-shot learning performance to `ALL` model, while each of `Cafe` and `News` models hardly shows in-context few-shot learning ability from Table 2. It is also noticeable that `Modu` model performs better than `Cafe` and `News` model although the size of `Modu` corpus is less than 1/10 of `Cafe` or `News` corpus, showing the corpus size is not the only factor to predict in-context learning performance. Likewise, it is also interesting that `Cafe+News` model also shows poor performance despite the same size to `Blog` and `ALL`, as shown in Table 4.

These differences in in-context learning are dramatic compared to the finetuning results we expect in general. For a comparative experiment between in-context learning and finetuning in our setting, we also finetuned the experimented models with LoRA (Hu et al., 2021). As Table 11 in Appendix C shows, the performance differences in finetuning are much smaller than in the case of in-context learning.

4.3 Effect of Corpus Size

Table 6 shows that reducing the corpus size from 150B to 56B does not decrease the performance severely despite training with 1/10 of corpus. However, the performance degradation of 6B tokens model is remarkable comparing to `ALL` model. Nevertheless, it is noticeable that 6B tokens model still performs much better than `Cafe+News` model, which trains 150B tokens of `Cafe` and `News` corpus.

We can also see the similar results for three Blog models of different sizes in Table 2. `Blog` and `Blog` 54B achieve similar performance. However, like in `ALL` 6B, `Blog` 27B performs quite worse than `Blog` 54B.

Figure 3 shows the comparison between 1.3B-sized model and 6.9B-sized model. In the 6.9B-sized models, the in-context few-shot performance with 56B tokens does not decrease significantly compared to 150B tokens, as in the 1.3B-sized models.

4.4 Effect of Combining Corpora

One of our main goals is to investigate the effects of combining multiple corpora from various sources on in-context learning performance. Table 4 shows that in-context few-shot learning ability can be emerged by combining two corpora, even if each of both corpora cannot provide in-context few-shot learning ability. For example, `KiN+Ency` model succeeds to make in-context learning ability in most tasks, while each of `KiN` and `Ency` fails in most tasks. Likewise, `Cafe+KiN` model succeeds to make in-context few-shot learning ability, while each of `Cafe` and `KiN` fails in most tasks. In-context zero-shot abilities of these models follow similar patterns as shown in Table 5.

This phenomenon is related to the argument that in-context learning emerges by multi-task learning. According to the argument, as the language modeling objective function requires a language model to learn variety of next word prediction tasks, the generalization pushes in-context learning ability on unseen tasks. In the example of `KiN+Ency` model, `KiN+Ency` may learn in-context learning ability of MRC task, by learning next word prediction tasks of both `Ency` (Wikipedia) and `KiN` (QnA).

Unlike these positive cases, we observe that combining corpora does not assure the emergence of competitive in-context learning. For example, from the case of `Cafe+News` in Table 4, even if the mixed corpus model shows slightly better performance on KorQuAD than each of two corpora, its in-context few-shot performances on NSMC, KorQuAD, and YNAT are still below the basis. Furthermore, the performances on NSMC and YNAT even decrease.

Table 5: In-context zero-shot learning performance with different corpus combination.

# of tokens	NSMC (Acc)	KorQuAD (EM)	AI Hub (BLEU) Ko→En	AI Hub (BLEU) En→Ko	YNAT (F1)
150B	84.59	56.17	6.15	23.36	59.57
56B	84.35	55.13	5.47	22.98	51.89
6B	74.70	36.72	3.97	17.81	30.24

Table 6: In-context few-shot learning performance of `ALL` with different size of the pretraining data. The dataset is randomly sampled from the original corpus.

4.5 Effect of Domain Relevance

Speaking of the few-shot results, Table 2 shows that the close relationship between a pretraining corpus and a downstream task does not always guarantee in-context few-shot learning ability on the downstream task. `KiN` and `Ency` do not perform well on KorQuAD task, although KorQuAD is an MRC task from Korean Wikipedia, `Ency` includes Korean Wikipedia, and `KiN` consists of question answering pair, respectively. Likewise, `News` does not perform well on YNAT task, although YNAT consists of news headline queries. Table 4 further shows that `News+KiN+Ency` model shows more degenerated F1 score on YNAT than `KiN+Ency`, even though a large amount of `News` corpus is added to `News+KiN+Ency` model.

For further investigation, we analyze vocabulary statistics of each corpus. Figure 1 shows the vocabulary overlapping ratio between pretraining corpora and downstream tasks. The result shows that high vocabulary overlap between a pretraining corpus and a downstream task does not indicate high downstream task performance. Although the `Modu` corpus has a large vocabulary overlapping ratio to AI Hub, in-context learning performances of the `Modu` model on the translation tasks are much lower than `Blog` and `KiN`.

The counter example of above supports is AI Hub task performance of `KiN` model. `KiN` model learned the pattern of Korean-English sentence pairs, since the corpus includes a lot of Korean questions on English language. While `KiN` model does not work well in other downstream tasks, the performance on AI Hub translation is competitive and makes the best performance in Ko→En among seven pretraining corpora.

In the zero-shot setting, on the other hand, do-

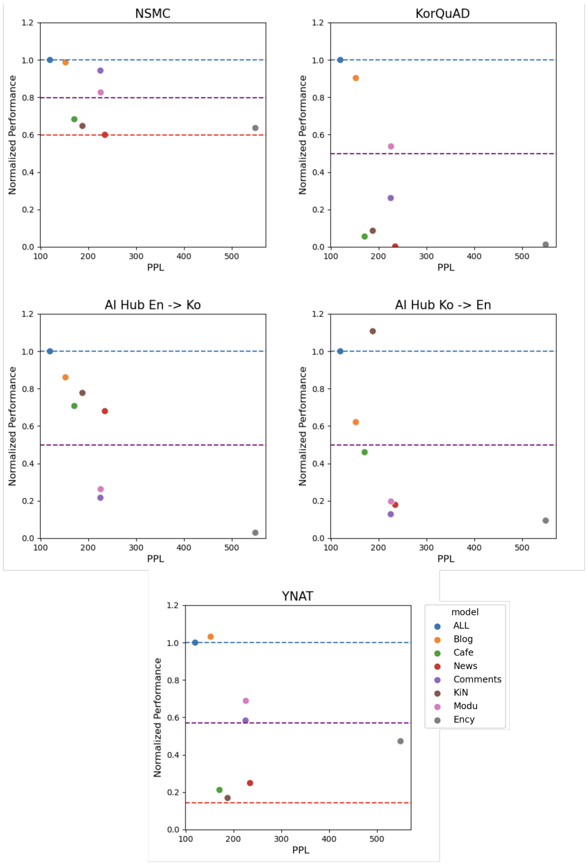

Figure 2: In-context few-shot learning performance of various corpus models and their PPL. A score of the model is divided by that of `ALL` to calculate the normalized performance. Blue and red lines denote the performance of `ALL` model and majority baseline, and the purple line represents the average of both defined in the caption of Table 4.

main relevance seems to affect more positively. For example, training the `News` corpus helps in-context zero-shot learning in KLUE-YNAT consistently. As shown in Tables 3 and 5, the models whose training corpus includes the `News` corpus (i.e., `News`, `Cafe+News`, and `News+KiN+Ency`) even perform better than the model trained whole HyperCLOVA corpus.

In the case of `KiN` and AI Hub, zero-shot performance increase for AI Hub tasks of the `KiN` model is less significant than few-shot. However, adding `KiN` corpus into the pretraining corpus in the experiments of Table 5 (i.e., `KiN+Ency`, `Cafe+KiN`, and `News+KiN+Ency`) makes a consistent performance increase, and the model outperform `ALL`.

4.6 Perplexity and Downstream Task

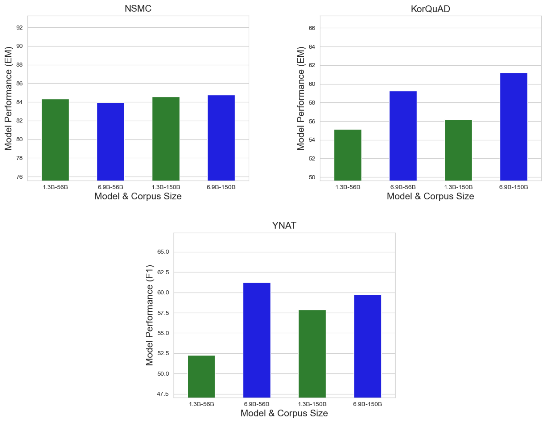

Figure 3: Comparison on two model sizes and two corpus sizes of the original HyperCLOVA corpus such as 1.3B-sized model and 6.9B-sized model, and 56B and 150B tokens. Few-shot results are reported. Green rectangle denotes 1.3B-sized model and blue rectangle denotes 6.9B-sized model.

Figure 2 presents the scatter plots of PPL (x-axis) and in-context few-shot learning performance (y-axis) on five downstream tasks for single corpus models and the `ALL` model. In Figure 2, we normalized in-context few-shot learning performance by dividing `ALL` model performance for calibrating various task metrics. Because we observe less explicit tendency of correlation between validation perplexity and in-context performance, we argue that it is difficult to hypothesize better perplexity assures emerging of in-context few-shot learning ability.

According to Table 2, `Blog` model shows both the lowest PPL and the best in-context learning performance, and `Ency` model shows both the highest PPL and the worst in-context learning performance. On the contrary, while `Cafe` model and `KiN` model shows the second and third lowest PPL, in-context few-shot learning ability was not observed. These results show that the perplexity does not serve as a strong predictor of in-context few-shot learning performance in comparing models trained using different corpora. Table 2 also shows that the corpus size affects in-context few-shot learning performance more than PPL. `Blog` 27B performs notably worse than `Blog`, but PPL relatively does not decrease as much.

Speaking of zero-shot results, it seems Table 3 shows that in-context zero-shot learning performances relatively more correlate with perplexity than the few-shot cases. Nevertheless, `Modu` still has both relatively high perplexity and relatively high in-context zero-shot learning performances.

Table 7 shows validation perplexity scores for

	Blog	Cafe	News	Comments	KiN	Modu	Ency	All
`Blog`	*126.89*	**201.15**	**83.98**	599.68	**138.95**	98.83	**108.17**	**152.40**
`Cafe`	**168.03**	*135.37*	107.78	**596.27**	163.94	124.71	142.15	170.85
`News`	281.33	432.90	*60.21*	1543.03	253.73	**87.65**	156.28	234.78
`Comments`	228.37	242.59	176.28	*390.30*	164.88	196.40	239.40	225.39
`KiN`	232.13	278.89	150.78	689.89	*50.06*	172.78	141.45	187.80
`Modu`	267.59	411.35	84.36	1086.04	243.19	*69.48*	136.02	226.01
`Ency`	841.53	1348.38	213.87	5889.79	543.69	266.11	*73.06*	549.40

Table 7: Validation perplexity scores per each subcorpus. All denotes the validation perplexity on our main validation set from seven corpus sources. *Italic* font denotes the validation PPL of their corpus domain, and **Bold** denotes second best after own corpus. Overall, `Blog` has the best overall validation perplexity in most tasks.

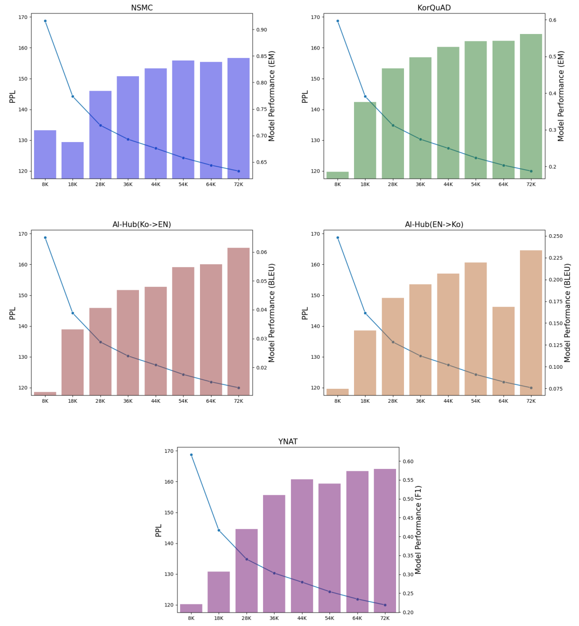

Figure 4: Relation between validation PPL and in-context few-shot learning performance for five downstream tasks as pretraining steps proceed. The results come from the 1.3B-sized `ALL` model.

each subcorpus. Each row corresponds to the model and each column corresponds to the validation set's subcorpus. Each validation set except All in Table 7 consists of 10,000 instances, and is the part of our main validation sets, consists of 70,000 instances.

On the other hand, Figure 4 shows that PPL and in-context learning performance correlate well in the perspective of training a single model. We can find that the correlation trends between the cases in the training and the cases between the corpus domain are different.

5 Discussion

Our knowledge can be used to increase the performance of in-context learning when the corpus is small or/and there exists demand for collecting more corpus. In the case of XGLM (Lin et al., 2021), which is a concurrent work on multilingual GPT-3, achieved better in-context learning performance for many languages. However, it does not reach the performance of a single language model. We hope our observation can give insight into what types of pretraining to be collected more, both for multilingual model and low-resource language model.

Another notable example comes from Gopher (Rae et al., 2021), which is a concurrent work on state-of-the-art in-context learner. Rae et al. (2021) determine the ratio between subcorpora based on the perplexity of the validation corpus. They implicitly claim that this ratio results in better downstream task performance, but do not address explicit evidence for this. On the other hand, we are in a position to doubt the strong correlation between perplexity and in-context learning, especially in the few-shot setting. We hope our findings contribute to making better in-context learners along with other research.

6 Conclusion

This paper investigates the effects of the source and the size of the training corpus on in-context learning ability, using the HyperCLOVA corpus. Our discoveries include that corpus sources play a crucial role in whether or not in-context learning ability will emerge in a large-scale language model.

One direction for future work is to investigate linguistic properties of corpus sources which make a competitive in-context learning model. For example, quantifying the difference between two corpora can shed light on how to select suitable corpora for NLP practitioners who build large-scale language models. In addition, intensive studies on different corpus sources other than the HyperCLOVA corpus can help understand the properties of in-context learning.

Broader Impact Statement

We present multiple pieces of evidence that models using only a part of the pretraining corpus are comparable with those trained with the entire corpus in terms of in-context performances. Although we leave the validation on larger-scale models, such as tens of billion parameters, to future work, our analysis presents a hint to effectively training LMs with smaller corpora. This approach can contribute to alleviating severe energy consumption issues caused by large-scale LMs.

Meanwhile, our study relates to the misuse and fairness of large-scale LMs. For example, reweighting domain-specific corpus might cause LMs to be biased inherent in the domain corpus. Therefore, alleviating domain corpus bias would be a valuable future direction.

Acknowledgment

The authors thank all the members of CLOVA, AI Lab for devoted supporting and discussion. In particular, they thank Joonsuk Park and Seok Ho Yoon for proofreading.

A Details on Experimental Results

Tables 8 and 9 show standard derivation value on Tables 2 and 4. Table 10 shows score difference with `ALL` in addition to in-context learning scores on Table 2. Figure 5, supporting Table 7, shows the validation perplexity of different model from different corpus.

B Details on Pretraining Corpus

Tables 12 and 13 show example instances of seven pretraining corpus in Korean and English, respectively.

For preprocessing steps of our pretraining corpus, we use HyperCLOVA corpus which is also used in (Kim et al., 2021) as described in Section 3.1. Therefore, we share the preprocessing steps of Kim et al. (2021). Appendix A in (Kim et al., 2021) describes their preprocessing methods on data descriptoin, data clearning, data anonymization, and data postprocessing.

B.1 Deduplication Preprocess

We additionally introduce the deduplication preprocess of HyperCLOVA corpus, which is used in (Kim et al., 2021). The deduplication preprocess was applied to construct HyperCLOVA corpus to prevent explicit duplication within and between subcorpora (Kim et al., 2021). According to the response of Kim et al. (2021), they use an in-house search engine and an in-house engineering trick to detect document pairs that are very similar to each other. There are two pipelined steps: (1) removing duplicates within subparts of the corpus, and then (2) removing duplicates between subparts of the corpus. Therefore, documents with high overlap do not exist throughout the documents. Here, the number of subparts is 29. These 29 subparts are categorized into the eight domains we deal with in the paper (i.e., `Blog`, `News`, `Cafe`, `Comments`, `KiN`, `Modu`, `Ency`, and `Others`). Overall, there is no explicit overlap between each corpus, since very similar documents have already been removed from the corpus. The overlap between eight HyperCLOVA subcorpora is quite small. There were many overlaps within the subpart of the corpus. However, the overlap between subparts of the corpus was only 0.024% of the total, according to the counts in the second pipelined step of deduplication between subparts.

C Experiments on LoRA

Table 11 shows the results of LoRA (Hu et al., 2021) finetuning on some models in Tables 2 and 4.

D Examples of Few-shot Prompt

Tables 14, 16, 18, and 19 show the example few-shot prompt of NSMC, KorQuAD, AI Hub, and YNAT, respectively. Tables 15, 17, and 20 show the translated version for NSMC, KorQuAD, and YNAT, respectively.

On the other hand, the number of random seed is one for KorQuAD. We explain why evaluation on KorQuAD with many random seeds is difficult, from the perspective of prompt design. The way we make randomness on trials is to change few-shot examples in the prompt. However, in the case of Kim et al. (2021) and in our case, there are no alternative examples to put into the prompt. The prompt examples of KorQuAD are one document and a few question-answer pairs, and not a few document-question-answer triples. In other words, in the prompt of KorQuAD, the number of the document is one. Thus, the document is used for both few-shot question-answer pairs and a query question for the inference. In KorQuAD, there are five corresponding question-answer pairs in each document. In the experimental setting of ours and Kim et al. (2021), four question-answers are put into the prompt and one question is used for the test. Therefore, there are no other question-answer pairs to replace the four pairs.

E Generalization to Other Languages

Someone can ask whether our results can be extended to other languages, including English. We have left experiments on non-Korean language as future work. However, we describe some explanations below to defend our experiments on the Korean language and to discuss why experiments on other languages are practically non-trivial.

First, we think our findings are basically generalizable to other languages. From the perspective of pretraining and in-context learning, fundamental differences between Korean and English were limitedly reported. For example, XGLM (Lin et al., 2021), a concurrent work on, also does not show critical evidence on language-specific properties.

Second, It is non-trivial to control various as-

Table 11: LoRA finetuning performance on different pretraining corpus and its combination.

pects of corpora for our purpose. Most corpus for in-context few-shot learners comes from crawled website which is not easy to distinguish from its original source. For example, 82% of OpenAI GPT-3 Corpus (Brown et al., 2020) is a filtered version of Common Crawl. In this regard, we used relatively a well-refined corpus which consist of several subcorpus from a single web service. (Please see also Section B.1 of this letter.) On the other hand, we have interests to extend our work onto Pile dataset (Gao et al., 2020), by controlling the subcorpora in the direction our study pursuits, in the future.

Abstract

Transformer-based models are not efficient in processing long sequences due to the quadratic space and time complexity of the self-attention modules. To address this limitation, Linformer and Informer reduce the quadratic complexity to linear (modulo logarithmic factors) via low-dimensional projection and row selection, respectively. These two models are intrinsically connected, and to understand their connection we introduce a theoretical framework of matrix sketching. Based on the theoretical analysis, we propose Skeinformer to accelerate self-attention and further improve the accuracy of matrix approximation to self-attention with column sampling, adaptive row normalization and pilot sampling reutilization. Experiments on the Long Range Arena benchmark demonstrate that our methods outperform alternatives with a consistently smaller time/space footprint[1].

1 Introduction

Transformer (Vaswani et al., 2017) utilizes softmax self-attention modules to capture the dependency between tokens in a sequence and has been widely used in various Natural Language Processing tasks. The time and space complexity of the dot-product self-attention is quadratic in the input sequence length, which restricts the largest sequence length and batch size. To adapt transformers to long sequences, documents have to be truncated, chunked using a sliding window, or processed in parallel on multiple GPUs. These additional operations usually cause the loss of long-range dependency and introduce additional computational costs.

In this paper, we focus on efficient self-attention methods (Xiong et al., 2021; Qiu et al., 2020; Zaheer et al., 2020; Beltagy et al., 2020; Kitaev et al., 2020a; Roy et al., 2021), among which Linformer (Wang et al., 2020b) and Informer (Zhou et al., 2020) are two representative approaches to reducing the $\mathcal{O}(n^2)$ self-attention to an $\widetilde{\mathcal{O}}(n)$ operation ($\widetilde{\mathcal{O}}(\cdot)$ means $\mathcal{O}(\cdot)$ modulo poly-log terms and n is the sequence length) in both space and time complexity. Linformer forms a low-rank factorization of the original attention by decomposing it into smaller attentions, while Informer allows each key to only attend to a certain number of queries.

To better understand self-attention, we introduce a theoretical framework, sketching (Woodruff, 2014), to help explain the key ideas in Informer and Linformer from the perspective of matrix approximation. Specifically, sketching methods replace the original matrix $\boldsymbol{B}$ with its random sketch $\boldsymbol{BS}$ to reduce computations. In Section 3.3 we introduce some concrete instances of commonly used distributions for constructing the random sketching matrix $\boldsymbol{S}$. Furthermore, taking matrix approximation as a general guideline, we recognize the deficiency in Informer and Linformer, that they either do not fully utilize the information in the value matrix $\boldsymbol{V}$, or deviate from the original self-attention output. This guideline also motivates us to propose **Skeinformer** through the theoretical analysis under the sketching framework.

To improve the approximation accuracy in terms of the original attention output, Skeinformer applies sub-sampling sketching to reduce time complexity and exploits the information from the value matrix $\boldsymbol{V}$ with **column sampling**. Skeinformer also incorporates an **adaptive row normalization** step, which approximates the un-selected rows by a vector with all elements $\frac{1}{n}$ and has significantly boosted the performance of Informer. In addition, we introduce a simple yet effective step, **pilot sampling reutilization**, which reuses the computation from pilot sampling to improve both approximation accuracy and training efficiency. Our experiments on the LRA benchmark show that Skeinformer con-

---

[*] Equal contribution. The majority of this work was done prior to the first author's internship at Amazon Alexa AI.

[1] Our code is released at `https://github.com/pkuzengqi/Skeinformer`

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5187 - 5199
July 10-15, 2022

sistently uses less space and time while achieving better accuracy than most baseline methods.

In summary, our contributions are twofold:

- We introduce sketching as a theoretical framework for analyzing and developing efficient transformers. Specifically, the randomized sketching theory covers these two methods from the perspective of approximate matrix multiplication. This framework connects the studies on efficient transformers and randomized sketching theory, so that future development in efficient transformers and sketching can benefit each other.
- We propose Skeinformer as a straightforward product of the sketching framework to accelerate the training and inference of transformers. Skeinformer consists of three components: the initial column sampling that incorporates the information from the value matrix $\boldsymbol{V}$ into the sampling probabilities, the adaptive row normalization that fills un-selected columns with the averaged selected columns, and the pilot sampling re-utilization.

2 Related Work

The ability to process long sequences is critical for many Natural Language Processing tasks, including Document Summarization (Xiao and Carenini, 2019; Huang et al., 2021), Question Answering (Wang et al., 2020a), Information Extraction (Li et al., 2021; Du and Cardie, 2020; Ebner et al., 2020; Du et al., 2022), and Machine Translation (Bao et al., 2021). However, the quadratic computational cost of self-attention in transformer-based models limits their application in long-sequence tasks. Recent methods have been proposed to accelerate attention computation by selectively attending to a subset of the tokens or with low-rank matrix approximation (Tay et al., 2020b).

Selective attention methods limit the scope of matrix operation with sparse attention patterns or column/row sampling methods. BlockBERT (Qiu et al., 2020) introduces sparse block structures into the attention matrix. Sparse Transformer (Child et al., 2019) introduces dilated patterns. Big Bird (Zaheer et al., 2020) proposes a combination of random, window, and global attention. Longformer (Beltagy et al., 2020) combines local windowed attention with task-motivated global attention. The most related work to ours is Informer (Zhou et al., 2020), which allows each key to only attend to the top queries under the Kullback-Leibler divergence based sparsity measurement.

Low-rank attention matrix approximation methods are based on the assumption of low-rank structure in the full self-attention matrix. Linformer (Wang et al., 2020b) compresses the size of the key and value matrices by the Johnson–Lindenstrauss transform (Johnson and Lindenstrauss, 1984). Performer (Choromanski et al., 2020) recognizes the attention score matrix as an empirical Gaussian kernel matrix and constructs a low-rank projection for both the query and key matrices through random Fourier features (Rahimi and Recht, 2007). Nyströmformer (Xiong et al., 2021) instead utilizes Nyström method (Williams and Seeger, 2000; Drineas and Mahoney, 2005) to approximate the attention score matrix. Skyformer (Chen et al., 2021) replaces the softmax structure with a Gaussian kernel and adapts the Nyström method to accelerate the computation.

Some other methods follow a similar principle to decompose the attention score matrix, although they are not necessarily aiming to approximate the original self-attention itself. The representative methods include Linear Transformer (Katharopoulos et al., 2020), which claims that the exponential transform of the dot-product in the softmax operation can be replaced by the direct matrix multiplication of the projected query and key matrices, and Reformer (Kitaev et al., 2020b), which forces the query and key matrices to be identical and applies locality-sensitive hashing (LSH) (Har-Peled et al., 2012) to simplify the computation of the attention score matrix. Those methods are effective alternatives of the original self-attention, while they do not fall into the scope of matrix approximation. We spare the discussion of those methods in this paper.

3 Sketching Framework

3.1 Problem Formulation

Given an input sequence $\boldsymbol{X} \in \mathbb{R}^{n \times d_{input}}$, where n is the sequence length and d_{input} is the embedding dimension, the dot-product attention for a single attention head in transformer (Vaswani et al., 2017) is defined as

$$\text{Attention}(\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}) = \text{softmax}\left(\frac{\boldsymbol{Q}\boldsymbol{K}^T}{\sqrt{p}}\right)\boldsymbol{V}$$

where $\boldsymbol{Q} = \boldsymbol{X}\boldsymbol{W}_Q$, $\boldsymbol{K} = \boldsymbol{X}\boldsymbol{W}_K$, and $\boldsymbol{V} = \boldsymbol{X}\boldsymbol{W}_V$. $\boldsymbol{W}_Q, \boldsymbol{W}_K, \boldsymbol{W}_V \in \mathbb{R}^{d_{input} \times p}$ are the query,

```
Algorithm 1: Skeinformer.
Input: query matrix $\boldsymbol{Q}$, key matrix $\boldsymbol{K}$, value matrix $\boldsymbol{V}$ (all are $n$-by-$p$), and sub-sample size $d$
Output: Attention output matrix $\boldsymbol{R}$ with the same shape as $\boldsymbol{V}$
Uniformly sample $d$ indices $j_1, \cdots, j_d$ with replacement;
Construct the $d \times p$ matrix $\boldsymbol{Q}_J$ as to the index set $J := \{j_k\}_{k=1}^{d}$, whose $k$-th row is $\boldsymbol{Q}_{(j_k)}$;
Compute the matrix $\boldsymbol{B}_J = \text{softmax}\left(\boldsymbol{Q}_J \boldsymbol{K}^T/\sqrt{p}\right)$ ;                    // pilot sampling
Based on $\boldsymbol{B}_J$, give the estimated sub-sampling probabilities $\{\hat{p}_i\}_{i=1}^{n}$ as in Equation (5);
With $\{\hat{p}_i\}_{i=1}^{n}$ sample $d$ indices $j'_1, \cdots, j'_d$ without replacement;
Construct the $d$-by-$p$ matrix $\boldsymbol{K}_{J'}$ (resp., $\boldsymbol{V}_{J'}$) according to the indices list $J' := \{j'_k\}_{k=1}^{d}$, whose $k$-th row is $\boldsymbol{K}_{(j'_k)}$
  (resp., $\boldsymbol{V}_{(j'_k)}$);
Compute the two matrices $\boldsymbol{A}^{J'} = \exp\left(\boldsymbol{Q}\boldsymbol{K}_{J'}^T/\sqrt{p}\right)$, and $\boldsymbol{R}_{J'} = \boldsymbol{A}^{J'}\boldsymbol{V}_{J'}$ ;          // column sampling
Construct a length $n$ column vector $\boldsymbol{g}$ whose $i$-th element is $(\prod_{k=1}^{d} a_{ij'_k})^{\frac{1}{d}}, \forall i \in [n]$;
Compute the row sum vector $\boldsymbol{d} := \boldsymbol{A}^{J'}\boldsymbol{1}_d + (n-d)\boldsymbol{g}$ ;          // adaptive row normalization
Denote the un-selected part of $\boldsymbol{V}$ as $\boldsymbol{V}_{(J')^C}$, and compute the vector $\boldsymbol{v} = \boldsymbol{V}_{(J')^C}^T \boldsymbol{1}_{n-d}$;

key, and value weight metrics that linearly project the input $\boldsymbol{X}$ of dimension d_{input} to an output tensor of dimension p.

To ease the future analysis, the softmax term can be rewritten into $\boldsymbol{D}^{-1}\boldsymbol{A}$, where $\boldsymbol{A} := \exp(\mathbf{Q}\mathbf{K}^T/\sqrt{p})$, and $\boldsymbol{D}$ is a diagonal matrix whose diagonal is $\exp(\boldsymbol{Q}\boldsymbol{K}^T/\sqrt{p}) \cdot \mathbf{1}$ ($\mathbf{1}$ is a size-n vector with all elements being 1).

3.2 Sketching Methods

Beyond current attempts to accelerate self-attention, research in the random matrix approximation community can be potentially applied to fast attention. Among the theoretical frameworks, the sketching method (Woodruff, 2014) is the most comprehensive one as its general concept can incorporate many different approaches.

The core idea of the sketching method is to replace an original matrix $\boldsymbol{B} \in \mathbb{R}^{n_B \times n}$ with its random sketch $\boldsymbol{B}\boldsymbol{S}$, where $\boldsymbol{S} \in \mathbb{R}^{n \times d}$ is a random sketching matrix. In practice, to apply the sketching method we plug an identity matrix into the original expression, and then formally replace the identity matrix with the product $\boldsymbol{S}\boldsymbol{S}^T$, as the distribution of $\boldsymbol{S}$ is usually designed to satisfy the constraint that

$$\mathbb{E}(\boldsymbol{S}\boldsymbol{S}^T) = \boldsymbol{I}. \tag{1}$$

Common methods to construct a sketching matrix include sub-Gaussian maps (Vershynin, 2010; Halko et al., 2011), subsampled randomized Hadamard transform (SRHT) (Ailon and Chazelle, 2006; Lu et al., 2013; Yang et al., 2017), sparse oblivious subspace embeddings (Cohen et al., 2016), very sparse random projection (Li et al., 2006), accumulative sketching (Chen and Yang, 2021), and sub-sampling sketching (Monte Carlo algorithms) (Drineas et al., 2006). Specifically, Informer and Linformer, two efficient transformer-based methods mentioned above, can be understood as applications of sub-sampling sketching and sub-Gaussian maps, respectively. We further elaborate the connections in the next subsection.

3.3 Sketching in Self-attention Approximation

A naïve step in applying sketching method to approximate the self-attention output $\boldsymbol{D}^{-1}\boldsymbol{A}\boldsymbol{V}$ is to construct a random sketch of the un-normalized attention score matrix $\boldsymbol{A}$, the bottleneck in computation. Informer and Linformer construct two types of sketches, $\boldsymbol{A}^T\boldsymbol{S}$ and $\boldsymbol{A}\boldsymbol{S}$ respectively.

3.3.1 Informer

Informer selects d important rows of $\boldsymbol{D}^{-1}\boldsymbol{A}$, though deterministically, to represent $\boldsymbol{D}^{-1}\boldsymbol{A}$. This process can be related to a sketched approximation $\boldsymbol{D}^{-1}\boldsymbol{S}\boldsymbol{S}^T\boldsymbol{A}$, where $\boldsymbol{S}$ is a sub-sampling matrix defined as follows:

Definition 3.1 (Sub-sampling matrix)**.** *Consider a discrete distribution which draws i with probability $p_i > 0, \forall i \in [n]$. For a random matrix $\boldsymbol{S} \in \mathbb{R}^{n \times d}$, if $\boldsymbol{S}$ has independent and identically distributed (i.i.d.) columns and each column $\boldsymbol{S}^{(j)}$ is $\frac{1}{\sqrt{dp_i}}\boldsymbol{e}_i$ with probability p_i, where $\boldsymbol{e}_i$ is the i-th column of the n-by-n identity matrix $\boldsymbol{I}_n$, then $\boldsymbol{S}$ is called a sub-sampling matrix with sub-sampling probabilities $\{p_i\}_{i=1}^{n}$.*

Some researchers in the field of approximate matrix multiplication have provided a practical guideline for the choice of the sub-sampling probabilities $\{p_i\}_{i=1}^n$ in $\boldsymbol{S}$. Specifically for the matrix multiplication $\boldsymbol{BC}$ of two arbitrary matrices $\boldsymbol{B}$ and $\boldsymbol{C}$, Drineas et al. (2006) approximate it with $\boldsymbol{BSS}^T\boldsymbol{C}$ and set the sampling probability p_i in $\boldsymbol{S}$ proportional to the product $\|\boldsymbol{B}^{(i)}\|_2\|\boldsymbol{C}_{(i)}\|_2$, where $\boldsymbol{B}^{(i)}$ is the i-th column in matrix $\boldsymbol{B}$ and $\boldsymbol{C}_{(i)}$ is the i-th row in matrix $\boldsymbol{C}$. For the product $\boldsymbol{D}^{-1}\boldsymbol{A}$, the probability in sketching will be $p_i = \frac{\sqrt{\sum_{j=1}^n a_{ij}^2}}{\sum_{j=1}^n a_{ij}}$, where a_{ij} is the j-th element of the i-th row in matrix $\boldsymbol{A}$.

The above sampling probability choice $\{p_i\}_{i=1}^n$ is highly related to the sparsity measurement used in Informer, which is $M_i = \ln \frac{\sum_{j=1}^n a_{ij}}{(\prod_{j=1}^n a_{ij})^{1/n}}$. Here p_i is the ratio between the quadratic mean and the arithmetic mean of $\{a_{ij}\}_{j=1}^n$; M_i is the logarithm of the ratio between the arithmetic mean and the geometric mean. It is clear that M_i will increase with p_i as these two ratios will both be large when $\{a_{ij}\}_{j=1}^n$ are highly non-uniform. We conclude that in Informer, the main idea to select the rows with high sparsity measurement can be taken as a special variant of the sub-sampling method above with probabilities $\{p_i\}$.

3.3.2 Linformer

Another type of sketch $\boldsymbol{AS}$ is mentioned (but not finally used) in Linformer. The sketching matrix $\boldsymbol{S}$ takes a form different from sub-sampling. The construction of $\boldsymbol{S}$ in Linformer is motivated by Johnson-Lindenstrauss (JL) transform, which applies the sketching matrix $\boldsymbol{S}$ satisfying the (ε, δ)-JL guarantee:

Definition 3.2 (Oblivious Johnson-Lindenstrauss guarantee (Johnson and Lindenstrauss, 1984)). *A distribution $\mathcal{D}$ over $\mathbb{R}^{n\times d}$ satisfies "oblivious Johnson-Lindenstrauss guarantee" if for some $\varepsilon, \delta \in (0, 1/2)$:*

$$\forall \boldsymbol{b} \in \mathbb{R}^n, \underset{\boldsymbol{S}\sim\mathcal{D}}{\mathbb{P}}\left(\left|\|\boldsymbol{Sb}\|_2^2 - \|\boldsymbol{b}\|_2^2\right| > \varepsilon\|\boldsymbol{b}\|_2^2\right) < \delta. \tag{2}$$

Specifically, a matrix with i.i.d. Gaussian elements can meet the above requirement. It has been proven (Johnson and Lindenstrauss, 1984) that with $d = \mathcal{O}(\varepsilon^{-2}\log(1/\delta))$, a Gaussian sketching matrix $\boldsymbol{S}$ can satisfy the oblivious (ε, δ)-JL guarantee. To extend the conclusion from a single vector $\boldsymbol{b} \in \mathbb{R}^n$ to a matrix $\boldsymbol{B} \in \mathbb{R}^{n_B\times n}$, the size d still needs to suffer from an additional $\log n_B$ term (Vershynin, 2010), which matches the bound in sub-sampling sketching (Drineas et al., 2006, Theorem 1).

However, the direct use of Gaussian sketching matrix, i.e. the approximation $\boldsymbol{D}^{-1}\boldsymbol{ASS}^T\boldsymbol{V}$ (Wang et al., 2020b, Eqn. (5)), requires the computation of the whole matrix $\boldsymbol{A}$. To avoid this computational burden, Linformer replaces the form of sketching method with softmax $\left((\boldsymbol{QK}^T/\sqrt{p})\boldsymbol{S}\right)\boldsymbol{S^TV}$, which sacrifices the accuracy for efficiency in some tasks as shown in later experimental results.

4 Methodology: Skeinformer

Based on the previous discussion, we observe that Informer omits the information from the value matrix $\boldsymbol{V}$, and Linformer deviates from the usual sketching form for efficiency. To address these issues and fully exploit the power of sketching, we strengthen the attention approximation with the following components.

In Section 4.1, we introduce column importance sampling, which allows the information incorporation from $\boldsymbol{V}$ to accelerate the matrix multiplication (compared to JL transform); in Section 4.2 and Section 4.3, we leverage the sampled columns to perform the row normalization and reuse the pilot row sampling, which further improves the approximation and makes the training more stable.

We describe the proposed method **Skeinformer** in Algorithm 1 and verify its performance on matrix approximation in Section 5. We also provide complexity analysis in Section 4.5 to show that our method enjoys the same $\mathcal{O}(n\log n)$ complexity as other methods.

4.1 Column Sampling

The row selection in Informer has been derived as a special variant of the sketching method and can be further improved by utilizing the information from $\boldsymbol{V}$, in a form similar to Linformer:

$$\boldsymbol{D}^{-1}\boldsymbol{ASS}^T\boldsymbol{V},$$

where $\boldsymbol{S}$ above is a sub-sampling matrix defined in Definition 3.1 with sampling probabilities

$$p_i \propto \|(\boldsymbol{D}^{-1}\boldsymbol{A})^{(i)}\|_2\|\boldsymbol{V}_{(i)}\|_2, \quad i = 1, 2, \ldots, n.$$

We remark that using the sub-sampling sketching in this way can both circumvent the computation burden of Gaussian sketching, and also allow the incorporation of the information from $\boldsymbol{V}$.

As $\boldsymbol{S}$ formally samples some columns from $\boldsymbol{D}^{-1}\boldsymbol{A}$, we name the procedure as column sampling in our method. The performance regarding

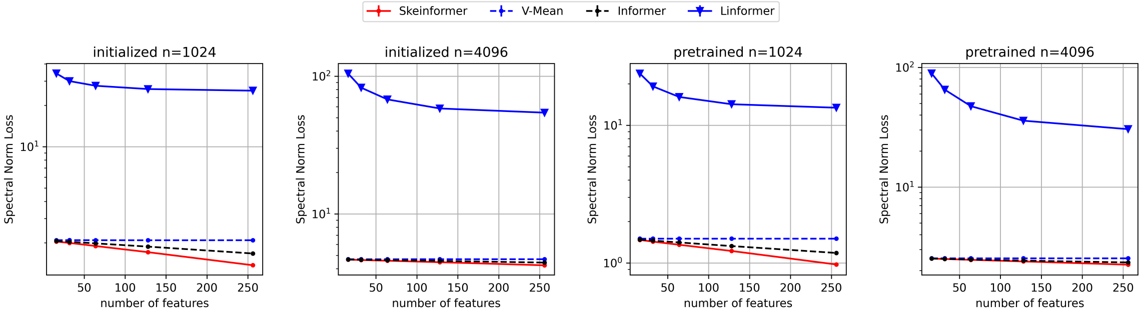

Figure 1: Spectral norm results with the sequence length of 1024 and 4096. Y axis: Lower percentage score means better approximation. X axis: Higher number of feature means larger computation cost. “V-Mean" is an artificial baseline against sampling that always uses a rank-one matrix $\frac{1}{n}\mathbf{1}\mathbf{1}^T V$ to approximate the original self-attention.

the Frobenius norm loss of the approximate matrix multiplication can be guaranteed by the following proposition:

Proposition 1 (Adapted from Theorem 1 (Drineas et al., 2006)). *Suppose the attention score matrix $\boldsymbol{B} := \boldsymbol{D}^{-1}\boldsymbol{A} \in \mathbb{R}^{n\times n}$, the value matrix $\boldsymbol{V} \in \mathbb{R}^{n\times p}$, the number of sampled columns $d \in \mathbb{Z}^+$ such that $1 \le d \le n$, and the sampling probabilities $\{p_i\}_{i=1}^n$ are such that $\sum_{i=1}^n p_i = 1$ and such that for a quality coefficient $\beta \in (0, 1]$*

$$p_i \ge \beta \frac{\|B^{(i)}\|\|V_{(i)}\|}{\sum_{i'=1}^n \|B^{(i')}\|\|V_{(i')}\|}, \forall i \in [n]. \quad (3)$$

Construct a sub-sampling matrix $\boldsymbol{S} \in \mathbb{R}^{n\times d}$ with sub-sampling probabilities $\{p_i\}_{i=1}^n$ as in Definition 3.1, and let $\boldsymbol{B}\boldsymbol{S}\boldsymbol{S}^T\boldsymbol{V}$ be an approximation to $\boldsymbol{B}\boldsymbol{V}$. Let $\delta \in (0, 1)$ and $\eta = 1+\sqrt{(8/\beta)\log(1/\delta)}$. Then with probability at least $1-\delta$,

$$\|\boldsymbol{B}\boldsymbol{V} - \boldsymbol{B}\boldsymbol{S}\boldsymbol{S}^T\boldsymbol{V}\|_F^2 \le \frac{\eta^2}{\beta d}\|\boldsymbol{B}\|_F^2\|\boldsymbol{V}\|_F^2. \quad (4)$$

Remark. Proposition 1 guides Informer and our method to pick the important rows and columns of the attention score matrix $\boldsymbol{B}$. In self-attention, it is feasible to compute the norm $\|V_{(i')}\|$ of each row in $\boldsymbol{V}$ with $\mathcal{O}(n)$ time, assuming the dimension p in each head is fixed and independent of n. However, similar to Informer, it is inefficient to exactly compute the ℓ-2 norm of each column in the n-by-n matrix $\boldsymbol{B}$, and we need pilot sampling as well to estimate the norm of the columns in $\boldsymbol{B}$. We show that $\mathcal{O}(\log n)$ samples in the pilot sampling are sufficient to guarantee the quality coefficient $\beta \ge \sqrt{\frac{1}{3}}$ with high probability by the following lemma. (See proof in Appendix.)

Lemma 1. *Assume for any $i \in [n]$, $\|\boldsymbol{B}^{(i)}\|^2/n$ is uniformly lower bounded by a constant C, where $\boldsymbol{B} := \boldsymbol{D}^{-1}\boldsymbol{A}$. For another constant $\delta \in (0, 1/2)$, we uniformly sample d indices $\{j_k\}_{k=1}^d$ from $[n]$ with replacement, and let d be a constant multiple of $\log(n/\delta)$. Then with probability at least $1-\delta$, the estimated sub-sampling probabilities*

$$\hat{p}_i := \frac{(\sum_{k=1}^d b_{j_k i}^2)^{\frac{1}{2}}\|V_{(i)}\|}{\sum_{i'=1}^n(\sum_{k=1}^d b_{j_k i'}^2)^{\frac{1}{2}}\|V_{(i')}\|}, \forall i \in [n], \quad (5)$$

satisfy the constraints (3) with $\beta = \sqrt{\frac{1}{3}}$, where b_{ji} is the element of $\boldsymbol{B}$ from the j-th row and i-th column.

This lemma states the sub-sampling weights used in our proposed method. Its computation only requires accesses to $\{\boldsymbol{B}^{(j_k)}\}_{k=1}^d$ obtained from the pilot sampling, and thus has greatly reduced the time cost. Combining the preceding lemma and Proposition 1, we conclude that with the sampling probabilities $\{\hat{p}_i\}_{i=1}^n$ estimated by $\mathcal{O}(\log n)$ pilot samples, the sampled d important columns suffice to capture the essence of the original output $\boldsymbol{B}\boldsymbol{V}$. We conclude this subsection with a remark that the theoretical result that sub-sampling sketching can well approximate the original self-attention, indeed matches the rank collapse phenomenon observed by Dong et al. (2021) that self-attention can be well approximated by a low-rank matrix.

4.2 Adaptive Row Normalization

In addition to the theoretical guarantee of the sub-sampling sketching method, we identify an important component behind Informer, row normalization, which implicitly fills the un-selected rows with $\frac{1}{n}$. The experiments in Section 5 reveal that even the rank-one pure row normalization benchmark $\frac{1}{n}\mathbf{1}\mathbf{1}^T V$, as an ablation, will have acceptable spectral norm loss $\|\boldsymbol{D}^{-1}\boldsymbol{A}\boldsymbol{V} - \frac{1}{n}\mathbf{1}\mathbf{1}^T V\|_2$. Therefore, we incorporate adaptive row normalization to provide an even better attention score distribution in each row. It fills un-selected columns with the averaged selected columns. Moreover, from the model training perspective, it allows the whole value matrix $\boldsymbol{V}$ in Skeinformer to participate in the computation (compared to only using the sub-sampling sketch $\boldsymbol{S}^T\boldsymbol{V}$), and thus can improve the efficiency of updating $\boldsymbol{W}_V$ during the training.

Specifically, in adaptive row normalization any row in the matrix $\boldsymbol{A}$ can be divided into two parts, the exactly computed elements in the selected columns with indices $\{j'_k\}_{k=1}^d \subset [n]$ and the other elements in the un-selected columns. For the latter, in each row, we set all the un-selected elements as the geometric mean of the selected ones, considering the exponentiation in softmax. We then perform row normalization based on the above construction, in which the i-th diagonal element in $\boldsymbol{D}$ is estimated as

$$\hat{d}_{ii} = \sum_{k=1}^{d} a_{ij_k} + (n-d)(\prod_{k=1}^{d} a_{ij_k})^{\frac{1}{d}}, \qquad (6)$$

where each a_{ij} is the corresponding element in matrix $\boldsymbol{A}$. Next we normalize rows composed of exact elements in the selected columns, and the other elements estimated with the mean value above. We comment that though the component of adaptive row normalization makes the proposed method inapplicable to Proposition 1, it benefits the performance on matrix approximation and avoid the cost to compute the diagonal normalization matrix $\boldsymbol{D}$. (c.f. Section 5)

4.3 Pilot Sampling Reutilization

Since we have already computed $\boldsymbol{B}_J$ in pilot sampling step (defined in Ln. 3 of Algorithm 1), we can exactly reproduce the d rows in the original self-attention output with an additional product $\boldsymbol{B}_J\boldsymbol{V}$ in $\mathcal{O}(n \log n)$ time. This allows for more precise approximation with little cost. In addition, the computation of those rows involves the whole key matrix $\boldsymbol{K}$, which benefits the training of the parameters $\boldsymbol{W}_K$.

4.4 Implementation Details

Applying the sub-sampling-based methods requires the support for padding masks commonly used in Natural Language Processing tasks. However, a naïve implementation of Algorithm 1 will result in the unnecessary sampling of the padding tokens. Therefore, we count the number of the unpadded tokens m, and only perform the pilot sampling within the certain range $[m]$. After the matrix $\boldsymbol{B}_J$ is computed, we set its columns belonging to the padded part to be all zero, so that the probability $\hat{p}_i$ of choosing column i from the padded part will be zero and the column will not be sampled in the later importance sampling. Similar modifications can also be applied to Informer to enable its applications in NLP tasks in Section 6.

4.5 Complexity Analysis

With the mild assumption in Lemma 1, we claim that our method can have an $\mathcal{O}(n \log n)$ time and space complexity. The claim is shown by the following analysis of the complexity, which heavily relies on the notations in Algorithm 1.

First, we point out that the row/column retrieving operation after index sampling can be implemented by only forming a view and thus the cost is negligible. For Line $1 \sim 4$ in Algorithm 1, the time complexity of the uniform pilot sampling is $\mathcal{O}(d) = \mathcal{O}(\log n)$, while the computation of the matrix $\boldsymbol{B}_J$ and the corresponding probabilities $\{\hat{p}_i\}_{i=1}^n$ costs $\mathcal{O}(nd) = \mathcal{O}(n \log n)$ time and space. For Lines $5 \sim 7$, with probabilities $\{\hat{p}_i\}_{i=1}^n$, the importance sampling takes $\mathcal{O}(n + d \log n) = \mathcal{O}(n)$ time, and similar to the computation above it takes $\mathcal{O}(n \log n)$ time and space to obtain $\boldsymbol{A}_{J'}$ and $\boldsymbol{R}_{J'}$. For Lines $8 \sim 10$, it is clear that the three vectors $\boldsymbol{g}$, $\boldsymbol{d}$, and $\boldsymbol{v}$ can be computed in $\mathcal{O}(n \log n)$ time. As for the last step in Line 11, since it just requires the matrix product involving a diagonal matrix, we can finish the computation also in $\mathcal{O}(n \log n)$ time and space. In summary, the total time and space complexity for Algorithm 1 is at most $\mathcal{O}(n \log n)$, much lower than the $\mathcal{O}(n^2)$ complexity for the original softmax self-attention.

Remark. The complexity above is derived based on the high probability bound in Proposition 1, which is different than the derivation by some previous methods to claim the linear $\mathcal{O}(n)$ complexity.

5 Approximation Evaluation

As a preliminary justification of our proposed methods, we compute the spectral norm loss, a common metric for approximate matrix multiplication, to evaluate the effect of different models to approximate the original self-attention. We compare the spectral norms of the differences between the outputs from vanilla self-attention and other fast attention methods given the same input $\mathbf{Q}, \mathbf{K}, \mathbf{V}$.

Specifically we compute $\|\boldsymbol{BV} - \boldsymbol{R}\|_2$, where $\boldsymbol{B} := \boldsymbol{D}^{-1}\boldsymbol{A}$ is the attention score matrix in the original method, and $\boldsymbol{R}$ is the output of each approximation method.

To construct the inputs $\mathbf{Q}, \mathbf{K}, \mathbf{V}$, we first truncate the raw text from Wikitext-2 dataset (Merity et al., 2017) into sequences of length 512. Then we transform the input X into $\mathbf{Q}, \mathbf{K}, \mathbf{V}$ with the query, key, and value weight metrices from a pretrained model or a randomly initiated model.

We report the spectral norm loss of different sketching-based methods in Figure 1. The results are averaged over 768 trials, and the error bars in the figure represent the standard error of the reported values. For size d (x-axis), either the number of columns/rows selected or the projection dimension, it is set in the range from 2^3 to 2^8.

V-Mean uses a rank-one matrix $\frac{1}{n}\mathbf{1}\mathbf{1}^T V$ to approximate the original self-attention, and thus its approximation error does not change with the size d. V-Mean can also be seen as an ablation for the row normalization step (equivalent to adaptive row normalization without sub-samples). We observe the row normalization step greatly contributes to the approximation of self-attention that involves a softmax structure. Among the candidates, Skeinformer tends to have the smallest spectral norm loss, especially when d is large. It attains a higher accuracy than Informer and Linformer regarding the matrix approximation performance.

6 Experiment

6.1 Benchmark

We experiment on Long Range Arena (LRA) benchmark (Tay et al., 2020a), including ListOps (Nangia and Bowman, 2018), Text Classification (Maas et al., 2011), Document Retrieval (Radev et al., 2013), Pathfinder (Linsley et al., 2018), and Image Classification (Krizhevsky et al., 2009). LRA is designed for long-context scenarios and more appropriate for evaluating efficient transformers comparing to GLUE (Mutton et al., 2007) with shorter input context . Following (Xiong et al., 2021) we use a 2-layer transformer model with 64 embedding dimensions, 128 hidden dimensions, and 2 attention heads for all experiments. More details can be found in Appendix.

6.2 Baseline Methods

We compare our method with the standard quadratic self-attention (Vaswani et al., 2017), Big Bird (Zaheer et al., 2020), Linformer (Wang et al., 2020b), Informer (Zhou et al., 2020), Performer (Choromanski et al., 2020), and Nyströmformer (Xiong et al., 2021). In addition to their vanilla implementations, we compare with standard self-attention without dropout (since most fast attention methods do not have this component), Linformer with unreduced Johnson-Lindenstrauss Transform (the original form that Linformer deviates from), and Informer with padding masks.

Ablation studies include replacing the column sampling with uniform sampling, disabling the adaptive row normalization or replacing it with the simple row normalization implemented in Informer, and disabling the pilot sampling reutilization.

For clarification, deep transformers or pretrained language models are not appropriate baselines. Training a deep transformer from scratch requires large computational resources and much more data to converge, and therefore is not adopted by previous work. A shallow transformer structure, on the other hand, has been justified by previous work to be enough for fair comparison in attention acceleration performance. Pretrained models are trained for token-level text-based tasks, and are not suitable for image pixel sequences (as in Pathfinder and Image Classification), character sequences (as in Text Classification) and math operation sequences (as in ListOps).

6.3 Results

We conclude the results in Table 1 and Table 2 with the following observations:

Most $\widetilde{\mathcal{O}}(n)$ attention acceleration methods have comparable or better performance with vanilla attention. After all models converge to their long-time limits, Linformer tends to have worse performance possibly due to the violation of the sketching form, while Skeinformer has the best overall performance.

While surprising, those approximation methods tend to outperform the original transformer in most tasks. We speculate the reason behind this phenomenon is that a good approximation can recover the main signals in the original self-attention matrix, and also restrain the noise via the sparse / low-rank structure. A similar phenomenon can be found in CNN (Sanyal et al., 2018), that a low-rank regularizer, such as SVD, applied to the representation of the intermediate layers can allow the model to have lower prediction errors. This speculation

Table 2: Training time (minute per thousand steps) and actual batch size (in batch accumulation) on LRA benchmark. Less training time per thousand steps indicates higher time efficiency. Higher batch size indicates higher space efficiency, and within a certain range means more accurate gradient estimations. we simulate the case of real-world applications of efficient transformers that models are trained with their maximum batch size conditioned on memory.

motivates us to turn to some theoretical framework for matrix approximation to better analyze the fast attention methods, which will potentially benefit transformer pruning, compression and distillation.

Skeinformer has the comparable general performance in terms of time/space complexity and classification accuracy. A long transformer is considered efficient when it (1) reduces space complexity and supports larger sequence length and larger batch size, (2) reduces time complexity with less training time per step and less total time to converge, and (3) shows comparable performance with vanilla softmax without much loss from approximation.

For convergence efficiency, Skeinformer efficiently converges to the long-time limit. Regarding the training efficiency, we focus on how soon the model can attain the stationary distribution of its long-time limit (He et al., 2019). The loss decay plot on ListOps in Appendix shows significant differences in the convergence rate of each method in addition to classification accuracy.

Though our method does not always outperform others (with the fastest convergence or the highest accuracy) , but we remark that **Skeinformer attains the best accuracy-efficiency trade-off** based on experimental results. On the opposite, some model converges fast but gets stuck in a local optimum, like Linformer in some cases.

7 Conclusion

We conclude in this paper that sketching can be applied as a theoretical framework for analyzing fast attention models, through which we are able to recognize the potential improvements upon previous work. Theoretical results are provided to guarantee the high accuracy of the approximation to the original self-attention by our proposed Skeinformer. We empirically validate the contributions of the components in Skeinformer, including column sampling, adaptive row normalization and pilot sampling reutilization, with extensive comparisons with various baseline and ablation methods.

A Further experiment Details

A.1 Implementation Details

As it is not realistic to exhaustively fine-tune all models and search for the best performance under limited computation resources, we instead replace the self-attention module in transformer with the various drop-in attention methods and keep other experimental settings the same. Following (Xiong et al., 2021) we use a 2-layer transformer model with 64 embedding dimensions, 128 hidden dimensions, and 2 attention heads for all experiments. Mean pooling is used in all classifiers.

For comparable computation complexity, we control the number of features used in all methods, which leads to 256 as the number of features in Skeinformer, 256 as k in Linformer, 256 as the number of landmarks in Nyströmformer, $(256/\log n)$ as the factor in Informer, and 256 as the number of features in Performer. Additionally, the number of random blocks and block size in Big Bird are by default 3 and 64, under which setting Big Bird will visit $640 \cdot n$ elements in the attention matrix while other models visit $256 \cdot n$ elements. A clearer complexity evaluation on the FLOPs of each method is provided in Appendix.

We use Adam optimizer (Kingma and Ba, 2015) with a learning rate of $1e-4$. Batch size is selected conditioned on the memory requirements of Skeinformer, which leads to 128 for Text Classification, 256 for ListOps, 64 for Document Retrieval, 512 for Pathfinder and 256 for Image. For methods reporting out-of-memory errors, we apply gradient accumulation and report the accumulated steps. Instead of setting a fixed epoch number, we train all models until convergence with a stopping strategy (if better performance is not observed for 10 checking steps on the validation set we will stop the training process).

We conduct all experiments on one Tesla V100 SXM2 16GB. For numerical consistency, all experiment results are averaged across three random runs.

A.2 LRA Dataset

We evaluate on five classification tasks in LRA benchmark (Tay et al., 2020a), excluding Pathfider-X, which fails all baseline models.

ListOps (Nangia and Bowman, 2018): This 10-label classification task requires the models to parse a sequence of length $2k$ of numbers and operators and evaluates their capacity of modeling hierarchically structured long sequences.

Text Classification on IMDb review dataset(Maas et al., 2011): This byte-Level binary classification task requires the model to analyze the sentiment of a sequence of length $4k$ by composing the unsegmented characters into higher-level meaningful units.

Document Retrieval on AAN dataset (Radev et al., 2013): This byte-Level binary classification task requires the model to compress long sequences of length $4k$ into representations for similarity score calculation in a two-tower setup without cross-attention.

Pathfinder on CIFAR-10 dataset(Linsley et al., 2018): This binary classification task requires the model to decide whether two points are connected by a dashed path on an image represented as a pixel sequence of length $4k$, and exams their capacity to capture long-range spatial dependency.

Image Classification (Krizhevsky et al., 2009): This 10-label classification task requires the models to learn the spatial relations between the flattened input pixels of length $1k$.

A.3 Validation Loss

We present the loss decay plots on all tasks in Figure 2. In the first subplot for the text classification task, we note all the methods quickly overfit the dataset. In all the other plots, our methods show the ability to both efficiently converge to the long-time limit and find better local minima with lower validation loss.

A.4 FLOPs

We conclude in this subsection the floating point operations (FLOPs) of each candidate model (excluding the ablation models). To ease the notation, given the sequence length n, we fix $p = 32, d = 256$. Assuming the matrices $\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}$ are given and omitting the non-leading term, we report the FLOPs of each model in Table 3. We additionally comment that Reformer is excluded from the table since its FLOPs are not fixed and depend on the frequency of collision after hashing of tokens, which changes with the input sequence.

A.5 Hyper-parameter Sensitivity

Figure 3 shows the accuracy and training time for Skeinformer using different batch sizes (64,128) and learning rates ($1e-3$,$1e-4$,$1e-5$) on text

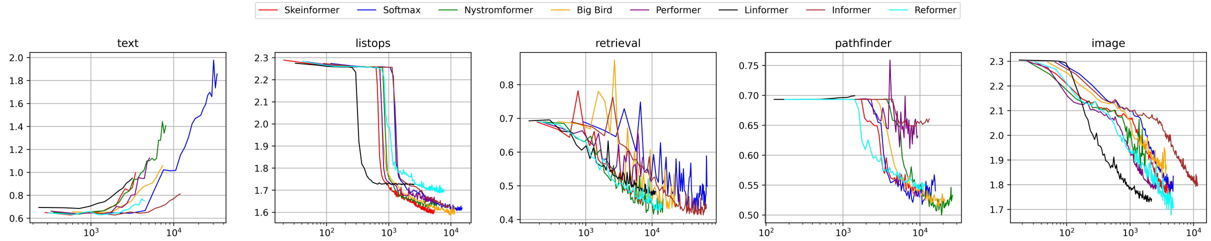

Figure 2: Validation loss (Y axis) changes with regard to training time (second, X axis).

Models	**FLOPs**
Standard	$2n^2p$
Big Bird	$5ndp$
Performer	$3ndp$
Nystromformer	$4ndp$
Linformer	$4ndp$
Informer	$3ndp$
Skeinformer	$4ndp$

Table 3: The leading terms of FLOPs in computing attention.

classification. The results are averaged across random trials. We observe that smaller learning rate offers slower convergence but to a better point.

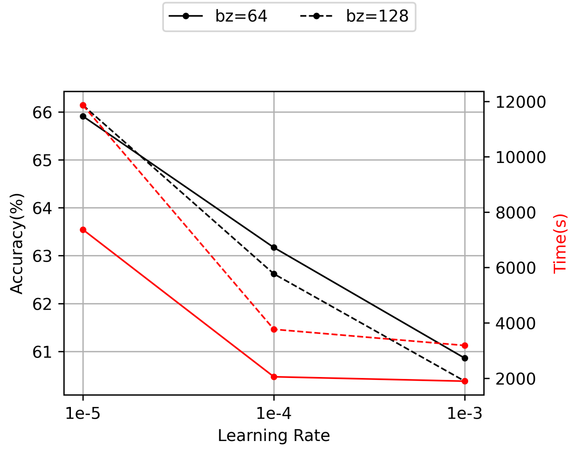

Figure 3: Testing accuracy and training time (Y axis) changes with regard to learning rate (X axis).

B Proof of Lemma 1

Proof. For each column $\boldsymbol{B}^{(i)}$, we first define a discrete random variable X_i, that with probability $\frac{1}{n}$, $X_i = b_{ji}, \forall j \in [n]$, where b_{ji} is the j-th element in $\boldsymbol{B}^{(i)}$. Since all the elements in $\boldsymbol{B}$ are bounded (within the range $[0, 1]$) due to the row normalization in softmax, we infer that for any $i \in [n], X_i^2 \in [0, 1]$ is a sub-Gaussian random variable with parameter $\sigma = \frac{1}{2}$ (Wainwright, 2019). Combine the conclusion with the assumption that $\mathbb{E}\, X_i^2 \leq C$, we have

$$\frac{X_i^2}{\mathbb{E}\, X_i^2} \sim \text{sub-Gaussian}\left(\sigma^2 = \frac{1}{4C^2}\right). \tag{7}$$

Then we uniformly sample d indexes $\{j_k\}_{k=1}^d$'s with replacement, and we estimate the squared norm of each column with the unbiased estimator $Y_i = \frac{n}{d}\sum_{k=1}^d b_{j_k i}^2$. We remark Y_i has the same distribution as $\frac{n}{d}\sum_{k=1}^d X_{i,(k)}^2$, where $X_{i,(k)}$'s are d i.i.d. copies of X_i. Therefore through a linear transform of Equation (7) we can derive that

$$\frac{Y_i}{n\,\mathbb{E}\, X_i^2} \sim \text{sub-Gaussian}\left(\sigma^2 = \frac{1}{4C^2 d}\right). \tag{8}$$

Notice different Y_i's may not be independent since they all rely on the same d rows in $\boldsymbol{B}$. However, we can still apply the maximal sub-Gaussian inequality (Boucheron et al., 2013) to have:

$$\mathbb{P}\left\{\max_{i\in[n]}\left|\frac{Y_i}{n\,\mathbb{E}\, X_i^2} - 1\right| > \frac{1}{2}\right\} \leq 2ne^{-\frac{C^2 d}{2}}. \tag{9}$$

If the high probability bound holds that $\max_{i\in[n]}\left|\frac{Y_i}{n\,\mathbb{E}\, X_i^2} - 1\right| \leq \frac{1}{2}$, we directly have that our estimators $Y_i \in [\frac{1}{2}\|\boldsymbol{B}^{(i)}\|^2, \frac{3}{2}\|\boldsymbol{B}^{(i)}\|^2], \forall i \in [n]$. In that case, the estimated sub-sampling probabilities satisfy that

$$\hat{p}_i = \frac{Y_i^{\frac{1}{2}}\|V_{(i)}\|}{\sum_{i'=1}^n Y_{i'}^{\frac{1}{2}}\|V_{(i')}\|} \geq \frac{\sqrt{1/2}\|\boldsymbol{B}^{(i)}\|\|V_{(i)}\|}{\sqrt{3/2}\|\boldsymbol{B}^{(i)}\|\|V_{(i')}\|}$$
$$= \sqrt{\frac{1}{3}}p_i, \forall i \in [n],$$

where p_i's are the optimal probabilities defined in the main paper.

In that case, to prove the lemma it suffices to pick a big enough sub-sample size d such that the right-hand side of Inequality (9) is smaller than δ. Simply solving the inequality leads to the desired result $d \geq \frac{2}{C^2}\log(\frac{2n}{\delta})$. ◇

Partner Personas Generation for Dialogue Response Generation

Hongyuan Lu, Wai Lam, Hong Cheng, Helen M. Meng
The Chinese University of Hong Kong
`{hylu,wlam,hcheng,hmmeng}@se.cuhk.edu.hk`

Abstract

Incorporating personas information allows diverse and engaging responses in dialogue response generation. Unfortunately, prior works have primarily focused on self personas and have overlooked the value of partner personas. Moreover, in practical applications, the availability of the gold partner personas is often not the case. This paper attempts to tackle these issues by offering a novel framework that leverages automatic partner personas generation to enhance the succeeding dialogue response generation. Our framework employs reinforcement learning with a dedicatedly designed critic network for reward judgement. Experimental results from automatic and human evaluations indicate that our framework is capable of generating relevant, interesting, coherent and informative partner personas, even compared to the ground truth partner personas. This enhances the succeeding dialogue response generation, which surpasses our competitive baselines that condition on the ground truth partner personas.

1 Introduction

Building informative and engaging dialogue agents (Zhang et al., 2020; Roller et al., 2021) is a popular research direction within the area of natural language processing. For the sake of engagement, diverse and consistent responses (Song et al., 2020, 2021) are important factors, and personas information (Zhang et al., 2018) gives rise to both. There are two types of personas, namely self persona and partner persona. The former refers to a self profile consisting of several sentences representing the dialogue agents. Such a persona allows producing consistent responses rather than solely relying on the personas that are randomly learned and embedded in the model parameters (Kim et al., 2020). The latter refers to a profile that represents the users. Leveraging such partner personas has been empirically shown to be helpful for dialogue response selection (Gu et al., 2021).

Unfortunately, the existence of partner personas suffers from the cold start (Schein et al., 2002; Zhang et al., 2014; Li et al., 2021) at the beginning of the conversation. Most of the works, if not all, (Li et al., 2016b; Mazaré et al., 2018; Song et al., 2019; Gu et al., 2019; Zhao et al., 2019; Madotto et al., 2019; Liu et al., 2020; Majumder et al., 2020; Wu et al., 2020a; Song et al., 2020) have been either overlooking partner personas or simply focusing on the impractical situation where partner personas guarantee to exist. In contrast, our work does not suffer from the practical issue when partner personas are missing during inference, and our proposed framework surpasses the baseline that conditions on the ground truth partner personas.

To our knowledge, this is the first attempt to formulate partner personas generation for improved performance on the downstream dialogue response generation. Our work is motivated by the underlying hypothesis that partner personas generation is plausible given the self personas and dialogue context. Automatic and human evaluation results support the hypothesis and indicate that generated personas are even more interesting than the ground truth, which improves the downstream dialogue response generation. This paper thus paves the way to exploit partner personas generation (PPG) for dialogue response generation (DRG).

We propose a novel framework composed of three major components, namely a personas generator, a dialogue response generator and a critic network. The personas generator generates partner personas, which the dialogue response generator conditions on. We employ reinforcement learning with a critic network that propagates the reward back to the generators for joint training.

Prior works have investigated partner persona retrieval (Zhang et al., 2018; Song et al., 2019). The human-constructed ground truth personas serve as the upper bound for such retrieval-based systems, and we argue that the ground truth is not coherent

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5200 - 5212
July 10-15, 2022

and diverse enough. Interestingly, we observe that the generative counterpart proposed in our framework generates relevant, informative and coherent partner personas, which further improves the succeeding dialogue response generation. It follows another advantage that our framework does not need an external database to retrieve from (Madotto et al., 2020; Xu et al., 2021).

One close work to ours is a multi-task framework for meta-learning (Lee et al., 2021) that uses personas reconstruction as an auxiliary task to improve response consistency. The differences are that theirs does not differentiate between self personas and partner personas, while ours does. Theirs indicates an improvement over personality consistency, while ours report improvements for the overall quality. We conduct an empirical comparison with their model by reconstructing the partner personas. Experimental results indicate that such a multi-task model does not work well in our problem setting. Very recently, Zhou et al. (2021) formulates personas generation as a Seq2Seq task for improved downstream response generation via multi-task learning. In contrast, our work leverages reinforcement learning to jointly train the partner personas generator and the response generator.

Automatic and human evaluation results indicate that our framework can generate partner personas that are more diverse and interesting than the ground truth partner personas and generate more diverse and engaging responses than the baseline conditioned on ground truth partner personas.[1]

2 Related Work

2.1 Personalized Dialgoue Generation

Conditioning on personas helps to produce informative and engaging responses. The most well-known multi-turn dialogue dataset conditioned on personal profiles is PERSONACHAT (Zhang et al., 2018), in which two crowdsourcers converse and find more about each other. The community has proposed many methods to better utilize self personas. Mazaré et al. (2018) employs a pre-training stage based on dedicatedly extracted large-scale persona-based dialogues. Zhao et al. (2019) fuses information in personas and dialogue context into individual contextualized representations by attending to different parts of both. Gu et al. (2019) exploits the interaction between personas, dialogue context and response to improve retrieval-based dialogue agents. Madotto et al. (2019) leverages meta-learning with several dialogues of the current speakers to enhance response personality. Welleck et al. (2019) releases a dataset for measuring dialogue consistency. Song et al. (2020) employs a multi-stage pipeline to improve response personality by response rewriting. Lee et al. (2021) uses multi-task learning for improved personality consistency in the meta-learning scenario. Gu et al. (2021) employs four different strategies for personas fusing to leverage both self persona. However, most of these works focus on exploiting self personas rather than partner personas, and they assume the existance of the gold partner personas.

2.2 User Profile Extraction

Li et al. (2014) leverages distant supervision to classify the spouse, education and job information from user twitters. Wu et al. (2020b) proposes a two-staged profile extractor that extracts attributes before extracting the underlying relationship. Wang et al. (2021) proposes to categorize the profile extraction task into two different difficulties, namely 'extraction' and 'inference', and they leverage a GPT-based generator to extract user profiles. These works have formulated user profile extraction as a classification task that conditions on an input sentence, and they aim at better profile extraction. In contrast, we propose to formulate personas generation to be conditioned dialogue input to be jointly trained with response generation. While ground truth personas serve as the upper bound for these user profile extractors, we empirically demonstrate that our reinforcement learning algorithm surpasses the response model conditioned on the ground truth partner personas. As supported by our human evaluation, we believe the underlying reason is that our model can leverage pre-trained generators to generate coherent and relevant partner personas.

2.3 Reinforcement Learning

Reinforcement learning (RL), or specifically, policy gradient methods (Williams, 1992), have been frequently adopted to both task-oriented dialogue agents (Roman Roman et al., 2020; Deng et al., 2021) or open-domain chitchat agents (Li et al., 2016c; Saleh et al., 2020). It can either propagate non-differentiable loss (Cai et al., 2019a) or optimize an expert reward such as ease of answering (Li et al., 2016c). It also adopts a scenario where a user simulator and a dialogue agent interact, and an

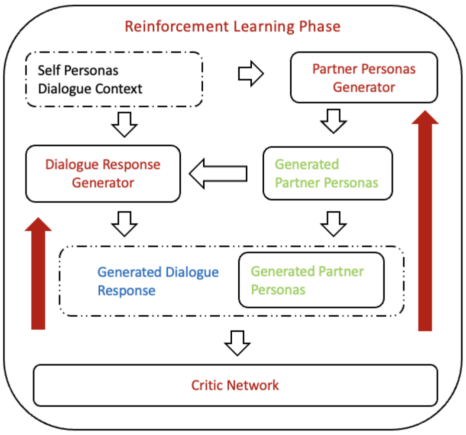

Figure 2: The illustrated reinforcement learning strategy that directly backpropagates the response-related rewards from the critic network to the partner personas generator and the dialogue response generator.

expert reward function can be defined to assign the goodness to each response generated (Roman Roman et al., 2020).

3 Proposed Framework

We propose a novel framework composed of three major components, namely a partner personas generator, a dialogue response generator and a reinforcement learning component with a critic network. Figure 1 depicts the inference flow of our setting. The input dialogue context with self persona is first fed into the partner personas generator. The generated partner personas output is then concatenated with the dialogue context and the self personas as the input into the dialogue response generator. In the beginning, we train our partner personas generator and dialogue response generator under supervised learning. In the training stage, we use the ground truth partner personas to train the dialogue response generator, and we replace it with generated partner personas in the inference stage. After the supervised learning stage, the second stage is a reinforcement learning stage which jointly optimizes both partner personas generator and dialogue response generator as depicted in Figure 2 to train the partner personas generator under the reward signal that is relevant to dialogue response generation as well as fine-tuning dialogue response generator trained on the generated partner personas.[2] Particularly, we employ a dedicatedly designed critic network that receives generated partner personas and generated dialogue responses as the input and output a reward that measures the relevance between the generated personas and responses and propagates back to the generators.

3.1 Partner Personas Generation (PPG)

A Seq2Seq neural network (Sutskever et al., 2014) is adopted as our partner personas generator for the task of partner personas generation (PPG). The concatenation of dialogue context $\mathbf{c}$ and self personas $\boldsymbol{s}$ is fed as an input into the partner personas generator. The personas generator then outputs an approximated partner personas $\hat{\boldsymbol{p}}$ conditioned on the input that maximises the following likelihood:

$$P\left(\hat{\boldsymbol{p}} \mid \boldsymbol{s}, \boldsymbol{c}\right)=\prod_{t=1}^{T} P\left(\hat{p}_t \mid \hat{p}_1, \ldots, \hat{p}_{t-1}, \boldsymbol{s}, \boldsymbol{c}\right),$$

where T represents the length of the generated partner personas and $\hat{p}_t$ represents the word at the position t that has been inferenced.

For training, the ground truth partner personas $\boldsymbol{p}$ is used and we train our generator to maximise the likelihood $P\left(\boldsymbol{p} \mid \boldsymbol{s}, \boldsymbol{c}\right)$. We generate the complete partner personas profiles in an one-off shot for all the dialogue samples.

3.2 Dialogue Response Generation (DRG)

We also adopt a Seq2Seq neural network for the task of dialogue response generation (DRG). During inference, the concatenation of dialogue context

---

[2] Section 5.7 presents an ablation study on reinforcement learning that demonstrates the effectiveness of this approach.

c, self personas $\boldsymbol{s}$, and generated partner personas $\hat{\boldsymbol{p}}$ is fed as an input into the dialogue response generator. The response generator then outputs a dialogue response $\hat{\boldsymbol{r}}$ conditioned on the input, which maximises the conditional likelihood: $P(\hat{\boldsymbol{r}} \mid \boldsymbol{s}, \hat{\boldsymbol{p}}, \boldsymbol{c})$.

For training, the ground truth partner personas $\boldsymbol{p}$ and the ground truth dialogue responses $\boldsymbol{r}$ are used.

3.3 Reinforcement Learning (RL)

We employ a critic network to compute the reinforcement learning rewards for our generators. We use a binary classifier as critic by extracting training instances $(\boldsymbol{s}, \boldsymbol{r}, \mathbb{L}{=}1)$,[3] $(\boldsymbol{s}^A, \boldsymbol{r}^A, \mathbb{L}{=}1)$ and $(\boldsymbol{s}^B, \boldsymbol{r}^B, \mathbb{L}{=}1)$. Then we can derive two negative samples as: $(\boldsymbol{s}^A, \boldsymbol{r}^B, \mathbb{L}{=}0)$ and $(\boldsymbol{s}^B, \boldsymbol{r}^A, \mathbb{L}{=}0)$. Thereafter, we fine-tune on a binary classifier to be used as our critic in RL on the training partition by minimizing the binary cross-entropy loss:

$$-\mathbb{L}log(P(\mathbb{L} \mid \boldsymbol{s}, \boldsymbol{r})) - (1-\mathbb{L})\log(1 - P(\mathbb{L} \mid \boldsymbol{s}, \boldsymbol{r})),$$

where the binary label $\mathbb{L}$ indicates whether the response is relevant to the personas.

We then use this classifier acting as a critic network that outputs $\hat{\mathbb{L}}$, conditioned on the generated partner personas $\hat{\boldsymbol{p}}$ and generated response $\hat{\boldsymbol{r}}$. The predicted binary label $\hat{\mathbb{L}}$ is then converted to a reward $\mathbb{R}$. $\mathbb{R}$ is a positive reward when $\hat{\mathbb{L}}{=}1$, and $\mathbb{R}$ is a negative reward when $\hat{\mathbb{L}}{=}0$. We empirically set the reward $\mathbb{R}$ for RL to {1, -1} for both PPG and DRG. We then update our RL agents with the following gradients:

$$\Delta\theta_{\text{PPG}} = -\mathbb{R}\nabla_{\theta_{\text{PPG}}} \log P(\hat{\boldsymbol{p}} \mid \boldsymbol{s}, \boldsymbol{c})$$

for the partner personas generator (PPG), and for the dialogue response generator (DRG):

$$\Delta\theta_{\text{DRG}} = -\mathbb{R}\nabla_{\theta_{\text{DRG}}} \log P(\hat{\boldsymbol{r}} \mid \boldsymbol{s}, \hat{\boldsymbol{p}}, \boldsymbol{c})$$

By formulating a reward that measures the relevance between generated partner personas and generated dialogue response, we are motivated by the following objectives:

- Further fine-tune the partner personas generator to generate personas that benefits the downstream dialogue response generation.
- Further fine-tune the dialogue response generator trained with ground-truth partner personas to adapt to noisy partner personas generated by the partner personas generator.

As mentioned in Section 3.1, the first motivation is that we are generating the complete personas profile. However, some of them can be irrelevant and unhelpful for the next-turn dialogue response generation. It could be challenging for the partner personas generator alone to identify which personas could be helpful. Therefore, we design such a reward to train the personas generator to learn to generate a set of personas that is more helpful for the downstream dialogue response generation. Our second motivation is that the dialogue response generator has not been exposed to the generated partner personas. We would like to fine-tune the response generator to mitigate the potential training-inference discrepancy. Experimental results indicate that our design empirically works well.

The previous work from Cai et al. (2019a) employed critic network for RL loss backpropagation. The major difference is that their critic is trained in an adversarial manner (Li et al., 2018) to pick up the gold response among other negative candidates. Also, their critic network conditions only on the dialogue response but not on the generated skeleton. In contrast, we aim for improved response generation with a classifier conditioning on both the generated personas and the generated response.

3.4 Evaluation Metrics

For both PPG and DRG, perplexity (PPL) is reported to measure the intrinsic performance with the ground truth output (Roller et al., 2021). We adopt well-known sequence evaluation metrics weighted BLEU (Papineni et al., 2002) and F-measure for ROUGE-L (Lin, 2004) as the extrinsic evaluations. For PPG, we also report Distinct-N with N={1,2} to measure the response diversity (Li et al., 2016a; Cai et al., 2019b; Gao et al., 2019) with the ratio of distinct unigrams/bigrams against total number of unigrams/bigrams generated.

4 Experimental Setup

4.1 Dataset

We conduct experiments on the PERSONACHAT (Zhang et al., 2018), the most well-known multi-turn dialogue dataset conditioned on personas. We follow the train/valid/test split from the PARLAI

---

[3] Our critic reports a test accuracy of about 75%. We empirically choose to use $\boldsymbol{s}$ instead of $\boldsymbol{p}$. The latter reports a test accuracy of about 60%. This indicates that it seems people talk more seldomly about their partner during the conversation, but they still do, and it is useful to exploit partner perspnas.

platform (Miller et al., 2017) that contains about 65,000/7,800/7,500 instances respectively. Each instance contains about 8 utterances on average and about 4 traits for each of the self and partner personas. We denote the dataset with this original personas as PersonaChat-ori. Later the original personas have been manually scrutinized by rephrasing, generalizing or specializing, which we denote as PersonaChat-rev. We apply the same preprocessing operation to both datasets. To train the critic for RL, we collected about 130,000 instances from the train split with equally distributed positive and negative samples.

4.2 Baselines and Comparison Models

E2E w/o Partner Personas This is an end-to-end (E2E) response generator without partner persona.

E2E w/ Partner Personas in Training With partial ground truth partner personas for training only.

E2E w/ Partner Personas in Training and Inference With ground truth partner personas for training and inference. During early experiments, we found that feeding all traits yields lower performance. Retrieving Top-3 relevant partner personas using BM25 (Robertson and Walker, 1994) yields the best performance on the original personas.

GPT-2 This is a comparison model fine-tuned on GPT-2 (Radford et al., 2019). We build the same three E2E systems described above, and the best model is selected, the third one.

TransferTransfo A comparison model built with a Transformer-based model pre-trained on general domain corpus, which is then fine-tuned on PersonaChat (Wolf et al., 2019).

PerCVAE This is a comparison model that employs a memory-augmented architecture incorporated with conditional variational autoencoder that exploits persona information (Song et al., 2019).

PAML This is a comparison model that leverages several dialogues collected from the same speaker to enhance response personality via meta-learning (Madotto et al., 2019). As the authors did not conduct experiments on the PersonaChat-rev and no preprocessing scripts are provided for the revised personas, we only report the results of their model on the PersonaChat-ori only.

MTL w/ Personas Reconstruction This is a multi-task learning (MTL) comparison model (Lee et al., 2021) trained to maximise the objective:

$$\alpha\mathcal{L}_{\text{PPG}} + (1-\alpha)\mathcal{L}_{\text{DRG}},$$

where $\mathcal{L}_{\text{PPG}}$ represents the auxiliary PPG likelihood, and $\mathcal{L}_{\text{DRG}}$ represents the DRG likelihood. α is weight tuned over the validation set, and both tasks condition on dialogue context and self personas and share the same model parameters.

5 Results

5.1 Dialogue Response Generation Results

We build our baselines, the partner personas generator and the dialogue response generator based on a state-of-the-art pre-trained dialogue model DialoGPT (Zhang et al., 2020) for parameters

Dialogue Context	Partner Personas		Dialogue Response		
	Gold Partner	**Generated Partner**	**Ours**	**E2E w/ Full**	**Human**
Hey ! Do you like music? I like metallica.	My favrourite band is metallica.	My favourite band is metallica.	Hi! I do! I love metallica!	I do.	I like country music mostly.
I know, I grew up in a horse ranch that is so large.	I also engjoy cooking meals with food from our garden.	I like to cook with the food I grow in my garden.	I have a small garden in my home.	I am sorry, I am not very tall.	I wish my childhood was as exciting.
I meditate. It helps with my anger, I can be pretty violent.	I am in the army.	I am an army ranger.	I am a general in the army.	I do not have time for things like that. I am a busy person.	Do you like to work for long hour? Do you have any pet?
Yes, I have 8 dogs, 7 cats and 17 birds.	–	I have a dog and two cats.	I have a dog and a cat.	I have a dog.	That is a lot! I have 3 cats and 2 dogs.

Table 2: Case studies that compare our framework against the baseline with the complete partner personas as well as the human response. We present the preceding partner utterance as dialogue context, and we give the most salient ground truth partner personas **(Gold Partner)** and generated partner personas **(Generated Partner)** for clarity.

initialization. More implementation details can be found in Appendx B.

The dialogue response generation results are presented in Table 1. Our framework with reinforcement learning attains the best over all the metrics on both PersonaChat-ori and PersonaChat-rev. This supports the usefulness of our framework, which generates reasonable personas and effectively enhances the succeeding dialogue response generation, through the use of RL.

Although TransferTransfo attains a better score on the PPL than the fine-tuned GPT-2, GPT-2 have better extrinsic scores than TransferTransfo. GPT-2 also has better overall scores than the E2E baselines without the complete partner personas. However, it is surpassed by the E2E baseline with the complete partner personas during training and inference.

The E2E baseline with the complete ground truth partner personas attains better scores on all of the metrics than our remaining baselines. Our framework with RL succeeds the performance of such a competitive baseline for both PersonaChat-ori and PersonaChat-rev, indicating our proposed framework's robustness against paraphrasal.

The multi-task learning comparison model (Lee et al., 2021) produces less promising results. Concretely, we postulate that the nature of PPG and DRG largely differs. The textual format of partner personas always initiates with first-person sentence starters, while dialogue responses are more general, ranging from greetings to goodbyes. Therefore, it could be hard to capture both in a single model.

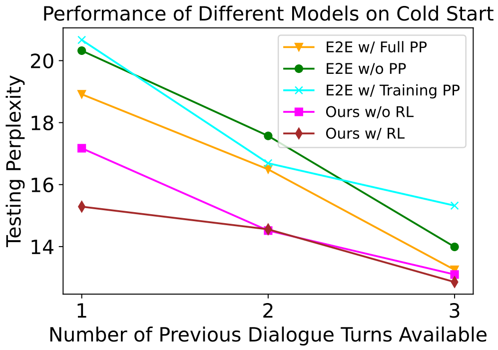

Figure 3: Analysis for the cold start problem with limited dialogue turns available. Note that all of these baselines are fine-tuned on DialoGPT.

5.2 Cold Start

Cold start is a common problem in recommender systems (Schein et al., 2002; Zhang et al., 2014; Li et al., 2021). This also applies to dialogue systems, as the partner personas are commonly missing in early turns. We conduct an analysis on the baselines and our framework when N turns are available where N={1,2,3}, using PersonaChat-ori. As demonstrated in Figure 3, all the methods attain a better PPL when N increases, which indicates the existence of the cold start. This is also the case for the baseline with ground truth personas, and we postulate that it fails to learn how to use partner personas during cold start due to the lack of clues. Our framework effectively mitigates the cold start problem and attains the best among them for all N.

5.3 Case Study on Dialogue Response Generation

Table 2 depicts the case study for response generation using PersonaChat-ori. In the first case,

Generated Partner Personas	**Ground Truth Partner Personas**
I am an army ranger. I secretly love my long deployments, because it gets me away from conventional life. I have a wife and two kids back in the states. I would be honored to give my life for my country. I am not afraid to die.	I am in the army. I am serving in South Korea. I was born in puerto rico. I am a violent person.
I drink protein powder with nothing but water. I like to watch mma. My prized possession is a bowie knife. I life weights, but I never do squats.	I am happy being single and alone. I only drink water. I go to the gym a days a week. I do not want children. I work in labor and delivery.
I like to watch football. My friends like watching it too. Its great fun. We drink beer and eat food.	I love watching football on Sunday. I have three dogs. My favroutie food is cheese piazza. I am a hair stylist.

Table 3: Case studies to show that our generated personas are relevant, informative and coherent.

Model	**PPL**↓	**B**	**R**	**D-1**	**D-2**
Gold	-	-	-	0.003	0.008
Our PPG	**56.2**	**2.99**	**22.5**	**0.012**	**0.042**
Gold	-	-	-	0.004	0.009
Our PPG	**111**	**1.34**	**20.8**	**0.013**	**0.042**

Table 4: Results for PPG. Upper for PERSONACHAT-ORI and lower for PERSONACHAT-REV. **B**, **R** and **D** represents BLEU, ROUGE and Distinct respectively.

our framework successfully recognizes that the partner is asking specifically for metallica. It then conditions on the generated personas to generate a much more entailed response than the baseline. The human response expresses negatively and thus seems less engaging. In the second case, our framework recognizes that the partner has a garden. It then talks about the garden rather than the irrelevant response from the baseline that we postulate is misled by the 'large' adjective in the dialogue context. The human response is potentially sarcastic if the partner is not joking, while our generation does not have such issue. For the third case, the baseline produces a response that could be potentially offensive, which could be biased by the word 'violent' in the dialogue context. In contrast, our framework recognizes the identity of the partner to generate a response without such an issue. The human response tends to raise a new topic and is less relevant. For the fourth case, we observe that the annotator sometimes converses based on the partner profile rather than his own traits. In this case, the annotator **(Dialogue Context)** said that he has many pets, which is not in his own traits **(Gold Partner)**. Rather, his conversation partner expressed his passion for animals in previous dialogue contexts. We postulate that the annotator attempted to engage the conversation by conditioning his partner personas and telling a relevant joke. Our PPG can recognize this, which further tweaks the model output to talk about dogs and cats rather than the dog only. These cases validate that leveraging partner personas is beneficial, and our framework can generate reasonable partner personas, which is not even in the ground truth.

5.4 Partner Personas Generation Results

Table 4 presents the quality measurements of the generated partner personas from our PPG with no RL. We observe that our models have much higher Distinct-N scores as the number of unique words in the generated output is much higher than the ground truth test personas. Compared to the ground truth personas that are limited sets of traits, our generator can leverage the power of pre-trained models for better diversity. The remaining metrics also report reasonable scores, suggesting the plausbility to formulate personas generation as a Seq2Seq task.

5.5 Case Study on Partner Personas Generation

Table 3 presents generated partner personas using PERSONACHAT-ORI. As depicted, our PPG can generate reasonable partner personas which are relevant to the ground truth partner personas. It sometimes gives a reasonable generation which is even not in the ground truth partner personas. In the first case, the generator successfully identifies the partner as being an army ranger. It then becomes rather positive than a violent person as given in the ground truth personas. Conditioning on such positive contents can give a positive response. In the second case, it recognizes the partner as a gym person, and imagines that the partner drinks protein and life weights, which is not in the ground truth personas. In the third case, the generator generates coherent personas, saying that the partner would drink beer and eat food while watching football, which is also not in the ground truth. We postulate that personas could be semantically closer to each other when they frequently co-occur in the training set. Our PPG then tends to generate more coherent

Criteria	E2E w/ Full PP	Our Framework
Appropriateness	42	58‡
Informativeness	41	59‡
Engagingness	40	60‡
Human-likeness	42	58‡

Table 5: Human evaluation results of dialogue response generation in winning percentages. ‡ indicates the results as passing a two-tailed binomial significance test with $p < 0.001$.

Criteria	Ground Truth	Our Framework
Coherence	41	59‡
Interestingness	39	61‡
Engagingness	44	56†
Human-likeness	47	53

Table 6: Human evaluation results of PPG in winning percentages. † and ‡ indicates the results as passing a two-tailed binomial significance test with $p < 0.05$ and $p < 0.001$ respectively.

personas by learning such semantical relationship.

Since our generated personas are relevant and coherent, we postulate it as the underlying reason why our method gives a better generalization to DRG. In contrast, as demonstrated by Table 3, ground truth personas tend to be more like discrete collections of traits. This could be the reason why some of our generated partner personas could beat the ground truth, which is also supported by our human evaluation in Section 5.6. This is a potential benefit of our approach compared to sentence-level user profile extraction (Li et al., 2014; Wu et al., 2020b; Wang et al., 2021) that is upper bounded by the discrete ground truth. We present more examples in Table 8 in the Appendix.

5.6 Human Evaluation

We hired experienced annotators who have degrees relevant to English Linguistics to conduct evaluation on PERSONACHAT-ORI. For both DRG and PPG, we present a questionnaire composed of 800 questions with randomly sampled 200 test instances to three annotators who compare model outputs under A/B testing. As in Zou et al. (2021) and ACUTE-Evals (Li et al., 2020), annotators follow the criteria which we present in Appendix D.

Table 5 presents the human evaluation results on dialogue response generation. Our framework trained under RL surpasses the E2E model that leverages both training and inference ground truth partner personas from all the aspects.

Model	PPL↓	BLEU	ROUGE
Ours w/ PPG	13.80	0.8293	17.42
Ours w/ DRG	13.17	0.8391	17.36
Ours w/ PPG&DRG	**13.05**	**1.0862**	**18.11**

Table 7: Ablation study for our proposed framework on PERSONACHAT-ORI.

Table 6 presents the human evaluation results on PPG. We observe that our PPG generates personas that are more coherent and interesting than the ground truth, which align with the facts observed in Section 5.4 and Section 5.5 indicating that our generated partner personas are more coherent and diverse.

5.7 Ablation Study

We conduct an ablation study on PERSONACHAT-ORI as reported in Table 7 to present the performance of our framework when one of the components is frozen during RL. The result indicates that our proposed framework yields the best result when both of the components are actively trained under RL. We also notice that scaling the RL reward for either PPG or DRG by 10 leads to minor decrease in the performance. Further scaling deteriorates the quality of response generation.

6 Conclusion

Our novel framework incorporates partner personas generation into dialogue response generation. It effectively mitigates the problem that partner personas are not available in practical applications as well as the cold start problem during early conversation. The experimental results with both automatic and human evaluation demonstrate that our framework generates coherent, diverse, interesting and engaging partner personas, even compared to the ground truth partner personas. We employ reinforcement learning with a dedicatedly designed critic network that boosts the response generation by conditioning on the generated personas. Automatic and human evaluation results indicate that our response generator surpasses our competitive baselines that condition on the ground truth partner personas. Extensive case studies demonstrate that our framework can generate satisfying dialogue responses and partner personas.

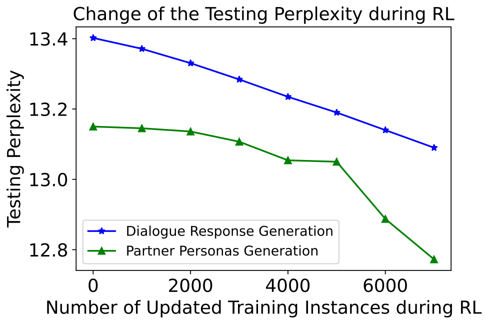

Figure 4: Change of the testing PPL during RL.

A Ethics Statement

The PERSONACHAT dataset used in this work is well-known and widely used. In our view, there is no known ethical issue with its usage. Large-scale pre-trained models are also employed, but they are widely known to be subject to potential problems such as generating offensiveness context. With its use, our partner personas generator could generate unseen personas, which are also subject to potential offensive generation. An offensiveness check can be incorporated to alleviate this problem for actual usage (Baheti et al., 2021).

B Implementation Details

For supervised phase, we set Adam (Kingma and Ba, 2015) as our optimizer, with hyperparameters $\eta = 5e{-}4$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e{-}8$. The models are fine-tuned for 2 epochs. For RL phase, we set Adam as our optimizer, with $\eta = 5e{-}6$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e{-}8$. We update the model parameters every 20 training instances and validate the model performance every 50 updates. DistilBERT (Sanh et al., 2019) is used to initialize the model parameters for the critic network. We set Adam as our optimizer, with hyperparameters $\eta = 5e{-}6$, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1e{-}8$. We fine-tune the critic for 1 epoch, and we freeze it empirically during RL. All the experiments are conducted based on the TRANSFORMERS library from HUGGINGFACE (Wolf et al., 2020).

C Analysis on Dialogue Reponse Generation

We present the progressive change of the testing perplexity for DRG and PPG on PERSONACHAT-ORI in Figure 4.[4] We observe that they improve simultaneously, which supports our motivation to use RL for joint training.

D Human Evaluation Criteria

- **(Appropriateness)**: *"Who is more appropriate given the previous dialogue context?"*
- **(Informativeness)**: *"Who is more diverse instead of null answers such as I do not know?"*
- **(Engagingness)**: *"Who would you prefer to talk with for a long conversation?"*
- **(Human-likeness)**: *"Which speaker do you think sounds more like a real person?"*
- **(Coherence)**: *"Which persona contains traits that are more coherent to each other?"*
- **(Interestingness)**: *"Which persona is more interesting and diverse?"*

The first four are from the existing work (Li et al., 2019; Zou et al., 2021) and we propose the last two for evaluating PPG. We report the first four for DRG, and we report the last four for PPG.

E Dataset Limitations

Our work uses an off-the-shelf persona-based conversational dataset PERSONACHAT (Zhang et al., 2018), which is collected and built by crowdsourcing to converse based on a fake set of discrete traits. There is no personal information and hence no ethics concern, but this might result in limited usefulness as there could be discrepancies between the collected samples and real-life conversation. It is also more expensive to collect real data. However, PERSONACHAT has been widely used by the community as a standard dataset. Many well-known persona-based datasets suffer from the same problem (Urbanek et al., 2019) as widely known.

Although Mazaré et al. (2018) proposed a useful method to collect large-scale persona-based dialogue datasets by extracting persona from user comments with classifiers trained on revised personas from PERSONACHAT which can improve the model performance on PERSONACHAT. For legal reasons, they did not release this dataset at the time of writing. Similarly, Zheng et al. (2019) proposed a persona-based dialogue dataset with diversified traits, but it is not currently online readily available.

Zhong et al. (2020) has followed the approach suggested by Mazaré et al. (2018) to build an empathetic conversation dataset based on personas.

---

[4] The result is scaled for the sake of space and clarity.

Generated Partner Personas
Personas A: I am a shy person, but I love to sing. Until recently, I ve never been able to sing in front of anyone. Anyways, I decided to give it a try and participaed in an audition for a talent show . My shyness made me panick and I didn t show up.
Personas B: I play the violin. I am married with 5 kids. I am nurse. I met my husband when I was a freshman in college .
Personas C: I am a soccer player. I am a goalie. My number is 42. Nike cleats are my favorite. I joined a new team last month.
Personas D: I have two kids, ages 2 and 6. I am from sterling heights, michigan . My favorite movie is titanic . I work part time at aldis. My husband owns a small auto repair shop.
Personas E: I am a retired computer programmer. I have one grandson and one daughter. I just turned 77. I love animals. I like watching british tv shows and movies .
Personas F: I like to go hunting. I like to remodel homes. I like to shoot a bow. My favorite holiday is halloween . I like to go shopping with my daughters.
Personas G: I have a large cd collection. I collect stamps. Favorite band is the beetles . I like vintage furniture .
Personas H: I like to drink wine. I enjoy reading history books. I am a teacher. I love to write stories while sitting in the grass in my back yard. I grew up in new hampshire.
Personas I: I am retired. I stay active. I have eight grandchildren. I have good health.
Personas J: I m a student. I like to go out to eat. I like listening to other rap music too. One of my favorite artists is drake . A hobby of mine is the drums. I also enjoy cooking .
Personas K: I have two children. I like to go on walks. I am from mexico. I used to be a chef, but I am a teacher now. I like to bake.
Personas L: I like to do all my shopping at walmart . I m deathly terrified of heights. I prefer to live where the weather s cold. Winter s my favorite time of the year. I m really excited to see how game of thrones ends.
Personas M: I like to cook. I am a foodie. I love to chat with my friends. I love kids and dogs. I like to go shopping with my daughters.
Personas N: My family hates my fiance. We will be traveling to niagra falls for our honeymoon. We are getting married in a park. My dog is the ring bearer.
Personas O: My favorite color is red. I have 2 dogs as pets. I leave the dogs home when I visit my parents. I love dogs. I work as a veterinarian s assistant .
Personas P: I am a musician. I wish I could spend more time at home. I like to write my own songs. I have taken formal music lessons since i was 5.
Personas Q: I love comics. I love reading. I ve started creating my own comics and presenting them to publishers. I decided to publish my creations on internet. I ve been rejected several times and thought of giving up with this .

Table 8: More generated personas. We highlight in pink for informativeness and in yellow for coherence.

However, their main focus is to investigate the impact of personas on empathetic dialogue generation. Therefore, we choose to follow the community to investigate our method on the most well-known dataset, PERSONACHAT.

F Computing Infrastructure

We run all our experiments on a single NVIDIA TITAN RTX with 24GB GPU memory. Fine-tuning the generators for 2 epochs as we have done on our preprocessed PERSONACHAT train split consumes about 3-4 hours. Fine-tuning our critic classifier for 1 epoch consumes about 1 hour. Our RL phase consumes about 15 hours to achieve the best validation loss before being early stopped. We report averaged results from 3 runs for our dialogue response generation and partner personas generation results reported in Table 1, Table 4 and Table 7.

Semantically Informed Slang Interpretation

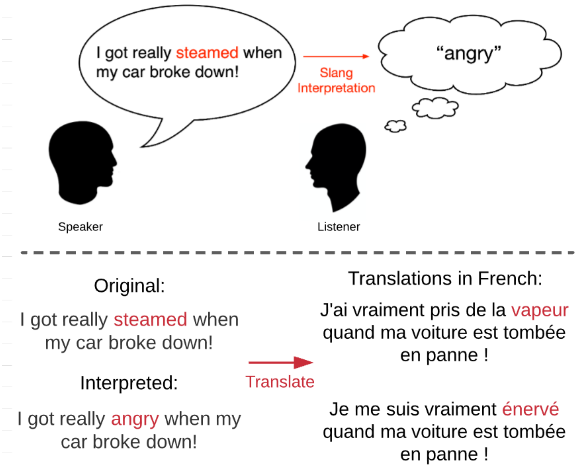
Abstract

Slang is a predominant form of informal language making flexible and extended use of words that is notoriously hard for natural language processing systems to interpret. Existing approaches to slang interpretation tend to rely on context but ignore semantic extensions common in slang word usage. We propose a semantically informed slang interpretation (SSI) framework that considers jointly the contextual and semantic appropriateness of a candidate interpretation for a query slang. We perform rigorous evaluation on two large-scale online slang dictionaries and show that our approach not only achieves state-of-the-art accuracy for slang interpretation in English, but also does so in zero-shot and few-shot scenarios where training data is sparse. Furthermore, we show how the same framework can be applied to enhancing machine translation of slang from English to other languages. Our work creates opportunities for the automated interpretation and translation of informal language.



Original:

I got really steamed when my car broke down!

Interpreted:

I got really angry when my car broke down!

Translations in French:

J'ai vraiment pris de la vapeur quand ma voiture est tombée en panne !

Je me suis vraiment énervé quand ma voiture est tombée en panne !

Figure 1: Illustrations of slang interpretation in English (top panel) and slang translation (bottom panel) from English to French on the original sentence (nonsensical), or on the interpreted version of the sentence (sensical).

1 Introduction

Slang is one of the most common forms of informal language, but interpreting slang can be difficult for both humans and machines. Empirical studies have shown that, although it is done instinctively, interpretation and translation of unfamiliar or novel slang expressions can be quite hard for humans (Braun and Kitzinger, 2001; Mattiello, 2009). Similarly, slang interpretation is also notoriously difficult for state-of-the-art natural language processing (NLP) systems, which presents a critical challenge to downstream applications such as natural language understanding and machine translation.

Consider the sentence "I got really *steamed* when my car broke down". As illustrated in Figure 1, directly applying a translation system such as Google Translate on this raw English sentence would result in a nonsensical translation of the slang term *steamed* in French. This error is due partly to the underlying language model that fails to recognize the flexible extended use of the slang term from its conventional meaning (e.g., "vapor") to the slang meaning of "angry". However, if knowledge about such semantic extensions can be incorporated into interpreting the slang prior to translation, as Figure 1 shows the system would be quite effective in translating the intended meaning.

Here we consider the problem of slang interpretation illustrated in the top panel of Figure 1. Given a target slang term like *steamed* in a novel query sentence, we want to automatically infer its intended meaning in the form of a definition (e.g., "angry"). Tackling this problem has implications in both machine interpretation and understanding of informal language within individual languages and translation between languages.

One natural solution to this problem is to use contextual information to infer the meaning of a slang term. Figure 2 illustrates this idea by showing the top infilled words predicted under a GPT-2

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5213 - 5231

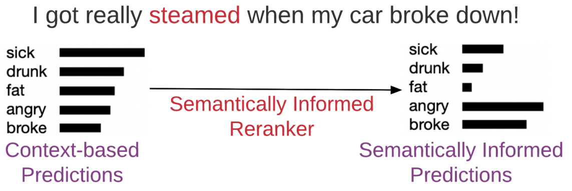

Figure 2: Workflow of the proposed framework.

(Radford et al., 2019) based language infill model (Donahue et al., 2020). Each of these words can be considered a candidate paraphrase for the target slang *steamed* conditioned on its surrounding words. Although the groundtruth meaning "angry" is among the list of top candidates, this model infers "sick" as the most probable interpretation. A similar context-based approach has been explored in a previous study led by Ni and Wang (2017) showing that a sequence-to-sequence model trained directly on a large number of pairs of slang-contained sentences along with their corresponding definitions from Urban Dictionary can be a useful starting point toward the automated interpretation of slang.

We present an alternative approach to slang interpretation that builds on but goes beyond the context-based models. Inspired by recent work on generative models of slang (Sun et al., 2019, 2021), we consider slang interpretation to be the inverse process of slang generation and propose a semantically informed framework that takes into account both contextual information and knowledge about slang meaning extensions (e.g., "vapor"→"angry") in inferring candidate interpretations. Our framework incorporates a semantic model of slang that uses contrastive learning to capture semantic extensions that link conventional and slang meanings of words (Sun et al., 2021). Under this framework, meanings that are otherwise far apart can be brought close, resulting in a semantic space that is sensitive to the flexible extended usages of slang. Rather than using this learned semantic space to generate novel slang usages, we apply it to the inverse problem of slang interpretation by checking whether a candidate interpretation may be suitably expressed as a slang using the to-be-interpreted slang expression. For example, "sick" and "angry" can both replace the slang *steamed* in a given context, but "angry" may be a more appropriate meaning to be expressed using *steamed* in the slang context. As such, we build a computational framework that takes into account the semantic knowledge of words as well as the context of slang in the interpretation process.

Figure 2 illustrates the workflow of our approach. We begin with a set of candidate interpretations informed by a context-based model (e.g., a language infill model), where the set would contain a list of possible meanings that fit reasonably in the given context. We then rerank this set of candidate interpretations by selecting the meaning that is most likely to be extended as slang from the to-be-interpreted slang expression.

For the scope of this work, we focus on interpreting slang expressions with existing word forms because extensive studies in slang have suggested that a high proportion of slang usages relies on the extended reuse of existing word forms (Warren, 1992; Green, 2010; Eble, 2012). We show that our framework can enhance state-of-the-art language models in slang interpretation in English and slang translation from English to other languages.[1]

2 Related Work

2.1 Natural Language Processing for Slang

Existing approaches in the natural language processing for slang focus on efficient construction, extension, and retrieval from dictionary-based resources for detection (Pal and Saha, 2013; Dhuliawala et al., 2016), interpretation (Gupta et al., 2019), and sentiment analysis of slang (Dhuliawala et al., 2016; Wu et al., 2018). These studies often rely on heuristic measures to determine or retrieve the meaning of slang and cannot generalize beyond what was available in the training data. Recent work such as Kulkarni and Wang (2018) and Pei et al. (2019) proposed deep learning based approaches to generalize toward unseen slang.

Closely related to our study is Ni and Wang (2017) that formulated English slang interpretation as a translation task (although they did not tackle slang machine translation *per se*). In this work, each slang query sentence in English is paired with the groundtruth slang definition (also in English), and such pairs are fed into a translation model. In addition, the spellings of slang word forms are also considered as input. In their model, both the context and the slang form are encoded using separate LSTM encoders. The two encoded representations are then linearly combined to form the encoded input for a sequence-to-sequence network (Sutskever et al., 2014). During training, the combined state is passed onto an LSTM decoder to train against

---

[1] Code and data available at: `https://github.com/zhewei-sun/slanginterp`

the corresponding definition sentence. During test time, beam search (Graves, 2012) is applied to decode a set of candidate definition sentences.

One key problem with this approach is that the Dual Encoder tends to rely on the contextual features surrounding the target slang but does not model flexible meaning extensions of the slang word itself. Similar issues are present in a language-model based approach, whereby one can use an infill model to infer the meaning of a target slang based solely on its surrounding words. Our work extends these context-based approaches by jointly considering the contextual and semantic appropriateness of a slang expression in a sentence, using generative semantic models of slang.

2.2 Generative Semantic Models of Slang

Recent work by Sun et al. (2019, 2021) proposed a neural-probabilistic generative framework for modeling slang word choice in novel context. Given a query sentence with the target slang blanked out and the intended meaning of that slang, their framework predicts which word(s) would be appropriate slang choices that fill in the blank. Relevant to their framework is a semantic model of slang that uses contrastive learning from Siamese networks (Baldi and Chauvin, 1993; Bromley et al., 1994) to relate conventional and slang meanings of words. This model yields a semantic embedding space that is sensitive to flexible slang meaning extensions. For example, it may learn that meanings associated with "vapor" can extend to meanings about "angry" (as in the *steamed* example in Figure 1).

Differing from slang generation, our work concerns the inverse problem of slang interpretation that has more direct applications in natural language processing particularly machine translation (e.g., of informal language). Building on work of slang generation, we incorporate the generative semantic model of slang in a semantically informed interpretation framework that integrates context to infer the intended meaning of a target slang.

3 Computational Framework

Our computational framework is comprised of three key components following the workflow illustrated in Figure 2: 1) A context-based baseline interpreter that generates an n-best list of candidate interpretations for a target slang in a query sentence; 2) A semantic model of slang that checks the appropriateness of a candidate interpretation to the slang context; 3) A reranker informed by the semantic model in 2) that re-prioritizes the candidate interpretations from the context-based interpreter in 1). We use this framework for both interpreting slang within English and translating slang from English to other languages.

3.1 Context-based Interpretation

We define slang interpretation formally as follows. Given a target slang term S in context C_S of a query sentence, interpret the meaning of S by a definition M. The context is an important part of the problem formulation since a slang term S may be polysemous and context can be used to constrain the interpretation of its meaning. We define a slang interpreter I probabilistically as:

$$I(S, C_S) = \arg\max_M P(M|S, C_S) \qquad (1)$$

Given this formulation, we retrieve an n-best list of candidate interpretations $\mathcal{K}$ (i.e., $|\mathcal{K}| = n$) based on an interpretation model of choice $P(M|S, C_S)$. Here, we consider two alternative models for $P(M|S, C_S)$: 1) a language-model (LM) based approach that treats slang interpretation as a cloze task, and 2) a sequence-to-sequence based approach similar to work by Ni and Wang (2017).

LM-based interpreter. The first model we consider is a language infill model in a cloze task, in which the model itself is based on large pre-trained language models such as GPT-2 (Radford et al., 2019). Although slang expressions may make sporadic appearances during training, this model is not trained specifically on a slang related task and thus serves as a baseline that reflects the state-of-the-art language-model based NLP systems (e.g., Donahue et al., 2020).

Given context C_S containing target slang S, we blank out S in the context and ask the language infill model to infer the most likely words to fill in the blank. This results in a probability distribution $P(w|C_S \backslash S)$ over candidate words w. The infilled words can then be viewed as candidate interpretations of the slang S:

$$\begin{aligned} I(S, C_S) =& D[\arg\max_w LM(w|C_S \backslash S) \\ &+ \mathbb{1}_{T(w)}[T(C_S \backslash S)]] \end{aligned} \qquad (2)$$

Here, D is a dictionary lookup function that maps a candidate word w to a definition sentence. In this case, we constrain the space of meanings considered to the set of all meanings corresponding to words in the lexicon. Additionally, we apply a Part-of-Speech (POS) tagger T to check whether the candidate word w shares the same POS tag as the blanked-out word in the usage context. Words that share the same POS tags are preferred in the list of n-best retrievals.

This baseline approach by itself does not take into account any (semantic) information from the target slang S. In the case where two distinctive slang terms may be placed in the same context, the model would generate the exact same output. However, this LM based approach does not require task-specific data to train. We show later that by reranking language model outputs, it is possible to achieve state-of-the-art performance using much less on-task data than existing approaches.

Dual encoder. Ni and Wang (2017) partly addressed the context-only limitation by encoding the slang term using a character-level recurrent neural network in an end-to-end model inspired by the sequence-to-sequence architecture for neural machine translation (Sutskever et al., 2014). We implement their dual encoder architecture as an alternative context-based interpreter to LM. In this model, separate LSTM encoders are applied on the context C_S and the character encoding of the to-be-interpreted slang S respectively. The two encoders are then linearly combined using learned parameters. The combined state is passed onto an LSTM decoder to train against the corresponding definition sentence in Urban Dictionary (as in the original work of Ni and Wang 2017). For inference, beam search (Graves, 2012) is applied to decode an n-best list of candidate definition sentences.

While this approach is trained directly on slang data and considers the slang word forms, it requires a large on-task dataset to be trained effectively. This model also does not take into account the appropriateness of meaning extension in slang usage. We next describe how a semantic model of slang can be incorporated to enhance the context-based interpreters.

3.2 Semantic Model of Slang

Given an n-best list of candidate interpretations $\mathcal{K}$ for the target slang S in context C_S, we wish to model the semantic plausibility of each candidate interpretation $k \in \mathcal{K}$. Specifically, we ask how likely one would relate the (conventional meaning of) target slang expression S to a candidate interpretation k. Sun et al. (2019, 2021) modeled the relationship between a to-be-expressed meaning and a word form using the prototype model (Rosch, 1975; Snell et al., 2017). We adapt this model in the context of slang interpretation:

$$\begin{aligned} f(k, S) &= sim(E_k, E_S) \\ &= \exp(-\frac{d(E_k, E_S)}{h_m}) \end{aligned} \tag{3}$$

E_k is an embedding for a candidate interpretation k and E_S is the prototypical conventional meaning of S computed by averaging the embeddings of its conventional meanings in dictionary ($\mathcal{E}_S$):

$$E_S = \frac{1}{|\mathcal{E}_S|} \sum_{E_{S_i} \in \mathcal{E}_S} E_{S_i} \tag{4}$$

The similarity function f can then be computed by taking the negative exponential of the Euclidean distance between the two resulting semantic embeddings. h_m is a kernel width hyperparameter.

Following Sun et al. (2021), we learn semantic embeddings E_k and E_{S_i} under a max-margin triplet loss scheme, where embeddings of slang sense definitions (E_{SL}) are brought close in Euclidean space to those of their conventional sense definitions (E_P) yet kept apart from irrelevant word senses (E_N) by a pre-specified margin m:

$$Loss = \Big[d(E_{SL}, E_P) - d(E_{SL}, E_N) + m\Big]_+ \tag{5}$$

The resulting contrasive sense encodings are shown to be sensitive to slang semantic extensions that have been observed during training. We leverage this knowledge to check whether pairing a candidate interpretation k with the slang expression S is likely given the common semantic extensions observed in slang usages.

3.3 Semantically Informed Reranking

We define a semantic scorer g over the set of candidate interpretations $\mathcal{K}$ and the to-be-interpreted slang S. The candidates are reranked based on the resulting scores to obtain semantically informed slang interpretations (SSI):

$$SSI(\mathcal{K}) = \arg\max g(k, S) \tag{6}$$

We define $g(\mathcal{K}, S)$ as a score distribution over the set of candidates $\mathcal{K}$ given slang S, where each score is computed by checking the semantic appropriateness of a candidate meaning $k \in \mathcal{K}$ with respect to target slang S by querying the semantic model f from Equation 3:

$$g(k, S) = P(k|S) \propto f(k, S) \tag{7}$$

In addition, we apply collaborative filtering (Goldberg et al., 1992) to account for a small neighborhood of words $L(S)$ akin to the slang expression S in conventional meaning:

$$g^*(k, S) \propto \sum_{S' \in L(S)} sim(S, S') g(k, S') \tag{8}$$

$$sim(S, S') = \exp(-\frac{d(S, S')}{h_{cf}}) \tag{9}$$

Here, $d(S, S')$ is the cosine distance between the two slang's word vectors and h_{cf} is a hyperparameter controlling the kernel width. The collaborative filtering step encodes intuition from studies in historic semantic change that similar words tend to extend to express similar meanings (Lehrer, 1985; Xu and Kemp, 2015), which was found to extend well in the case of slang (Sun et al., 2019, 2021).

4 Datasets

We use two online English slang dictionary resources to train and evaluate our proposed slang interpretation framework: 1) the Online Slang Dictionary (OSD)[2] dataset from Sun et al. (2021) and 2) a collection of Urban Dictionary (UD)[3] entries from 1999 to 2014 collected by Ni and Wang (2017). Each dataset contains slang gloss entries including a slang's word form, its definition, and at least one corresponding example sentence containing the slang term. We use the same training and testing split provided by the original authors and only use entries where a corresponding non-informal entry can be found in the online version of the Oxford Dictionary (OD) for English[4], which allows the retrieval of conventional senses for all slang expressions considered. We also filter out entries where the example usage sentence contains none or more than one exact references of the corresponding slang expression. When a definition entry has multiple example usage sentences, we treat each example sentence as a separate data entry, but all data entries corresponding to the same definition entry will only appear in the same data split. Table 1 shows the size of the datasets after pre-processing. While OSD contains higher quality entries, UD offers a much larger dataset. We thus use OSD to evaluate model performance in a low resource scenario and UD for evaluation of larger neural network based approaches.

5 Evaluation and Results

5.1 Evaluation on Slang Interpretation

We first evaluate the semantically informed and baseline interpretation models in a multiple choice task. In this task, each query is paired with a set of definitions that construe the meaning of the target slang in the query. One of these definitions is the groundtruth meaning of the target slang, while the other definitions are incorrect or negative entries sampled from the training set (i.e., all taken from the slang dictionary resources described). To score a model, each definition sentence is first compared with the model-predicted definition by computing the Euclidean distance between their respective Sentence-BERT (Reimers and Gurevych, 2019) embeddings. The ideal model should produce a definition that is semantically closer to the groundtruth definition, more so than the other competing negatives. For each dataset, we sample two sets of negatives. The first set of negative candidates contains only definition sentences from the training set that are distinct from the groundtruth definition. We consider two definition sentences to be distinct if the overlap in the number of content words is less than 50%. The other set of negative definitions is sampled randomly. We measure the performance of the models by computing the standard mean reciprocal rank (MRR) of the groundtruth definition's rank when checked against 4 other sampled negative definitions.

We train the semantic reranker on all definition entries in the respective training sets from the two data resources. When training the Dual Encoder, we use 400,431 out-of-vocabulary slang entries (i.e., entries with a slang expression that does not contain a corresponding lexical entry in the standard dictionary) from UD in addition to the in-vocabulary entries used to train the reranker. This is necessary since the baseline Dual Encoder performs poorly without a large number of training entries. Similarly, training the Dual Encoder directly on the OSD training set does not result in an adequate model for comparison. We instead train the Dual Encoder on all UD entries and experiment with the resulting interpreter on OSD. Any UD

Dataset	# of unique slang word forms	# of slang definition entries	# of context sentences	# of definitions in the test set	# of context sentences in the test set
OSD	1,635	2,979	3,718	299	405
UD	9,474	65,478	65,478	1,242	1,242

Table 1: Summary of basic statistics for the two online slang dictionaries used in the study.

Model	Distinctively sampled candidates	Randomly sampled candidates
Dataset 1: Online Slang Dictionary (OSD) (Sun et al., 2021)		
Language Infill Model (LM Infill) (Donahue et al., 2020), n = 50	0.532	0.502
+ Semantically Informed Slang Interpretation (SSI)	**0.557**	**0.563**
Dual Encoder* (Ni and Wang, 2017), n = 5	0.584	0.583
+ SSI	**0.592**	**0.588**
Dual Encoder*, n = 50	0.568	0.602
+ SSI	**0.616**	**0.607**
* Dual Encoders trained on UD data after filtering out slang in OSD test set.		
Dataset 2: Urban Dictionary (UD) (Ni and Wang, 2017)		
LM Infill, n = 50	0.517	0.521
+ SSI	**0.569**	**0.579**
Dual Encoder, n = 5	0.556	0.555
+ SSI	**0.573**	**0.572**
Dual Encoder, n = 50	0.547	0.550
+ SSI	**0.582**	**0.584**

Table 2: Evaluation of English slang interpretation measured in mean-reciprocal rank (MRR). Predictions are ranked against 4 negative candidates distinctively or randomly sampled, yielding MRR=0.457 for the random baseline.

entries corresponding to words found in the OSD testset are filtered out in this particular experiment. Detailed training procedures for all models can be found in Appendix A.

Table 2 summarizes the multiple-choice evaluation results on both slang datasets. In all cases, applying the semantically informed slang interpretation framework improves the MRR of the respective baselines under both types of negative candidate sampling. On the UD evaluation, even though the language infill model (LM Infill) is not trained on this specific task, LM infill based SSI is able to select better and more appropriate interpretations than the dual encoder baseline, which is trained specifically on slang interpretation with more than 7 times the number of definition entries for training. We also find that while increasing the beam size (specified by n) in the sequence-to-sequence based Dual Encoder model impairs its performance, SSI can take advantage of the additional variation in the generated candidates and outperform its counterpart with a smaller beam size.

Table 3 provides example interpretations predicted by the models. The *lit* example shows a case where the semantically informed models were able to correctly pinpoint the intended definition, among alternative definitions that describe individuals. The *lush* example suggests that the SSI model is not perfect and points to common errors made by the model including predicting definitions that are more general and applying incorrect semantic extensions. In this case, the model predicts the slang *lush* to mean "something that is not cool" because polarity shift is a common pattern in slang usage (Eble, 2012), even though the groundtruth definition does not make such a polarity shift in this specific example.

Note that the improvement brought by SSI is less prominent in the OSD experiment where the Dual Encoder trained on UD was used. This is

Query (target slang in ***bold italic***):	That chick is ***lit***!
Groundtruth definition of target slang:	Attractive.
LM Infill baseline prediction:	Cute, beautiful, adorable.
LM Infill + SSI prediction:	Hot, cool, fat.
Dual Encoder baseline prediction:	Another word for bitch.
Dual Encoder + SSI prediction:	Word used to describe someone who is very attractive.
Query:	That Louis Vuitton purse is ***lush***!
Groundtruth definition of target slang:	High quality, luxurious. (British slang.)
LM Infill baseline prediction:	Amazing, beautiful, unique.
LM Infill + SSI prediction:	Lovely, stunning, expensive.
Dual Encoder baseline prediction:	Something that is cool or awesome.
Dual Encoder + SSI prediction:	An adjective used to describe something that is not cool.

Table 3: Example queries from OSD and top predictions made from both the baseline language infill models (LM Infill) and the Dual Encoder models with $n = 50$, along with top predictions from the enhanced semantically informed slang interpretation (SSI) models. Additional examples can be found in Appendix B.1.

expected because the Dual Encoder is trained to generate definition sentences in the style of UD entries, whereas the SSI is trained on OSD definition sentences instead. The mismatch in style between the two datasets might have caused the difference in performance gain.

5.2 Zero-shot and Few-shot Interpretation

Recent studies in deep learning have shown that large neural network based models such as GPT-3 excel at learning new tasks in a few-shot learning setting (Brown et al., 2020). We examine to what extent the superior performance of our SSI framework may be affected by fine-tuning the LM baseline model in zero-shot and few-shot scenarios. We finetune the language infill model (LM Infill) on the first example usage sentence that correspond to each definition entry in the OSD dataset, resulting in 2,979 sentences. Given an example sentence, we mask out the slang expression and train the language infill model to predict the corresponding slang term. We randomly shuffle all examples and finetune LM Infill for one epoch. We then compare the resulting model with the off-the-shelf LM using examples in the test set that were not used in finetuning (i.e., entries with usage sentences that do not correspond to the first example usage sentence of a definition entry). This results in 106 novel examples for evaluation.

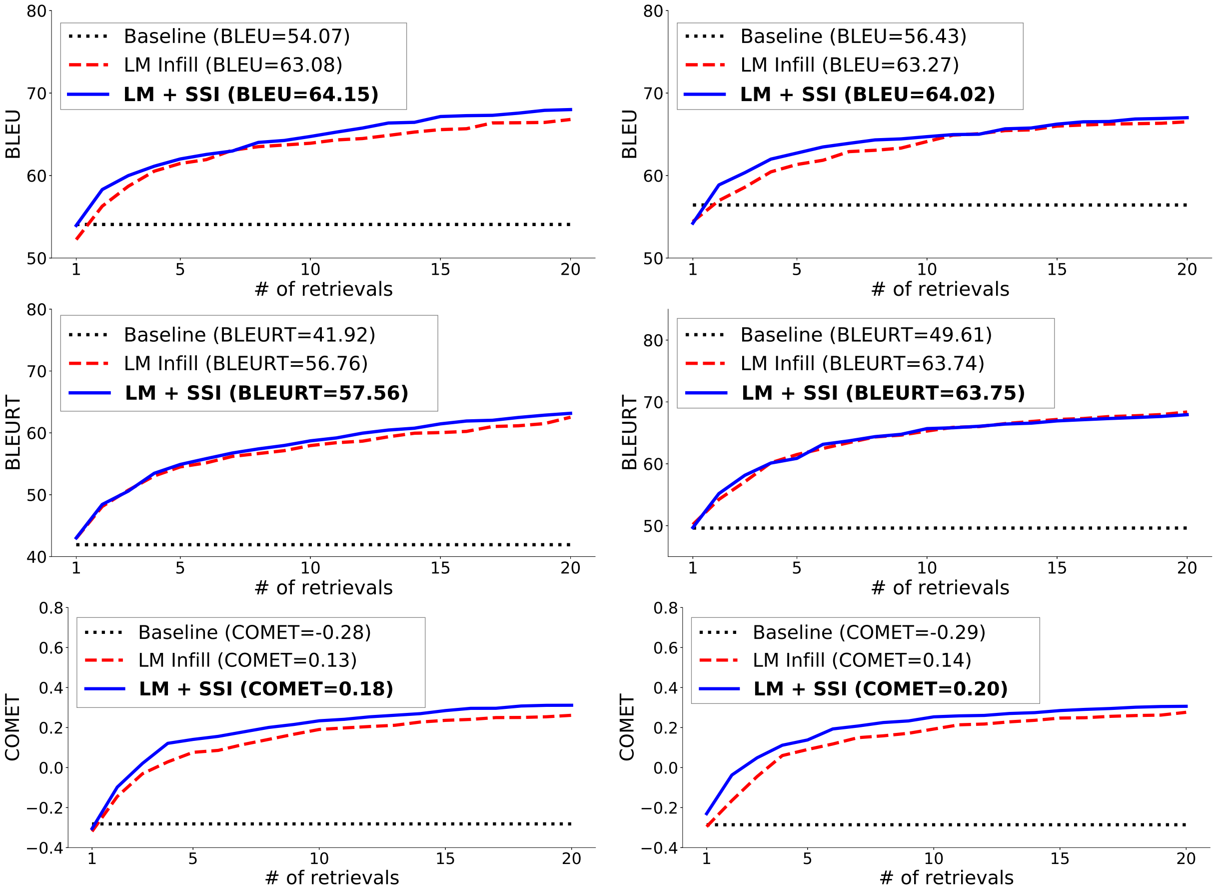
Table 4 shows the result of this experiment. While finetuning does improve test performance (a 6 point gain in MRR), it remains beneficial to consider semantic information in slang context. In both the zero-shot and the few-shot cases, SSI brings significant performance gain even though SSI itself is only trained on entries from the training set.

Model	Distinct negatives	Random negatives
LM Zero-shot, $n = 50$	0.444	0.443
+ SSI	**0.571**	**0.565**
LM Few-shot, $n = 50$	0.504	0.513
+ SSI	**0.567**	**0.564**

Table 4: Interpretation results on OSD measured in mean-reciprocal rank (MRR) before and after finetuning the language infill model.

5.3 Evaluation on Slang Translation

We next apply the slang interpretation framework to neural machine translation. Existing machine translation systems have difficulty in translating source sentences containing slang usage partly because they lack the ability to properly decode the intended slang meaning. We make a first attempt in addressing this problem by exploring whether machine interpretation of slang can lead to better translation of slang. Given a source English sentence containing a slang expression S, we apply the LM based slang interpreters to generate a paraphrased word to replace S. The paraphrased sentence would then contain the intended meaning of the slang in its literal form. Here, we take advantage of the LM-based approaches' ability to directly generate a paraphrase instead of a definition sentence (i.e., without dictionary lookup D in Equation 2), which allows direct insertion of the resulting interpretation into the original sentence.



(a) English to French

(b) English to German

Figure 3: Translation scores of translated sentences with the slang replaced by n-best interpretations. Curves show sentence-level BLEU, BLEURT, and COMET scores of the best translation within the top-n retrievals. Aggregate scores integrated over the first 20 retrievals are shown in parenthesis. Baselines are obtained by directly translating the original sentence containing slang.

We perform our experiment on the OSD test set because it contains higher quality example sentences than UD. To mitigate potential biases, we consider only entries that correspond to single word slang expressions, and that the slang has not been seen during training (where the slang attaches to a different slang meaning than the one in the test set). For the remaining 102 test entries, we obtain gold-standard translations by first manually replacing the slang word in the example sentence with its intended definition, condensed to a word or short phrase to fit into the context sentence. We then translate the sentences to French and German using machine translation.

We make all machine translations using pre-trained 6-layer transformer networks (Vaswani et al., 2017) from MarianMT (Tiedemann and Thottingal, 2020), which are trained on a collection of web-based texts in the OPUS dataset (Tiedemann, 2012). Here, we select models pre-trained on web-based texts to maximize the baseline model's ability to correctly process slang. We evaluate the translated sentences using three metrics: 1) Sentence-level BLEU scores (Papineni et al., 2002) computed using *sentence_bleu* implementation from NLTK (Bird et al., 2009) with smoothing (*method4* in NLTK, Chen and Cherry, 2014) to account for sparse n-gram overlaps; 2) BLEURT scores (Sellam et al., 2020) computed using the pre-trained *BLEURT-20* checkpoint; 3) COMET scores (Rei et al., 2020) computed using the pre-trained *wmt20-comet-da* checkpoint. For COMET scores, we replace slang expressions in the source sentences with their literal equivalents to reduce confusion that the COMET model might have on slang.

Figure 3 summarizes the results. Overall, the semantically informed approach tends to outperform the baseline approaches for the range of top retrievals (from 1 to 20) under all three metrics considered, with the exception of BLEURT evaluated on German where the semantically informed approach gives very similar performance as the

Query (target slang in ***bold italic***):	I want to go get coffee but it's ***bitter*** outside.
Definition of target slang:	Abbreviated form of bitterly cold.
Groundtruth interpreted sentence:	I want to go get coffee but it's *bitterly cold* outside.
Original query sentence translation:	Je veux aller prendre un café mais c'est amer dehors. (*BLEU:* 65.0, *BLEURT:* 59.8, *COMET:* 0.77)
Gold-standard translation:	Je veux aller prendre un café, mais il fait très froid dehors.
LM Infill interpretation & translation:	
(1) I want to go get coffee but it's *raining* outside.	Je veux aller prendre un café mais il *pleut* dehors. (*BLEU:* 68.1, *BLEURT:* 79.9, *COMET:* 0.97)
(2) I want to go get coffee but it's *closed* outside.	Je veux aller prendre un café mais il *est fermé* dehors. (*BLEU:* 70.7, *BLEURT:* 53.9, *COMET:* -0.15)
LM Infill + SSI interpretation & translation:	
(1) I want to go get coffee but it's *cold* outside.	Je veux aller prendre un café, mais il fait *froid* dehors. (*BLEU:* 90.3, *BLEURT:* 92.7, *COMET:* 1.20)
(2) I want to go get coffee but it's *warm* outside.	Je veux aller prendre un café mais il fait *chaud* dehors. (*BLEU:* 78.1, *BLEURT:* 79.1, *COMET:* 1.12)

Table 5: An example of machine translation of slang, without or with the application of the SSI framework. The top 2 interpreted and translated sentences are shown for each model with BLEU, BLEURT, and COMET scores against the gold-standard translation shown in parentheses. More examples can be found in Appendix B.4.

language model baseline. While not all predicted interpretations correspond to the groundtruth definitions, the set of interpreted sentences often contain plausible interpretations that result in improved translation of slang. Table 5 provides some example translations. We observe that quality translations can be found reliably with a small number of interpretation retrievals (i.e., around 5) and the quality generally improves as we retrieve more candidate interpretations. Our approach may be ultimately integrated with a slang detector (e.g., Pei et al. 2019) to produce fully automated translations in natural context that involves slang.

6 Conclusion

The flexible nature of slang is a hallmark of informal language, and to our knowledge we have presented the first principled framework for automated slang interpretation that takes into account both contextual information and knowledge about semantic extensions of slang usage. We showed that our framework is more effective in interpreting and translating the meanings of English slang terms in natural sentences in comparison to existing approaches that rely more heavily on context to infer slang meaning.

Future work in this area may benefit from principled approaches that model the coinage of slang expressions with novel word forms and multi-word expressions with complex formation strategies, as well as how slang terms emerge in specific individuals and groups. Our current study shows promise for advancing methodologies in informal language processing toward these avenues of future research.

Ethical Considerations

We analyze entries of slang usage in our work and acknowledge that such usages may contain offensive information. We retain such entries in our datasets to preserve the scientific validity of our results, as a significant portion of slang usage aligns to possibly offensive usage context. In the presentation our of results, however, we strive to select examples or illustrations that minimize the extent to which offensive content is represented. We also acknowledge that models trained on datasets such as the Urban Dictionary have a greater tendency to generate offensive language. All model outputs shown are results of model learning and do not reflect opinions of the authors and their affiliated organizations. We hope that our work will contribute to the greater good by enhancing AI system's ability to comprehend such offensive language use, allowing better filtering of online content that may be potentially harmful.

A Training Procedures

A.1 Baseline Models

We train two context-based slang interpreters described in Section 3.1 as our baseline models. For the LM-based interpreter, we use a pre-trained language infill model from Donahue et al. (2020) based on the GPT-2 (Radford et al., 2019) architecture. Here, we obtain the n-best list of interpretations by retrieving the list of infilled words with the highest infill probability. Words containing non-alphanumeric characters are filtered out. For the dictionary lookup function D in Equation 2, if a matching dictionary entry can be found in Oxford Dictionary (OD), the top definition sentence is retrieved as the definition sentence for the input word. Otherwise, the word itself is used as the definition. In addition to the word‘s original form, we apply lemmatization or stemming to the original form using NLTK (Bird et al., 2009) to find matching dictionary entries. To check for Part-of-Speech (POS) tags, we apply the Flair tagger (Akbik et al., 2018) on the context sentence with the slang expression replaced by a mask token and use counts from Histwords (Hamilton et al., 2016) to determine POS tags for individual words.

To train the Dual Encoder, we use LSTM encoders with 256 and 1024 hidden units to encode a slang expression's spelling and its usage context respectively, with 100 and 300 dimensional input embeddings for the characters and words respectively. Following Ni and Wang (2017), we use random initialization for the input embeddings and use stochastic gradient descent (SGD) with an adaptive learning rate. We train the model for 20 epochs beginning with a learning rate of 0.1 and add an exponential decay of 0.9 every epoch. We reserve 5% of the training examples as a development set for hyperparameter tuning. We train the model for 20 epochs on a Nvidia Titan V GPU and took 12 hours to complete. During inference, we obtain the n-best list of interpretations by running a beam search of corresponding beam width on the LSTM decoder.

A.2 Semantic Reranker

We obtain the contrastive sense encodings (CSE) described in Section 3.2 by using 768-dimensional Sentence-BERT (Reimers and Gurevych, 2019) embeddings as our baseline embedding. Following Sun et al. (2021), we train the contrastive network with a 1.0 margin (m in Equation 5) using Adam (Kingma and Ba, 2015) with a learning rate of 2^{-5}, resulting in 768-dimensional definition sense presentations. We reserve 5% of the training examples as a development set for hyperparameter tuning. The contrastive models are trained on a Nvidia Titan V GPU for 4 epochs. The OSD model took 85 minutes to train and the UD model took 8 hours. We follow the training procedure from Sun et al. (2021) to estimate the kernel width parameters (h_m in Equation 3 and h_{cf} in Equation 9) via generative training when it is computationally feasible to do so and otherwise use 0.1 as our default value.

We check the similarity between two expressions in Equation 9 by comparing their fastText (Bojanowski et al., 2017) embeddings. For collaborative filtering, the neighborhood of words $L(S)$ in Equation 8 is defined as the 5 closest words (including the query word itself) in the dataset's slang expression vocabulary to the query word, measured in terms of cosine similarity between their respective fastText embeddings. We use the list of stopwords from NLTK (Bird et al., 2009) to check whether a word is a content word. We apply the *simple_preprocess* routine from Gensim (Rehurek and Sojka, 2011) before checking for the degree of content word overlap between two sentences.

B Additional Results

B.1 Additional Interpretation Examples

Table 7 show additional example interpretations made by the models evaluated in Section 5.1. The first three examples illustrate cases where the semantically informed models were not able to predict the exact definitions, but came up with definitions that are more closely related to the groundtruth compared to the baseline. The latter two examples show cases where the semantically informed models fail to make an improvement.

B.2 Effect of Context Length

In the model evaluation described in Section 5.1, we control for the content-word length of the usage context sentence to examine its effect with respect to interpretation performance for both the baseline and the semantically informed models. Figure 4 shows the results partitioned by the number of content words in the example usage sentence excluding the slang expression, evaluated against four distinctively sampled candidates. To our surprise, we do

Model	Distinct negatives	Random negatives
Dual Encoder, $n = 5$	0.604	0.598
+ SSI	**0.612**	**0.599**
Dual Encoder, $n = 50$	0.583	0.570
+ SSI	**0.627**	**0.633**

Table 6: Interpretation results on OSD measured in mean-reciprocal rank (MRR) when training the Dual Encoder without filtering out entries corresponding to words in the OSD testset.

not observe any consistent trends when controlling for context length. Interpretation performance for both the context-based baseline models and their semantically informed variants is fairly consistent under different context length.

B.3 Finetuning Dual Encoder

We consider the case of finetuning the Dual Encoder by training it on all available UD data entries and test on the full OSD test set. Under this scenario, the Dual Encoder model would have seen examples of slang in the OSD test set, though the difference between the definition sentences and usage examples would not allow it to memorize the exact answer. While examining how much knowledge can be transfered from one dataset to another, we also apply the SSI reranker trained on OSD training data on the finetuned results to simulate a stronger baseline model. Table 6 shows the results. When compared to the zero-shot results in Table 2, finetuning on entries corresponding to the same slang, albeit coming from two very different resources, does noticeably improve interpretation accuracy. Moreover, applying SSI to the improved interpretation candidates from the finetuned Dual Encoder further increases interpretation accuracy. This finding suggests that the improvement brought by SSI can indeed generalize in cases where the baseline context-based interpretation model outputs better interpretation candidates.

B.4 Machine Translation Examples

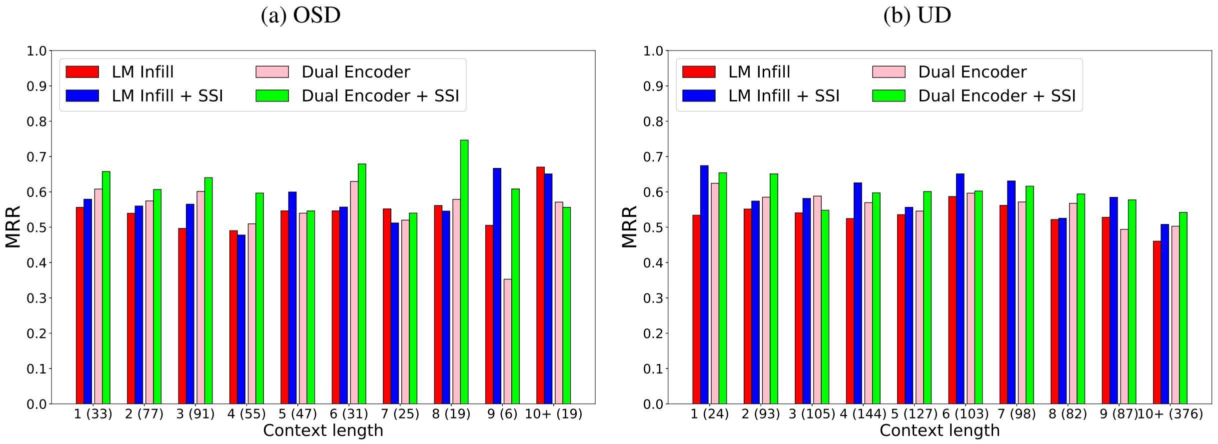
Table 8 to Table 11 show full example translations (English to French) made for the experiment described in Section 5.3, translating sentences containing slang before and after applying slang interpretation.

C Data Permissions

At the time when the research is performed, Online Slang Dictionary (OSD) explicitly forbids automated downloading of data from its website service. We therefore have obtained written permission from its owner to download and use the dataset for personal research use. We download data from the online version of the Oxford Dictionary (OD) under personal use. We cannot publically share the two datasets used above as a result. Readers interested in obtaining the exact datasets used in this work must first obtain relevant permission from the respective data owner before the authors of this work can share the data. The Urban Dictionary (UD) dataset is obtained from the authors of Ni and Wang (2017) under a research only license. We release entries relevant to our study with the original data license attached.

[Example 1]	
Query (target slang in ***bold italic***):	That girl has a ***donkey***.
Groundtruth definition of target slang:	Used to describe a girl's butt in a good way.
LM Infill baseline prediction:	Name, crush, boyfriend.
LM Infill + SSI prediction:	Horse, dog, puppy.
Dual Encoder baseline prediction:	Penis.
Dual Encoder + SSI prediction:	Girl with big ass and big boobs.
[Example 2]	
Query:	I am an ***onion***.
Groundtruth definition of target slang:	A native of Bermuda.
LM Infill baseline prediction:	Adult, man, athlete.
LM Infill + SSI prediction:	Ren, adult, guard.
Dual Encoder baseline prediction:	An idiot.
Dual Encoder + SSI prediction:	An asian person.
[Example 3]	
Query:	In Blastem version 4, they really ***nerf*** the EnemyToaster.
Groundtruth definition of target slang:	In an update or sequel to a video game, to make a weapon weak or weaker, such that it's like a Nerf gun.
LM Infill baseline prediction:	Were, called, attack.
LM Infill + SSI prediction:	Made, hacked, came.
Dual Encoder baseline prediction:	To do something.
Dual Encoder + SSI prediction:	To beat someone in the face with your penis.
[Example 4]	
Query:	I heard Steve was sent to the ***cooler*** for breaking and entering.
Groundtruth definition of target slang:	Reform school.
LM Infill baseline prediction:	School, house, class.
LM Infill + SSI prediction:	Bathroom, kitchen, grounds.
Dual Encoder baseline prediction:	Slang term for the police.
Dual Encoder + SSI prediction:	One of the most dangerous things in the world the best.
[Example 5]	
Query:	Do you have any ***safety***
Groundtruth definition of target slang:	Marijuana.
LM Infill baseline prediction:	Money, friends, cash.
LM Infill + SSI prediction:	Self, shoes, money.
Dual Encoder baseline prediction:	Marijuana.
Dual Encoder + SSI prediction:	Word that is used to describe something that is very good.

Table 7: Additional examples: Example OSD slang entries with predicted definitions from both the language infill model (LM Infill) and the Dual Encoder model with n = 50, along with predictions from the corresponding semantically informed slang interpretation (SSI) models.



(a) OSD

(b) UD

Figure 4: Evaluation of slang interpretation performance measured in mean-reciprocal rank (MRR) for all models with $n = 50$. Test entries are partitioned based on the number of content words (excluding the slang expression itself) found within the corresponding example usage sentence. Number of entries corresponding to each context length is shown in parenthesis on the x-axis legend.

[Example 1]	
Query (target slang in ***bold italic***):	Let’s smoke a ***bowl*** of marijuana.
Definition of target slang:	a marijuana smoking pipe. Most frequently bowls are made out of blown glass, but can be made of metal, wood, etc.
Groundtruth interpreted sentence:	Let’s smoke a *pipe* of marijuana.
Original query sentence translation:	Faisons fumer un bol de marijuana. (*BLEU:* 78.1, *BLEURT:* 66.1, *COMET:* 1.05)
Gold-standard translation:	Faisons fumer une pipe de marijuana.
LM Infill interpretation & translation:	
(1) Let’s smoke a *for* of marijuana.	Fumons un *pour* de la marijuana. (*BLEU:* 47.1, *BLEURT:* 20.6, *COMET:* -0.58)
(2) Let’s smoke a *in* of marijuana.	On fume un *peu* (little) de marijuana. (*BLEU:* 51.6, *BLEURT:* 64.8, *COMET:* 0.48)
(3) Let’s smoke a *myself* of marijuana.	Nous allons fumer *moi-même* de la marijuana. (*BLEU:* 51.8, *BLEURT:* 32.4, *COMET:* -0.55)
(4) Let’s smoke a *or* of marijuana.	Fumons un *ou* de marijuana. (*BLEU:* 45.4, *BLEURT:* 32.2, *COMET:* -1.04)
(5) Let’s smoke a *vapor* of marijuana.	Fumons une *vapeur* de marijuana. (*BLEU:* 56.4, *BLEURT:* 57.0, *COMET:* 0.40)
LM Infill + SSI interpretation & translation:	
(1) Let’s smoke a *pot* of marijuana.	Faisons fumer un *pot* de marijuana. (*BLEU:* 79.5, *BLEURT:* 78.8, *COMET:* 1.15)
(2) Let’s smoke a *pipe* of marijuana.	Faisons fumer une *pipe* de marijuana. (*BLEU:* 100.0, *BLEURT:* 99.1, *COMET:* 1.32)
(3) Let’s smoke a *pack* of marijuana.	Faisons fumer un *paquet* de marijuana. (*BLEU:* 77.7, *BLEURT:* 68.3, *COMET:* 0.80)
(4) Let’s smoke a *leaf* of marijuana.	Faisons fumer une *feuille* de marijuana. (*BLEU:* 79.9, *BLEURT:* 48.2, *COMET:* 1.21)
(5) Let’s smoke a *cigarette* of marijuana.	Faisons fumer une *cigarette* de marijuana. (*BLEU:* 75.7, *BLEURT:* 81.7, *COMET:* 1.25)

Table 8: Additional examples of machine translation of slang, without or with the application of the SSI framework. The top 5 interpreted and translated sentences are shown for each model with BLEU, BLEURT, and COMET scores against the gold-standard translation shown in parentheses.

[Example 2]	
Query:	That band was so totally ***vast***.
Definition of target slang:	Cool or anything good.
Groundtruth interpreted sentence:	That band was so totally *cool*.
Original query sentence translation:	Ce groupe était si vaste. (*BLEU:* 53.2, *BLEURT:* 32.9, *COMET:* -0.59)
Gold-standard translation:	Ce groupe était tellement cool.
LM Infill interpretation & translation:	
(1) That band was so totally *popular*.	Ce groupe était tellement *populaire*. (*BLEU:* 74.5, *BLEURT:* 78.7, *COMET:* 0.43)
(2) That band was so totally *good*.	Ce groupe était si *bon*. (*BLEU:* 51.8, *BLEURT:* 77.0, *COMET:* 0.32)
(3) That band was so totally *different*.	Ce groupe était complètement *différent*. (*BLEU:* 57.2, *BLEURT:* 50.3, *COMET:* -0.07)
(4) That band was so totally *famous*.	Ce groupe était si *célèbre*. (*BLEU:* 54.4, *BLEURT:* 66.2, *COMET:* -0.21)
(5) That band was so totally *new*.	Ce groupe était totalement *nouveau*. (*BLEU:* 64.2, *BLEURT:* 50.2, *COMET:* -0.21)
LM Infill + SSI interpretation & translation:	
(1) That band was so totally *huge*.	Ce groupe était tellement *énorme*. (*BLEU:* 81.1, *BLEURT:* 56.0, *COMET:* 0.15)
(2) That band was so totally *big*.	Ce groupe était tellement *grand*. (*BLEU:* 83.0, *BLEURT:* 50.7, *COMET:* -0.19)
(3) That band was so totally *important*.	Ce groupe était si *important*. (*BLEU:* 55.9, *BLEURT:* 49.9, *COMET:* -0.58)
(4) That band was so totally *cool*.	Ce groupe était tellement *cool*. (*BLEU:* 100.0, *BLEURT:* 97.9, *COMET:* 1.29)
(5) That band was so totally *bad*.	Ce groupe était si *mauvais*. (*BLEU:* 52.3, *BLEURT:* 62.9, *COMET:* -0.48)

Table 9: Continuation of Table 8.

[Example 3]	
Query (target slang in ***bold italic***):	Man, I ain't been to that place in a ***fortnight***!
Definition of target slang:	An unspecific, but long-ish length of time.
Groundtruth interpreted sentence:	Man, I ain't been to that place in a *long time*!
Original query sentence translation:	Je ne suis pas allé à cet endroit en une quinzaine! (*BLEU:* 36.1, *BLEURT:* 61.2, *COMET:* 0.57)
Gold-standard translation:	Je n'y suis pas allé depuis longtemps!
LM Infill interpretation & translation:	
(1) Man, I ain't been to that place in a *while*!	Je ne suis pas allé à cet endroit depuis un *moment*! (*BLEU:* 46.9, *BLEURT:* 76.5, *COMET:* 0.88)
(2) Man, I ain't been to that place in a *million*!	Je ne suis pas allé à cet endroit dans un *million*! (*BLEU:* 38.8, *BLEURT:* 25.1, *COMET:* -1.17)
(3) Man, I ain't been to that place in a *both*!	Je ne suis pas allé à cet endroit dans les *deux*! (*BLEU:* 42.2, *BLEURT:* 25.7, *COMET:* -0.98)
(4) Man, I ain't been to that place in a *vanilla*!	Mec, je n'ai pas été à cet endroit dans une *vanille*! (*BLEU:* 16.2, *BLEURT:* 7.3, *COMET:* 1.53)
(5) Man, I ain't been to that place in a *ignment*!	Mec, je n'ai pas été à cet endroit dans un *ignement*! (*BLEU:* 16.2, *BLEURT:* 12.7, *COMET:* -1.31)
LM Infill + SSI interpretation & translation:	
(1) Man, I ain't been to that place in a *week*!	Je ne suis pas allé à cet endroit en une *semaine*! (*BLEU:* 38.2, *BLEURT:* 49.8, *COMET:* 0.45)
(2) Man, I ain't been to that place in a *minute*!	Je ne suis pas allé à cet endroit en une *minute*! (*BLEU:* 38.8, *BLEURT:* 42.5, *COMET:* -0.36)
(3) Man, I ain't been to that place in a *hour*!	Je ne suis pas allé à cet endroit en une *heure*! (*BLEU:* 38.7, *BLEURT:* 35.8, *COMET:* -0.51)
(4) Man, I ain't been to that place in a *decade*!	Je n'y suis pas allé depuis une *décennie* (*BLEU:* 68.8, *BLEURT:* 81.8, *COMET:* 1.03)
(5) Man, I ain't been to that place in a *day*!	Je ne suis pas allé à cet endroit en une *journée*! (*BLEU:* 37.1, *BLEURT:* 49.7, *COMET:* -0.30)

Table 10: Continuation of Table 9.

[Example 4]	
Query:	I want to go get coffee but it’s ***bitter*** outside.
Definition of target slang:	Abbreviated form of bitterly cold.
Groundtruth interpreted sentence:	I want to go get coffee but it’s *bitterly cold* outside.
Original query sentence translation:	Je veux aller prendre un café mais c’est amer dehors. (*BLEU:* 65.0, *BLEURT:* 59.8, *COMET:* 0.77)
Gold-standard translation:	Je veux aller prendre un café, mais il fait très froid dehors.
LM Infill interpretation & translation:	
(1) I want to go get coffee but it’s *raining* outside.	Je veux aller prendre un café mais il *pleut* dehors. (*BLEU:* 68.1, *BLEURT:* 79.9, *COMET:* 0.97)
(2) I want to go get coffee but it’s *closed* outside.	Je veux aller prendre un café mais il est *fermé* dehors. (*BLEU:* 70.7, *BLEURT:* 53.9, *COMET:* -0.15)
(3) I want to go get coffee but it’s *pouring* outside.	Je veux aller chercher du café, mais ça *coule* dehors. (*BLEU:* 51.9, *BLEURT:* 31.6, *COMET:* -0.38)
(4) I want to go get coffee but it’s *been* outside.	Je veux aller prendre un café, mais ça a *été* dehors. (*BLEU:* 68.4, *BLEURT:* 27.1, *COMET:* -0.88)
(5) I want to go get coffee but it’s *starting* outside.	Je veux aller prendre un café, mais ça *commence* dehors. (*BLEU:* 68.5, *BLEURT:* 31.0, *COMET:* -0.57)
LM Infill + SSI interpretation & translation:	
(1) I want to go get coffee but it’s *cold* outside.	Je veux aller prendre un café, mais il fait *froid* dehors. (*BLEU:* 90.3, *BLEURT:* 92.7, *COMET:* 1.20)
(2) I want to go get coffee but it’s *warm* outside.	Je veux aller prendre un café mais il fait *chaud* dehors. (*BLEU:* 78.1, *BLEURT:* 79.1, *COMET:* 1.12)
(3) I want to go get coffee but it’s *driving* outside.	Je veux aller prendre un café mais il *conduit* dehors. (*BLEU:* 70.4, *BLEURT:* 26.5, *COMET:* -0.69)
(4) I want to go get coffee but it’s *closing* outside.	Je veux aller prendre un café mais il se *ferme* dehors. (*BLEU:* 69.8, *BLEURT:* 23.2, *COMET:* -0.81)
(5) I want to go get coffee but it’s *dark* outside.	Je veux aller prendre un café, mais il fait *noir* dehors. (*BLEU:* 82.3, *BLEURT:* 73.7, *COMET:* 0.80)

Abstract

Different from previous fact extraction and verification tasks that only consider evidence of a single format, FEVEROUS brings further challenges by extending the evidence format to both plain text and tables. Existing works convert all candidate evidence into either sentences or tables, thus often failing to fully capture the rich context in their original format from the converted evidence, let alone the context information lost during conversion. In this paper, we propose a Dual Channel Unified Format fact verification model (DCUF), which unifies various evidence into parallel streams, i.e., natural language sentences and a global evidence table, simultaneously. With carefully-designed evidence conversion and organization methods, DCUF makes the most of pre-trained table/language models to encourage each evidence piece to perform early and thorough interactions with other pieces in its original format. Experiments show that our model can make better use of existing pre-trained models to absorb evidence of two formats, thus outperforming previous works by a large margin. Our code and models are publicly available[1].

1 Introduction

The task of fact extraction and verification aims to extract evidence and verify a given claim. Previous efforts focus on dealing with text format evidence from unstructured documents (Nie et al., 2019; Zhong et al., 2020; Kruengkrai et al., 2021) or evidence from a single given table (Chen et al., 2020; Yang et al., 2020; Eisenschlos et al., 2020). Recently, Aly et al. (2021) propose a new realistic setting, FEVEROUS, i.e., fact extraction and verification over unstructured and structured information. In FEVEROUS, models should not only extract evidence sentences/table cells from millions of passages, but also combine the evidence in different formats to verify a given claim.

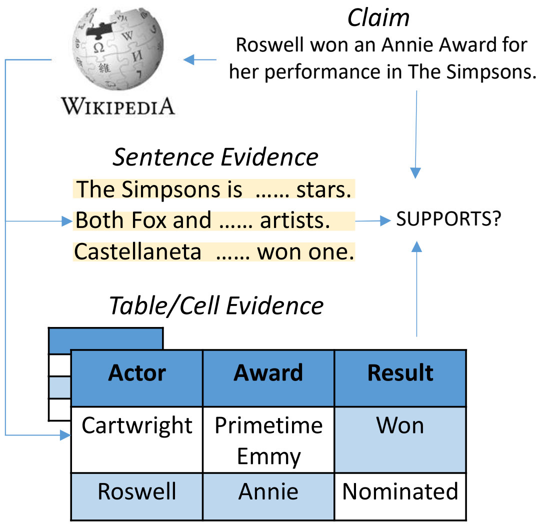

Figure 1: An excerpt example from FEVEROUS.

Previous works on FEVEROUS generally convert all evidence pieces into either plain text (Aly et al., 2021; Saeed et al., 2021; Malon, 2021) or several tables (Bouziane et al., 2021). However, format conversions inevitably lose rich context information for the converted evidence, thus may mislead the subsequent encoding and interaction steps. For example, in Figure 1, the entire top two rows are indispensable to understand the table cell *Won*. It is difficult to identify all related context cells and design a general conversion method to render them into sentences, but these connections can be easily caught by pre-trained table models (Herzig et al., 2020; Yin et al., 2020). On the other side, identifying/re-organizing crucial elements in a sentence to construct a table is also challenging. Simply inserting a whole sentence in a table cell (Bouziane et al., 2021) will make the new cells much larger (and unique) than normal ones, thus can not make the most of general pre-trained table models (Herzig et al., 2020; Yin et al., 2020) as we

expect.

Considering the inevitable expense in format conversion, we believe that each evidence in its original format can contribute necessary information to final verification, thus should be better encoded in its original format. This further indicates that we should design both sentence-to-table and table(cell)-to-sentence conversion methods to obtain all evidence in both formats, and maintain two parallel encoders to absorb the two formats, respectively. An advantage of doing so is to maximally encourage early interaction, which proves more effective than pair-wise encoding (Tymoshenko and Moschitti, 2021; Jiang et al., 2021)

When converting table evidence into sentences, previous works either convert table cells to a concatenation of key-value pairs (Aly et al., 2021; Malon, 2021), or construct sentences in a coordinate-description style (Kotonya et al., 2021a). They pay less attention to the conventional organization of tables structures. We observe that, in a table, the column headers usually represent the types/properties and the row headers often denote entities or scopes. We argue that one should consider these conventions to convert a table cell evidence into more natural sentences, and later pre-trained language models will be able to better capture the contextualized semantics of the table cells from generated sentences. On the other hand, existing pre-trained table models are trained to analyze one table at one time, while previous evidence conversion methods produce several small tables for one instance. It would be necessary to properly organize all evidence in one table so that pre-trained table models can allow the most interactions among all evidence pieces.

In this paper, we propose a dual channel unified format verification model (DCUF) to allow each evidence piece encoded in its original format and maximally maintain its original rich context, while encouraging further interactions with other evidence. DCUF converts each evidence into both textual and tabular formats in respective channels, and apply corresponding pre-trained models to learn the representations for the final verification. With the dual channel setting and carefully designed evidence conversion methods, DCUF makes better use of pre-trained language/table models to perform early and thorough interactions among all evidence and also between the claim and evidence.

In summary, we make the following contributions in this paper: (1) we propose DCUF, a novel model to maintain various evidence in two unified formats and allow each evidence piece to interact with other evidence in its best form. Experiments show that DCUF outperforms all previous works in literature. (2) we propose a context-aware evidence conversion method that can properly organize evidence of different formats, which fits current pre-trained language/table models hence take their most advantage to obtain accurate and focused representations.

2 Our Model

The FEVEROUS task can be formalized as, given a claim q and Wikipedia dump, a model is asked to find the evidence set consisting of sentences S and table cells C, and predict the veracity label of the claim accordingly. The veracity label set includes "SUPPORTS", "REFUTES" and "NOT ENOUGH INFORMATION".

2.1 Model Overview

Following the widely adopted fact verification pipeline (Thorne et al., 2018; Aly et al., 2021), we take three steps to solve the FEVEROUS task (i) retrieving pages from the Wikipedia dump; (ii) extracting evidence from the retrieved pages, and (iii) verifying the claim according to extracted evidence.

Specifically, for the document retrieval step, we narrow the search space with an information retrieval model DRQA (Chen et al., 2017) and then rerank the retrieved pages. For the evidence retrieval step, we design a multi-turn cell selector to extract sentence evidence and table evidence respectively, and select evidence cells from tables. Finally, we propose a Dual Channel Unified Format verification model (DCUF, shown in Figure 2) for the verification step. DCUF converts evidence to a unified table/sentence format with carefully-designed evidence conversion and re-organization methods in each channel, and combine dual-channel encodings to make the final prediction.

2.2 Document Retrieval

An efficient and effective document retriever is required since the Wikipedia dump containing millions of pages. We first narrow the search space to several hundred pages (m_0) with an efficient information retrieval method based on TF-IDF, namely, DRQA (Chen et al., 2017). A RoBERTa-based

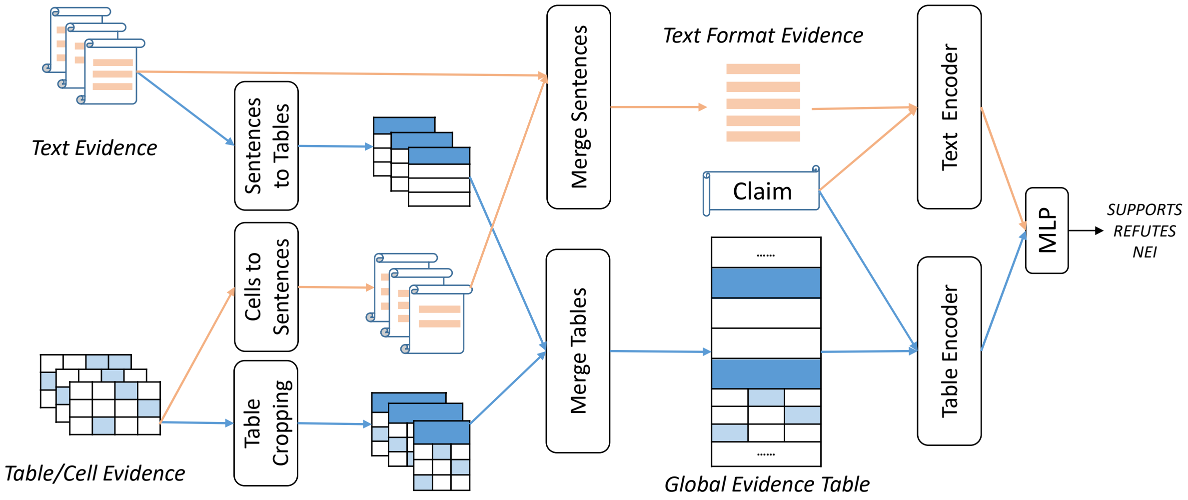

Figure 2: The architecture of our verification model. Orange lines show how we arrange the evidence into a text format, while blue ones show how to arrange into a table format.

re-ranker (Saeed et al., 2021) and a BM25-based re-ranker are then applied in parallel to re-rank the m_0 document candidates. We combine the results of two re-rankers and keep top m documents since BM25 focuses more on entity matching and RoBERTa-based re-ranker pays more attention to the overall sentence structure. The document scores are calculated as the sum of their rankings in the two re-rankers. Documents with lower scores have higher priority.

We further notice that the first several words of a claim always contain the page titles needed. We therefore derive a position-aware sub-sequence matching to strengthen the page retriever. We also remove pages with a long Wikipedia title starting with a specified year that is not contained in the claim.

2.3 Evidence Retrieval

We use DRQA (Chen et al., 2017) to extract k sentences $S = \{s_i\}_{i=1}^{k}$ and n tables $T = \{t_i\}_{i=1}^{n}$ from the retrieved pages, respectively. Then we select cells from the extracted tables. Many instances in the FEVEROUS dataset require evidence cells from more than one table, and each retrieved table has different relevance score to the claim. However, the widely-used cell extractor (Aly et al., 2021) reserves cells from only one table in their implementation.

We thus propose a Multi-turn Cell Selector (MCS), which retrieves cells from all evidence tables and consider the importance of the retrieved tables. A basic cell selector concatenates a given claim q and a flattened candidate evidence table t_i and feeds it into a sequence tagger to decide whether each cell in the table should be selected. MCS implements this procedure in a multi-turn manner, since each table has a different relevance score to the given claim. In the first turn, MCS selects the table most related to the given claim and feeds it to the basic cell selector. All cells with a selection score larger than the threshold g will be added to the cell evidence set C. In the second turn, all tables ranked second in T are the input to the basic selector. If the number of cells in C has not reached the upper limit, MCS adds the newly selected cells in the second turn to C. MCS repeats this procedure for n loops and we will get the cell evidence set $C = \{c_i\}_{i=1}^{o_j}$. o_j is the number of cells selected as evidence for the j^{th} instance.

2.4 Unified Format Encodings

Since the evidence can be of two formats, textual format and tabular (or cell) format, we convert each evidence of one format to another, so that we will get a unified representation of all evidence and could easily assemble them. We propose two conversion methods, i.e., cells-to-sentences and sentences-to-tables for the original tabular evidence and textual evidence, respectively. We carefully design the evidence conversion and re-organization methods to make converted evidence natural, thus take better advantage of the pre-trained language/table models.

2.4.1 Text Format Encoding

We consider the table conventions, i.e., row headers in general tables usually represent attribute types, and convert table cells into natural sentences, thus make better use of pre-trained language models to perform early interaction over the claim and all evidence.

There are two types of tables on the Wikipedia pages, (i) general tables and (ii) Infoboxes. For general tables, we ignore header cells selected by the evidence retriever and convert content cells selected into text format. For each cell, we identify its row header cell and column header cell. We find that most general-typed tables are column tables, which means they only contain column headers. However, the first column of a table, in many cases, indicates the object name and others are attributes. Therefore, if a cell does not have an explicit header cell, we choose the first cell of the same row to be its row header cell. We observe that the row header cell for a general table always indicates the object name, the column header cell indicates the attribute type, and the cell itself is the attribute value for the object. We thus form the corresponding text for a cell in a general table as "<column header> for <row header> is <cell value>." For Infoboxes, it is a different story. The row header is always the attribute type, the column header is the field that the attribute belongs to, and the Wikipedia title is the object name. Therefore, the text representation of each cell in an Infobox is formulated as "<column header> : <row header> of <Wikipedia title> is <cell value>". As shown in Figure 3, "21-24 minutes" is a selected cell, its row header "Running Time" is the attribute type, and the header cell "Production" is the field which the attribute "Runing time" belongs to. Thus, the cell will be converted to "Production: Running time of The Simpsons is 21-24 minutes."

Claim verification on a set of evidence containing many cells often requires operations on cells in the same column, such as maximum and summary (Aly et al., 2021). Therefore, we pack the texts from cells in the same column together. These texts are joined by semicolons and form a piece of column text. Each column is converted into a sentence. As shown in Figure 3, the cells "December 17, 1989" and "October 11, 1990" are jointly converted to one sentence, "Season premiere for 1 is December 17, 1989; Season premiere for 2 is October 11, 1990." The given claim, the extracted text evidence, and the column texts are concatenated together to form the input to the text format evidence encoder, separated by the separator "</s>" in the RoBERTa model. Column texts from the same table are adjacent, and sentences from the same Wikipedia page are arranged together.

2.4.2 Table Format Encoding

As shown in the right part of Figure 3, we propose to construct a single evidence table containing all evidence candidates, both textual and tabular, since most existing table pre-training models are designed to and trained to analyze one single table at one time. Making better use of the pre-training models helps to perform early and thorough evidence interaction.

The method of converting text format evidence to tabular format is straightforward. We group the evidence sentences from the same Wikipedia page. If there are n evidence sentences from the same Wikipedia page, we construct a table of $n+1$ rows and 1 column. The only cell in the first row is a header cell containing the Wikipedia title. And for other rows, each row has one cell, and in that cell is a piece of sentence evidence from that page. Assuming there are evidence sentences from m pages, we will get m table units after this step.

As the pre-training table model has a capacity limit, we crop irrelevant cells first to compress the extracted tables. To be precise, rows and columns containing no selected cells are removed. After that, we add one cell row to the top of each cropped table, this cell contains the title of the Wikipedia page from which the table is extracted. If there are n extracted tables, we will get n cropped table from this step.

We get a global evidence table by stacking the m tables from sentences and n tables from tabular evidence, as illustrated in Figure 3. Then, we feed the claim and the global evidence table to a pre-trained table model, TAPAS (Herzig et al., 2020), and get the tabular format evidence representation.

2.4.3 Dual-Channel Verdict Prediction

The final verdict prediction is based on the dual channel encoding. Therefore, each evidence can be encoded in its original format while interacting with all evidence pieces and the claim.

We concatenate the text format evidence encoding h_{text} and the tabular format evidence encoding h_{tab} to obtain a joint format encoding for prediction. With a feed-forward network and a softmax layer, we obtain the veracity probability distribution of the claim and the predicted label is the one

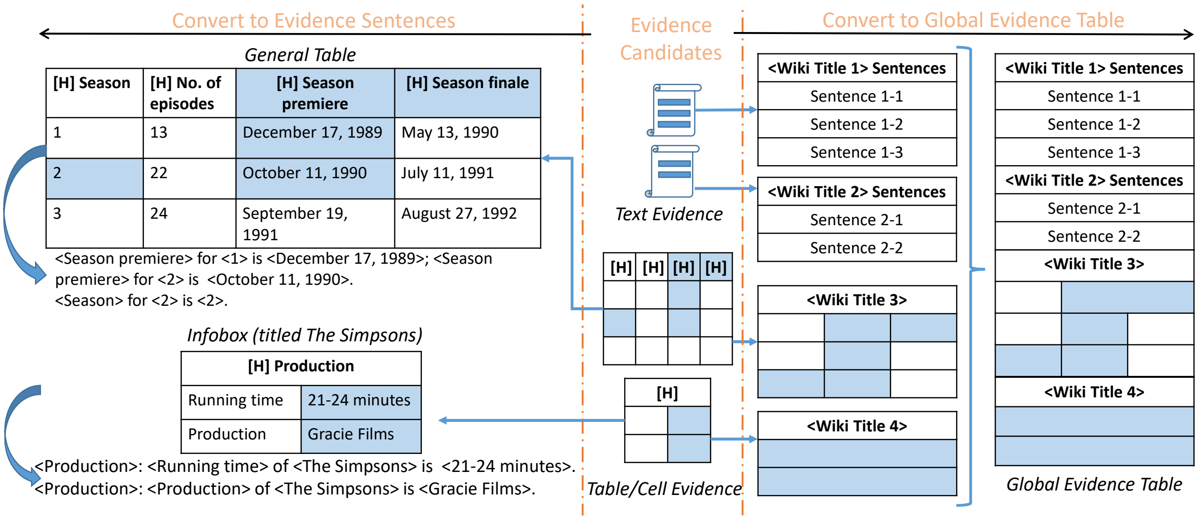

Figure 3: An example of our evidence conversion methods. Cells with [H] are explicitly specified header cells. Light blue cells are the selected cells. The left part shows how we convert evidence to a unified text format, while the right shows how to convert all evidence candidates into a global evidence table.

with the largest probability:

$$h = [h_{\text{text}}; h_{\text{tab}}] \tag{1}$$

$$\mathrm{p}\left(y|q,S,T,C\right) = \mathrm{Softmax}\left(\mathrm{FNN}\left(h\right)\right) \tag{2}$$

$$\hat{y} = argmax_y \mathrm{p}\left(y|q,S,T,C\right) \tag{3}$$

where $\mathrm{p}\left(y|S,T,C\right)$ represents the probability of each alternative label y given the claim q, evidence sentences S and evidence tables T.

To strengthen the model's ability to predict the veracity label with the evidence set containing irrelevant pieces, we construct two instances for each claim in the training set. One is the claim with the gold evidence provided by the FEVEROUS dataset, and the other is the claim with extracted evidence pieces from previous evidence extraction steps. We use the cross-entropy loss function:

$$L = -\frac{1}{N}\sum_{i=1}^{N}\log\left(\mathrm{p}\left(\hat{y}=y_i|q,S,T,C\right)\right) \tag{4}$$

where y_i is the true veracity label of the i^{th} instance. N is the size of the training set.

3 Experiments

We evaluate our models on the FEVEROUS dataset, where each claim is annotated with a gold veracity label and several gold evidence sets. Any one of the evidence sets is sufficient to verify the claim. More details about the FEVEROUS dataset are in Appendix.

The FEVEROUS dataset provides two official metrics, namely label accuracy (Acc.) and FEVEROUS score. Label accuracy calculates the ratio of the instances whose veracity label is correctly predicted. FEVEROUS score is the ratio of the instances whose veracity label is correct and the extracted evidence set is sufficient. Here, sufficient evidence sets are defined as the evidence sets covering one of the gold evidence sets provided in the FEVEROUS dataset. Note that there are at most 25 table cells and 5 sentences to calculate the scores.

3.1 Implementation Details

In the document retrieval step, the number of pages retrieved by the BM25-based retriever m_0 is 150. We keep the top 5 pages for evidence extraction after page re-ranking. For evidence retriever, the top k =5 sentences and top n =2 tables are extracted from the retrieved pages. The gate of cell selection g is 0.25 and a maximum of 25 cells are selected in total for each claim.

We use an Adam optimizer (Kingma and Ba, 2015) with a linear learning rate scheduler. The rate of warm-up steps is 20%. The peaking learning rate for parameters in pre-trained language models is 10^{-5} and 10^{-3} for other parameters. The batch size is 24, implemented with gradient accumulation techniques. DCUF takes about 5 hours to run on a single NVIDIA A100 Tensor Core GPU (40GB).

The RoBERTa-based re-ranker is initialized from the hugging face checkpoint[2] without further fine-tuning. The TAPAS checkpoint is fine-tuned with a table fact verification task, Tabfact (Chen

et al., 2020) [3]. Same as the baselines, the sentence evidence encoder is RoBERTa-large tuned with several NLI and verification tasks[4].

Document Retriever Details For BM25 re-reranker, all page candidates of every 200 adjacent instances are merged to build the BM25 index for these instances. Each document in the Wikipedia dump is represented by the concatenation of its title and the first 64 words of its content for the BM25 re-ranker. We use NLTK[5] to remove stop words and lemmatize the remains. For position-aware entity matching, if a sub-sequence, with more than two words, in the first ten words of a given claim is a page title in the Wikipedia dump and it is not in the m documents we replace the page of the lowest priority with it.

3.2 Main Results

The overall performance of our model on the development set and the test set are shown in Table 1. We get an increase of 5.77% on the FEVEROUS score and 7.91% on the accuracy over the previous best model FaBULOUS (Bouziane et al., 2021) on the development set. For the test set, the increase is 6.96% and 7.14% in Feverous score and label accuracy, respectively. These results suggest the effectiveness of our proposed DCUF model. The evidence format of a global evidence table is consistent to the input of pre-trained table models. Thus, DCUF can make better use of the internal ability of pre-trained models than previous works which concatenate linearized tables or max-pool lots of claim-table pair encoding (Bouziane et al., 2021). Moreover, DCUF also performs better than another well-performing model, CARE (Kotonya et al., 2021b). DCUF converts cells to meaningful sentences that are similar to the inputs of PLMs pre-training stage, which makes better use of the PLMs ability.

We also conduct experiments with the gold evidence to investigate the effectiveness of our verification model. The results are shown in Table 2. DCUF obtains an increase of 2.88% on accuracy over the previous best result and 3.68% over RoBERTa-based models. With all evidence candidates in the same format and preserving context information, our system can make better use of the pre-trained language/table models and perform early and thorough interactions among evidence and between the claim and evidence.

Models	Accuracy
Fabulous-Max	80
Papelo-RoBERTa	82.9
NCU	84
Fabulous-Joint	84
Papelo-T5	84.8
DCUF	**87.68**

Table 2: Model accuracy on the development set with gold evidence as model input.

Evidence Extraction Results The document retrieval results are shown in Table 3. In Table 3, experiments show that both BM25 re-ranker and RoBERTa re-ranker can improve the document retrieval quality to a great extent compared to vanilla DrQA page retriever, with whole evidence set recall improvement of 8.63% and 12.56% respectively. The combination of them can further enlarge this gap to 16.22%. We find that the average number of pages in the merged set of top-5 BM25 re-ranked

[5] `https://www.nltk.org`

Models	MAP	Rec-single	Rec-set
DrQA@150	91.13	90.00	89.29
DrQA	69.32	66.91	65.50
BM25 RR	77.98	75.32	74.13
RoBERTa RR	82.56	78.65	78.06
Combined RR	85.13	82.29	81.72
+ Rule Enhancement	88.11	85.20	84.82

Table 3: Document retrieval results on the development set. RR means re-ranker. Rec-single is the recall of single evidence. Rec-set considers all evidence for a instance as a whole. It is the recall with top-5 pages retrieved without special statement.

Models	Table	Sent	Cell	All
Official Baseline	56	53	28.70	30
FaBULOUS	-	56.6	34.2	40.4
MCS	75.59	62.54	58.41	43.22

Table 4: Categoried evidence recall on the development set. The recall is calculated with at most 3 tables, 5 sentences and 25 table cells.

results and top-5 RoBERTa re-ranked results is 7.75 in the development set. It proves that these two re-rankers tend to focus on different aspects when evaluating the correlation of the given claim and a page candidate. The rule-based enhancement methods, namely matching position-aware entities and removing pages with unmatched year, bring a a further improvement of 3.10%. It indicates that document retrievers should take the word positions in the given claim into consideration. Without any training procedure or Dense Retriever (which is time-consuming), we get a whole set recall of 84.82% when retrieving 5 pages for each claim.

Table 4 shows the evidence extraction results. With MCS, we achieve an increase of 29.71% on cell recall and 13.22% on the overall evidence recall over FaBULOUS. The result indicates that considering only one table is not enough and we should pay attention to the relevance scores of the input tables especially when the cell selector is somewhat weak.

3.3 Ablation Study

We evaluate the effect of each part of DCUF with a collection of ablation experiments. The Experiment settings are as follows. (1) **w/o Table Format Encoding** We only use the unified text format evidence encoding for verdict prediction. (2) **w/o Table Format Encoding** We only use the unified table format evidence encoding for verdict prediction. (3) **w/o Dual-Channel Predictor** We use the verdict predictor in the baseline to predict the veracity label.

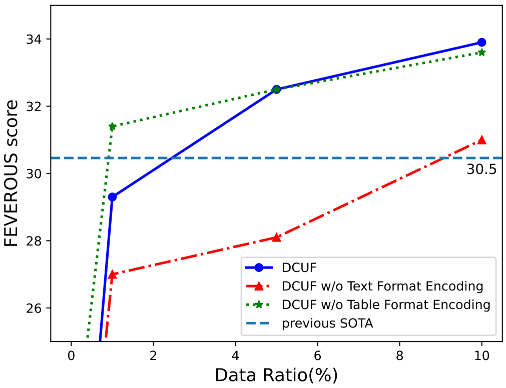

Figure 4: Few shot results on the development set.

Models	Feverous	Accuracy
DCUF	**35.77**	**72.91**
w/o Table Format Encoding	35.16	72.05
w/o Text Format Encoding	32.41	66.80
w/o Dual Channel Predictor	27.91	58.40

Table 5: Ablation results on the development set.

The results are shown in Table 5. The FEVEROUS score and accuracy drop consistently when we remove the unified table format encoding or the unified text format encoding. Especially, the FEVEROUS score drops by 3.34% when only using the unified tabular encoding for prediction. With only unified text format encoding, the FEVEROUS score drops by 0.61%, which may contribute to pre-trained table models, such as TAPAS, being still weaker compared to pre-trained language models. However, with our carefully-designed context-aware unified format conversion, verdict prediction upon one format encoding outperforms all previous results. To relieve the effect of different evidence extraction methods, we train the verdict prediction model in the baseline with our evidence extraction results. We see a great drop, with accuracy dropping of 14.51% and FEVEROUS score by 7.86%, which proves that our combined unified format verdict prediction model can keep the context needed when converting the evidence format and help the extracted evidence perform early interaction in a unified format.

4 Analysis

Few-shot Results Figure 4 shows the FEVEROUS score on the development set when we train unified DCUF, DCUF without text format encoding and DCUF without table format encoding verdict predictors on 1%, 5% and 10% instances of the training set respectively. We find that, training on only 10% instances, all of the three settings outperform previous SOTA results, with the dual channel predictor achieving the best FEVEROUS score of 33.9%. Meanwhile, with only 1% of the training set, namely, 713 instances, the unified text format predictor outperforms previous SOTA result by 0.9%. These improvements may contribute to our carefully-designed format conversion methods. The text format evidence converted from cells is similar to sentences in natural language when keeping much context information in the conversion procedure. And the concatenated claim-evidence string is the same as previous fact verification tasks on which the RoBERTa checkpoint is fine-tuned. Meanwhile, a given claim, and a single global evidence table are consistent to the input requirements in the pre-training step of TAPAS. With few new parameters introduced and an input form strictly complying with the requirements of pre-trained models and previous single format fact-checking tasks, DCUF could make the most of the pre-training stage and, thus, learn well in the few-shot setting.

We also find that when training with only 1% instances, the unified text format predictor outperform other two settings. As the number of training instances increase, dual-channel predictor learns how to combine information from the two channel, thus achieving better results.

Error Analysis We find that when converting cells to text with rule-based methods, there are inevitably noise or not fluent sentences introduced.

One problem is caused by the latent header cells. As shown in Table 6(a), the cell "Team" is selected but not explicitly marked as a header cell, so a meaningless sentence "Senior career*: Years for Aramais Yepiskoposyan is Team." is derived from this cell. Meanwhile, although the header cells indicating the attribute type are usually nouns, there are some exceptions. Infobox Table 6(b) is an example. The selected cell "Sir Roger Manwood" is converted to a fluent and meaningful evidence sentence "Information: Founder for Sir Roger Manwood's School is Sir Roger Manwood.". However, "Information: Established for Sir Roger Manwood's School is 1563; 457 years ago." is not a sentence that conforms to English grammar. And sometimes, the latent row header which indicates the object name is confusing. For example, the cell "Marcia Wallace" in Table 6(c) is converted to a sentence "Actor for 179 is Marcia Wallace." Without the header "Episodes", what "179" refers to is confusing. Assessing and polishing the converted sentence may help to solve the problems presented above.

5 Related Works

Fact Verification over Unstructured Evidence Thorne et al. (2018) proposed FEVER, a large-scale dataset of claims based on Wikipedia articles. Language models have better performance compared to other methods e.g. ESIM-based models(Hanselowski et al., 2018; Nie et al., 2019). BERT-based models make the prediction based on collected evidence in a direct aggregating rule(Soleimani et al., 2020) or a graph-based approach(Zhou et al., 2019; Zhong et al., 2020).

Fact Verification over Structured Evidence Benchmarks for fact verification on structured evidence are built on tables collected from Wikipedia(Chen et al., 2020) or scientific articles(Wang et al., 2021). Many previous works search latent programs as an intermediary to reason over the given table. They directly encode programs (Chen et al., 2020)or construct heterogeneous graphs (Shi et al., 2020; Yang et al., 2020) with the claim, the table and the programs. Another way is to linearize the input table and perform table pre-training (Chen et al., 2020) and add additional table-aware embeddings (Herzig et al., 2020; Eisenschlos et al., 2020) to enhance the table encoding. However, in these datasets, the evidence is only one given table, and models are not requested to find out the evidence cells explicitly.

Fact Verification over Structured and Unstructured Evidence FEVEROUS (Aly et al., 2021) is the first dataset of fact verification on structured and unstructured evidence. Many previous works follow the baseline settings and convert all evidence to text format to perform evidence interaction. They transform each cell to header-value pairs (Aly et al., 2021; Malon, 2021) or in a cell location indication type (Kotonya et al., 2021a). They pay less attention to making the converted text more consistent with natural language expressions or identifying what the context cells represent. Bouziane et al. (2021) propose to convert all evidence to tables. They simply convert each sentence to a 2-cell table with the Wikipedia title and itself instead of packing closely-tied evidence and building a global evidence table. There are also works focusing on the first two steps two improve the final results. Saeed et al. (2021) propose to add a document re-ranker to strengthen the document retrieval. Multi-hop Dense Retriever (Bouziane et al., 2021) and T5 generator (Malon, 2021) are introduced to better extract multi-hop evidence.

6 Conclusion

In this paper, we propose DCUF, a dual channel unified format model for fact verification over structured and unstructured data. With context-aware evidence format conversion, DCUF gets a unified text format representation of all evidence and a global evidence table of them at the same time. The dual channel design helps us make the most of existing pre-trained language/table models to encourage all evidence pieces to interact with each other in their best forms as early as possible. Experiments show that, with dual-channel unified format encoding, our proposed DCUF achieves state-of-the-art performance and also comparable results in few-shot settings.

A Statistics of the FEVEROUS dataset

The FEVEROUS is an open-domain English dataset. It contains 87,026 claims, and the claim length is 225.3 on average. Each claim averagely needs 1.4 sentences and 3.3 cells (0.8 tables) to be verified. 34,963 instances need only text format evidence, 28,760 only table format and 24,667 need a combination of the two formats. There are 49,115 instances labeled SUPPORTS, 33,669 labeled Refutes and the rest 4,242 instances are labeled NEI. Detailed label and evidence distributions are shown in Table 7.

	Train	**Dev**	**Test**
Supported	41,835(59%)	3,908(50%)	3,372 (43%)
Refuted	27,215(38%)	3,481(44%)	2,973 (38%)
NEI	2,241 (3%)	501 (6%)	1,500 (19%)
Total	71,291	7,890	7,845
Sentences	31,607(41%)	3,745(43%)	3589 (42%)
Cells	25,020 (32%)	2,738(32%)	2816 (33%)

Abstract

Data augmentation is an effective approach to tackle over-fitting. Many previous works have proposed different data augmentations strategies for NLP, such as noise injection, word replacement, back-translation etc. Though effective, they missed one important characteristic of language–compositionality, meaning of a complex expression is built from its sub-parts. Motivated by this, we propose a compositional data augmentation approach for natural language understanding called TreeMix. Specifically, TreeMix leverages constituency parsing tree to decompose sentences into constituent sub-structures and the Mixup data augmentation technique to recombine them to generate new sentences. Compared with previous approaches, TreeMix introduces greater diversity to the samples generated and encourages models to learn compositionality of NLP data. Extensive experiments on text classification and SCAN demonstrate that TreeMix outperforms current state-of-the-art data augmentation methods.

S1:They will find little interest in this poor film.	
S2:It comes as a touching love story.	
Method	**Example**
EDA (Wei and Zou, 2019)	They will **this** find little interest in **bad movie**.
AEDA (Karimi et al., 2021)	They will find **?** little in **!** this poor movie**;**.
Noise (Xie et al., 2017)	**Thes** will **fi** little **intres** _ this poor film .
SSMix (Yoon et al., 2021)	They will find little interest in **love** poor film
Replacement (Kolomiyets et al., 2011)	They will find **limited** interest in this **odd** film.
Back Translation (Edunov et al., 2018)	They will **show** little interest in this **strange** film.
TreeMix	They will find little interest in this **touching love story**.

Table 1: Input-level DAs for Text-Classification. EDA includes random deletion, swapping, and insertion. AEDA randomly inserts punctuation. SSMix swaps tokens based on their saliency. The replacement method randomly substitutes words with synonyms. In Back-translation, the source sentences are first translated into another language, and then back again.

1 Introduction

Data augmentation (DA) has won great popularity in natural language processing (NLP) (Chen et al., 2021; Feng et al., 2021) due to the increasing demand for data and the expensive cost for annotation. DA aims at increasing the quantity and diversity of the datasets by generating more samples based on existing ones, which helps make the training process more consistent and improves the model's capacity for generalization (Xie et al., 2020). For instance, existing DA methods often leverage word-level manipulation (Wei and Zou, 2019; Kobayashi, 2018; Karimi et al., 2021) and model-based sentence generation (Edunov et al., 2018; Ng et al., 2020). As mixup-based (Zhang et al., 2018) augmentation achieving huge success in computer vision (Yun et al., 2019; Uddin et al., 2021; Kim et al., 2021), some recent works start to adapt mixup to NLP, such as at the hidden level (Guo et al., 2019; Chen et al., 2020b) and at the input level (Yoon et al., 2021; Shi et al., 2021).

Despite these empirical success, DA methods still suffer from key limitations. Simple rules based augmentation methods (Wei and Zou, 2019; Kobayashi, 2018; Karimi et al., 2021) show little to none effect over large pretrained language models. While mixup-based augmentation methods demonstrate huge potential, such interpolation at the hidden or input level has limited capability to capture explicit linguistic properties in text (Guo et al., 2019; Chen et al., 2020b; Yoon et al., 2021). Moreover, current DA methods exhibit limited ability in compositional generalization. Take a look at the following example from a BERT-based model that is fine-tuned using the SST2 dataset from the

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5243 - 5258
July 10-15, 2022

GLUE Benchmark:

This film is good and everyone loves it.	😄	99%
This film is poor and I do not like it.	😭	99%
This film is good and I do not like it.	😄	99%

The first two examples are correctly classified. Despite that the last one is composed of fragments from the first two, the model fails to produce a correct or plausible label (in terms of characterizing a sentence's sentiment), demonstrating poor performance in compositional generalization.

However, compositionality is one key aspect of language that the meaning of a complex sentence is built from its subparts. Prior work also shows that syntax trees (e.g., tree-based LSTMs) are helpful to model sentence structures for better text classification (Shi et al., 2018). However, leveraging compositional structures for data augmentation has not received much attention in the language technologies communities, with a few exceptions in semantic parsing (Andreas, 2020; Herzig and Berant, 2021).

To this end, we propose a compositional data augmentation method for natural language understanding, i.e., TreeMix (Figure 1). TreeMix is an input-level mixup method that utilizes constituency parsing information, where different fragments (phrase of a subtree) from different sentences are recombined to create new examples that were never seen in the training set; new soft labels will also be strategically created based on these fragments at the same time. In this way, TreeMix not only exploits compositional linguistic features to increase the diversity of the augmentation, but also provides reasonable soft labels for these mixed examples.

Empirically, we find that TreeMix outperforms existing data augmentation methods significantly on a set of widely used text classification benchmarks. To validate the compositional effectiveness of TreeMix, we experiment with SCAN (Lake and Baroni, 2018)—a task requires strong compositional generalization, and find that TreeMix exhibits reasonable ability to generalize to new structures built of components observed during training.

2 Related Work

2.1 Generic Data Augmentation

Most prior work operates data augmentation at different levels (Chen et al., 2021). **Token-level** DA methods manipulate tokens or phrases while preserving syntax and semantic meaning as well as labels of the original text, such as synonymy words substitutions (Wang and Yang, 2015; Zhang et al., 2015; Fadaee et al., 2017; Kobayashi, 2018; Miao et al., 2020) where synonyms are detected following pre-defined rules or by word embedding similarities. These methods has limited improvement (Chen et al., 2021) over large pretrained language models (PLMs). Besides, introducing noise by random insertion, replacement, deletion, and swapping (Wang et al., 2018; Wei and Zou, 2019; Karimi et al., 2021; Xie et al., 2020) is expected to improve the robustness of the model. **Sentence-Level** DA methods increase the diversity by generating distinct examples, such as via paraphrasing (Yu et al., 2018; He et al., 2020; Xie et al., 2020; Kumar et al., 2020; Chen et al., 2020b; Cai et al., 2020) or back translation (Sennrich et al., 2016; Edunov et al., 2018). Other line of work used label-conditioned generation methods that train a conditional generation model such as GPT-2 or VAE to create new examples given labels as conditions (Bergmanis et al., 2017; Liu et al., 2020b,a; Ding et al., 2020; Anaby-Tavor et al., 2020). Although these methods can produce novel and diverse text patterns that do not exist in the original datasets, they require extensive training. **Hidden-Level** DA methods mainly manipulate hidden representations by perturbation (Miyato et al., 2019; Zhu et al., 2020; Jiang et al., 2020; Chen et al., 2020c; Shen et al., 2020; Hsu et al., 2017, 2018; Wu et al., 2019; Malandrakis et al., 2019) and interpolation like mixup (Zhang et al., 2018) to generates new examples (Miao et al., 2020; Cheng et al., 2020; Chen et al., 2020b; Guo et al., 2019, 2020; Chen et al., 2020a).

2.2 Compositional Data Augmentation

Compositional augmentation aims at increasing the diversity of the datasets and improving the compositional generalization capability of the resulting models (Jia and Liang, 2016; Andreas, 2020). These methods often recombine different components from different sentences to create new examples following a set of pre-designed linguistic rules such as lexical overlaps (Andreas, 2020), neural-symbolic stack machines (Chen et al., 2020d), and substructure substitution (Shi et al., 2021). Compositional methods have been applied in a set of NLP tasks, such as sequence labeling (Guo et al., 2020), semantic parsing (Andreas, 2020), constituency

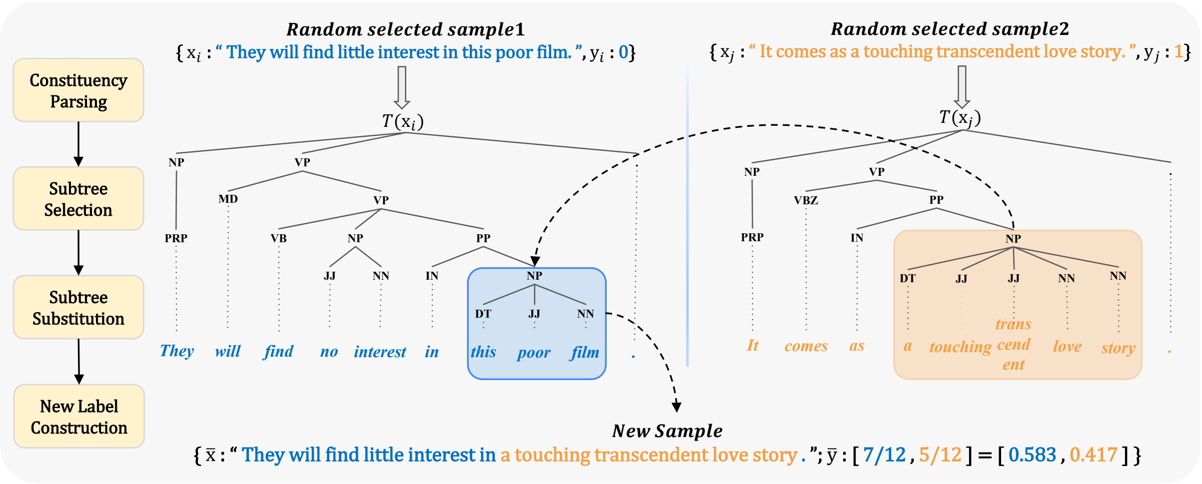

Figure 1: Illustration of TreeMix for single sentence classification

parsing (Shi et al., 2020, 2021), dependency parsing (Dehouck and Gómez-Rodríguez, 2020; Shi et al., 2021), named entity recognition (Dai and Adel, 2020), text generation (Feng et al., 2020), and text classification (Yoon et al., 2021; Shi et al., 2021). Our work also falls into this category.

The most relevant are Shi et al. (2021) and Yoon et al. (2021). However, Shi et al. (2021) only performs constituent substructure combinations with examples from the same category, thus inadequate in creating diverse enough augmentation with newly created labels.

Besides, Yoon et al. (2021) simply swaps the most and least salient spans, heavily relying on the model's performances in estimating salient spans, and failing to consider these sentences' linguistic structures. Our proposed TreeMix fills these gaps by allowing the composition of sentences from different label categories, by utilizing rich consistency based structures in text, and by strategically generating soft labels for these augmented instances.

3 Method

Our work is motivated by Mixup (Zhang et al., 2018), which creates virtual samples by mixing inputs. Given two random drawn examples $(\mathbf{x}_i, \mathbf{y}_i)$ and $(\mathbf{x}_j, \mathbf{y}_j)$, where $\mathbf{x}$ denotes the input sample and $\mathbf{y}$ is the corresponding one-hot label, Mixup creates a new sample by:

$$\overline{\mathbf{x}} = \lambda \mathbf{x}_i + (1-\lambda)\mathbf{x}_j,$$
$$\overline{\mathbf{y}} = \lambda \mathbf{y}_i + (1-\lambda)\mathbf{y}_j,$$

where $\lambda \in [0, 1]$. Mixup can be easily implemented in continuous space, hence some prior works (Chen et al., 2020b) have extended it to NLP by performing interpolation in hidden space.

We improve upon Mixup by incorporating compositionality of language, a key characteristic that is essential to generalization but neural models often fall short in capturing (Lake and Baroni, 2018). Instead of interpolating with the whole sample, TreeMix, our newly proposed method, creates new sentences by removing phrases of sentences and reinserting subparts from other sentences. TreeMix makes use of constituency trees to decompose a sentence into meaningful constituent parts, which can then be removed and recombined to generate new augmentation samples. We aim to improve models' compositionality generalization ability by training on large amount of samples produced by TreeMix. An example of using TreeMix for single sentence classification is shown in Figure 1.

3.1 TreeMix

Let $\mathbf{x}_i = \{x_i^1, x_i^2, ..., x_i^l\}$ denotes a sequence with length l and its corresponding label in one-hot encoding as $\mathbf{y}_i$. We run a constituency parser on $\mathbf{x}_i$ to get its parsing tree as $T(\mathbf{x}_i)$. In order to get meaningful subparts of a sequence, we traverse the parsing tree recursively and get all the subtrees with more than one child. Denote the collection of subtrees as $S(\mathbf{x}_i) = \{t_i^k\}$, where t_i^k denotes the k-th subtree of sample $\mathbf{x}_i$. For a subtree t_i^k, it covers a continuous span $t_i^k \triangleq [x_i^{r_k}, ..., x_i^{s_k}]$ of $\mathbf{x}_i$ that starts with index r_k and ends with index s_k. For example, as shown in the left part of Figure 1, the subtrees of the example sentence can cover spans such as `this poor film`, `in this poor film`, `no interest` etc.

They will find little interest in this poor film.	
$[\lambda_L, \lambda_U]$	**possible selected sub-trees**
[0.1,0.3]	(little interest),(this poor film)
[0.3,0.5]	(in this poor film)
[0.5,0.7]	(little interest in this poor film)

Table 2: Examples of possible candidate subtrees with different λ intervals

For a given sample $(\mathbf{x}_i, \mathbf{y}_i)$, we randomly sample another data point $(\mathbf{x}_j, \mathbf{y}_j)$ from the training set. We run the constituency parser on both sentences and get their subtree sets $S(\mathbf{x}_i)$ and $S(\mathbf{x}_j)$, based on which we can sample subtrees to exchange. We introduce two additional hyper-parameters λ_L and λ_U to constraint the length of subtrees to sample. λ_L and λ_U, measured in terms of length ratio of the subtree to the original sentences, sets the lower and upper limits of the subtrees to sample. Intuitively, λ controls the granularity of the phrases that we aim to exchange. We would like that the length of phrase to exchange to be reasonable. If it is too short, then the exchange cannot introduce enough diversity to the augmented sample; otherwise if it is too long, the process might inject too much noise to the original sentence. We set λ to be the ratio in order to be invariant to the length of original sentences. Table 2 shows some subtree examples with different length constraints. We define the length constrained subtree set as:

$$S_\lambda(\mathbf{x}) \triangleq \{t | t \in S(\mathbf{x}), s.t. \frac{|t|}{|\mathbf{x}|} \in [\lambda_L, \lambda_U]\}.$$

Here $|.|$ denotes the length of a sequence or a subtree. For two sentences $\mathbf{x}_i$ and $\mathbf{x}_j$, we randomly sample two subtrees $t_i^k \in S_\lambda(\mathbf{x}_i)$ and $t_j^l \in S_\lambda(\mathbf{x}_j)$ and construct a new sample by replacing t_i^k with t_j^l, i.e.

$$\bar{\mathbf{x}} \triangleq [x_i^1, ..., x_i^{r_k-1}, \underbrace{x_j^{r_l}, ..., x_j^{s_l}}_{t_j^l}, x_i^{s_k+1}, ...x_i^l] \tag{1}$$

where $t_j^l = [x_j^{r_l}, ..., x_j^{s_l}]$ replaces $t_i^k = [x_i^{r_k}, ..., x_i^{s_k}]$. Figure. 1 shows an example of TreeMix, where the subtree `a touching transcend love story` replaces the subtree `this poor film`.

```
Algorithm 1: Dataset construction

      Randomly select two samples $(\mathbf{x}_i, \mathbf{y}_i)$
        and $(\mathbf{x}_j, \mathbf{y}_j) \in \mathcal{D}$
      $(\bar{\mathbf{x}}, \bar{\mathbf{y}}) = \text{TreeMix}((\mathbf{x}_i, \mathbf{y}_i), (\mathbf{x}_j, \mathbf{y}_j))$
        $\mathcal{D}' \leftarrow \mathcal{D}' \cup \{(\bar{\mathbf{x}}, \bar{\mathbf{y}})\}$
  end
```

Label Creation for TreeMix Creating a valid label for the augmented sample $\bar{\mathbf{x}}$ is a challenging problem. Similar to that of Mixup (Zhang et al., 2018), we use a convex combination of original labels of two sentences as the new label for the augmented sample:

$$\bar{\mathbf{y}} = \frac{l_i - |t_i^k|}{l_i - |t_i^k| + |t_j^l|}\mathbf{y}_i + \frac{|t_j^l|}{l_i - |t_i^k| + |t_j^l|}\mathbf{y}_j, \tag{2}$$

where l_i is the length of $\mathbf{x}_i$ and $|t_i^k|, |t_j^k|$ are the length of the subtrees. In the new sentence, $l_i - |t_i^k|$ words from $\mathbf{x}_i$ are kept and $|t_j^l|$ words from sentence $\mathbf{x}_j$ are inserted.

In Equation 2, $\frac{l_i - |t_i^k|}{l_i - |t_i^k| + |t_j^l|}$ is the fraction of words that come from $\mathbf{x}_i$, which determines the weight of $\mathbf{y}_i$. The label is then created based on the conjecture that the change in labels is proportional to the length changes in the original sentences. We provided a set of augmentation examples from TreeMix in Table A.1 in Appendix.

Pairwise Sentence Classification Task The above mainly used single sentence classification as the running example for TreeMix. Here we argue that TreeMix can easily be extended to pairwise sentence classification problem, where the relationship between the sentences is the label.

Formally, for a given sample $(\mathbf{x}_i, \mathbf{x}'_i, \mathbf{y}_i)$, we randomly sample another sample $(\mathbf{x}_j, \mathbf{x}'_j, \mathbf{y}_j)$ and run the parser and get the subtree sets of each sentence $S(\mathbf{x}_i), S(\mathbf{x}'_i)$ and $S(\mathbf{x}_j), S(\mathbf{x}'_j)$. Then we randomly sample subtrees $t_i^k \in S_\lambda(\mathbf{x}_i), t_{i'}^{k'} \in S_\lambda(\mathbf{x}'_i)$ and $t_j^l \in S_\lambda(\mathbf{x}_j), t_{j'}^{l'} \in S_\lambda(\mathbf{x}'_j)$. We construct $\bar{\mathbf{x}}$ by replacing t_i^k with t_j^l and $\bar{\mathbf{x}}'$ by replacing $t_{i'}^{k'}$ with $t_{j'}^{l'}$. The new label is created as:

$$\begin{aligned}\bar{\mathbf{y}} = &\frac{l_i + l_{i'} - |t_i^k| - |t_{i'}^{k'}|}{l_i + l_{i'} - |t_i^k| - |t_{i'}^{k'}| + |t_j^l| + |t_{j'}^{l'}|}\mathbf{y}_i + \\ &\frac{|t_j^l| + |t_{j'}^{l'}|}{l_i + l_{i'} - |t_i^k| - |t_{i'}^{k'}| + |t_j^l| + |t_{j'}^{l'}|}\mathbf{y}_j.\end{aligned} \tag{3}$$

The meanings of the notations are the same as in Equation 2.

Our main algorithm is shown in Algorithm 1. Although not all sentences created by TreeMix are fluent or even valid new sentences, they contains subparts with different meanings that encourage the models to build rich representation of sentences in a compositional manner. Note that the augmented labels are convex combination of original labels, only when the model learns the representations of two parts together can they predict both labels with different weights.

3.2 Training Objective

Our model is trained on a combination of the original samples and augmentation samples to obtain a trade-off between regularization and noise injection. The final training objective is:

$$\mathcal{L} = \underset{(\mathbf{x},\mathbf{y})\sim D}{\mathbb{E}} \left[-\mathbf{y}^{\intercal} \log P_{\theta}(\mathbf{y}|\mathbf{x})\right] + \gamma \underset{(\bar{\mathbf{x}},\bar{\mathbf{y}})\sim D'}{\mathbb{E}} \left[-\bar{\mathbf{y}}^{\intercal} \log P_{\theta}(\bar{\mathbf{y}}|\bar{\mathbf{x}})\right], \quad (4)$$

γ is the weight[1] on the augmentation samples.

4 Experiment

4.1 Datasets

To test TreeMix's effectiveness, we experiment with a variety of text classification benchmarks, as shown in Table 3. We use accuracy as a metric, and exclude datasets from GLUE (Wang et al., 2019) that are not suitable for mixup, including CoLA that measures linguistic acceptability and will be ruined by mixup operations, and WNLI that is too small to show a method's validity.

4.2 Experiment Setup

The proposed TreeMix method creates new samples by combining text spans based on the constituency tree's information, thus we use the Stanford CoreNLP toolkit[2] to obtain parsing related information (Manning et al., 2014). We use the pretrained language model *bert-base-uncased* for sequence classification task from HuggingFace. With seeds ranging from 0 to 4 and $\lambda_L = 0.1, \lambda_U = 0.3$, we use TreeMix to generate twice and five times more samples than the original training set[3]. We replicate the original dataset to the same size as the augmentation datasets in the training stage to ensure that the model receives the same amount of data from the original dataset and the augmentation dataset for each training batch.

Dataset	Task	Class	Size
Single Sentence Classification			
SST2	Sentiment	2	67k/1.8k
TREC-fine	Question	47	5.5k/500
TREC-coarse	Question	6	5.5k/500
AG_NEWS	News	4	12k/4k
IMDb	Sentiment	2	12.5k/12.5k
Pair Sentence Classification			
RTE	NLI	2	3.5k/300
MRPC	Paraphrase	2	3.7k/400
QNLI	QA	2	105k/5.5k
QQP	Paraphrase	2	364k/40.4k
MNLI	NLI	3	393k/9.8k

Table 3: Dataset name or split name, task category and number of label class, Size used for training and testing. For tasks from GLUE, Size indicates (#train:#validation); for TREC, AG_NEWS and IMDb, Size indicates (#train:#test).

If not specified, we train the model for 5 epochs, with a maximum sequence length of 128 and batch size of 96. The model is optimized using the AdamW optimizer with an eps of 1e-8 and a learning rate of 2e-5. Table C.1 in Appendix contains detailed hyper-parameter settings for each dataset.

4.3 Baseline

We compare TreeMix with the following benchmarks: (1) No augmentation (BERT): standard training without any augmentation, (2) EDA that randomly performs insertion, replacement, swap and deletion to the text. (3) AEDA that randomly inserts punctuation to the text. (4) Back translation(BT) (Edunov et al., 2018): texts are translated between English and German using Transformer architectures trained on WMT16 English-German. (5) GPT3Mix(Yoo et al., 2021) designs prompts and utilizes GPT3 to generate new examples to train the model. (6) SSMix (Yoon et al., 2021) applies mixup based on the saliency (Simonyan et al., 2014) of tokens, similar to PuzzleMix (Kim et al., 2020) and SaliencyMix (Uddin et al., 2021). (7) EmbedMix is the pretrained-language-model version of WordMixup in Guo et al. (2019), which performs mixup on the embedding level. (8) TMix (Chen et al., 2020b) first encodes two inputs separately, then performs the linear interpolation of two embeddings at a certain encoder layer, and fi-

nally forward-passes the combined embedding in the remaining layers.

5 Results and Analysis

5.1 Performance On Full Dataset

The results of TreeMix on the entire datasets are shown in Table 4. TreeMix outperforms all baselines significantly on single sentence classification tasks, demonstrating the superiority of using compositional substructure for substitution and augmentation. For instance, On SST2, it improves by 0.98%. Compared to other methods, the improvement was more than doubled.

This is because that, unlike SSMix which substitutes the text spans based on the saliency, our TreeMix makes use of the constituency information to help identify linguistically informed sentence substructures, and by recombining these components, the compositional diversity of the datasets can be maximized. With our TreeMix generated samples, the model can see more combinations of the substructures in the training stage that aren't available in the original corpus, leading to better generalization ability.

When it comes to sentence relationship classification tasks, TreeMix is also very effective. For example, It improves by 2.47% on the RTE data set, whereas the best improvement of other methods is only 0.3%, and it improves by 0.82% on QNLI, where other data augmentation methods have little effect. We hypothesized that, when two constituent parts from one sentence pair are embedded into another sentence pair, the inherent relationship is also embedded. This better helps the models on how to to identify two pairs of relationships in a single sample, which further increases its capacity to categorize these challenging adversarial sentences. Since TreeMix works by increasing dataset diversity and providing models with more text patterns to learn, it has very significant improvements for these relatively small datasets such as RTE and TREC, compared to these large datasets such as AG NEWS,QQP and MNLI that already have a lot of diversity and text patterns.

5.2 Influence of Constituency Information

To determine the importance of constituency information, we designed a Random Mixup (RandMix) that randomly selects text spans as long as the ratio of span length to sentence length is less than

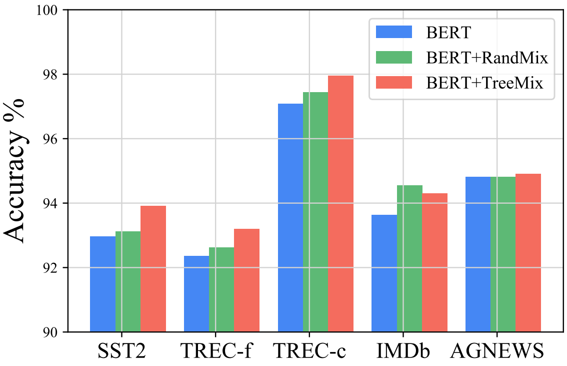

Figure 2: Performance of RandMix and TreeMix on single sentence classification datasets, scores are averaged over 5 random seeds.

a particular threshold λ_{rand}[4]. The rest setting of RandMix is the same as TreeMix. We compare TreeMix and RandMix on single sentence classification datasets in Figure 2.

We found that, both RandMix and TreeMix are quite effective, but TreeMix outperforms RandMix on most datasets. For instance, TreeMix exceeds RandMix by 0.8% on SST2, 0.6% on TREC-f, and 0.5% on TREC-c. One exception is on IMDb, where the average sentence length is much longer. The reason for the poorer performance of TreeMix is due to the sparse parsing results on long sentences; since there are many subtrees, substituting any single part might bring very minimal change to the entire sentence.

5.3 Influence of Training Set Size

To examine the influence of TreeMix with different training set sizes, we uniformly sample 1%, 2%, 5%, 10%, and 20% of the data from the training set to investigate TreeMix in low-resource situations. The entire test set is used to evaluate the model's generalization ability. Since TreeMix generates more examples for training, we use RandMix to generate the same number of extra samples as a comparison to ensure the data size is fair. The results are summarized in Figure 3.

We found that, (1) TreeMix outperforms RandMix in all settings, further demonstrating the advantage of the compositional substructure with the constituency information over the randomly selected spans. (2) Both mixup methods can significantly improve the model's performance in the case of extreme data scarcity (e.g, 1% and 2%). (3) When the amount of data is sufficient (e.g, more than

Table 4: Results of comparison with baseline on full datasets, TREC-f and TREC-c indicates TREC-fine and TREC-coarse respectively. Scores are averaged over 5 random seeds. For GLUE tasks, we report accuracy of validation sets, and for other datasets we report test accuracy. EDA and AEDA will seriously damage the sentence relationship and harm the accuracy; GPT3Mix only reports full data experiments results on SST2 in original paper. We only report the results of back translation on small dataset due to the heavy computational cost.

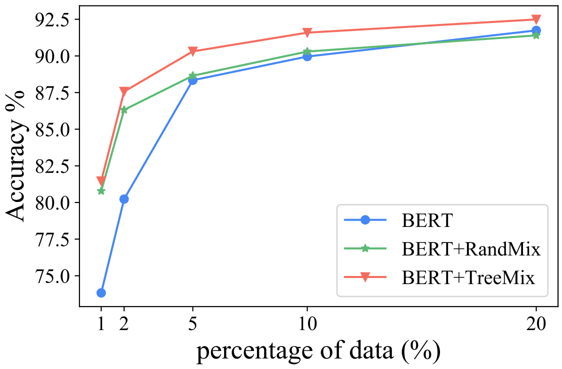

Figure 3: Results on SST2 varying data size. Scores are averaged over 5 random seeds.

Datasets	BERT	TM(same)	TM(cross)
SST2	92.96	93.78	**93.92**
TREC-fine	92.36	92.60	**93.20**
TREC-coarse	97.08	97.74	**97.95**
IMDb	93.63	94.22	**94.34**
AGNEWS	94.67	94.47	**94.71**
MRPC	84.90	85.34	**85.34**
RTE	68.15	70.25	**70.62**
QNLI	90.54	90.87	**91.36**
QQP	90.67	90.85	**90.88**
MNLI	84.27	84.33	**84.45**

Table 5: Performance with TreeMix performed (1) within same classes TM(same) and (2) cross different classes TM(cross), averaged over 5 runs.

5%), TreeMix outperforms RandMix by a significant margin. However, TreeMix only slightly outperforms RandMix when there is a severe lack of data (e.g, 1% and 2%). This is due to that the too small datasets often contain very limited structures, thus constraining TreeMix's ability to increase text patterns and compositional diversity. (4) The relative improvement of TreeMix over conventional training without augmentation diminishes as the amount of data increases, largely due to that additional augmented text patterns might overlap with those already existing in the dataset, resulting in limited improvement.

5.4 Influence of Cross-Category Mixing

Different from prior work Shi et al. (2021), TreeMix allows the composition of sentences from different label categories. To test whether this cross-label category mixup is more effective than a within-label category mixup, we conducted ablation studies with TreeMix on samples in the same class[5]. Table 5 shows the results. Across all datasets, we found that TreeMix that combines data from different classes is more effective than combining data from the same class, consistent with findings in Zhang et al. (2018). When given only labels from one category, current models have a tendency to make simple or spurious judgments based on the most frequently occurring words. However the semantics of the sentence are complicated beyond simple words. For example, the model is likely to classify a sentence like *"I like this good movie"* as positive because of the words *"like"* and *"good"*, but if *"good movie"* is replaced with *"bad*

---

[5] Section D.2 in Appendix discuss the effect of constraining the length and label of the swapped subtree on the result

film", the model must perceive the different constituent parts within the sentence. This ability can only be obtained when the model is trained on the cross-category generated samples.

5.5 Influence of Length Ratio

Dataset	BERT	λ =[0.1,0.3]	λ =[0.3,0.5]
SST2	92.96	**93.92**	93.05
TREC-fine	92.36	**93.2**	92.25
TREC-coarse	97.08	**97.95**	96.94
IMDb	93.63	**94.34**	93.29
AG NEWS	94.67	**94.72**	94.53
MRPC	84.90	**85.34**	84.93
RTE	68.15	**70.62**	70.35
QNLI	90.54	**91.36**	90.78
QQP	90.67	**90.88**	90.54
MNLI	84.27	**84.45**	83.78

Table 6: Performance with different length ratio intervals λ

The only constraint we impose on TreeMix is the length ratio of the subtree controlled by λ. We select subtrees that are between 10% and %30 and between 30% and 50% of the length of the sentence, respectively. Table 6 shows the results.

On all datasets, $\lambda = [0.1, 0.3]$ outperforms $\lambda = [0.3, 0.5]$, which is in line with Zhang et al. (2018)'s observation that giving too high mixup ration values can lead to underfitting. Another linguistic explanation for the scenario follows: When $\lambda = [0.3, 0.5]$, TreeMix may select longer text spans, which usually contain unique constituency components like *SBAR*; The exchange of these spans will severely damage the sentence's semantic and grammatical structure, causing the model to become confused. As a result, TreeMix with larger switching spans performs poorly, and even worse than baseline on some datasets.

5.6 Compositional Generalization

To quantify TreeMix's overall ability of compositional generalization beyond classification tasks, we conducted experiments on SCAN (Lake and Baroni, 2018) dataset, which is a command execution dataset widely used to test for systematic compositionality. It contains simple source commands and target action sequences. We test on commonly used challenging splits: *addprim-jump, addprim-turn-left, around-right*, where primitive commands (e.g "*jump*") only appear alone during training but will be combined with other modifiers (e.g "*jump twice*") during testing. A model that works well for this task should learn to compose the primitive commands with the modifiers and generates corresponding execution. With TreeMix, we can generate the compositional commands that are not seen in the training set.

Method	JUMP	TURN-L	AROUND-R
Baseline	$0^{\dagger}$	49% †	$0^{\dagger}$
WordDrop	$0^{\dagger}$	51% †	$0^{\dagger}$
SwitchOut	$0^{\dagger}$	16% †	$0^{\dagger}$
SeqMix	49%†	99% †	$0^{\dagger}$
TreeMix	**72%**	**99%**	**0%**
GECA	87%†	-	$82^{\dagger}$
GECA+WordDrop	51%†	-	$61^{\dagger}$
GECA+SwitchOut	77%†	-	$73^{\dagger}$
GECA+SeqMix	98%†	-	89 †
GECA+TreeMix	**99%**	-	**91%**

† denotes the result is extracted from the original paper

Table 7: Experimental results (accuracy) on SCAN.

The new command generation process is the same as in single sentence classification, except that we increase the length constraint λ_U to 1 to allow the exchange of the commands with only one word. After we synthesize new commands, we follow the rules in Lake and Baroni (2018) to translate valid commands into actions and filter out ungrammatical commands. We follow the settings in Andreas (2020) and use the following data augmentation methods as baselines: (1) WordDrop that drops words randomly; (2) SwitchOut (Wang et al., 2018) that randomly replaces words with other random words from the same vocabulary; (3) SeqMix (Guo et al., 2020) which creates new synthetic examples by softly combining in-put/output sequences from the training set, and (4) GECA (Andreas, 2020) that performs enumerated valid swaps.

As shown in Table 7, TreeMix outperforms SwitchOut and WordDrop for all splits. TreeMix by itself does not perform as well as GECA, but when being combined with GECA, it demonstrates very strong results. TreeMix outperforms SeqMix in all splits, due to the fact that TreeMix can more precisely find the linguistically rich compositional segments of a sentence, as evidenced by the results of the comparisons of TreeMix and SSMix in Section 5.1 and TreeMix and RandMix in Section 5.3. A closer look at these augmented samples show that TreeMix can generate all possible combinations of "*jump*" and other modifiers like "*left*" and "*around*"; these previously unseen command combinations further validates TreeMix's ability to improve the dataset's compositional diversity. TreeMix demonstrates weak performances on the *around-right* split, where the model observes commands "*around*" and "*right*" in isolation at the training stage, and it has to derive the meaning of "*around right*" at the test time. Because the word "*around*" cannot be parsed as a single subtree for swap. Instead, it always appears in a subtree with the word "*left*", preventing TreeMix from generating the phrase "*turn right*". Despite its limitations on *around-left*, TreeMix performs well on all other splits and can be easily combined with other data augmentation methods, demonstrating the compositional generalization ability of TreeMix beyond classification tasks.

6 Conclusion

This work introduced TreeMix, a compositional data augmentation approach for natural language understanding. TreeMix leverages constituency parsing tree to decompose sentences into substructures and further use the mixup data augmentation technique to recombine them to generate new augmented sentences. Experiments on text classification and semantic parsing benchmarks demonstrate that TreeMix outperforms prior strong baselines, especially in low-resource settings and compositional generalization.

Table A.1: Examples of TreeMix on SST2 datasets, the number following sentence is label, bold tokens are selected phrase for substitution

B The necessity of merged loss techniques

We provide a detailed discussion of the techniques proposed in 3.2. We first investigate the noise contained in the augmentation dataset, then we figure out how the unbalance dataset will affect the performance. In the second part, we vary the weight parameter γ to see how it affects the model's learning process.

B.1 Noise and Unbalance

All mixup methods, as previously stated, introduce noise into the dataset. This noise in the text includes grammatical structure confusion and multiple semantic meanings in the sentences. The model will be overwhelmed by the noise if trained solely on the generated augmentation dataset, and will even perform worse than the baseline. In terms of the unbalance problem, we find that training the model without replicating the original dataset to the same size as the augmentation dataset hurts the model's performance. The results are shown in the table B.1.

Table B.1: Merged Loss indicates results following techniques in 3.2, Augmentation indicates the model is trained on the generated dataset alone. No Replicate indicates Merged Loss without replication of the original training set.

B.2 Weight parameter

We vary weight parameter γ to find optimal balance point between diversity and linguistic grammar, the results are shown in figure 4. Performance on the two classification tasks follows a similar pattern. Both increase with increasing weight and then rapidly decrease with increasing weight after reaching the highest point. Performance is weaker than the baseline when the weight value exceeds 0.7. We find the model achieves the best performance with $\gamma \in \{0.2, 0.5\}$. For single sentence classification tasks, when $\gamma = 0.5$ the model always gets higher accuracy, and $\gamma = 0.2$ is better for these sentence relation classification datasets.

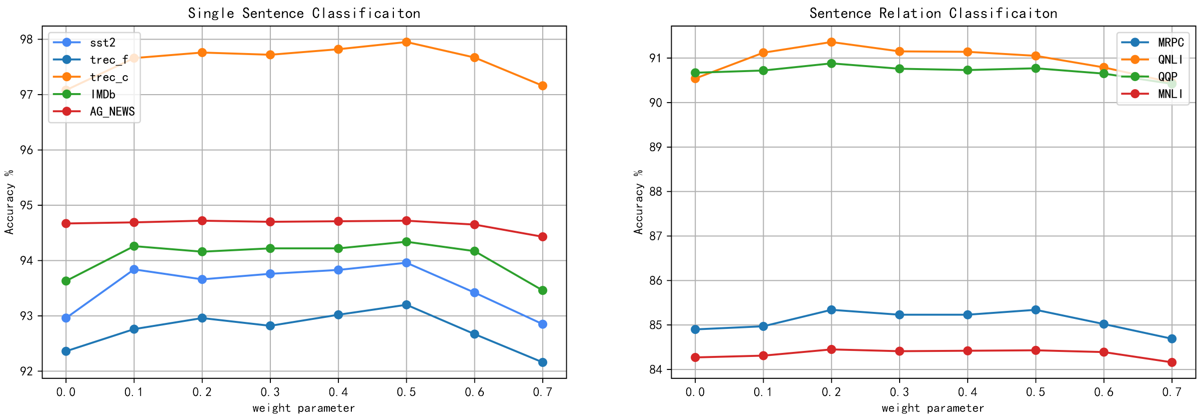

Figure 4: The performance when varying the value of the weight parameter on single sentence classification (left) and sentence relation classification (right)

Datasets	epoch	batch size	aug batch size	val steps	sequence length	aug weight
SST2	5	96	96	100	128	0.5
TREC-f	20	96	96	100	128	0.5
TREC-c	20	96	96	100	128	0.5
IMDb	5	8	8	500	512	0.5
AGNEWS	5	96	96	500	128	0.5
MRPC	10	32	32	100	128	0.2
RTE	5	32	32	50	128	-0.2
QNLI	5	96	96	100	128	0.2
QQP	5	96	96	300	128	0.2
MNLI	5	96	96	100	128	0.2

Table C.1: Best settings for different datasets

C Hyper-parameters for each datasets

We explore different parameter combinations and find the best ones for each task, as in Tab C.1. There are some exceptions, such as TREC datasets, where the model cannot converge even with 10 epochs, so we increase the training epochs to 20 for this dataset. IMDb's examples are extremely long, with an average length of more than 200 words. Along with this change, we increased the truncation length to 512 and the batch size to 8 to fully capture the semantic meaning. RTE is the most unusual. First, when we train using original RTE datasets, the accuracy deviation is really substantial, reaching up to 4%. Second, we find that $\gamma = -0.2$ is optimum for this set, which contradicts previous findings.

D Ablation Study

Shi et al. (2021) has proposed a similar study that uses constituency information for mixup. There are a few significant differences between our approaches. To begin with, their method is too restricted; they only perform mixup between examples from the same category, and they require the substituted subtree's label to be the same. Second, because they are limited to the same class examples, they are unable to devise a method for adding a soft label to the example. Instead, we only use TreeMix in the previous settings with the length constraint. Several other constraints in the subtree selection process are investigated in this section, and we achieve better performance than Shi et al. (2021) by giving the subtree selection process more freedom, and we validate that their work is a special case of our method by examining how other constraints affect the performance. This section's values are the averages of five runs with seeds ranging from 0 to 4

D.1 What is the difference between different amounts of data?

TreeMix has the potential to generate an infinite amount of augmented data in theory. However, due to TreeMix's principle, it can only improve performance to a point when the size of the augmentation data set reaches a certain limit. We investigated how many augmentation datasets the model needs. Table D.1 shows the results of producing twice and five times the augmentation data for experiments.

Dataset	Size	BERT	TM(x2)	TM(x5)
RTE	3.5k	68.15	70.57	**70.62**
MRPC	3.7k	84.90	85.22	**85.37**
TREC-f	5.5k	92.36	**93.2**	92.85
TREC-c	5.5k	97.08	97.71	**97.95**
IMDb	12.5k	93.63	**94.34**	94.24
SST2	67k	92.96	**93.92**	93.92
QNLI	105k	90.54	**91.36**	91.34
AGNEWS	120k	94.67	**94.71**	94.69
QQP	364k	90.67	**90.88**	90.83
MNLI	393k	84.27	**84.45**	84.41

Table D.1: Improvement of performance on all datasets with different amount of augmentation datasets, *TM(x2)* indicates generating twice as much augmentation data than the original data, *TM(x5)* indicates five times than original data, datasets in the table are listed in order of size

The key to getting the best results is to strike a balance between the original datasets and the augmentation datasets in terms of diversity and linguistic confusion. With more augmentation datasets, the model will learn more patterns while also observing more grammatically poor samples, which could negatively impact performance. We discovered that augmentation datasets twice the size of the original dataset produce the best results for larger datasets. This is in line with our previous theoretical analysis: large datasets inherently include more patterns and diversity, which helps the model generalize better. Maintaining the original linguistic grammar while increasing diversity in these datasets is, therefore, more important. When working with smaller datasets, it's better to train with more augmentation data. For models to train on these datasets, we believe diversity is more important than linguistic grammar.

TREC-fine is an exception. We attribute it to the datasets' excessive classes (up to 47 classes within only 5.5k training samples): each class has a very limited number of samples, and if we create overly augmented dataset samples, the limited samples of each category are insufficient to resist injected linguistic noise. As a result, for TREC-fine, x2 is preferable to x5. For a smaller dataset, we recommend generating five times as much augmentation data as possible, and for a larger dataset, we recommend generating twice as much augmentation data.

D.2 Is it beneficial to keep the swapped subtree's label or length the same?

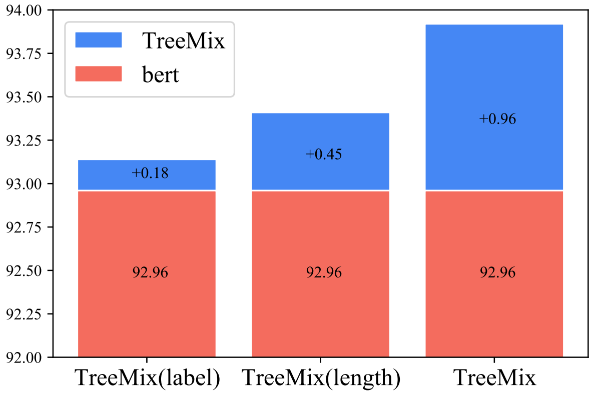

Figure 5: Performance on SST2 with different subtree selection constraints, green part is bert performance, orange part is improvement of TreeMix when applying different constraints, TreeMix(label) indicates only select subtrees with same phrase label, TreeMix(length) indicates only select subtrees with same length. TreeMix indicates without any constraints

Each subtree has its own label (e.g., VP and NP) and corresponds to a specific text span. When selecting subtrees, we can use these characteristics as additional constraints. Figure 5 shows the results.

When we impose restrictions on the subtree selection process, the experimental results clearly show that performance suffers.

We hypothesize that this is because in datasets with similar sentence lengths, subtrees of the same phrase label or phrase length tend to have similar structures (e.g., tree height, relative position in the sentence). Although the exchange of such subtrees can retain the original linguistic grammar of the text to some extent (e.g., replacing a noun phrase with another noun phrase will not significantly disrupt the sentence) and maintain similar sentence length, it cannot exploit the potential compositional diversity in the datasets as efficiently as TreeMix without any constraints, resulting in lower diversity augmentation datasets and limited improvement compared to the baseline. In terms of the comparison of *TreeMix(label)* and *TreeMix(length)*, we find that *TreeMix(label)* prefers simple phrases such as NP and VP because these are the most common phrases occurring in sentences, and this exchange will not improve the diversity of the datasets. For example, in "I like this apple," replacing "apple" with "orange" will not provide innovative text patterns.

Syn2Vec: Synset Colexification Graphs for Lexical Semantic Similarity

Abstract

In this paper we focus on patterns of colexification (co-expressions of form–meaning mapping in the lexicon) as an aspect of lexical-semantic organization, and use them to build large scale synset graphs across BabelNet's typologically diverse set of 499 world languages. We introduce and compare several approaches: *monolingual* and *cross-lingual colexification graphs*, popular *distributional models*, and *fusion approaches*. The models are evaluated against human judgments on a semantic similarity task for nine languages. Our strong empirical findings also point to the importance of universality of our graph synset embedding representations with no need for any language-specific adaptation when evaluated on the lexical similarity task. The insights of our exploratory investigation of large-scale colexification graphs could inspire significant advances in NLP across languages, especially for tasks involving languages which lack dedicated lexical resources, and can benefit from language transfer from large shared cross-lingual semantic spaces.

1 Introduction

Distributional models like word embeddings have been widely used in Natural Language Processing (NLP) (Iacobacci et al., 2016; Devlin et al., 2014; Hewlett et al., 2016). They operate under the assumption that words appearing in similar contexts have similar meanings, and thus close representations. However, as do other unsupervised learning models, they suffer from classic limitations – i.e., there is no guarantee that all context words contribute to the meaning of the target word, while, in fact, it is possible that some low frequency words, with poorly-trained embeddings, are highly semantically connected. Also, they don't distinguish between topically related words and near synonyms.

Dictionaries and thesauruses, on the other hand, have traditionally offered an alternative approach, through their discrete lists of fine-grained senses, textual definitions, and relationships with other senses. Given a sufficiently large dictionary of many fine-grained sense representations in many of the world's languages, one could perform sophisticated semantic tasks on word senses (Conia and Navigli, 2020). In fact, investigating universal and areal cross-linguistic variations in the lexicon has been the focus of lexical typology. One increasingly popular empirical method of investigating senses based on cross-linguistic comparison in typological studies has been that of colexification patterns. "A given language is said to colexify two functionally distinct senses if, and only if, it can associate them with the same lexical form" (François, 2008), reflecting natural semantic connections (Haspelmath, 2003). For example, 'fire' and 'firewood' are colexified in Kamoro (New Guinea language) as 'uta' and in Wayuu (Arawakan language) as 'siki', but receive distinct lexemes in English and Romanian. Each polysemous lexeme as a whole is language-specific, yet a great number of lexical polysemies are each attested across multiple languages.

In this paper, we investigate semantic structures in the lexicon as manifested by colexification patterns in a large number of languages and assess, at a large scale, their usefulness to the Lexical Semantic Similarity (LSIM) task (Vulić et al., 2020a). We used one of the largest digital lexical resources to date, BabelNet 5.0 (953.4M (concept) lexicalizations in 499 languages[1]) to build and process colexification graphs.

Specifically, we make the following contributions: **1)** Propose a simple, yet effective algorithm to automatically construct large-scale synset similarity graphs based on the principle of colexification, and use the graphs to generate high-quality

---

[1] BabelNet 5.0's claim of supporting 500 languages seems to be a typo. There are only 499 (see "Languages and Coverage" tab) `https://babelnet.org/statistics`

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5259 - 5270
July 10-15, 2022

synset and word representations. **2)** Demonstrate the importance of universality of our graph synset embedding representations with no need for any language-specific adaptation when evaluated on LSIM. **3)** Show that our proposed approach significantly outperforms state-of-the-art synset and word embedding techniques on the LSIM task. **4)** When combined with knowledge-based approaches like our cross-lingual colexification patterns, purely unsupervised distributional models like fastText and BERT result in better alignment with human perception, as measured on the LSIM task.

Our findings and models contribute to advances in computational modeling of natural language understanding across languages, and offer new insights into linguistic typology.

2 Related Work

The concept of colexification has been introduced by Haspelmath (2003) to distinguish senses in the grammatical domain, but has been formalized for the field of lexicon by François (2008) who, in a cross-linguistic study of the world's lexicons, investigated colexification patterns captured in a semantic map. Unlike Haspelmath who showed that 12 diverse languages are sufficient to build a stable semantic map, Francois posits that, in fact, the number of distinctions between senses increases with the number and variety of considered languages. Following these studies, List et al. (2018) built a weighted colexification graph using data from 195 languages in 44 language families, with subsequent improved language coverage versions (Rzymski et al., 2020a). Here, closely-related or similar concepts tend to be often densely connected (List et al., 2018; Georgakopoulos et al., 2021). Youn et al. (2016) constructed colexification graphs in the domain of natural objects (celestial and landscape) and investigated their polysemy distributions for the task of semantic similarity. We also take advantage of recurrent patterns in semantic structure across different language families. However, unlike them, we found some evidence that geographical and cultural differences matter in the human perception of our cross-linguistically connected concepts. Pericliev et al. (2015) distinguished between homonymy and polysemy by investigating the colexifications of 100 basic concepts. Georgakopoulos et al. (2021) discovered cross-linguistic similarities based on colexification patterns of verbs of vision and hearing in the the domain of perception-cognition. Jackson et al. (2019) relied on colexification patterns to test the universality of emotion perception. Like us, they show that, while there are shared structures of (affective) meanings across cultures, there are also some variations. Di Natale et al. (2021) tested whether colexification patterns in multilingual resources are correlated with affective meaning similarity between words. Bao et al. (2021) showed that no two concepts are colexified in every language by analyzing colexification data from three resources: BabelNet, Open Multilingual WordNet (Bond and Foster, 2013), and the Database of Cross-Linguistic Colexifications (CLICS3) (Rzymski et al., 2020b).

Although the scope of research on colexification varies across projects, most studies have assumed that colexification captures some degree of semantic similarity. Indeed, this is implied to some extent by the very definition of colexification, and supported by previous results in linguistics and NLP, suggesting that more commonly colexified meanings across languages require less cognitive effort to relate and recall (Xu et al., 2020). However, such a connection between cross-linguistic colexification patterns and semantic similarity has not been fully assessed at a large scale. Given that features of the lexicon are not easily identifiable across many languages, one solution is to rely on large data repositories to unveil cross-linguistic generalizations. However, since most languages lack dedicated lexical resources for semantic similarity (henceforth, *low-resource languages*), one option is to *transfer lexico-semantic knowledge from large shared cross-lingual semantic spaces*. In this paper, as part of a large scale empirical study, we show that lexico-semantic associations captured by cross-lingual colexification patterns in BabelNet contribute significantly in assessing if two words are semantically similar.

3 Synset Cross-Lingual Colexification

Under the colexification framework, the primary unit of observation for lexical typology is no longer the word, but the sense – a functionally-based criterion of concept definition (François, 2008). In this project, however, we use *the synset* as the primary unit. For us, this is also a technical consideration, since only synsets can be compared across languages, especially in BabelNet. Lexical concepts are grouped into sets of cognitive (near) synonyms, called synsets, each encoding a distinct meaning. Synsets are connected through lexical relations and conceptual/semantic relations (i.e., hyperonymy, hyponymy, meronymy, etc.). In this paper, we use only lexical relations to capture colexifications between meanings. For instance, the lexical relation between the senses of 'fire' and 'firewood' of the word uta (in Kamaro) is a case of *strict colexification*. *Loose colexifications* like derivationally-related forms can show interesting semantic associations, but are not considered here.

Two synset concepts that are colexified in at least one language are usually perceived as somehow semantically connected, either directly or indirectly. However, proving such connectedness is by no means an easy task. The accurate description of lexical data often requires taking into account the many functional properties of real-world referents as well as culture-specific aspects of a language or geographic area. Such cases might capture underlying linguistic phenomena such as metaphor, metonymy, hyperonymy, analogical extension, and a rich set of cases of semantic shifts unique to each language or language family (Juvonen and Koptjevskaja-Tamm, 2016) – whose analysis falls within the scope of semantic or etymological studies, and beyond our goal here. Instead, our purpose is to organize cross-linguistic sense information in a way that captures various semantic connections between senses, allowing one to zoom in and out on aspects of the lexicon in cross-linguistic comparative studies. We rely here on the powerful structure of BabelNet that maps concepts (i.e., synsets) across a large, typologically diverse set of languages. This allows us to empirically examine at a large scale the contribution of such a rich body of knowledge to the task of semantic similarity - such empirical evidence is still lacking in the field. Our model of semantic connection between synsets (we call *Syn2Vec*) is simple: Given the set of concepts (synsets) of a lexeme, we assign a semantic link between every synset-synset pair. We want to investigate the idea that, as more and more languages are explored, and more and more senses are amassed, the resulting graph of cross-linguistic inter-connected synset concepts will capture aspects of semantic knowledge that might be missing in one language alone.

Given this intuition, next we briefly introduce the lexical resource used and our proposed algorithm to construct colexification graphs which model the synset semantic connections. We hypothesize that the conceptual representations of lexical typology captured by our cross-lingual colexification patterns do match, to some extent, the language-internal perception of native speakers, and test this hypothesis empirically on the LSIM task.

Algorithm 1 Construction of Colexification Graph: Given a set of languages L and corresponding vocabularies V, create graph edges between all colexified synset pairs (nodes).

```
function CONSTRUCTGRAPH($L, V$)
    $CSP \leftarrow \{\}$                          ▷ Colexified Synset Pairs.
    for $l \in L$ do
        for $x \in V_l$ do
            if $|S_x| \geq 2$ then
                for $\{s_1, s_2\} \in \binom{S_x}{2}$ do
                    $CSP \leftarrow CSP \cup \{s_1, s_2\}$
                end for
            end if
        end for
    end for
    $G \leftarrow$ graph
    for $\{s_1, s_2\} \in CSP$ do
        $G(s_1, s_2) \leftarrow 1$
    end for
    return $G$
end function
```

A. The Lexical Resource, BabelNet. To collect synset information, we use BabelNet (Navigli and Ponzetto, 2010), to our knowledge, the largest cross-linguistic semantic network that extends the popular WordNet (Miller, 1995) by integrating other resources (Wikipedia, Wiktionary, etc). Every BabelNet synset (20.3M total) is identified as either a concept or named entity, and we only use concept synsets (7.2M) for our analysis. The maximum and minimum numbers of (concept[2]) lexemes in a language are 6.1M (English) and 1.8M (Parthian), respectively.

B. Building the Colexification Graphs. We denote the set of languages as $L = \{l_1, l_2, ..., l_N\}$, and the language vocabulary lists as $V = \{V_{l_1}, V_{l_2}, ..., V_{l_N}\}$. The vocabulary for each language is represented by $V_{l_n} = \{x_1, x_2, ..., x_{|V_{l_n}|}\}$ where the elements x_k are lexemes. For each lexeme x_k we have a corresponding set of synsets $S_{x_k} = \{s_1, s_2, ..., s_{|S_{x_k}|}\}$. For a colexification graph G, nodes represent synsets, and edge weights the semantic connection between two synsets. We denote the weight for each edge $\{s_1, s_2\}$ in the graph as $G(s_1, s_2) = G(s_2, s_1)$ (undirected graph). Algorithm 1 details the graph construction.

In this study, we examine two types of colexification graphs: (1) Monolingual, and (2) Cross-

---

[2] We filter out lexemes that have no concept synsets.

lingual. For monolingual graphs, we choose one language l and provide $L = \{l\}$ and $V = \{V_l\}$ to Algorithm 1. For the cross-lingual graph, we use all languages, i.e. $L = \{l_1, l_2, ..., l_N\}$, $V = \{V_{l_1}, V_{l_2}, ..., V_{l_N}\}$. In BabelNet, the same concept in each language will be mapped to a common synset and thus be represented as a node in the colexification graph.[3]

C. Creating Synset and Word Embeddings. As we like to capture lexico-semantic associations, given a colexification graph G, we assume that vector representations of the nodes (synsets) that are close to one another are similar as computed by cosine distance in the embedding space. We use a recently-developed node embedding approach, ProNE (Zhang et al., 2019), which, compared to other popular node embedding techniques like Deepwalk and Node2Vec (Perozzi et al., 2014; Grover and Leskovec, 2016), is much faster and demonstrates superior node representations on several classification datasets using a lib-linear classifier. We use the Python implementation from `nodevectors`[4] with all default hyperparameters.

In predicting the lexical similarity of two words, we assume that their perceptual similarity is determined by summing the synset embeddings of each word, then comparing the results. Thus, a word embedding w is computed as:

$$w = \sum_{s \in S_{Babel(w)}} s_{emb} \tag{1}$$

where s_{emb} is the embedding for synset s and $S_{Babel(w)}$ is the set of synsets of word w in BabelNet. Prior to each semantic similarity task, we normalize each word embedding to have magnitude one. Next, we take all evaluation words and perform mean centering, then Principal Component Analysis[5] (PCA) following (Ghannay et al., 2016), as we empirically found this improves performance.

4 Baselines

We evaluate the quality of our BabelNet dictionary approach by comparing it to high-quality and popular word and synset embedding approaches. We want to test whether the structural regularities observed in distributed text representations provide a route past some of the limitations of dictionaries, whether these two representations are comparable, and whether their combination might benefit the task of lexical similarity. Specifically, we compare to the well-known static word embedding approach fastText (Joulin et al., 2016), and an approach that extracts contextualized representations of words from a pretrained BERT language model (Vulić et al., 2020b), which we call "BERT." We also compare to "ARES", a recent synset/sense embedding model (Scarlini et al., 2020) that builds representations for each synset by collecting relevant contexts and extracting contextual embeddings of lemmas belonging to each synset from a pretrained language model (BERT). Similar to (Scarlini et al., 2020), we rely on ARES synset embeddings for our multilingual analysis. To compute ARES word embeddings, we follow Equation (1), but use the pretrained ARES multilingual synset embeddings[6]. We re-implement the BERT baseline[7], but use pretrained word embeddings for fastText[8].

5 Experimental Setup

Lexical semantic similarity (LSIM) seeks to accurately measure the perceived similarity in meaning between two words and does so by the Spearman's rank correlation[9] between similarity scores of human judgments and those computed automatically (cosine similarity of the words' vector representations). We rely here on Multi-SimLex (Vulić et al., 2020a), arguably the most comprehensive semantic similarity evaluation resource to date, which contains monolingual lists of 1,888 word pairs, with aligned concepts in 13 typologically diverse languages[10]. Diverse criteria were used here to test whether two words are semantically similar, and not vaguely associated. Thus, the Multi-SimLex datasets could be used as "an intrinsic evaluation benchmark to assess the quality of lexical representations based on monolingual, joint multilingual, and transfer learning paradigms" (Vulić et al., 2020a). Of the original 13 languages, we limit our

---

[3] We removed the three BabelNet noisy lexemes (with >1,000 synsets): the empty string "" (common to all languages); and "asteroid list" in both Russian (RU) and Armenian (HY): "список_астероидов" in (RU); "աստերոիդների_ցանկ" in (HY).

Table 2: BabelNet statistics for evaluation languages given our experimental setup (using concept synsets only). "All" column indicates cumulative statistics over all 499 languages. Polysemous lexemes have two or more synsets.

study to 9 languages: Arabic (AR), Spanish (ES), English (EN), Finnish (FI), French (FR), Hebrew (HE), Polish (PL), Russian (RU), Mandarin Chinese (ZH). Thus, we can directly compare with other baselines that are only readily available for languages with large pretrained language models.

Cross-lingual lexical semantic similarity (CLSIM) is identical to LSIM, except the words in each word pair are from different languages. Multi-SimLex (Vulić et al., 2020a) also makes available these cross-lingual similarity scores, excluding AR.

Colexification Evaluation Setups. We evaluate monolingual and cross-lingual colexification-based synset embeddings[11] in three variants:

COLEX$_{\text{mono}}$: Construct the colexification graph using one language only. Build word embeddings from synset embeddings using Equation (1).

COLEX$_{\text{cross}}$: Same procedure as COLEX$_{\text{mono}}$ except that we use all 499 languages to construct the colexification graph. The purpose is to capture the full complexity of the BabelNet data.

COLEX$_{\text{maxsim}}$: We use here the same synset embeddings from COLEX$_{\text{cross}}$. Specifically, following (Camacho-Collados and Pilehvar, 2018), for each evaluation word pair in the test set, we determine their similarity score by computing the maximum similarity among all pairs of synset embeddings. We perform PCA on the entire set of COLEX$_{\text{cross}}$ synset embeddings prior to similarity computation.

6 Results and Discussion

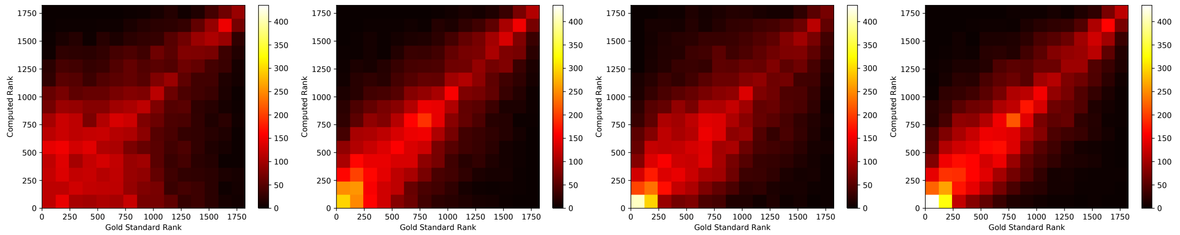
We introduce here various experiments to compare multiple methods. Since BERT and fastText can form representations from arbitrary string inputs, they have no out-of-vocabulary (OOV) words, while all methods relying on external resources (ARES and COLEX) require synset information for any word included in our experiments. For fair comparison, we limit our study to word pairs that include **both** words in the vocabulary of **all** approaches. Table 1 and Fig. 3 show the total number of word pairs (of the original 1,888) used for evaluation (relevant BabelNet stats in Table 2)[12].

We also use heatmaps (correlation plots) to give a clearer visual overview of the correlation between human judgments (i.e., gold standard) and our models' outputs, by word pair similarity rank (an ordinal measure) for all pairs in the test sets. Figure 1 shows the overall correlation

---

[11] All experiments were performed on an x86-64 server with a 32-core Intel(R) Xeon(R) Silver 4215R CPU and 754GB RAM. The node embedding process for the largest graph (COLEX$_{\text{cross}}$) took 20 minutes and 30GB of RAM. Our code is publicly available at `https://github.com/jharvill23/Syn2Vec`.

[12] OOV words breakdown by method: Table 5 (A.2)



(a) COLEX$_{mono}$ (b) COLEX$_{cross}$ (c) fastText (d) C+F Fusion

Figure 1: Heatmaps showing correlation of human rank judgments (X-coordinate) and overall computed ranks (Y-coordinate) for word pairs across all nine evaluation languages for four approaches: (a) COLEX$_{mono}$; (b) COLEX$_{cross}$, (c) fastText; (d) C+F Fusion (C: COLEX$_{cross}$ and F: fastText). The density of word pairs per square is represented by the square's color. Higher rank indicates that words in a given word pair are determined to be more similar, whereas low rank indicates dissimilarity.

plots for all the test sets combined comparing our dictonary models (COLEX$_{mono}$, COLEX$_{cross}$), the best baseline (fastText), and our best fusion model (COLEX$_{cross}$+fastText). The color intensity of a square region corresponds to the number of word pairs in that region. We analyze the results of these different experiments next.

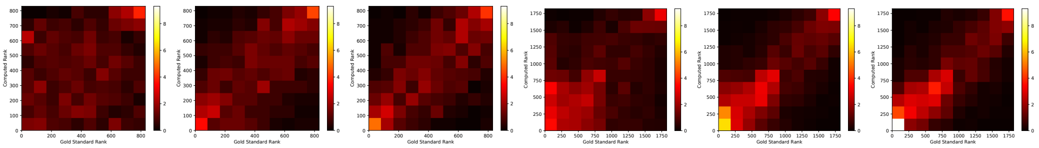
Cross-lingual vs. Monolingual Colexification. Cross-lingual colexification approaches COLEX$_{cross}$ and COLEX$_{maxsim}$ outperform the monolingual model COLEX$_{mono}$ by a large margin for every test language, and overall (Table 1). More specifically, the COLEX$_{cross}$ heatmap (Fig.1) shows significantly improved agreement on most dissimilar word pairs (i.e., the bottom left yellow squares), while more clearly converging on semantically similar instances (upper right squares), and reducing mis-ranked instances (away from the diagonal). This brings supporting empirical evidence for our main claim: *adding concepts (synsets) and edges in other languages captured as colexification patterns substantially contributes to the lexical similarity task.* For instance, unrelated words like 'aggressive'-'curved', 'airport'-'piece' are penalized by COLEX$_{cross}$, bringing the ranks closer to the gold standard. At the other end, the model better scores very similar pairs (like near synonyms): 'weird'-'strange', 'amazingly'-'fantastically', 'area' - 'region', 'capability'-'competence'. Various cases of colexification also bring to surface interesting lexico-semantic differences across languages – like 'charcoal'-'coal' or 'understand'-'know' which are not connected in English, but are colexified in other languages like Romanian – {'cărbune', 'jar', tăciune'} and {'a cunoaşte', 'a pricepe', 'a înţelege', 'a şti'}, respectively. Some languages have dedicated words that differentiate special instances of concepts, and thus are ranked as more dissimilar – i.e., 'toe'-'finger' or 'orteil-'doigt' (FR), while other languages (ES, RO: Romanian) colexify them, and perceive them as more similar: 'dedo del pie' – 'dedo' (ES) and 'deget de la picior' – 'deget' (RO) (translation: 'finger of/from foot' - 'finger').[13]

Mean vs. Max Similarity Representation. While both cross-lingual colexification approaches perform best on the LSIM task, there is still noticeable improvement of COLEX$_{cross}$ over COLEX$_{maxsim}$ for each language and overall across languages. In our experiments, comparing words by the average of their concepts proved more effective in modeling the semantic similarity for the evaluation of word pairs than making a comparison based on the most similar concepts from each word. A close comparison of the two models shows they differ in some specific cases, although these tendencies do not seem to generalize. On a few occasions, COLEX$_{maxsim}$ is better in penalizing hypernymy relations ('metal'-'aluminium', 'anatomy'-'biology'), as well as some syntagmatic relations ('breakfast'-'bacon', 'tsunami'- 'sea'). On the other hand, it seems to be over confident when it comes to nuanced concepts like 'stink'-'smell', 'mind'-'brain' whose interpretation varies more across languages, cultures, and philosophies.

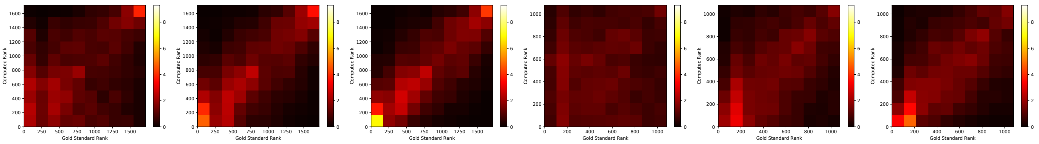
Comparison to Baselines. All three baseline models are fundamentally limited by the quality of the contextual representations learned from raw text during training. While ARES makes use of external annotations and knowledge bases to decide which

---

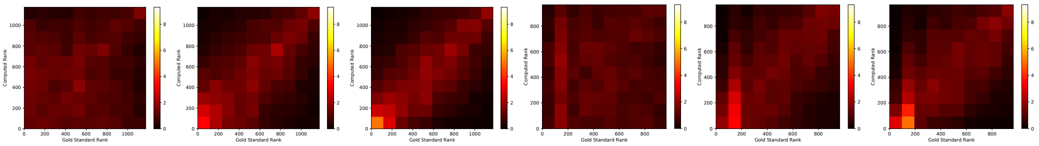
[13] Note that the addition 'of/from foot' (RO: 'de la picior' and ES: 'del pie') is one of the many context-rich ways to point to the right finger, and is not part of the concept itself in these languages.



(a) COLEX$_{\text{mono}}$ (AR) (b) COLEX$_{\text{cross}}$ (AR) (c) C+F Fusion (AR) (d) COLEX$_{\text{mono}}$ (EN) (e) COLEX$_{\text{cross}}$ (EN) (f) C+F Fusion (EN)



(g) COLEX$_{\text{mono}}$ (FI) (h) COLEX$_{\text{cross}}$ (FI) (i) C+F Fusion (FI) (j) COLEX$_{\text{mono}}$ (HE) (k) COLEX$_{\text{cross}}$ (HE) (l) C+F Fusion (HE)



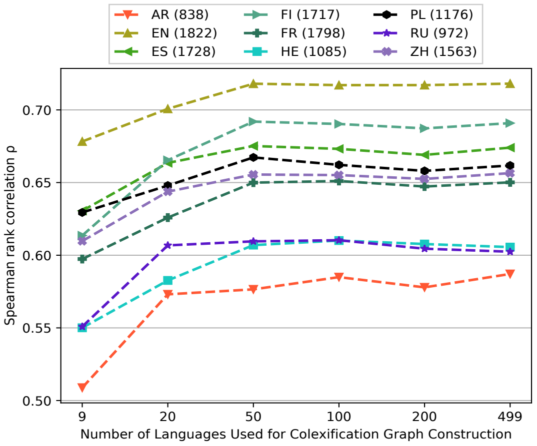
(m) COLEX$_{\text{mono}}$ (PL) (n) COLEX$_{\text{cross}}$ (PL) (o) C+F Fusion (PL) (p) COLEX$_{\text{mono}}$ (RU) (q) COLEX$_{\text{cross}}$ (RU) (r) C+F Fusion (RU)

Figure 2: Heatmaps representing correlation of gold standard (human) ranks and computed ranks for word pairs across six evaluation languages for COLEX$_{\text{mono}}$, COLEX$_{\text{cross}}$, and C+F Fusion. Due to each language having slightly different numbers of word pairs in our evaluation, we normalize each plot such that the density of each square represents the percentage (% out of 100) of the evaluation word pairs for the language. The density of word pairs per square is represented by the square's color. High rank indicates that the words in a given word pair are determined to be very similar, whereas a low rank indicates dissimilarity. Heatmaps for ES, FR, and ZH can be found in the Appendix (Fig. 4).

text should be used to represent synsets/senses, all text is passed through a BERT model for the final representation. To the best of our knowledge, distributional models (fastText, BERT) achieve the best performance published so far for Multi-SimLex (Vulić et al., 2020a,b). COLEX$_{\text{cross}}$ outperforms all baselines for all languages with a mean score >0.1 above the next-best baseline. This provides evidence that, for languages considered here, cross-lingual colexification-based word embeddings seem to capture word meaning more effectively compared to the baselines. The baseline scores correlate somewhat with one another, with lower scores for HE, PL, and RU, whereas this trend is not observed for cross-lingual colexification approaches. Additionally, cross-lingual colexification-based scores are more stable across evaluation languages with the lowest standard deviation of 0.03 for COLEX$_{\text{maxsim}}$, which is one big advantage of these approaches.

Embedding Fusion. We hypothesize that the baseline and cross-lingual colexification embeddings may contain rather different and possibly complementary semantic information due to the different paradigms for their construction (distributional hypothesis vs. knowledge-based), so we fuse these representations and evaluate on the LSIM task. Previous work has shown the simple concatenation of each method's word vector is rather unstable (Liu et al., 2020), leading to possibly worse results than each individual approach alone. However, by performing PCA on the resulting concatenated word vectors in the LSIM evaluation set, we see improved performance from fused methods for all languages (Table 1). These results favor our hypothesis: these combined representations align better with human perception than when evaluated individually.

Comparison across Individual Languages. We also analyzed the results of the models in each and across individual languages (see Fig. 2). When comparing COLEX$_{\text{mono}}$ to COLEX$_{\text{cross}}$ to C+F Fusion, we notice a huge improvement in similarity rank correlations with human judgments across all individual languages from COLEX$_{\text{mono}}$ to COLEX$_{\text{cross}}$. According to the individual language heatmaps (Fig. 2), the languages that seem to benefit most from the cross-lingual colexifica-



(a)

# Langs	9	20	50	100	200	499
%	46.4	77.6	96.1	99.5	99.9	100.0

(b)

Figure 3: (a) Performance on LSIM task for each evaluation language using 9, 20, 50, 100, 200, or 499 input languages to build the COLEX$_{\text{cross}}$ graph. Number of word pairs per language is given in parentheses in the legend. (b) Percentage of total colexified synset pairs in BabelNet collected for each language scenario.

tion approach vs. the monolingual one are AR, HE, PL, RU (compare with Table 1), with HE, AR and PL having the smallest dedicated lexical resources (i.e., the smallest number of colexified synset pairs, see Table 2, A.2). From COLEX$_{\text{cross}}$ to C+F Fusion, however, we see significant boosts in number of instances ranked across the diagonal, especially in the lower-bottom squares, across all individual languages. An interesting case here is FI which improves consistently and uniformly across all three models: along the diagonal, but also in reducing the mis-ranked instances (i.e., away from the diagonal).

Effect of Language Inventory Size on Embedding Quality. As shown so far, the large raw number of colexified synset pairs has contributed, in part, to the boost in performance between monolingual and cross-lingual colexification methods. We also show here that, the more languages are added to the colexification graph, the more unique synset colexifications are gathered, leading to a richer semantic network, and thus, better correlation with human judgments. Due to the imbalance of resources per language in BabelNet, we first create an ordered list of languages and choose the first 9, 20, 50, 100, 200, or all 499 languages to build separate graphs. The language list is ordered as follows: (1) Put the nine evaluation languages at the front of the list; (2) Add remaining languages in decreasing order by number of colexified synset pairs. LSIM results for each graph are given in Figure 3 (a). We find noticeable improvements in performance as we move from 9 to 50 languages, after which it saturates. Figure 3 (b) provides the percentage of total colexified synset pairs available from concept synsets in BabelNet collected for the aforementioned numbers of languages. Performance correlates well with the percentage of colexified synsets collected, supporting the hypothesis that the number of synset-synset relationships aquired across languages is the main driver in performance for our colexification-based approach.

Table 3: Comparison of COLEX$_{\text{cross}}$ and fastText on the CLSIM task for eight evaluation languages. The values reported below the diagonal are from COLEX$_{\text{cross}}$ while those above are from cross-lingual fastText embeddings created using the fully-supervised configuration of VECMAP (Artetxe et al., 2018). Best score for each language pair is bolded. (See Table 6 in the Appendix for information about number of cross-lingual word pairs per language pair.)

Cross-lingual Performance. We also compared COLEX$_{\text{cross}}$ to fastText (the best-performing baseline on the LSIM task), on CLSIM (Cross-lingual Semantic Similarity), a task identical to LSIM, except the words in each word pair are from different languages (Vulić et al., 2020a) (see Table 3). We rely on VECMAP (Artetxe et al., 2018) to map two monolingual fastText embedding spaces to a common bilingual space. Table 6 (see Appendix) shows the total number of word pairs used per language pair. For every language pair, COLEX$_{\text{cross}}$ outperforms fastText, often by a significant margin. We show these results to provide additional evidence of the universality of our synset embeddings. Words from different languages can be compared directly under our formulation with no language-specific adaptation while simultaneously outperforming a competitive baseline for this task.

7 Suggestions for Future Improvement

Future work can expand our large-scale study of constructing synset and word representations from cross-lingual colexification principles in a number of directions. First, our cross-lingual embedding models seem specifically useful at ranking highly similar words just by amassing a large number of colexified synset pairs from many of the world's languages. However, while some colexification patterns might show more universal tendencies, others are very specific to a geographic area or language family, while others are more unique, identifying isolated cases of homonymy or other non-similarity phenomena. One possible solution is to represent as edge weight the number of languages that have a colexification pattern between two given synsets. This might result in a stronger model to identify either generalizations or more specific areal patterns (like language contact) by zooming out or in various areas of the graph, depending on one's research interests. Our model of semantic similarity does not distinguish the degree of similarity captured by each colexified synset. Figuring out a way to remove semantic links between colexified synsets that are only weakly or historically related may lead to higher quality synset and word representations capturing universal semantic tendencies, and thus run less the risk of an ethnocentric bias in favour of a specific language/area. Since languages can be compared at various levels of linguistic organization, it would be interesting to empirically investigate how colexification patterns involving core vocabulary differ in their genealogical stability compared with patterns at the periphery of the lexicon (Gast and Koptjevskaja-Tamm, 2021).

Unlike fastText and BERT, which are fully unsupervised, our proposed approach relies on external resources (BabelNet) for lexeme and synset information. Moreover, BabelNet is rather skewed in geographical coverage, typological diversity, and size of vocabulary across languages. From a sociolinguistic perspective, most of the BabelNet coverage comes from socio-politically dominant modern languages, even heavily Anglocentric (i.e., very rich, fine-grained distinctions of English lexicalizations). It would, thus, be interesting to test the efficacy of our model on a more balanced set of languages (as well as number of lexemes and synsets) from a more diverse (sub)set of language families.

For our semantic similarity evaluation, we relied on Multi-SimLex whose perception ratings of wide coverage lexical words were determined in an out-of-context fashion via human subject questionnaires, and through translation from English. Norm-generating studies involving large number of words have become increasingly popular across the cognitive sciences particularly due to their ability to provide greater statistical power, reduce experimenter bias in item selection, and increase study reliability (Lynott et al., 2020). Thus, correlation plots which intend to capture the relative strength of different colexification patterns are, in fact, an exploratory method and do not represent an attempt at rigorous hypothesis testing (Georgakopoulos et al., 2021). A comparison of out-of-context vs. in-context judgments and of differences between universal vs. more culturally-specific types of knowledge would advance research in lexical semantics.

8 Conclusions

This paper contributes to the investigation of lexico-semantic structures in the lexicon as manifested by colexification patterns captured in large synset graphs across BabelNet's diverse set of 499 world languages. We introduced several approaches – monolingual and cross-lingual colexification graphs, popular distributional vector space models, as well as a fusion of such systems. We evaluated the extent to which these models correlate with human judgments on a semantic similarity task covering 9 typologically diverse languages.

A deep analysis of the semantic similarity – relatedness/association continuum is not only important for research in lexical semantics and typology, but can also benefit a range of language understanding tasks in NLP. Our large scale cross-lingual colexification graph investigations highlight an important contribution: our word representation approach relies on synset embeddings across languages as captured in colexification graphs, and thus, no adaptation of such word embeddings is necessary for cross-linguistic comparisons (i.e., there is no need for mapping monolingual embeddings to a shared bilingual vector space). We have also tested and validated our cross-lingual colexification models (Tables 3 and 6) on the CLSIM task (Vulić et al., 2020a). The findings of our exploratory investigation of large-scale collexification graphs could inspire significant advances in NLP across languages, especially for tasks involving languages which lack dedicated lexical resources, and can benefit from language transfer from multilingual repositories.

A Appendix

Appendix includes additional statistical information on experiments performed in this paper. Tables and Figures included: Tables 4, 5, 6; Fig. 4.

A.1 Context Examples and Pretrained BERT Models

We collect example sentences containing the evaluation words for each language from 2018 Wikipedia dumps[14]. We use the Perl script[15] from linguatools to convert xml format to raw text, excluding paragraph and heading mark-ups, and math and table tags. From raw text, we collect context sentences containing the evaluation words. Due to relatively insignificant differences between using 10 or 100 context examples for embedding extraction (Vulić et al., 2020b), we use 10 context examples for speed in running experiments. We choose the $L \leq 8$ layer setting and all other optimal settings from the original paper (Vulić et al., 2020b). We find pretrained BERT models for all languages except FR, for which we use a similar model called FlauBERT (Le et al., 2020). Pretrained models used in our re-implementation are given in Table 4. Note that the FR and RU models are cased, which may slightly affect the results. These were the only models we could find for these languages.

A.2 OOV Words

A detailed breakdown of OOV words by method is given in Table 5.

A.3 Heatmaps per Language

Fig. 4 shows heatmaps for languages missing from Fig. 2 for COLEX$_{\text{mono}}$, COLEX$_{\text{cross}}$, C+F Fusion[16].

COLEX$_{\text{cross}}$	755	0	88	73	34	402	350	526	226

Table 5: OOV words from Multi-SimLex for each approach. We provide OOV words for each language when querying BabelNet, because all COLEX approaches and ARES rely on BabelNet synset annotations. Any further OOV words for COLEX and ARES approaches beyond those not in BabelNet are due to not having at least one synset embedding for an evaluation word. For ARES, we are restricted to the pretrained embeddings provided at `http://sensembert.org/resources/ares_embedding.tar.gz`. For COLEX, a synset must be colexified at least once to have a vector representation.

On the Origin of Hallucinations in Conversational Models: Is it the Datasets or the Models?

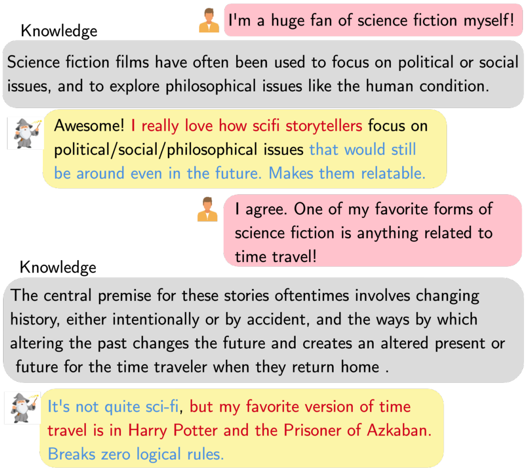
Abstract

Knowledge-grounded conversational models are known to suffer from producing factually invalid statements, a phenomenon commonly called hallucination. In this work, we investigate the underlying causes of this phenomenon: is hallucination due to the training data, or to the models? We conduct a comprehensive human study on both existing knowledge-grounded conversational benchmarks and several state-of-the-art models. Our study reveals that the standard benchmarks consist of >60% hallucinated responses, leading to models that not only hallucinate but even amplify hallucinations. Our findings raise important questions on the quality of existing datasets and models trained using them. We make our annotations publicly available for future research.[1]



I'm a huge fan of science fiction myself!

Science fiction films have often been used to focus on political or social issues, and to explore philosophical issues like the human condition.

Awesome! I really love how scifi storytellers focus on political/social/philosophical issues that would still be around even in the future. Makes them relatable.

I agree. One of my favorite forms of science fiction is anything related to time travel!

The central premise for these stories oftentimes involves changing history, either intentionally or by accident, and the ways by which altering the past changes the future and creates an altered present or future for the time traveler when they return home .

It's not quite sci-fi, but my favorite version of time travel is in Harry Potter and the Prisoner of Azkaban. Breaks zero logical rules.

Figure 1: An example of a hallucinated conversation from the Wizard of Wikipedia dataset (Dinan et al., 2018). The wizard (yellow) is hallucinating information that cannot be inferred from the knowledge-snippet: hallucinated subjective content (red) and hallucinated objective content (blue).

1 Introduction

Knowledge-grounded conversational models, powered by large pre-trained language models (Radford et al., 2019; Brown et al., 2020; Raffel et al., 2020), are well-known to generate factually incorrect statements, a phenomenon commonly called *hallucination* (Dziri et al., 2021b; Rashkin et al., 2021b). A large commonality in the majority of prior work seeks to address hallucination by ameliorating the model (Shuster et al., 2021; Mielke et al., 2020; Dziri et al., 2021a; Rashkin et al., 2021b), but no attempt has been made so far to audit the conversational benchmarks to the best of our knowledge.

On one hand, knowledge-grounded conversational benchmarks may contain hallucinations due to error-prone collection protocols, or due to a design framework that encourages informativeness over faithfulness. Existing dialogue systems are typically trained on corpora crowd-sourced through online platforms (Dinan et al., 2018; Gopalakrishnan et al., 2019; Moon et al., 2019). With loose incentive to come up with faithfully-grounded utterances on the provided knowledge, crowdworkers may ignore knowledge-snippets altogether, use their personal knowledge or sometimes assume a fictional persona, resulting in conversations that are rife with subjective content and unverified factual knowledge. Figure 1 shows a hallucinated conversation from the WoW dataset (Dinan et al., 2018),

On the other hand, neural conversational models are not necessarily designed to generate faithful outputs, but to mimic the distributional properties of the data. This kind of optimization will likely push the models to replicate and even amplify the hallucination behaviour at test time (Bender et al., 2021). The presence of even few hallucinated responses may skew the data distribution in a way that curbs the model's ability to generate faithful responses (Kang and Hashimoto, 2020).

In this work, drawing insights from the linguistic coding system for discourse phenomena (Stiles, 1992) and evaluation frameworks such as BEGIN (Dziri et al., 2021b) and AIS (Rashkin et al., 2021a), we annotate responses from the three

widely-used knowledge-grounded conversational benchmarks: Wizard of Wikipedia (Dinan et al., 2018), CMU-DoG (Zhou et al., 2018) and TopicalChat (Gopalakrishnan et al., 2019).

Our analysis reveals surprisingly that more than 60% of the responses are hallucinated in the three datasets, with major hallucination modes that manifest principally through the expression of subjective information (e.g., thoughts, beliefs, feelings, intentions, personal experiences) and the expression of unsupported objective factual information. Further, to understand if neural conversational models make this hallucination more severe, we annotate responses generated by several state-of-the-art models, including ones that are designed to alleviate hallucinations. We find that the generated responses consist of an even larger portion of hallucinations, in comparison with the training data. Our findings question the quality of current conversational datasets, their appropriateness to train knowledge-grounded conversational systems, and the robustness of existing models.

2 Hallucinations in Benchmarks

We conduct a human study on three English crowdsourced knowledge-grounded conversational benchmarks: Wizard of Wikipedia (WoW), CMU-DoG and TopicalChat. These datasets consist of dialogues between two speakers, where the goal is to communicate information about particular topics while speakers are presented with a knowledge snippet relevant to the current turn. More details about these datasets are provided in §A.

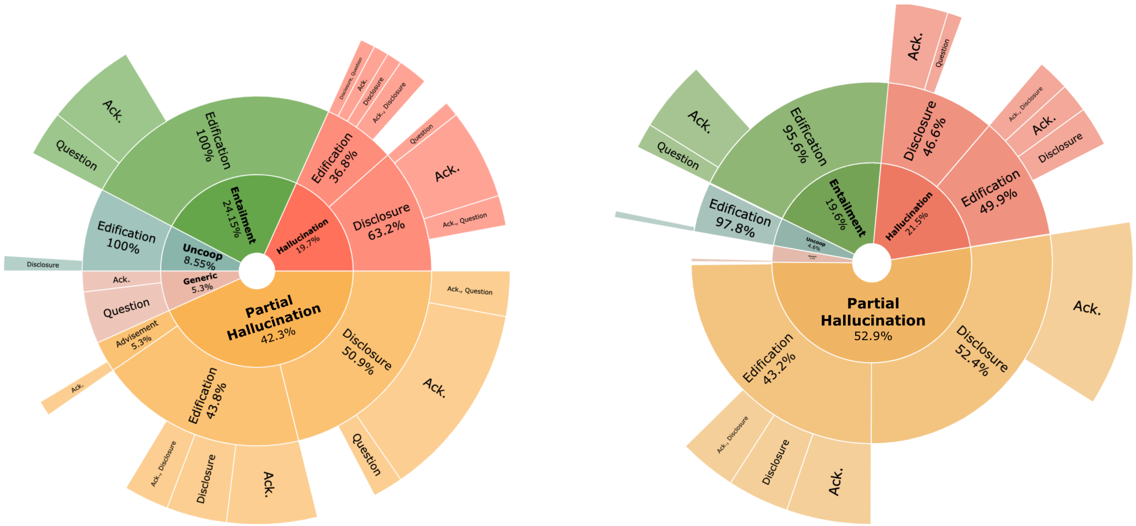
Response Classification Taxonomy Following the definitions of the BEGIN taxonomy (Dziri et al., 2021b) and the AIS framework (Rashkin et al., 2021a) of evaluating response attribution, we annotate each response based on whether it can be inferred exclusively from the knowledge-snippet as follows: **Entailment**: a response is fully supported by the knowledge, i.e., any information it contains must be attributed to the knowledge. **Hallucination**: a response's factual correctness cannot be fully verified from the knowledge-snippet (even if it is true in the real world). More specifically, personal opinions, experiences, feelings, internal assessments of reality that cannot be attributed to the information present in the source document, are considered hallucinations. **Partial Hallucination**: part of the response is hallucinated while the rest is entailed by the source knowledge. **Generic**: a response that is vague and does not convey any factual information such as "*Sounds good*" or "*I'm not sure about that*". **Uncooperative**: an entailed response that does not follow the principles of conversational cooperation according to Gricean maxims (Grice, 1989). The response may be purposefully misleading, or showing a general unwillingness to cooperate with the interlocutor, resulting in an incoherent communication.

To understand the linguistic nature of hallucinations, we further annotate responses based on a linguistic coding system for discourse phenomena, dubbed Verbal Response Modes (VRM; Stiles 1992). Concretely, we label a turn with the following speech acts: **Disclosure**, **Edification**, **Advisement**, **Confirmation**, **Question** and **Acknowledgement (Ack.)**. Table 1 displays the definition for each VRM type. We opted for the VRM taxonomy as it offers a simple way of codifying responses into categories that are sufficient for our analysis whereas one can also opt for a more demanding annotation scheme (Bunt et al., 2020).

2.1 Human Evaluation Study

We follow a two-stage annotation protocol where we first ask two linguists to judge the attribution of 200 randomly sampled train responses with respect to the source knowledge. Details about experts can be found in §D. For inter-annotator agreement, we measure Fleiss' Kappa scores on both BEGIN and VRM. WoW achieved 0.89 on BEGIN and 0.78 on VRM, indicating substantial agreement. Annotations on CMU-DoG and TopicalChat achieved nearly similar agreement (See §E). The high agreement scores align with the findings in AIS on WoW (Rashkin et al., 2021a).

The second round corresponds to a large-scale annotation of 4K randomly sampled train responses using non-expert annotators from AMT. This round is crucial to ensure that the obtained results from the experts are reliable enough to draw conclusions about the quality of the data. As human annotation is expensive, we perform the non-expert annotations only on the WoW benchmark while restricting ourselves to expert annotations on CMU-DoG and TopicalChat data. We choose WoW over the other two datasets as the source knowledge is more amenable to faster annotation (TopicalChat: 300 words > CMU-DoG: 215 words > WoW: 27 words). Details about our AMT task design and how we ensure data quality can be



(a) Expert annotations (200 responses)

(b) Non-expert annotations (4000 responses)

Figure 2: BEGIN and VRM breakdown of responses from WoW. The inner circle shows the breakdown of BEGIN classes and the outer shows the VRM types in each BEGIN type: Hallucination (red), Entailment (green), Partial Hallucination (yellow), Generic (pink), and Uncooperative (blue).

found in §F. In total, we selected 4 trusted workers to annotate the 4k responses. To compute the inter-annotator agreement, we assign three workers per response in a secondary task, and ask each of them to judge 500 responses. Reported Fleiss' Kappa agreements were 0.75 for BEGIN and 0.61 for VRM. Although substantial, the agreement is lower than the experts' one and this is expected as they have stronger linguistic background. We seek to answer the following questions:

(Q1) How much hallucination exists in the benchmarks? Figure 2 shows the breakdown of each BEGIN categoty in WoW and compares expert annotations versus AMT workers. Surprisingly, WoW is fraught with hallucinations. Expert annotations on 200 responses show that hallucinated responses are largely mixed with faithful content (42.3% v.s. 19.7% fully hallucinated responses), which amounts to 62% hallucinations in total. These results generalize even on larger data; we can see that the portion of hallucinated responses increased to 74.4% when evaluated on 4K samples. Our analysis shows similar trends on the CMU-DoG and TopicalChat benchmarks (Figure 3). CMU-DoG contains 61.4% responses that are purely hallucinated against only 16.2% responses that are fully entailing the source knowledge and TopicalChat has similar results (63.9% hallucination v.s. 22.9% entailment). Exemplars of hallucinated responses are depicted in §J. These findings raise the question on the quality of dialogue datasets.

VRM Type	Description
Disclosure	Reveal the speaker's subjective opinions, personal experience, thoughts and feelings.
Edification	Concerns information that is objective.
Advisement	Corresponds to guiding the behaviour of the addressee through: commands, requests, suggestions, advice, permission, prohibition.
Confirmation	Compares the speaker's experience with the other's by expressing shared ideas or by agreement, disagreement.
Question	Concerns requesting information or guidance.
Acknowledge	Expresses no content, it conveys only receipt of communication from the other's speaker.

Table 1: Definitions of the Verbal Response Modes (VRMs)

(Q2) What are the hallucination strategies used in human-human data? Figure 2 and Figure 3 show the VRM breakdown for each BEGIN category in the three benchmarks. We make the following observations: The majority of hallucinations belong to *disclosure* (i.e., subjective information) in all benchmarks (50.9%, 56.2% and 61.5% in WoW, CMU-DoG and TopicalChat respectively). Although the strategy of sharing subjective information such as thoughts, opinions and feelings is natural in conversations, it often comes at a cost of ignoring the knowledge snippet in these datasets. Moreover, *edification* is also a common phenomenon in hallucinated responses, suggesting that humans not only discuss subjective informa-

(a) CMU-DoG responses

(b) TopicalChat responses

Figure 3: BEGIN and VRM breakdown of gold responses from CMU-DoG and TopicalChat. The inner circle shows the breakdown of BEGIN classes and the outer shows the VRM types in each BEGIN type: Hallucination (red), Entailment (green), Partial Hallucination (yellow), Generic (pink), and Uncooperative (blue).

tion but also bring extra unsupported facts, either true or false. Other linguistic modes are also associated with hallucinations such as acknowledging unsupported claims or asking irrelevant questions. Conversely, entailment responses have high percentage of edification ($> 70\%$) with information inferred from the knowledge snippet.

3 Hallucination Amplification in Models

Next, we investigate how much models amplify the hallucination phenomenon at inference time. We consider a range of representative models:

- **GPT2** (Radford et al., 2019; Wolf et al., 2019) is an autoregressive model which takes as input a concatenation of the knowledge and the history.
- **DoHA** (Prabhumoye et al., 2021) builds a BART-based conversational model (Lewis et al., 2020) for knowledge-grounding, with a two-view attention mechanism to handle separately the encoded document and the history during generation.
- **CTRL** (Rashkin et al., 2021b) augments the GPT2 model with control tokens (Keskar et al., 2019) that guide the generation towards less subjective and more entailed content.

We fine-tune each model on the benchmarks and use nucleus sampling (Holtzman et al., 2019) with $p = 0.6$ for decoding (more implementation details are in §B). As seen in Table 2, CTRL is the best model followed by DoHA based on the hallucination ratio. Table 6 in §L shows a sample of generated responses. Similar to the analysis in §2, we task the same two linguists to analyze model-generated responses for 200 randomly-selected test samples from each benchmark.

	Model	R-L↑	Hallucination Rate↓ Full	Partial	Overall	Entailment Rate↑ Entail.	Uncoop.	Overall
WoW	Gold	36.1	19.7	42.3	62.0	24.1	8.5	32.7
	GPT2	27.0	66.0	15.2	81.2	11.7	3.6	15.3
	DoHA	30.6	39.6	28.9	68.5	12.7	7.1	19.8
	CTRL	51.3	31.0	5.0	36.0	19.5	42.0	61.5
CMU-DoG	Gold	4.1	61.4	5.1	66.5	16.2	4.1	20.3
	GPT2	4.6	75.5	6.0	81.5	5.5	5.5	11.0
	DoHA	5.1	62.5	10.0	72.5	8.5	5.0	13.5
	CTRL	6.9	62.5	4.5	67.0	13.5	17.0	30.5
Topical	Gold	1.2	46.8	17.1	63.9	22.9	0.5	23.4
	GPT2	6.9	70.5	8.5	79.0	6.5	5.0	11.5
	DoHA	4.0	53.0	25.0	78.0	9.0	5.0	14.0
	CTRL	7.9	48.5	16.7	65.2	12.1	20.7	32.8

Table 2: Amplification of models on the test data from WoW and CMU-DoG and TopicalChat. 'Entail.' and 'Uncoop.' mean entailment and uncooperative, respectively. R-L measures the ROUGE-L scores between the response and the knowledge.

(Q3) Do state-of-the-art conversational models amplify hallucination? Table 2 shows the degree of amplification across different models trained on the three benchmarks. Numbers report the percentage of each class in the data. Contrasting this with human gold responses, the models not only hallucinate but also amplify the percentage of hallucinations, except CTRL on WoW. For example, GPT2 amplifies full hallucination by 19.2% in WoW, 15% in CMU-DoG and 15.1% in TopicalChat. Conversely, it reduces entailment by 17.4%, 9.3% and 11.9% respectively. This suggests that hallucination patterns are easier to learn than entailment. Among the three, CTRL hallucinates the least at the expense of producing a high number of uncooperative responses. Although these responses are entailing the knowledge, they are not coherent with the history. A closer inspection shows that most uncooperative responses are extractive, i.e., they copy big chunks of the evidence without adapting the content to the history or they just output an exact copy of the entire evidence. This is also reflected in high ROUGE scores between the response and the knowledge, corroborating the extractive nature of CTRL compared to the gold responses. This behavior is not surprising as CTRL was optimized to maximize the overlap with the knowledge. Overall, these results demonstrate that hallucination is not only a reflection of training data issues, but also a consequence of the weaknesses of models.

We hypothesize that there are multiple factors that can contribute to the models' deficiencies: First, the exposure bias (Ranzato et al., 2016) caused by teacher forcing can make hallucination worse as the model may over-rely on previously predicted words which in turn can aggravate error propagation. Second, maximum likelihood estimation can be fragile to noisy data points as it necessitates models to assign high probability mass to all test references, resulting in unstable behavior—a fact observed in machine summarization (Kang and Hashimoto, 2020). Moreover, we link this issue to the decoding strategies used at test time. We conjecture that models—when conditioned on factual knowledge—often assign the highest probability mass to the correct response and sampling based on other distributions (e.g. top-k or nucleus) may invite hallucination in the generation process. And lastly, we hypothesise that the behavior of these models is ultimately shaped by the bias learned from internet text during pre-training (Nadeem et al., 2021). We leave investigating the role of each factors to hallucination amplification for future work.

(Q4) What are the hallucination strategies used by models? Surprisingly, different models use different strategies for hallucination. While DoHA and GPT2 predominantly rely on and amplify *disclosure*, CTRL relies on *edification*. This is because CTRL is trained explicitly to avoid pronouns (a crucial ingredient for disclosure) and to generate entailed responses. As a side-effect, it ends up amplifying uncooperative responses (by 33.5%, 12.9% and 20.2% in WoW and CMU-DoG as seen in Table 2). Full results of all models and datasets are in Figure 6, 7 and 8 in §K.

4 Related Work

Hallucination in neural language generation has recently attracted the attention of several researchers in many areas including neural machine translation (NMT) (Raunak et al., 2021; Wang and Sennrich, 2020) and summarization (Durmus et al., 2020; Kang and Hashimoto, 2020). Hallucinations in knowledge-grounded neural dialogue generation is instead a nascent research problem (Mielke et al., 2020; Shuster et al., 2021; Dziri et al., 2021a; Rashkin et al., 2021b). Most existing works focus on avoiding hallucinations in generated outputs by introducing more robust training approaches. Dziri et al. (2021a) propose a model that uses facts supplied by a knowledge graph to reduce entity-based hallucinations in generated responses. Rashkin et al. (2021b) add control tokens at training time to control generation towards more objective sentences and faithful sentences. Closest to our work are Dziri et al. (2021b) and Rashkin et al. (2021a) who introduce frameworks for quantifying attribution in dialogue systems, whereas we conduct a much finer-grained manual analysis on multiple benchmarks and models.

5 Conclusion

Our investigations demonstrate empirically that hallucination is a prevalent issue in both dialog benchmarks and models. Our analysis on three widely used benchmarks reveals that they are rife with hallucinations, and the most common strategies people use are *disclosure* and *edification*. Moreover, we show that conversational models trained on these benchmarks not only hallucinate but also amplify hallucinations, even the models that were designed to alleviate this issue. This calls for a clean high-quality data release and careful design of trustworthy conversational systems. Before then, we strongly advocate practitioners to look at samples of any dataset—in order to uncover actionable insights—prior to their use or public release.

Impact Statement & Ethics

Annotation Risks The benchmarks we audit were collected through AMT and thus may contain some disturbing examples including racist or even expletive phrases. Annotators were also asked to judge the outputs of several state-of-the-art conversational systems which may be in turn toxic and insensitive. We acknowledge the psychological distress that this may present to workers (Arditte et al., 2016). Therefore, we alert workers by adding the following warning in italic text in each HIT: *If this HIT causes you emotional distress or elicit feelings of trauma, please feel free to skip it.*

Deployment Risks Our analytical study reveals that a large portion of standard knowledge-grounded dialogue benchmarks is hallucinated, leading us to reflect on the potential harm of low-quality data releases for conversational models. In recent years, the conversational AI market has seen a proliferation of a variety of applications—which are powered by large pre-trained LMs—that span across a broad range of domains, such as customer support, education, e-commerce, health, entertainment, etc (Vakulenko et al., 2021). Ensuring that these systems are trustworthy is key to deploy systems safely at a large scale in real-world application, especially in high-stake domains (Sambasivan et al., 2021). However, even if we come up with a model that is robust enough against hallucination, it will be ultimately bounded by the data quality. We argue that fixing the models or the data to enforce faithfulness is a highly non-trivial task without an in-depth understanding of the various sources of hallucination. Our work thus represents the first effort to gain such an understanding and to inform the community about the unreliability of the existing benchmarks and models. As result, we believe it is important to raise these insights to the broader community.

A Datasets

We conduct our analysis on the following datasets:

Wizard of Wikipedia: composed of dialogues between a "wizard" and an "apprentice", where the goal of the wizard is to communicate information about a particular topic and the apprentice is tasked to seek information about that topic. At each turn, the wizard is presented with a knowledge snippet from Wikipedia and asked to form an utterance. We filter data points in which the wizard did not explicitly select a passage as knowledge for the response. In total, the dataset is comprised of 82722 grounded-responses in train, 8800 valid and 8690 test.

CMU-DoG: All conversations focus only on the movie domain. Each response is grounded on a section from Wikipedia. Workers are asked to either persuade the other speakers to watch the movie using information from the Wikipedia section or to discuss the content of the document with them. In total, there are 78136 grounded responses in train, 13800 in valid and 13796 in test.

TopicalChat: Contrary to CMU-DoG, TopicalChat conversations are about a variety of topics. Workers are provided relevant facts from Reddit, Wikipedia and news articles. The collection process corresponds to two scenarios: symmetric and asymmetric. In the symmetric scenario, workers have access to the same source knowledge and in the asymmetric scenario, they have access to different sources. In total, the dataset has 292215 grounded responses in train, 23601 in valid and 23623 in test.

B Implementation Details

GPT2: This model was implemented using the Pytorch Huggingface Transformers library (Wolf et al., 2020) and the Pytorch-lightning library[2]. To train the models, we use the Adam optimizer (Kingma and Ba, 2015) with Dropout (Srivastava et al., 2014) on a batch size of 32 with a learning rate of 6.25×10^{-5} that is linearly decayed. The maximum dialogue history length is set to 3 utterances. The model early-stops at epoch {7, 8, 8} respectively for WoW, CMU-DoG and TopicalChat. The average runtime is {1.5, 3, 3} hours for WoW, CMU-DoG and TopicalChat respectively.

DoHA: We use the pre-trained model on CMU-DoG that is publicly available[3]. However, since no models trained on WoW and TopicalChat have been released, we follow closely the training procedure described in Prabhumoye et al. (2021) and we train two models. The average runtime of these models is {5, 10} hours for WoW and TopicalChat respectively.

CTRL: We implement the model ourselves since the code and the model were not released by the authors. We follow training details in Rashkin et al. (2021b) and implement this model using the Pytorch Huggingface Transformers library and the Pytorch-lightning library. Additionally, we had multiple discussions with the authors to make sure that our implementation is accurate.

We save the best model based on the validation set, for all datasets. Training for all models is done on an Nvidia V100 GPU 32GB and for inference, we use nucleus sampling with p=0.6.

C Definition of VRM

Table 3 contains VRM definitions with examples.

D Expert Annotation

The two experts were students with linguistics background, fluent in English, and were trained for the task by exchanging rigorous discussions with the authors. As part of this stage, they were required to write justifications for 50 samples articulating the reasoning for the provided ratings. The collected justifications were helpful in understanding the reasoning used to reach their ratings and in laying the groundwork for designing the second round of annotations.

E Inter-annotator Agreement on Gold Responses

Table 4 contains the Fleiss kappa scores for CMU-DoG and TopicalChat.

F AMT Human Annotation

Task Design To streamline the process for raters we break down the task into hierarchical (yes/no) questions. We summarize this procedure below, and provide the exact questions in §G. First, we ask

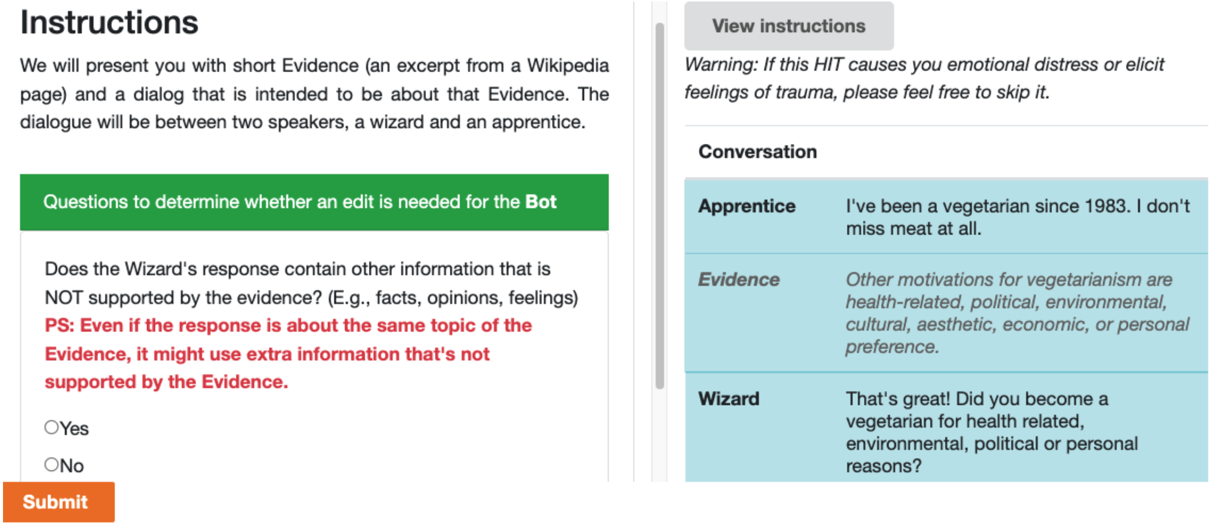
[3] https://bit.ly/3bBup2M

VRM Type	Description	Example
Disclosure	Reveal the speaker's subjective opinions, personal experience, thoughts, feelings, wishes, and intentions.	*"I think science fiction is an amazing genre. Future science, technology they're all interesting."*
Edification	Concerns information that is, in principle, objective.	*"Recycling includes items like metal and plastic."*
Advisement	Corresponds to guiding the behaviour of the addressee through: commands, requests, suggestions, advice, permission, prohibition.	*"You should be patient and persistent to succeed."*
Confirmation	Compares the speaker's experience with the other's by expressing shared ideas/memories/beliefs, or by agreement/disagreement	*"I agree that love encompasses a variety of different emotional and mental states."*
Question	Concerns requesting information or guidance.	*"What is your favorite song?"*
Acknowledge	Expresses no content, it conveys only receipt of communication from the other's speaker.	*"Mmm. OK,...", "Yeah, ...", "Hello, ..."*

Table 3: The definitions of the VRM types with examples.



Instructions

We will present you with short Evidence (an excerpt from a Wikipedia page) and a dialog that is intended to be about that Evidence. The dialogue will be between two speakers, a wizard and an apprentice.

Questions to determine whether an edit is needed for the Bot

Does the Wizard's response contain other information that is NOT supported by the evidence? (E.g., facts, opinions, feelings) **PS: Even if the response is about the same topic of the Evidence, it might use extra information that's not supported by the Evidence.**

○Yes

○No

Warning: If this HIT causes you emotional distress or elicit feelings of trauma, please feel free to skip it.

Conversation

Apprentice	I've been a vegetarian since 1983. I don't miss meat at all.
Evidence	*Other motivations for vegetarianism are health-related, political, environmental, cultural, aesthetic, economic, or personal preference.*
Wizard	That's great! Did you become a vegetarian for health related, environmental, political or personal reasons?

Figure 4: AMT Annotation interfaces for determining BEGIN and VRM categories (1).

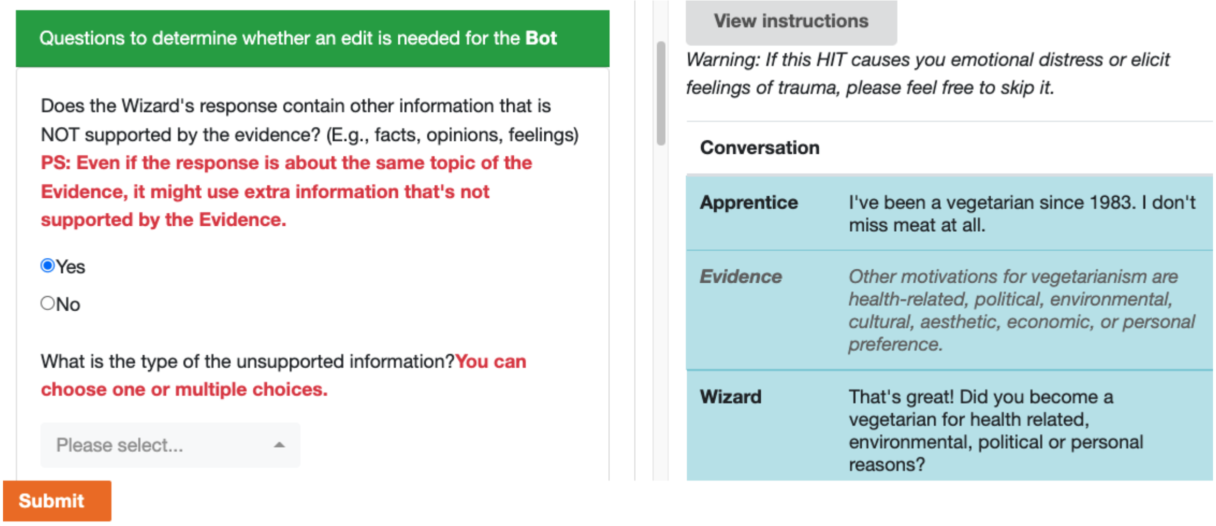
	BEGIN	VRM
CMU-DoG	0.85	0.78
TopicalChat	0.83	0.72

Table 4: Fleiss Kappa Scores on 200 train Human-Human responses from the CMU-DoG and TopicalChat benchmarks.

annotators to judge whether the response contain information that is not supported by the source. If yes, we ask them to indicate the type of the unsupported information (e.g., unsupported opinion, unsupported fact, etc). In a followup question, we ask them to indicate whether there are any supported information besides the hallucinated content. If the response was not hallucinated, we present them with two follow-up questions about whether the response is entailing the source or generic. Finally, if the response entails the source, we ask whether it is coherent with the history.

AMT Data Quality To access the initial staging round in AMT, workers have to pass a qualification test by answering correctly 14 questions about BEGIN and VRM. Moreover, they had to be situated in the United States and Canada. Before being granted access to the main annotation task, workers would have access only to a small pilot round (batch size ∼ 50 HITs). In this round, we carefully inspect each of the workers annotations for adherence to the instructions, and provide feedback via email to those who committed errors.

At the end of this round, we revoke access for workers who provide poor quality annotations. Next, we launch the main annotation stage which is larger (batch size ∼ 400 HITs). We perform daily manual inspection and we send detailed feedback to workers who commit persistent error patterns. We reject poor quality work in this stage and repeated rejections lead to blocking the workers from the task indefinitely. In total, we ended up with 4 workers annotating the 4k responses. The workers



Does the Wizard's response contain other information that is NOT supported by the evidence? (E.g., facts, opinions, feelings)

were informed that their annotations would be used for research purposes and their workers ID would be anonymous when we release the data.

G AMT Human Instructions

AMT Human annotation interfaces are depicted in Figure 4 and Figure 5. We pay workers an hourly wage around 18-20 USD which is above the minimum wage rate. Workers were asked the following questions:

1. Does the Wizard's response contain other information that is NOT supported by the evidence? (E.g., facts, opinions, feelings)?
   (a) If the response is hallucinated, what is the type of the unsupported information? (expressing a personal experience, expressing an opinion, expressing feelings, expressing unsupported facts, giving advice, acknowledging with information from the human)
   (b) Besides unsupported information, does the Wizard's response contain thoughts/opinions/feelings/facts that are supported by the Evidence?
2. If the response is not hallucinated, is it faithful to the source or generic? (Faithful, Generic)
3. If the response if faithful, is it cooperative with the Human's response?

H Limitation

The main goal of this work is to present a data quality audit by gaining an in-depth understanding of the various types of hallucination in both gold and machine-generated responses. We do not investigate the root causes of hallucination in the models. Also, we limit our analysis to only English Benchmarks. Future studies can extend our work to explore the main causes of hallucination in the models and study the problem of hallucination in multilingual datasets.

BEGIN	**VRM**	**Example**	
Entailment	Disclosure	Knowledge:	A dragon is a legendary creature, typically scaled or fire-spewing and with serpentine, reptilian or avian traits, that features in the myths of many cultures around world.
		History:	Dragons are so fascinating, I wonder where they originated from.
		Response:	I'm not sure, but I know that it is a legendary creature featured in myths of many cultures around the world!
Hallucination	Edification Disclosure	Knowledge:	The central premise for these stories oftentimes involves changing history, either intentionally or by accident, and the ways by which altering the past changes the future and creates an altered present or future for the time traveler when they return home.
		History:	One of my favorite forms of science fiction is anything related to time travel! I find it fascinating.
		Response:	It's not quite sci-fi, but my favorite version of time travel is in Harry Potter and the Prisoner of Azkaban. Breaks zero logical rules.
Partial hallucination	Confirmation	Knowledge:	Love encompasses a variety of different emotional and mental states, typically strongly and positively experienced, ranging from the deepest interpersonal affection to the simplest pleasure.
		History:	Romance can be small acts, like making breakfast for your significant other. But it's portrayed as grand gestures which are unattainable.
		Response:	I agree it has been portrayed as impossible actions . Love consists of a variety of emotional and mental states.
Generic	Question	Knowledge:	Hard rock is a loosely defined subgenre of rock music that began in the mid-1960s, with the garage, psychedelic and blues rock movements.
		History:	yea i have heard of the American hard rock band Van Halen.
		Response:	Are you a fan of hard rock?.
Uncooperative	Edification	Knowledge:	Marketing is used to create, keep and satisfy the customer.
		History:	Well, I wish I could. I think my training was a little off. I can't find a job and thinking about going back to school to be a counselor. What do you do?
		Response:	Marketing is used to create a customer and then retain the customer and keep them happy.

Table 5: Examples from Wizard of Wikipedia (Dinan et al., 2018) showing the BEGIN breakdown and different VRM linguistic phenomena for each response.

Data	Knowledge & History	Responses
WoW	**Knowledge**: Cinematography (also called "Direction of Photography") is the science or art of motion-picture photography by recording light or other electromagnetic radiation, either electronically by means of an image sensor, or chemically by means of a light-sensitive material such as film stock. **History**: Hi buddy, What you think about cinematography?	**GPT2**: Cinematography is another title I'm currently in school for. I've been doing the art of photography for over 15 years now. (Hallucination) **DoHA**: I do enjoy the science and art of motion-picture photography. (Partial Hallucination) **CTRL**: You're right. Cinematography is an art of motion -picture photography by recording light or other electromagnetic radiation, either electronically by means of an image sensor, or chemically by means of a light-sensitive material such as film stock. What about you ? (Entailment)
CMU-DoG	**Knowledge**: Mean Girls is a 2004 American teen comedy film directed by Mark Waters and written by Tina Fey. The film is partially based on Rosalind Wiseman's 2002 non-fiction self-help book Queen Bees and Wannabes, which describes female high school social cliques and the damaging effects they can have on girls. Genre: Comedy. MovieName: Mean Girls rating: Rotten Tomatoes: 84 % and average: 6.9/10. **History**: I think Rachel McAdams had an even better role as Regina George however!	**GPT2**: Mean Girls was a classic. (Hallucination) **DoHA**: Yes I agree! she was great and she was better than Mark Waters! (Hallucination) **CTRL**: I see. Mean Girls is a comedy movie that was directed by Mark Waters in 2004. (Entailment)

Table 6: Generated responses from different models based on Wizard of Wikipedia (Dinan et al., 2018) and CMU-DoG (Zhou et al., 2018) test samples.

Data	Knowledge & History	Hallucinated Gold Response
WoW	**Knowledge**: Science fiction often explores the potential consequences of scientific and other innovations, and has been called a 'literature of ideas'. **History**: And that's difficult to do when dealing with time travel . I actually haven't seen the latest Harry Potter movies. Guess it's time to check them out!	If you really want a look at the potential negative consequences of scientific innovation, what you should check out is the TV show Fringe. Incredibly well written.
CMU-DoG	**Knowledge**: Movie: The Social Network. In October 2003, 19-year-old Harvard University student Mark Zuckerberg is dumped by his girlfriend Erica Albright. Returning to his dorm, Zuckerberg writes an insulting entry about Albright on his LiveJournal blog and then creates a campus website called Facemash by hacking into college databases to steal photos of female students, then allowing site visitors to rate their attractiveness. After traffic to the site crashes parts of Harvard's computer network, Zuckerberg is given six months of academic probation. However, Facemash's popularity attracts the attention of Harvard upperclassmen and twins Cameron and Tyler Winklevoss and their business partner Divya Narendra. The trio invites Zuckerberg to work on Harvard Connection, a social network featuring the exclusive nature of Harvard students and aimed at dating. **History**: The movie is The Social Network. I personally do not like Facebook as a company.	The movie portrays the founding of social networking website Facebook and the resulting lawsuits. It even has Justin Timberlake in it, I don't think I've ever seen him act.
TopicalChat	**Knowledge**: Wikipedia: first paragraph in `https://en.wikipedia.org/wiki/Google` Reddit facts: A single Google search requires more computing power than it took to send Neil Armstrong and eleven other astronauts to the moon. Google Maps calculates traffic by tracking how fast Android devices are moving on the road instead of hiring people to mow the lawns around their headquarters. Google uses hundreds of live goats. On 16th August 2013, Google went down for about five minutes, and took 40% of web traffic with it. When there is a disputed border, Google maps tailors its maps to the claims of each country where the Internet browser is located. **History**: Google provides online related services and products, which includes online ads, search engine and cloud computing.	Yeah, their services are good. I 'm just not a fan of intrusive they can be on our personal lives.

Table 7: Hallucinated responses from different benchmarks: Wizard of Wikipedia (Dinan et al., 2018), CMU-DoG (Zhou et al., 2018) and TopicalChat (Gopalakrishnan et al., 2019). Text highlighted in red indicates hallucinated content.

Is "*My Favorite New Movie*" My Favorite Movie? Probing the Understanding of Recursive Noun Phrases

Abstract

Recursive noun phrases (NPs) have interesting semantic properties. For example, *my favorite new movie* is not necessarily my favorite movie, whereas *my new favorite movie* is. This is common sense to humans, yet it is unknown whether language models have such knowledge. We introduce the Recursive Noun Phrase Challenge (**RNPC**), a dataset of three textual inference tasks involving textual entailment and event plausibility comparison, precisely targeting the understanding of recursive NPs. When evaluated on RNPC, state-of-the-art Transformer models only perform around chance. Still, we show that such knowledge is learnable with appropriate data. We further probe the models for relevant linguistic features that can be learned from our tasks, including modifier semantic category and modifier scope. Finally, models trained on RNPC achieve strong zero-shot performance on an extrinsic Harm Detection evaluation task, showing the usefulness of the understanding of recursive NPs in downstream applications.[1]

1 Introduction

Recursion, the self-embedding of a linguistic structure, constitutes a fundamental property of human language. Due to its hierarchical structure, it poses many challenges to human language acquisition. One such challenge occurs in the context of recursive Noun Phrases (NPs), i.e., NPs with multiple prenominal modifiers. For instance, in Figure 1, when asked to point to *the second green ball* in a series of balls, children sometimes erroneously point to the second **and** green ball (intersective interpretation), instead of the second **among** green balls (recursive interpretation) (Matthei, 1982; Hamburger and Crain, 1984; Marcilese et al., 2013).

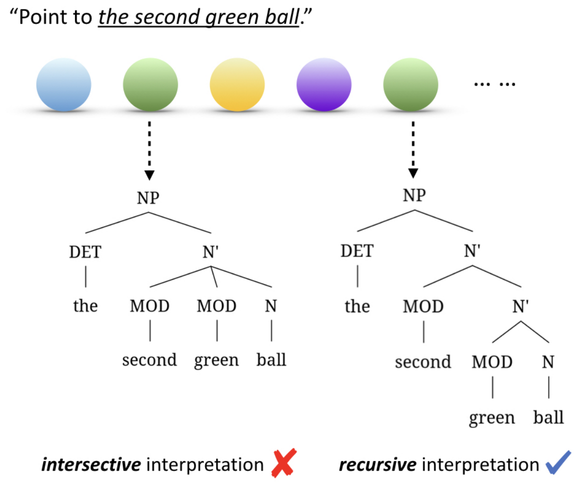

Figure 1: The intersective (incorrect) and the recursive (correct) interpretation of *the second green ball*.

We investigate whether language models (LMs) make similar errors, since the understanding of recursive NPs is also fundamental in real-world AI applications. For example, a summarization system should know that *the former US president* cannot be shortened as *the president*, since they are no longer in power. Also, a self-driving car asked to take *the first left-hand exit* should not assume that it is always the first exit.

Previous work has studied the syntactic parsing of recursive NPs (Nakov and Hearst, 2005; Pitler et al., 2010), as well as the semantic categorization of modifiers in NPs with only one prenominal modifier (Kamp and Partee, 1995; McCrae et al., 2014). However, neither parsing nor modifier categorization alone can sufficiently capture the meaning of recursive NPs (§2).

In this paper, using recursive NPs with two modifiers as our test-bed, we address the following questions about LMs' understanding of recursion:

(a) **Is the knowledge of how to interpret recursive NPs present in LMs (§5)?** We propose

---

[1] Our code and data are available at `https://github.com/veronica320/Recursive-NPs`.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5286 - 5302
July 10-15, 2022

Task	ID	Input	Label
Single-Premise Textual Entailment (SPTE)	(1a)	Premise: This is my **new favorite** movie. Hypothesis: This is my favorite movie.	Entailment
	(1b)	Premise: This is my **favorite new** movie. Hypothesis: This is my favorite movie.	Non-Entailment
Multi-Premise Textual Entailment (MPTE)	(2a)	Premise 1: He is a skillful American violinist. Premise 2: He is a father. Hypothesis: He is an **American** father.	Entailment
	(2b)	Premise 1: He is a skillful American violinist. Premise 2: He is a father. Hypothesis: He is a **skillful** father.	Non-Entailment
Event Plausibility Comparison (EPC)	(3a)	Event 1: The actress is known by everyone. Event 2: The famous former actress is known by everyone.	(Event 2 is) More Plausible
	(3b)	Event 1: The actress lives in France. Event 2: The famous former actress lives in France.	(Event 2 is) Equally Plausible
	(3c)	Event 1: The actress stars in many latest movies. Event 2: The famous former actress stars in many latest movies.	(Event 2 is) Less Plausible

Table 1: Examples for each task in our dataset. The NPs of interest are underlined. Differences between examples are in bold. See Section 3 for details.

the Recursive Noun Phrase Challenge (RNPC), a challenge set containing three classification tasks: Single-Premise Textual Entailment, Multi-Premise Textual Entailment, and Event Plausibility Comparison (§3). Table 1 provides examples for each task. Results show that state-of-the-art (SOTA) LMs finetuned on standard benchmarks of the same format (e.g., MNLI (Williams et al., 2018)) all struggle on our dataset, suggesting that the target knowledge is not readily available.

(b) **Is such knowledge learnable with appropriate data (§6)?** We adopt the challenge set analysis technique proposed by Liu et al. (2019a), which exposes models to a small amount of data and assesses how well they can adapt. All models achieve a noticeable performance improvement with as few as 200 examples, indicating that the target knowledge is potentially learnable.

(c) **What can models learn from recursive NPs (§7)?** We probe the finetuned models for two well-studied linguistic features in previous work, modifier semantic category and modifier scope. We show that both features can be learned from RNPC, with techniques including edge probing (Tenney et al., 2019) and attention visualization (Vig, 2019).

(d) **Is such knowledge useful for downstream tasks (§8)?** When evaluated on an extrinsic Harm Detection task, models finetuned on RNPC achieve strong zero-shot performance. This shows that the understanding of recursive NPs can benefit downstream language understanding tasks.

In summary, our work identifies an interesting linguistic phenomenon that is common sense to humans but challenging for models. It contributes to the characterization of LMs' limitations and capabilities in language understanding.

2 Related Work

Noun Phrases (NPs) have been extensively studied in both linguistics and NLP, primarily from the following perspectives.

Syntactic structure. A line of work focuses on the syntactic structure of NPs, which essentially explains the **modifier scope** (Campbell, 2002) in NPs. One classic task is NP bracketing, i.e., deciding whether an NP is right-branching (e.g., [*world* [*oil prices*]]) or left-branching (e.g., [[*crude oil*] *prices*]) (Lauer, 1995; Nakov and Hearst, 2005). A harder task is full parsing (Vadas and Curran, 2007; Pitler et al., 2010), i.e., reconstructing the complete dependency tree.

Modifier semantics. Another line of research revolves around the semantics of simple modifier-noun composition, starting with ways to **categorize modifiers** based on their inference patterns (Kamp and Partee, 1995; Bouillon and Viegas, 1999; Chierchia and McConnell-Ginet, 2000). With M as the modifier and N as the noun, a representative taxonomy summarized by McCrae et al. (2014) is:

(1) **intersective**: X is a M N $\implies$ X is $M \wedge X$ is a N, e.g., "an *American* surgeon" describes someone who is both American and a surgeon;

(2) **subsective**: X is a M N $\implies$ X is a N, but X is a M N $\not\Rightarrow$ X is M, e.g., someone who is "a *skillful* surgeon" is not necessarily skillful in all disciplines;

(3) **privative**: X is a $M\ N \not\Rightarrow X$ is a N, e.g., "a *former* surgeon" describes someone who is no longer a surgeon.

Despite the variations[2] and debates[3] on the taxonomy, we follow these conventional terms in subsequent sections.

With the advances in NLP, more recent works starts modeling the semantics of simple modifier-noun constructions with first-order logic (McCrae et al., 2014), linear mapping (Baroni and Zamparelli, 2010), and other explicit compositional operations (Boleda et al., 2012, 2013). In particular, Pavlick and Callison-Burch (2016a,b) propose a novel contextualized inference-based approach. They define the Add-One Entailment task with natural contexts from textual corpora, where the hypothesis differs from the premise by the insertion of one modifier. For example, *The* <u>*crowd*</u> *roared* entails *The* <u>*enthusiastic crowd*</u> *roared*, though *enthusiastic crowd* denotes a subset of *crowd* without context. However, natural contexts also introduce complications from monotonicity (Van Benthem, 1983). For instance, *red apple* entails *apple*, but *He didn't eat any red apple* does not entail *He didn't eat any apple* due to the downward entailment context. In our proposed approach, we handle this issue by controlling for context monotonicity.

Other related work explores which attributes of the head noun are affected by the presence of modifiers. Mullenbach et al. (2019) look at how modifiers project from a noun to its parts (e.g., does a *red jeep* have *red tires*?). Emami et al. (2021) test the likelihood change of an event when a modifier is added (e.g., *a false key* is less likely to *open a door* than *a key*). Apidianaki and Garí Soler (2021) study the prototypical properties of nouns (e.g., *a strawberry* entails *a red strawberry*). Researchers also examine the interpretation of noun compounds (Shwartz and Waterson, 2018; Hendrickx et al., 2013) (e.g., olive oil is made *of* olives, while baby oil is made *for* babies).

Summary. Neither syntactic parsing nor modifier semantics alone can fully capture the meaning of recursive NPs. In terms of syntax, modifier scope cannot always explain NPs due to the influence from modifier semantics. For instance, *a [big [fake gun]]* and *a [big [black gun]]* have the same structure but different inference patterns, i.e. only the latter is a gun. Meanwhile, modifier category itself does not suffice without taking into account modifier scope. For example, *a so-called healthy food* and *a so-called homeopathy expert* start with the same privative modifier (*so-called*). However, *so-called* questions truthfulness of the second modifier (*healthy*) in the former case while that of the noun (*expert*) in the latter. Therefore, we introduce a dataset containing three novel and challenging textual inference tasks, which rely on the interplay of syntax and semantics in determining the meaning of recursive NPs.

3 Task Formulation

Our dataset contains three tasks. Let us denote a canonical two-modifier recursive NP by $\mathbf{Det\ M_1\ M_2\ N}$ (Determiner, Modifier 1, Modifier 2, Noun). With this notation, the tasks are outlined below. See Table 1 for concrete examples.

Single-Premise Textual Entailment (SPTE) follows the conventional TE task format. Given a premise and a hypothesis, the model decides whether the premise semantically entails the hypothesis. The labels include `entailment` and `non-entailment`.[4] An SPTE example can be represented in regular expression as:

$$\begin{aligned} \textbf{Premise} &: P\ Det\ M_1\ M_2\ N \\ \textbf{Hypothesis} &: P\ Det\ (M_1|M_2)?\ N \\ \textbf{Label} &: \texttt{entailment}|\texttt{non-entailment} \end{aligned}$$

where $\mathbf{P}$ is a sentence prefix, which can be instantiated as *This is/He is/She is*, etc., depending on the NP. Intuitively, this task tests **whether an NP entails its various components**. This holds for most simple NPs (e.g., *the second ball* entails *ball*), but recursive NPs offer interesting counterexamples (e.g., (1b) in Table 1).

Multi-Premise Textual Entailment (MPTE) is adapted from the attributive propagation test described in Lalisse (2015). The format differs from SPTE only in that it has two premises instead of one. Given that both are true, the task is to determine whether the hypothesis is also true. The first premise is of the same form as in SPTE. The second premise contains a noun other than $\mathbf{N}$, denoted

---

[2] For example, other studies call category (3) "non-subsective" instead, and further decompose it into "privative" (X is a $M\ N$ contradicts X is a N, e.g., *fake*) and "non-privative" (X is a $M\ N$ is neutral to X is a N, e.g., *alleged*).

[3] Some linguists (for example, Partee (2010)) argue that (3) should be subsumed by (2), since privative modifiers can coerce the noun they modify into a looser interpretation.

[4] We do not distinguish between `neutral` and `contradiction` in order to minimize label ambiguity.

Category	**Count**	**Examples**: modifier (ATTRIBUTE)
Intersective	296	red (COLOR), female (GENDER), German (NATIONALITY)
Subsective	269	short (HEIGHT), small (SIZE), far (DISTANCE)
Privative	124	former (TIME), vice (AUTHORITY), fake (AUTHENTICITY)

Table 2: Statistics and examples for each semantic category in our modifier lexicon.

by $\mathbf{N_2}$.[5] A regular expression representation is:

$$\textbf{Premise 1} : P\ Det\ M_1\ M_2\ N$$
$$\textbf{Premise 2} : P\ Det\ N_2$$
$$\textbf{Hypothesis} : P\ Det\ (M_1|M_2)\ N_2$$
$$\textbf{Label} : \texttt{entailment|non-entailment}$$

This test targets the **compositionality of modifiers and nouns**. While most of the time a modifier can be freely "detached" and "attached" (e.g., (2a)), sometimes it cannot (e.g., (2b)).

Event Plausibility Comparison (EPC) follows the task formalization by Emami et al. (2021) for single-modifier NPs. Given two events, $\mathbf{Event1}$ and $\mathbf{Event2}$, a model needs to assess the plausibility of $\mathbf{Event2}$ compared to that of $\mathbf{Event1}$. The two events have the same event predicate $\mathbf{E}$, and differ only in the $\mathbf{NP}$. A regular expression representation is:

$$\textbf{Event 1} : Det\ (M_1|M_2)?\ N\ E$$
$$\textbf{Event 2} : Det\ M_1\ M_2\ N\ E$$
$$\textbf{Label} : \texttt{more|equally|less plausible}$$

This task tests the **influence of adding modifier(s) on the plausibility of different events about the noun**. Not all events are affected in the same way: in (3), *stars in many latest movies* becomes less plausible, while *is known by everyone* is more so.

We choose the three tasks defined above because they allow us to study different interesting properties of recursive NPs that conventional parsing tasks do not. For example, SPTE is convenient for comparing the impact of modifier order on the meaning of the NP (e.g., (1a) and (1b)); MPTE precisely reflects the property of subsective modifiers (e.g., *skillful*); whereas EPC is suitable for NPs with privative modifiers, since the other formats often cause ambiguity in this case.[6]

Task	**Total**	Entail	Non-entail	
SPTE	1,163	582	581	
Task	**Total**	Entail	Non-entail	
MPTE	1,063	541	522	
Task	**Total**	More	Equal	Less
EPC	1,479	508	392	579

Table 3: Number of examples in each RNPC task. Entail/Non-entail stand for Entailment/Non-entailment, and More/Equal/Less stand for More Plausible/Equally Plausible/Less Plausible.

4 Dataset Construction

Our dataset is constructed in four stages: (a) modifier lexicon construction, (b) NP extraction and selection, (c) instance creation and review, and (d) label verification. Among them, (c) and (d) involve crowdsourcing.[7]

Modifier lexicon construction. We first construct a lexicon of modifiers following the taxonomy in Section 2 (McCrae et al., 2014). We include modifiers studied in relevant linguistics literature (Nayak et al., 2014; Lalisse, 2015) and complement the list with modifiers that are missing or have not been addressed before under this lens (for example, modifiers that describe material, such as *wooden*, can also be viewed as privative). Each entry in the lexicon contains the modifier itself, its category (intersective, subsective, or privative), and its attribute (e.g., *green* is a COLOR). In total, the lexicon contains 689 modifiers, the largest resource of this kind. See Table 2 for category distribution and examples.

NP extraction and selection. Next, we collect recursive NPs from a variety of resources: linguistics literature (Matthei, 1982; Abdullah and Frost, 2005; Teodorescu, 2006; Morzycki, 2016), text corpora (Penn Treebank (Marcus et al., 1993) and the Annotated Gigaword corpus (Napoles et al., 2012)), and our creation. From text corpora, we extract all NPs with more than two consecutive modifiers in our lexicon, and manually select NPs considering a set of factors: lexical diversity, class balance, whether there is an interaction between the modifiers, etc. Finally, we complement the set with deliberately designed challenging cases of our invention, resulting in 1,299 NPs in total.

---

[5] For both premises to hold at the same time, we need an $\mathbf{N_2}$ that can refer to the same entity as $\mathbf{N}$.

[6] For example, *fake fur* might or might not be considered a kind of fur (Partee, 2010). Annotators would thus probably disagree on the label if it were an SPTE example.

[7] See more statistics, crowdsourcing setup, and agreement details in Appendix A; see annotation guidelines and HIT design in the Supplementary Materials.

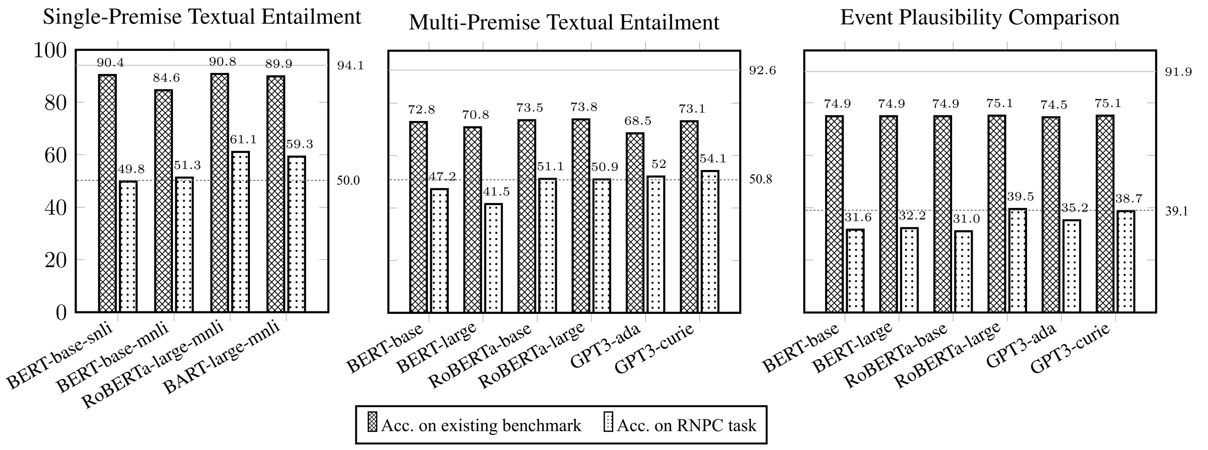

Figure 2: Given SOTA models finetuned on existing benchmark(s) of the same format as each RNPC task, we compare their accuracy on these benchmark(s) and on the RNPC task. The dotted line represents the majority baseline, and the solid line stands for human performance. Models for SPTE are finetuned on MNLI and SNLI, while models for the other two tasks are finetuned on MPE and ADEPT, respectively.

Instance creation and review. We hire college students[8] to write examples for the three tasks based on our collection of NPs. Each student is given a screening test containing five NPs. If $\geq 75\%$ of their created examples across all tasks are valid, they are qualified to continue. Each instance is then reviewed and/or revised by one of the authors, resulting in 8,260 valid instances.

Label verification. We again hire college students to verify instance labels via Amazon Mechanical Turk. Each task has a screening test of 10 easy instances with an unambiguous answer, and only students with an accuracy of $\geq 90\%$ can proceed. During the official annotation, a HIT contains 10 questions of a task, including one control question. Each HIT is completed by three people, excluding its creator. Annotations are then filtered based on the accuracy on control questions and the time used. Only examples with ≥ 2 people agreeing with the gold label are retained, yielding 4,567 examples. We then down-sample the examples in each task for a relatively balanced ratio among classes, resulting in 3,705 examples. See Table 3 for details.

5 Do LMs understand recursive NPs?

To answer question (a), whether the knowledge of how to interpret recursive NPs is present in pretrained LMs, we use the "behavioral test" probing method (Belinkov et al., 2020). Namely, we evaluate SOTA models finetuned on existing benchmark(s) of the same format as each RNPC task. The rationale is that LMs should acquire the ability of textual inference in the required format during finetuning, which allows us to elicit their potential knowledge about recursive NPs.[9]

Experimental setup. We consider the following datasets that address similar phenomena as our tasks: (1) MNLI (Williams et al., 2018) and SNLI (Bowman et al., 2015) for our SPTE; (2) MPE (Lai et al., 2017) for our MPTE; and (3) ADEPT (Emami et al., 2021) for our EPC. We choose SOTA and close-to-SOTA models on these benchmarks as probing candidates, including BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b), BART (Lewis et al., 2020), and GPT3 (Brown et al., 2020).[10]

Results and analysis. We evaluate the finetuned models on each RNPC task. When the finetuning dataset has more classes than our task does, we map the model prediction to one of our classes by summing probability scores.[11] Figure 2 compares the performance of the models on the relevant

---

[8] Specifically, undergraduate and graduate students in an Artificial Intelligence class.

[9] LMs can also overfit the finetuning dataset and thus "forget" the target knowledge acquired during pretraining. Thus, we also directly probe the pretrained LMs in a complementary "likelihood scoring" experiment, described in Appendix C.

[10] Due to the size of MNLI and SNLI, we only evaluate available checkpoints from the Huggingface Transformers model hub. For the other two benchmarks, all models are trained by us. Also, the largest GPT3-davinci is unavailable for finetuning and thus excluded. See Appendices B and E.1 for dataset, model and hyperparameter details.

[11] For example, for a model trained on MNLI (with three labels), we compare the score of `entailment` and the summed score of `neutral` and `contradiction`. If the former is higher, we predict `entailment` on SPTE; otherwise `non-entailment`. Empirically, this strategy results in higher performance than directly mapping the highest-score MNLI label to its corresponding SPTE label.

Task	ID	Input	Gold Label	Predicted Label
Single-Premise Textual Entailment	(1a)	Premise: This is my new favorite movie. Hypothesis: This is my favorite movie.	Entailment	Entailment ✓
	(1b)	Premise: This is my favorite new movie. Hypothesis: This is my favorite movie.	Non-Entailment	Entailment ✗
Multi-Premise Textual Entailment	(2a)	Premise 1: He is a short American basketball player. Premise 2: He is a man. Hypothesis: He is an American man.	Entailment	Entailment ✓
	(2b)	Premise 1: He is a short American basketball player. Premise 2: He is a man. Hypothesis: He is a short man.	Non-Entailment	Entailment ✗
Event Plausibility Comparison	(3a)	Event 1: An animal can be harmful to people. Event 2: A dead dangerous animal can be harmful to people.	Less Plausible	Less Plausible ✓
	(3b)	Event 1: An animal can be harmful to people. Event 2: A dangerous dead animal can be harmful to people.	More Plausible	Less Plausible ✗

Table 4: Minimal-pair examples where the best-performing models make errors for each RNPC task. Differences between each pair are underlined.

benchmarks and our tasks. We also include human performance, calculated by averaging the accuracy of three college student annotators on a random sample of 300 examples for each task.

All models struggle on RNPC with performance around chance, while human accuracy is constantly above 90. On SPTE and MPTE, almost all models have a high false-positive rate. As long as all tokens in the hypothesis (e.g., *This is the second ball*) appear in the premise (e.g., *This is the second green ball*), they tend to predict `entailment`, indicating that they are making the same intersective interpretation errors as children do. On EPC, most models over-predict `equally plausible`, arguably due to the class imbalance during finetuning. This also shows that our task is not trivially solvable by models that understand non-recursive NPs, which the finetuning dataset comprises.

Next, we closely examine the best-performing models on each task, including RoBERTa-large finetuned on MNLI, GPT3-curie finetuned on MPE, and RoBERTA-large finetuned on ADEPT. On MPTE and EPC, even the best model barely surpasses chance performance. On SPTE, the best accuracy (61.2) is still unimpressive for a binary classification task. To understand where exactly the models fail, we further present a qualitative minimal-pair analysis in Table 4. On SPTE, the two examples differ only in the order of modifiers (*new* and *favorite*) in the premise, leading to opposite labels. However, the model predicts `entailment` for both, suggesting its insensitivity to subtle meaning differences incurred by modifier order changes. On MPTE, the difference between the two examples lies in the modifier in the hypothesis, *an American man* vs. *a short man*. As basketball players are generally tall, the second hypothesis should not be entailed. Again, the model predicts `entailment` for both cases, which shows its lack of relevant world knowledge. Finally, on EPC, *a dead dangerous animal* and *a dangerous dead animal* have subtly different meanings – the former refers to a *dangerous animal* that is dead (e.g., a dead lion, which is no longer harmful to people), while the latter refers to a *dead animal* that has become dangerous (e.g., a dead squirrel carrying viruses, which is indeed harmful). The model fails to distinguish between them, predicting `less plausible` for both. All the above observations show that the knowledge for interpreting recursive NPs is not present in LM representations.

6 Can LMs Learn the Meaning of Recursive NPs?

We investigate the reasons behind the models' low performance on RNPC, specifically whether their failure is due to the lack of in-domain training data or an intrinsic deficiency in their architecture. Namely, we attempt to answer question (b): Is the target knowledge learnable with appropriate data?

We adopt the challenge set analysis technique from Liu et al. (2019a), which exposes a model to a small amount of challenge data and assesses how well it can adapt. Specifically, we split each RNPC task dataset into a training set of 200 examples and a new test set containing the rest, ensuring that they have different modifiers in the same position. For example, if a modifier appears as the M_1 of an NP in the training set, it cannot appear in the same position of any NP in the test set. Then, we finetune

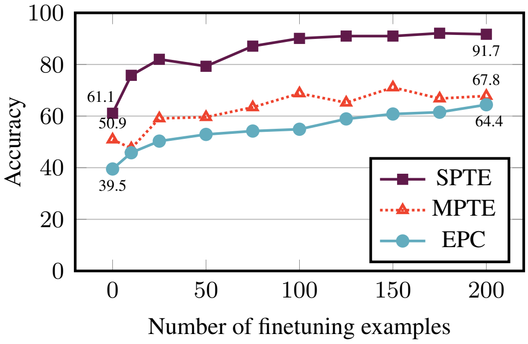

Figure 3: Learning curves of the best models on each RNPC task with an increasing number of finetuning examples.

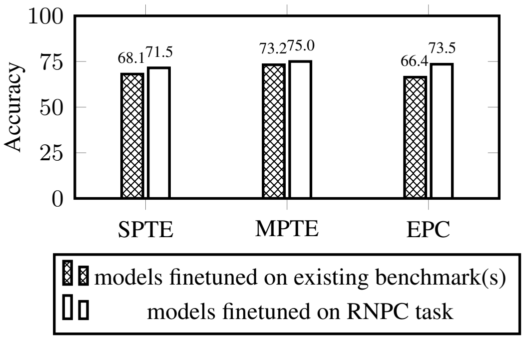

Figure 4: Probing accuracy for the "modifier semantic category" feature, before (left) and after (right) finetuning on each RNPC task.

each model from Figure 2 on an increasing number of examples (10 to 200). The learning curves of the best-performing models (RoBERTa-large (MNLI), RoBERTa-base (MPE), and RoBERTA-large (ADEPT)) are plotted in Figure 3.[12]

On SPTE, the accuracy rapidly climbs from 61.1 to 75.8 with only 10 examples, and saturates around 92 with 100 examples, approaching human performance (94.1). The learning curve on MPTE has more fluctuations, with a peak at 71.1 (150 examples) and a final score of 67.8. On EPC, starting around chance (39.5), the accuracy progressively increases up to 64.4 with 200 examples. These results indicate that the target knowledge is learnable with appropriate training data. Furthermore, SPTE may be the easiest task, since it only requires local knowledge about the meaning of the modifiers and the noun. By contrast, MPTE and EPC involve world knowledge (e.g., basketball players are generally tall among the population), as well as global reasoning between components in a sentence (e.g., the relationship between the event and the modifiers), which may explain the remaining large gap between model and human performance (> 90).

7 What can LMs learn from RNPC?

Given that the target knowledge is learnable, we now address question (c): What linguistic features have the models learned from RNPC? We probe for two features extensively studied in the relevant literature (cf. §2), using different techniques.

Modifier semantic category. We first investigate if models have learned the semantic category of modifiers using the "edge probing technique" (Tenney et al., 2019). Namely, each modifier is categorized as intersective, subsective, or privative (McCrae et al., 2014). The entailment pattern of individual modifiers is an important factor in determining the meaning of the entire NP.

Given a finetuned model, we take the contextualized representation of each modifier in the last hidden layer. Then, we attach a linear head on top of the token representation as an "auxiliary classifier". We choose linear classifiers because more expressive ones like Multi-Layer Perceptron are more likely to capture the target feature themselves (Hewitt and Liang, 2019). The token representations are then frozen, while the linear head is trained to predict the semantic category of the modifiers.[13]

We probe the models finetuned on RNPC from Section 6, as well as the models finetuned on existing benchmarks for comparison. The results are shown in Figure 4. For all tasks, the probing accuracy is higher for models finetuned on RNPC than on existing benchmarks. The increase is small for SPTE (3.4) and MPTE (2.8), but more obvious for EPC (7.1). This is somewhat counter-intuitive since modifier category is defined in terms of entailment patterns, but models learn it better from EPC than from TE tasks. Nonetheless, the overall trend shows that models can learn the semantic category of modifiers to some extent after being finetuned on our datasets. Since the absolute increase is limited, we plan to explore ways to quantify the actual amount of learned knowledge in future work.

Modifier scope. We also probe for the scope of the first modifier ($\mathbf{M_1}$) in recursive NPs ($\mathbf{Det\ M_1\ M_2\ N}$). Specifically, we focus on privative $\mathbf{M_1}$'s, since they can have different scopes when interacting with different $\mathbf{M_2}$'s and $\mathbf{N}$'s. For instance, in the NP *a former American diplomat*, *former* negates *diplomat* ($\mathbf{N}$), but the person is still American; while in *a former beginner drummer*, it negates *beginner* ($\mathbf{M_2}$), but the person may still be

---

[12] See Appendix E.2 for model and hyperparameter details.

[13] See Appendix E.3 for an illustration of the method.

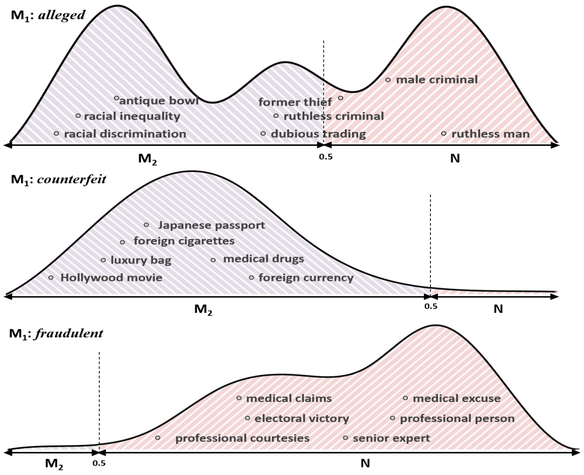

Figure 5: A case study of modifier scope. Each subfigure shows the frequency distribution of the attention ratio r $(0 < r < 1)$ for an $\mathbf{M_1}$, divided into two sides at 0.5. The $\mathbf{M_2}$ side contains NPs where $\mathbf{M_1}$ attends more to $\mathbf{M_2}$ than to $\mathbf{N}$; vice versa for the $\mathbf{N}$ side.

a drummer.[14] This difference cannot be captured by the semantic category of *former*.

As a proxy for the scope of $\mathbf{M_1}$, we use attention visualization, a widely adopted technique to study token correlations (Vig, 2019).[15] We choose BERT-base finetuned on 200 MPTE examples from Section 6 as the model to be probed for a case study.

Let us denote any token in a given NP as $\mathbf{x}$. We define $\mathbf{A_x}$, the average of the weights of all attention heads from $\mathbf{M_1}$ to $\mathbf{x}$ in the final layer, representing how much $\mathbf{M_1}$ attends to token $\mathbf{x}$. We then calculate the ratio $r = \mathbf{A_N}/(\mathbf{A_N} + \mathbf{A_{M_2}})$ $(0 < r < 1)$. If $r < 0.5$, then $\mathbf{M_1}$ attends more to $\mathbf{M_2}$; else, $\mathbf{M_1}$ attends more to $\mathbf{N}$. For each privative modifier, we take all NPs containing it in the M_1 position in our dataset and plot the distribution of r. Figure 5 shows three examples (*alleged*, *counterfeit*, or *fraudulent*) representing different patterns.

As shown in the first sub-figure, *alleged* attends more to either $\mathbf{M_2}$ and $\mathbf{N}$ depending on the NP. For example, it attends more to $\mathbf{M_2}$ in *an alleged antique bowl* (0.454), since the NP describes a bowl that may not be antique. Inversely, *an alleged male criminal* is on the $\mathbf{N}$ side (0.517), since they are most likely male but may not be a criminal.

The second sub-figure indicates that *counterfeit* mainly attends to $\mathbf{M_2}$. For instance, *a counterfeit Hollywood movie* (0.382) is still a movie, but is probably not made in Hollywood. This is similar to the cases of *luxury bag*, *medical drugs*, *foreign cigarettes*, etc. On the contrary, *fraudulent* mainly attends to $\mathbf{N}$, as shown in the third sub-figure. The *fraudulent medical claims* (0.559) are not valid claims but still on medical grounds. The same holds for *electoral victory*, *medical excuse*, etc.

Additionally, we notice that there are some boundary cases close to the $\mathbf{r} = \mathbf{0.5}$ division line, like *ruthless criminal* and *former thief* in the *alleged* sub-figure. A plausible explanation is that $\mathbf{M_1}$ is questioning both $\mathbf{M_2}$ and $\mathbf{N}$ in these cases (e.g., *an alleged ruthless criminal* is not necessarily ruthless or a criminal). Overall, the above results indicate that models finetuned on our tasks can capture modifier scope in recursive NPs.

8 Is RNPC useful for downstream tasks?

We finally address question (d): How can such knowledge benefit downstream tasks? We choose the task of Harm Detection (Banko et al., 2020) for extrinsic evaluation. Concretely, we consider the scenario where a user interacts with a task-oriented agent like Siri or Alexa, and the agent needs to determine whether the involved activity in the user query is potentially harmful. The definition of "harm" can be user-dependent. Here, we consider an activity to be harmful if it may cause pain, physical injury, or be illegal for **minors**. We choose this task because many false positives come from recursive NPs. For example, *how to make a homemade bomb* is obviously `harmful` while *how to make a homemade bath bomb* is `harmless`.

We collect a small test set from wikiHow, a website of how-to articles. Each article title is considered a query (e.g., *how to make a cake*). Then, we compile a list of 74 keywords about harmful entities (e.g., *bomb*, *fire*, *drugs*), only 12 of which occur in RNPC. We then select wikiHow queries containing at least an NP with one of the 74 keywords as the head noun, and sample a small subset for manual annotation. Each query is labeled as `harmful` or `harmless`, depending on whether it involves a harmful activity as defined above. After data cleaning and re-balancing, we obtain 170 queries, with a 1:1 positive/negative ratio.

---

[14] Admittedly, there can be alternative interpretations: say, one can also imagine that *a former beginner drummer* describes a person who is no longer a drummer at all. However, in that case, it is enough to say *a former drummer* instead, considering the Gricean maxim of quantity. Therefore, here we still focus on the first interpretation, which is more straightforward.

[15] There have been recent debates on the faithfulness of this method (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019). Therefore, we do not use attention weights to make claims about **how** our models work, but only **what** they capture, with attention weights.

Model	**Acc.**	**P**	**R**	**F_1**
Always `harmful`	50.0	50.0	**100.0**	66.7
GPT3-ada	49.4	49.7	98.8	66.1
GPT3-curie	59.4	60.5	54.1	57.1
GPT3-davinci	51.3	50.6	**100.0**	67.2
RoBERTa-large (SPTE) (**ours**)	58.2	54.5	**100.0**	70.5
RoBERTa-large (EPC) (**ours**)	**72.9**	**66.4**	92.9	**77.5**

Table 5: Zero-shot performance of models trained on RNPC on the Harm Detection task. Baselines include a model that always predicts `harmful` and GPT3.

We design two zero-shot harm classifiers using models finetuned on our entire SPTE and EPC dataset. They share a few pre-processing steps: first, all NPs are extracted from the input query; then, NPs containing a keyword from our list in the head noun position are retained. For each retained NP (e.g., *a water gun*), we check if it is indeed a harmful entity using either the SPTE or the EPC model. The input to the SPTE model is a premise of the form "This is {NP}" (e.g., *This is a water gun*) and a hypothesis of the form "This is (a/an) {N}" (e.g., *This is a gun*). If the output label is `entailment`, we classify the query as `harmful`, otherwise `harmless`. Likewise, using the EPC model, we form two events given the retained NP: "(A/An) {N} is harmful" and "{NP} is harmful". If the second event is predicted as more or equally plausible compared to the first, the query is considered `harmful`.

We compare our two classifiers to a simple baseline that always predicts `harmful` as well as to three GPT3 models.[16] Both classifiers meaningfully exceed the simple baseline, and the EPC-based classifier outperforms all the other methods by 10+ in terms of accuracy and F_1. This shows that the understanding of recursive NPs is beneficial for downstream tasks without any training data. To understand why EPC is more suitable than SPTE for this task, we further examine the errors they make. One major error type concerns polysemous keywords such as *shot*. For instance, the SPTE model mistakenly predicts *how to have a good basketball shot* to be `harmful` because *a good basketball shot* is still a *shot* (*shot* can mean both "shooting a gun" and "shooting a ball"). There are also some queries out of the scope of the EPC model, e.g., *how to make a sake bomb*. Since *sake bomb* is a cocktail, the gold label is `harmful` as our target users are minors. The EPC model correctly predicts that *a sake bomb* is less harmful than *a bomb*, but fails to capture that it may still be harmful (for minors).

9 Conclusion

We introduce RNPC, a challenge set targeting the understanding of recursive NPs, a fundamental aspect of human common sense. Pretrained LMs with SOTA performance on Natural Language Understanding benchmarks have poor mastery of this knowledge, but can still learn it when exposed to small amounts of data from RNPC. Using different probing techniques, we show that models can learn relevant linguistic features, including modifier category and scope, from RNPC. They also achieve strong zero-shot performance on an extrinsic Harm Detection task, indicating the transferability of this knowledge. For future work, we hope to investigate other linguistic phenomena as a step towards comprehensively characterizing LMs' limitations and capabilities in language understanding.

A Dataset Construction Details

A.1 RNPC Statistics

NPs. RNPC has 1,299 NPs. For an NP in the form of $\mathbf{Det\ M_1\ M_2\ N}$, the two modifiers M_1 and M_2 can each belong to one of three possible semantic categories (intersective, subsective, or privative), resulting in nine possible combinations. We plot the distribution of NPs with different combinations in RNPC in Table 6. Note that the distribution is not balanced because certain categories (e.g., NPs containing privative modifiers) yield many more minority class examples for our three tasks (e.g., `non-entailment` in SPTE). Thus, considering the final class balance in RNPC tasks, we include more NPs of certain categories.

Training and test sets for finetuning. In the experiment where we finetune models on RNPC, described in Section 6, we split again the dataset for each task into a training set and a new test set, ensuring no overlap of modifiers occurring in the same position. The training set contains 200 examples, which are gradually provided to the model. The test set contains the remaining examples. Table 7 shows the number of examples for each task.

A.2 Crowdsourcing Details

In the construction of RNPC, we hire college students as crowdworkers for instance creation and label verification. Specifically, they are undergraduate and graduate students in an Artificial Intelligence class (CIS 421/521 and MCIT 521 at the University of Pennsylvania), with good English proficiency. Both tasks are given as optional extra credit assignments in the class. Participation is solely voluntary. Before participation, students can preview the tasks, and are given a clear description of how the data will be used at the beginning of the instructions.

During instance creation, we provide detailed instructions on how to write high-quality examples for each task, which can be found in the Supplementary Materials. Annotations are collected via Google Forms. With 100 valid instances (equivalent to 2.5-4.75 hours of work, depending on their proficiency), students can earn 1% in extra credit of the overall course grade.

During label verification, we host our questions on Amazon Mechanical Turk. We design a HIT type for each RNPC task, which is also included in the Supplementary Materials. With 600 correctly answered questions (equivalent to 3.5-4 hours of work), students can earn 1% in extra credit of the overall course grade. We calculate the inter-annotator agreement using Krippendorff's alpha.[17] The agreement is 0.843 for SPTE, 0.575 for MPTE, and 0.933 for EPC.

$\mathbf{M_1}$ / $\mathbf{M_2}$	**Int.**	**Sub.**	**Pri.**
Int.	13	37	74
Sub.	138	109	162
Pri.	99	420	250

Table 6: Number of NPs in RNPC with different combinations of modifier category in the M_1 and M_2 position. Possible categories include intersective, subsective, and privative.

Task	**Train**	**Test**
SPTE	200	963
MPTE	200	863
EPC	200	1,279

Table 7: Number of examples in the training and testing split for each RNPC task in the finetuning experiment.

Dataset	**Train**	**Dev**	**Test**
MNLI	392,702	20,000	20,000
SNLI	550,152	10,000	10,000
MPE	8,000	1,000	1,000
ADEPT	12,892	1,611	1,612

Table 8: Number of examples in existing datasets of the same format used for finetuning.

A.3 Debiasing and Anonymization

The collected data does not contain any information that names or uniquely identifies individual people or offensive content. We ensure this by 1) manually reviewing the set of extracted NPs from corpora, and filtering out any NP that contains any sensitive/offensive information, 2) not requesting any personal information during human annotation, and 3) manually reviewing each RNPC example written by the human participants.

B Existing Benchmarks for Finetuning

We use the following benchmark datasets for finetuning. Each of them has the same format as one of our RNPC tasks. Table 8 shows the number of examples in each dataset.

MNLI. The Multi-Genre Natural Language Inference corpus (Williams et al., 2018) is a dataset of 433k textual entailment examples, labeled as entailment, contradiction, or neutral. It covers a

---

[17] `https://pypi.org/project/krippendorff`

range of genres of spoken and written text. The language in the dataset is English. The corpus is released under the OANC's license, the Creative Commons Share-Alike 3.0 Unported License, and the Creative Commons Attribution 3.0 Unported Licenses, depending on the portion.

SNLI. The Stanford Natural Language Inference corpus (Bowman et al., 2015) is a crowdsourced dataset of textual entailment examples, labeled as entailment, contradiction, or neutral. The sentences are written by humans doing a novel grounded task based on image captioning. The language in the dataset is English. The dataset is released under the Creative Commons Attribution-ShareAlike 4.0 International License.

MPE. Lai et al. (2017) introduce a Multiple Premise Entailment Task dataset. This is a novel textual entailment task that requires inference over multiple premise sentences. Each example consists of four premise sentences (captions from a FLICKR30K image), one hypothesis sentence (a simplified FLICKR30K caption), and one label (entailment, neutral, or contradiction) that indicates the relationship between the set of four premises and the hypothesis. The language in the dataset is English. The license of the dataset is unspecified.

ADEPT. Emami et al. (2021) introduce a dataset of the Adjective-Dependent Plausibility Task (ADEPT). Each example contains a base sentence, and a slightly modified sentence obtained by adding an adjective to a noun in the base sentence. The dataset is created to support explorations into how certain classes of adjectives might influence the plausibility of events depicted in natural language sentences. The textual data come from Wikipedia, the Common Crawl, and ConceptNet. The language of the dataset is English. ADEPT is released under the CC BY-SA 3.0 license. It is intended to be used only for research, exploratory evaluation, and auditing, which our use is consistent with.

C Probing Pretrained LMs

C.1 Motivation

When addressing question (a), we finetune pretrained LMs on existing benchmarks of the same format as each RNPC task, assuming that the finetuning process allows models to do textual inference in the required format. However, it is possible that this assumption does not hold, because LMs can overfit the finetuning data beyond just learning the format. Then even if the target knowledge is present in pretrained LMs, *catastrophic forgetting* (Kemker et al., 2018) can happen during finetuning.

C.2 Task Conversion

We complement Section 5 with another experiment, where we directly probe pretrained LMs using a prompting method inspired by the line of work on LMs as knowledge bases (Petroni et al., 2019). Specifically, we convert each RNPC task to a likelihood comparison task:

SPTE. Given the original formulation which has a premise and a hypothesis, we define L_{entail} as the **conditional likelihood** that the hypothesis is necessarily true given the premise, assigned by an LM. Contrarily, $L_{non-entail}$ stands for the conditional likelihood that the hypothesis is NOT necessarily true given the premise.[18] If $L_{entail} > L_{non-entail}$, the model is considered to predict `entailment`, and vice versa.

MPTE. The conversion method is the same as that for SPTE, except that in the conditional likelihood computation, we now consider the concatenation of two premises as the given condition.

EPC. Given the original formulation with two events, Event 1 and Event 2, we define L_1 and L_2 as the **(unconditional) likelihood** of Event 1 and Event 2 assigned by an LM, respectively. We then choose a threshold θ,[19] and compare it to the absolute difference between L_1 and L_2. If the difference is smaller than θ, we consider the model prediction as `equally likely`. Otherwise, the model prediction is `more likely` if L_2 is higher, and `less likely` if L_1 is higher.

For Causal LMs (e.g., GPT), the likelihood is computed with standard left-to-right language modeling scores. For Masked LMs (e.g., BERT, RoBERTa, BART), the likelihood is computed with pseudo-log-likelihood scores (Salazar et al., 2020).

C.3 Sanity Check

Before evaluating LMs on the converted RNPC, we perform a sanity check to see if our formalization makes sense to LMs, i.e., whether they understand the meaning of *necessarily* and *not necessarily*.

---

[18] For example, if the original SPTE example has the premise *This is the second green ball* and the hypothesis *This is the second ball*, then L_{entail} equals to L(*This is necessarily the second ball* | *This is the second green ball*), and $L_{non-entail}$ equals to L(*This* ***isn't*** *necessarily the second ball* | *This is the second green ball*).

[19] In the range [0.1, 0.5, 1, 2, 3, 5], 0.5 is the empirical optimal.

Model	SPTE	MPTE	EPC
gpt2-base	59.4	52.8	33.4
gpt2-medium	**62.6**	53.6	33.6
gpt2-large	61.4	56.1	32.4
gpt2-xl	61.7	**56.9**	31.7
gpt3-ada	55.2	55.2	33.2

Table 9: Accuracy of SOTA pretrained models directly evaluated on RNPC tasks.

We write 50 sentence pairs for likelihood comparison, all consisting of simple commonsense knowledge. For example, comparing *A human being is necessarily female* and *A human being isn't necessarily female*, the second sentence should be more likely; while for *Humans are necessarily mortal* and *Humans aren't necessarily mortal*, the first sentence should be more likely. Such comparisons do not require any knowledge about recursive NPs, and involve only common entities and facts. If models understand *necessarily* and *not necessarily* correctly, they should find the task easy.

To our surprise, almost all Masked LMs we test (BERT-base/large, RoBERTa-base/large) fail the sanity check, mostly performing around chance (50 accuracy). However, most Causal LMs (GPT-2-base/medium/large/xl, GPT-3-ada) reasonably perform above chance, with accuracy scores ranging from 70 to 80. We suspect that pseudo-log-likelihood scores are not entirely suitable for our purposes; also, the task is harder than expected due to reporting bias, as the tested knowledge (e.g., *not all humans are female*) is potentially too obvious to be explicitly stated in the pretraining data.

C.4 Results

We evaluate LMs that pass the sanity check on the converted RNPC, and report their performance in Table 9. Despite the decent performance on the sanity check examples (70-80), the accuracy on RNPC is remarkably lower. Compared to our original results of probing the finetuned models, the optimal performance on SPTE and MPTE slightly improves, while accuracy on EPC decreases. However, the same patterns hold: most models perform around or slightly above chance, with a large difference from human performance. These findings further strengthen our answer to question (a), i.e. LMs do not inherently have the knowledge to interpret recursive NPs.

Model	Acc.	P	R	F_1
BERT-base (SNLI)	49.8	49.9	77.0	60.5
BERT-base (MNLI)	51.3	50.7	97.8	66.8

Table 12: Full results of SOTA models evaluated on EPC. The finetuning dataset is ADEPT for all models.

D Full Results

In Section 5, we evaluate SOTA LMs on RNPC tasks. In addition to accuracy, we also report precision, recall, and F-1 score here. Tables 10, 11 and 12 show the full results for each task, respectively.

E Implementation Details

E.1 Models Finetuned on Existing Benchmarks

In Section 5, we evaluate SOTA LMs finetuned on existing benchmarks of the same format on RNPC. We use four different pretrained models, BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b), BART (Lewis et al., 2020), and GPT3 (Brown et al., 2020), in different sizes. The first three are implemented with HuggingFace Transformers[20], and the last is from OpenAI's standard API[21].

The pretrained model checkpoints we use include: `bert-base-uncased` (110M parameters), `bert-large-uncased` (336M parameters), `roberta-base` (125M param-

---

[20] `https://github.com/huggingface/transformers`

[21] `https://beta.openai.com/docs/api-reference`

eters), `roberta-large` (335M parameters), `facebook/bart-large` (406M parameters), `GPT3-ada` (350M parameters), and `GPT3-curie` (6.7B parameters).[22] Their licenses include Apache License 2.0 (BERT and BART), GNU General Public License v2.0 (RoBERTa), and MIT license (GPT3).

Due to the size of MNLI and SNLI, we use existing checkpoints available on the Huggingface Transformers model hub. For all other datasets, we finetune the pretrained models using the `SequenceClassification` pipeline on Huggingface, or the standard prompt completion finetuning API on OpenAI.[23] The finetuning scripts are adapted from the `text-classification` example in the HuggingFace Transformers repository.[24] We performed hyperparameter search in the following range:

- batch size: [4, 8, 16, 32]
- learning rate: [1e-5, 1e-6]
- number of epochs: [2, 3, 5]
- max sequence length: [64, 128]

The optimal hyperparameter values and finetuned models are available on the HuggingFace model hub.

We run our finetuning experiments on an NVIDIA GeForce RTX 2080 Ti GPU, with half-precision floating point format (FP16). The finetuning takes 2 to 5 hours depending on the task.

E.2 Models Finetuned on RNPC

In Section 6, we address the question of whether LMs can learn the meaning of recursive NPs. We finetune each model from Section E.1 on an increasing number of examples of each RNPC task. The model architectures, the pipelines used, the range of hyperparameter search, and the computing resources used are all the same as in the previous subsection. After being finetuned on 200 examples, the best performing models are RoBERTa-large (MNLI) for SPTE, RoBERTa-base (MPE) for MPTE, and RoBERTA-large (ADEPT) for EPC. The optimal hyperparameter values and finetuned models on the full 200 examples of each RNPC task are available on the HuggingFace model hub.

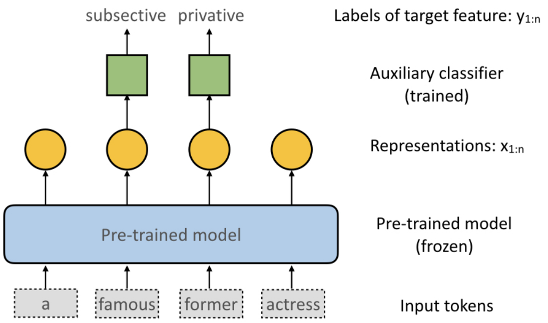

Figure 6: An illustration of the Edge Probing method. Figure adapted from Tenney et al. (2019).

E.3 The "Edge Probing" Method

In Section 7, we adopt the Edge Probing technique from Tenney et al. (2019) to investigate if the modifier category feature can be learned from our tasks.

To reintroduce the general idea of this method, consider the following setup: we have data $D = \{(x_1, y_1), (x_2, y_2), ..., (x_n, y_n)\}$, where $(x_1, x_2, ..., x_n)$ are the model representations to be probed and $(y_1, y_2, ..., y_n)$ are the labels of a linguistic feature we are interested in probing for. The goal is to see if $(x_1, x_2, ..., x_n)$ encodes $(y_1, y_2, ..., y_n)$.

In our case, given an NP of the form $\mathbf{Det\ M_1\ M_2\ N}$, $(x_1, x_2, ..., x_n)$ are the token representations of the best-performing models after being finetuned on each RNPC task, as mentioned in Section E.2, and $(y_1, y_2, ..., y_n)$ are the semantic categories of $\mathbf{M_1}$ and $\mathbf{M_2}$.

We freeze the representations $(x_1, x_2, ..., x_n)$, and attach a simple auxiliary classifier (or probing classifier) on top of them. The auxiliary classifier is trained to predict the semantic category y_i corresponding to every modifier token representation x_i. In our case, we choose a linear classifier as the probing classifier. The assumption is that the expressivity of the auxiliary classifier should be limited, or otherwise it might learn the target feature itself. Based on this assumption, the accuracy of predicting y indicates the extent to which the model representations encode the target feature. The method is illustrated in Figure 6.

Specifically, the linear classifier is an `SGDClassifier` implemented with scikit-learn.[25] We perform hyperparameter search in the following range:

E.4 Models Used for Extrinsic Evaluation

In Section 8, one of the models we compare to is GPT3. We exploit three versions of different sizes, `GPT3-ada`, `GPT3-curie`, and `GPT3-davinci`, using the same API described in Section E.1. The models are evaluated in a zero-shot setting, where we only provide the following task description:

> Given a "how-to" query, determine if the task is harmful to a teenager. The answer should be Yes or No.

Each input question is then formatted as:

> Question: Is "{how-to query}" harmful?
> Answer:

For every how-to query in our test set, we use the concatenation of the task description and the instantiated input question as the prompt, and let the model generate a one-token continuation. The top generated token is always *Yes* or *No*, implying that GPT3 has a good understanding of the task format.

F Ethical Considerations

F.1 Limitations

Assumptions. One assumption we make in answering question (a) is that LMs finetuned on existing benchmarks can learn the required format without overfitting the specific domains of the finetuning data. Suppose this assumption does not hold, then even if the target knowledge is present in pretrained LMs, they can "forget" it during finetuning. Therefore, the finetuning process does not allow us to elicit the target knowledge from pretrained LMs. To address this issue, we complement the behavioral test probing method with another experiment to directly probe the pretrained LMs via likelihood scoring. See Section C for details.

Another assumption occurs in our answer to question (d). We assume that a query is harmful if it contains a harmful entity. However, in practice, there can be queries like *How to prevent a fire*, which does contain a harmful entity (*fire*) but is precautionary instead of harmful. Our model does not take into account factors like predicates in context, and will therefore identify all such cases as false positives.

Scope of claims. Our first three claims (i.e. answers to question (a)-(c)) are only verified to hold on the RNPC dataset, which 1) is in English and 2) mainly consists of NPs in the news domain. Our last claim (i.e. answer to question (d)) is only verified to hold on the harm detection dataset we collect, which 1) is also in English, 2) consists of how-to queries in the domain of human activities, and 3) is annotated based on a non-exhaustive keyword list of harmful entities.

Moreover, part of our answer to question (b) (i.e. LMs have learned the feature of modifier semantic category from RNPC) is qualitative. The absolute increase in the probing accuracy after finetuning is limited, so it is likely not the entire picture. Quantifying to what extent LMs have learned this feature is an interesting direction for future work.

F.2 Risks

The risks associated with the study are minimal.

Harm detection models. Our harm detection models are intended for research purposes only. They are designed for specific types of harmful queries, i.e. those with harmful entities. One should not deploy them directly in real life since they are by no means applicable under all scenarios.

Data collection. Our human participants may experience slight discomfort due to boredom during data collection. To minimize this, we make sure that it is entirely voluntary to participate and discontinue at any time.

F.3 Intended Use

Our models and data should be used for research purposes only. They should not be deployed in the real world as anything other than a research prototype, especially commercially.

Original or *Translated*? A Causal Analysis of the Impact of Translationese on Machine Translation Performance

Abstract

Human-translated text displays distinct features from naturally written text in the same language. This phenomena, known as *translationese*, has been argued to confound the machine translation (MT) evaluation. Yet, we find that existing work on translationese neglects some important factors and the conclusions are mostly correlational but not causal. In this work, we collect CAUSALMT, a dataset where the MT training data are also labeled with the human translation directions. We inspect two additional critical factors, the *train-test direction match* (whether the human translation directions in the training and test sets are aligned), and *data-model direction match* (whether the model learns in the same direction as the human translation direction in the dataset). We show that these two factors have a large causal effect on the MT performance, in addition to the *test-model direction mismatch* highlighted by existing work on translationese. In light of our findings, we provide a set of suggestions for MT training and evaluation.[1]

1 Introduction

MT has long been concerned with the artifacts introduced by *translationese*, the human-translated text that is systematically different from naturally written text in the same language (Toury, 1980; Gellerstam, 1986; Toury, 1995; Baker, 1993; Baroni and Bernardini, 2006). For a translation system translating from language X to language Y, there can be two types of test data: sentences that originated in language X and are human-translated into language Y (denoted as $X \overset{\text{H}}{\rightarrow} Y$), and sentences that originated in language Y and human-translated into language X (denoted as $X \overset{\text{H}}{\leftarrow} Y$).[2]

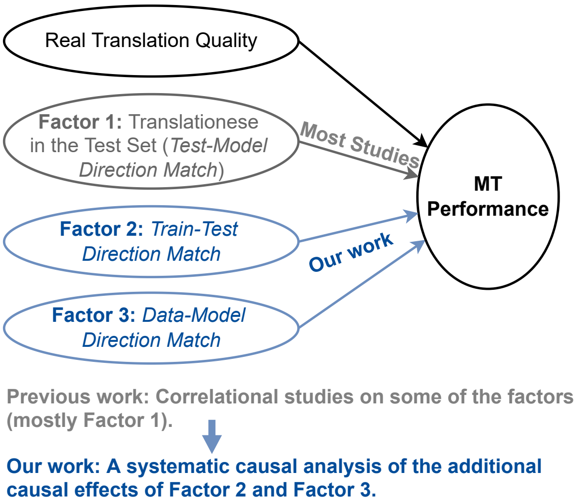

Figure 1: Three different factors illustrate the impact of translationese on MT performance. Previous work mainly focuses on how translationese in the test set (Factor 1) inflates BLEU score and makes it favor some translation systems over others. Our work investigates the causal effects of the other two key factors, the train-test direction match (Factor 2; i.e., whether the training set and the test set share the same human translation direction), and data-model direction match (Factor 3; i.e., whether the dataset collection direction and model translation direction are the same).

The main concern raised by this distinction of the two sets is whether the reported performance on a mixed test set truly reflects the actual translation quality. Previous work in MT has shown that translationese is a confounder in evaluating translation quality (Lembersky et al., 2012; Toral et al., 2018; Läubli et al., 2018; Freitag et al., 2020).

Recent studies on causality have also brought to attention the importance of distinguishing the *data-model direction match*, namely whether the data collection direction is the same as or opposite to the model direction, also known as *causal* or *anti-causal* learning (Jin et al., 2021b; Veitch et al., 2021; Schölkopf et al., 2012). If the dataset is collected by human annotators who see the input X and produce an output Y, then learning an X-to-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5303 - 5320
July 10-15, 2022

Y model is causal learning, and learning a Y-to-X model is anticausal learning.

In this work, we study the artifacts in MT brought by translationese from the viewpoint of causality, specifically, the match between the data and model directions. We consider two factors of variation in MT: *human translation direction* (in both the training and the test set) and *model translation direction*. Thus, we formulate the effect of translationese in the test set as the *test-model direction match* problem, and causal/anticausal learning as the *data-model direction match* problem. Further, we identify the third important factor, the *train-test direction match* problem, namely, whether the training set and the test set are collected with the same human translation direction. We study the causal influences of these three factors on MT performance in Figure 1. Previous work has mainly studied the artifacts introduced by the test-model direction match on MT performance (Toral et al., 2018; Graham et al., 2020; Edunov et al., 2020), but little considers the other two factors, the train-test and data-model direction match (Kurokawa et al., 2009; Larkin et al., 2021). Moreover, most analyses are based on correlation but not causation (Graham et al., 2020).

In this paper, we use causal inference (Pearl, 2009; Peters et al., 2017) to re-investigate previous conclusions about the most studied relationship between the test-model direction match and MT performance. We calibrate the effect of test-model direction match by analyzing the causal effects of the two other factors, the train-test and data-model direction match. In our causal analyses, we use interventions to study the effect of train-test direction match, and covariate matching to study the effect of data-model direction match, by controlling for covariates such as sentence lengths and content.

We build CAUSALMT, a new dataset on five language pairs labeled with the human translation directions, and statistically verify that translationese tends to be simpler and more verbose, corroborating previous observations on translationese (Toury, 1980; Gellerstam, 1986; Toury, 1995; Baker, 1993). Then, we rigorously analyze CAUSALMT, leading to the following new insights and contributions:

C1. Previous work claims that translationese in the test set inflates MT model performance and thus suggests removing the translationese-to-original half of the test set (Toral et al., 2018; Zhang and Toral, 2019; Graham et al., 2020; Barrault et al., 2019). Our work shows that the translationese-to-original half of the test set does not necessarily inflate MT performance in all cases. In some cases, it can even be more challenging than the other half, depending on the human translation direction in the training corpus. Hence, we suggest still reporting performance on both test sets, and also reporting the training data direction if available.

C2. Previous work (Burlot and Yvon, 2018) claims that back-translation (BT) (Sennrich et al., 2016) is usually more effective than self-training (ST) (He et al., 2019). Our work shows that BT is not necessarily better than ST in all cases. This result also depends on how the pseudo-parallel corpus aligns with the human translation direction in the test set. We suggest choosing BT or ST depending on this direction match.

C3. Previous work claims that BT's performance improvement is largely reflected on the translationese-to-original half of the test set, but the improvement is very small on the other half (Toral et al., 2018; Freitag et al., 2019). Our work shows that the improvement of BT can be larger on the other half of the test set as well, as long as the pseudo-parallel corpus aligns with the human translation direction in the test set.

C4. Our work shows that data-model direction match also has a large causal effect on the MT performance of up to 12.25 BLEU points after adjusting for other covariates using the backdoor adjustment (Pearl, 1995).

2 CAUSALMT Dataset

To investigate the effect of train-test direction match and data-model direction match, we need to collect translation data in different human translation directions.

2.1 Data Collection

To construct our CAUSALMT dataset consisting of a large number of translation pairs labeled with the human translation direction,[3] we use the EuroparlExtract toolkit (Ustaszewski, 2019) to filter

---

[3] Most existing datasets do not distinguish the human translation direction for the training set (Kolias et al., 2014; Barrault et al., 2019). Some works train a classifier to identify the human translation direction (Kurokawa et al., 2009; Riley et al., 2020), but they are not our ideal choice since this classification may rely on the domain difference of the two directions (Rabi-

Table 1: Detailed characteristics of the CAUSALMT dataset. We first report the number of translation pairs in the training set (# Training Samples), and for each parallel corpus ($X \xrightarrow{H} / \xleftarrow{H} Y$), we report the following statistics in both language X and Y (denoted as "*stats in X/stats in* Y"): the number of words per sample (# Words/Sample), number of sentences per sample (# Sents/Sample), percentage of samples with passive voice, vocabulary size, and the expansion factor. The expansion factor from language X to language Y (X:Y) is calculated by the average word count per sample in language X divided by the average word count per sample in language Y.

translation pairs by meta-information (e.g., the tag specifying the original language of the speaker). Specifically, in the Europarl corpus (Koehn, 2005), we iterate over each transcript that has an origination label and mark a sentence as original text if the original language of the speaker is the same as the language this sentence is in, or otherwise mark it as the translated text. After extracting the direction-labeled language pairs, we remove all duplicates in the entire dataset. Since our study needs to compare training on parallel corpora of the same language pair but with two different human translation directions, e.g., De$\xrightarrow{H}$En and De$\xleftarrow{H}$En, we control the size of the two corpora to be the same by downsampling the larger set.

Among all language pairs we can obtain, we keep five language pairs with the largest number of data samples. As in Table 1, the CAUSALMT dataset contains over 200K translation pairs in each training set of three language pairs and over 90K translation pairs in each training set of the other two language pairs. The development set and test set contain 1K and 2K translation pairs for all language pairs in each direction, respectively.

2.2 Dataset Characteristics

We analyze the characteristics of the CAUSALMT dataset in light of how translated text differs from naturally written text in the same language.

Our findings echo the observations by previous work on the distinct features of translationese (Toury, 1980; Gellerstam, 1986; Toury, 1995; Baker, 1993; Baroni and Bernardini, 2006; Volansky et al., 2015). For example, translationese tends to be simpler and more standardized (Baker, 1993; Toury, 1995; Laviosa-Braithwaite, 1998), such as having a smaller vocabulary and using certain discourse markers more often (Baker, 1993, 1995, 1996). Translationese also tends to be influenced by the source language in terms of its lexical and word order choice (Gellerstam, 1986).

In the CAUSALMT data, we observe three properties. (1) Within each language pair (e.g., German and English), the same language's *translationese always has a smaller vocabulary* than its naturally written text corpus. For example, the translationese German in De$\xleftarrow{H}$En has only 113K vocabulary, which is 5K smaller than the vocabulary of the German corpus in De$\xrightarrow{H}$En. (2) *Translationese tends to be more verbose*. For each language pair, we calculate the expansion factor from language X to language Y (X:Y) as the average word count per sample in language X divided by the average word count per sample in language Y. For example, for each (English, German) translation pair, the number of English words is 1.13 times that of German words when English is the translationese (i.e., en:de expansion factor=1.13). On the other hand, the en:de expansion factor is only 1.04 when English is the naturally written text. (3) We use a syntax-based parser to detect the percentage of samples with passive voice in English, details of which are in Appendix B. There is a clear distinction that *translationese English tends to use more passive voice than original English*, e.g., 14.94% translationese samples in the passive voice in the En$\xleftarrow{H}$Es corpus in contrast with 11.49% original English samples in the reverse direction.

3 The Overshadowing Effect of Train-Test Direction Match

The first analysis of this paper aims to calibrate the most studied relationship of the test-model direction match and MT performance by considering the additional effect of the *train-test direction match*.

---

novich and Wintner, 2015). Our dataset is an extended version of our prior study (Jin et al., 2021b), but ours is significantly larger to enable the various analyses in our study.

Previous work observes that the translationese-to-original test set inflates the score. To evaluate a model with the X-to-Y translation direction, traditionally, the test set is a mixture of two halves, one with the human translation direction $X \xrightarrow{\text{H}} Y$ (aligned) and the other $X \xleftarrow{\text{H}} Y$ (unaligned, or translationese-to-original) (Bojar et al., 2018).

Previous studies propose that the unaligned, translationese-to-original test set is easier to translate than the other aligned test set because translationese inputs are easy for the MT model to handle (Toral et al., 2018; Zhang and Toral, 2019; Graham et al., 2020). The inflated test performance caused by translationese has long been speculated (Lembersky et al., 2012; Toral et al., 2018; Läubli et al., 2018), and recent work has statistically verified the correlation (Graham et al., 2020).

With the previous understanding, some works suggest removing the unaligned half of the test set (Toral et al., 2018; Zhang and Toral, 2019; Graham et al., 2020), which was adopted by the 2019 WMT shared task (Barrault et al., 2019), whereas others suggest keeping both but reporting the performance separately (Freitag et al., 2019; Edunov et al., 2020). The motivations from the two sides are that in the unaligned half, although the source text being translationese is an easy input to the model, its target text being naturally written text makes the evaluation more natural.

This "inflation" depends on train-test direction match. We take a step back from the argument on whether the unaligned test set positively or negatively affects the MT performance evaluation. Instead, we call attention to the fact that, beyond the test-model direction match, there can be other factors also playing a critical in the MT performance evaluation, i.e., the train-test direction match.

For a given machine translation task to learn the X-to-Y translation, there can be two questions: the question from previous work is whether we should use the test set aligned with the model translation direction (T1) or the test set unaligned with the model translation direction (T2) to evaluate the model fairly, whereas the question answered by our work is *which training data should be used to achieve the best performance*.

Our analysis aims to obtain causal conclusions on how intervening on the train-test direction match affects the MT performance. Therefore, we control all other possible confounders. For each language pair, we control the total training data size to be the same[4] when varying the portion of data in two directions. We also enumerate all other possible interventions, such as varying the two model translation directions and reporting performance on two different halves of the test set with two human translation directions. We also control that all translation models use the same Transformer architecture (Vaswani et al., 2017) by fairseq (Ott et al., 2019), with experimental details in Appendix C.

100%	42.46	40.00	100%	45.42	37.56

Table 2: BLEU points of all five language pairs on training sets mixed by $\alpha\%$ $X \xrightarrow{\text{H}} Y$ and $(1 - \alpha\%)$ $X \xleftarrow{\text{H}} Y$ data, where the mixture rate $\alpha = 0, 25, 50, 75, 100$. We always use T1 to denote the test set aligned with the model direction, and T2 to denote the unaligned one. For readability, we use * to denote the translationese language. For example, "(de, en*)" means original German and translated English pairs.

---

[4] A side benefit of controlling the training data size is that our experiments can help answer what the best nature (i.e., human translation direction) of the training data given a fixed annotation or computation budget is. We leave the space for future work to increase the total training set size with all available training data in both directions.

We report the experiment results of how intervening the train-test direction match affects the MT performance in BLEU score (Papineni et al., 2002) in Table 2. The main takeaways are as follows:

(1) It is not always the case that, for the same model, the unaligned test set T2 yields higher/more inflated results than the aligned test set T1. When the training data has 75–100% aligned training samples, performance reported on T2 is, in most cases, no longer larger than that on the other half. With such training data, usually, T1 inflates the BLEU score more.

(2) The train-test direction match can have an overshadowing effect over the artifacts introduced by the translationese-to-original test set, since no matter which test set we use, the more matched the train and test directions are, the higher the performance reported on T1 than T2 is. Specifically, as we vary the portion of the aligned training data from 0 to 100%, the performance on T1 keeps increasing, and the performance on T2 keeps decreasing. Additionally, if the training data has about 0–50% samples aligned with the model translation direction, then, in many cases, T2 is higher than T1, which might explain the previous observations that T2 inflates the BLEU score (Toral et al., 2018; Graham et al., 2020). To account for another possible interpretation, such as the domain shift between the training and test sets, we also conduct an additional evaluation using the newstest2014 test sets, which do not share any domain similarity with our training sets, but still support our observation (in Appendix Table 6).

Hence, the two constructive suggestions for future work are that (1) it is important to still report on both test sets, and also the training data direction if available, and (2) parallel training data in the same direction with the test set is more helpful.

Monolingual data in the original language of the test set is more helpful. With the intuition that the train-test direction match is a crucial factor for MT performance, we also look into its implications on semi-supervised learning.

Given additional monolingual data, a common question in MT is what type of monolingual data to use, and the accompanying question, whether to use self-training (ST) for the source language monolingual corpus (He et al., 2019; Yarowsky, 1995) or back-translation (BT) for the target language monolingual corpus (Bojar and Tamchyna, 2011; Sennrich et al., 2016; Poncelas et al., 2018). We reframe the question as "*with abundant monolingual data from both languages, but limited computation resources, which data (together with the corresponding semi-supervised learning method) should we choose?*"

Table 3: Performance on the en-fr and en-de test sets of *newstest2014*. There are two test sets for each task, where * marks the translated language. We use an equal mixture of supervised data in two human translation directions ("*Sup. on Equal Mix*"). Both ST and BT generate pseudo-parallel data (marked by **), with which we find that **aligned** directions between the test set and the pseudo-parallel data lead to larger performance gain.

In previous work, BT is the most widely used technique (Bojar et al., 2018; Edunov et al., 2018; Ng et al., 2019; Barrault et al., 2019, p. 15), and is reported to outperform ST (Burlot and Yvon, 2018). Another line of previous work inspects the performance gain by BT. Some argue that BT is helpful mostly on the test set aligned with the model (Toral et al., 2018; Freitag et al., 2019; Edunov et al., 2020, Appendix A Table 7) but not the unaligned test set, while others show that BT improves performance on both test sets (Edunov et al., 2020).

We re-inspect the two previous lines of work, and find (1) BT does *not always* outperform ST, especially when ST can make use of the monolingual data in the original language of the test set (to produce pseudo-aligned training data), and (2) the performance gain by BT is *not always* larger on the unaligned test set, but depends on the model direction, especially when BT generates pseudo-aligned training data with the test set.

We implement BT by Edunov et al. (2020), and ST by He et al. (2019). To fairly compare the performance of ST vs. BT, for each language pair X and Y, we split half both training corpora into $X\overset{\mathrm{H}}{\rightarrow}Y$-Half1, $X\overset{\mathrm{H}}{\rightarrow}Y$-Half2, $Y\overset{\mathrm{H}}{\rightarrow}X$-Half1, and $Y\overset{\mathrm{H}}{\rightarrow}X$-Half2. We construct the supervised training data as an equal mix (i.e., α=50) combining $X\overset{\mathrm{H}}{\rightarrow}Y$-Half1 and $Y\overset{\mathrm{H}}{\rightarrow}X$-Half1. The development data is the combination of both development sets, which is also an equal mix.

To train ST or BT, we use the second halves of the training data only as the monolingual corpora. For example, if the translation task is English-to-German translation, ST generates a pseudo-parallel corpus with original English paired with machine-translated pseudo-German, which we denote as (en, de**). For readability, we mark the machine-translation direction with ST and BT by ** and the human translation direction by *.

Our hypothesis is that the machine-translated text pairs (en, de**) will also show similar properties as the human-translated training data (en, de*). Specifically, the more the pseudo-training data is aligned with the test set, the higher performance the semi-supervised learning method will achieve. This is confirmed by the experiment results in Table 3, where, across all settings, no matter which semi-supervised learning method is used, when the pseudo-training data has the same translation direction as the test set, the resulting performance is generally higher. The experiments conducted on CAUSALMT test sets also generally show the same trend, and, due to the space limit, we include the results in the Appendix Table 7.

4 Causal Effect of Data-Model Direction Match

The second contribution of this work is to inspect how much another factor, the data-model direction match, causally affects the MT performance. Formally, our research question is that, for a given translation task X-to-Y, considering an equal mix of the test set, does the human translation direction of the training data still matter? If so, how large is the effect, and is it language-/task-dependent?

This section will use causal inference to isolate the effect of data-model direction match from other possible confounders and discuss its effect in different languages and translation tasks.

4.1 Correlation in Previous Experiments

Our previous experiments show that data-model direction match *correlates* with MT performance. Specifically, for each translation task in Table 2, there is a clear difference between the causal learning and anticausal learning model. We copy this naïve difference to the "Diff" column of Table 5.

This naïve difference represents $\mathbb{E}_{\text{aligned\_corpus}}[S] - \mathbb{E}_{\text{unaligned\_corpus}}[S]$, which compares the performance score S on the aligned corpus and S on the unaligned corpus, without controlling for potential confounders. The famous "correlation does not imply causation" implies that this formulation cannot answer the causal question, as the two expectation terms are taken over two different distributions that are not necessarily comparable. However, by Reichenbach's Common Cause Principle (Reichenbach, 1956), correlation implies the existence of some common cause behind the two correlated variables, which motivates us to investigate the causal relationship in the next section.

4.2 Setup of the Causal Effect Estimation

Formulating the causal effect. Instead of just correlational analyses, we aim to estimate the average causal effect (ACE) (Holland, 1988; Pearl, 2009) of the data-model direction match (i.e., causal vs. anticausal learning) M on the translation performance S:[5]

$$\begin{aligned} \mathrm{ACE} = {} & P(S=s|\mathrm{do}(M=1)) \\ & - P(S=s|\mathrm{do}(M=0))\,, \end{aligned} \tag{1}$$

where, according to do-calculus (Pearl, 1995) in causal inference, the operator $\mathrm{do}(M = 0 \text{ or } 1)$ means to intervene on the data-model direction match to be 0 (i.e., anticausal learning) or 1 (i.e., causal learning). The ACE formulation is about how much the model performance S will differ if intervening the data-model direction match M to be 0 or 1.

To estimate the ACE, we first draw the causal graph considering all variables that can interfere with the relationship between data-model direction match and MT performance. The main additional factors we need to control for are in the causal graph in Figure 2. We make the assumption that it is very likely that the two corpora of different human translation directions also vary by sentence

---

[5] Note that there are two notions of causality here, one is the intervention we are interested in, namely the data-model direction match, known as causal vs. anticausal learning, and the other is the meta-level causality we are interested in, namely how much the data-model direction match (as a binary variable) causally affect the translation performance.

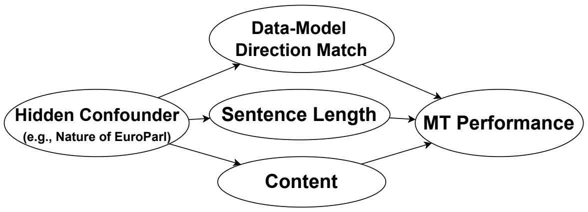

Figure 2: Causal graph about how the data-model direction match M affects MT performance score S, considering the other covariates Z including the distribution of sentence lengths and content.

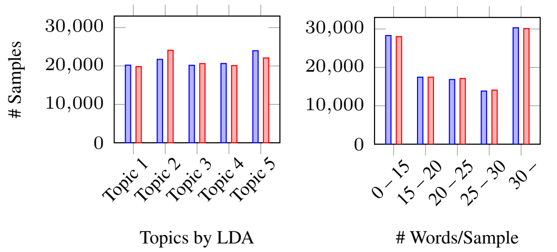

Figure 3: Distribution of topics and sentence lengths after matching, using the German-English language pair (between De$\xrightarrow{H}$En and De$\xleftarrow{H}$En) as an example.

Corpus	Matched Pairs
De$\xrightarrow{H}$En	Let me make some comments on specific points.
De$\xleftarrow{H}$En	However, I have one or two points.
De$\xrightarrow{H}$En	From our perspective, it is now urgently necessary that the Council also accepts this proposal, so that the negotiations can commence as soon as possible.
De$\xleftarrow{H}$En	That greater urgency has been recognised in the Council suggestion that we should have an intergovernmental conference beginning next year, something which we subscribe to.
De$\xrightarrow{H}$En	We want a European Union that is strong, effective and democratic, and all those who want to make it no more than a free trade zone within Europe will have a fight on their hands.
De$\xleftarrow{H}$En	I agree that the European Union needs an integrated, coherent and consistent European energy policy that maintains Europe's competitiveness, safeguards our environmental objectives and ensures our security of supply.

Table 4: Examples of matched pairs between the De$\xrightarrow{H}$En and De$\xleftarrow{H}$En corpora.

lengths and the distribution of content (Bogoychev and Sennrich, 2019) due to a hidden confounder (i.e., a common cause) such as the nature of Europarl. Note that since our research question is about which training data matters for given a translation task, the data-model direction match is equivalent to the human translation direction of the training data, as the model translation direction is fixed.

Given the causal graph in Figure 2, the ACE in Eq. (1) can be calculated by conditioning on the set of variables Z which blocks the backdoor paths (Pearl, 1995) between M and S. (Z fits the backdoor criterion (Pearl, 1993) in that the sentence lengths and content block all non-directed paths from M to S, and neither is a descendant of any node on the directed path from M to S.) An intuitive interpretation can be that when we directly look at the correlation between the data-model direction match and MT performance, it might also be due to that different corpora have different distributions of sentence lengths and content. Therefore, we need to control the sentence lengths and content so that the performance difference will be solely due to the data-model direction match.

Formally, the ACE using the do-notation can be calculated by conditioning on Z. Specifically, we integrate over the distribution of $P(Z)$, and calculate the difference in the conditional probability distribution $P(S=s|M=1,Z=z) - P(S=s|M=0,Z=z)$ of S given the data-model direction match value M conditioned on the other key variables Z for each of its possible value $\boldsymbol{z}$, as shown in Eq. (2):

$$\begin{aligned}\text{ACE} = \int_{\boldsymbol{z}} &[(P(S=s|M=1,Z=\boldsymbol{z}) \\ &- P(S=s|M=0,Z=\boldsymbol{z}))P(\boldsymbol{z})] \quad (2)\\ &= \mathbb{E}_{\boldsymbol{z}}[S|M=1,Z=\boldsymbol{z}] \\ &- \mathbb{E}_{\boldsymbol{z}}[S|M=0,Z=\boldsymbol{z}]\,. \quad (3)\end{aligned}$$

Finally, we estimate it by comparing the expected values of the model performance score S given $M=0$ or 1 over all possible values of the covariate Z as in Eq. (3).

Causal effect estimation by matching. To estimate the ACE in Eq. (3), the intuition is that we need to take care of the covariates in Z so that the aligned setting and the unaligned setting are comparable. We follow the covariate matching method in causal inference (Rosenbaum and Rubin, 1983; Iacus et al., 2012) and adjustment in the high-dimensional setting of text (Roberts et al., 2020; Veitch et al., 2020). Specifically, matching is a method in causal inference to subsample the treated (i.e., the aligned corpus with the model direction) and control samples (i.e., the unaligned corpus with the model direction) so that the covariates of interest are matched.

We aim to match pairs of samples, one from the causal corpus and the other from the anticausal corpus, where we constrain them to share similar contents and similar sentence lengths. In our

Table 5: BLEU points of causal learning (Cau.) vs. anticausal (Ant.) directions after controlling for topics and lengths. We calculate the ACE by taking each model's average performance on T1 and T2, and comparing how much causal models outperform anticausal models (**ACE**). In comparison, we show the naïve difference (Diff) by directly comparing the results of causal and anticausal models in Table 2 without topic and length control.

implementation, for each sentence in the causal corpus, we select its most similar match in the anticausal corpus using Dinic's maximal matching algorithm (Dinic, 1970).

Empirically, we limit the sentence length ratio of each matched pair to be no larger than 1.1 and the content to have a cosine similarity larger than 0.7, following the threshold to match a content-similar pseudo-parallel corpus in Jin et al. (2019). To calculate the content-wise similarity of a pair of samples, we represent each sentence by the sentence BERT embedding (Reimers and Gurevych, 2019). In cases of multiple languages as candidates to match the sentence embeddings in, we set a prioritization order of "En>De>Fr>Es" for sentence embedding matching. The prioritization order roughly follows the training data sizes of the multilingual version (Reimers and Gurevych, 2020) of the sentence transformer in the four languages. Note that since the set of factors to control is in a high-dimensional vector space, it is less realistic to use other common matching methods such as propensity score stratification and matching, as pointed out by Roberts et al. (2020).

We check the quality of our matching heuristics. Taking the German-English language pair as an example, we plot the distributions of topics by Latent Dirichlet Allocation (LDA) topic modeling (Blei et al., 2001) and distributions of sentence lengths across the De$\xrightarrow{H}$En and De$\xleftarrow{H}$En corpora in Figure 3. We also list some example matched pairs in English in Table 4. Further statistics of the matched corpora are in Appendix E.1.

Finally, based on the matched datasets that control for the sentence lengths and contents, ACE can be calculated by the average difference in MT performance of models trained on the two directions of the new datasets.

4.3 Causal Effect Results

We have three observations from the results in Table 5: (1) The data-model direction match is a clear cause for MT performance. The ACE of data-model direction match on MT performance can be up to 12.25 BLEU points, for example, in the Spanish-to-English translation task. (2) The ACE varies by language and translation tasks. For the English-Spanish language pair, both translation directions get higher BLEU points if the models are trained in the causal learning direction. For other language pairs, the causal effects of data-model direction match are clear, although varying from positive to negative values, the reasons for which are worth future studies. (3) The results of naïve differences (Diff) are, in most cases, smaller than that of the causal analysis by ACE. This indicates that the correlational analysis neglects other important factors such as the sentence length and content, which might also be reflected in the overall difference. The causal analysis is a more appropriate method to isolate the influence of the data-model direction match.

5 Related Work

Linguistic studies have long observed the distinct properties of translationese from text originally authored in the same language (Toury, 1980; Gellerstam, 1986; Baker, 1993; Toury, 1995). Recent work in MT identifies that the source side of the translationese-to-original portion of the test sets (i.e., test sets unaligned with the model direction) is easier (Graham et al., 2020), echoing with many previous observations (Toral et al., 2018; Lembersky et al., 2012; Läubli et al., 2018) and thus some suggest to exclude this portion from future test sets, in particular human evaluations (Toral et al., 2018; Zhang and Toral, 2019; Graham et al., 2020; Barrault et al., 2019). Nevertheless, Freitag et al. (2019) demonstrate that it is worth reporting automatic metric scores on both directions separately as both types of test sets evaluate different properties of translation quality. In follow-up work, Freitag et al. (2020) introduce paraphrased test sets that overcome the problems of translationese for test sets, not solving the problem for the training data though.

Based on this speculated inflation of MT performance due to translationese in the test set, further work inspects what previous conclusions about the effectiveness of MT models should be recalibrated. Some discover that models with BT mostly improve on the inflated test set but not the other more challenging portion (Toral et al., 2018; Freitag et al., 2019; Edunov et al., 2020, Appendix A Table 7) and raise concerns that BT is not as effective as expected. Others argue that BT can still improve on both test sets (Edunov et al., 2020).

While for almost all test sets the original language of each example is known, the majority of training data does not contain this meta information. Studies of the impact of translationese on training examples are thus mostly based on Europarl where meta information is given. For instance, Ozdowska and Way (2009) argue that the original side of each training sample is important when building a statistical machine translation (SMT) system. Kurokawa et al. (2009); Koppel and Ordan (2011); Sominsky and Wintner (2019) build classifiers to automatically detect the direction of each training sample. Riley et al. (2020) use a CNN classifier to separate the training data at scale and bias the NMT model via tagging to generate translations that look like the original text. Human evaluation demonstrates that this produces more accurate and natural translations. Further, Amponsah-Kaakyire et al. (2021) investigate the impact of training samples generated with pivot ("relay") languages.

Our work differs from all previous work in that we conduct causal inference (Pearl, 2009; Peters et al., 2017) to contribute causal insights on how translationese affects MT.

6 Future Work

We list several directions for potential future work: (1) It will be meaningful to explore whether the conclusions of this paper can generalize to higher-resource data and a wider variety of languages. (2) In real-world MT systems, it is important not only to answer whether aligned training data or unaligned training data is better (when deciding how to distribute the budget to collect data for a usage scenario with a fixed direction), but also to investigate how to utilize the mixed training data (when trying to make the best use of the existing data) and contribute to the best possible translation systems. Riley et al. (2020); Larkin et al. (2021); Freitag et al. (2022) suggest adding a tag per sample specifying the direction to make use of the unaligned data. Future work can also explore if there can be an end-to-end model jointly inferring the human translation direction and signaling the model to deal with the aligned and unaligned directions differently. (3) In our study, Table 5 mainly confirms the causal effects of the data-model direction match on the MT performance, but the actual reasons for positive and negative ACEs are still worth further investigation.

7 Conclusion

In conclusion, this work study the causal effects of three important factors on MT performance: the test-model, train-test, and data-model direction match. We provide suggestions for future study in MT, such as using more training data in the aligned direction and paying attention to whether the nature of the translation task is causal or anticausal.

Ethical Considerations

Data Privacy and Bias: This research mainly focuses on translation using the Europarl (Koehn,

2005) corpus, which is widely adopted in the community. There are no data privacy issues or bias against certain demographics with regard to this dataset.

Potential Use: The potential use of this study is to improve future MT practice in terms of both evaluation and training.

Generalizability: Most conclusions in this study are language-agnostic and potentially help MT in all language pairs, although due to the limitations of available data, the study mainly uses the common languages, English, German, French, and Spanish, in a relatively low-resource setting of around 100K to 200K data. It will be meaningful to explore whether the conclusions of this paper can generalize to higher-resource data and a wider variety of languages. There is a possibility that the findings of the study will need to be further adjusted in different settings, which we strongly encourage future work to explore.

Limitations: First, the current study mainly looks into clear cases of causal or anticausal learning, but there can potentially be a third case where both languages are translated from a third language, as pointed out in Riley et al. (2020, Figure 1), which is worth exploring for future work.

Second, this work extracts human translation directions from the Europarl corpus, with the assumption that the speakers at the European Parliament tend to be native speakers. It might also be possible that the Europarl corpus contains text annotated as originals but from non-native speakers, but since the European Parliament is a highly formal and important venue, the speakers tend to be at least proficient users of that language, if not native. In addition, for non-English languages in our corpus, it is highly likely that the speech comes from a native speaker.

Third, in addition to the length and content factors considered in this work, it could be interesting to look at other factors that can constitute the Z variable in Eq. (3). Some motivations include that the data-model direction match seems to be a clear cause for the MT performance, and the fact that it does not always show a very large causal effect might mean that there are additional hidden variables to take into consideration.

Lastly, due to financial budgets, we did not use human evaluation in addition to the BLEU score reported in this work. We released all outputs of our model so future work can feel free to evaluate our results by human evaluation or various other automatic evaluation metrics. See more discussions on recommended evaluation metrics in Appendix D.3.

Acknowledgments

We sincerely thank Prof Rico Sennrich for his constructive suggestions on improving the message we present from our experiments to the MT community, and Isaac Caswell at Google Translate for proofreading our paper. We thank Claudia Shi for the insightful discussions on the matching method and suggestions on papers to cite. We thank Shaoshu Yang and Di Jin for supporting us with computational resources. We thank Zhiheng Lyu for helping to code a fast version of the sentence similarity matching.

Zhijing Jin is supported by the Open Phil AI Fellowship and the Vitalik Buterin PhD Fellowship from the Future of Life Institute.

Author Contributions

Jingwei Ni conducted most of the MT experiments, collected the most updated version of CAUSALMT dataset, and performed various analyses.

Zhijing Jin designed the project, conducted the causal inference experiments, structured the first version of the codes to run the MT experiments, and collected the first version of CAUSALMT dataset which is also used in our previous study (Jin et al., 2021a).

Markus Freitag helped design the storyline of the translationese part, gave insights on what analyses are important, and provided suggestions on the evaluation.

Mrinmaya Sachan and **Bernhard Schölkopf** guided the project and provided substantial contributions to the storyline of the paper.

Everyone contributed to writing the paper.

A Reproducibility, License, and Copyright

We open-source our codes and datasets, which are both uploaded to the submission system. In our data, we include all three variations: the full CausalMT dataset, the split used for the semi-supervised learning experiments, and the subset after matching the contents and sentence lengths. In our codes, we include all commands with hyperparameters to help future work to reproduce our results.

The codes and data are under MIT license. Note that the Europarl dataset has no copyright restriction, according to its official website.[6]

B Linguistic Property Analysis

We also open-source the codes to calculate the linguistic properties of our dataset in Table 1. We use the Python library Stanza[7] (Qi et al., 2020) to tokenize the sentences when calculating the number of sentences per sample. For computational efficiency, we use NLTK[8] (Bird et al., 2009) to tokenize the words and count the vocabulary.

We use the Python library spaCy[9] (Honnibal and Montani, 2017) to calculate the punctuation per sample. We use a passive voice checker[10] (only available in English). For the expansion factor, we formatted Table 1 using the ratio of the two languages in a descending alphabetical order of each language pair. In our table, it happens to be the ratio of the more verbose language to the less verbose language in each language pair.

C Implementation Details

C.1 Preprocessing

To prepare the text for the models, we follow the preprocessing scripts of fairseq (Ott et al., 2019).[11] Specifically, we use the Moses tokenizer (Koehn et al., 2007),[12] the default byte pair encoding (BPE) size of 40K subwords, and remove sentence pairs that of larger than 1.5 length ratio from the training set.

C.2 Evaluation Script

We use the fairseq script[13] to calculate the BLEU score (Papineni et al., 2002) of each translation model, with a beam width of 5, BPE removed, and detokenized by moses.

C.3 Model Details

We use the sequence-to-sequence Transformer model (Vaswani et al., 2017) implemented by the fairseq library (Ott et al., 2019). Specifically, we use a six-layer Transformer, a label smoothing of 0.1, a weight decay of 0.0001, a dropout of 0.3, 4000 warming updates, and a learning rate of 0.0005. All results are reported by a single run but a fixed random seed.

For the semi-supervised learning, we implement the BT model following Edunov et al. (2020) to use the Facebook-FAIR system of the WMT'19 news shared translation task.[14] All the hyperparameters are the same as the supervised system, with a learning rate of 0.0007 on both the supervised training data and the generated pseudo-parallel corpus. We implement the ST model by He et al. (2019) following their script,[15] and also keep the hyperparameters the same as the supervised model.

C.4 Training Details

We train the supervised learning model and each step in the semi-supervised learning scripts for 1000 epochs. We select the model with the best performance on the development set and report the final evaluation results on the test set.

All experiments are run on NVIDIA RTX2080 GPUs. Each supervised learning experiment takes around 32 GPU hours, and each semi-supervised learning experiment takes about 128 GPU hours.

D Additional Experimental Results

D.1 Effect of Train-Test Direction Match on Supervised Learning

To inspect the influence of train-test direction match on the MT performance, we conduct all experiments on our CausalMT test sets and also the standard newstest2014 test sets. For the supervised learning performance, we list the performance on

Table 6: Effect of train-test direction match on the en-fr and en-de test sets of *newstest2014*.

the CAUSALMT test sets in the main paper in Table 2, and list the additional performance on the newstest2014 test sets in Table 6.

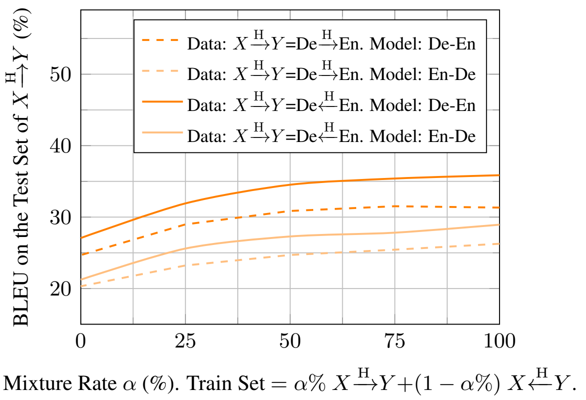
For better visualization of the trends, we also provide line plots of the same experimental results in Table 2. Specifically, we plot the results of German-English translation in Figure 4a using our previous experiment results in Table 2. We also include the diagram of all five language pairs in Figure 4b.

In Figure 4a, we use lines with the same darkness of color for the same model trained on different data directions. Results show that the data-model direction match matters significantly. Taking the German-to-English translation models (- - - and —), the two data directions can cause up to 4.53 difference in BLEU points. In the current figures, we also see that the data direction with a smaller expansion factor is a better training corpus than the other one.

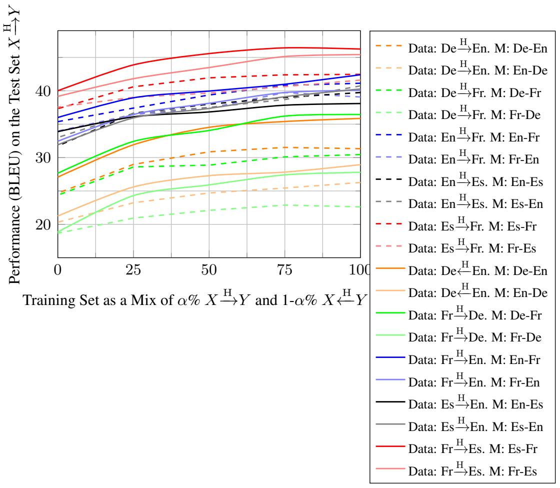
We use the same line type (dashed or solid) for models trained on the same data. Using the same data, the performance of the two different directions of models cannot be compared directly because the target language is different, causing the BLEU calculation to be different.

D.2 Effect of Train-Test Direction Match on Semi-Supervised Learning

For the semi-supervised learning performance, we show the performance on the newstest2014 test sets in Table 3 in the main paper, and performance on the test sets of CAUSALMT in Table 7. Note that the decrease of ST performance on En-Es and Es-Fr pairs is possible because ST is more sensitive to the quality of the model learned on the supervised data, and these language pairs have a smaller training



(a) Translation performance between German and English on different mixtures of training sets combining $\alpha\% \; X \xrightarrow{H} Y$ data and $(1-\alpha\%) \; X \xleftarrow{H} Y$ data, where $\alpha = 0, 25, 50, 75, 100$. Note that there are four settings between German and English, by varying two different data origins ($X \xrightarrow{H} Y$ data = De$\xrightarrow{H}$En or De$\xleftarrow{H}$En) and two different translation task directions (German-to-English (De-En) translation or English-to-German (En-De) translation).



(b) Translation performance between all five language pairs on different mixtures of training sets combining $\alpha\% \; X \xrightarrow{H} Y$ data and $(1-\alpha\%) \; X \xleftarrow{H} Y$ data, where the mixture rate $\alpha = 0, 25, 50, 75, 100$.

data size of 90K compared with 200K+ data for all the other language pairs.

D.3 Non-BLEU Evaluation Metrics

Due to financial constraints, we did not use human evaluation in addition to the BLEU score in our study. However, we encourage future studies in this line of work to include human evaluation results, as evaluation is important given the nature of such work, and human evaluation is reported to be more reflective of the real translation quality (Edunov et al., 2020).

To make it convenient for follow-up work, we open-source all the outputs generated by our model

Table 7: Performance analogous to Table 3 but on our CAUSALMT test sets.

to our GitHub. We also encourage future work to adopt more evaluation metrics such as COMET and BLUERT, which are among the metrics that correlates the best with human judgements according to the metric task at WMT Freitag et al. (2021). COMET, for instance, correlates better with human judgements than BLEU (Kocmi et al., 2021) and goes further string matching.

E Implementation Details for Causal Inference

E.1 Statistics of the Matched Corpora

We list the statistics of the matched corpora in Table 8, and analyze its linguistic properties in Table 9.

Human Trans. Dir.	Train	Dev	Test
De $\xrightarrow{H}$En	107K	1K	2K
En $\xrightarrow{H}$De	107K	1K	2K
De $\xrightarrow{H}$Fr	133K	1K	2K
Fr $\xrightarrow{H}$De	133K	1K	2K
En $\xrightarrow{H}$Fr	87K	1K	2K
Fr $\xrightarrow{H}$En	87K	1K	2K
En $\xrightarrow{H}$Es	47K	1K	2K
Es $\xrightarrow{H}$En	47K	1K	2K
Es $\xrightarrow{H}$Fr	50K	1K	2K
Fr $\xrightarrow{H}$Es	50K	1K	2K

Table 8: Dataset statistics for five language pairs after matching. Each language pair has data from two human translation directions (Human Trans. Dir.), e.g., De$\xrightarrow{H}$En and De$\xleftarrow{H}$En.

E.2 Confirming the Causal Graph by Causal Discovery

To check our causal graph assumption, we first verify whether data-model direction match is a cause for MT performance using causal discovery.

We use the causal discovery algorithm, fast causal inference (FCI) (Spirtes et al., 2000a), to verify that the data-model direction match causally affects the translation performance, conditioned on other factors such as the sentence length and topics.

FCI is the most appropriate causal inference method for this analysis since there might exist hidden confounders that affect the MT performance, which normal causal discovery methods such as score-based methods (Heckerman et al., 1999; Huang et al., 2018) and other constraint-based algorithms like Peter-Clark (PC) algorithm (Spirtes et al., 2000b, §5.4.2, pp. 84–88) cannot handle (Glymour et al., 2019). FCI gives asymptotically correct results in the presence of confounders, and outputs Markov equivalence classes, i.e., a set of causal structures satisfying the same conditional independences.

Given a language pair X and Y, we generate eight sets of experiment results, by varying the two training directions, two test directions, and two model directions. We extract the test samples of all eight experiments, and since each test set is 2K, there are 16K samples in total. On the 16K samples, besides keeping the label of their data-model direction match, translation performance in BLEU, we also calculate the other factors such as the test-model direction match, train-test direction

Visual Commonsense in Pretrained Unimodal and Multimodal Models

Abstract

Our commonsense knowledge about objects includes their typical visual attributes; we know that bananas are typically yellow or green, and not purple. Text and image corpora, being subject to reporting bias, represent this world-knowledge to varying degrees of faithfulness. In this paper, we investigate to what degree unimodal (language-only) and multimodal (image and language) models capture a broad range of visually salient attributes. To that end, we create the Visual Commonsense Tests (ViComTe) dataset covering 5 property types (color, shape, material, size, and visual co-occurrence) for over 5000 subjects. We validate this dataset by showing that our grounded color data correlates much better than ungrounded text-only data with crowdsourced color judgments provided by Paik et al. (2021). We then use our dataset to evaluate pretrained unimodal models and multimodal models. Our results indicate that multimodal models better reconstruct attribute distributions, but are still subject to reporting bias. Moreover, increasing model size does not enhance performance, suggesting that the key to visual commonsense lies in the data.[1]

1 Introduction

The observation that human language understanding happens in a rich multimodal environment has led to an increased focus on visual grounding in natural language processing (NLP) (Baltrusaitis et al., 2019; Bisk et al., 2020), driving comparisons between traditional unimodal text-only models and multimodal models which take both text and image inputs. In this work, we explore to what extent unimodal and multimodal models are able to capture commonsense visual concepts across five types of relations: color, shape, material, size, and visual co-occurrence (cf. Fig. 1). We further explore how this ability is influenced by reporting bias (Gordon and Van Durme, 2013), the tendency of large corpora to over- or under-report events. We define visual commonsense as knowledge about generic visual concepts, e.g. “knobs are usually round”, and we measure this knowledge via frequency distributions over potential properties (e.g. round, square, etc). A visually-informed language model should be able to capture such properties. Our color, shape, material, and co-occurrence data are mined from Visual Genome (Krishna et al., 2016), and our size data are created from object lists. They contain a large number of examples of per-object attribute distributions and “object-attribute” pairs.

Paik et al. (2021) evaluate language models' color perception using a human-annotated color dataset (CoDa), finding that reporting bias negatively influences model performance and that multimodal training can mitigate those effects. In this work, we confirm those findings while extending the evaluation to a broader range of visually salient properties, resulting in a more comprehensive metric for visual commonsense. In order to elicit visual commonsense from language models, we utilize soft prompt tuning (Qin and Eisner, 2021), which trains optimal templates by gradient descent for each model and relation type that we explore. We also utilize knowledge distillation to enhance a text-only model's visual commonsense ability, where the vision-language model serves as the teacher.

The major contributions of this work are: (1) we design a comprehensive analytic dataset, ViComTe, for probing English visual commonsense, that is applicable to any language model; (2) we use ViComTe to study models' ability to capture empirical distributions of visually salient properties. We examine unimodal language models, multimodal vision-language (VL) models, and a knowledge-distilled version of a VL model; and (3) we analyze the effects of reporting bias on the visually-grounded vs. ungrounded datasets and models.

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5321 - 5335
July 10-15, 2022

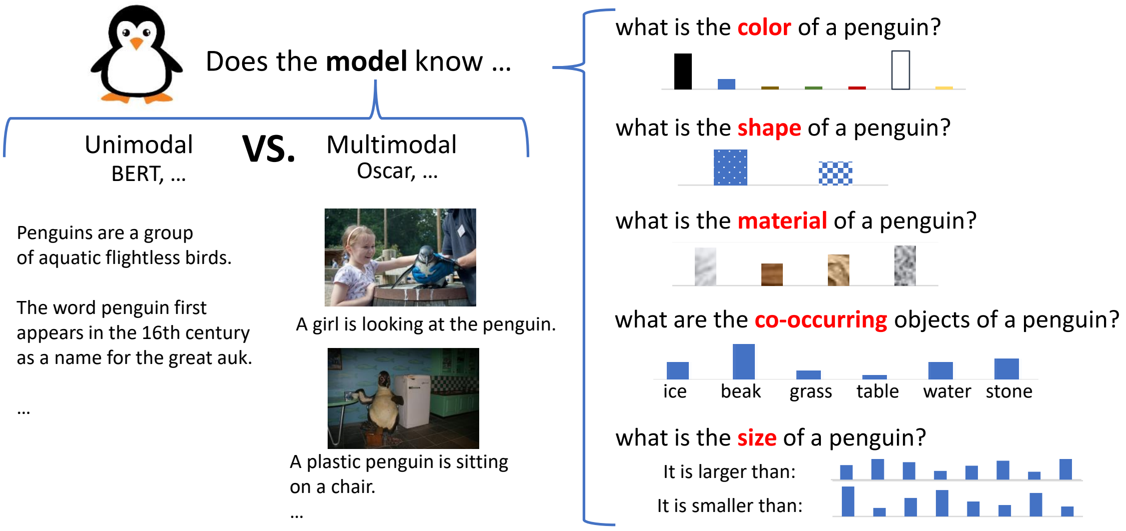

Figure 1: We compare unimodal and multimodal models' abilities to capture visual commonsense knowledge. The commonsense knowledge is evaluated on five relation types: color, shape, material, size, and visual co-occurrence. We compare the model outputs with the gold distribution from ViComTe, which is mined from Visual Genome.

2 Related Work

2.1 Vision-Language Modeling

Recent advances in vision-language (VL) modeling have led to increased success on benchmark tasks. Most VL models learn joint image and text representations from cross-modal training of transformers with self-attention, including LXMERT (Tan and Bansal, 2019), ViLBERT (Lu et al., 2019), VisualBERT (Li et al., 2019), UNITER (Chen et al., 2020), etc. Oscar (Li et al., 2020) additionally uses object tags in images as anchor points to facilitate the learning of image-text alignments and VinVL (Zhang et al., 2021) presents an improved object detection model. CLIP (Radford et al., 2021) learns by predicting caption-image alignment from a large internet corpus of (image, text) pairs.

While our work uses textual prompt tuning techniques, there have also been work on visual prompt engineering to enhance the performance of pre-trained vision-language models. Zhou et al. (2021) model context in prompts as continuous representations and learn to optimize that context. Yao et al. (2021) develop a cross-modal prompt tuning framework that reformulates visual grounding as a fill-in-the-blank problem for both image and text.

2.2 Visual Commonsense

In one of the early attempts at learning visual commonsense, Vedantam et al. (2015) measure the plausibility of a commonsense assertion in the form of (obj1, relation, obj2) based on its similarity to known plausible assertions, using both visual scenes and accompanying text. Zellers et al. (2021) learn physical commonsense via interaction, and use this knowledge to ground language. Frank et al. (2021) probe whether VL models have learned to construct cross-modal representations from both modalities via cross-modal input ablation.

Note that our definition of visual commonsense differs from that of Zellers et al. (2019), where the model is required to perform commonsense reasoning based on an image. Our definition of visual commonsense is more similar to the idea of stereotypic tacit assumptions (Prince, 1978) – the propositional beliefs that humans hold about generic concepts, such as "dogs have to be walked". Weir et al. (2020) probe neural language models for such human tacit assumptions and demonstrate the models' success. We extend this intuition to visual concepts and explore how visual information may help language models to capture such assumptions.

There has also been earlier work on the McRae feature norms (McRae et al., 2005), in which human annotators wrote down attributes that describe the meaning of words. For instance, "car" can be labeled as "has four wheels" and "apple" can be labeled as "is green". Silberer et al. (2013) expand the McRae dataset into a set of images and their visual attributes and construct visually grounded distributional models that can represent image features with visual attributes.

Zhu et al. (2020) examine the "language prior" problem in Visual Question Answering models, where models tend to answer based on word frequencies in the data, ignoring the image contents. In this work, we explore to what extent such a language prior is recruited absent a visual input.

2.3 Reporting Bias

Pretrained language models such as BERT (Devlin et al., 2019) are trained on billions of tokens of text, capturing statistical regularities present in the training corpora. However, their textual training data can suffer from reporting bias, where the frequency distribution of specific events and properties in text may not reflect the real-world distribution of such properties (Gordon and Van Durme, 2013). For example, while grass is typically green, this may be under-reported in web corpora (as it is assumed to be true), and while motorcycle crashes may be more common in the real world, plane crashes are mentioned far more in news text (Gordon and Van Durme, 2013). Misra et al. (2016) highlight the reporting bias in "human-centric" image annotations and find that the noise in annotations exhibits a structure that can be modeled.

3 Dataset: ViComTe

3.1 Dataset Mining

For each relation color, shape, material, size, and object co-occurrence, our data take the form of (subject, object) tuples extracted from object distributions per subject. The goal is to predict the object and its distribution from the subject and relation. Table 1 summarizes the number of classes and subject-object pairs for each relation.[2]

Color, Shape, Material For color, shape, and material, the subject is a noun and the object is the color, shape, or material property of the noun, mined from attributes of Visual Genome (VG) (Krishna et al., 2016).[3] We manually create a list of single-word attributes for each relation, and only VG subjects that are matched with a specific attribute for more than a threshold number of times are recorded, in order to avoid noise in the dataset. The thresholds for color, material, and shape are 5, 2, and 1, respectively, chosen based on the availability of attributes of each relation in VG. VG attributes are filtered with the following steps: (1) attribute "Y colored / made / shaped" is treated as "Y"; (2) select only the last word for compound attributes (e.g. treat "forest green" as "green"); (3) similar attributes are merged into a main attribute class (e.g. "maroon" and "crimson" become "red").

The above procedure produces a distribution over the set of attributes for each subject noun. From that distribution, a (subject, object) data instance is generated for each subject where the object is the attribute that associates with it the most. See the first three rows of Table 1 for examples.

Size Size is separated into `size_smaller` and `size_larger`, where the subject is a noun and the object is another noun that is smaller or larger, respectively, than the subject. To form the size dataset, we obtain a set of concrete nouns that appears in VG, which we manually classify into 5 size categories (`tiny`, `small`, `medium`, `large`, and `huge`). Typical objects in each category includes *pill*, *book*, *table*, *lion*, *mountain*, respectively. We randomly pick two nouns from different categories to form a (subject, object) pair.

Visual Co-occurrence The visual co-occurrence dataset is generated in a similar way to the color, shape, and material datasets. Co-occurrence distribution is extracted from Visual Genome where two objects that occur in the same scene graph together for more than 8 times are recorded, and a (subject, object) instance is generated for each subject, where the object is the noun that co-occurs with the subject the most.

3.2 Data Grouping

Following Paik et al. (2021), we split the color, shape, and material datasets each into three groups: SINGLE, MULTI, and ANY. The SINGLE group is for subjects whose most common attribute covers more than 80% of the probability, e.g., the color of *snow* is almost always white. The MULTI group is defined as subjects not in the SINGLE group where more than 90% of the probability falls in the top 4 attribute classes, e.g., the color of a penguin in Fig. 1. The rest of the subjects are in the ANY group. Lower model performance for the SINGLE group would indicate the influence of reporting bias. For example, if the model is unable to correctly capture the distribution of the color of *snow*, it is likely because the color of snow has low probability of being reported in the training corpus, as people know it is white by default.

Wikipedia	All	33.4 ± 30.6	302	543.6	1758.0	49.8	
	SINGLE	29.6 ± 29.9	110	352.2	345.8	35.0	35.5
	MULTI	33.9 ± 30.9	119	500.8	1242.0	27.6	
	ANY	38.2 ± 30.4	73	902.0	3000.2	161.2	

Table 2: Evaluation of ViComTe (mined from VG) and Wikipedia-mined color datasets by comparing with the human-annotated dataset CoDa. Reported are the average Spearman correlation (×100), number of common subjects, average number of occurrences of the common subjects, average number of occurrences of subjects with top- and bottom-5 Spearman correlations, and the percentage of top-1 attributes being matched for the single group. ViComTe has higher correlations with human annotations.

3.3 Templates

In order to elicit model response and extract target objects and distributions from text, we manually design a set of templates for each relation. There are 7 templates for color, shape, and material each, 8 for size, and 4 for visual co-occurrence. See Table 1 for example templates.

3.4 Wikipedia Data

In order to compare text-based and visually-grounded data, we mine the color, shape, and material datasets from Wikipedia data, which is typically used in model pretraining. To mine these text-based datasets, we combine the sets of subjects in VG, take the manual list of attributes as objects again, and extract (subject, object) pairs if the pair matches any of the pre-defined templates. In Section 3.5 we will show the advantages of the VG-mined dataset over this text-based dataset.

3.5 Dataset Evaluation

To ensure the validity of ViComTe, we compare our color dataset with the human-annotated CoDa dataset (Paik et al., 2021), which we assume is close to real-world color distributions and has minimal reporting bias. We see a reasonably strong correlation with CoDa, indicating that the ViComTe dataset is a good and cost-effective approximation to human annotations.

Metrics We report the Spearman's rank-order correlation between the two distributions in comparison, averaged across all subjects. The Spearman correlation is used instead of the Pearson correlation since for our purpose the rank of the object distributions is more important than the exact values, which may change due to data variability. The top-1 accuracy (Acc@1) is the percentage of the objects with the highest probability in the source distributions matching those in the target distributions. These two metrics are also used in later sections when evaluating model distributions.

Analysis Table 2 shows the detailed results of the evaluation of the ViComTe and Wikipedia color datasets by comparing with the human-annotated dataset, CoDa. We can see that ViComTe has much higher Spearman correlation with CoDa, as well as substantially higher top-1 accuracy for the SINGLE group. The correlation is expected to be low for the ANY group, because objects in the ANY group can have many possible colors.

Reporting bias is present in both datasets, as the average number of occurrences of SINGLE group subjects are much fewer than that of the MULTI and ANY group subjects. Counter-intuitively, for ViComTe, the highly-correlated SINGLE group subjects have fewer average occurrences than the ones with low correlations. This is contrary to our expectation that more frequent objects would better reflect the human-perceived distribution and can be explained by SINGLE subjects being easier to represent even without a large amount of data.

One example where the Wikipedia distribution diverges from the CoDa distribution is “penguin”, whose most likely color in CoDa is black, followed by white and gray; however, its top color in Wikipedia is blue, because “blue penguin” is a specific species with an entry in Wikipedia, even if it is not as common as black and white penguins. One example where the VG distributions diverge from CoDa is “mouse”, because in VG, most occurrences of “mouse” are computer mice, which are most commonly black, whereas when asked about the word “mouse”, human annotators typically think about the animal, so that the most likely colors in CoDa are white and gray.[4]

3.6 Dataset splits

Each of the color, shape, material, size, and co-occurrence datasets is split into 80% training data and 20% test data. All evaluation metrics are reported on the test set. The training set is used for the logistic regression and the soft prompt tuning algorithm (Section 4.2).

4 Probing Visual Commonsense

4.1 Models

We examine 7 pretrained transformer-based models and 2 variations of them, trained on a variety of data. BERT (Devlin et al., 2019), ALBERT (Lan et al., 2020), and RoBERTa (Liu et al., 2019) are trained on text only using a masked language modeling objective (MLM). Oscar (Li et al., 2020) is a vision-language model based on the BERT architecture, trained with an combined MLM and contrastive loss on text-image pairs. VisualBERT (Li et al., 2019) is another vision-language model based on BERT that learns joint representation of images and text. Tan and Bansal (2020) introduce the “vokenization” method, which aligns language tokens to their related images, mitigating the shortcomings of models trained on visually-grounded datasets in text-only tasks. Since our task is purely text-based, we also experiment with a pretrained vokenization model (BERT + VLM on Wiki). Finally, we use representations from CLIP (ViT-B/32) (Radford et al., 2021), which is trained with a contrastive image-caption matching loss.

Distilled Oscar As our experiments involve exclusively textual inputs, we develop a knowledge-distilled version of Oscar (“Distilled”) which corrects for the lack of image input in our task. Knowledge distillation (Hinton et al., 2015; Sanh et al., 2019) is the process of transferring knowledge from one model to another, where the student model is trained to produce the output of the teacher model. Here, we use Oscar as the teacher and BERT as the student. The training data is part of the Oscar pretraining corpus: COCO (Lin et al., 2014), Flickr30k (Young et al., 2014), and GQA (Hudson and Manning, 2019), and the Distilled Oscar model has access to the text data only. We use the Kullback-Leibler loss to measure the divergence between the output logits of BERT and Oscar, and optimize the pretrained BERT on that loss to match the outputs of Oscar. Configurable parameters are set the same as for Oscar pretraining.

CaptionBERT Since VL models are trained largely on caption data, it could be that the differences between a text-only model and a VL model come not from a difference in modalities – text vs. images and text – but from a difference in domain – webtext vs. image captions. In order to disentangle the effects of the domain difference from those of visual inputs, we train a BERT model from scratch (“CaptionBERT”) on Oscar’s caption-based text data (the same data as for the Distilled model). If CaptionBERT, which does not have exposure to visual inputs, performs better than BERT and similarly to VL models (which are trained with visual inputs), it would suggest that the training domain matters more than the modality. If, on the other hand, CaptionBERT performs worse than VL models, it would highlight the importance of modality.

4.2 Evaluation Methods

We compare the visual commonsense abilities of pretrained unimodal and multimodal models. Given a list of prompts and a subject word, each model outputs the distribution of the target word. Following Paik et al. (2021), we apply zero-shot probes to models that are trained on a language modeling objective, and conduct representation probes for those that are not. We report the prediction accuracy and the Spearman correlation of the output distribution with the true distribution.

We use models trained with an MLM objective (BERT, Distilled, etc) directly for zero-shot predic-

---

[4] Additional examples are provided in Appendix A.3.

tion of masked tokens.[5] For Oscar we add a word-prediction head on top of it. The results across templates are aggregated in two modes. In the "best template" mode, for each example, the highest Spearman correlation among all templates is reported, and the top-1 result is regarded as correct if the true target object is the same as the top-1 result of any of the templates. In the "average template" mode, the output distribution is the mean of the distributions across all templates.

Since CLIP is not trained on a token-prediction objective, we implement logistic regression on top of the frozen encoder output, to predict the target attribute or object. The input is each of the templates with the subject [X] filled with an input in the dataset. Like Paik et al. (2021), to give the model ample chance of success, we take the template that results in the best test accuracy score, report that accuracy and the Spearman correlation associated with that template. For the classification head, we use the Scikit-Learn implementation of Logistic Regression (random_state=0, C=0.316, max_iter=2000) (Pedregosa et al., 2011).

Soft prompt tuning In order to overcome the limitation of self-designed prompts, we incorporate prompt tuning technique that learns soft prompts by gradient descent, from Qin and Eisner (2021).[6] The algorithm minimizes the log loss:

$$\sum_{(x,y)\in E_r} -\log \sum_{\mathbf{t}\in T_r} p(y|\mathbf{t}, x)$$

for a set of example pairs E_r and template set T_r.

4.3 Size Evaluation

The size dataset differs from the other datasets in that we use relative sizes (X is larger/smaller than Y), as absolute size information is hard to obtain. Thus, we use two evaluation strategies for size.

Rank partition First, as in the previous prediction task, given a template such as "[X] is larger than [Y]" and an object [X], we ask the model to predict the distribution of [Y], taking only the distribution D of nouns in the size dataset. For the current object [X], we take the nouns in size categories that are smaller than the category of [X] (N_{sm}), and those that are in larger categories (N_{lg}). Let the length of N_{sm} be m and the length of N_{lg} be n. Then for the "larger" templates, we compute the average percentage of overlap between the top n objects in D and N_{lg} and that between the bottom m objects in D and and N_{sm}. For the "smaller" templates, the "top" and "bottom" are reversed.

Adjective projection The second approach follows that of van Paridon et al. (2021), which projects the word to be evaluated onto an adjective scale. In this case, we compute the word embeddings of the adjectives "small" and "large" and the nouns from models, so the scale is $\overrightarrow{\text{large}} - \overrightarrow{\text{small}}$ and the projection is calculated by cosine similarity. For instance, for the example noun "bear", the projection score is given by:

$$cos\_sim(\overrightarrow{\text{large}} - \overrightarrow{\text{small}}, \overrightarrow{\text{bear}})$$

With good word embeddings, larger nouns are expected to have higher projection scores. The validity of the adjective scales from word representations is shown by Kim and de Marneffe (2013).

4.4 Measuring Model Reporting Bias

We measure the reporting bias of our models by comparing model performance on datasets with different levels of reporting bias and on the SINGLE, MULTI, ANY groups of the ViComTe dataset.

We assume that CoDa contains no reporting bias, in which case we can interpret Table 2 as showing that ViComTe contains a relatively small amount of it, and Wikipedia contains a relatively large amount. Thus, a larger correlation of model outputs with ViComTe and a smaller one with Wikipedia would indicate less model reporting bias.

Also, since the SINGLE group subjects are those whose attribute distribution concentrates on a single attribute, these subject-attribute pairs are less likely to be reported in text corpora or even image annotations. Therefore, lower model correlation on the SINGLE group than the MULTI and the ANY groups would be a sign of model reporting bias.

5 Results

The experimental results show that multimodal models outperform text-only models, suggesting their advantage in capturing visual commonsense. However, all models are subject to the influence of reporting bias, as they correlate better with the distributions from Wikipedia than those from CoDa

---

[5] For the target words that contain more than one subword tokens, we use the first token as the target.

	Distilled	57.1 ± 21.9	64.6	**50.5 ± 12.3**	**82.8**	**45.4 ± 14.8**	**66.2**	**13.0 ± 10.1**
	BERT$_l$	37.6 ± 30.3	30.3	49.2 ± 12.6	78.4	43.7 ± 15.1	53.3	11.4 ± 8.0
	Oscar$_l$	57.6 ± 21.6	65.3	50.1 ± 12.2	81.3	45.2 ± 15.2	65.8	12.8 ± 9.6

Table 3: Spearman correlation and top-1 accuracy (both × 100) of zero shot probing, before and after soft prompt tuning ("N" and "Y" for the "Tune" column). This is the "average template" case where the output distribution is the mean of distributions across all templates. The Spearman correlation reported is the mean across all subjects ± standard deviation, comparing the output distribution and the Visual Genome distribution. The subscripts b and l indicate the size of the model, and Distilled is the BERT model after distilling from Oscar. Asterisk indicates where there is *no* significant difference between BERT$_b$ and Oscar$_b$ (t-test p-value > 0.05).

and ViComTe. Prompt tuning and knowledge distillation substantially enhance model performance, while increasing model size does not.

5.1 Results with MLM Objective

Color, Shape, Material The resulting model performance for the "average template" mode is shown in Table 3. Prompt tuning is done in this mode only. Note that because the top-1 accuracy is taken among all possible classes of each relation, it should be interpreted together with the number of classes (Table 1).

We can see from Table 3 that Oscar does better than BERT in almost all cases. Significant difference between Oscar (base) and BERT (base) is seen in most cases. Also, after soft prompt tuning, both the Spearman correlation and the accuracy substantially improved. Although there is considerable variation of the Spearman correlations, we find consistent improvement per example with both prompt tuning and multimodal pretraining (Appendix A.2).

Table 3 also shows that knowledge distillation helps improve the performance of BERT in all cases, and the distilled model can sometimes even outperform the teacher model, Oscar. Moreover, the large version of each model does not always outperform its base counterpart, suggesting that increasing the size of the model does not enhance the model's ability to understand visual commonsense. Instead, training with visually grounded data does.

Fig. 2 illustrates the Spearman correlations of different models with the color distributions from CoDa, ViComTe and Wikipedia, under the "best template" mode.[7] All models correlate moderately

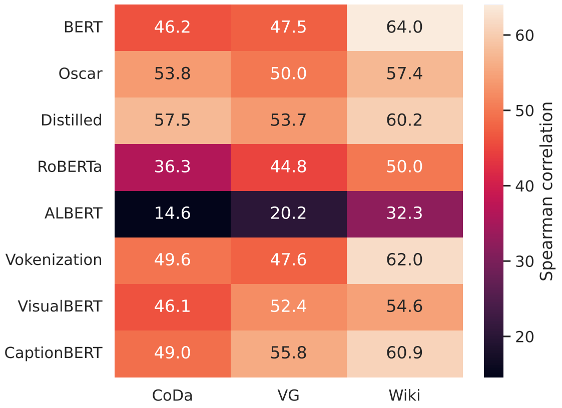

Figure 2: Spearman correlations (×100) for color, under the "best template" case, for base models on CoDa, VG, and Wikipedia. While all models correlate the best with Wikipedia, BERT is the most biased.

with all three datasets, with the highest correlations to Wikipedia, indicating text-based reporting bias in all model types. BERT has the largest correlation gap between Wikipedia and CoDa, whereas the visually-grounded models have smaller gaps, indicating less reporting bias in VL models.

Visual Co-occurrence Table 3 also contains the results on visual co-occurrence before and after prompt tuning. Only the Spearman correlations are reported, because the top-1 accuracy is meaningless due to the large number of possible co-occurring objects with any noun.

Before prompt tuning, BERT has small Spearman correlations, suggesting that it may contain little knowledge about the visual co-occurrence relationship. Oscar demonstrates more such knowledge under the zero-shot setting. After prompt tuning, all model performances improve.

---

[7] Appendix A.2 contains further details.

	Color		Shape		Material		Co-occur
Model	**Spearman ρ**	**Acc@1**	**Spearman ρ**	**Acc@1**	**Spearman ρ**	**Acc@1**	**Spearman ρ**
BERT$_b$	48.0 ± 21.6	51.4	53.2 ± 13.4	78.4	41.3 ± 15.6	51.1	30.2 ± 11.7
Oscar$_b$	**52.5 ± 20.8**	63.1	54.4 ± 14.8	**80.6**	**43.2 ± 14.4**	**63.0**	31.2 ± 12.1
CLIP	51.9 ± 20.8	**63.8**	**54.5 ± 13.9**	79.9	42.9 ± 15.0	**63.0**	**31.3 ± 11.6**

Table 4: Spearman correlation and top-1 accuracy (both × 100) with a logistic regression head on model encoder outputs. Oscar and CLIP have comparable performance, both slightly better than BERT.

		Color		Shape		Material	
Group	**Model**	**Spearman ρ**	**Acc@1**	**Spearman ρ**	**Acc@1**	**Spearman ρ**	**Acc@1**
SINGLE	BERT$_b$	36.8 ± 19.0	54.8	48.3 ± 12.3	83.0	35.9 ± 14.3	51.6
	Oscar$_b$	39.9 ± 15.3	60.3	**49.3 ± 11.6**	87.0	**38.5 ± 12.8**	**65.1**
	CLIP	**41.0 ± 15.2**	**66.3**	49.2 ± 14.5	**90.0**	38.1 ± 12.8	64.1
MULTI	BERT$_b$	49.7 ± 21.2	42.3	**65.9 ± 16.9**	59.5	53.8 ± 16.2	51.3
	Oscar$_b$	**51.2 ± 19.9**	50.6	65.2 ± 17.4	64.9	**56.2 ± 13.0**	53.9
	CLIP	50.5 ± 21.1	**55.4**	64.6 ± 18.9	**67.6**	56.2 ± 14.3	**59.2**
ANY	BERT$_b$	56.5 ± 19.5	46.1	100.0 ± 0	–	58.7 ± 15.2	**35.7**
	Oscar$_b$	**62.5 ± 18.9**	**58.4**	100.0 ± 0	–	60.4 ± 17.1	**35.7**
	CLIP	60.3 ± 18.2	55.8	100.0 ± 0	–	**63.5 ± 20.5**	21.4

Table 5: Per-group Spearman correlation and top-1 accuracy (both × 100) with a logistic regression head on model encoder outputs. Note that the ANY group for shape only has one example, so the accuracy is less meaningful and is omitted. All models have higher correlations in the MULTI and ANY groups than the SINGLE group, which is a sign of reporting bias.

5.2 Results with Classification Head

Table 4 shows the results of BERT, CLIP, and Oscar when topped with a classification head. We observe that Oscar and CLIP achieve similar performance and both outperform BERT. Note that, while Visual Genome is part of Oscar's pretraining corpus and one might suspect that that gives it an advantage, CLIP is trained on a large corpus from web search that is unrelated to Visual Genome. Therefore, we can conclude that multimodal models pretrained on both images and text outperform text-only models.

Table 5 breaks down the results in Table 4 into three subject groups. Oscar and CLIP outperform BERT in almost all cases. The top-1 accuracy is higher for the SINGLE group than for the MULTI and ANY groups, perhaps because the SINGLE group subjects have only one most likely target attribute, which may be easier to predict. Note that the Spearman correlations for all three models become higher from group SINGLE to MULTI to ANY. Paik et al. (2021) argue that higher correlation for the ANY and MULTI groups is a sign of model reporting bias, as objects in those two groups are more often reported. Thus, the results here indicate that reporting bias is still present in multimodal models.

5.3 Results: Size Relation

Table 6 shows results of the rank partition method (Section 4.3), before and after prompt tuning. Surprisingly, prompt tuning does not help in this case. Moreover, the performance for the "larger" templates is higher than that of the "smaller" templates, suggesting that the models contain inherent preference towards the "larger" templates.

Tune	Model	Larger	Smaller
N	BERT$_b$	80.0	67.1
	Oscar$_b$	79.5	67.7
	Distilled	**84.6**	60.7
	BERT$_l$	80.9	66.1
	Oscar$_l$	79.4	**70.7**
Y	BERT$_b$	69.9	55.7
	Oscar$_b$	70.6	57.3
	Distilled	70.6	57.3
	BERT$_l$	70.0	55.7
	Oscar$_l$	70.6	57.3

Table 6: Percent correct for size relation, for "larger" and "smaller" templates, before and after soft prompt tuning. Interestingly, tuning does not help with size.

Fig. 3 shows the results of the adjective projection method.[8] For BERT and Oscar, we use the average embedding of the subword tokens of the nouns projected onto that of the adjectives "large" and "small". For CLIP, we take the textual encoder outputs as the embeddings, resulting in a different score range from that of BERT and Oscar. The results show the following trend: larger objects are projected onto the "large" end of the spectrum, although the trend is sometimes broken towards the "huge" end. This may be due to the "huge" group

---

[8] Appendix A.2 contains per-object plot for BERT vs Oscar.

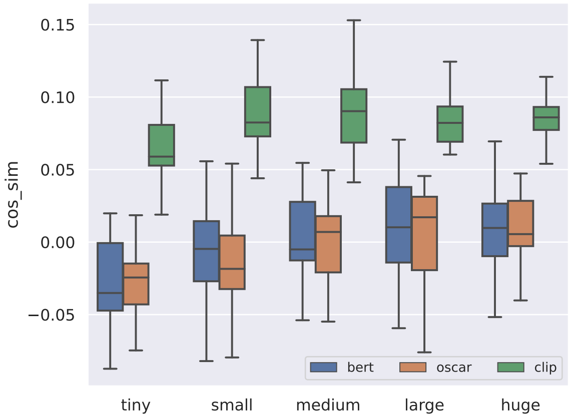

Figure 3: The size projection scores, where the x-axis indicates the object groups. Outliers are omitted. All three models perform reasonably well, as larger objects have higher cosine similarities in general.

including nouns such as “pool” and “house” which can be modified by a relative size indicator “small”.

5.4 Analysis and Limitations

In Table 3, the accuracy of BERT for shape is particularly low (only 6.7%), despite that shape has only 12 classes. We hypothesize that this is due to reporting bias on shape in the text corpora that BERT is trained on. This hypothesis is supported by mining sentences from Wikipedia that contain (noun, attribute) pairs, where we see that the relation shape has fewer number of occurrences than material and color (Appendix A.3).

We also investigate whether the advantage of the visually-grounded models over pure-language models comes from the domain difference between web corpora and image captions, or the presence of actual visual input. Although its teacher is trained with visual inputs, the Distilled model is trained only on captions data and its performance matches that of Oscar, so we hypothesize that grounded training data enhance models’ ability to capture visual commonsense. The CaptionBERT results support the hypothesis in favor of domain difference, since it performs better than BERT in both CoDa and VG (Fig. 2). Nevertheless, the visual inputs also have an effect, as Oscar has a higher correlation than CaptionBERT on CoDa. Thus, it seems that both domain and modality affect the ultimate model performance.

Finally, although multimodal models show improvement on the task, sometimes the improvement is not significant and the resulting correlations are still weak. Further work is needed to enhance the visual commonsense abilities of the models and mitigate reporting bias, and our datasets can serve as an evaluation method.

6 Conclusion

In this paper, we probe knowledge about visually salient properties from pretrained neural networks. We automatically extract dataset of five visual relations: color, shape, material, size, and co-occurrence, and show that our ViComTe dataset has a much higher correlation with human perception data for color than data mined from Wikipedia. We then apply several probing techniques and discover that visually-supervised models perform better than pure language models, which indicates that they can better capture such visual properties. Distilling the knowledge from a visually-supervised model into a pure language model results in comparable performance with the teacher model.

We also observe less reporting bias in both visually-grounded text (VG-mined datasets) than Wikipedia text and visually-grounded models (Oscar, DistilledOscar, VisualBERT, and CLIP) than pure language models. However, visually-grounded models are still subject to the influence of reporting bias, as seen in the per-group analysis, where both types of models perform better for the MULTI group than the SINGLE group.

A Appendix

A.1 List of Objects

Table 7 shows the list of all possible attributes for relations color, shape, and material. Table 8 shows the list of objects in the five categories of relation size. Visual co-ocurrence has a large number of objects that are not listed here for space reasons.

Relation	Classes
Color	**black**, **blue** (aqua, azure, cyan, indigo, navy), **brown** (khaki, tan), **gray** (grey), **green** (turquoise), **orange** (amber), **pink** (magenta), **purple** (lavender, violet), **red** (burgundy, crimson, maroon, scarlet), **silver**, **white** (beige), **yellow** (blond, gold, golden)
Shape	**cross**, **heart**, **octagon**, **oval**, **polygon** (heptagon, hexagon, pentagon), **rectangle**, **rhombus** (diamond), **round** (circle), **semicircle**, **square**, **star**, **triangle**
Material	**bronze** (copper), **ceramic**, **cloth**, **concrete**, **cotton**, **denim**, **glass**, **gold**, **iron**, **jade**, **leather**, **metal**, **paper**, **plastic**, **rubber**, **stone** (cobblestone, slate), **tin** (pewter), **wood** (wooden)

Table 7: List of all objects for relation color, shape, and material. Inside the parentheses are the attributes that are grouped into the object class.

Size	Objects
Tiny	ant, leaf, earring, candle, lip, ear, eye, nose, pebble, shrimp, pendant, spoon, dirt, pill, bee
Small	bird, tomato, pizza, purse, bowl, cup, mug, tape, plate, potato, bottle, faucet, pot, knob, dish, book, laptop, menu, flower, pillow, clock, teapot, lobster, duck, balloon, helmet, hand, face, lemon, microphone, foot, towel, shoe
Medium	human, door, dog, cat, window, lamp, chair, tire, tv, table, desk, sink, guitar, bicycle, umbrella, printer, scooter, pumpkin, monitor, bag, coat, vase, deer, horse, kite
Large	elephant, car, tree, suv, pillar, stairway, bed, minivan, fireplace, bus, boat, cheetah, wall, balcony, bear, lion
Huge	building, airplane, plane, clocktower, tower, earth, pool, mountain, sky, road, house, hotel, tank, town, city, dinasour, whale, school

Table 8: List of objects in five size categories.

A.2 Additional Probing

Best template mode Table 9 contains zero-shot results under the "best template" mode, for BERT (base), Oscar (base), BERT distilled from Oscar, RoBERTa (base), ALBERT (base), Vokenization, and VisualBERT (base). These results demonstrate similar trends as the ones in the "average template" mode.

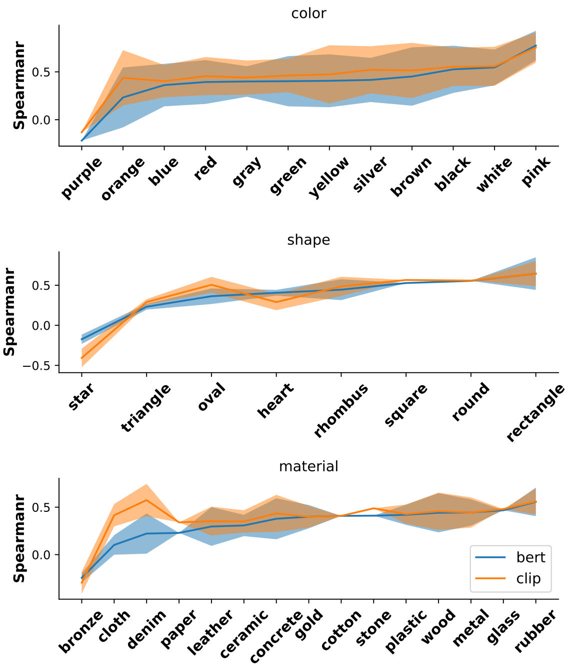

Figure 4: Spearman correlation per object class for BERT and CLIP with the logistic regression head, for color, shape, and material. The error margins are the standard deviations.

Per-object analysis Fig. 4 illustrates the fine-grained Spearman correlation ± standard deviation per object group for BERT and CLIP.

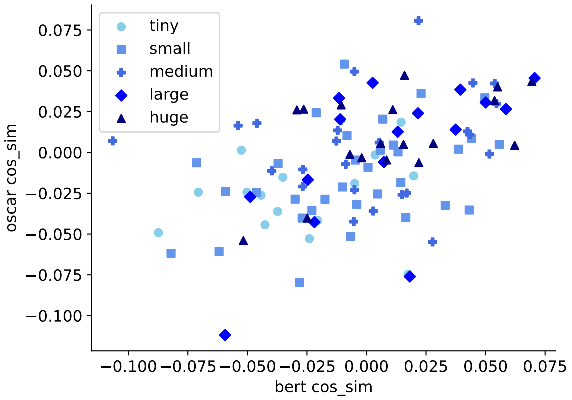

Figure 5: The size projection scores from BERT and Oscar, where each point is one object. Cosine similarities are correlated between Oscar and BERT.

Size per-object Fig. 5 shows how the per-object projection scores on the size spectrum from BERT and Oscar are correlated.

	Color		**Shape**		**Material**		**Cooccur**
Model	**Spearman ρ**	**Acc@1**	**Spearman ρ**	**Acc@1**	**Spearman ρ**	**Acc@1**	**Spearman ρ**
BERT$_b$	47.5 ± 21.6	41.8	48.2 ± 12.0	64.3	41.9 ± 15.4	55.3	6.1 ± 4.0
Oscar$_b$	50.0 ± 19.8	59.8	**52.7** ± **10.0**	89.3	**46.5** ± **13.7**	**74.6**	10.1 ± 7.2
Distilled	53.7 ± 21.3	57.7	51.4 ± 11.1	74.3	46.0 ± 13.6	**74.6**	10.4 ± 7.8
RoBERTa$_b$	44.8 ± 19.8	41.6	45.4 ± 12.4	69.3	33.0 ± 15.5	39.1	1.1 ± 1.4
ALBERT$_b$	20.2 ± 24.8	13.4	29.8 ± 15.7	13.6	25.0 ± 17.9	27.8	6.6 ± 5.1
Vokenization	47.6 ± 20.9	51.6	49.8 ± 13.1	72.9	39.4 ± 16.0	52.5	6.0 ± 3.7
VisualBERT	52.4 ± 19.8	65.3	48.7 ± 12.9	66.4	43.4 ± 15.5	59.5	**10.7** ± **8.1**
CaptionBERT	**55.8** ± **20.6**	**70.0**	51.3 ± 11.8	**91.4**	42.6 ± 15.4	54.6	10.2 ± 7.5

Table 9: Spearman correlation and top-1 accuracy (both × 100) of zero shot probing. This is the “best template” case discussed in Section 4.1.

Per-Subject Comparison Fig. 6 and Fig. 7 show how the Spearman correlations of 10 individual subjects improve after soft prompt tuning and after multimodal pretraining. Consistent improvement can be seen in color, material, and cooccurrence. Although we report average Spearman correlations in Table 3 and there are large standard deviations, here we show that when improvement is observed collectively, it is also consistent across subjects. With shape, the improvement is less obvious (45.9 to 50.4 for prompt tuning and 49.2 to 50.4 for multimodal pretraining).

A.3 Error Analysis

Data The three subjects with the highest and lowest Spearman correlation are shown in Fig. 8 and Fig. 9.

Wikipedia Table 10 shows the number of (noun, attribute) pairs of the three relation types in Wikipedia. Shape has fewer occurrences than material and color.

	Color	**Shape**	**Material**
Total	331480	195921	307879
Avg 12	27623.3	16326.8	24634.7

Table 10: First row is the total number of occurrences of (noun, attribute) pairs for relations shape, material, and color in Wikipedia. Second row is the average number of occurrences across the top 12 attributes for each relation. Shape has the fewest number of occurrences.

Model Table 11 shows the errors made by BERT and Oscar in the “average template” mode before prompt tuning. Overall, subjects with low correlation are those that are less often reported in Visual Genome as well as in textual data.

A.4 Resources

BERT, RoBERTa, ALBERT We use the Huggingface implementations of BERT, RoBERTa, and ALBERT.

Oscar See the GitHub repository for the code and pretrained Oscar: `https://github.com/microsoft/Oscar`.

CLIP We use the CLIP model released by OpenAI: `https://github.com/openai/CLIP`.

Vokenization See the GitHub repository for the pretrained model: `https://github.com/airsplay/vokenization`.

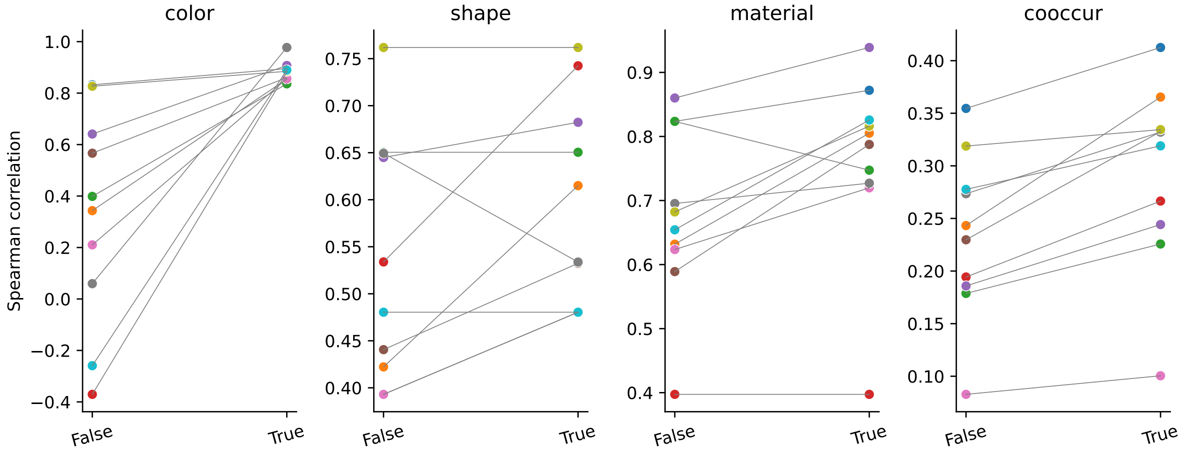

Figure 6: Spearman correlation of 10 subjects for each relation type before and after soft prompt tuning, with Oscar (base). Almost all individual subject has increased correlation after prompt tuning, except in relation shape.

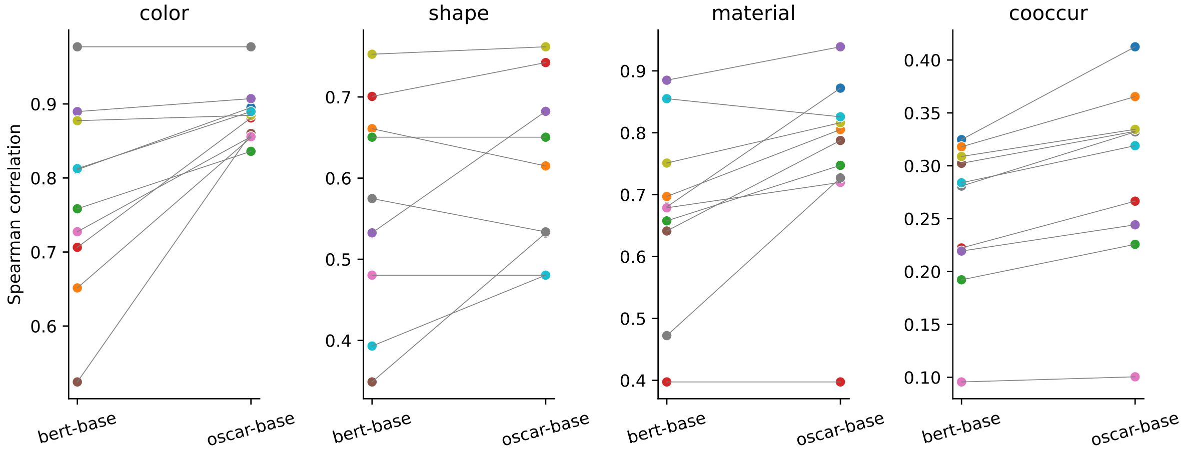

Figure 7: Spearman correlation of 10 subjects for each relation type with BERT (base) and Oscar (base), after soft prompt tuning. Almost all individual subject has higher correlation with Oscar than with BERT, except in relation shape.

	High Corr Subjs		**Low Corr Subjs**	
Relation	**BERT**$_b$	**Oscar**$_b$	**BERT**$_b$	**Oscar**$_b$
Color	lace, jacket, design	balloon, jacket, apple	flush, water faucet, muffler	hinge, leg, slack
Shape	mirror, vase, container	chair, pizza, vase	connector, log, knot	banana, toast, phone
Material	wall, tray, board	fence, wall, shelf	sheep, fabric, patch	elephant, rug, patch

Abstract

To enable building and testing models on long-document comprehension, we introduce QuALITY, a multiple-choice QA dataset with context passages in English that have an average length of about 5,000 tokens, much longer than typical current models can process. Unlike in prior work with passages, our questions are written and validated by contributors who have read the entire passage, rather than relying on summaries or excerpts. In addition, only half of the questions are answerable by annotators working under tight time constraints, indicating that skimming and simple search are not enough to consistently perform well. Our baseline models perform poorly on this task (55.4%) and significantly lag behind human performance (93.5%).

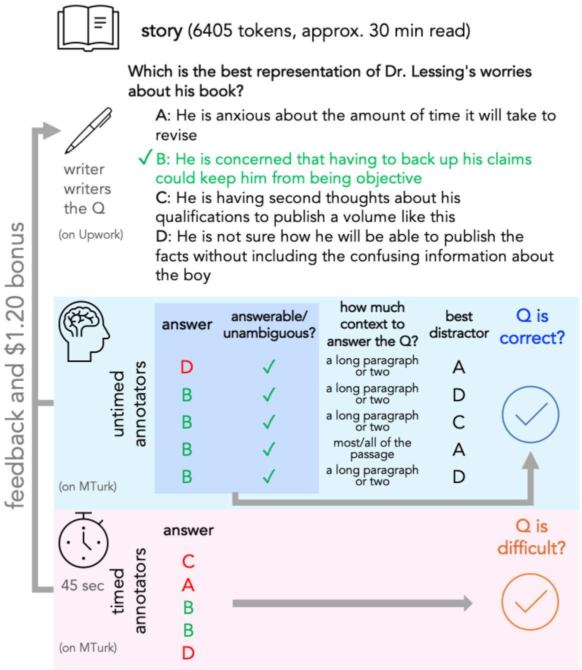

Figure 1: The crowdsourcing pipeline with an example. One writer reads the passage and writes 10 questions. Each question is validated by three or five annotators who read the full article, plus five more who have only 45 seconds per question. Writers receive feedback from both validations between writing batches. If a majority of timed annotators get the question wrong, but the untimed annotators get it right, we classify the example as HARD and give the writer a bonus.

1 Introduction

Most of the best models for natural language understanding are restricted to processing only a few hundred words of text at a time, preventing them from solving tasks that require a holistic understanding of an entire passage. Moving past this limitation would open up new applications in areas like news comprehension, summarization, or applied question answering. We think that new benchmark datasets will help us do this. Most existing datasets (Rajpurkar et al., 2018; Fan et al., 2019; Lelkes et al., 2021) use shorter contexts that humans can read within a few minutes. While there are open-domain QA datasets that require longer contexts (Joshi et al., 2017; Zhu et al., 2021), finding a short excerpt that answers the questions at hand often suffices; however, long-document QA requires understanding a long context as a whole to correctly answer questions.

NarrativeQA (Kočiský et al., 2018) is the most established existing long-text benchmark for language understanding. It's a free-text-response QA dataset built around movie scripts and books, with an average of about 63k tokens of input per question. The authors creatively use *summaries* of the texts as the basis for their questions to make data collection relatively efficient. This protocol leads to short answers (avg. 4.7 tokens), and few questions require complex explanation-based reasoning: >60% are what/who questions and <10% are why/reason questions. Further, the sources are usually famous, such that they are analyzed and discussed widely in the training data used by large language models. Additionally, the generation-based format comes with the hurdle of determining how

Source	Dif.	Question	Answer Options	Label
Gutenberg	Hard	Why was the Volpla vocabulary limited when the narrator took a few into the valley?	(a) They had not been alive long enough to learn enough English to communicate well (b) They were encountering concepts that were unfamiliar from the lab environment (c) They are not smart enough to have a fully developed language, no matter how hard they try (d) They were confusing their own language with English, having trouble keeping the languages separate	b
	Easy	What is Russell's greatest fear?	(a) Being disappointed (b) Losing his mind (c) Being lost and alone (d) Living forever	c
Slate	Hard	Which is NOT a reason why the narrator is concerned with the antichrist?	(a) Evangelical Christians are preaching that the end of the world is coming soon. (b) He is concerned that Christians will become violent toward Jews. (c) He thinks his life will be more important and influential than the average person. (d) He is conducting research for his dissertation.	d
	Easy	Why does the author tell a story about his vehicle?	(a) To talk about how fast he drives (b) To make a point about what has the most impact on the economy (c) To talk about safe driving speeds (d) To make a point about how many different things impact the unemployment rate	b
Misc.	Hard	How does Sara feel about the Chevrolet ad?	(a) She thinks it's a final chance to bond with her father (b) She is sorry she did not watch the whole ad before she reacted to it (c) She is upset at the glorification of the military (d) he is frustrated that it tokenized a Mexican family	b
	Easy	Why did Birmingham build over the Victorian era relics?	(a) To create space for a Maglev train (b) To erase their history (c) They were running out of room (d) To make technological progress	d

Table 1: Representative examples randomly selected from the training and dev sets in QuALITY.

to fairly assess accuracy, as metrics like BLEU, ROUGE, or BERTScore may not accurately convey the quality of generations (Wang et al., 2020; Durmus et al., 2020). To ease the burden of evaluation, we opt for a multiple-choice format to evaluate a model's long-document understanding ability.

We introduce our dataset QuALITY, Question Answering with Long Input Text, Yes![2] This is a multiple-choice QA dataset that uses English source articles of 2k–8k tokens.[3] We collect this dataset using a creative crowdsourcing pipeline that ensures the examples have unambiguous answers but are still challenging. We instruct example writers to carefully read the full source article before writing questions, and to then write questions that are unambiguous and require consolidating information from multiple parts of the text. Then, to ensure our questions require readers to understand the larger context from the passage, in addition to running standard validation where annotators read the text and answer the questions, we also run speed validation (§2.3). In speed validation, annotators only have access to the text for 45 seconds, so they can only skim or search for phrases to answer the question. If a question is unanswerable in this setting but unambiguous and answerable in the standard untimed setting, we use it as a signal for question difficulty. This crowdsourcing process is slow and expensive ($9.10/question),[4] but we successfully collect a challenging, high-quality, long-document multiple-choice QA dataset. QuALITY has 6,737 questions in total, of which 3,360 questions are in the difficult subset, QuALITY-HARD. Table 1 shows representative EASY and HARD examples from different types of source texts.

We test the Longformer (including the LED variant), RoBERTa, DeBERTaV3, and T5 models, using as much of the full source text as possible. In particular, for models whose context lengths are much shorter than the average article length, we test two-step systems with an extraction step that passes shorter contexts to the QA model. For text extraction, we use ROUGE-1 recall, fastText, or DPR based matching with the questions. The best model performance is achieved by DeBERTaV3-large with DPR-based extraction, with an accuracy of 55.4%. The best model's accuracy on QuALITY-HARD is 46.7%. Model accuracy is far below human accuracy on QuALITY, where human accuracy is 93.5% on the full dataset and 89.1% on

---

[2] The data is available, along with links to code and additional resources, at `https://github.com/nyu-mll/quality`. Results on QuALITY will be collected on a dedicated leaderboard at `https://nyu-mll.github.io/quality/` and through the multitask SCROLLS benchmark (Shaham et al., 2022).

[3] 1.5k–6k words, not counting punctuation.

[4] This includes the cost of question writing and validation for questions that were discarded after validation.

QuALITY-HARD.

2 Data Collection

2.1 Overview

Sources In order to create a dataset that is both broadly usable and meets the goal of containing long input texts, we use only sources that are licensed under CC-BY (or more permissive licenses) and contain articles of at least 2k tokens that are likely to allow for complex questions. We ultimately use Project Gutenberg fiction stories (mostly science fiction),[5] Slate magazine articles from the Open American National Corpus (Fillmore et al., 1998; Ide and Suderman, 2004), and other nonfiction articles taken from The Long+Short,[6] Freesouls,[7] and the book Open Access (Suber, 2012). Table 3 shows how many articles and questions come from each. Most of the Gutenberg texts are from the 1950s–1970s, while the other texts are mostly from the 1990s and after.

Texts are provided with the original HTML tags indicating paragraph breaks and basic formatting (e.g., italics), and it is in this format, with images removed, that we present the texts to our writers and annotators. In our dataset release, we also include a version of each file with this information stripped away, as current models, including our baselines, are not trained to consume these tags.

We set a maximum length for the texts at 6k words using word-level tokenization without counting HTML tags.[8] For around 40% of the Gutenberg articles, the full text data is much longer; in these cases, we truncate the texts and manually check to make sure the truncation happens at a reasonable location (i.e., not in the middle of a paragraph).

Stages of Data Collection We collect data over several rounds to provide writers with feedback throughout the process. We iterate through the following pipeline each round: (i) we assign writers a set of passages, and they write 10 questions for each (§2.2), (ii) annotators complete speed validation (§2.3.1), (iii) annotators complete untimed validation (§2.3.2), and (iv) we award writers bonuses and send feedback based on the annotations.

2.2 Question Writing

We hire 22 writers—most with degrees or professional experience in literature or teaching—from the freelancing platform Upwork and design a multi-part incentive structure to encourage difficult yet answerable questions. Details about hiring and writer qualifications are in Appendix A.1.1.

The Writing Task We design a feedback and incentive structure to encourage writers towards questions that are answerable, unambiguous, and difficult. Writers construct examples over multiple rounds, and they receive (i) detailed feedback based on the two validation tasks and (ii) bonuses based on how many of their questions met our criteria for HARD questions. Each writer constructs 10 questions with four answer options for a given passage, and they complete 6–30 such passages each round. Each passage is assigned to two writers, so there are 20 questions for each passage before filtering. Writers earn an average rate of \$21.05/hr, after bonuses. Details about this process and the timeline are in Appendix A.1.2.

2.3 Data Validation

We use two validation tasks to evaluate if (i) the questions are difficult by testing if they are answerable under strict time constraints (speed validation) and (ii) the questions have a single correct answer (untimed validation). We recruit 45 annotators via Amazon Mechanical Turk (MTurk); details on the qualification process are in Appendix A.2.1.

2.3.1 Speed Validation

We want to ensure that the questions require understanding of the full text to answer correctly. If a person can quickly identify the answer to a question, such as through skimming or ctrl-F-style in-browser search, then the question does not require broader understanding of the passage, and a model is likely to be able to identify the correct answer via extractive methods. More precisely, we aim to collect questions for which annotators, in the aggregate, are unable to select the correct answer under strict time constraints, and we construct a speed validation task to test this. Questions that pass this bar make up the HARD subset of QuALITY.

To our knowledge, this is a novel data collection method—it is inspired by adversarial collection methods (Nie et al., 2020; Bartolo et al., 2020) as a way of collecting more challenging data. As model performance on our dataset is very low, a true ad-

[6] `http://thelongandshort.org`

[7] `http://freesouls.cc`

[8] With spaCy tokenization, the maximum number of tokens is larger (Figure 2).

versarial design would not be practical because model behavior would not provide enough signal to the crowdworkers, and we would risk limiting the usefulness of QuALITY as a test set for a full range of models (Bowman and Dahl, 2021). Thus, we design this task in a way that writers can reason about what would be difficult for *another human* as opposed to a model, and we award bonuses based on that metric.

Procedure We collect five annotations per question; within each task, questions appear one at a time to ensure the time limit is consistent for each question. The worker first reads the question and the four answer options without access to the passage. Then they press a button to reveal the passage, and they have 40 seconds to skim or search for keywords (e.g., with ctrl+F) to determine the correct answer. After the timer runs out, the passage disappears, and they have 5 more seconds to select an answer. Appendix A shows the user interface.

Each task consists of 10 questions from different passages, and the order of the answer options is randomized. Within each task, there are nine questions written by the Upwork writers and one question written by the authors as a catch question. We pay workers $2.25 per task and award a bonus of $0.20 for each correct answer. On average, workers earn a bonus of $1.03 per task, and we estimate based on workers' survey responses that each task takes 11-12 minutes, for an effective rate of just over $17/hr. We use the catch questions to track annotator performance and ensure that all workers are performing well above chance on these examples, indicating that they are consistently making a faithful effort to find the answer in the text (see Appendix A.2.2 for additional details on the task, catch questions, and annotator performance).

2.3.2 Untimed Validation

To ensure all questions in QuALITY are correct and unambiguous, we conduct a validation task without a time limit, but with strong incentives towards accuracy. We collect three annotations for each example in the training set, and five annotations for each example in the dev and test sets.

Procedure Each task consists of one passage with all 20 questions created by the writers. Each of the 20 reading comprehension questions has three evaluation questions immediately below it. We instruct workers to first read the passage carefully and then answer all the questions. Each task pays $6.50, with a $0.50 bonus for each question in which both the reading comprehension question and evaluation question 1 (see below) agree with the majority vote label.[9] We estimate based on survey responses that workers spend about 50–60 minutes on this task; the average bonus rate is $8.13 per task, for an average rate of $15.96/hr.

Question	Answer Options
Q1. Is the question answerable and unambiguous?	○ Yes, there is a single answer choice that is the most correct. ○ No, two or more answer choices are equally correct. ○ No, it is unclear what the question is asking, or the question or answer choices are unrelated to the passage.
Q2. How much of the passage/text is needed as context to answer this question correctly?	○ Only a sentence or two of context ○ At least a long paragraph or two of context ○ At least a third of the passage for context ○ Most or all of the passage for context
Q3. Which of the options that you did not select was the best "distractor" item?	○ Option 1 ○ Option 2 ○ Option 3 ○ Option 4

Table 2: Evaluation questions asked after each reading comprehension question during untimed validation.

Evaluation Questions We ask the three evaluation questions in Table 2 immediately following each reading comprehension question to assess question quality. Q1 is used to determine inclusion into the final dataset, as we exclude any questions for which the majority of annotators marked that the question was either ambiguous or unanswerable. Q2 and Q3 are used for feedback to the writers.

We find that responses to the evaluation questions slightly differ between the HARD and EASY subsets. For Q1, individual raters are less likely to rate a HARD question as answerable and unambiguous (92.8%) compared to an EASY question (95.1%). For Q2, in the HARD subset, 26.1% of the time, the question is rated as needing at least a third of the context or more (the 3rd and 4th options), compared to 21.7% of the time in the EASY subset. In the HARD subset, 81.3% of the questions are rated as needing at least a long paragraph or two of context, compared to 73.9% in the EASY subset.

---

[9] Bonuses were $0.40 in round 1 and based only on reading comprehension questions. We updated both following our evaluation of the results and worker feedback.

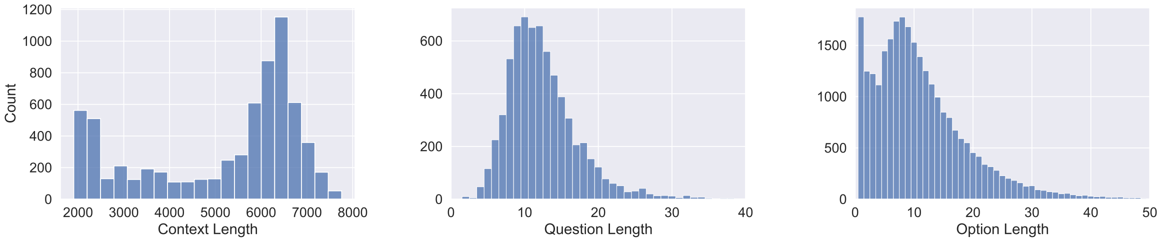

Figure 2: Article length, question length, and option length in QuALITY. The average length of an article, question, and option is 5,159 tokens, 12.5 tokens, and 11.2 tokens, respectively. The maximum length of an article, question, and option is 7,759 tokens, 103 tokens, and 75 tokens, respectively. The histograms are truncated to only keep the visible mass.

Annotator Performance We track annotator performance throughout data collection and remove any workers whose accuracy falls below 75% in any given round. Annotator agreement on the reading comprehension questions for each passage is high, with a median Krippendorff's alpha of 0.71. Agreement on Q1 is also high, with 92.6% individual agreement with the majority vote, with the two 'No' options collapsed for analysis (alpha values are less valuable on such a skewed question). As Q2 and Q3 are more subjective, responses are noisy, with median alpha values of 0.12 and 0.21, respectively. Additional details and our protocol for reannotating data are in Appendix A.2.3.

3 Dataset Information and Analysis

After aggregating the labels assigned via untimed validations with the original writer's label, we calculate the gold label via majority vote of annotators.[10] We only keep questions for which (i) a majority vote label (strictly larger than 50%) can be assigned and (ii) the majority of annotators rate the questions as answerable and unambiguous. 6,737 out of 7,620 (88.4%) questions meet these inclusion criteria. The HARD subset corresponds to questions that the majority of the annotators answer incorrectly in the speed validation setting, and this constitutes 49.9% of the final dataset.

3.1 Human Accuracy

We estimate human accuracy on QuALITY on a random sample of 20 passages (367 questions). Each question is annotated by 3 new annotators who had not previously annotated that passage, and whose labels do not contribute to the assignment of the gold label. We calculate the majority vote of the annotators, which yields an accuracy of 93.5% relative to the gold label. This breaks down to 89.1% on the HARD subset and 97.0% on the EASY subset. Annotators marked 98.5% of questions as answerable and unambiguous.

3.2 Size and Splits

We split the data into train/dev/test sets[11] such that there is minimal overlap in question writers among train/dev/test sets. This ensures that a model will not be rewarded for overfitting to any idiosyncrasies of a single writer's style. Table 3 shows the number of articles in QuALITY and HARD questions for each of the split. Gutenberg sources result in the highest proportion of HARD questions, and misc. sources result in the lowest proportion.

3.3 Length

Figure 2 shows the article lengths. The two peaks in the histogram correspond to articles from Slate and Gutenberg. The average context length is 5,159 tokens, much longer than other existing challenging QA datasets—CosmosQA (Huang et al., 2019) and RACE (Lai et al., 2017) contain an average context length of 70 and 322 tokens, respectively. We plot question length and option length in Figure 2 as well. The average question length is 12.5 tokens, and the average option length is 11.2 tokens.

3.4 Lexical Overlap

Prior work has shown that a lot of questions in existing datasets such as SQuAD can be answered by exploiting lexical overlap of the question with the article (Weissenborn et al., 2017). To under-

---

[10] This gold label calculation follows MNLI (Williams et al., 2018) but is more conservative as the writer's label is never a tie-breaking vote. The gold label and writer's label, both provided in the dataset, differ for ∼4% (274/7620) of questions.

[11] The test labels are not publicly released. The test set performance can be obtained by submitting to a leaderboard discussed in footnote 2.

Split	Gutenberg				Slate				Misc				All			
	Art.	All Qs	HARD Qs	% HARD	Art.	All Qs	HARD Qs	% HARD	Art.	All Qs	HARD Qs	% HARD	Art.	All Qs	HARD Qs	% HARD
Train	118	2000	1056	52.8	22	355	142	40.0	10	168	53	31.5	150	2523	1251	49.5
Dev	86	1552	873	56.2	19	351	149	42.5	10	183	43	23.5	115	2086	1065	51.1
Test	81	1486	828	55.7	25	450	170	37.8	10	192	46	24.0	116	2128	1044	49.1
All	285	5038	2757	54.7	66	1156	461	40.0	30	543	142	26.2	381	6737	3360	49.9

Table 3: Data splits within QuALITY. Items that did not pass untimed validation are excluded from this table. 'Art.' shows the number of articles. 'HARD Qs' is the number of questions in QuALITY-HARD.

stand how effective this heuristic is in QuALITY, we compute the lexical overlap between the options and the article in QuALITY. The lexical overlap is computed as the fraction of the tokens in the option which are present in the article. Figure 7 in the Appendix plots the distribution of lexical overlap for the correct options and the incorrect options—since each question has three incorrect options, we use the maximum lexical overlap among the three. Simply predicting the option with the highest lexical overlap achieves only 26.6% accuracy, so correct options do not have a higher lexical overlap than the incorrect options, making it difficult for models to rely on this heuristic.

3.5 Question Types

Question Type	# EASY	# HARD	% total
what	1361	1471	42.2
why	832	825	24.6
how	385	416	11.9
which	253	244	7.4
who	151	132	4.2
how + meas.	51	75	1.9
yes/no	53	55	1.6
where	43	42	1.3
when	35	34	1.0
other	155	124	4.1

Table 4: Different question types in QuALITY, split by HARD and EASY subsets. 'How + meas.' collapses multiple questions with 'how' plus some measurement, such as 'how long' or 'how many.' Examples of each question type are in Appendix Table 7.

We analyze the proportion of question types by automatically categorizing each question based on the first question word it contains.[12] Table 4 shows that QuALITY contains many questions that require complex responses about "how" and "why" an event happened in a greater proportion of cases than similar datasets such as NarrativeQA. However, we do not observe that our measure of question difficulty varies by question type.

3.6 Reasoning Strategies

As a qualitative analysis, we manually annotate the reasoning strategy needed in each question and present the results in Table 5. We take a random subset of 500 questions from the full dataset and manually annotate them. Each question is annotated by two of the authors; any disagreements in categorization are resolved via discussion. As we do not read the full passages, it is not always possible to determine the reasoning strategy, but we consider both the question and answer options in categorizing each item.

We find that many of the questions rely on (i) reasoning about the best description, (ii) determining the correct explanation for why something happened, or (iii) the reader making an interpretation or using symbolism. All three of these reasoning types are likely to rely on broader context from the passage, compared to questions about who did something or where something happened. For example, the question *How do you think Meredith feels about the rest of the crew?* requires a description of the character's feelings (description), and it also requires the reader to interpret the character's feelings (symbolism/interpretation) and reason about the relation between different characters (relation). We also find that, despite questions using "what" being the most frequent in the question-types analysis, very few of the questions in QuALITY depend on reasoning about objects or entities. Rather, most of these "what" questions ask for the description of a person or situation, or they ask for an interpretation from the reader. Further details about this analysis, the categories used, and examples of each reasoning type are in Appendix B.2.

---

[12] In cases where the question starts with an auxiliary verb, or where there is no question word but an auxiliary verb appears after a comma, we categorize the question as "yes/no."

Reasoning Type	# HARD/ 251	# EASY/ 249	% of total
Description	89	77	33.2
Why/reason	73	83	31.2
Symbolism/interpretation	76	63	27.8
How/method	25	19	8.8
Event	17	18	7.0
Person	11	17	5.6
Not/except	13	6	3.8
Relation	12	7	3.8
Entity	7	9	3.2
Finish the Phrase	3	12	3.0
Location	5	7	2.4
Numeric	5	6	2.2
Object	5	4	1.8
What if	3	4	1.4
Duration	1	2	0.6

Table 5: Qualitative assessment on a random 500 example subset of QuALITY, split by difficulty, and categorizing the different kinds of things that need to be reasoned about. Questions can require multiple reasoning types, so values do not add up to 100%.

4 Baseline Experiments

4.1 Models

Long-Context Models We experiment with the Longformer model (Beltagy et al., 2020), which uses a combination of sliding-window local attention and global attention to encode long inputs. The Longformer encoder models support up to 4,096 tokens. We test Longformer because it is likely to fit most or all of the context needed to answer the questions for the majority of examples in QuALITY.[13] We also experiment with Longformer Encoder-Decoder (LED) which supports up to 16,384 encoder input tokens.[14]

Extractive Models As an alternative to feeding the whole input context into a transformer model or truncating, we also test retrieval methods to score and extract relevant sentences from the passage and feed only the selected sentences as inputs to a given model. We can thus use a wider range of higher-performing short-sequence transformer models, at the cost of missing some input context.

Using the question as a retrieval query, we score each sentence in the passage relative to the query. We then select sentences in order of descending relevance until we reach 300 words.[15] We then sort the selected sentences based on the original passage order and use the concatenation as the 'passage' for that example.

We consider three scoring methods. First, we use ROUGE-1 recall relative to the query. Second, we use cosine similarity based on bag-of-words of fastText (Bojanowski et al., 2017) embeddings. Third, we use DPR (Karpukhin et al., 2020), a model trained for open-domain retrieval for QA. Because DPR tackles span-based question-answering, the *reader* model is unsuitable for our multiple-choice dataset. However, we can use the *retriever* model for extraction, using the separate question- and context-encoders to encode our question and context sentences to vector representations. We then score similarity based on the negative Euclidean (L^2) distance.

After extraction, we apply standard models for multiple-choice question-answering: RoBERTa (Liu et al., 2019) and DeBERTaV3 (He et al., 2021) encoder models, and the T5 (Raffel et al., 2020) encoder-decoder model. To establish an upper bound of how well extractive models can do, we also introduce an oracle baseline in which we apply the same extraction strategy described above, but we use the correct answer as the extraction query.

Question-Only Baselines To test for dataset artifacts, we consider a baseline where we only give the models the questions and answer options, leaving out the passage.

Supplementary Training Data To supplement the training examples in QuALITY, we incorporate additional training examples from the RACE task dataset (Lai et al., 2017). Like QuALITY, RACE is a passage-based, four-way multiple-choice question-answering dataset. Although the passages are much shorter (321.9 words on average), the training set is large (∼88k questions), so we can expect reasonable knowledge transfer from RACE to QuALITY. We use the full RACE dataset, including both middle-school and high-school questions, for our intermediate training.

We consider three fine-tuning formats: (1) fine-tuning on QuALITY data, (2) fine-tuning on RACE and zero-shot evaluating on QuALITY, and (3) applying intermediate training (Phang et al., 2018; Pruksachatkun et al., 2020) by first fine-tuning on RACE and then fine-tuning on QuALITY.

4.2 Results and Analysis

Table 6 shows model performance on the test set. The results on the development set and additional

Table 6: Accuracy on the full QuALITY test set and the QuALITY-HARD subset (formatted as full / HARD). The "Full" column has results from training with the source inputs truncated to fit into memory. R-1 (ROUGE-1), fastText, DPR are three extraction ("Extr") methods (§4.1) used to select relevant portions of the source text.

results from training just on RACE are in Appendix D.3. All results in Table 6 fall well below human performance. There is a gap of 38.1 points between our current best-performing model (DeBERTaV3-large trained on RACE→QuALITY, using DPR-based extraction) and human performance on the full test set. On QuALITY-HARD, this gap increases to 42.4 points.

Comparing models using different training data, we see that the RACE→QuALITY results outperform RACE results in most cases (Table 9). Fine-tuning on QuALITY contributes to a small performance gain. Both RACE and RACE→QuALITY significantly outperform the QuALITY only results, likely because of the small size of the QuALITY training set, though this suggests that knowledge transfer from RACE is useful.

In terms of extraction strategies, DPR-based extraction almost always produces the best result. In terms of models, DeBERTaV3-large consistently performs best. Compared to the RoBERTa and DeBERTa models fined-tuned on short contexts, the Longformer and LED models appear to struggle to learn the task from the long inputs, underperforming even the RoBERTa-base extraction-based models. We speculate that a combination of more long-context training data and better long-context models may improve performance beyond the extraction-based models. As with other models, intermediate training on RACE improves performance on QuALITY.

Question-Only Baselines The best-performing question-only baseline is DeBERTaV3-large using the RACE→QuALITY setting for training, achieving an accuracy of 43.3%. The corresponding performance is only 12.1 percentage points lower than the DeBERTaV3-large's performance with text excerpts from DPR. This small margin of improvement may indicate that current models are not effectively using the input contexts.

QuALITY-HARD Model performance is always lower on QuALITY-HARD than on the full test-set, even on the question-only baselines. This suggests that speed-validation filtering yields more challenging questions for human annotators *and* models.

Extraction by Oracle Answer We show in Appendix D.3, Table 11 the results of the oracle-answer-based extraction on the development set. Compared to Table 10, using the oracle answers for extraction improves performance significantly (topping out at 78.3%), but is still below human performance by 15 points. This demonstrates that extracting relevant excerpts alone is insufficient to solve QuALITY questions, and that QuALITY questions require reasoning over the full passage.

5 Related Work

Rogers et al. (2021) survey the QA dataset explosion of recent years and the many formats and types of QA datasets. TriviaQA (Joshi et al., 2017) and SearchQA (Dunn et al., 2017) contain questions with more than one document as the context, but since the supporting documents are collected after writing the question-answer pairs, most questions can be answered after retrieving a short context. HotpotQA (Yang et al., 2018), QAngaroo (Welbl et al., 2018), and ComplexWebQuestions (Talmor and Berant, 2018) are constructed to have more challenging questions which require multi-hop reasoning across multiple paragraphs. However, there has been recent work (Jiang and Bansal, 2019; Min et al., 2019) showing that these datasets contain reasoning shortcuts and a large fraction of the questions can be answered with single-hop reasoning.

NarrativeQA (Kočiský et al., 2018), the most similar work to ours, uses entire Gutenberg books and film scripts as contexts, with an average length of 60k tokens. The authors creatively make data-collection tractable by using Wikipedia summaries for the books as context when crowdsourcing questions. Unlike QuALITY, NarrativeQA is a free-form generation-based task. While there are many existing multiple-choice QA datasets (Richardson et al., 2013; Hill et al., 2015; Lai et al., 2017; Bajgar et al., 2016; Huang et al., 2019), they use much shorter contexts (<500 tokens) than our dataset.

A primary challenge of building a long-document QA dataset like QuALITY or NarrativeQA is building a tractable crowdsourcing pipeline that enables collecting high-quality examples. Roit et al. (2020) collect a challenging QA-SRL dataset by carefully hiring and training crowdworkers, with a strict qualification followed by two hours of training with extensive feedback. Nangia et al. (2021) compare crowdsourcing methods for collecting high-quality QA data and find that a long training process with iterative feedback and qualifications is an effective strategy.

6 Conclusion

We introduce the long-document QA dataset QuALITY. This dataset was crowdsourced and validated by humans to ensure that the questions are answerable, unambiguous, and challenging. The QuALITY-HARD subset, comprising half the dataset, consists of questions that are unanswerable by annotators working under tight time constraints, helping ensure that skimming and simple search do not yield high performance.

We find that our baseline models significantly lag behind human performance on QuALITY, with a 38.1 percentage point gap between human annotators and the best performing model. The gap is even wider on QuALITY-HARD, at 42.3 points. We hope that research that aims at this gap will contribute to expanding the scope of texts on which effective NLU systems can be applied.

Ethical Considerations

Both the authors of our source texts and the authors of our questions are based primarily in the US, and represent a relatively privileged, educated population. A system that performs well on our dataset is, thus, only demonstrating its effectiveness on mainstream US English, and should not be presumed to be effective on text in other languages or language varieties.

A Details on Writing, Speed Validation, and Untimed Validation

A.1 Writing

A.1.1 Writer Recruitment

We need writers who have good reading comprehension skills and/or writers who have experience constructing reading comprehension questions (e.g., literature teachers who have experience writing tests for their students). We hire two groups of writers on the freelancing platform Upwork (the second group two months after the first group, after we decided to increase the final size of the dataset).

For each group, we advertise a task titled *Writing college-level reading comprehension questions*. The job post is visible to all U.S. Upwork freelancers, and we specifically send out job invitations to promising freelancers who are writers or teachers, or who have college-level degrees in English, Literature, Creative Writing, Philosophy, Education, or similar fields. In the original job ad, we explain who we are and tell them how we will use their data. Specifically, we include the following phrase: "The data we collect through this project will be made publicly available for AI research. We will not distribute any identifying information about you, the writers."[16]

For the first group, we received 104 applications in the span of two weeks. Of those, we selected 26 people to complete a qualification task as a paid interview. For the second group, we received 65 applications and interviewed 11. The interview task consists of (i) reading through detailed instructions, (ii) reading through a tutorial example passage with 10 example questions, each with an explanation of what made it a good or a bad question, and (iii) writing 10 reading comprehension questions for a new passage; regardless of whether we eventually hire them, we pay workers $30 and estimate that this task takes 2 hours to complete. Three authors (of this paper) then assess each writer's work using the following criteria: (i) whether the writer-provided correct answers are actually the correct answers, (ii) whether the questions are answerable and unambiguous, and (iii) whether more than just a few sentences of context are needed to correctly answer the questions. Based on these criteria, we select the top performing 15 writers to continue on to the main task in the first group, and 7 in the second group.

Of the 22 writers we hire after the interview, 15 have a college degree in English, literature, philosophy, creative writing, or education; 4 of these 15 writers are Ph.D. students or graduates. 11 of the 22 writers have taught high-school or college-level English or literature classes; among these 11 writers, 7 have 5+ years of teaching experience. 2 of the 22 writers mention that they write novels.

A.1.2 Writing Task

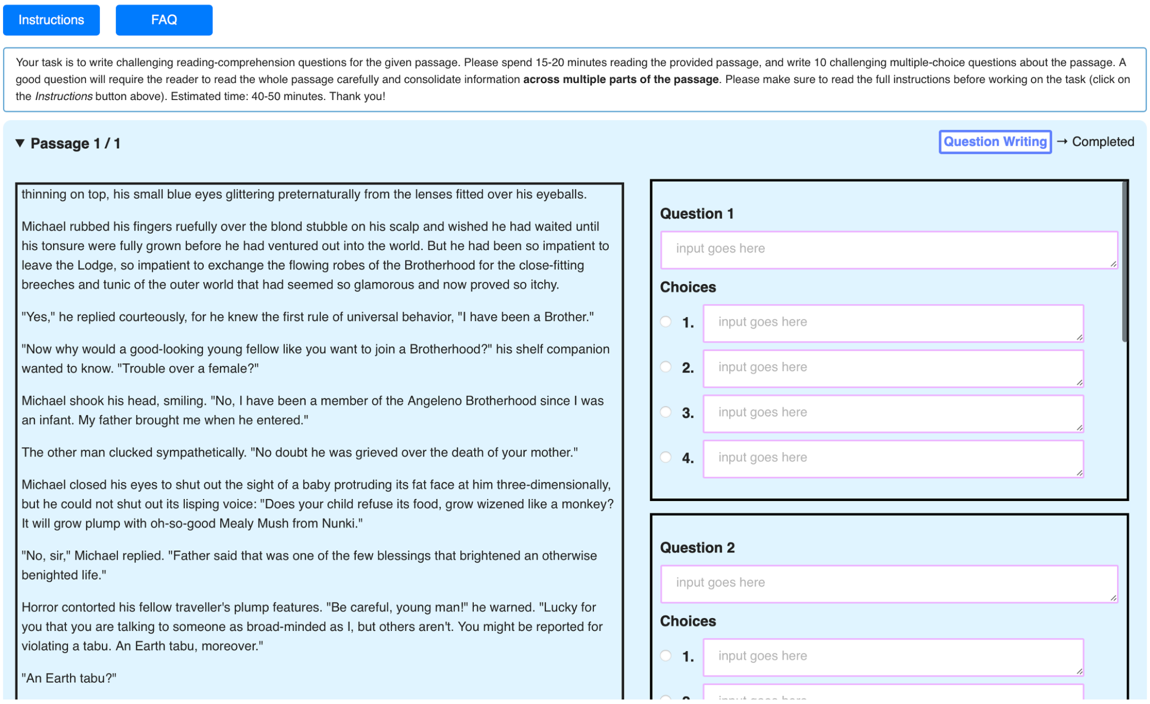
Each writer constructs 10 questions for a given passage, completing 6-30 passages in a given round and continuing for three complete rounds.[17] Each round is followed by feedback (detailed below) to allow writers to improve for the next round. Writers earn $12.50 per passage and receive a bonus of $1.20 for each question that meets the following criteria: (i) the majority of validators agree with the writer's original label, (ii) the majority of validators rated the question as answerable and unambiguous, and (iii) the majority of validators answered the question *incorrectly* in the speed validation task (§2.3.1). On average, writers receive bonuses on 4.2 questions per passage, resulting in average earnings of $17.54 per passage. Based on writer self-reports, the median time to complete one writing task is about 50 minutes, for an effective rate of $21.05/hr. Upwork charges fees on the workers' end. We account for this by adding an extra 20% to their pay, bringing our final cost to $2.10 per question.

Besides using the monetary bonus as an incentive for writing answerable, unambiguous, and difficult questions, we also instruct writers that their questions should use the entire context. Throughout the course of data collection, we provide writers with detailed feedback based on validations (detailed in §2.3.2) and this feedback includes information about how much of the passage needed to be read in order to answer the question. We monitor the proportion of questions that require more than a few paragraphs of context to answer correctly; if this rate significantly lags behind other writers, we inform the writers that their work is falling below expectations and ask them to be more careful with this issue in the next round. We also

---

[16] We later obtained consent from writers who chose to allow us to name them in the Acknowledgments section.

[17] On average, group 1 writers complete 6, 14, 30 articles for the three batches, respectively; group 2 writers complete 6, 14, 20 articles for the three batches, respectively. The writing time limits for batches 1, 2, 3 are around 1, 2, 3 weeks, respectively. Validation for any batch takes less than a week.



Your task is to write challenging reading-comprehension questions for the given passage. Please spend 15-20 minutes reading the provided passage, and write 10 challenging multiple-choice questions about the passage. A good question will require the reader to read the whole passage carefully and consolidate information **across multiple parts of the passage**. Please make sure to read the full instructions before working on the task (click on the *Instructions* button above). Estimated time: 40-50 minutes. Thank you!

thinning on top, his small blue eyes glittering preternaturally from the lenses fitted over his eyeballs.

Michael rubbed his fingers ruefully over the blond stubble on his scalp and wished he had waited until his tonsure were fully grown before he had ventured out into the world. But he had been so impatient to leave the Lodge, so impatient to exchange the flowing robes of the Brotherhood for the close-fitting breeches and tunic of the outer world that had seemed so glamorous and now proved so itchy.

"Yes," he replied courteously, for he knew the first rule of universal behavior, "I have been a Brother."

"Now why would a good-looking young fellow like you want to join a Brotherhood?" his shelf companion wanted to know. "Trouble over a female?"

Michael shook his head, smiling. "No, I have been a member of the Angeleno Brotherhood since I was an infant. My father brought me when he entered."

The other man clucked sympathetically. "No doubt he was grieved over the death of your mother."

Michael closed his eyes to shut out the sight of a baby protruding its fat face at him three-dimensionally, but he could not shut out its lisping voice: "Does your child refuse its food, grow wizened like a monkey? It will grow plump with oh-so-good Mealy Mush from Nunki."

"No, sir," Michael replied. "Father said that was one of the few blessings that brightened an otherwise benighted life."

Horror contorted his fellow traveller's plump features. "Be careful, young man!" he warned. "Lucky for you that you are talking to someone as broad-minded as I, but others aren't. You might be reported for violating a tabu. An Earth tabu, moreover."

"An Earth tabu?"

Figure 3: The writing UI.

encourage writers to write difficult distractors, and the feedback we provide also contains what annotators think is the most difficult distractor for each question (§2.3.2).

If writers have fewer than 40% of questions meet the above three bonus criteria *and* fewer than 75% of questions meet criteria (i) and (ii), we exclude them from future writing rounds: One writer was excluded after batch 1, and one writer was excluded after batch 2, for this reason. We also exclude two writers who missed deadlines by significant margins. Two other writers voluntarily left the project before finishing all three batches.

A.1.3 The Writing UI

Figure 3 shows our writing UI. A writer creates 10 multiple-choice questions with four answer options each on each page. Before the interview task and each batch of data collection, we explain our bonus structure to the writers. In order to encourage writers towards writing the types of questions that require understanding of the general context from the passage, we provide the following examples of themes that questions can target in order to spur writers' creativity and provide suggestions if they have trouble coming up with difficult questions; however, they do not have to follow our suggestions.

- Characters' feelings and motivations
- Causes and consequences of described events
- Definitions, properties, and processes explained in a passage
- The summary and lesson of a passage
- What would have happened had a character made a different choice

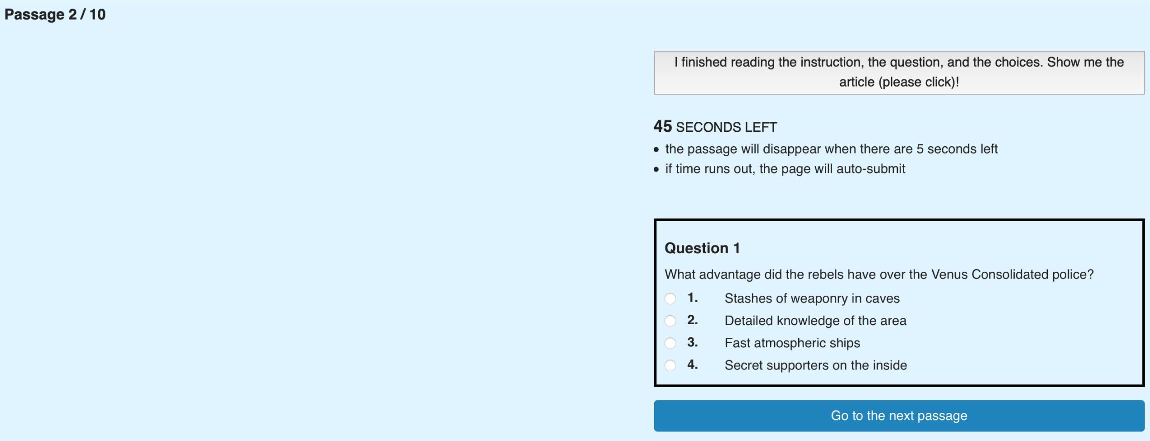
We also allow writers to skip a given passage in case they find that they would be unable to write high-quality questions for that passage. Specifically, we tell writers the following.

> If a passage is too difficult to write questions for, you can skip the article by choosing another URL to work on. We recommend that you do this if: (1) The text is hard to read due to major formatting issues. (2) The text is very technical or relies on cultural knowledge that you're unfamiliar with. (3) You think the passage is much too boring. We ideally want you to write questions for passages you find interesting!

A.2 Validation

A.2.1 Annotator Recruitment

We recruit annotators via Amazon Mechanical Turk (MTurk). We use a qualification task to identify annotators with good reading comprehension skills.



Passage 2 / 10

Figure 5: The speed validation UI after clicking the top-right button.

This task is open to all workers with more than 1000 tasks (HITs) accepted and a HIT accept rate of at least 98%. We pay $5 for completing the qualification task, plus a $5 bonus for passing it. The task consists of a ∼3000-word passage with 10 multiple choice questions written or reviewed by the authors, each with a series of evaluation questions asking about the quality of that question. Of the 10 questions, 2 are intentionally ambiguous[18] in order to test if workers can accurately identify poorer quality questions.

In order to pass the qualification, workers need to (i) get at least 6/7 or 7/8 of the unambiguous questions correct, (ii) correctly identify at least one of the two ambiguous questions as ambiguous/unanswerable, and (iii) correctly identify at least half of the unambiguous questions as unambiguous. A total of 148 crowdworkers completed the task, and 45 of them passed (30.4%). All workers who pass the qualification are invited to complete tasks as part of both the speed validation and the untimed validation. We make it clear in this task as well as the main speed validation and untimed validation tasks who we are and which research group we are affiliated with. In order to help workers understand that we plan to use their data for research purposes related to language technologies, we also include the following in the FAQ section of each hit: "With your help, we think we'll be able to build some pretty exciting technologies to help computers better understand human language."

A.2.2 Speed Validation

Catch Questions We expect accuracy in the speeded task to be fairly low, so we construct catch questions to ensure that workers are not randomly guessing without attempting to find the correct an-

---

[18] We later found that one question was *unintentionally* ambiguous; we do not use this question in assessing whether workers pass the qualification.

swer. These trials are written by the authors and are designed to be answerable with only 45 seconds of access to the passage. For example, a catch question may ask who spoke a quote, like "Who said 'You're a wizard Harry!'?", where a single ctrl+F search of the quote gives the annotator the answer. Another catch question may have four options, three of which are clearly improbable. We do not validate the catch questions for correctness in the untimed validation, and so we do not include them in the final dataset, but we release them as a supplemental file for reproducibility.

Payment For most of the tasks, we pay workers \$2.25 per HIT and award a bonus of \$0.20 for each correct answer. However, during the first of six rounds, we paid \$2.00 per HIT with a \$0.18 bonus for each correct answer. After asking workers for feedback about the task via a survey, we decided to increase the rate of pay because workers reported spending slightly longer on the task than we originally estimated.

Task Procedure Each MTurk task consists of 10 speed validation questions from different randomly chosen articles. In each task, once the annotator clicks into the page, they have unlimited time to read the question and the answer options, but the article is not shown (Figure 4). Then, the annotator clicks the button that says "I finished reading the instruction, the question, and the choices. Show me the article (please click)!" As soon as the annotator clicks the button, the countdown clock of 45 seconds starts, and the article appears (Figure 5). The annotator can make the choice and submit at any time.

When there are only 5 seconds left, the article hides itself. The annotator has 5 seconds to make the choice. If the time expires, the page auto-submits, and we record that the annotator did not make a choice, which we score as incorrect. The exact instructions that the annotator sees are as follows:

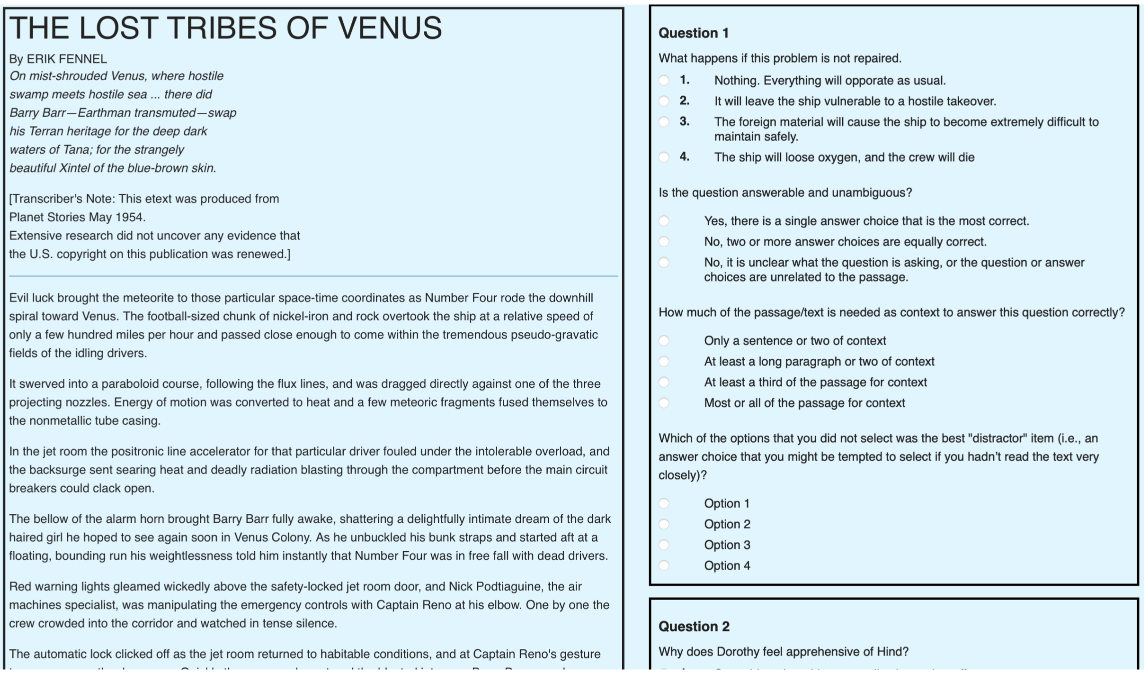
> In this task, you will see a long text passage and a multiple choice question that can be answered from that text. Read the question and select the best answer option. You only have **45 seconds** to choose an answer, so this is not enough time to read the whole passage. We encourage you to skim and use keyword-based searches (e.g., using ctrl+F) during this time. Even if you are unsure of the answer, you should make an educated guess.
>
> After 45 seconds, your answer will be locked in and submitted. If you have not provided an answer at the end of 45 seconds, you will not be able to answer this question and will be automatically moved to the next question. We will not reject your work for a couple of blank answers, but excessive failures to answer will result in a loss of the qualification to complete these HITs.
>
> You will not be penalized for wrong answers. We will give you a bonus of **\$0.20** for each correct answer. Thus, it is in your best interest to attempt each question, even if it is just a guess. A few of the questions will be answerable in just 45 seconds, and we do expect you to get these right reasonably often.

Annotator Performance Individual annotators consistently scored well above the chance rate of 25% on the catch questions. In all cases where an annotator's accuracy fell below 50% in a round, they were removed from future rounds. Two annotators fell below this threshold, though in that round they had also performed below threshold in the untimed validation. No annotators needed to be removed *solely* based on performance in the speed validation task. Average overall accuracy on the catch questions was 83.8%, indicating that most workers were able to develop a strategy for finding a correct answer when it could be found.

Accuracy on the questions written by Upwork writers was 48.2% overall, but annotators got better at this task over time, likely by developing new strategies to search for answers. Average accuracy was 39.5% in the first round, rising to 58.4% in the final round of data collection. When the majority of annotators (at least 3/5) are able to answer questions correctly in this setting, we exclude that question from the HARD subset.

A.2.3 Untimed Validation

Figure 6 shows the UI for untimed validation. As two writers each write 10 questions for the same article, there are 20 unique questions per article. Each validation UI page contains all 20 sets of questions, and each set of questions contains the



THE LOST TRIBES OF VENUS

By ERIK FENNEL

On mist-shrouded Venus, where hostile
swamp meets hostile sea ... there did
Barry Barr—Earthman transmuted—swap
his Terran heritage for the deep dark
waters of Tana; for the strangely
beautiful Xintel of the blue-brown skin.

[Transcriber's Note: This etext was produced from
Planet Stories May 1954.
Extensive research did not uncover any evidence that
the U.S. copyright on this publication was renewed.]

Evil luck brought the meteorite to those particular space-time coordinates as Number Four rode the downhill spiral toward Venus. The football-sized chunk of nickel-iron and rock overtook the ship at a relative speed of only a few hundred miles per hour and passed close enough to come within the tremendous pseudo-gravatic fields of the idling drivers.

It swerved into a paraboloid course, following the flux lines, and was dragged directly against one of the three projecting nozzles. Energy of motion was converted to heat and a few meteoric fragments fused themselves to the nonmetallic tube casing.

In the jet room the positronic line accelerator for that particular driver fouled under the intolerable overload, and the backsurge sent searing heat and deadly radiation blasting through the compartment before the main circuit breakers could clack open.

The bellow of the alarm horn brought Barry Barr fully awake, shattering a delightfully intimate dream of the dark haired girl he hoped to see again soon in Venus Colony. As he unbuckled his bunk straps and started aft at a floating, bounding run his weightlessness told him instantly that Number Four was in free fall with dead drivers.

Red warning lights gleamed wickedly above the safety-locked jet room door, and Nick Podtiaguine, the air machines specialist, was manipulating the emergency controls with Captain Reno at his elbow. One by one the crew crowded into the corridor and watched in tense silence.

The automatic lock clicked off as the jet room returned to habitable conditions, and at Captain Reno's gesture

Question 1

What happens if this problem is not repaired.

○ **1.** Nothing. Everything will opporate as usual.
○ **2.** It will leave the ship vulnerable to a hostile takeover.
○ **3.** The foreign material will cause the ship to become extremely difficult to maintain safely.
○ **4.** The ship will loose oxygen, and the crew will die

Is the question answerable and unambiguous?

○ Yes, there is a single answer choice that is the most correct.
○ No, two or more answer choices are equally correct.
○ No, it is unclear what the question is asking, or the question or answer choices are unrelated to the passage.

How much of the passage/text is needed as context to answer this question correctly?

○ Only a sentence or two of context
○ At least a long paragraph or two of context
○ At least a third of the passage for context
○ Most or all of the passage for context

Which of the options that you did not select was the best "distractor" item (i.e., an answer choice that you might be tempted to select if you hadn't read the text very closely)?

○ Option 1
○ Option 2
○ Option 3
○ Option 4

Question 2

Why does Dorothy feel apprehensive of Hind?

Figure 6: The (untimed) validation UI.

reading comprehension question and the three additional evaluation prompts. Therefore, in total, there are 80 prompts on each page. The annotator has to complete all 80 before they can submit the page and complete the task. The exact instructions that the annotators read for this task are as follows:

> In this task, you will answer multiple choice questions corresponding to a long article. Each passage comes with 20 sets of questions. Each set contains a comprehension question and three evaluation questions. Please read each passage carefully before answering the questions for that passage. Estimated time: 45-55 minutes.
>
> If it is impossible to say which of the other answer options is correct, then select the answer option that is *closest* to correct.
>
> You will receive a bonus of $0.50 for each reading comprehension question that you correctly answer. We consider the answer to be correct if your response of the reading comprehension question and the first evaluation question **both** agree with the most common answer from other workers and the original writer. If there's no agreement on an answer, we count it as correct for everyone. This means that it's possible to receive a total bonus of $10.00 on this HIT.
>
> We expect you to answer most of the questions correctly; however, we understand that some questions may be difficult, ambiguous, or mal-formed. If you answer a large number of questions incorrectly, we will disqualify you from future work on this task.
>
> For the second and third evaluation questions, we will check if your choices agree with the majority of other workers who work on the same task, but your bonus is not dependent on these answers. The results will also be used to determine whether you retain the qualification for future batches of this task, but to a lower threshold because these questions tend to be more subjective.

Annotator Performance Individual annotator agreement with the gold label is 91.2% for all data collected in the main data collection (not including the responses collected to measure human accuracy described in §3.1). Throughout the course of the study, workers need to maintain at least 75% accuracy each round to keep the qualification and continue to the next round. In a few cases, we identify passages that are themselves ambiguous or

Question Type	# EASY	# HARD	% total	Example from the Training Set
what	1361	1471	42.2	What is the immediate significance of Ed defending the ads on his Facebook?
why	832	825	24.6	Why does Howell not want Linton to approach Snead in the restaurant?
how	385	416	11.9	How does Barker view his own film?
which	253	244	7.4	Which word least describes McGill?
who	151	132	4.2	Who is the most hated celebrity of 1999?
how + meas.	51	75	1.9	How many caves had Garmon and Rolf traveled through before their crash?
yes/no	53	55	1.6	Was it Nelson's decision to become part of the military?
where	43	42	1.3	Where was the space craft heading in the end?
when	35	34	1.0	When did the Hanseatic League begin?
other	155	124	4.1	Dole's quote would have been perceived as ______ if it had included included the exclamation points from his tone?

Table 7: Different question types in QuALITY, split by HARD and EASY subsets. 'How + meas.' collapses multiple questions with 'how' plus some measurement, such as 'how long' or 'how many.'

especially difficult. In these cases, we do not use those passages in computing by-round accuracy for the annotators. We exclude a total of 11 workers throughout the course of data collection for low accuracy, most of them after the first or second round.

Data Reannotation During each untimed validation round, we keep track of the rate at which each worker agrees with the original writers' labels for each question in order to quickly identify cases where either (i) a worker has misunderstood the passage, or (ii) a worker is putting insufficient effort towards the task. For any tasks where the individual annotator disagrees with the writer's labels on at least 40% of questions, we automatically re-post that passage for reannotation and replace the data, with the assumption that the annotator may have misunderstood something crucial in the passage.[19] After all the annotations are complete, we calculate the gold label answer via majority vote of annotators plus the original writer's label, and assess individual annotator accuracy. If any worker is excluded in a round for low accuracy (i.e., below 75% accuracy), we discard all of their responses from that round, reannotate and replace their data, and re-calculate the gold label and accuracy scores.

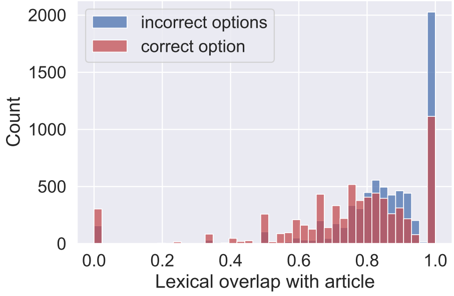


Figure 7: Lexical overlap of the correct and incorrect options with the context. Since each question has three incorrect options, we use the option with the highest lexical overlap.

B Data

Switchboard Data In order to increase the diversity of genres we use as context passages, we attempted to include Switchboard conversations. However, after presenting just 12 such conversations to our writers, we decided to discard all the Switchboard questions because many writers informed us that it was very difficult to come up with difficult questions for the Switchboard conversations. The writers indicated they found the Switchboard articles more difficult because the conversations are relatively short and usually involve very simple everyday topics, without the kinds of plot twists that are more common in short stories or complex details that are more common in long-form articles.

Lexical Overlap We analyze the lexical overlap between the answer options and the passage text (detailed in §3.4. In Figure 7, we plot the lexical overlap of both the correct answer option and the incorrect answer option with the passage.

B.1 Question Types

As described in §3.5, we analyze the different question types in QuALITY, split by HARD and EASY subsets, and present these results along with examples in Table 7. Most of the questions in the 'other' category are finish-the-phrase style questions, and

---

[19] We identified 10 passages that, after multiple rounds of reannotation, were not passing this threshold. This may be due to one of the writers misunderstanding the passage and thereby creating several ambiguous questions, so for these 10 passages, we chose to include *all* annotations collected rather than replace annotators' data.

for the example in the table, the answer options are different ways that sentence could be completed. Note that in most of the yes/no questions, the answer options include the necessary reasoning to support the yes/no answer, meaning that these are often complex, multi-part questions. Examples shown in Table 7 are randomly selected from the training set, with the caveat that we selected the 'when' question by hand, since about half of the questions categorized as 'when' are referencing some timepoint (e.g., 'when X happened, what did ...')

B.2 Reasoning Types

For the purposes of this analysis, we define reasoning type as the category that needs to be reasoned about in selecting the correct answer option (e.g., 'person' is usually a 'who' question and corresponds to answer options that are characters or people) or the type of strategy that must be used in answering (e.g., 'symbolism/interpretation' requires the reader to extrapolate from the context or identify something not stated in a passage, like its theme). We identify 15 categories of reasoning types to include in our analysis. These categories are initially inspired by those used in NarrativeQA, but we adapt them to our dataset, as we find that many questions in QuALITY do not fit their categorization. These categories are not mutually exclusive, and nearly a third of the questions are categorized as two or more types.

Reasoning Type Definitions The following includes definitions of all the categories used, along with at least one hand-selected example to demonstrate a question belonging to that category. All in-text examples are selected out of the training set.

- **Description**: The question relies on the reader reasoning about which description is correct. Often these questions are about describing a character's feelings ('How do Lowry and the Exec feel about the Venusians?') or point of view ('How is the book "Living a Normal Sex Life" seen by these people?'), describing a feature of the story ('What makes Grannie Annie's writing remarkable?'), or describing an individual ('Which word least describes Don?')
- **Why/reason**: The question relies on the reader reasoning about the cause or explanation for something in the story. Most of these questions begin with 'why' and ask about the cause of an event ('Why does the crew get off the ship with Moran?'), causes of characters' feelings ('Why does Ben take offence to Cobb's comments about spacemen?'), or characters' internal motivations ('Why does Joseph lie about the water supply?'), though other questions formulate this differently while still asking for the underlying reason ('What makes Gubelin an outlier in the present day?' and 'What is the purpose of a comanalysis?').
- **Symbolism/interpretation**: The question relies on the reader making an interpretation that goes beyond what is explicitly said in the story, or it asks about symbolism or themes from the story. Many questions explicitly ask the reader to interpret what message the author was trying to convey ('What point is being made by comparing Fight Club to the UFC?') or what tone the story takes ('What is the tone like throughout the story?'). Other questions require the reader to predict what will happen next ('What will happen next to Jery?') or ask about the use of literary cues like irony ('What is ironic about Earth's customer service policy?').
- **How/method**: The question relies on reasoning about how something happened or the method that was used. Most of these questions rely on the question word 'how' to ask about a process ('How did Meryl Streep prepare for the role of Roberta?'), the manner in which something happens ('How did Templin find about about Pendleton's death?'), or a method by which something happens ('How does the shape of Starre's ship benefit them?').
- **Event**: The question relies on reasoning about an event, or asks for an event as the answer option. The majority of these questions focus on what someone did/plans to do ('What did Joe and Glmpauszn plan to do?') or what happened to someone ('What happened to Morgan Brockman by the end of the passage?').
- **Person**: The question relies on reasoning about which person or people are involved. Most ask about a specific person ('Who is Owen Fiss and what did he do?'), though many questions of this type still require rea-

Question	Answer Options	Reasoning Types
What would have happened if Click's camera broke in the crash?	(a) Irish would have died on impact. (b) They would have returned immediately to Luna Base. (c) They would have caught Gunther faster. (d) They would have continued to believe the monsters were real.	What if; Event
What isn't a reason for narrator to be so skeptical of Gorb?	(a) Gorb looked just like an Earthling (b) Gorb was asking for too much money (c) Gorb had no proof to back up his claims (d) he had never heard of Wazzenazz	Why/reason; not/except
How many caves had Garmon and Rolf traveled through before their crash?	(a) thirty seven (b) forty seven (c) thirty (d) forty	Numeric
How do you think Meredith feels about the rest of the crew?	(a) She has a close bond of respect and (platonic) love for the rest of the members (b) She respects and loves one person the most (c) She's become friends with them slowly over time and appreciates them all (d) She respects one person the most and loves another person the most	Description; symbolism/terpretation; relation
The less you share...	(a) ...the more privacy you have. (b) ...the more your intellectual property is protected. (c) ...the less power you have. (d) ...the less your cultural goods will be appropriated.	Symbolism/interpretation; finish the phrase
How did Meryl Streep prepare for the role of Roberta?	(a) She learned to play the violin without any former instrument training. (b) She began to act very helplessly and feeble around the rest of the cast. (c) She is a method actor and became very vulnerable. (d) She made herself look dumpy and thick-waisted.	How/method

Table 8: Full examples of the annotations from our analysis of reasoning types on a subset of questions from QuALITY. Examples are taken from analyzed examples from the training set. Examples are selected non-randomly and are intended to demonstrate a range of reasoning types observed.

soning about the entire passage to answer ('Who seems to have the least to hide in the text?').

- **Not/except**: The question requires the reader to select the answer option that *least* answers the question, flipping the typical way a multiple-choice task is performed. All of these questions use some word to indicate this flipping, such as 'least' ('Which word least describes McGill?'), 'not' ('What word doesn't describe the natives from Tunpesh?'), or 'except' ('Dole makes all of the following charges against the New York Times EXCEPT for:').

- **Relation**: The question relies on reasoning about the relationship between two or more characters, as in 'Who is Sporr and what is his authority in calling the narrator Yandro?' or questions that ask about how one character feels about another ('How does Jakdane feel about Trella?').

- **Entity**: The question relies on reasoning about a non-human entity or a group, as in 'We can assume that Saladin's army represents which group?'.

- **Finish the phrase**: The form of the question requires either a fill-in-the-blank style response or is a partial phrase that must be completed by selecting the correct answer option. Often, these questions do not include an explicit question word. Some of them have a blank written in ('The film reviewer is generally _____ the actors in "Princess Mononoke," and ______ the actors in "The Limey," respectively:') and others are just a partial sentence ('The less you share...').

- **Location**: The question relies on reasoning about a place, as in 'What city is Temple-Tracy in?'.

- **Numeric**: The question relies on finding or computing the correct numeric option, as in 'How many caves had Garmon and Rolf traveled through before their crash?'.

- **Object**: The question relies on reasoning about an object, as in 'What does Captain Hannah use as an organic processor?'.

- **What if**: The question requires the reader to make an inference about what *would have been true* if some fact from the story were changed, and most of these questions explicitly set up the counterfactual scenario ('What

Table 9: Accuracy on the full QuALITY test set and the QuALITY-HARD subset (formatted as full / HARD). The "Full" column has results from training with the source inputs truncated to fit into memory. R-1 (ROUGE-1), fastText, DPR are three extraction methods (§4.1) used to select relevant portions of the source text. Results for training on QuALITY and RACE→QuALITYare identical to Table 6 in the main text, this table simply presents those results alongside results from training only on RACE.

would have happened if the Peace State had not crash landed?').

- **Duration**: The question relies on reasoning about how long something happened for or how much time passed between two events, as in 'How long did Maggie care for Ben before he finally awoke after rescuing him?'.

Annotation Details Three authors of this paper analyze a set of 500 randomly selected questions. One author annotates all 500, and the other two annotators analyze 250 each, such that each example is annotated by two unique individuals. Following annotation, the authors discuss any disagreements and adjust their original coding once consensus is reached. Using this consensus approach allows for clarification of the categories during and after annotation, which leads to an internally consistent coding scheme.

Sample Annotations Table 8 shows a set of representative example annotations from this analysis, demonstrating several sentences that were categorized as more than one reasoning type.

C More Details on Analysis

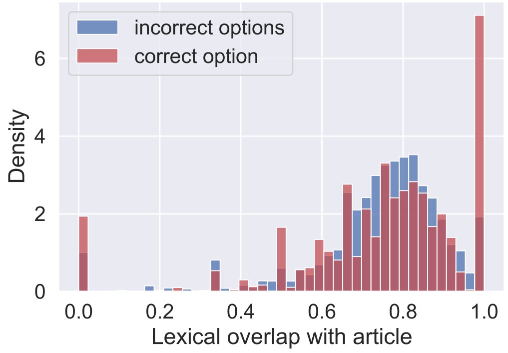

Figure 8: Lexical overlap of all the correct and incorrect options with the article. The distribution is normalized since there are thrice as many incorrect options as there are correct options.

Lexical Overlap In addition to comparing lexical overlap of the correct option and the maximum lexical overlap of the incorrect option with the article (Section 3.4), we also plot a normalized distribution of lexical overlap for all the correct and incorrect options in Figure 8. Despite a higher fraction of the correct options having complete overlap

with the article, models would not be able to exploit this heuristic, since other incorrect options for the same question may have complete overlap. This is demonstrated by the plot in Figure 7 and the fact that a baseline which relies on the lexical overlap heuristic only achieves 26.6% accuracy.

D More Details on Modeling

D.1 Extraction

For ROUGE-1 scoring, we use the `rouge-score` Python package.[20]

For fastText scoring, we use SpaCy with the `en_core_web_sm` model for tokenization, and use embeddings trained on Common Crawl, [21] using the top 300k words in the vocabulary.

For DPR, we use the Transformers package (Wolf et al., 2020), using the `facebook/dpr-ctx_encoder-multiset-base` and `facebook/dpr-question_encoder-multiset-base` models for encoding the context and query respectively.

D.2 Training

The full sets of hyperparameters used for tuning our baselines are shown in Table 12 and Table 13.

For RoBERTa, DeBERTaV3 and Longformer models, we train on QuALITY for 20 epochs. Where we do intermediate training on RACE, we do so for 3 epochs. Warmup is set to 10% of the full training steps.

D.3 Results

Table 10 shows the results on development set. Table 11 shows the results using oracle-answer-based extraction. Please refer to the discussion in Section 4.2.

Abstract

Interpretability methods are developed to understand the working mechanisms of black-box models, which is crucial to their responsible deployment. Fulfilling this goal requires both that the explanations generated by these methods are correct *and* that people can easily and reliably understand them. While the former has been addressed in prior work, the latter is often overlooked, resulting in informal model understanding derived from a handful of local explanations. In this paper, we introduce explanation summary (ExSum), a mathematical framework for quantifying model understanding, and propose metrics for its quality assessment. On two domains, ExSum highlights various limitations in the current practice, helps develop accurate model understanding, and reveals easily overlooked properties of the model. We also connect understandability to other properties of explanations such as human alignment, robustness, and counterfactual similarity and plausibility.

1 Introduction

Understanding a model's behavior is often a prerequisite for deploying it in the real world, especially in high-stake scenarios such as financial, legal, and medical domains. Unfortunately, most high-performing models, such as neural networks, are black-boxes. Thus, model-agnostic interpretability techniques have been developed, with the majority being "local" – algorithms that produce an explanation for a specific input at a time (e.g., Li et al., 2016; Ribeiro et al., 2016).

Even with these local explanations, there are still two hurdles to overcome before achieving the ultimate goal of complete understanding of a model. First, some local explanations may not correctly (or faithfully) represent the model's reasoning process (Jacovi and Goldberg, 2020), as has been demonstrated both theoretically (Nie et al., 2018) and empirically (Adebayo et al., 2018) in prior work. As a result, correctness evaluation has received much attention in the community (e.g., Samek et al., 2016; Arras et al., 2019; Zhou et al., 2022).

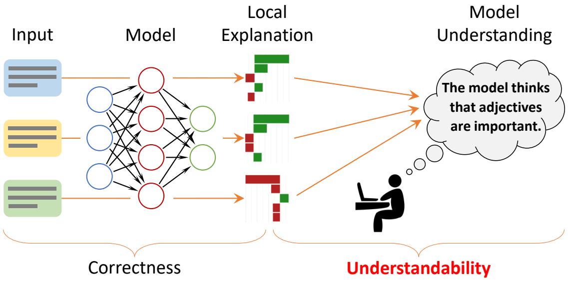

Figure 1: Local model explanations need to be both correct and easily understandable. While much prior work (e.g., Zhou et al., 2022) has studied the former property, this paper focuses on the latter, which has thus far been largely ignored.

Another mostly overlooked property of explanations is their *understandability*. As the model understanding pipeline depicted in Fig. 1 shows, explanations need to be both correct and easily understandable, since even correct explanations are not as valuable if they lead to incorrect understanding. However, the concept of understandability has yet to be formalized, and instead users often derive model understanding from few examples in a non-rigorous (and potentially incorrect) manner.

Consider the sentiment classification task shown in Fig. 2. On a test input, the model makes the correct prediction of positive sentiment. Obviously, this evidence is insufficient to conclude that "*in general*, the model classifies positive inputs correctly", because even a random-guess model is correct 50% of the time on a single instance. Instead, statistics such as the confusion matrix serve to rigorously support (or refute) generalization claims about model *performance* – for example, "the model is correct 97.6% of the time on positive inputs" – ensuring an accurate understanding of model performance.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5359 - 5378
July 10-15, 2022

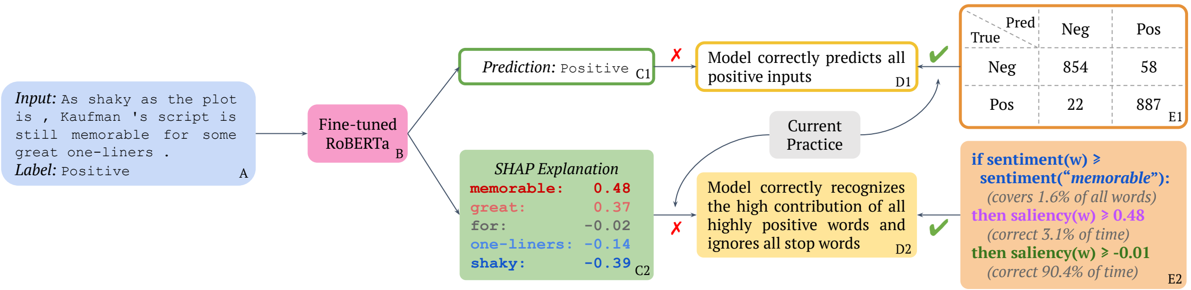

Figure 2: An analogy between understanding model prediction (top route) and model explanation (bottom route). A test input (A) is fed into a fine-tuned RoBERTa model (B), which generates a correct prediction (C1) and reasonable explanation (C2). While generalized claims of understanding model *performance* (D1) are made rigorously from quantitative statistics such as the test set confusion matrix (E1), claims of understanding model *behavior* (D2) are predominantly derived informally from one or few explanations (C2). In this paper, we argue the necessity of formalizing this process, and propose the explanation summary (ExSum) framework (E2), which reveals the severe limitations of the *ad hoc* model understanding (D2).

Do we understand model *behaviors* in the same rigorous way? Fig. 2 shows that the SHAP score (Lundberg and Lee, 2017) of the word "*memorable*" is highest at 0.48, while that of "*for*" is negligible at -0.02. Therefore, it is tempting to conclude that "*in general*, the model recognizes the high positive contribution of highly positive words and ignores stop words" – as expected for an accurate sentiment classifier. However, this is a generalization from a single instance, and thus potentially unreliable. We need the "confusion matrix" analogue for such claims, which to the best of our knowledge does not exist, making it hard to derive model understanding from local explanations.

In this paper, we propose ExSum, a mathematical framework to formalize model understanding. In ExSum, each piece of "model understanding" is specified precisely via a rule that links inputs to attribution values. For example, the tentative understanding described in the previous paragraph could be formalized as "words more positive than *memorable* (as measured by the word sentiment score given in the dataset, e.g., *flawless*, *charming*, etc) have SHAP attribution value in the [0.48, 1] range." This precise definition allows for quantitative evaluations. For example, this rule covers 1.6% of all words in the corpus, and is only correct 3.1% of the time. For the rule to be 90% correct, we need a wide and uninformative range of [-0.01, 1], indicating that a hasty generalization from "*memorable*" is unwarranted. Similarly, a saliency range of [-0.05, 0.05] for stop words is only correct 64% of the time: over 1/3 of stop words have *non*-negligible saliency – an understanding that is easily available with ExSum, but might be missed with informal explanation inspection. We define metrics to establish the quality profile of each rule and present a tool that makes it easy for users to construct ExSum rules from local explanations. Finally, we demonstrate how ExSum reveals the various drawbacks in the current practices of *ad hoc* model understanding, and allows for better understanding of model behavior in two separate tasks.

2 On Generalized Model Understanding

Besides the practical example above, we start from first principles and argue that *generalized* model understanding is the central concept for explanation usefulness. Local explanations are *mathematical descriptions (MD) of some aspect of model behavior, for specific inputs*. For example, gradient saliency (in the embedding space) is the sensitivity of the prediction to infinitesimal changes in the token embedding; occlusion saliency is the prediction change if individual embeddings are zeroed out. It is with these mathematical descriptions that people associate *high-level interpretations (HL) of model behavior*, such as associating the above two metrics with word importance. This (unconscious) train of thought can be described as follows:

$$x \to \text{MD} \to \text{HL}.$$

Crucially, people rarely study MD or HL for one *specific* input, as explanations are often used to understand broader model behaviors, such as reliance upon spurious correlation, non-discrimination of a protected class, or usage of unknown scientific principles. We elaborate upon these use cases in App. A to demonstrate that people implicitly or explicitly seek generalized model understanding.

From another perspective, analogous to why people ultimately focus on the *generalization* accuracy of a model, they (should) focus on *generalized* model understanding derived from local explanations.

For example, after observing that *some* highly polar words have high contribution for a sentiment classification model, people conclude that *all* highly polar words have high contribution. This process can be formalized as follows:

$$\left.\begin{array}{c} x_1 \to \mathrm{MD}_1 \to \mathrm{HL}_1 \\ \ldots \\ x_n \to \mathrm{MD}_n \to \mathrm{HL}_n \end{array}\right\} \to \mathrm{HL}^{(\mathrm{g})},$$

where $\mathrm{HL}^{(\mathrm{g})}$ is the *generalized* high-level model understanding. This generalization is too informal, not least because the step from MD_i to HL_i is itself already informal. Alternatively, we propose to generalize at the MD level, as follows:

$$\left.\begin{array}{c} x_1 \to \mathrm{MD}_1 \\ \ldots \\ x_n \to \mathrm{MD}_n \end{array}\right\} \to \mathrm{MD}^{(\mathrm{g})} \to \mathrm{HL}^{(\mathrm{g})}.$$

Since MDs are rigorously defined mathematical quantities (e.g., the prediction of the sentence drops by 32% after the embedding of "great" is zeroed out), we can define and evaluate the quality of their generalization, and $\mathrm{HL}^{(\mathrm{g})}$ can also include any failures and anomalies. As each MD is a local explanation, we call $\mathrm{MD}^{(\mathrm{g})}$ the *explanation summary* (EXSUM), and proceed by instantiating this principle for feature attribution explanations.

3 The EXSUM Framework

3.1 Setup and Notation

We focus on the classification setting, but all the ideas below can extend straightforwardly to regression. We have an input space $\mathcal{X}$ and output space $\mathcal{Y} = \{1, ..., K\}$ of K classes. A data point is an input-output pair $d = (x, y) \in \mathcal{D} = \mathcal{X} \times \mathcal{Y}$, distributed as $\mathbb{P}_D$. We consider a model $m : \mathcal{X} \to \Delta^{K-1}$ where $m(x)$ is the predicted class distribution on the probability simplex.

Feature attribution explainers assign an attribution, also known as saliency or importance, to each input feature, such as a token in a text input. For an instance (x, y), each feature of x is called a fundamental explanation unit (FEU), defined as $u = (x, y, l) \in \mathcal{U}$ with $1 \leq l \leq L_x$ as the feature index. $e(u) \in \mathcal{E}$ represents the attribution value assigned to it, where $\mathcal{E}$ is the attribution space, such as $[-1, 1]$ for normalized explanations. $e(u_-) = \left(e_x^{(1)}, ..., e_x^{(l-1)}, e_x^{(l+1)}, ..., e_x^{(L_x)}\right) \in \mathcal{E}_-^*$ denotes the explanations on all other FEUs of x.

We *define* a distribution $\mathbb{P}_U$ over $\mathcal{U}$ such that the probability (or probability density) of $u = (x, y, l)$ is $1/L_x$ of that of d under the data distribution $\mathbb{P}_D$. In other words, sampling of u can be performed in two steps: first draw an instance $d = (x, y) \sim \mathbb{P}_D$, then a feature index $l \sim \mathrm{Unif}(\{1, ..., L_x\})$.

3.2 EXSUM Rules

An EXSUM rule formalizes a piece of model understanding, such as that for positive words in Fig. 2, which we use as the running example.

Definition 3.1 (EXSUM rule)**.** An EXSUM rule r is defined by two functions. A binary-valued *applicability function* $a : \mathcal{U} \to \{0, 1\}$ determines whether the rule applies to a given FEU, with 1 being applicable and 0 otherwise. We use $a(\mathcal{U}) = \{u \in \mathcal{U} : a(u) = 1\}$ to denote the *applicability set*. A set-valued *behavior function* is defined as $b : a(\mathcal{U}) \times \mathcal{E}_-^* \to \mathcal{P}(\mathcal{E})$ where $\mathcal{P}(\mathcal{E})$ is the power set (i.e., the set of all subsets) of $\mathcal{E}$. This function predicts a set of possible explanation values for the FEU, called the *behavior range*. The rule is written as $r = \langle a, b\rangle$. We abbreviate $b(u, e(u_-))$ as $b(u)$ and refer to the two functions as a- and b-functions.

For FEU $u = (x, y, l)$, the a-function typically depends only on x_l, but could depend on the entire input x (e.g., for long sentences) or the output y (e.g., for positive class). In our example, it tests whether the sentiment score is greater than that of the word "*memorable*" (0.638). The b-function usually outputs a constant range. Since "*memorable*" has a saliency of 0.479, the range is [0.479, 1.0].

3.3 Additional Examples

While we expect most rules to use rather simple a- and b-functions, they can also be more complex with more nuanced aspects. For the following examples, recall that $u = (x, y, l)$. An applicability function can target words only in long sentences using a conjunction with $\mathrm{len}(x) \geq L$, where L is the threshold. We can also target inputs with ambivalent predictions with $\max_c m(x)_c \leq 0.6$, where $\max_c m(x)_c$ is the probability of the predicted class. For behavior functions, to indicate the first word of the sentence has higher saliency than the rest, we can define $b(u, e_-) = (\max_{l' \geq 2} e_-^{(l')}, 1.0]$, where the a-function selects the first word (i.e. $a(u) = \mathbb{1}_{l=1}$). Similarly, to describe that an FEU has higher saliency than all the verbs in a sentence, we can can use $b(u, e_-) = \Big(\max_{l':\text{is\_verb}(x_{l'})}\{e_-^{(l')}\}, +\infty\Big)$.

3.4 ExSum Rule Unions

Since a single ExSum rule is designed to capture one aspect of model understanding, multiple rules are often necessary for comprehensive understanding. However, conflicts can occur when multiple rules apply to the same FEU but the b-functions are different. We resolve them by defining the composition of two or more rules into a *rule union*.

Definition 3.2 (Precedence-Mode Composition)**.** Two rules, $r = \langle a, b\rangle$ and $r' = \langle a', b'\rangle$, can be composed into a precedence-mode rule union $r^* = r > r'$ defined as $r^* = \langle a^*, b^*\rangle$ where

$$a^*(u) = \mathbb{1}\{a(u) + a'(u) \geq 1\}, \tag{1}$$

$$b^*(u) = \begin{cases} b(u) & \text{if } a(u) = 1, \\ b'(u) & \text{if } a(u) = 0, a'(u) = 1, \end{cases} \tag{2}$$

represent the a- and b-functions of rule union r^*, with semantics similar to those for rules.

For example, if we want to split positive adjectives into a separate rule from other positive words, we create a rule to test for part-of-speech and sentiment score, and assign a higher precedence to this rule, such that the original rule is only applicable to the remaining non-adjectives. One useful practice is to include a lowest-precedence catch-all rule that covers everything not addressed by other rules, with a constant $a(u) = 1$ function, which leaves no FEUs unaccounted for.

Definition 3.3 (Intersection-Mode Composition)**.** Two rules, $r = \langle a, b\rangle$ and $r' = \langle a', b'\rangle$, can be composed into an intersection-mode rule union $r^* = r \,\&\, r'$ defined as $r^* = \langle a^*, b^*\rangle$ where

$$a^*(u) = \mathbb{1}\{a(u) + a'(u) \geq 1\}; \tag{3}$$

$$b^*(u) = \begin{cases} b(u) & \text{if } a(u) = 1, a'(u) = 0, \\ b'(u) & \text{if } a(u) = 0, a'(u) = 1, \\ b(u) \cap b'(u) & \text{if } a(u) = a'(u) = 1. \end{cases} \tag{4}$$

Unlike precedence-mode, intersection-mode composition is symmetric with respect to the two rules. This mode is helpful when each property of an FEU has a corresponding behavior range, and the final behavior range of an FEU depends on FEU's properties. For example, if verbs have a behavior range of [-0.4, 0.4] and strongly positive words have a behavior range of [0.3, 1], a strongly positive verb would have a behavior range [0.3, 0.4], or the intersection of the two constituent ranges. In our case studies, however, we do not encounter any situations in which intersection-mode compositions were preferable.

Since rule unions are also defined by a- and b-functions, they can form other rule unions in the same way. Recursively, this results in a list of rules composed into a single rule union, written as $r^* = (r_3 > r_1) \& ((r_4 \& r_2) > r_5)$. This rule union represents our *generalized model understanding*.

3.5 Quality Metrics

We propose three metrics for establishing the quality profiles of ExSum rules or rule unions.

Definition 3.4 (Coverage)**.** The coverage of a rule (union) $r = \langle a, b\rangle$ is defined as follows:

$$\kappa(r) = \mathbb{E}_{U\sim\mathbb{P}(U)}\left[a(U)\right]. \tag{5}$$

This represents the fraction of FEUs that we attempt to understand. While individual rules may have low coverage because they specialize in aspects of the model behavior, we want their union to have high coverage to achieve a comprehensive understanding of the model and prevent model prediction from being excessively affected by the uncovered (i.e. unexplained) input features. For our positive word rule, the coverage is the frequency of those words in the corpus and not surprisingly is only 1.6%. By contrast, including a catch-all rule in the union maxes out its coverage value at 100%.

Definition 3.5 (Validity)**.** Let $\mathbb{P}_{a(U)}$ be $\mathbb{P}_U$ truncated to the set of applicable FEUs. The validity of a rule (union) $r = \langle a, b\rangle$ is then defined as follows, capturing the intuitive notion of a "correct" understanding:

$$\nu(r) = \mathbb{E}_{U\sim\mathbb{P}_{a(U)}}\left[\mathbb{1}\{e(U) \in b(U)\}\right]. \tag{6}$$

For our example, we compute it as the frequency that the saliency of those words is actually in the range of [0.479, 1] – which turns out to be only 3.1% of the time. However, validity alone is not sufficient, as it increases with wider behavior range. We thus establish sharpness as a competing metric.

Definition 3.6 (Sharpness)**.** Let $\mathbb{P}_E$ be the probability measure corresponding to the marginal distribution over explanation values generated by the explainer on $u \sim \mathbb{P}_U$. The sharpness of a rule (union) $r = \langle a, b\rangle$ is defined as follows:

$$\sigma(r) = \mathbb{E}_{U\sim P_{a(U)}}\left[1 - \mathbb{P}_E(b(U)_{\setminus U})\right], \tag{7}$$

where $b(U)_{\setminus U} = b(U)\setminus\{U\}$ removes the actual attribution value U from the behavior range to prevent penalizing sharpness simply because the attribution value is very common (e.g., zero for sparse explanations), in which case $\mathbb{P}_E$ is discrete at U.

Sharpness represents precision in the understanding, as $1-\sigma(r)$ gives the probability that a random FEU explanation value is correct. Thus, a lack of precision represented by a wide behavior range has minimal sharpness. We use the probability measure $\mathbb{P}_E$ to define the "size", as it is consistent across all explanation distributions, most of which are non-uniform. A more general interpretation of sharpness is the consistency of the described model behavior: if a behavior range is wide (e.g., containing very positive *and* negative saliencies), then it is less sharp, and hence less useful. $\mathbb{P}_E$ could be replaced by an application-specific diversity measure, though the precision notion may be lost.

There is generally a trade-off between validity and sharpness, as more precise rules (i.e., those with narrower behavior ranges) are less likely to be valid. For our rule, the probability of a *random* word saliency being in [0.479, 1.0] is 0.2%, indicating that explanation values are rarely higher than 0.479. This makes sharpness very high at 99.8%. However, the rule is not useful because of its low validity; i.e., it is almost never correct. By comparison, the looser range of [-0.01, 1.0] has 90.4% validity but 28.6% sharpness. There is another trade-off between coverage and the two, since a larger set of covered FEUs tends to be more diverse, making it harder to write a b-function that remains as valid and sharp simultaneously.

Since these metrics are all expected values, we can estimate them by their empirical estimate from a dataset (i.e., a simple average), and $\mathbb{P}_E$ can be constructed by kernel density estimation.

4 ExSum Development Process and GUI

We describe a systematic procedure for authoring ExSum rule unions from scratch and utilize it in Sec. 5. Starting from an empty rule union with no FEUs covered, we iteratively create rules that target uncovered FEUs. Each rule describes one model behavior, such as that for highly positive words. For a rule, the a- and b-functions need to be defined, which may involve setting and tuning parameters, such as the sentiment threshold. Last, we add a lowest precedence catch-all rule if any FEUs remain uncovered. During this process, we may also merge or split rules and change the composition structure according to the metric values.

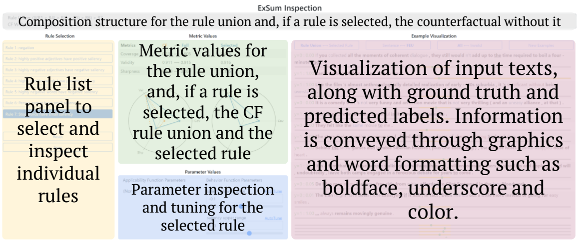

Figure 3: ExSum inspection GUI.

To support these steps, we developed a Python Flask-based (Grinberg, 2018) graphical user interface (GUI, Fig. 3). Users can visualize the FEUs, with font formatting for their coverage and validity. Users can also filter for uncovered or invalid FEUs, iteratively constructing and refining the rule union. ExSum rule definitions usually include parameters such as the sentiment threshold. Manually selecting correct values for the parameters is tedious, so the lower middle panel of the GUI implements automatic parameter tuning for a given target metric value. Installation and usage instructions for the GUI are available on the project page[1].

5 Evaluation

We construct ExSum rule unions for SST and QQP models (details in App. B). We split the test set into a *construction set* to create the rule union and tune its parameters (analogous to the training and validation set in supervised model training) and an *evaluation set* to compute unbiased estimates of the metric values (analogous to the test set).

5.1 Sentiment Classification

Setup We use SHAP explanations (Lundberg and Lee, 2017) for fine-tuned RoBERTa (Liu et al., 2019), and take 300 random sentences as the construction set, with the remaining 1910 sentences as the evaluation set. We compute five features for each FEU: sentiment score, part of speech (POS), named entity recognition (NER), dependency tag (DEP) and word frequency. For example, the word "same" in the sentence "*They felt like the* <u>*same*</u> *movie to me .*" has sentiment score of 0.028, POS = ADJ, NER = O, DEP = amod, and frequency of 7.14e-4, with SHAP saliency of -0.82.

Current Practice We evaluate the current practice of extracting *informal* model understanding from local explanation inspection against the three

---

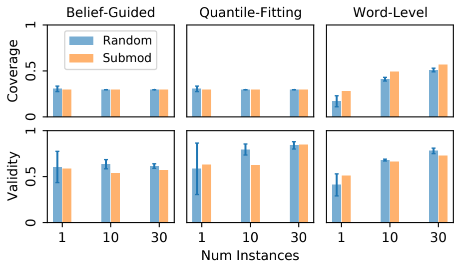

Figure 4: Coverage and validity metrics for the three current practice modes. Tab. 4 of App. B.1.1 presents the complete numerical data (also with sharpness).

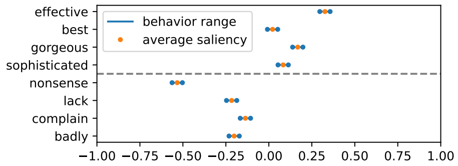

Figure 5: Behavior ranges can vary widely and unpredictably on similar words for WL rules.

metrics. We assess three values of K, the number of inspected instances: 1, for the typical *ad hoc* setting of generalization from a single explanation, 10, for a more careful investigation, and 30, which is quite cumbersome for manual inspection. These examples are selected either randomly or by submodular pick (Ribeiro et al., 2016). Next, we consider three ways to extract model understanding – belief-guided (BG), quantile-fitting (QF) and word-level (WL) – and apply them to create rules on strongly positive words and stop words introduced in Sec. 1. For the strongly positive word rule, BG mandates that words more positive than the average sentiment score should have an above-average saliency score, representing the belief of a positive correlation between the two. For the stop word rule, a saliency range belief of [-0.05, 0.05] is averaged with the observed range. For both rules, QF extracts the 5%-95% quantile interval of the saliencies for words covered by the respective rule. WL, by contrast, creates a behavior range *for each word seen*, with 0.03 margin on both sides. App. B.1.1 presents technical details for these.

We formalize the understanding derived from the selected instances and plot their coverage and validity metrics on the evaluation set in Fig. 4. For BG and QF, the bars represent the average metric value of the positive word and stop word rules. For WL, the bars represent the metric for the rule union consisting of an individual rule for each unique word. Error bars for the random pick represent the standard deviation across five iterations. Tab. 4 of App. B.1.1 presents the complete statistics for all metric values, and we highlight several findings.

- A very small number of samples (e.g., 1) exhibit large variance for random pick, and low validity for both pick methods. This confirms the intuition that model understanding from very few explanations should be avoided.
- BG overall yields low validity, because its "beliefs" turn out to be quite incorrect. This suggests a strong prior belief about how the model works could lead to incorrect conclusions.
- While submodular pick can select a more diverse set of words, to the particular benefit of the coverage of WL[2], its validity is generally lower due to under-representation of common words.
- Although WL achieves highest coverage *and* validity, it has > 500 rules at K=30, with similar words having very different ranges, as shown in Fig. 5 – a conglomerate (almost) impossible to make sense of. It also overfits, as the evaluation set validity is much lower than the construction set validity (which is 100% by construction).
- At K=10, only the stop word rule with random pick QF achieves validity $> 80\%$, indicating that even the more careful practices are unreliable.

All the drawbacks call for a principled way to derive robust model understanding with enforceable metric values (e.g. validity). As we demonstrate next, given a large construction set and automatic parameter tuning assistance, we can create such a ExSum rule union. Finally, as a meta-point, the above discussion above of various limitations would not be possible without the proposed ExSum formalization and metric definitions.

ExSum Construction We create a rule union consisting of nine rules, with target validity of 90% and tune the sharpness accordingly. Tab. 1 summarizes the individual and aggregate metrics.

Clearly, high validity comes at the cost of low sharpness. Since (1 − sharpness) is the probability that a random FEU has an explanation value within the behavior range, this around 90.7% validity should be put into a context where the random baseline achieves a validity of around 75%. In this sense, we attain only a crude understanding of the local explanations that misses many subtleties.

Nonetheless, Rule 3 (strongly positive words)

---

[2] The other two are less affected because the subject of the rule (e.g., stop words) largely dictates which words it covers.

Idx	Rule	Cov%	Val%	Shp%
1	Negation	1.2	89.5	65.1
2	Strongly neg. adj	3.2	91.6	83.5
3	Strongly pos. words	5.1	91.9	40.0
4	Strongly neg. non-adj	1.2	89.9	71.4
5	Person name	2.4	90.9	28.4
6	Stop words	47.5	90.8	23.5
7	Zero-sentiment words	17.1	90.0	15.6
8	Weakly pos. words	15.4	91.2	11.3
9	Weakly neg. words	5.7	91.7	31.4
Union	On construction set	100	90.7	26.1
	On evaluation set	100	89.4	26.2

Table 1: Metrics for SST rules and rule union.

Idx	Rule	Cov%	Val%	Shp%
1	Matching words neg. pred	11.7	90.9	39.5
2	Matching words pos. pred	12.4	90.3	38.6
3	Non-matching words neg. pred	18.7	90.0	35.5
4	Question mark neg. pred	5.2	90.2	36.5
5	Question mark pos. pred	3.8	90.0	23.1
6	Stop words neg. pred	22.3	90.0	32.8
7	Stop words pos. pred	12.6	90.5	12.5
8	Negation words neg. pred	0.3	90.0	36.0
9	Negation words pos. pred	0.1	95.7	7.2
10	All else neg. pred	4.0	92.1	23.5
11	All else pos. pred	8.8	90.3	5.7
Union	On construction set	100	90.3	29.3
	On evaluation set	100	90.0	29.1
Word Avg	On construction set	100	90.8	29.4
	On evaluation set	82.3	84.4	29.4

Table 2: Metrics for QQP rules and rule union. The last two rows are for the baseline at the end of Sec. 5.2.

and Rule 6 (stop words) achieve better validity-sharpness trade-off than their counterparts created using the *ad hoc* BG and QF methods above. Moreover, the WL rules cover all words seen in the analyzed instances – analogous, in a sense, to our ExSum rule union. While the validity-sharpness trade-off is comparable between the two, ours has 100% coverage due to the effectively "catch-all" Rule 7, while WL rules have less than 60%. Most importantly, as our rule union is composed of nine semantically organized rules, it is much more interpretable than WL, which include more than 500 unpredictably varying rules (Fig. 5).

The fact that the ExSum rule union reveals the imprecision and limitations of our model understanding while still performing better than current practice emphasizes the need for more formal and quantitative model understanding, as well as the development of methods that are easier to *understand*, in addition to being correct. Below, we highlight two sets of rules that quantitatively support or refute our intuition, and cover the rest in App. B.1.2.

Rule 2, 3, 4, 8, 9: Sentiment-carrying words. We expect a sentiment classifier to recognize sentiment-laden words. To test our intuition, we create rules for positive and negative words, and further split each set of words into two according to sentiment strength, resulting in four rules. For the two rules on strong words, we find that wide behavior ranges of [0.01, 1] and [-1, -0.01] are necessary to achieve 90% validity, suggesting the looseness of the model understanding. However, we do observe that negative adjectives (but not positive ones) are modeled much better, where a range of [-1, -0.06] is sufficient for the same validity. Thus, we create a separate Rule 2, with very high sharpness of 84.2%. For the two rules on words of weaker sentiment, even wider ranges of [-0.11, 1] and [-1, 0.05] are necessary. Since both ranges encroach upon the other side, the model often considers these words to have an impact opposite to their intrinsic meaning, but we fail to extract further understanding. In addition, negative rules are much sharper than positive ones, suggesting that the model considers a negative word to be stronger evidence for a negative prediction than its positive counterpart.

Rule 6: Stop words. While stop words (e.g., "the", "of") *should* have negligible impact on prediction (and saliency values close to zero), a narrow behavior range of [-0.05, 0.05] only has 64% validity. We create this rule for all stop words with 90% target validity and use different ranges on different words for better sharpness. On average, we get [-0.07, 0.12], demonstrating that they can sometimes be more influential than even strong sentiment words. The ranges also tilt to the positive side, uncovering a grammaticality bias wherein prediction is more negative for grammatically incorrect sentences with stop words masked out by SHAP.

5.2 Paraphrase Detection

Setup We use LIME explanations (Ribeiro et al., 2016) for a fine-tuned BERT model (Devlin et al., 2019), with 500 random test sentences as the construction set and the remaining $\approx$ 40k as the evaluation set. We remove the word sentiment feature but add the question ID (1 or 2) of each FEU.

ExSum Construction QQP is a more complex domain than SST, since the label is the semantic equivalence of *two* sentences. The metric values for the ExSum are summarized in Tab. 2. Below, we describe how expectations for the model are validated, but a hidden – and somewhat surprising – phenomenon is also uncovered. All other rules are documented in App. B.2.1.

Rule 1, 2: Matching words. Due to the nature of the task, we expect the model to rely heavily on matching words. For such a word u, defined as (proper) noun, verb, adjective or pronoun that has exactly one case-insensitive match v in the other question, we expect similar saliency to their match due to symmetry, or formally its saliency $s_u \in [s_v - \alpha, s_v + \beta]$, where α and β are lower and upper margins. This behavior function is non-constant, with output depending on the saliency values of other words in the sentence.

For the same margin, FEUs for pairs of negative predictions have much higher validity than positive ones, so we split the rule into two based on the prediction. Despite a less than 1% difference in sharpness (Tab. 2), we have $\alpha = \beta = 0.07$ for the negative rule, but 0.18 for the positive rule, suggesting that the matching words make a much larger and more unpredictable contribution to positive predictions. Interestingly, all other rules had wider intervals for positive predictions as well.

Rule 3: Non-matching words. Next we study model behaviors for non-matching words, defined analogously to matching ones. Following the previous split based on predicted label, we designed two rules. The negative rule has a reasonably sharp behavior range of [-0.35, 0.01] at 90% validity. Given that LIME saliency is the linear regression coefficient on a neighborhood created by word erasure, we conclude that the *presence* of these non-matching words mostly causes the prediction to tilt toward the non-paraphrase (i.e. negative) class, indeed a very reasonable behavior. However, we cannot find a range with 10% sharpness at 90% validity for the positive rule and thus discard it.

With regard to the sharpness contrast by predicted label, one explanation is that the model defaults to a negative prediction, since many negative pairs consist of completely unrelated questions and the model decision is largely insensitive to input perturbations, leading to stable LIME coefficients. On the other hand, a positive prediction requires the cooperation of all parts of both questions. Depending on the exact sentence structure, the importance of each word to the match are different and hard to predict, which prevents the rules from being sharp.

Word Average Baseline Here, we introduce a new baseline as an "automated" version of WL rules in SST. Specifically, for each word in the construction set, we compute a behavior range around its average saliency, with sharpness of 29.4% (matching that of our ExSum rule union). As Tab. 2 shows, the resulting rule union is much worse than our manual one on both evaluation set coverage and validity, which is not surprising as the word saliency *should* be more context-dependent, due to the matching mechanism of paraphrase detection. Moreover, with more than 2,000 constituent rules, the rule union barely qualifies as any sort of *generalized* model understanding.

6 Related Work

As discussed in Sec. 1, explanation evaluation usually has a focus on correctness (or faithfulness) – i.e., whether the explanation truly reflects the model's reasoning process. This includes sanity checks (Adebayo et al., 2018), proxy metrics (Samek et al., 2016; Arras et al., 2019), and explicit ground truth (Zhou et al., 2022). The understandability issue has been much less studied, with the exception by Zheng et al. (2021), who proposed an evaluation specifically for rationale models (Lei et al., 2016). ExSum, however, addresses *post hoc* explanations of general black-box models.

In addition, a few prior works have attempted to capture the "end-to-end" utility of explanations: whether access to explanations leads to performance increase in certain tasks. Hase and Bansal (2020) propose a model-teaching-human setup, subsequently extended by Pruthi et al. (2022) into an automated evaluation procedure. Bansal et al. (2021) study whether explanations can improve human-machine teaming performance. While these studies report mostly negative results, pinpointing the root cause is difficult due to their end-to-end nature. Poor *understanding* of the explanations may be a major reason, as indicated by ExSum.

Last, some authors have proposed methods for understanding model predictions beyond individual instances. For example, the anchor method (Ribeiro et al., 2018) generates an explicit domain of applicability for each explanation, while Lakkaraju et al. (2016) and Lakkaraju et al. (2019) proposed to learn "patches" of the input space specified by logical predicates. ExSum also emphasizes the need to understand models that generalizes across instances, and uses logical predicates in the formulation, but focuses on model understanding via *explanations* instead of direct *predictions*, which can capture a wider variety of *behaviors* (e.g. the matching and non-matching behaviors of the QQP model). Furthermore, the fine-grained analysis of behaviors allows us to investigate whether models are "correct for the correct reason."

7 The Many Faces of Understandability

The central thesis of this paper is quite simple and intuitive: in order to understand a model from local explanations, we need to understand those local explanations. While ExSum is the first framework to explicitly formalize and quantify the notion of understandability, we argue that it is connected to many often-discussed and desirable properties of explanation (further details in App. C).

Human Alignment Users sometimes expect explanations that are aligned with their expectations. For example, the fact that highly salient words convey strong sentiment is taken as evidence for the quality of an explanation method by Li et al. (2016). In image classification, this concept is typically implemented as a pointing game between the high-saliency region and the segmentation mask of the predicted class (Fong and Vedaldi, 2017). However, alignment does not imply correctness, as the model could use any spurious correlations, which should be faithfully highlighted by the explainer. However, higher-alignment explanations are indeed *more understandable*, since by definition they agree more with human intuition. Thus, an alignment-based evaluation can be considered as one of understandability. Nonetheless, understandability can also be achieved by correcting human expectations, e.g., users realizing that punctuations are actually important for predictions (contrary to expectations).

Robustness It is often argued that explanations should be robust (Ghorbani et al., 2019) – similar inputs should induce similar explanations. However, robustness can be at odds with correctness: if the model truly applies vastly different logic for two very close inputs – such as a pair of inputs that only differ in the root feature of a decision tree – then their explanations should be distinct, as they are routed down two different sub-trees. Nonetheless, slow-varying explanations are generally easier to understand than those that change erratically and unpredictably (independent of their correctness), and thus robustness is related to understandability.

Counterfactual Similarity and Plausibility Counterfactual explanations (e.g. Ross et al., 2021) indicate how the input should change in order to alter the model prediction. Besides the success rate of achieving target prediction, they are often evaluated on similarity (the magnitude of input change) and plausibility (the naturalness of the changed input). Both properties can serve as proxies for understandability: it is easier to relate an input to another similar and natural input than to a totally different or abnormal one. However, App. C presents two cases where they should *not* be similar or plausible but remain understandable, to highlight certain model behaviors.

8 Discussion and Conclusion

Traditionally, model explanations are evaluated on correctness (or faithfulness), i.e., whether they correspond to how models actually make predictions, e.g., reliance on spurious correlations (Zhou et al., 2022; Adebayo et al., 2022). Such evaluation, however, does not answer the equally important question of whether these (presumably correct) explanations are understandable. Even faithful explanations can lead users into error, if misunderstood (e.g., trusting a model incorrectly).

In a sense, the most correct explanation for an input is the literal trace of model computation, but it is also arguably the least understandable (or useful). As we abstract away from low-level details and use higher-level concepts such as word sentiment, the resulting explanation loses correctness but gains understandability. At the other extreme are explanations that are trivially understandable but completely wrong, such all attribution values being 0 (i.e., no feature impacts the model prediction). Thus, a trade-off often occurs between these two desiderata, and we need to choose a sweet spot.

Concretely, we propose ExSum rules and rule unions, along with three quality metrics to formalize and evaluate understandability. Such rigorous investigations stand in contrast to current *ad hoc* practices, which are prone to yielding unreliable and coarse model understanding. For SST and QQP datasets, ExSum demonstrates that our model understanding is quite limited and imprecise, even with very reasonable explanations. *Being aware of this is an asset.* While ExSum helps us to recognize that our understanding is incomplete, it still helps uncover unexpected model behaviors that warrant further investigation.

Limitations and Ethical Impacts

Limitations

One notable requirement of ExSum is the extensive human involvement in constructing and optimizing its rules. However, this process is necessary, as the alternative of generalizing from a few explanations has various flaws, depicted in Fig. 2 and Fig. 4. Practically, we spent about 3 hours on each rule union in Sec. 5, and our effort was streamlined by the systematic process and GUI presented in Sec. 4, which could be further improved by methods that automatically propose candidate rules.

In addition, another area requiring human involvement is the FEU feature definitions, which are often domain-dependent: both the sentiment score and the matching word features reflect the nature of the tasks. Other features may be necessary for other tasks. For example, in question-answering, one important FEU feature could be the kind of interrogative word used in the question (e.g., "what" vs. "when" vs. non-interrogative words). If important features are missed, the quality of the ExSum rules – and, hence, the model understandings – will suffer accordingly.

Last, the difficulty of obtaining overall high-quality model understanding may result from the fundamental limitations of word-level attribution-based explanations, which cannot account for higher-level interactions. ExSum could aid in the development of new explanation methods that are easier for humans to understand. As a first step, we explore defining and evaluating model understanding obtained from instance-based explanations with whole input as FEUs. App. D details the investigation, which raises questions such as the reliability of such explanations.

Ethical Impacts

As interpretability methods are increasingly deployed for quality assurance, auditing and knowledge discovery purposes, it is important to ensure the legitimacy of any conclusions drawn from explanations. While the correctness of these explanations is often studied, we argue their understandability should be equally emphasized, and evaluations with our newly proposed ExSum framework and GUI reveal many problems of existing *ad hoc* procedures. Thus, a more careful treatment on the understandability aspect is necessary for well-calibrated model understandings and responsible model deployment in the real world.

A Real World Use Cases for Explanations

Here, we discuss several scenarios in which people use local explanations to understand models, and argue that people invariably derive *generalized* model understanding from these explanations.

A.1 Spurious Correlation Identification

Natural datasets can contain many spurious correlations. For example, in a COVID-19 chest X-ray dataset, most positive images (i.e., patients diagnosed with COVID-19) come from a pneumonia-specializing hospital and contain a watermark of the hospital name, while most negative images from other hospitals do not. Thus, a model could achieve very high accuracy by simply detecting the watermark rather than genuine medical signals. Similar spurious correlations could also be present in the text domain, such as the correlation between an exclamation mark and the positive sentiment class, or between the word "*not*" and the contradiction class in natural language inference.

It is crucial for people to be aware of the shortcuts that models may take, and one possible way to highlight such behaviors is via feature attribution, which in the examples above would assign an abnormally high score to the watermark region, exclamation mark, or the word "*not*." Assuming the explanations do indeed exhibit such patterns, when people claim a model relies on spurious correlation, they mean this in a general sense: for example, the model is likely to focus on the watermark in *any* image that contains it, rather than in only a specific set of images.

A.2 Fairness Assurance

Similar to spurious correlation features, other features should not have a high impact, but for reasons of fairness. For example, decisions made by a loan approval model should not be affected by gender[3], therefore the gender feature should not have a high attribution score.

If we observe that the gender of one applicant heavily impacts the model's decision, we may suspect the model is discriminative; conversely, observing that it has minimal impact could increase our assurance of the model's fairness. However, such single-instance observations are fundamentally exploratory, and claims about the model's fairness or discrimination must be established using a *population* of instances to determine whether the trend persists generally.

A.3 Model-Guided Human Learning

In some cases, a very accurate and "super-human" model could be a source for knowledge discovery. Consider the task of early-stage cancer detection from CT scans, which is challenging for doctors. If a label is generated from follow-up visits tracking whether patients develop cancer after a certain number of years, a model achieving better test accuracy than doctors is likely to use certain cues that would be missed by humans or not known to be linked to cancer.

For these models, explanation methods such as saliency maps could be used to help doctors make better diagnoses, or assist scientists in the creation of new pathological theories. Similarly to the above two use cases, *generalized* model understanding across different inputs are necessary, because doctors need to apply what they have learned to new patients, and scientists require new theories to hold broadly.

B Additional Evaluation Details

Tab. 3 summarizes the key parameters of our experiment. Both saved models are publicly accessible from Huggingface Hub, and the model names in the table are links to the respective model checkpoints. For normalization, we divided all explanation values for all test set instances by a single scaling factor such that the maximum magnitude of new explanations is 1.

B.1 SST Sentiment Classification

For the explainer, we used the PartitionSHAP algorithm implemented by the `shap` repository[4]. Fig. 6 shows the explanations on three sentences (after normalization).

---

[3] There could be other features that correlate with gender, such as job title, but we ignore such possibilities for simplicity.

[4] `https://shap.readthedocs.io/en/latest/`

Task	Dataset	Model	Acc.	F1	Explainer
Sentiment	SST-2	RoBERTa	95.6%	0.957	SHAP
Paraphrase	QQP	BERT	90.7%	0.875	LIME

Table 3: A summary of tasks, models (fine-tuned on respective datasets), and explainers for the two case studies.

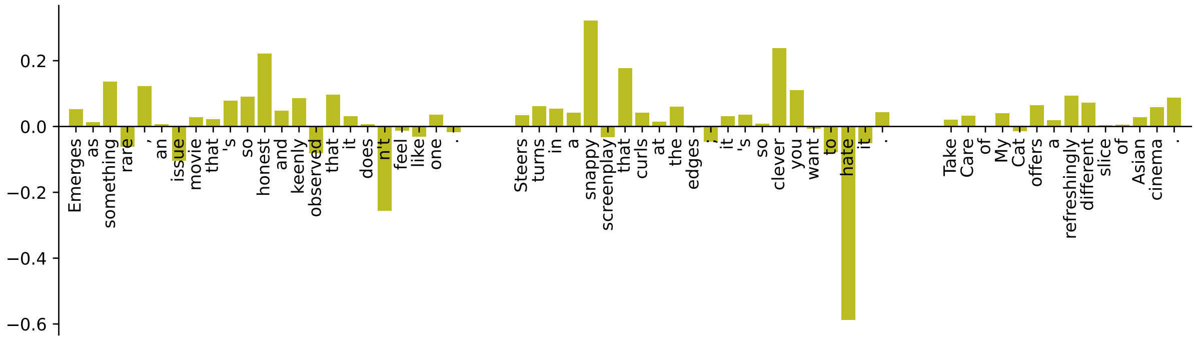

Figure 6: SHAP explanation visualization for three SST inputs.

B.1.1 Details of Current Practices

Here, we provide an extended description of the three current practices, and how they are applied on the handful of selected examples, collectively called the "sample" below.

The first method, "belief guided" (BG), represents the practice wherein the user has some expectations (or beliefs) about the attributions of certain words, and modifies (or updates) them after observing explanations on some actual test inputs. It operates differently for the two rules on positive-sentiment and stop words, as follows.

1. For positive-sentiment words, the prior belief is that a word with a higher sentiment score (one of the FEU features provided by the SST dataset) should also receive more positive attribution. This leads to a rule that applies to all words with a sentiment score greater than α, and has a behavior function that outputs a constant range of $[\beta, 1]$ (recall that SHAP attribution values are normalized to $[-1, 1]$ range). It then computes the value of α as the mean sentiment score and β as the mean attribution value for all words in the sample with positive sentiment scores.

2. For the stop words – defined as those with parts of speech AUX, DET, ADP, CCONJ, SCONJ, PRON, PART, and PUNCT – it has a prior belief that they should have a attribution value range of [-0.05, 0.05] (i.e., not important to model prediction), and computes the observed attribution range $[\alpha, \beta]$ for stop words in the sample. The final behavior range as predicted by the behavior function of this rule is the average of these two: $[-(0.05 + \alpha)/2, (0.05 + \beta)/2]$.

The second method, "quantile fitting" (QF), represents the practice wherein the user fully follows the observed data without any prior beliefs. Specifically, for a set of words, it collects all attribution values for words within the set and then creates a rule that applies to this set, with the behavior function predicting a constant range of 5% to 95% quantile of these attribution values. For the two rules for positive-sentiment and stop words, the set of words (and hence the applicability functions) is defined in the same way as for the BG method above.

The last method, "word-level" (WL), can be considered a more extreme version of QF, where the user not only lacks any prior expectations for the explanations but also considers each word individually. For example, if the user observes that the word "brilliant" has an attribution value of 0.5 in one sentence and the word "fantastic" has attribution of 0.8 in another, they would *not* conclude that other, similarly positive words would have attributions approximately within the range of $[0.5, 0.8]$. Specifically, for every distinct word w in the sample, this method builds a rule that applies only to that word, with a constant behavior function that outputs a range of $[\min(s_w) - 0.03, \max(s_w) + 0.03]$, where s_w is the list of attributions received by different occurrences of w. In many cases, especially given a small sample, word w only appears once, in which case s_w is a list containing only that attribution value.

Tab. 4 presents the metric values of the above methods. Fig. 4 of Sec. 5.1 depicts a graphic summary.

		belief-guided		quantile-fitting		word-level
K	pick	positive	stop word	positive	stop word	seen words
	SP	10, 72, 50	49, 45, 65	10, 63, 44	49, 63, 45	28, 51, 61
1	RND μ	12, 63, 57	49, 58, 53	12, 45, 56	49, 73, 33	17, 41, 68
	RND σ	6, 25, 27	0, 9, 6	6, 32, 29	0, 24, 21	6, 12, 10
	SP	10, 61, 61	49, 47, 63	10, 78, 34	49, 72, 38	49, 66, 48
10	RND μ	10, 71, 52	49, 56, 56	10, 75, 32	49, 84, 25	41, 68, 48

B.1.2 Complete Rule Union Description

Below, we present the details of the construction process for rules not discussed in Sec. 5.1.

- ***Rule 1: Negation words have negative saliency.*** We found that negation words – *not*, *n't*, *no*, *nothing* and those with NEG dependency tag – almost invariably receive (sometimes highly) negative saliency, regardless of the sentence label or sentiment of the word being modified. We create a rule that predicts a constant behavior range $[-1.0, 0.002]$, with 89.5% validity and 65.1% sharpness. Although the validity is under our 90% target, we found that to make it higher, the upper limit of the behavior range needs to be 0.1, which results in an extremely low sharpness of 11%. Thus, we decided against it.

- ***Rule 5: Person names have positive saliency.*** During our initial inspection, we found several cases where the name of a person (e.g. director or actor) have positive saliency values. Thus, we create this rule from the NER tag, covering 2.3% of words. However, after parameter tuning, we found that while many of the words have positive saliency, the correct characterization is that they all have small saliency values, as a behavior range of $[-0.06, 0.1]$ achieves 91.6% validity. However, since SHAP saliencies are mostly concentrated around 0, this range achieves a meager sharpness of 26.8%. Despite this, we still decide to keep it.

- ***Rule 7: Zero-sentiment words have small saliency.*** Besides stop words, we should expect words that do not carry sentiment, such as most nouns and verbs (e.g., *movie* and *get*), to have small saliency magnitudes. Due to the wide range of words applicable under this rule, we choose the saliency range to be $[-0.15, 0.15]$ for $\geq 90\%$ validity, but this range yields lowest sharpness of 13.5%.

- ***Rule 8, 9: Weakly positive/negative words have weakly positive/negative saliency.*** Finally, we set up two rules to capture words that have sentiment of neither zero (covered by Rule 19) nor high-magnitude (covered by Rule 3 – 5). To achieve 90% validity, we require a behavior range of $[-0.11, 1]$ for weakly positive words and $[-1, 0.05]$ for weakly negative words, unfortunately again with quite low sharpness. Notably, both ranges need to "spill over" to the other side of zero for the required validity.

B.2 QQP Paraphrase Detection

For the explainer, we used the LIME algorithm implemented by the `lime` repository[5]. Fig. 7 depicts the explanations on two pairs (after normalization).

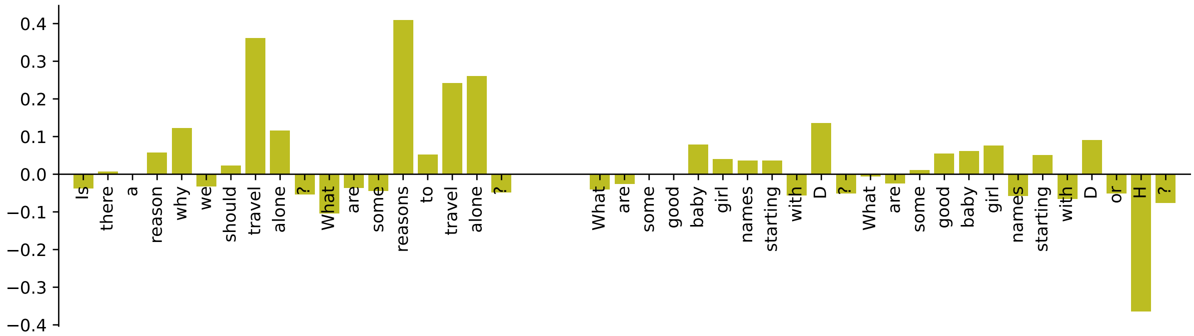

Figure 7: LIME explanation visualization for two QQP pairs.

B.2.1 Complete Rule Union Description

Below, we present details of the construction process for rules not discussed in Sec. 5.2.

- ***Rule 4, 5: Saliency for trailing question marks.*** Since the dataset is composed of pairs of questions, the vast majority of sentences conclude with question marks. These should be purely decorative and syntactic, and so should have small saliency, similar to stop words. However, we observe that the saliencies assigned to them for positive and negative predictions are very different, so we create two rules for these two cases. With a 90% validity target, the saliency range is [-0.04, 0.03] for negative predictions and [-0.07, 0.06] for positive predictions. Again, the saliencies for positive predictions demonstrate more variation than those for negative ones.

- ***Rule 6, 7: Saliency for stop words.*** Similar to SST, we use these two rules to ensure stop words should *not* be influential. We split the stop word group into finer segments by part of speech, to achieve higher sharpness. On average, the range is [-0.07, 0.03] for negative predictions and [-0.09, 0.1]for positive predictions, which again demonstrate a much higher degree of variation.

- ***Rule 8. 9: Saliency for negation words.*** In the SST case, we found that negation words typically have negative saliency regardless of the sentiment label, and test whether this holds for QQP as well. Following on our previous findings, we use two rules to separately model inputs of positive and negative predictions. We find that the range is [-0.1, 0.24] for positive predictions and [-0.21, 0.01] for that for negative predictions. Curiously, the same negative saliency trend is preserved here as well, but only for inputs with negative predictions.

- ***Rule 10, 11: Saliency for everything else.*** Finally, we designed two lowest-precedence "catch-all" rules to complete the coverage. The range for positive prediction FEUs is [-0.13, 0.25]. For negative prediction inputs, we find that breaking them according to different parts of speech (nouns, verbs, adjectives, and everything else) is helpful, with verbs having a particularly narrow saliency range of [-0.05, 0.05]. On average, the saliency range is approximately [-0.09, 0.05].

C Understandability as a Unified Theme

In this section, we elaborate on how understandability is the unified theme behind many properties of explanations that seem "orthogonal" to correctness. Specifically, we discuss three properties: human alignment , robustness, and counterfactual similarity and plausibility.

---

[5] `https://github.com/marcotcr/lime/`

C.1 Human Alignment

Many prior works have assessed how much explanations agree with human expectation. For example, Li et al. (2016) observed that the word "hate " contributes the most to a negative sentiment prediction in many inputs, and used it to argue the explanation is correct. In a similar sentiment classification task, Bastings et al. (2019) used the high degree of overlap between the extracted rationale and strong-sentiment words to argue the superior quality of a neural rationale model (Lei et al., 2016). In computer vision, this alignment is often implemented as a pointing game that computes the intersection-over-union (IoU) metric between the salient region and the semantic segmentation mask of the predicted class (Simonyan et al., 2014; Fong and Vedaldi, 2017), as shown in Fig. 8. For a model that predicts breast cancer onset using patients' genetic information, Covert et al. (2020) demonstrated that many of the influential genes identified by their explainer were indeed known to be associated with the disease.

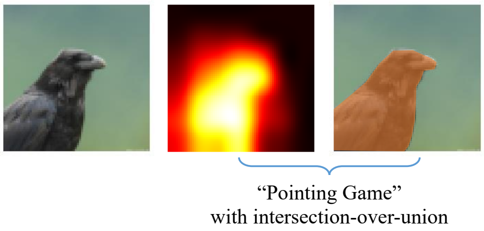

Figure 8: A pointing game used to quantify human alignment for visual explanations.

As discussed in App. A.1, models could use any unexpected spurious correlation, such as the green background in Fig. 8. For these models, correct explanations should have low alignment scores. When correctness (or faithfulness) is the sole desideratum of interpretability methods, it is unclear what purposes these alignment evaluations serve. Some authors (e.g. Jacovi and Goldberg, 2020) have even argued they are fundamentally misleading and flawed in nature as they focus on *plausibility*, which is sometimes at odds with the goal of correctness.

However, from the perspective of *understandability*, high-alignment explanations are arguably very understandable, simply because they align closely with human expectation. Thus, given the same level of correctness, a higher-alignment explainer may be preferable.

C.2 Robustness

Besides human alignment, robustness – i.e. that similar inputs should have similar explanations – is also argued to be a favorable property for explanation. For example, Ghorbani et al. (2019) argued that explanations are fragile due to their adversarial vulnerability, Alvarez-Melis and Jaakkola (2018a) empirically estimated the Lipschitz constant for many explainers, and Alvarez-Melis and Jaakkola (2018b) proposed an inherently interpretable model that is explicitly regularized for explanation robustness.

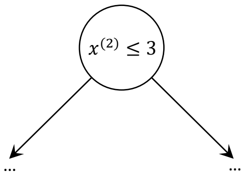

Figure 9: A decision tree that splits on the second feature at the root node.

Robustness generally conflicts with correctness. If, for two inputs, the model is using distinct reasoning patterns, the correct explainer should faithfully report distinct explanations for them. One straightforward example is the decision tree model shown in Fig. 9, where the root node splits on the second feature at a threshold value of 3. For two inputs x_1 and x_2 that agree on all features except the second one, with $x_1^{(2)} = 2.99$ and $x_2^{(2)} = 3.01$, since they are sent down two different sub-trees at the very beginning, the model is likely to use for totally different features.

Nonetheless, as implicitly argued by the works above, erratic model behaviors are less understandable because they make it more difficult to identify generalizable patterns compared with slowly varying explanations in the input space. Thus, robustness is another aspect of the same understandability desideratum.

C.3 Counterfactual Similarity and Plausibility

Unlike feature attribution explainers that assign importance to individual features, counterfactual (CF) explainers (e.g., Ross et al., 2021) directly generate whole inputs but for a target predicted class. Thus, a CF explanation indicates how to cross the decision boundary from the input.

Naturally, the fundamental requirement of CF explanations is achieving the target prediction, which is typically known as validity. However, this is trivially satisfiable by simply finding a training instance with the target prediction, along with other ways such as creating adversarially perturbed or nonsensical inputs. Thus, two additional requirements are often enforced: similarity and plausibility. The former says that the CF explanation should be close to the original input (with regard to, for example, edit distance), and the latter says the CF explanation should be plausible, or natural. Tab. 5 depicts various CF explanations and their satisfaction of the three requirements.

Input: This restaurant is the best I have been, with especially great food.				
CF	Type	Val.	Sim.	Plau.
This restaurant is the *worst* I have been, with especially *terrible* food.	“good” CF	✓	✓	✓
Rude service!	training set look-up	✓	✗	✓
This *resturant* is the best I have been, with especially great food.	adversarial typo injection	✓	✓	✗
Fjwpeaf fawekl fka erj sfdlk erjlm adl erio fd	nonsensical inputs	✓	✗	✗

Table 5: CF explanations that are all valid but differ in similarity and plausibility metrics.

Validity for CF can be considered as the correctness analogy for feature attribution, but the purposes of similarity and plausibility are not readily apparent. As CF explanations represent ways to cross the decision boundary, people need to meaningfully understand how the CF instance is related to the original input. It is difficult to relate two dissimilar instances, and an implausible CF instance is generally unexpected. Thus, similarity and plausibility are required to make CF explanations more understandable.

Interestingly, if our true goal is the understandability of the relationship between the input and its CF explanation, there are cases where similarity or plausibility is *not* desirable. First, consider a sentence length classifier that predicts positive for sentences of at least 10 words, and negative otherwise. Given an input of three words, the CF explainer should generate *dissimilar* CF instances of at least 10 words in order to correctly illustrate the decision boundary, while instances of even more words would be helpful for understanding the “at least 10 words” logic. Second, consider a classifier trained on a typo-free dataset and having high probability of making mistakes on inputs that contain typos. To illustrate this behavior, CF explanations should contain randomly (not adversarially) injected typos, which are *implausible*, but useful as long as the typo injection is understood by people.

D Additional Details on Instance-Based Explanations

In this section, we describe our initial attempt at extending the ExSum framework to another type of explanations: instance-based explanations (IBE). The IBE for an input x is a set of instances and their predictions $\{(x_i, \widehat{y}_i)\}$, where x and x_i are semantically related (e.g., negation). We define $\widehat{y}_i$ as the predicted probability of positive class.

Type	$b(\widehat{y})$	ν	σ
Entity change	$\widehat{y} \pm 0.05$	91.4	56.5
Minor insert	$\widehat{y} \pm 0.05$	89.1	57.3
Negation	other-side$(\hat{y})$	30.4	50.0
Negation	same-side$(\hat{y})$	69.6	49.9
Negation ($\leq$ 6 words)	other-side$(\hat{y})$	56.2	49.7

Table 6: Instance-based explanation metrics on SST.

We use POLYJUICE (PJ, Wu et al., 2021) to generate instances of three semantic operations. *Entity change* replaces a proper noun (e.g. actor name) with another using "lexical" mode of PJ. *Minor insert* adds a short text to the sentence using "insert" mode. *Negation* generated a negated version of the input using "negation" mode. For each operation type, our expectation for model behavior is formalized as a range $b(\widehat{y})$ on $\widehat{y}$. We expect the prediction to be unchanged by the first two operations allowing for a margin of 0.05, but changed to the other side of 0.5 by negation. We then define validity $\nu = \mathbb{E}_{\widehat{Y}, \widehat{Y}_i}\left[\mathbb{1}_{\widehat{Y}_i \in b(\widehat{Y})}\right]$ and sharpness $\sigma = 1 - \mathbb{P}_{\widehat{Y}}[b(\widehat{Y})]$ analogously.

Tab. 6 summarizes the results. While our expectation is mostly confirmed for entity change and minor insert, it is notably violated in the case of negation, with only 30.4% validity, indicating model prediction is on the *same* side 69.6% of time. Upon further evaluation, we find that validity drops with sentence length, with short sentences of six words or fewer having much higher validity (for other-side). Since the PJ rewriting model is learned rather than manually defined and negation is more complex than the other two operations, there are two failure modes, as presented in Tab. 7. In the first, a negation is applied to the input sentence, but on a part irrelevant to the sentiment. In the second, the generated sentence is not a negation of the input by any reasonable standard.

These examples highlight the importance of clearly defining the operation: rather than a generic

Input sentence	"Negated" sentence
Human Nature initially succeeds by allowing itself to go crazy , but ultimately fails by spinning out of control .	Human Nature initially succeeds by allowing itself to go crazy , but ultimately fails by not coming to consciousness .

Tailored to entertain !	No tails !

Table 7: Failure cases of POLYJUICE negations. The first half shows examples where the negation is irrelevant to the sentiment. The second half includes examples where the negation fails to appear.

negation, we would need the negation to happen on the "sentiment-carrying" part. It is also crucial to ensure that the generator is of a high quality in order to minimize the chance of generating nonsensical outputs. Despite many advances in generative language modeling, it have been shown to be undesirable in many ways (e.g., Holtzman et al., 2019), all of which affect the quality of the counterfactual explanation.

At a high level, IBE explains the local prediction by illustrating ways to cross (e.g., negation) or not cross (e.g., entity change) the decision boundary in the (very) high-dimensional input space. However, as the negation case indicates, we must be careful about the exact definition of the rewriting (e.g., negating any part of the input or the "sentiment-carrying" part only), as it could have a significant impact on the conclusion. Furthermore, it is difficult for any rewriting mechanism to achieve 100% validity due to the high dimensionality, the multitude of possible ways of rewriting, and the imperfection of the model. Focusing only on the mistakes (or ignoring them altogether) yields incomplete model understanding. Instead, the validity metric, which indicates the *generalized* model behavior, should be used to.

There are many potentially fruitful directions for future work. First, the quality of instances obviously depend on the generative models, which, while impressive, are known to be flawed in many ways (e.g., Holtzman et al., 2019; Nadeem et al., 2021; Wolfe and Caliskan, 2021). Second, each rule essentially covers the entire input space. Partitioning the input space in some way may allow for identification of both more and less consistent areas, which is makes the applicability function much more difficult to define as it now takes whole sentences rather than individual words. Finally, unlike feature attribution, which conveys the single notion of "importance," different instances of the same input can reveal different aspects of model behavior, calling for a potentially different definition of coverage, which measures completeness of understanding.

Maximum Bayes Smatch Ensemble Distillation for AMR Parsing

Abstract

AMR parsing has experienced an unprecendented increase in performance in the last three years, due to a mixture of effects including architecture improvements and transfer learning. Self-learning techniques have also played a role in pushing performance forward. However, for most recent high performant parsers, the effect of self-learning and silver data augmentation seems to be fading. In this paper we propose to overcome this diminishing returns of silver data by combining Smatch-based ensembling techniques with ensemble distillation. In an extensive experimental setup, we push single model English parser performance to a new state-of-the-art, 85.9 (AMR2.0) and 84.3 (AMR3.0), and return to substantial gains from silver data augmentation. We also attain a new state-of-the-art for cross-lingual AMR parsing for Chinese, German, Italian and Spanish. Finally we explore the impact of the proposed technique on domain adaptation, and show that it can produce gains rivaling those of human annotated data for QALD-9 and achieve a new state-of-the-art for BioAMR.

1 Introduction

Adoption of the Transformer architecture (Vaswani et al., 2017) for Abstract Meaning Representation (AMR) parsing (Cai and Lam, 2020; Fernandez Astudillo et al., 2020) as well as pretrained language models (Bevilacqua et al., 2021; Zhou et al., 2021b; Bai et al., 2022) have enabled an improvement of above 10 Smatch points (Cai and Knight, 2013), the standard metric, in the last two years.

Data augmentation techniques have also shown great success in pushing the state-of-the-art of AMR parsing forward. These include generating silver AMR annotations with a trained parser (Konstas et al., 2017; van Noord and Bos, 2017), with multitask pre-training and fine-tuning (Xu et al., 2020) as well as combining AMR to source text and silver AMR generation (Lee et al., 2020) and stacked pre-training of silver data from different models – from low performance to high performance silver data (Xia et al., 2021). However, the latest BART-based state-of-the-art parsers, have shown diminishing returns for data augmentation. Both SPRING (Bevilacqua et al., 2021) and Structured-BART (Zhou et al., 2021b) gain a mere 0.5 Smatch from self-learning, compared with over 1 point gains of the previous, less performant, models. Since performance scores are already above where inter annotator agreement (IAA) is assumed to be, i.e. 83 for newswire and 79 for web text reported in (Banarescu et al., 2013), one possible explanation is that we are reaching some unavoidable performance plateau.

In this work we show that we can achieve significant performance gains close to 2 Smatch point with the newly proposed data augmentation technique, contrary to the results from the previous state-of-the-art systems. The main contributions of this paper are as follows:

- We propose to combine Smatch-based model ensembling (Barzdins and Gosko, 2016; Hoang et al., 2021) and ensemble distillation (Hinton et al., 2015) of heterogeneous parsers to produce high quality silver data.
- We offer a Bayesian ensemble interpretation of this technique as alternative to views such as Minimum Bayes Risk decoding (Goel and Byrne, 2000) and name the technique Maximum Bayes Smatch Ensemble (MBSE).
- Applied to English monolingual parsing, MBSE distillation yields a new single system state-of-the-art (SoTA) on AMR2.0 (85.9) and AMR3.0 (84.3) test sets.
- Trained with Structured-mBART[1], it yields new SoTA for Chinese (63.0), German (73.7),

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 5379 - 5392
July 10-15, 2022

Italian (76.1) and Spanish (77.1) cross-lingual parsing.

- Applied to domain adaptation, MBSE distillation achieves the performance comparable to human annotations of QALD-9 training data and achieves new SoTA on BioAMR test set.
- We release QALD-9-AMR treebank[2] at, which comprises 408 training and 150 test sentences.

2 Maximum Bayes Smatch Ensemble

Ensemble distillation (Hinton et al., 2015) integrates knowledge of different teacher models into a student model. For sequence to sequence models, e.g. machine translation, it is possible to ensemble models by combining probabilities of words given context at each time step (Kim and Rush, 2016; Freitag et al., 2017). Syntactic and semantic parsers model a distribution over graphs that is harder to integrate across teacher models in an optimal way. For particular cases like dependency parsing, it is possible to ensemble teachers based on the notion of edge attachment (Kuncoro et al., 2016), which is related to the usual evaluation metric, Label Attachment Score (LAS). However, AMR graphs are quite complex and not explicitly aligned to words. The standard Smatch (Cai and Knight, 2013) metric approximates the NP-Complete problem of aligning nodes across graphs with a hill climbing algorithm. This illustrates the difficulty of achieving consensus across teachers for AMR ensembling.

Prior work ensembling AMR graphs has leveraged Smatch directly or its hill climbing strategy for ensembling. The ensemble in (Barzdins and Gosko, 2016) selects, among a number of candidate AMRs, the one that has the largest average Smatch with respect to all sampled AMRs. The ensemble in (Hoang et al., 2021), modifies the candidate AMRs to increase consensus as measured by coverage. Then it selects from the union of original and modified graphs for the one with highest coverage or largest average Smatch. One possible intepretation of both techniques is that of Minimum Bayes Risk (MBR) decoding, a well established method in Automatic Speech Recognition (ASR) (Goel and Byrne, 2000) and Machine Translation (MT) (Kumar and Byrne, 2004). Assuming that we have a model predicting a graph from an input sentence $p(g \mid w)$, normal decoding entails searching among model outputs g for the one that has the highest likelihood according to the model $p(g \mid w)$. MBR searches instead for the model output that minimizes the risk with respect to the distribution of possible human (gold) outputs for a given input

$$\hat{g} = \arg\min_{g}\{E_{p(g^h|w)}\{R(g, g^h)\}\}$$

where $p(g^h \mid w)$ is the distribution of correct human outputs, e.g. given by multiple annotators, and R is a risk function that measures how severe deviations from g^h are. In this case risk would be minus Smatch. Since in practice $p(g^h \mid w)$ is not available, MBR takes often the strong assumption of replacing $p(g^h \mid w)$ by the model distribution itself $p(g \mid w)$.

Here we suggest another Bayesian interpretation, that requires less strong assumptions than MBR, a Bayesian model ensemble (Wilson and Izmailov, 2020). Indeed techniques above can be seen as solving

$$\hat{g} = \arg\max_{g\in\mathcal{G}}\{E_{p(\mathcal{M}|\mathcal{D})}\{\text{Smatch}(g, \tilde{g}_{\mathcal{M}})\}\}$$

where $p(\mathcal{M} \mid \mathcal{D})$ is the distribution of models $\mathcal{M}$ given training data $\mathcal{D}$, approximated by a sample average of models of different architectures or different random seeds, and

$$\tilde{g}_{\mathcal{M}} = \text{post}\left(\arg\max_{y}\left\{\prod_{t=1}^{|y|} p_{\mathcal{M}}(y_t \mid y_{<t}, w)\right\}\right)$$

is the output of a conventional decoding process for each parser prediction distribution $p_{\mathcal{M}}$, including post-processing $\text{post}()$. This process differs across models indexed by $\mathcal{M}$, for example y can be transition actions or linearized graphs and $\text{post}()$ running the state-machine or linearized graph post-processing[3]. $\mathcal{G}$ is the space of candidate graphs, which in Barzdins and Gosko (2016) are the AMRs resulting from decoding each sample from $p(\mathcal{M} \mid \mathcal{D})$ and in Hoang et al. (2021) are those same graphs plus the modified pivot graphs. There is in principle no restriction on how to build the set $\mathcal{G}$. *Decoding* a graph $g \in \mathcal{G}$ means here selecting the member of that set maximizing the expected Smatch and is different from each parser's decoding process.

---

[2] https://github.com/IBM/AMR-annotations

[3] We consider only auto-regressive models in this work but this approach could also encompass e.g. graph-based parsers.

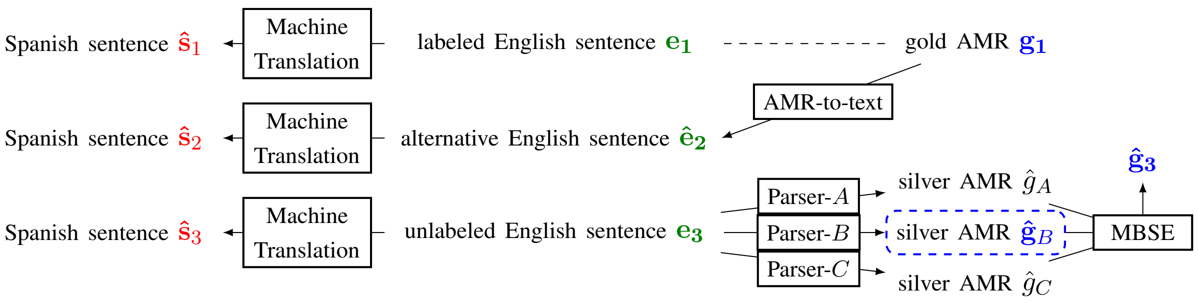

Figure 1: Data augmentation framework: Given a labeled example in English $(\mathbf{e_1}, \mathbf{g_1})$, we use an AMR-to-text generation system to generate an alternative input text $\mathbf{\hat{e}_2}$ for $\mathbf{g_1}$ following (Lee et al., 2020). Given a sentence $\mathbf{e_3}$, and various state-of-the-art off-the-shelf parser outputs (A, B, C), Maximum Bayes Smatch Ensemble (MBSE) produces a single annotation for each input sentence by selecting from existing AMRs or their modified versions. MBSE is only applied to unlabeled English sentences to produce $\mathbf{\hat{g}_3}$. Following (Damonte and Cohen, 2018), we translate the English sentences to e.g. Spanish, to yield new training samples $(\mathbf{\hat{s}_1}, \mathbf{g_1})$, $(\mathbf{\hat{s}_2}, \mathbf{g_1})$, $(\mathbf{\hat{s}_3}, \mathbf{\hat{g}_3})$ to train a Spanish cross-lingual parser. We use the English pairs $(\mathbf{e_1}, \mathbf{g_1})$, $(\mathbf{\hat{e}_2}, \mathbf{g_1})$, $(\mathbf{e_3}, \mathbf{\hat{g}_3})$ to train an English parser.

If we replace $\mathrm{Smatch}()$ by an indicator function on the decoding outputs $1_{g=\tilde{g}_{\mathcal{M}}}$, then

$$\hat{g} = \arg\max_{g \in \mathcal{G}} \{E_{p(\mathcal{M}|\mathcal{D})}\{1_{g=\tilde{g}_{\mathcal{M}}}\}\}$$

recovers majority voting of AMR graphs. Since the space of graphs is exponentially large on the input size, this would be too sparse to attain meaningful vote counts. The propagation of the uncertainty in $p(\mathcal{M} \mid \mathcal{D})$ through the $\mathrm{Smatch}()$ transformation both solves the sparsity problem, and allows optimization on a space that is better related to the target metric. The method will be henceforth described here as Maximum Bayes Smatch Ensemble distillation (MBSE distillation).

In what follows, we will consider three versions for ensembling, the Smatch version of Hoang et al. (2021) (graphene-Smatch), the average-Smatch selection of Barzdins and Gosko (2016), and a greedy version of Barzdins and Gosko (2016) where we select the two highest Smatch AMRs and from that pair, keep the graph with the highest Smatch with respect to the remaining graphs (greedy-select). The greedy-select algorithm is given in Algorithm 1 of Appendix A and performs similarly to the average-Smatch of Barzdins and Gosko (2016).

3 Silver Training Strategy

We now describe the AMR silver training strategy proposed in this work. This strategy creates high quality English and cross-lingual AMR annotations for unlabeled data with MBSE and alternative input sentences of gold AMRs via AMR-to-text.

As depicted in Fig. 1, we start with 1) a set of gold-labeled (English sentence, AMR) pairs, 2) a set of unlabeled English sentences and 3) pre-trained English-to-foreign language Machine Translation systems. Assuming N off-the-shelf AMR parsers, we train each of the N parsers using the gold data with their respective training procedure. More than one random seed may be trained for some parsers, leading to more than N AMR parses for each input sentence.

After the parsers have been trained, we use them to parse the unlabeled English text as in Konstas et al. (2017). Interpreting the set of trained models as samples of the model distribution, we apply the MBSE distillation methods described in Section. 2. We apply all variations of the MBSE algorithms including graphene-Smatch, greedy-select and average-Smatch algorithms.

For English parsers, the MBSE distilled AMR annotations are added to the human-annotated gold treebanks for enhanced model training. For cross-lingual parsers, we translate all English input sentences to the target foreign languages and train respective cross-lingual parsers with pairs of (Foreign language input sentences, AMR graphs in English), following (Damonte and Cohen, 2018).

Following Lee et al. (2020), we also apply an AMR-to-text model (Mager et al., 2020; Ribeiro et al., 2021; Bevilacqua et al., 2021) to generate additional sentences for human-annotated AMR. We filter out the generated texts if they are too similar (BLEU > 0.9) or too dissimilar (BLEU < 0.1) to the original input texts, as measured by BLEU (Papineni et al., 2002). AMR-to-text generation[4] is used for cross-lingual AMR parser training only.

Table 1: Corpus statistics for the standard benchmark experiments on AMR2.0 and AMR3.0 test sets (left) and domain adaptation experiments (right). Silver indicates the unlabeled data for silver training.

4 Experimental Setup

4.1 Corpus Statistics and QALD-9-AMR

Table 1 details the corpora considered for the standard benchmark experiments on AMR2.0 and AMR3.0 test sets (lef) and out-of-domain data used for domain adaptation experiments (right). Silver indicates the unlabeled data for silver AMR acquisition. SQuAD2.0-Q(uestions) are for QALD-9 (silver^{q}) and PubMed, BioNLP-2011 (Kim et al., 2011) and CRAFT (Cohen et al., 2017) for BioAMR (silver^{b}).

Since there were no human annotations of QALD-9 corpus, we created QALD-9-AMR treebank. QALD-9 training/test data have been annotated by 3 skilled resident human annotators with experience in AMR annotations over a year. Each of the annotators annotated both the train and test data sets, followed by cross validation by each other. The final annotations were adjudicated by the most experienced annotator. Inter-annotator agreement (IAA) rate on a subset of 158 training sentences is over 95% in Smatch. The data is made publicly available under an Apache2 license.

4.2 Parsing Models
