Recent explorations of large-scale pre-trained language models (PLMs) have revealed the power of PLMs with huge amounts of parameters, setting off a wave of training ever-larger PLMs. However, it requires tremendous computational resources to train a large-scale PLM, which may be practically unaffordable. In addition, existing large-scale PLMs are mainly trained from scratch individually, ignoring that many well-trained PLMs are available. To this end, we explore the question how could existing PLMs benefit training large-scale PLMs in future. Specifically, we introduce a pre-training framework named "knowledge inheritance" (KI) and explore how could knowledge distillation serve as auxiliary supervision during pre-training to efficiently learn larger PLMs. Experimental results demonstrate the superiority of KI in training efficiency. We also conduct empirical analyses to explore the effects of teacher PLMs' pre-training settings, including model architecture, pre-training data, etc. Finally, we show that KI could be applied to domain adaptation and knowledge transfer. The implementation is publicly available at `https://github.com/thunlp/Knowledge-Inheritance`.

1 Introduction

Recently, it has become a consensus in the NLP community to use pre-trained language models (PLMs) as the backbone for various downstream tasks (Han et al., 2021; Min et al., 2021). Despite the great follow-up efforts of exploring various pre-training techniques and model architectures, researchers find that simply enlarging the model capacity, data size and training steps can further improve the performance of PLMs (Kaplan et al., 2020; Li et al., 2020b). This discovery sets off a wave of training large-scale PLMs (Raffel et al., 2019; Brown et al., 2020; Fedus et al., 2021).

Although huge PLMs have shown awesome performance (Bommasani et al., 2021), it requires tremendous computational resources to train large-scale PLMs (Schwartz et al., 2019), raising severe environmental concerns on the prohibitive computational costs. Moreover, existing PLMs are generally trained from scratch individually, ignoring that many well-trained PLMs are available. This leaves us an important question: *how could existing PLMs benefit training larger PLMs in future?*

Considering that humans can leverage the knowledge summarized by their predecessors to learn new tasks, so that the learning process could become efficient; similarly, it is worth inheriting the implicit knowledge distributed in existing PLMs. In this sense, we could distill the knowledge summarized by an existing small PLM during pre-training to efficiently learn larger PLMs. We dub the above process as *knowledge inheritance* (KI). This intuition is similar to reversed KD (Yuan et al., 2020) in the field of computer vision. They indicate that a delicate student model could still benefit from a teacher with an inferior architecture for a specific downstream task.

However, the success of reversed KD in supervised downstream tasks does not guarantee its feasibility under the scenario of large-scale self-supervised pre-training. Therefore, in this paper,

July 10-15, 2022

we strive to answer the following research questions: (*RQ1*) could distilling knowledge from an existing trained PLM benefit large PLMs' training from scratch? (*RQ2*) Considering human beings are able to hand down knowledge from generation to generation, could KI similarly be sequentially performed among a series of PLMs with growing sizes? (*RQ3*) As more and more PLMs with different pre-training settings (model architectures, training data, training strategies, etc) emerge, how would different settings affect the performance of KI? (*RQ4*) Besides training a large PLM from scratch, when adapting an already trained large PLM to a new domain, how could smaller domain teachers benefit such a process?

In conclusion, the contributions of this paper are summarized as follows: (1) we are the first to formulate the problem of knowledge inheritance, and demonstrate the feasibility of inheriting the knowledge from previously trained PLMs for efficiently training larger ones; (2) we show that the learned knowledge in PLMs could accumulate and further be passed down from generation to generation; (3) we systematically conduct empirical analyses to show the effects of various teacher pre-training settings, which may indicate how to select the most appropriate PLM as the teacher for KI; (4) we further show that during domain adaptation, an already trained large PLM could benefit from multiple small PLMs of different domains under the KI framework. The above empirical studies indicate that KI can well support cross-model knowledge transfer, providing a promising direction to share the knowledge learned by different PLMs and continuously promote their performance.

2 Related Work

Efficient Pre-training for NLP. Recently, researchers find that the performance of PLMs can be simply improved by increasing the model size, data size and training steps (Liu et al., 2019; Raffel et al., 2019; Kaplan et al., 2020), sparking a wave of training ever-larger PLMs. For instance, the revolutionary GPT-3 (Brown et al., 2020), which contains 175 billion parameters, shows strong capabilities for language understanding and generation. This means that utilizing PLMs with huge parameters for downstream tasks may greatly relieve the cost of manual labeling and model training for new tasks. However, larger models require greater computational demands (Patterson et al., 2021). To this end, researchers propose to accelerate pre-training by mixed-precision training (Shoeybi et al., 2019), distributed training (Shoeybi et al., 2019), large batch optimization (You et al., 2020), etc.

Another line of methods (Gong et al., 2019; Gu et al., 2021; Chen et al., 2022; Qin et al., 2022) proposes to pre-train larger PLMs progressively. They first train a small PLM, and then gradually increase the depth or width of the network based on parameter recycling (PR). Although PR could be used for the goal of KI, these methods typically have strict requirements on the architectures of both models, which is not flexible for practical uses; instead, we resort to KD as the solution for KI without architecture constraints. In addition, different from KI, PR is not applicable for absorbing knowledge from multiple teacher models and domain adaptation. More detailed comparisons between KI and PR are discussed in appendix E.

Knowledge Distillation for PLMs. Knowledge Distillation (KD) (Hinton et al., 2015) aims to compress a large model into a fast-to-execute one. KD has renewed a surge of interest in PLMs recently. Some explore KD at different training phases, e.g., pre-training (Sanh et al., 2019), downstream fine-tuning (Sun et al., 2019; Krishna et al., 2020), or both of them (Jiao et al., 2020); others explore distilling not only the final logits output by the large PLM, but also the intermediate hidden representations (Sanh et al., 2019; Jiao et al., 2020; Sun et al., 2020). Conventional KD presumes that teacher models play pivotal roles in mastering knowledge, and student models generally cannot match their teachers in performance. When it comes to the scenario of KI, since student models have larger capacities, the performance of teacher models is no longer an "upper bound" of student models. Outside NLP, researchers recently demonstrate that a student model could also benefit from a poor teacher for a specific downstream task (Yuan et al., 2020) (reversed KD). Based on the prior explorations, in this paper, we investigate the application of reversed KD in pre-training.

3 Knowledge Inheritance

Task Formulation. Given a textual input $\mathbf{x} = \{x^1, \ldots, x^n\}$ and the corresponding label $\mathbf{y} \in \mathbb{R}^K$, where K is the number of classes for the specific pre-training task, e.g., the vocabulary size for masked language modeling (MLM) (Devlin et al., 2019), a PLM $\mathcal{M}$ converts each token

$x^j \in \mathbf{x}$ to task-specific logits $\mathbf{z}^j = [z_1^j, ..., z_K^j]$. $\mathbf{z}^j$ is then converted to a probability distribution $\mathcal{P}(x^j;\tau) = [p_1(x^j;\tau), ..., p_K(x^j;\tau)]$ using a softmax function with temperature τ. $\mathcal{M}$ is pre-trained with the objective $\mathcal{L}_{\text{SELF}}(\mathbf{x}, \mathbf{y}) = \mathcal{H}(\mathbf{y}, \mathcal{P}(\mathbf{x};\tau))$, where $\mathcal{H}$ is the loss function, e.g., cross-entropy for MLM. Assume that we have a well-trained small PLM $\mathcal{M}_S$ optimized with the self learning objective $\mathcal{L}_{\text{SELF}}$ (such as MLM), our goal is leveraging $\mathcal{M}_S$'s knowledge to efficiently train a larger PLM $\mathcal{M}_L$ on the corpora $\mathcal{D}_L = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{|\mathcal{D}_L|}$.

Investigated Methodology. Specifically, imparting $\mathcal{M}_S$'s knowledge to $\mathcal{M}_L$ on $\mathcal{D}_L$ is implemented by minimizing the Kullback-Leibler (KL) divergence between two probability distributions output by $\mathcal{M}_S$ and $\mathcal{M}_L$ on the same input $\mathbf{x}_i \in \mathcal{D}_L$, i.e., $\mathcal{L}_{\text{KI}}(\mathbf{x}_i; \mathcal{M}_S) = \tau^2 \text{KL}(\mathcal{P}_{\mathcal{M}_S}(\mathbf{x}_i;\tau) || \mathcal{P}_{\mathcal{M}_L}(\mathbf{x}_i;\tau)))$. In addition, $\mathcal{M}_L$ is also encouraged to conduct self-learning by optimizing $\mathcal{L}_{\text{SELF}}(\mathbf{x}_i, \mathbf{y}_i)$. Both $\mathcal{L}_{\text{SELF}}$ and $\mathcal{L}_{\text{KI}}$ are balanced with an inheritance rate α:

$$
\begin{aligned}
\mathcal{L}(\mathcal{D}_L; \mathcal{M}_S) &= \sum_{(\mathbf{x}_i,\mathbf{y}_i)\in\mathcal{D}_L} (1-\alpha)\mathcal{L}_{\text{SELF}}(\mathbf{x}_i, \mathbf{y}_i) + \alpha\mathcal{L}_{\text{KI}}(\mathbf{x}_i; \mathcal{M}_S) \\
&= \sum_{(\mathbf{x}_i,\mathbf{y}_i)\in\mathcal{D}_L} (1-\alpha)\mathcal{H}(\mathbf{y}_i, \mathcal{P}_{\mathcal{M}_L}(\mathbf{x}_i;1)) \\
&\quad + \alpha\tau^2 \text{KL}(\mathcal{P}_{\mathcal{M}_S}(\mathbf{x}_i;\tau) || \mathcal{P}_{\mathcal{M}_L}(\mathbf{x}_i;\tau))).
\end{aligned} \tag{1}
$$

Since larger models generally converge faster and can achieve better final performance (Li et al., 2020b), $\mathcal{M}_L$ becomes more and more knowledgeable during the learning process, and would surpass the teacher eventually. Thus, it is necessary to encourage $\mathcal{M}_L$ increasingly learning knowledge on its own, not only following the teacher's instructions. Additionally, after $\mathcal{M}_L$ has surpassed its teacher, it no longer needs the guidance from $\mathcal{M}_S$ and should conduct pure self-learning from then on. Therefore, different from reversed KD, we dynamically change the inheritance rate α. Specifically, for a total training steps of T, we linearly decay α_t with a slope of $\frac{\alpha_T}{T}$. The student only inherits knowledge from the teacher for $\frac{T}{\alpha_T}$ steps, and then conducts pure self-learning, i.e., $\alpha_t = \max(1 - \alpha_T \times \frac{t}{T}, 0)$. Formally, at step t, the loss function for inheriting knowledge of $\mathcal{M}_S$ on $\mathcal{D}_L$ is formulated as:

$$
\mathcal{L}(\mathcal{D}_L; \mathcal{M}_S) = \sum_{(\mathbf{x}_i,\mathbf{y}_i)\in\mathcal{D}_L} (1-\alpha_t)\mathcal{L}_{\text{SELF}}(\mathbf{x}_i, \mathbf{y}_i) + \alpha_t\mathcal{L}_{\text{KI}}(\mathbf{x}_i; \mathcal{M}_S). \tag{2}
$$

Note the logits of $\mathcal{M}_S$ on $\mathcal{D}_L$ can be pre-computed and saved offline so that we do not need to re-compute the logits of $\mathcal{M}_S$ when training $\mathcal{M}_L$. This process is done once and for all.

4 Empirical Analysis

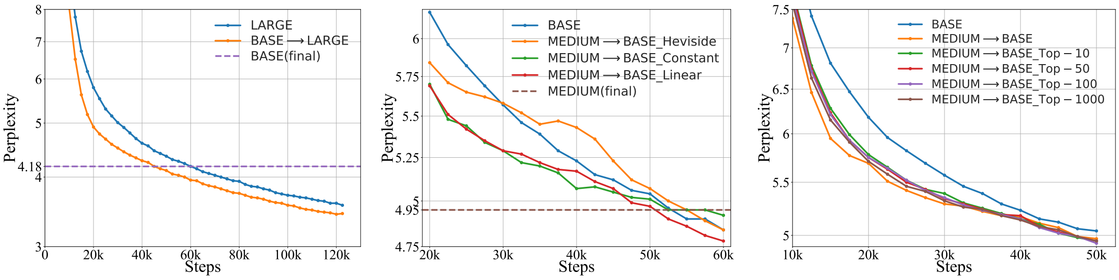
In this section, we answer our research questions proposed before. Specifically, (1) we first demonstrate the effectiveness of KI in § 4.1. (2) Then we show PLMs can accumulate knowledge over generations in § 4.2. (3) We also investigate the effects of different pre-training settings of the teacher models in § 4.3. (4) Finally, we show that KI could benefit domain adaptation, and a trained PLM can learn more efficiently with the help of multiple domain teachers in § 4.4. Detailed pre-training hyper-parameters are listed in appendix B.

4.1 RQ1: How Could Knowledge Inheritance Benefit Large PLMs' Training?

Setting. Our KI framework is agnostic to the specific self-supervised pre-training task and the PLM architecture. Without loss of generality, we mainly focus on the representative MLM task and use the model architecture of RoBERTa (Liu et al., 2019). Specifically, we first choose RoBERTa$_{\texttt{BASE}}$ (denoted as `BASE`) as the teacher ($\mathcal{M}_S$) and RoBERTa$_{\texttt{LARGE}}$ (denoted as `LARGE`) as the student ($\mathcal{M}_L$). We also experiment on auto-regressive language modeling using GPT (Radford et al., 2018) to show KI is model-agnostic.

For pre-training data, we use the concatenation of Wikipedia and BookCorpus (Zhu et al., 2015) same as BERT (Devlin et al., 2019), with roughly $3,400$M tokens in total. All models ($\mathcal{M}_S$ and $\mathcal{M}_L$) are trained for 125k steps, with a batch size of $2,048$ and a sequence length of 512. Note the whole training computations are comparable with those of BERT. We pre-train $\mathcal{M}_L$ by inheriting $\mathcal{M}_S$'s knowledge under KI (denoted as "`BASE` → `LARGE`"). We compare it with "`LARGE`" that only conducts self-learning from beginning to end.

For performance evaluation, we report the validation perplexity (PPL) during pre-training and the downstream performance on development sets of eight GLUE (Wang et al., 2019) tasks. Note compared with the self-learning baseline, in KI, the logits output by $\mathcal{M}_L$ are additionally used to calculate $\mathcal{L}_{\text{KI}}$, we empirically find that the additional computations caused by it are almost negligible compared with the cumbersome computations in Transformer blocks. Therefore, it requires almost the same computational cost between KI and the baseline for



(a) (b) (c)

Figure 1: (a) The validation PPL curve for pre-training $\mathcal{M}_L$ under KI framework (`BASE` $\rightarrow$ `LARGE`) and the self-learning baseline (`LARGE`). The teacher's (`BASE`) performance is 4.18. (b) Pre-training `BASE` under KI with three strategies for the inheritance rate α_t: `Linear`, `Heviside` and `Constant`. The teacher's (`MEDIUM`) performance is 4.95. (c) Pre-training `BASE` under KI with top-K logits, we vary K in $\{10, 50, 100, 1000\}$, respectively.

each step. Hence, we report the performance w.r.t training step (Li et al., 2020a), while the performance w.r.t. FLOPs (Schwartz et al., 2019) and wall-clock time (Li et al., 2020b) can be roughly obtained by stretching the figure horizontally.

Overall Results. As shown in Figure 1 (a), we conclude that: (1) **training $\mathcal{M}_L$ under KI converges faster than the self-learning baseline**, indicating that inheriting the knowledge from an existing teacher is far more efficient than solely learning such knowledge. That is, to achieve the same level of validation PPL, KI requires fewer computational costs. Specifically, under the guidance of $\mathcal{M}_S$, whose validation PPL is 4.18, `BASE` $\rightarrow$ `LARGE` achieves a validation PPL of 3.41 at the end of pre-training, compared with baseline (`LARGE`) 3.58. After `BASE` $\rightarrow$ `LARGE` stops learning from the teacher at the 40k-th step, it improves the validation PPL from 4.60 (`LARGE`) to 4.28, which is almost the performance when the baseline `LARGE` conducts self-learning for 55k steps, thus saving roughly 27.3% computational costs[1]. The results in Table 1 show that (2) **$\mathcal{M}_L$ trained under KI achieves better performance than the baseline on downstream tasks at each step**. We also found empirically that, under the same setting (e.g., data, hyper-parameters and model architectures), lower validation PPL generally indicates better downstream performance. Since the performance gain in downstream tasks is consistent with that reflected in PPL, we only show the latter for the remaining experiments. Concerning the energy cost, for the remaining experiments, unless otherwise specified, we choose `MEDIUM` (9 layers, 576 hidden size) as $\mathcal{M}_S$ and `BASE` as $\mathcal{M}_L$.

Effects of Inheritance Rate. We set α_t in Eq. (2) to be linearly decayed (denoted as `Linear`) to gradually encourage $\mathcal{M}_L$ exploring knowledge on its own. We analyze whether this design is necessary by comparing it with two other strategies: the first is to only learn from the teacher at first and change to pure self-learning (denoted as `Heviside`) at the 35k-th step; the second is to use a constant ratio (1 : 1) between $\mathcal{L}_{\text{SELF}}$ and $\mathcal{L}_{\text{KI}}$ throughout the whole training process (denoted as `Constant`). We can conclude from Figure 1 (b) that: (1) **annealing at first is necessary**. The validation PPL curve of `Linear` converges the fastest, while `Heviside` tends to increase after $\mathcal{M}_L$ stops learning from the teacher, indicating that, due to the difference between learning from the teacher and self-learning, annealing at first is necessary so that the performance won't decay at the transition point (the 35k-th step). (2) **Supervision from the teacher is redundant after $\mathcal{M}_L$ surpasses $\mathcal{M}_S$**. Although `Constant` performs well in the beginning, its PPL gradually becomes even worse than the other two strategies. This indicates that after $\mathcal{M}_L$ has already surpassed $\mathcal{M}_S$, it will be encumbered by keeping following guidance from $\mathcal{M}_S$.

Saving Storage Space with Top-K Logits. Loading the teacher $\mathcal{M}_S$ repeatedly for KI is cumbersome, and an alternative way is to pre-compute and save the predictions of $\mathcal{M}_S$ offline once and for all. We show that using the information of top-K logits (Tan et al., 2019) can reduce the memory footprint without much performance decrease. Specifically, we save only top-K probabilities of $\mathcal{P}_S(x^j; \tau)$ followed by re-normalization, instead of the full distribution over all tokens. For RoBERTa,

---

[1] If we load `BASE` and compute its logits during pre-training, 18.7% FLOPs can be saved roughly, since the forward passes of the small teacher also take up a small part.

Step	Model	CoLA	MNLI	QNLI	RTE	SST-2	STS-B	MRPC	QQP	Avg

Table 1: Downstream performances on GLUE tasks (dev). KI requires fewer pre-training steps to get a high score after fine-tuning. Detailed results at different training steps are illustrated in appendix A.6.

the dimension of $\mathcal{P}_S(x^j;\tau)$ is decided by its vocabulary size, which is around $50,000$. We thus vary K in $\{10, 50, 100, 1000\}$ to see its effects in Figure 1 (c), from which we observe that: **top-K logits contain the vast majority of information**. Choosing a relatively small K (e.g., 10) is already good enough for inheriting knowledge from the teacher without much performance decrease. Previous work also indicates the relation between KD and label smoothing (Shen et al., 2021), however, we show in appendix F that the improvements of KI are not because of benefiting from optimizing smoothed targets, which impose regularization.

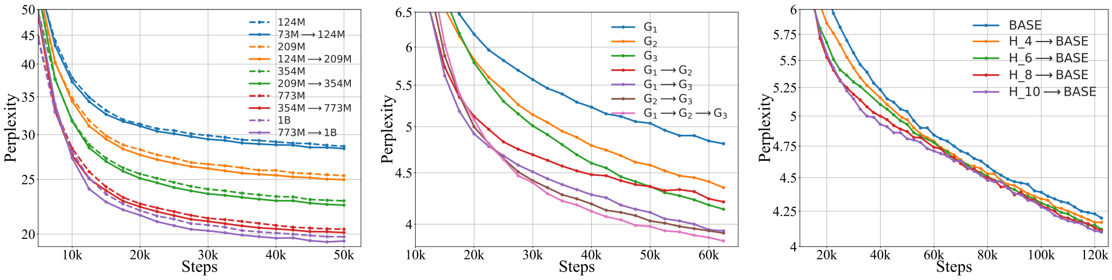
Experiments on GPT. To demonstrate that KI is model-agnostic, we conduct experiments on auto-regressive language modeling and choose GPT (Radford et al., 2018) architecture with growing sizes of $\{$73M, 124M, 209M, 354M, 773M, 1B$\}$ parameters in total, respectively. The detailed architectures are specified in Table 6. All the teacher models are pre-trained for 62.5k steps with a batch size of $2,048$. As reflected in Figure 2 (a), training larger GPTs under our KI framework converges faster than the self-learning baseline, which demonstrates **KI is agnostic to the specific pre-training objective and PLM architecture**.

4.2 RQ2: Could Knowledge Inheritance be Performed over Generations?

Human beings can inherit the knowledge from their antecedents, refine it and pass it down to their offsprings, so that knowledge can gradually accumulate over generations. Inspired by this, we investigate whether PLMs also have this kind of pattern. Specifically, we experiment with the knowledge inheritance among three generations of RoBERTa with roughly 1.7x growth in model size: G_1 (`BASE`, 125M), G_2 (`BASE_PLUS`, 211M) and G_3 (`LARGE`, 355M), whose architectures are listed in Table 6. All models are trained from scratch for 125k steps with a batch size of $2,048$ on the same corpus. We compare the differences among (1) self-learning for each generation (denoted as G_1, G_2 and G_3), (2) KI over two generations (denoted as $G_1 \rightarrow G_2$, $G_1 \rightarrow G_3$ and $G_2 \rightarrow G_3$), and (3) KI over three generations (denoted as $G_1 \rightarrow G_2 \rightarrow G_3$), where G_2 first inherits the knowledge from G_1, refines it by additional self-exploring and passes its knowledge down to G_3. The results are drawn in Figure 2 (b). Comparing the performance of G_2 and $G_1 \rightarrow G_2$, G_3 and $G_1 \rightarrow G_3$, or G_3 and $G_2 \rightarrow G_3$, we can again demonstrate the superiority of KI over self-training as concluded before. Comparing the performance of $G_1 \rightarrow G_3$ and $G_1 \rightarrow G_2 \rightarrow G_3$, or $G_2 \rightarrow G_3$ and $G_1 \rightarrow G_2 \rightarrow G_3$, it is observed that the performance of G_3 benefits from the involvements of both G_1 and G_2, which means knowledge could be accumulated through more generations' involvements.

4.3 RQ3: How Could $\mathcal{M}_S$'s Pre-training Setting Affect Knowledge Inheritance?

Existing PLMs are typically trained under quite different settings, and it is unclear how these different settings will affect the performance of KI. Formally, we have a series of well-trained smaller PLMs $\overline{\mathcal{M}_S} = \{\mathcal{M}_S^1, ..., \mathcal{M}_S^{N_S}\}$, each having been optimized on $\overline{\mathcal{D}_S} = \{\mathcal{D}_S^1, ..., \mathcal{D}_S^{N_S}\}$, respectively. Considering that the PLMs in $\overline{\mathcal{M}_S}$, consisting of varied model architectures, are pre-trained on different corpora of various sizes and domains with arbitrary strategies, thus the knowledge they master is also manifold. In addition, $\mathcal{M}_L$'s pre-training data $\overline{\mathcal{D}_L}$ may also consist of massive, heterogeneous corpora from multiple sources, i.e., $\overline{\mathcal{D}_L} = \{\mathcal{D}_L^1, ..., \mathcal{D}_L^{N_L}\}$. Due to the difference between $\overline{\mathcal{D}_L}$ and $\overline{\mathcal{D}_S}$, $\mathcal{M}_S$



(a)

(b)

(c)

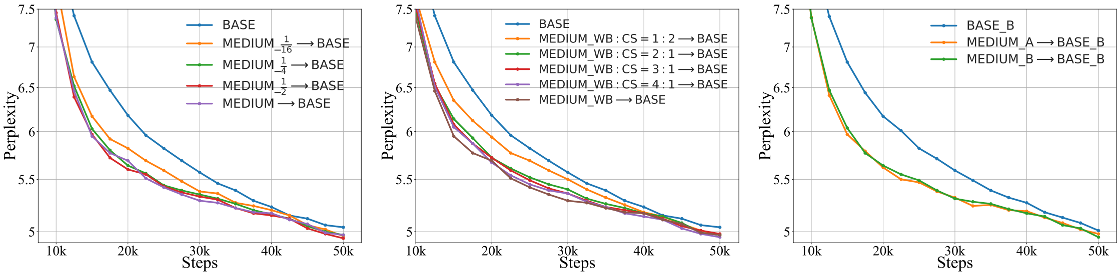
Figure 2: (a) Experiments on GPT. (b) KI over generations. (c) Effects of $\mathcal{M}_S$'s architecture (depth).

may be required to transfer its knowledge on instances unseen during its pre-training. Ideally, we want $\mathcal{M}_S$ to teach the courses it is skilled in. Therefore, it is essential to choose the most appropriate teacher for each composition $\mathcal{D}_L^* \in \overline{\mathcal{D}_L}$. To this end, we conduct thorough experiments to analyze the effects of several representative factors: model architecture, pre-training data, $\mathcal{M}_S$'s pre-training step (appendix A.2) and batch size (appendix A.3).

Effects of Model Architecture. Large PLMs generally converge faster and achieve lower PPL, thus serving as more competent teachers. We experiment with two widely chosen architecture variations, i.e., depth (number of layers) and width (hidden size), to explore the effects of $\mathcal{M}_S$'s model architectures. We choose `BASE` (12 layer, 768 hidden size) as $\mathcal{M}_L$'s architecture, and choose the architecture of $\mathcal{M}_S$ to differ from $\mathcal{M}_L$ in either depth or width. Specifically, for $\mathcal{M}_S$, we vary the depth in $\{4, 6, 8, 10\}$, and the width in $\{384, 480, 576, 672\}$, respectively, and pre-train $\mathcal{M}_S$ under the same setting as $\mathcal{M}_L$. The PPL curve for each teacher model is shown in appendix A.7, from which we observe that deeper / wider teachers with more parameters converge faster and achieve lower PPL. After that, we pre-train $\mathcal{M}_L$ under KI leveraging these teacher models. As shown in Figure 2 (c) and appendix A.4, **choosing a deeper / wider teacher accelerates $\mathcal{M}_L$'s convergence**, demonstrating the benefits of learning from a more knowledgeable teacher. Since the performance of PLMs is weakly related to the model shape but highly related to the model size (Li et al., 2020b), it is always a better strategy to choose the larger teacher if other settings are kept the same. In experiments, we also find empirically that, the optimal duration of learning from the teacher is longer for larger teachers, which means it takes more time to learn from a more knowledgeable teacher.

Effects of Pre-training Data. In previous experiments, we assume $\mathcal{M}_L$ is pre-trained on the same corpus as $\mathcal{M}_S$, i.e., $\mathcal{D}_L = \mathcal{D}_S$. However, in real-world scenarios, it may occur that the pre-training corpus used by both $\mathcal{M}_L$ and $\mathcal{M}_S$ is mismatched, due to three main factors: (1) **data size.** When training larger models, the pre-training corpus is often enlarged to improve downstream performance, i.e., $|\mathcal{D}_S| \ll |\mathcal{D}_L|$; (2) **data domain.** PLMs are trained on heterogeneous corpora from various sources (e.g., news articles, literary works, etc.), i.e., $\mathcal{P}_{\mathcal{D}_S} \neq \mathcal{P}_{\mathcal{D}_L}$. The different knowledge contained in each domain may affect PLMs' generalization in downstream tasks; (3) **data privacy.** Even if both size and domain of $\mathcal{D}_S$ and $\mathcal{D}_L$ are ensured to be the same, it may be hard to retrieve the pre-training corpus used by $\mathcal{M}_S$ due to privacy concerns, with an extreme case: $\mathcal{D}_L \cap \mathcal{D}_S = \emptyset$. The gap between $\mathcal{D}_S$ and $\mathcal{D}_L$ may hinder $\mathcal{M}_S$'s successful knowledge transfer. We thus design experiments to analyze the effects of these factors, with three observations concluded:

- **Obs. 1: PLMs can image the big from the small for in-domain data**. To evaluate the effects of data size, we first pre-train teacher models on different partitions of the original training corpus under the same setting by randomly sampling $\{\frac{1}{16}, \frac{1}{8}, \frac{1}{4}, \frac{1}{2}, \frac{1}{1}\}$ of it, resulting in teacher models with final validation PPL of $\{5.43, 5.15, 5.04, 4.98, 4.92\}$, respectively. The final validation PPL increases as we shrink the size of $\mathcal{M}_S$'s pre-training corpus, which implies that training with less data weakens the teacher's ability. Next, we compare the differences when their knowledge is inherited by $\mathcal{M}_L$. As reflected in Figure 3 (a), however, the performance of KI is not substantially undermined until only $\frac{1}{16}$ of the original data is leveraged by the teacher. This indicates that PLMs can well image the overall data distribution even if it only sees a small part. Hence,



(a) (b) (c)

Figure 3: Effects of $\mathcal{M}_S$'s pre-training (a) data size, (b) data domain and (c) data privacy for KI.

when training larger PLMs, unless the data size is extensively enlarged, its impact can be ignored.

- **Obs. 2: Inheriting on similar domain improves performance**. To evaluate the effects of data domain, we experiment on the cases where $\mathcal{D}_S$ and $\mathcal{D}_L$ have domain mismatch. Specifically, keeping data size the same, we mix Wikipedia and BookCorpus (WB) used before with computer science (CS) papers from S2ORC (Lo et al., 2020), whose domain is distinct from WB, using different proportions, i.e., $\text{WB} : \text{CS} = \{1:2, 2:1, 3:1, 4:1\}$, respectively. We pre-train $\mathcal{M}_S$ on the constructed corpora, then test the performance when $\mathcal{M}_L$ inherits these teachers' knowledge on the WB domain data. As shown in Figure 3 (b), with the domain of the constructed corpus $\mathcal{M}_S$ is trained on becoming gradually similar to WB, the benefits from KI become more obvious, which means it is essential that both $\mathcal{M}_S$ and $\mathcal{M}_L$ are trained on similar domain of data, so that $\mathcal{M}_S$ can successfully impart knowledge to $\mathcal{M}_L$ by teaching the "right" course.

- **Obs. 3: Data privacy is not that important if the same domain is ensured**. To evaluate the effects of data privacy, we experiment in an extreme case where $\mathcal{D}_S$ and $\mathcal{D}_L$ have no overlap at all. To avoid the influences of size and domain, we randomly split the WB domain training corpus $\mathcal{D}$ into two halves ($\mathcal{D}_A$ and $\mathcal{D}_B$) and pre-train two teacher models (denoted as $\texttt{MEDIUM}_\texttt{A}$ and $\texttt{MEDIUM}_\texttt{B}$) on them. After pre-training, both of them achieve almost the same final PPL (4.99) on the same validation set. They are then inherited by the student model `BASE` on $\mathcal{D}_B$ (denoted as $\texttt{MEDIUM}_\texttt{A} \rightarrow \texttt{BASE}_\texttt{B}$ and $\texttt{MEDIUM}_\texttt{B} \rightarrow \texttt{BASE}_\texttt{B}$), which is exactly the pre-training corpus of $\texttt{MEDIUM}_\texttt{B}$ and has no overlap with that of $\texttt{MEDIUM}_\texttt{A}$. We also choose $\mathcal{M}_L$ that conducts pure self-learning on $\mathcal{D}_B$ as the baseline (denoted as $\texttt{BASE}_\texttt{B}$). It is observed from Figure 3 (c) that, there is little difference between the validation PPL curves of $\texttt{MEDIUM}_\texttt{A} \rightarrow \texttt{BASE}_\texttt{B}$ and $\texttt{MEDIUM}_\texttt{B} \rightarrow \texttt{BASE}_\texttt{B}$, indicating that whether the pre-training corpus of $\mathcal{M}_S$ and $\mathcal{M}_L$ has data overlap or not is not a serious issue as long as they share the same domain. This is meaningful when organizations aim to share the knowledge of their PLMs without exposing either the pre-training data or the model parameters due to privacy concerns.

4.4 RQ4: How Could Knowledge Inheritance Benefit Domain Adaptation?

With streaming data of various domains continuously emerging, training domain-specific PLMs and storing the model parameters for each domain can be prohibitively expensive. To this end, researchers recently demonstrated the feasibility of adapting PLMs to the target domain through continual pre-training (Gururangan et al., 2020). In this section, we further extend KI and demonstrate that domain adaptation for PLM can benefit from inheriting knowledge of existing domain experts.

Specifically, instead of training large PLMs from scratch, which is the setting used before, we focus on adapting $\texttt{BASE}_\texttt{WB}$, which has been well-trained on the WB domain for 125k steps, to two target domains, i.e., computer science (CS) and biomedical (BIO) papers from S2ORC (Lo et al., 2020). The proximity (vocabulary overlap) of three domains is listed in appendix D. We assume there exist two domain experts, i.e., $\texttt{MEDIUM}_\texttt{CS}$ and $\texttt{MEDIUM}_\texttt{BIO}$. Each model has been trained on CS / BIO domain for 125k steps. Note their training computation is far less than $\texttt{BASE}_\texttt{WB}$ due to fewer model parameters. Hence, either $\texttt{MEDIUM}_\texttt{CS}$ or $\texttt{MEDIUM}_\texttt{BIO}$ is no match for $\texttt{BASE}_\texttt{WB}$ in WB domain but has richer knowledge in CS / BIO domain. For evaluation, we compare both (1) the validation PPL on the target domain and (2) the performance (test F1) on downstream tasks, i.e. ACL-ARC (Jurgens et al., 2018) for CS domain and CHEMPROT (Kringelum et al., 2016) for BIO domain. Before adaptation,

SL	71.7	3.15	83.7	2.71	70.5	3.97	82.7	3.36	67.7	5.95	81.7	4.84	68.3	11.7	81.1	10.5
KI	**72.2**	**3.15**	**83.9**	**2.70**	**71.8**	**3.42**	**83.1**	**2.92**	**69.8**	**3.90**	**82.6**	**3.32**	**69.1**	**5.70**	**81.3**	**4.64**

Table 3: The results when $\texttt{BASE}_{\texttt{WB}}$ is post-trained on two new domains simultaneously with self-learning (SL) or knowledge inheritance (KI). We report both validation PPL ($\mathrm{PPL}_{\mathrm{B}}$ / $\mathrm{PPL}_{\mathrm{C}}$) and downstream performance ($\mathrm{F1}_{\mathrm{B}}$ / $\mathrm{F1}_{\mathrm{C}}$) for BIO / CS domain. We observe that SL exhibits severe overfitting when data is relatively scarce.

$\texttt{BASE}_{\texttt{WB}}$ achieves a PPL of 5.41 / 4.86 and F1 of 68.5 / 81.6 on CS / BIO domain, while $\texttt{MEDIUM}_{\texttt{CS}}$ achieves 2.95 (PPL) and 69.4 (F1) on CS domain, $\texttt{MEDIUM}_{\texttt{BIO}}$ achieves 2.55 (PPL) and 83.6 (F1) on BIO domain. This demonstrates the superiority of two teachers over the student in their own domain despite their smaller model capacity.

We compare two strategies for domain adaptation: (1) only conducting self-learning on the target domain and (2) inheriting knowledge from well-trained domain teachers. Specifically, $\texttt{BASE}_{\texttt{WB}}$ is post-trained for additional 4k steps on either CS or BIO domain to learn new knowledge. In addition, considering that in real-world scenarios, it can be hard to retrieve enough pre-training data for a specific domain, due to some privacy issues. Hence, we conduct experiments with different sizes of domain corpus. In Table 2, $\texttt{BASE}_{\texttt{WB}}$ is post-trained on either CS or BIO domain while in Table 3, it is trained on synthetic domain data (BIO : CS = 1 : 1) to absorb knowledge from two domains simultaneously (we assume $\mathcal{M}_L$ is trained with the optimal teacher selection strategy, i.e., each teacher imparts the knowledge on its own domain data). It can be concluded from Table 2 and Table 3 that:

(1) **KI is more training-efficient**. Compared with self-learning, inheriting knowledge from domain teachers achieves lower final PPL and improved performance in domain-specific downstream tasks, indicating that, for domain adaptation, KI is more training-efficient so that an already trained large PLM could absorb more knowledge from new domain with the same training budget. (2) **KI is more data-efficient**. The PPL gap between KI and SL is further enlarged when there is less domain-specific data available for adaptation, which means KI is more data-efficient especially under the low-resource setting, where domain data is scarce. In other words, only providing a small portion of domain-specific data is enough for satisfactory adaptation performance under KI, while self-learning exhibits overfitting to some extent. (3) **Large PLMs can simultaneously absorb knowledge from multiple domains and thus become omnipotent**. From Table 3, we observe $\texttt{BASE}_{\texttt{WB}}$ achieves improved performance on both domains after being taught by two teachers simultaneously. KI shows superiority over self-learning. However, simultaneous learning overfits training data more easily and its performance on either domain is no match for learning only one domain at a time.

5 Conclusion and Future Work

In this work, we propose a general knowledge inheritance (KI) framework that leverages previously trained PLMs for training larger ones. We conduct sufficient empirical studies to demonstrate its feasibility. In addition, we show that KI could well support knowledge transfer over a series of PLMs with growing sizes. We also comprehensively analyze various pre-training settings of the teacher model that may affect KI's performance, the results shed light on how to choose the most appropriate teacher PLM for KI. Finally, we extend KI and show that, during domain adaptation, an already trained large PLM could benefit from smaller domain teachers. In general, we provide a promising direction to share and exchange the knowledge learned by different models and continuously promote their performance.

In future, we aim to explore the following directions: (1) the **efficiency** of KI, i.e., given limited computational budget and pre-training corpus, how to more efficiently absorb knowledge from teacher models. Potential solutions include denoising teacher models' predictions and utilizing more information from the teacher. How to select the most representative data points for KI is also an interesting topic; (2) the **effectiveness** of KI under different settings, i.e., how can KI be applied if the teachers and the students are pre-trained on different vocabularies, languages, pre-training objectives and modalities.

Finally, we believe it is vital to use fair benchmarking that can accurately and reliably judge each KI algorithm. Thus, we suggest future work to: (1) conduct all experiments under the same computation environment and report the pre-training hyper-parameters and hardware deployments in detail, (2) evaluate the downstream tasks with multiple different random seeds and choose tasks that give relatively stable and consistent results, which could serve as better indicators for PLMs' effectiveness. In addition, it is also essential that PLMs are tested on diverse downstream tasks which evaluate PLMs' different abilities, (3) save the checkpoint more frequently during pre-training and evaluate the downstream performance, which can better indicate the trend of PLMs' effectiveness, and (4) open-source all the codes and model parameters for future comparisons.

Acknowledgments

This work is supported by the National Key R&D Program of China (No. 2020AAA0106502), Institute Guo Qiang at Tsinghua University, NExT++ project from the National Research Foundation, Prime Minister's Office, Singapore under its IRC@Singapore Funding Initiative, and Beijing Academy of Artificial Intelligence (BAAI). This work is also supported by the Pattern Recognition Center, WeChat AI, Tencent Inc. Yujia Qin and Yankai Lin designed the methods and the experiments. Yujia Qin, Jing Yi and Jiajie Zhang conducted the experiments. Yujia Qin, Yankai Lin and Xu Han wrote the paper. Zhiyuan Liu, Peng Li, Maosong Sun and Jie Zhou advised the project. All the authors participated in the discussion.

Appendices

A Additional Experiments and Analysis

A.1 Effects of Model Size

We experiment on four PLMs with roughly 1.7x growth in model size: $\mathcal{M}_1$ (RoBERTa$_{\texttt{MEDIUM}}$, 73.5M), $\mathcal{M}_2$ (RoBERTa$_{\texttt{BASE}}$, 125M), $\mathcal{M}_3$ (RoBERTa$_{\texttt{BASE\_PLUS}}$, 211M) and $\mathcal{M}_4$ (RoBERTa$_{\texttt{LARGE}}$, 355M), whose architectures are listed in Table 6. We first pre-train a teacher PLM $\mathcal{M}_i$ ($\mathcal{M}_S$) for 125k steps with a batch size of $2,048$ under the same setting then train a larger one $\mathcal{M}_{i+1}$ ($\mathcal{M}_L$) by inheriting $\mathcal{M}_i$'s knowledge under KI framework (denoted as $\mathcal{M}_i \rightarrow \mathcal{M}_{i+1}, i \in \{1,2,3\}$). We compare $\mathcal{M}_i \rightarrow \mathcal{M}_{i+1}$ with $\mathcal{M}_{i+1}$ that conducts self-learning from beginning to end. As shown in Figure 4, the superiority of KI is observed across all models. In addition, with the overall model size of $\mathcal{M}_S$ and $\mathcal{M}_L$ gradually increasing, the benefits of KI become more evident, reflected in the broader absolute gap between the PPL curve of $\mathcal{M}_i \rightarrow \mathcal{M}_{i+1}$ and $\mathcal{M}_{i+1}$ when i gradually grows. This implies that with the advance of computing power in future, training larger PLMs will benefit more and more from our KI framework.

A.2 Effects of $\mathcal{M}_S$'s Pre-training Steps

Longer pre-training has been demonstrated as an effective way for PLMs to achieve better performance (Liu et al., 2019) and thus become more knowledgeable. To evaluate the benefits of more pre-training steps for $\mathcal{M}_S$, we first vary RoBERTa$_{\texttt{MEDIUM}}$'s pre-training steps in $\{62.5\text{k}, 125\text{k}, 250\text{k}, 500\text{k}\}$, and keep all other settings the same. After pre-training, these teacher models achieve the final validation PPL of $\{5.25, 4.92, 4.72, 4.51\}$, respectively. Then we compare the performances when RoBERTa$_{\texttt{BASE}}$ learn from these teacher models and visualize the results in Figure 4, from which we can conclude that, inheriting knowledge from teachers with longer pre-training time (steps) helps $\mathcal{M}_L$ converge faster. However, such a benefit is less and less obvious as $\mathcal{M}_S$'s pre-training steps increase, which means after enough training computations are invested, the teacher model enters a plateau of convergence in validation PPL, and digging deeper in knowledge becomes even harder. The bottleneck lies in other factors, e.g., the size and diversity of pre-training data, which hinder $\mathcal{M}_S$ from becoming more knowledgeable. We also found empirically that, after being pre-trained for 125k steps on the corpus with a batch size of $2,048$, all the models used in this paper have well converged, and longer pre-training only results in limited performance gain in either PPL or downstream performance.

A.3 Effects of $\mathcal{M}_L$'s Batch Size

Batch size is highly related to PLM's training efficiency, and previous work (Liu et al., 2019; Li et al., 2020b; You et al., 2019) found that slow-but-accurate large batch sizes can bring improvements to model training, although the improvements become marginal after increasing the batch size beyond a certain point (around $2,048$). BERT (Devlin et al., 2019) is pre-trained for $1,000$k steps with a batch size of 256, and the computational cost is equivalent to training for 125k steps with a batch size of $2,048$ (Liu et al., 2019), which is the pre-training setting chosen in our main paper. Choosing RoBERTa$_{\texttt{MEDIUM}}$ as the teacher model and RoBERTa$_{\texttt{BASE}}$ as the student model, in Figure 4 we compare the validation PPL as we vary the batch size in $\{256, 512, 1024, 2,048\}$, controlling for the number of passes through the pre-training corpus. We also vary the peak learning rate in $\{1.0 \times 10^{-4}, 2.5 \times 10^{-4}, 3.8 \times 10^{-4}, 5.0 \times 10^{-4}\}$ and pre-train for $\{1,000\text{k}, 500\text{k}, 250\text{k}, 125\text{k}\}$ steps, respectively, when increasing the batch size. We observe that increasing the batch size results in improved final validation PPL, which is aligned with previous findings (Liu et al., 2019). When adjusting batch size, KI accelerates the convergence unanimously, and its benefits become more evident when training with a smaller batch size, reflected in the absolute improvement in final validation PPL. We hypothesize that this is because learning from the smoothed target probability of KI, containing rich *secondary information* (Yang et al., 2019) or *dark knowledge* (Furlanello et al., 2018), makes the pre-training process more stable. The student PLM is prevented from fitting to unnecessarily strict distributions and can thus learn faster.

A.4 Additional Experiments of the Effects of Teacher Model $\mathcal{M}_S$'s architecture (width)

We show in Figure 5 the validation PPL of $\mathcal{M}_L$ when choosing the teacher PLM $\mathcal{M}_S$ with different hidden sizes ($\{384, 480, 576, 672\}$). As mentioned in our main paper, choosing a wider teacher

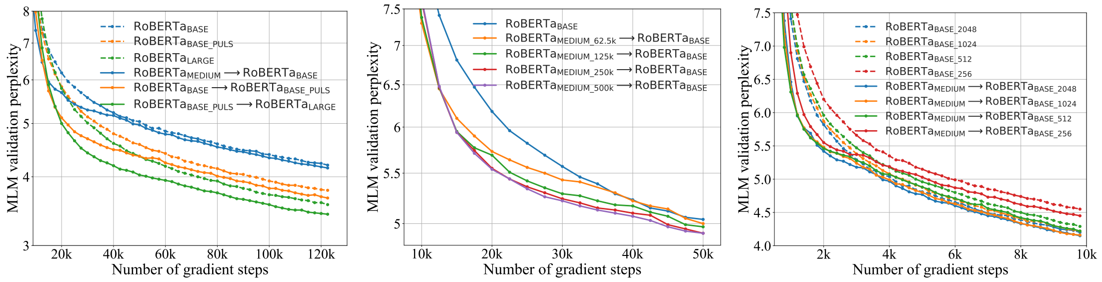

Figure 4: Left: effects of $\mathcal{M}_L$'s model size. Middle: effects of $\mathcal{M}_S$'s number of pre-training steps. Right: effects of $\mathcal{M}_L$'s batch size.

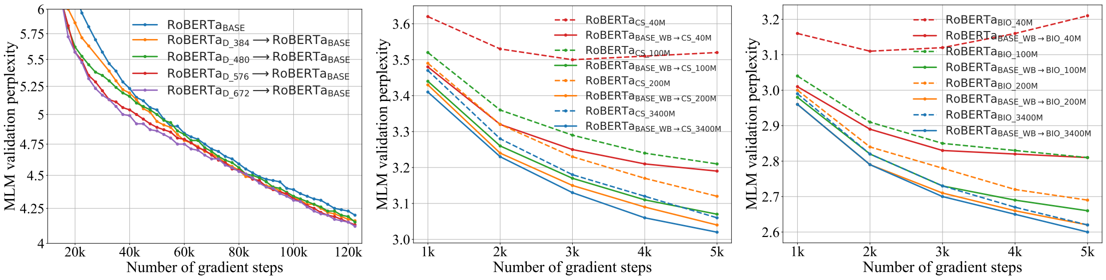

Figure 5: Left: the PPL curve when choosing the teacher PLM with different hidden sizes. Middle & Right: adapting $\text{RoBERTa}_{\texttt{BASE\_WB}}$ to CS (middle) / BIO (right) domain with different number of training steps on different sizes of domain data. We compare two strategies: self-learning and KI. For example, $\text{RoBERTa}_{\texttt{CS\_3400M}}$ denotes post-training $\text{RoBERTa}_{\texttt{BASE\_WB}}$ with the self-learning strategy on the $3,400$M token CS domain corpus. $\text{RoBERTa}_{\texttt{BASE\_WB}\rightarrow\texttt{CS\_3400M}}$ denotes post-training $\text{RoBERTa}_{\texttt{BASE\_WB}}$ with the KI strategy on the $3,400$M token CS domain corpus.

model improves the training efficiency of the student PLM.

A.5 Additional Experiments of Knowledge Inheritance for Domain Adaptation

Domain	Strategy	$3,400$M	200M	100M	40M
CS	SL	6.71	7.01	7.39	8.77
	KI	8.63	9.39	9.48	9.87
BIO	SL	7.29	6.61	8.16	10.34
	KI	10.74	10.78	10.93	11.66

Table 4: The validation PPL on the source domain (WB) after $\text{RoBERTa}_{\texttt{BASE\_WB}}$ is post-trained on the target domain (CS / BIO) with self-learning (SL) and knowledge inheritance (KI).

Different Number of Post-training Steps. In the main paper, we adapt $\text{RoBERTa}_{\texttt{BASE\_WB}}$ to either CS or BIO domain by post-training it for 4k steps. We further vary the number of training steps in $\{1\text{k}, 2\text{k}, 3\text{k}, 4\text{k}, 5\text{k}\}$ and visualize the validation PPL in Figure 5. We also experiment on different sizes of domain corpus, i.e., $3,400$M, 200M, 100M, 40M tokens, respectively, as done in the main paper. We observe that generally the validation PPL on each domain decreases with the training step growing, and the performance of KI is always better than self-learning. The improvement of KI over self-learning is further enlarged when there is less target domain data available, demonstrating that KI is more data-efficient and can work well in low-resource settings. In addition, self-learning exhibits overfitting problems when the data size of the target domain is relatively small, which is not observed under our KI framework, which means KI can mitigate overfitting under low-resource settings.

Catastrophic Forgetting on the Source Domain. Table 4 lists the validation PPL on the source domain (WB) after $\text{RoBERTa}_{\texttt{BASE\_WB}}$ is post-trained on the target domain (CS / BIO) with self-learning (SL) and knowledge inheritance (KI) for 4k steps. We show the results w.r.t. different sizes of domain corpus ($3,400$M, 200M, 100M and 40M tokens). We observe that after domain adaptation, the validation PPL on the source domain increases, which means PLMs may forget some key knowledge on the source domain when learning new knowledge

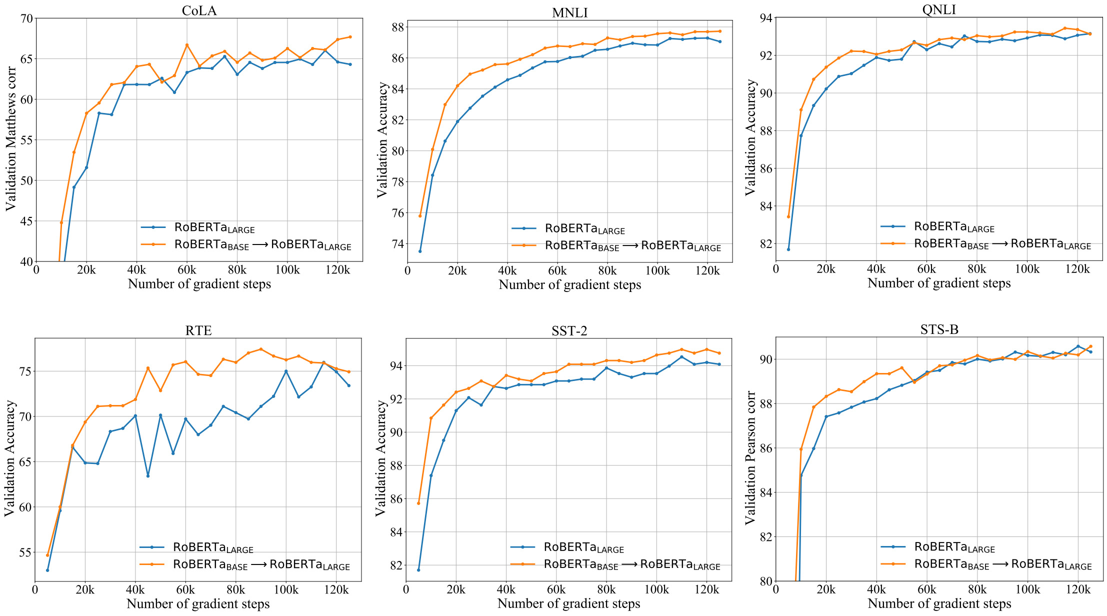

Figure 6: Downstream performance visualization on six GLUE tasks comparing RoBERTa$_{\text{LARGE}}$ and RoBERTa$_{\text{BASE}}$ → RoBERTa$_{\text{LARGE}}$. For CoLA, RTE, SST-2 and STS-B, we repeat fine-tuning for 5 times; for MNLI and QNLI, we repeat fine-tuning for 3 times.

in the target domain, i.e., the catastrophic forgetting problem. In addition, we find that the problem is more evident for KI than self-learning. We expect future work to further explore how to mitigate the catastrophic forgetting.

A.6 Detailed Downstream Performances on GLUE Tasks

Figure 6 visualizes the downstream performance of RoBERTa$_{\text{LARGE}}$ and RoBERTa$_{\text{BASE}}$ → RoBERTa$_{\text{LARGE}}$ on the dev sets of six GLUE tasks at different pre-training steps with an interval of 5k. It can be observed that the downstream performance of RoBERTa$_{\text{BASE}}$ → RoBERTa$_{\text{LARGE}}$ rises faster than the baseline, which means it takes fewer pre-training steps for our KI framework to get a high score in downstream tasks. Aligned with previous findings (Li et al., 2020b), we found MNLI and SST-2 to be the most stable tasks in GLUE, whose variances are lower.

We also list the average GLUE performance for RoBERTa$_{\text{BASE}}$ → RoBERTa$_{\text{LARGE}}$ and the baseline RoBERTa$_{\text{LARGE}}$ in Table 5, from which we observe that the baseline at 70k-th step achieves almost the same GLUE performance as our method at 40k-th step, which means our framework saves around 42.9% FLOPs, much higher than the reported 27.3% FLOPs saved based on the pre-training PPL metric in the main paper. In addition, our method achieves almost the same GLUE performance as the baseline at the final step (125k) with only 70k steps, which means our framework saves 44% FLOPs in total. Both the perplexity in the pre-training stage and performance in downstream tasks can be chosen as the evaluation metric for measuring the computational cost savings. However, in this paper, we choose the former because it is more stable and accurate than the latter. We find empirically that some GLUE tasks like CoLA have higher variances than others, which might make the measurement inaccurate.

Besides, when discussing the effects of model architectures in the main paper, we only show the validation PPL of each model during pre-training, we visualize the corresponding downstream performance (MNLI) in Figure 7, from which it can be observed that learning from teacher models with more parameters helps achieve better downstream performance at the same pre-training step. In general, we observe that, under our setting, the performance gain in downstream tasks is aligned with that reflected in validation PPL during pre-training.

A.7 Teacher Models' Validation PPL Curves during Pre-training for "Effects of Model Architecture"

Figure 7 visualizes the validation PPL curves for all the teacher models used in the experiments

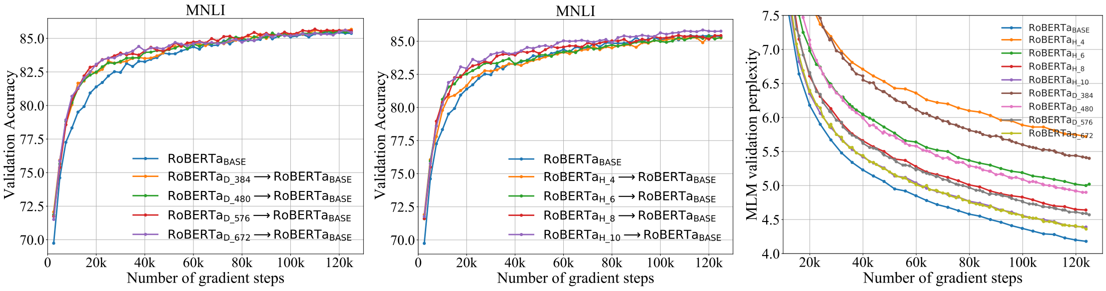

Figure 7: Left & Middle: downstream performances corresponding to the experiments on effects of $\mathcal{M}_S$'s model architecture (width (left) & depth (middle)). Right: validation PPL during pre-training for the teacher models used in experiments of effects of teacher model architecture.

Step	RoBERTa$_{\texttt{BASE}}$	RoBERTa$_{\texttt{BASE}}$ $\rightarrow$ RoBERTa$_{\texttt{LARGE}}$
5k	61.8	68.8
10k	75.6	78.1
15k	79.3	81.5
20k	80.4	82.8
25k	81.7	83.6
30k	82.4	83.9
35k	83.1	84.1
40k	83.6	84.5
45k	82.8	85.2
50k	83.9	84.6
55k	83.4	85.2
60k	84.0	85.7
65k	84.1	85.3
70k	84.3	85.5
75k	85.0	85.8
80k	84.7	85.8
85k	84.8	86.2
...	...	...
125k	85.5	86.1

Table 5: Average GLUE performance comparing both RoBERTa$_{\texttt{BASE}}$ and RoBERTa$_{\texttt{BASE}}$ $\rightarrow$ RoBERTa$_{\texttt{LARGE}}$ at different pre-training steps.

on the effects of model architecture. The teacher models differ from RoBERTa$_{\texttt{BASE}}$ in either the depth or width. Specifically, we vary the depth in $\{4, 6, 8, 10\}$ (denoted as $\{$RoBERTa$_{\texttt{H\_4}}$, RoBERTa$_{\texttt{H\_6}}$, RoBERTa$_{\texttt{H\_8}}$, RoBERTa$_{\texttt{H\_10}}\}$), and the width in $\{384, 480, 576, 672\}$ (denoted as $\{$RoBERTa$_{\texttt{D\_384}}$, RoBERTa$_{\texttt{D\_480}}$, RoBERTa$_{\texttt{D\_576}}$, RoBERTa$_{\texttt{D\_672}}\}$). Generally, PLMs with larger model parameters converge faster and achieve better final performance.

B Pre-training Hyper-parameters

In Table 6, we list the architectures we used for all models, covering the details for the total number of trainable parameters (n_{params}), the total number of layers (n_{layers}), the number of units in each bottleneck layer (d_{model}), the total number of attention heads (n_{heads}), the inner hidden size of FFN layer (d_{FFN}) and the learning rate when batch size is set to $2,048$ (lr). The training-validation ratio of pre-training data is set to $199 : 1$. We set the weight decay to 0.01, dropout rate to 0.1, and use linear learning rate decay. Adam is chosen as the optimizer. The learning rate is warmed up for the first 10% steps. The hyper-parameters for Adam optimizer is set to $1 \times 10^{-6}, 0.9, 0.98$ for $\epsilon, \beta_1, \beta_2$, respectively. For a fair comparison, all experiments are done in the same computation environment with 8 NVIDIA 32GB V100 GPUs. Table 7 describes the total number of pre-training steps for each ($\mathcal{M}_L$, $\mathcal{M}_S$) pair chosen in our experiments.

C Fine-tuning Hyper-parameters

Table 8 describes the hyper-parameters for ACL-ARC, CHEMPROT and GLUE tasks. The selection of these hyper-parameters closely follows (Liu et al., 2019) and (Gururangan et al., 2020).

D Domain Proximity of WB, CS and BIO

Table 9 lists the domain proximity (vocabulary overlap) of WB, CS and BIO used in this paper.

E Comparison between Knowledge Inheritance and Parameter Recycling

Parameter recycling (i.e., progressive training) first trains a small PLM, and then gradually increases the depth or width of the network based on parameter initialization. It is an orthogonal research direction against our KI, and has many limitations as follows:

Architecture Mismatch. Existing parameter recycling methods (Gong et al., 2019; Gu et al., 2021) require that the architectures of both small PLMs

Model Name	n_{params}	n_{layers}	d_{model}	n_{heads}	d_{FFN}	lr (bs $= 2,048$)

Table 7: The total number of steps for teacher-guided learning for different ($\mathcal{M}_L$, $\mathcal{M}_S$) pairs.

and large PLMs are matched to some extent, however, our KI does not have such a requirement. For example, Gong et al. (2019); Gu et al. (2021) either requires the number of layers, or the hidden size/embedding size of a large PLM to be the integer multiples of that of a small PLM. Hence, it is not flexible to train larger PLMs with arbitrary architectures, making parameter recycling hard to be implemented practically. Besides, there are more and more advanced non-trivial Transformer modifications appearing (we refer to Lin et al. (2021) for details), e.g., pre-normalization, relative embedding, sparse attention, etc. It is non-trivial to directly transfer the parameters between two PLMs if they have different inner structures. Nevertheless, our KI framework will not be influenced by such architectural mismatches.

Inability for Multi-to-one Knowledge Inheritance. It is non-trivial to support absorbing knowledge from multiple teacher models by jointly recycling their model parameters. Instead, it is easy to implement for KI. As shown in our experiments, we demonstrate that under our framework, large PLMs can simultaneously absorb knowledge from multiple teachers.

Inability of Knowledge Inheritance for Domain Adaptation. Parameter recycling is hard to support continual learning, which makes large PLMs absorb knowledge from small ones in a lifelong manner. In real-world scenarios, numerous PLMs of different architectures are trained locally with

HyperParam	ACL-ARC & CHEMPROT	GLUE

different data. These small PLMs can be seen as domain experts, and it is essential that larger PLMs can continuously benefit from these existing PLMs efficiently by incorporating their knowledge so that larger PLMs can become omnipotent. As described before, it is easy to implement for our framework and we have demonstrated the effectiveness.

Model Privacy. Parameter recycling requires the availability of the parameters of an existing PLM, which may be impractical due to some privacy issues, e.g., GPT-3 only provides API access for prediction instead of the model parameters. Instead, our KI framework does not presume access to an existing model parameter since the predictions of the small model can be pre-computed and saved offline. This superiority will further make it possible for API-based online knowledge transfer.

F Comparing Label Smoothing and Knowledge Inheritance

Previous work shows the relation between label smoothing and knowledge distillation to some extent (Shen et al., 2021). To demonstrate that the success of our KI is not because of learning from a more smoothed target, we conduct experiments comparing both label smoothing and our KI in Table 10. Specifically, for label smoothing, PLMs optimize a smoothed target $\mathbf{y}_i^S = (1-\alpha) * \mathbf{y}_i + \alpha * \vec{\mathbf{1}}/(K-1)$, where $\alpha = 0$ denotes learning from scratch with no label smoothing, larger α means a more smoothed target for PLMs to learn from, K denotes the vocabulary size. Specifically, we choose α from $\{0.1, 0.2, 0.3\}$. It can be concluded from the results in Table 10 that adding label smoothing into the pre-training objectives of PLMs leads to far worse performance than the vanilla baseline, which shows that the improvements of our knowledge inheritance framework are non-trivial: larger PLMs are indeed inheriting the "knowledge" from smaller ones, instead of benefiting from optimizing a smoothed target, which imposes regularization.

Bi-SimCut: A Simple Strategy for Boosting Neural Machine Translation

Pengzhi Gao, Zhongjun He, Hua Wu, and Haifeng Wang
Baidu Inc. No. 10, Shangdi 10th Street, Beijing, 100085, China
`{gaopengzhi,hezhongjun,wu_hua,wanghaifeng}@baidu.com`

Abstract

We introduce Bi-SimCut: a simple but effective training strategy to boost neural machine translation (NMT) performance. It consists of two procedures: bidirectional pretraining and unidirectional finetuning. Both procedures utilize SimCut, a simple regularization method that forces the consistency between the output distributions of the original and the cutoff sentence pairs. Without leveraging extra dataset via back-translation or integrating large-scale pretrained model, Bi-SimCut achieves strong translation performance across five translation benchmarks (data sizes range from 160K to 20.2M): BLEU scores of 31.16 for `en` → `de` and 38.37 for `de` → `en` on the IWSLT14 dataset, 30.78 for `en` → `de` and 35.15 for `de` → `en` on the WMT14 dataset, and 27.17 for `zh` → `en` on the WMT17 dataset. SimCut is not a new method, but a version of Cutoff (Shen et al., 2020) simplified and adapted for NMT, and it could be considered as a perturbation-based method. Given the universality and simplicity of SimCut and Bi-SimCut, we believe they can serve as strong baselines for future NMT research.

1 Introduction

The state of the art in machine translation has been dramatically improved over the past decade thanks to the neural machine translation (NMT) (Wu et al., 2016), and Transformer-based models (Vaswani et al., 2017) often deliver state-of-the-art (SOTA) translation performance with large-scale corpora (Ott et al., 2018). Along with the development in the NMT field, consistency training (Bachman et al., 2014) has been widely adopted and shown great promise to improve NMT performance. It simply regularizes the NMT model predictions to be invariant to either small perturbations applied to the inputs (Sato et al., 2019; Shen et al., 2020) and hidden states (Chen et al., 2021) or the model randomness and variance existed in the training procedure (Liang et al., 2021).

Specifically, Shen et al. (2020) introduce a set of cutoff data augmentation methods and utilize Jensen-Shannon (JS) divergence loss to force the consistency between the output distributions of the original and the cutoff augmented samples in the training procedure. Despite its impressive performance, finding the proper values for the four additional hyper-parameters introduced in cutoff augmentation seems to be tedious and time-consuming if there are limited resources available, which hinders its practical value in the NMT field.

In this paper, our main goal is to provide a simple, easy-to-reproduce, but tough-to-beat strategy for training NMT models. Inspired by cutoff augmentation (Shen et al., 2020) and virtual adversarial regularization (Sato et al., 2019) for NMT, we firstly introduce a simple yet effective regularization method named SimCut. Technically, SimCut is not a new method and can be viewed as a simplified version of Token Cutoff proposed in Shen et al. (2020). We show that bidirectional backpropagation in Kullback-Leibler (KL) regularization plays a key role in improving NMT performance. We also regard SimCut as a perturbation-based method and discuss its robustness to the noisy inputs. At last, motivated by bidirectional training (Ding et al., 2021) in NMT, we present Bi-SimCut, a two-stage training strategy consisting of bidirectional pretraining and unidirectional finetuning equipped with SimCut regularization.

The contributions of this paper can be summarized as follows:

- We propose a simple but effective regularization method, SimCut, for improving the generalization of NMT models. SimCut could be regarded as a perturbation-based method and serves as a strong baseline for the approaches of robustness. We also show the compatibility of SimCut with the pretrained language models such as mBART (Liu et al., 2020).

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3938 - 3948
July 10-15, 2022

- We propose Bi-SimCut, a training strategy for NMT that consists of bidirectional pretraining and unidirectional finetuning with SimCut regularization.

- Our experimental results show that NMT training with Bi-SimCut achieves significant improvements over the Transformer model on five translation benchmarks (data sizes range from 160K to 20.2M), and outperforms the current SOTA method BiBERT (Xu et al., 2021) on several benchmarks.

2 Background

2.1 Neural Machine Translation

The NMT model refers to a neural network with an encoder-decoder architecture, which receives a sentence as input and returns a corresponding translated sentence as output. Assume $\mathbf{x} = x_1, ..., x_I$ and $\mathbf{y} = y_1, ..., y_J$ that correspond to the source and target sentences with lengths I and J respectively. Note that y_J denotes the special end-of-sentence symbol $\langle eos \rangle$. The encoder first maps a source sentence $\mathbf{x}$ into a sequence of word embeddings $e(\mathbf{x}) = e(x_1), ..., e(x_I)$, where $e(\mathbf{x}) \in \mathbb{R}^{d \times I}$, and d is the embedding dimension. The word embeddings are then encoded to the corresponding hidden representations $\mathbf{h}$. Similarly, the decoder maps a shifted copy of the target sentence $\mathbf{y}$, i.e., $\langle bos \rangle, y_1, ..., y_{J-1}$, into a sequence of word embeddings $e(\mathbf{y}) = e(\langle bos \rangle), e(y_1), ..., e(y_{J-1})$, where $\langle bos \rangle$ denotes a special beginning-of-sentence symbol, and $e(\mathbf{y}) \in \mathbb{R}^{d \times J}$. The decoder then acts as a conditional language model that operates on the word embeddings $e(\mathbf{y})$ and the hidden representations $\mathbf{h}$ learned by the encoder.

Given a parallel corpus $\mathcal{S} = \{\mathbf{x}^i, \mathbf{y}^i\}_{i=1}^{|\mathcal{S}|}$, the standard training objective is to minimize the empirical risk:

$$\mathcal{L}_{ce}(\theta) = \mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y}) \in \mathcal{S}} [\ell(f(\mathbf{x}, \mathbf{y}; \theta), \ddot{\mathbf{y}})], \tag{1}$$

where ℓ denotes the cross-entropy loss, θ is a set of model parameters, $f(\mathbf{x}, \mathbf{y}; \theta)$ is a sequence of probability predictions, i.e.,

$$f_j(\mathbf{x}, \mathbf{y}; \theta) = P(y|\mathbf{x}, \mathbf{y}_{<j}; \theta), \tag{2}$$

and $\ddot{\mathbf{y}}$ is a sequence of one-hot label vectors for $\mathbf{y}$.

2.2 Cutoff Augmentation

Shen et al. (2020) introduce a set of cutoff methods which augments the training by creating the partial views of the original sentence pairs and propose Token Cutoff for the machine translation task. Given a sentence pair $(\mathbf{x}, \mathbf{y})$, N cutoff samples $\{\mathbf{x}^i_{\text{cut}}, \mathbf{y}^i_{\text{cut}}\}_{i=1}^N$ are constructed by randomly setting the word embeddings of $x_1, ..., x_I$ and $y_1, ..., y_J$ to be zero with a cutoff probability p_{cut}. For each sentence pair, the training objective of Token Cutoff is then defined as:

$$\mathcal{L}_{tokcut}(\theta) = \mathcal{L}_{ce}(\theta) + \alpha\mathcal{L}_{cut}(\theta) + \beta\mathcal{L}_{kl}(\theta), \tag{3}$$

where

$$\mathcal{L}_{ce}(\theta) = \ell(f(\mathbf{x}, \mathbf{y}; \theta), \ddot{\mathbf{y}}), \tag{4}$$

$$\mathcal{L}_{cut}(\theta) = \frac{1}{N}\sum_{i=1}^{N} \ell(f(\mathbf{x}^i_{\text{cut}}, \mathbf{y}^i_{\text{cut}}; \theta), \ddot{\mathbf{y}}), \tag{5}$$

$$\begin{aligned}\mathcal{L}_{kl}(\theta) = &\frac{1}{N+1}\{\sum_{i=1}^{N} \text{KL}(f(\mathbf{x}^i_{\text{cut}}, \mathbf{y}^i_{\text{cut}}; \theta) \| p_{\text{avg}}) \\ &+ \text{KL}(f(\mathbf{x}, \mathbf{y}; \theta) \| p_{\text{avg}})\},\end{aligned} \tag{6}$$

$$\begin{aligned}p_{\text{avg}} = &\frac{1}{N+1}\{\sum_{i=1}^{N} f(\mathbf{x}^i_{\text{cut}}, \mathbf{y}^i_{\text{cut}}; \theta) \\ &+ f(\mathbf{x}, \mathbf{y}; \theta)\},\end{aligned} \tag{7}$$

in which $\text{KL}(\cdot\|\cdot)$ denotes the Kullback-Leibler (KL) divergence of two distributions, and α and β are the scalar hyper-parameters that balance $\mathcal{L}_{ce}(\theta)$, $\mathcal{L}_{cut}(\theta)$ and $\mathcal{L}_{kl}(\theta)$.

3 Datasets and Baseline Settings

In this section, we describe the datasets used in experiments as well as the model configurations. For fair comparisons, we keep our experimental settings consistent with previous works.

Datasets We initially consider a low-resource (IWSLT14 `en`↔`de`) scenario and then show further experiments in standard (WMT14 `en`↔`de`) and high (WMT17 `zh`→`en`) resource scenarios in Sections 5 and 6. The detailed information of the datasets are summarized in Table 1. We here conduct experiments on the IWSLT14 English-German dataset[1], which has 160K parallel bilingual

---

	IWSLT	WMT	
	`en↔de`	`en↔de`	`zh→en`
train	160239	4468840	20184941
valid	7283	6003	2002
test	6750	3003	2001

Table 1: Number of sentence pairs used in our machine translation experiments.

sentence pairs. Following the common practice, we lowercase all words in the dataset. We build a shared dictionary with 10K byte-pair-encoding (BPE) (Sennrich et al., 2016) types.

Settings We implement our approach on top of the Transformer (Vaswani et al., 2017). We apply a Transformer with 6 encoder and decoder layers, 4 attention heads, embedding size 512, and FFN layer dimension 1024. We apply cross-entropy loss with label smoothing rate 0.1 and set max tokens per batch to be 4096. We use Adam optimizer with Beta $(0.9, 0.98)$, 4000 warmup updates, and inverse square root learning rate scheduler with initial learning rates $5e^{-4}$. We use dropout rate 0.3 and beam search decoding with beam size 5 and length penalty 1.0. We apply the same training configurations in both pretraining and finetuning stages which will be discussed in the following sections. We use `multi-bleu.pl`[2] for BLEU (Papineni et al., 2002) evaluation. We train all models until convergence on a single NVIDIA Tesla V100 GPU. All reported BLEU scores are from a single model. For all the experiments below, we select the saved model state with the best validation performance.

4 Bi-SimCut

In this section, we formally propose Bidirectional Pretrain and Unidirectional Finetune with Simple Cutoff Regularization (Bi-SimCut), a simple but effective training strategy that can greatly enhance the generalization of the NMT model. Bi-SimCut consists of a simple cutoff regularization and a two-phase pretraining and finetuning strategy. We introduce the details of each part below.

4.1 SimCut: A Simple Cutoff Regularization for NMT

Despite the impressive performance reported in Shen et al. (2020), finding the proper hyper-parameters $(p_{\text{cut}}, \alpha, \beta, N)$ in Token Cutoff seems to be tedious and time-consuming if there are limited resources available, which hinders its practical value in the NMT community. To reduce the burden in hyper-parameter searching, we propose SimCut, a simple regularization method that forces the consistency between the output distributions of the original sentence pairs and the cutoff samples.

Our problem formulation is motivated by Virtual Adversarial Training (VAT), where Sato et al. (2019) introduces a KL-based adversarial regularization that forces the output distribution of the samples with adversarial perturbations $\boldsymbol{\delta}_{\mathbf{x}} \in \mathbb{R}^{d\times I}$ and $\boldsymbol{\delta}_{\mathbf{y}} \in \mathbb{R}^{d\times J}$ to be consistent with that of the original samples:

$$\mathrm{KL}(f(e(\mathbf{x}), e(\mathbf{y}); \theta) \| f(e(\mathbf{x}) + \boldsymbol{\delta}_{\mathbf{x}}, e(\mathbf{y}) + \boldsymbol{\delta}_{\mathbf{y}}; \theta)).$$

Instead of generating perturbed samples by gradient-based adversarial methods, for each sentence pair $(\mathbf{x}, \mathbf{y})$, we only generate one cutoff sample $(\mathbf{x}_{\text{cut}}, \mathbf{y}_{\text{cut}})$ by following the same cutoff strategy used in Token Cutoff. For each sentence pair, the training objective of SimCut is defined as:

$$\mathcal{L}_{simcut}(\theta) = \mathcal{L}_{ce}(\theta) + \alpha \mathcal{L}_{simkl}(\theta), \qquad (8)$$

where

$$\mathcal{L}_{simkl}(\theta) = \mathrm{KL}(f(\mathbf{x}, \mathbf{y}; \theta) \| f(\mathbf{x}_{\text{cut}}, \mathbf{y}_{\text{cut}}; \theta)).$$

There are only two hyper-parameters α and p_{cut} in SimCut, which greatly simplifies the hyper-parameter searching step in Token Cutoff. Note that VAT only allows the gradient to be backpropagated through the right-hand side of the KL divergence term, while the gradient is designed to be backpropagated through both sides of the KL regularization in SimCut. We can see that the constraints introduced by $\mathcal{L}_{cut}(\theta)$ and $\mathcal{L}_{kl}(\theta)$ in (3) still implicitly hold in (8):

- $\mathcal{L}_{cut}(\theta)$ in Token Cutoff is designed to guarantee that the output of the cutoff sample should close to the ground-truth to some extent. In SimCut, $\mathcal{L}_{ce}(\theta)$ requires the outputs of the original sample close to the ground-truth, and $\mathcal{L}_{simkl}(\theta)$ requires the output distributions of the cutoff sample close to that of the original sample. The constraint introduced by $\mathcal{L}_{cut}(\theta)$ then implicitly holds.
- $\mathcal{L}_{kl}(\theta)$ in Token Cutoff is designed to guarantee that the output distributions of the original sample and N different cutoff samples

VAT	29.45	35.52
R-Drop	30.73	37.30
Token Cutoff	30.89	37.61
SimCut	**30.98**	**37.81**

Table 2: SimCut achieves the superior or comparable performance on IWSLT14 `en` ↔ `de` translation tasks over the strong baselines such as VAT, R-Drop, and Token Cutoff.

should be consistent with each other. In SimCut, $\mathcal{L}_{simkl}(\theta)$ guarantees the consistency between the output distributions of the original and cutoff samples. Even though SimCut only generates one cutoff sample at each time, different cutoff samples of the same sentence pair will be considered in different training epochs. Such constraint raised by $\mathcal{L}_{kl}(\theta)$ still implicitly holds.

4.2 Analysis on SimCut

4.2.1 How Does the Simplification Affect Performance?

We here investigate whether our simplification on Token Cutoff hurts its performance on machine translation tasks. We compare SimCut with Token Cutoff, VAT, and R-Drop (Liang et al., 2021), a strong regularization baseline that forces the output distributions of different sub-models generated by dropout to be consistent with each other. Table 2 shows that SimCut achieves superior or comparable performance over VAT, R-Drop, and Token Cutoff, which clearly shows the effectiveness of our method. To further compare SimCut with other strong baselines in terms of training cost, we summarize the validation BLEU score along the training time on IWSLT14 `de`→`en` translation task in Table 3. From the table, we can see that the BLEU score of SimCut continuously increases in the first 1500 minutes. The results on VAT are consistent with the previous studies on adversarial overfitting, i.e., virtual adversarial training easily suffering from overfitting (Rice et al., 2020). Though SimCut needs more training time to converge, the final NMT model is much better than the baseline. For the detailed training cost for each epoch, Token Cutoff costs about 148 seconds per epoch, while SimCut costs about 128 seconds per epoch. Note that the training cost of Token Cutoff is greatly influenced by the hyper-parameter N. We set N to be 1 in our experiments. With the increasing of N, the training time of Token Cutoff will be much longer. Due to the tedious and time-consuming hyper-parameter searching in Token Cutoff, we will not include its results in the following sections and show the results of SimCut directly.

4.2.2 How Does the Bidirectional Backpropagation Affect Performance?

Even though the problem formulation of SimCut is similar to that of VAT, one key difference is that the gradients are allowed to be backpropagated bidirectionally in the KL regularization in SimCut. We here investigate the impact of the bidirectional backpropagation in the regularization term on the NMT performance. Table 4 shows the translation results of VAT and SimCut with or without bidirectional backpropagation. We can see that both VAT and SimCut benefit from the bidirectional gradient backpropagation in the KL regularization.

4.2.3 Performance on Perturbed Inputs

Given the similar problem formulations of VAT and SimCut, it is natural to regard cutoff operation as a special perturbation and consider SimCut as a perturbation-based method. We here investigate the robustness of NMT models on the perturbed inputs. As discussed in Takase and Kiyono (2021), simple techniques such as word replacement and word drop can achieve comparable performance to sophisticated perturbations. We hence include them as baselines to show the effectiveness of our method as follows:

- **UniRep**: Word replacement approach constructs a new sequence whose tokens are randomly replaced with sampled tokens. For each token in the source sentence $\mathbf{x}$, we sample $\hat{x}_i$ uniformly from the source vocabulary, and use it for the new sequence $\mathbf{x}'$ with probability $1 - p'$:

$$x'_i = \begin{cases} x_i, & \text{with probability } p', \\ \hat{x}_i, & \text{with probability } 1 - p'. \end{cases} \tag{9}$$

We construct $\mathbf{y}'$ from the target sentence $\mathbf{y}$ in the same manner. Following the curriculum learning strategy used in Bengio et al. (2015), we adjust p' with the inverse sigmoid decay:

$$p'_t = \max(q, \frac{k}{k + \exp{(\frac{t}{k})}}), \tag{10}$$

where q and k are hyper-parameters. p'_t decreases to q from 1, depending on the training epoch num-

Minutes	10	30	60	90	150	300	600	900	1200	1500
Transformer	11.51	31.20	34.19	34.88	**35.17**	34.86	34.43	34.28	34.23	33.95
VAT	1.87	20.08	31.69	33.95	35.41	35.78	**35.81**	35.63	35.17	34.99
R-Drop	2.11	26.32	32.81	34.25	35.88	36.91	37.18	37.43	**37.52**	37.43
Token Cutoff	2.16	28.88	32.82	34.61	35.90	36.84	37.70	37.81	**37.93**	37.83
SimCut	1.99	25.12	32.21	33.66	34.93	36.37	37.31	37.62	37.89	**38.10**

Table 3: On the IWSLT14 `de→en` validation set, the BLEU score increases over time in model training using SimCut. In contrast, the BLEU scores of the other strong baselines all stop increasing before 1500 minutes. The results suggest that the use of SimCut can effectively alleviate the model training from overfitting.

Method	`en→de`	`de→en`
VAT	29.45	35.52
+ Bi-backpropagation	29.69	36.26
SimCut	30.98	37.81
- Bi-backpropagation	30.29	36.91

Table 4: Bidirectional backpropagation achieves better performance on IWSLT14 `en` ↔ `de` translation tasks compared with unidirectional backpropagation in the KL regularization.

SimCut	**37.81**	**36.94**	**33.16**	**27.93**

Table 5: The model trained by SimCut achieves high robustness on the perturbed test set and high performance on the clean test set. Entries represent BLEU scores on IWSLT14 `de→en` test set when we inject perturbations to source sentences with different probability.

ber t. We use p'_t as p' in epoch t. We set q and k to be 0.9 and 25 respectively in the experiments.

- **WordDrop**: Word drop randomly applies the zero vector instead of the word embedding $e(x_i)$ or $e(y_i)$ for the input token x_i or y_i (Gal and Ghahramani, 2016). For each token in both source and target sentences, we keep the original embedding with the probability β and set it to be the zero vector otherwise. We set β to be 0.9 in the experiments.

We construct noisy inputs by randomly replacing words in the source sentences based on a predefined probability. If the probability is 0.0, we use the original source sentence. If the probability is 1.0, we use completely different sentences as source sentences. We set the probability to be 0.00, 0.01, 0.05, and 0.10 in our experiments. We randomly replace each word in the source sentence with a word uniformly sampled from the vocabulary. We apply this procedure to IWSLT14 `de→en` test set. Table 5 shows the BLEU scores of each method on the perturbed test set. Note that the BLEU scores are calculated against the original reference sentences. We can see that all methods improve the robustness of the NMT model, and SimCut achieves the best performance among all the methods on both the clean and perturbed test sets. The performance results indicate that SimCut could be considered as a strong baseline for the perturbation-based method for the NMT model.

As shown in Table 6, the baseline model completely ignores the translation of "in spielen (in games)" due to the replacement of "denken (think)" with "festgelegten (determined)" in the source sentence. In contrast, our model successfully captures the translation of "in spielen" under the noisy input. This result shows that our model is more robust to small perturbations in an authentic context.

4.2.4 Effects of α and p_{cut}

We here investigate the impact of the scalar hyperparameters α and p_{cut} in SimCut. α is a penalty parameter that controls the regularization strength in our optimization problem. p_{cut} controls the percentage of the cutoff perturbations in SimCut. We here vary α and p_{cut} in $\{1, 2, 3, 4, 5\}$ and $\{0.00, 0.05, 0.10, 0.15, 0.20\}$ respectively and conduct the experiments on the IWSLT14 `de→en` dataset. Note that SimCut is simplified to R-Drop approximately when $p_{\text{cut}} = 0.00$. The test BLEU scores are reported in Figure 1. By checking model performance under different combinations of α and p_{cut}, we have the following observations: 1) A too small α (e.g., 1) cannot achieve as good performance as larger α (e.g., 3), indicating a certain de-

Input	wir denken (festgelegten), dass wir in der realität nicht so gut sind wie in spielen.
Reference	we feel that we are not as good in reality as we are in games.
Vaswani et al. (2017) on Input	we think we're not as good in reality as we are in games.
on Noisy Input	we realized that we weren't as good as we were in real life.
SimCut on Input	we think in reality, we're not as good as we do in games.
on Noisy Input	we realized that we're not as good in reality as we are in games.

Table 6: SimCut is more robust to small perturbations in an authentic context. SimCut captures the translation of "in spielen" under the noisy input while the vanilla Transformer ignores the translation of "in spielen" due to the replacement of "denken" with "festgelegten".

gree of regularization strength during NMT model training is conducive to generalization. Meanwhile, an overwhelming regularization ($\alpha = 5$) is not plausible for learning NMT models. 2) When $\alpha = 3$, the best performance is achieved when $p_{\text{cut}} = 0.05$, and $p_{\text{cut}} = 0.00$ performs suboptimal among all selected probabilities. Such an observation demonstrates that the cutoff perturbation in SimCut can effectively promote the generalization compared with R-Drop.

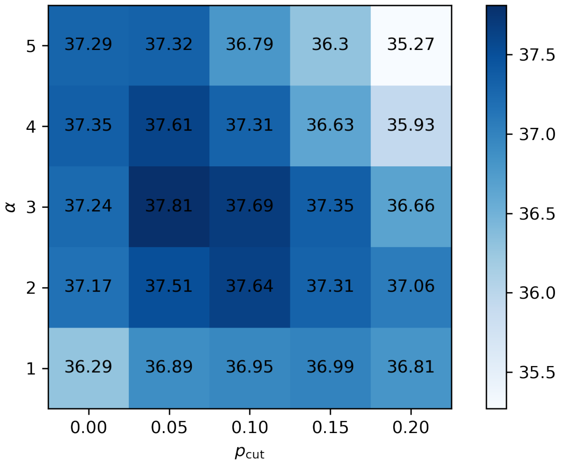

Figure 1: BLEU scores with different α and p_{cut} on IWSLT14 `de→en` dataset.

4.2.5 Is SimCut Compatible with the Pretrained Language Model?

The multilingual sequence-to-sequence pretrained language models (Song et al., 2019; Liu et al., 2020; Xue et al., 2021) have shown impressive performance on machine translation tasks, where the pretrained models generally learn the knowledge from the large-scale monolingual data. It is interesting to investigate whether SimCut can gain performance improvement based on the pretrained language model. We adopt mBART (Liu et al., 2020) as the backbone model, which is a sequence-to-sequence denoising auto-encoder pretrained on CC25 Corpus[3]. We conduct experiments on IWSLT14 `de→en` dataset and only remove the duplicated sentence pairs following mBART50 (Tang et al., 2021) in the data preprocessing step. The source and target sentences are jointly tokenized into sub-word units with the 250K SentencePiece (Kudo and Richardson, 2018) vocabulary of mBART. We use case-sensitive sacreBLEU (Post, 2018) to evaluate the translation quality, and the methods applied in the experiments are as follows:

Method	`de→en`
Transformer	32.4
mBART	38.5
mBART with SimCut	**39.3**

Table 7: SimCut achieves better performance on IWSLT14 `de→en` translation task compared with the standard finetuning approach based on mBART.

- Transformer: The Transformer model is randomly initialized and trained from scratch. We utilize the same model and training configurations discussed in Section 3.

- mBART: The Transformer model is directly finetuned from mBART. We utilize the default training configurations of mBART.

- mBART with SimCut: The Transformer model is finetuned from mBART with SimCut regularization. We utilize the default training configurations of mBART.

From Table 7 we can see that SimCut could further improve the translation performance of mBART,

which again shows the effectiveness and universality of our method.

4.3 Training Strategy: Bidirectional Pretrain and Unidirectional Finetune

Bidirectional pretraining is shown to be very effective to improve the translation performance of the unidirectional NMT system (Ding et al., 2021; Xu et al., 2021). The main idea is to pretrain a bidirectional NMT model at first and use it as the initialization to finetune a unidirectional NMT model. Assume we want to train an NMT model for “English→German”, we first reconstruct the training sentence pairs to “English+German→German+English”, where the training dataset is doubled. We then firstly train a bidirectional NMT model with the new training sentence pairs:

$$\mathop{\mathbb{E}}_{(\mathbf{x},\mathbf{y})\in\mathcal{S}}[\ell(f(\mathbf{x},\mathbf{y};\theta),\ddot{\mathbf{y}})+\ell(f(\mathbf{y},\mathbf{x};\theta),\ddot{\mathbf{x}})], \quad (11)$$

and finetune the model with “English→German” direction. We follow the same training strategy in Ding et al. (2021) and apply SimCut regularization to both pretraining and finetuning procedures. Table 8 shows that bidirectional pretraining and unidirectional finetuning strategy with SimCut regularization could achieve superior performance compared with strong baseline such as R-Drop.

Comparison with Existing Methods We summarize the recent results of several existing works on IWSLT14 `en`↔`de` benchmark in Table 9. The existing methods vary from different aspects, including Virtual Adversarial Training (Sato et al., 2019), Mixed Tokenization for NMT (Wu et al., 2020), Unified Dropout for the Transformer model (Wu et al., 2021), Regularized Dropout (Liang et al., 2021), and BiBERT (Xu et al., 2021). We can see that our approach achieves an improvement of 2.92 BLEU score over Vaswani et al. (2017) and surpass the current SOTA method BiBERT that incorporates large-scale pretrained model, stochastic layer selection, and bidirectional pretraining. Given the simplicity of Bi-SimCut, we believe it could be considered as a strong baseline for the NMT task.

5 Standard Resource Scenario

We here investigate the performance of Bi-SimCut on the larger translation benchmark compared with the IWSLT14 benchmark.

5.1 Dataset Description and Model Configuration

For the standard resource scenario, we evaluate NMT models on the WMT14 English-German dataset, which contains 4.5M parallel sentence pairs. We combine newstest2012 and newstest2013 as the validation set and use newstest2014 as the test set. We collect the pre-processed data from Xu et al. (2021)’s release[4], where a shared dictionary with 52K BPE types is built. We apply a standard Transformer Big model with 6 encoder and decoder layers, 16 attention heads, embedding size 1024, and FFN layer dimension 4096. We apply cross-entropy loss with label smoothing rate 0.1 and set max tokens per batch to be 4096. We use Adam optimizer with Beta $(0.9, 0.98)$, 4000 warmup updates, and inverse square root learning rate scheduler with initial learning rates $1e^{-3}$. We decrease the learning rate to $5e^{-4}$ in the finetuning stage. We select the dropout rate from 0.3, 0.2, and 0.1 based on the validation performance. We

use beam search decoding with beam size 4 and length penalty 0.6. We train all models until convergence on 8 NVIDIA Tesla V100 GPUs. All reported BLEU scores are from a single model.

5.2 Results

We report test BLEU scores of all comparison methods and our approach on the WMT14 dataset in Table 10. With Bi-SimCut bidirectional pretraining and unidirectional finetuning procedures, our NMT model achieves strong or SOTA BLEU scores on `en→de` and `de→en` translation benchmarks. During the NMT training process, we fix p_{cut} to be 0.05 and tune the hyper-parameter α in both R-Drop and SimCut based on the performance on the validation set. Note that the BLEU scores of R-Drop are lower than that reported in Liang et al. (2021). Such gap might be due to the different prepossessing steps used in Liang et al. (2021) and Xu et al. (2021). It is worth mentioning that Bi-SimCut outperforms BiBERT on `de→en` direction even though BiBERT incorporates bidirectional pretraining, large-scale pretrained contextualized embeddings, and stochastic layer selection mechanism.

6 High Resource Scenario

To investigate the performance of Bi-SimCut on the distant language pairs which naturally do not share dictionaries, we here discuss the effectiveness of Bi-SimCut on the Chinese-English translation task.

6.1 Dataset Description and Model Configuration

For the high resource scenario, we evaluate NMT models on the WMT17 Chinese-English dataset, which consists of 20.2M training sentence pairs, and we use newsdev2017 as the validation set and newstest2017 as the test set. We firstly build the source and target vocabularies with 32K BPE types separately and treat them as separated or joined dictionaries in our experiments. We apply the same Transformer Big model and training configurations used in the WMT14 experiments. We use beam search decoding with beam size 5 and length penalty 1. We train all models until convergence on 8 NVIDIA Tesla V100 GPUs. All reported BLEU scores are from a single model.

Method	`share`	`zh→en`
Transformer	x	25.53
Transformer	✓	25.31
SimCut	x	26.86
SimCut	✓	26.74
Bi-SimCut Pretrain	✓	26.13
+ SimCut Finetune	✓	**27.17**

Table 11: Our method achieves strong performance on the WMT17 `zh→en` translation benchmark. `share` denotes whether a shared dictionary is applied.

6.2 Results

We report test BLEU scores of the baselines and our approach on the WMT17 dataset in Table 11. Note that `share` means the embedding matrices for encoder input, decoder input and decoder output are all shared. The NMT models with separated dictionaries perform slightly better than those with the shared dictionary. We can see that our approach significantly improves the translation performance. In particular, Bi-SimCut achieves more than 1.6 BLEU score improvement over Vaswani et al. (2017), showing the effectiveness and universality of our approach on the distant language pair in the NMT task.

7 Related Work

Adversarial Perturbation It is well known that neural networks are sensitive to noisy inputs, and adversarial perturbations are firstly discussed in the filed of image processing (Szegedy et al., 2014; Goodfellow et al., 2015). SimCut could be regarded as a perturbation-based method for the robustness research. In the field of natural language processing, Miyato et al. (2017) consider adversarial perturbations in the embedding space and show its effectiveness on the text classification tasks. For the NMT tasks, Sato et al. (2019) and Wang et al. (2019) apply adversarial perturbations in the embedding space during training of the encoder-decoder NMT model. Cheng et al. (2019) leverage adversarial perturbations and generate adversarial examples by replacing words in both source and target sentences. They introduce two additional language models for both sides and a candidate word selection mechanism for replacing words in the sentence pairs. Takase and Kiyono (2021) compare perturbations for the NMT model in view of computational time and show that simple perturbations are sufficiently effective compared with complicated adversarial perturbations.

Consistency Training Besides perturbation-based methods, our approach also highly relates to a few works of model-level and data-level consistency training in the NMT field. Among them, the most representative methods are R-Drop (Liang et al., 2021) and Cutoff (Shen et al., 2020). R-Drop studies the intrinsic randomness in the NMT model and regularizes the NMT model by utilizing the output consistency between two dropout sub-models with the same inputs. Cutoff considers consistency training from a data perspective by regularizing the inconsistency between the original sentence pair and the augmented samples with part of the information within the input sentence pair being dropped. Note that Cutoff takes the dropout sub-models into account during the training procedure as well. We want to emphasize that SimCut is not a new method, but a version of Cutoff simplified and adapted for the NMT tasks.

8 Conclusion

In this paper, we propose Bi-SimCut: a simple but effective two-stage training strategy to improve NMT performance. Bi-SimCut consists of bidirectional pretraining and unidirectional finetuning procedures equipped with SimCut regularization for improving the generality of the NMT model. Experiments on low (IWSLT14 `en`↔`de`), standard (WMT14 `en`↔`de`), and high (WMT17 `zh`→`en`) resource translation benchmarks demonstrate Bi-SimCut and SimCut's capabilities to improve translation performance and robustness. Given the universality and simplicity of Bi-SimCut and SimCut, we believe: 1) SimCut could be regarded as a perturbation-based method, and it could be used as a strong baseline for the robustness research. 2) Bi-SimCut outperforms many complicated methods which incorporate large-scaled pretrained models or sophisticated mechanisms, and it could be used as a strong baseline for future NMT research. We hope researchers of perturbations and NMT could use SimCut and Bi-SimCut as strong baselines to make the usefulness and effectiveness of their proposed methods clear. For future work, we will explore the effectiveness of SimCut and Bi-SimCut on more sequence learning tasks, such as multilingual machine translation, domain adaptation, text classification, natural language understanding, etc.

Abstract

Prompt tuning (PT) is a promising parameter-efficient method to utilize extremely large pre-trained language models (PLMs), which can achieve comparable performance to full-parameter fine-tuning by only tuning a few soft prompts. However, PT requires much more training time than fine-tuning. Intuitively, knowledge transfer can help to improve the efficiency. To explore whether we can improve PT via prompt transfer, we empirically investigate the transferability of soft prompts across different downstream tasks and PLMs in this work. We find that (1) in zero-shot setting, trained soft prompts can effectively transfer to similar tasks on the same PLM and also to other PLMs with a cross-model projector trained on similar tasks; (2) when used as initialization, trained soft prompts of similar tasks and projected prompts of other PLMs can significantly accelerate training and also improve the performance of PT. Moreover, to explore what decides prompt transferability, we investigate various transferability indicators and find that the overlapping rate of activated neurons strongly reflects the transferability, which suggests how the prompts *stimulate* PLMs is essential. Our findings show that prompt transfer is promising for improving PT, and further research shall focus more on prompts' stimulation to PLMs. The source code can be obtained from `https://github.com/thunlp/Prompt-Transferability`.

1 Introduction

Pre-trained language models (PLMs), such as BERT (Devlin et al., 2019) and GPT (Radford et al., 2018) have achieved great performance on various natural language processing (NLP) tasks (Han et al., 2021). Recently, people have found that extremely large PLMs can achieve remarkable improvements, and various large PLMs are continually developed (Brown et al., 2020; Raffel et al., 2020; Zhang et al., 2021; Zeng et al., 2021; Wei et al., 2021; Sun et al., 2021), which contain up to hundreds of billions of parameters.

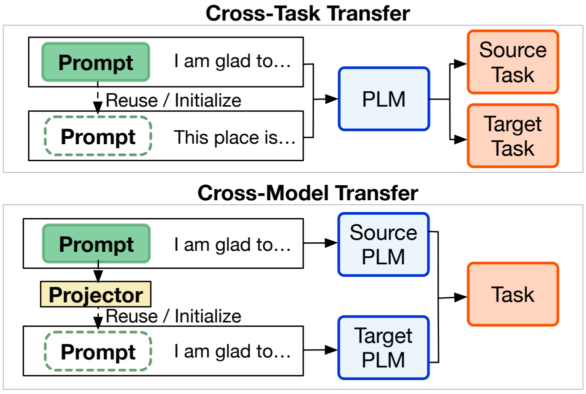

Figure 1: We explore prompt transferring across different tasks (cross-task) and PLMs (cross-model) with directly reusing prompts and initializing prompt tuning.

Considering the extremely large scale of these state-of-the-art PLMs, conventional full-parameter fine-tuning methods become extremely expensive. Hence, various parameter-efficient tuning methods (Houlsby et al., 2019; Ben Zaken et al., 2021; Lester et al., 2021; Li and Liang, 2021; Liu et al., 2021) are explored, among which prompt tuning (PT) has attracted broad research attention. PT prepends some *soft prompts*, which are essentially learnable virtual tokens, into the input sequences and only trains them while keeping all the PLM's parameters fixed. The training objective is to generate desired outputs in the same way as the pre-training tasks. PT can match the downstream task performance of fine-tuning with only thousands of tunable parameters (Lester et al., 2021) when the PLM has billions of parameters.

Although PT is an effective approach to utilizing extremely large PLMs, it requires much more

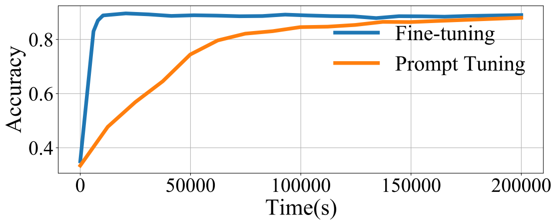

Figure 2: Validation accuracies against training time of fine-tuning and PT for RoBERTa$_{\text{LARGE}}$ on MNLI. PT takes much more training time.

training time than fine-tuning to reach the convergence as shown in Figure 2; hence, it is worthwhile to explore how to improve the efficiency of PT. In this work, we attempt to improve PT via **prompt transfer** across different tasks and models. Knowledge transfer across tasks (Vu et al., 2020) and models (Qin et al., 2021) have been widely used to improve the efficiency and effectiveness of NLP systems. Intuitively, soft prompts are the only tuned parameters in PT and thus shall concentrate the knowledge required to solve tasks conditioned on PLMs. Thus transferring the trained prompts is promising to accelerate PT.

As shown in Figure 1, we empirically analyze the transferability of prompts across different tasks (*cross-task transfer* setting) and PLMs (*cross-model transfer* setting) in this paper. The empirical analysis is conducted on 17 NLP tasks of 6 types and two representative PLM series: RoBERTa (Liu et al., 2019b) and T5 (Raffel et al., 2020). In cross-task transfer, the prompt transfer can be done by directly reusing the trained prompts of the source task on the target task. However, in cross-model transfer, directly reusing prompts is intractable since the semantic spaces of different PLMs are inconsistent; hence, we develop various **prompt projectors** to project the soft prompts trained on the source PLM to the semantic space of the target PLM. We conduct two lines of experiments: (1) We investigate the **zero-shot transfer performance** and find that the transferability of prompts is influenced by task types. In cross-task transfer, the soft prompts can directly transfer to same-type tasks and achieve non-trivial performance, but poorly transfer to different-type tasks requiring different language skills. In cross-model transfer, we can successfully train a prompt projector with PT on a task, but the trained projector also only well generalizes to the same-type tasks of the projector-training task. (2) To accelerate PT, we propose to **transfer prompts with initialization**. In cross-task transfer, we start PT with the trained soft prompts of similar tasks as initialization. While in cross-model transfer, the initialization is the projected prompts of the same task trained on the source PLM. The two methods are dubbed as TPT$_{\text{TASK}}$ and TPT$_{\text{MODEL}}$, which are short for transferable prompt tuning. Experiments show that they can both accelerate PT to some extent and also achieve a certain performance improvement.

Furthermore, we explore why can the prompts transfer and what decides their transferability. To this end, we design various prompt similarity metrics from different perspectives and examine how well they can serve as **transferability indicators**, i.e., how well they correlate with prompt transfer performance. Experiments find that our novel method of measuring prompt similarity via model activations in feed-forward layers is better correlated with prompt transferability than prompt embedding distance-based metrics. This suggests the prompts are essentially stimulating PLM's inner ability distributing among neurons to do specific NLP tasks, and future prompt transfer works should focus more on how the PLMs respond to different prompts' stimulation rather than the prompts' embedding properties.

To summarize, our contributions are three-fold: (1) We thoroughly analyze the transferability of prompts across different tasks and models, and show that improving PT with prompt transfer is possible and promising. (2) We propose to transfer prompts with initialization, which enhances both PT's efficiency and effectiveness. (3) We explore the effectiveness of various prompt similarity metrics serving as transferability indicators and demonstrate how the prompts stimulate PLMs to decide the transferability, which may facilitate further transferrable PT research.

2 Related Work

Prompt Tuning GPT-3 (Brown et al., 2020) demonstrates remarkable few-shot performance by prepending textual prompts before the inputs and thus helps the PLM to generate desired outputs of NLP tasks directly. Motivated by this, many works have tried to improve various NLP tasks by creating manually-crafted (Schick and Schütze, 2021a,b; Mishra et al., 2021) or automatically-searched (Jiang et al., 2020; Shin et al., 2020; Gao et al., 2021) *hard prompts*, which are discrete tokens but not necessarily human-readable. Furthermore, *soft prompts* (Hambardzumyan et al., 2021; Qin and Eisner, 2021; Zhong et al., 2021; Liu et al., 2021) are proposed, which are tuneable embeddings rather than tokens in the vocabularies and can be directly trained with task-specific supervision. Lester et al. (2021) demonstrate that prompt tuning (PT) method can match the performance of full-parameter fine-tuning when the PLM has billions of parameters. This suggests that PT is promising to utilize extremely large PLMs. However, the much more training time needed to reach the convergence makes PT inefficient. In this work, we show that prompt transfer can improve the effectiveness to some extent with knowledge transfer, and empirically analyze the transferability of prompts across tasks and PLMs.

Knowledge Transfer Cross-task knowledge transfer (Ruder, 2017) has been a long-standing way to improve the effectiveness and efficiency of NLP systems. In the PLM era, some works propose to tune the PLMs on intermediate tasks (Phang et al., 2018; Pruksachatkun et al., 2020; Gururangan et al., 2020; Wang et al., 2019a; Vu et al., 2020; Poth et al., 2021) before fine-tuning on specific target tasks to achieve certain benefits. Vu et al. (2020) empirically analyze the transferability between tasks in this setting.

These explorations are all for fine-tuning. Considering the potential of PT, we believe the transferability and knowledge transfer methods for PT are worth exploring. As a prior attempt, Lester et al. (2021) demonstrate that PT's cross-domain transferability is stronger than fine-tuning.

Similar to our work, recent work (Vu et al., 2021) also explores the cross-task transfer with prompt initialization and prompt similarity metrics based on cosine similarity. However, Vu et al. (2021) focus on improving the effectiveness of PT but we attempt to improve the efficiency. Additionally, we explore more transferability indicators, especially the overlapping rate of activated neurons, and also investigate cross-model transfer, which is inspired by previous cross-model knowledge transfer works such as Net2Net (Chen et al., 2016), knowledge distillation (Hinton et al., 2015) and knowledge inheritance (Qin et al., 2021).

3 Preliminary

Here we introduce the basic knowledge about PT (§ 3.1) as well as the downstream tasks (§ 3.2) and models (§ 3.3) investigated in experiments.

3.1 Prompt Tuning

In this work, we study the PT method that is capable of tuning large PLMs (Lester et al., 2021; Liu et al., 2021), i.e., we only explore the PT method freezing PLM parameters. PT prepends some virtual tokens, i.e., the *soft prompts*, into the inputs of the PLM to provide knowledge about downstream tasks. The soft prompts are essentially tunable embedding vectors, which are trained with the objective enforcing the PLM to generate desired outputs of the downstream task in the same way of the pre-training objective.

Formally, given an input sequence with n tokens $X = \{x_1, x_2, \ldots, x_n\}$, we first prepend l randomly initialized soft prompts $P = \{\mathbf{p}_1, \mathbf{p}_2, \ldots, \mathbf{p}_l\}$ before them, where $\mathbf{p}_i \in \mathbb{R}^d$ is an embedding vector, and d is the input dimension of the PLM. The training objective is to maximize the likelihood of decoding the desired output y:

$$\mathcal{L} = p(y|P, x_1, \ldots, x_n), \tag{1}$$

where only P is learnable. For the language understanding tasks, y is the label token corresponding to the label of X. For the conditional generation tasks, y is a sequence. Especially, for the models pre-trained with the masked language modeling objective like RoBERTa, we additionally prepend a special `[MASK]` token before the prompts and train the prompts to let the PLM fill y into it.

3.2 Investigated NLP Tasks

To comprehensively study the prompt transferability across various NLP tasks, we involve 17 diverse tasks, which can be divided into 6 types: (1) **Sentiment Analysis (SA)**, including `IMDB` (Maas et al., 2011), `SST-2` (Socher et al., 2013), `laptop` (Pontiki et al., 2014), `restaurant` (Pontiki et al., 2014), Movie Rationales (`Movie`) (Zaidan et al., 2008) and TweetEval (`Tweet`) (Barbieri et al., 2020); (2) **Natural Language Inference (NLI)**, including `MNLI` (Williams et al., 2018), `QNLI` (Wang et al., 2019b) and `SNLI` (Bowman et al., 2015); (3) **Ethical Judgment (EJ)**, including `deontology` (Hendrycks et al., 2021) and `justice` (Hendrycks et al., 2021); (4) **Paraphrase Identification (PI)**, including `QQP` (Sharma et al., 2019) and `MRPC` (Dolan and Brockett, 2005); (5) **Question Answering (QA)**, including `SQuAD` (Rajpurkar et al., 2016) and `NQ-Open`

(Lee et al., 2019); (6) **Summarization (SUM)**, including `Multi-News` (Fabbri et al., 2019) and `SAMSum` (Gliwa et al., 2019). Details for these tasks, evaluation metrics, label tokens, implementations are in appendix A.

3.3 Investigated Models

We investigate prompt transferability for two series of PLMs: RoBERTa (Liu et al., 2019b) and T5 (Raffel et al., 2020), which represent two mainstream pre-training types: masked language modeling and sequence-to-sequence pre-training. Considering RoBERTa can only predict a single token (or a fixed length of tokens) under prompt tuning paradigm, for the conditional generation tasks (QA and SUM) that output multiple tokens, we only investigate T5. We mainly report results for the two largest versions of PLMs, i.e., $\text{RoBERTa}_{\text{LARGE}}$ and T5_{XXL}. The more detailed results for the other sizes are attached in appendix.

4 Cross-Task Transfer

We empirically study the cross-task transferability of soft prompts (§ 4.1) and try to improve the effectiveness and efficiency of PT with transfer (§ 4.2).

4.1 Zero-shot Transfer Performance

To study the cross-task transferability, we first examine PT's zero-shot transfer performance, i.e., we conduct PT on a source task, then directly reuse the trained prompts on other target tasks and evaluate their performance. The results are shown in Figure 3[1], from which we can observe that: (1) For the tasks within the same type, transferring soft prompts between them can generally perform well and may even outperform vanilla PT on the target task, especially when the source task has more data (the case of transferring from `IMDB` to `Movie` in Figure 3 (a) and transferring from `restaurant` to `laptop` in Figure 3 (b)), which demonstrates that it is promising to improve PT's effectiveness and efficiency with knowledge transfer from similar tasks. (2) For the tasks of different types, the transferability of soft prompts among them is generally poor, and transferring soft prompts often achieve similar performance to randomly initialized prompts.

(3) However, some tasks can transfer to different-type tasks to some extent, such as the QA and SUM tasks to SA tasks in Figure 3 (b). To understand this, it is worthwhile to explore what controls the transferability between prompts, and we do some preliminary study in § 6.

4.2 Transfer with Initialization

To improve the effectiveness and efficiency of PT with cross-task transfer, we explore a cross-task transferable prompt tuning (TPT_{TASK}) method, which initializes soft prompts with well-trained prompts of the most similar task and then starts PT.

For a target task, we start TPT_{TASK} with trained prompts of the source task achieving the best zero-shot transfer performance in Figure 3. From the results of the performance and training time comparisons[2] in Table 1, we can see TPT_{TASK} can mostly achieve better or comparable performance to vanilla PT starting from random initialization, and TPT_{TASK} generally takes less training time.

5 Cross-Model Transfer

We further study the cross-model transferability of soft prompts. Intuitively, cross-model transfer allows us to train prompts on a small and computationally efficient PLM and use them on a massive and computationally expensive PLM, which will be much more efficient and environment-friendly. We investigate the feasibility of cross-model transfer on transferring from a source PLM ($\text{RoBERTa}_{\text{LARGE}}$) to a larger and heterogeneous target PLM (T5_{XXL}), which shall be the most difficult setting. Appendix C shows the experimental results of other settings. Directly reusing trained soft prompts between different PLMs is infeasible since their embedding spaces are different. Hence, we investigate how to do cross-model prompt projection (§ 5.1) and see the transfer performance (§ 5.2). Furthermore, we explore to improve PT with cross-model transfer initialization (§ 5.3).

5.1 Cross-Model Prompt Projection

To project the trained soft prompts of a PLM to the semantic space of a different PLM, we train projectors with various objectives and examine their effectiveness. A good way to train the cross-model projectors may need some task-specific supervisions, but the trained projector shall generalize to different tasks so that the efficiency for learning the new tasks on the target model could be improved.

Formally, given the prompt of the source PLM $P^s = \{\mathbf{p}_1^s, \ldots, \mathbf{p}_l^s\}$, we concatenate the l virtual

---

[1] More results on other PLMs are left in appendix B.1.

[2] Training time comparisons are left in appendix B.3.

Table 1: Performance on 17 NLP tasks of vanilla prompt tuning (**PT**) and prompt tuning with transferring initialization (TPT$_{\text{TASK}}$), which initialize PT with the one performing best in zero-shot transfer, as well as the convergence speedup (the quotient of the training steps of **PT** by the training time of TPT$_{\text{TASK}}$ reaching convergence) and comparable-result speedup (the quotient of the training time of **PT** by the training time of TPT$_{\text{TASK}}$ achieving comparable performance to **PT**). N/A represents the tasks that RoBERTa$_{\text{LARGE}}$ cannot conduct, or we fail to speed up training with TPT$_{\text{TASK}}$.

tokens into a unified vector $\mathbf{P}^s \in \mathbb{R}^{ld_s}$. The projector $\mathbf{Proj}(\cdot)$ is to project it to $\tilde{\mathbf{P}}^s \in \mathbb{R}^{ld_t}$ in the semantic space of the target PLM, where d_s and d_t are the input embedding dimensions of the source and target PLM, respectively. We parameterize the projector with a two-layer perceptron as follows:

$$\tilde{\mathbf{P}}^s = \mathbf{Proj}(\mathbf{P}^s) = \mathbf{W}_2(\sigma(\mathbf{P}^s\mathbf{W}_1 + \mathbf{b}_1)) + \mathbf{b}_2, \quad (2)$$

where $\mathbf{W}_1 \in \mathbb{R}^{d_h \times ld_s}, \mathbf{W}_2 \in \mathbb{R}^{ld_t \times d_h}$ are trainable matrices, $\mathbf{b}_1 \in \mathbb{R}^{d_h}, \mathbf{b}_2 \in \mathbb{R}^{ld_t}$ are biases, σ is a non-linear activation function. We investigate two learning objectives to train the projector[3]:

Distance Minimizing We firstly try to learn cross-model projections by minimizing the distance between the projected prompt and the parallel prompt $\mathbf{P}^t$ originally trained on the target PLM with the same task, i.e., the training objective is to minimize their L_2-distance $\|\mathbf{Proj}(\mathbf{P}^s) - \mathbf{P}^t\|_2$.

Task Tuning We then try to train the cross-model projector with task-specific supervision signals on

Table 2: Cross-model prompt transfer (RoBERTa$_{\text{LARGE}}$ to T5$_{\text{XXL}}$) results, including non-transfer baselines (vanilla PT and randomly generated prompts), zero-shot transfer performance of various projectors, and TPT$_{\text{MODEL}}$ results (performance, convergence speedup, and comparable-result speedup similar to Table 1). TPT$_{\text{MODEL}}$ adopts the Task Tuning projectors to project the soft prompts.

the target PLM. Specifically, we directly tune the projected prompts on some tasks and back propagate the supervision signals to train the projector weights, so that the projector can learn how to stimulate the target PLM and thus may generalize to transfer the prompts of other tasks.

These methods rely on some tasks (parallel trained soft prompts or training data) to train the projector. The projector learning methods are agnostic to the specific training tasks used, and we choose `laptop` and `MNLI` in experiments.

5.2 Zero-shot Transfer Performance

The zero-shot transfer performance of various projector-learning methods are shown in Table 2[4] (a). We can observe that: (1) **Distance Minimizing** works well to transfer the prompts of the projector-training task, but falls back to random performance on the other unseen tasks, which is not practically usable. This is consistent with our findings in § 6 that the embedding distances do not strongly correlate to prompt transferability. (2) **Task Tuning** performs better and successfully generalizes to same-type unseen tasks of the projector-training tasks (e.g. NLI tasks for the projectors trained with `MNLI`), which proves the feasibility of practical cross-model prompt transfer. (3) The projectors trained with **Task Tuning** still cannot work for different-type tasks, which may be limited by the cross-task prompt transferability investigated in § 4.1. This urges further attention to developing universal cross-model projections.

5.3 Transfer with Initialization

Similar to § 4.2, we further study whether the projected soft prompts can initialize PT on the target PLM and accelerate training as well as improve performance. We propose cross-model transferable prompt tuning, TPT$_{\text{MODEL}}$, which adopts the **Task Tuning** projectors to project the soft prompts trained on the source PLM into the target PLM and initialize PT with the projected prompts.

The performance and speedup are shown in Table 2 (b). We can see that, for the tasks within the same type of the projector-training task, compared to vanilla PT, TPT$_{\text{MODEL}}$ can mostly achieve comparable or better performance with much less training time, which demonstrates that practical cross-model prompt transfer is promising for improving the efficiency and effectiveness of PT.

6 Exploring Transferability Indicator

Based on the positive results in cross-task and cross-model transfer, we explore why the soft prompts can transfer across tasks and what decides the transferability between them, which may shed light on the mechanisms behind PT and help to design transferable PT methods. We explore various **prompt similarity metrics** and examine how well do they align with the zero-shot transfer performance. If a similarity metric can well indicate transferability, it suggests the factors considered in designing

---

[4] More results on other PLMs are left in appendix C.2.

this metric decide the prompt transferability. Moreover, the prompt similarity metrics can qualify task similarities using the trained soft prompts as task embeddings and may help in developing cross-task transfer methods. As a straightforward example, if we build a *prompt warehouse* containing prompts of diverse tasks, we can retrieve prompts of similar tasks for a new task with a certain similarity metric and better improve PT with TPT_{TASK}.

6.1 Prompt Similarity Metric

We explore the following two kinds of metrics:

Embedding Similarity We firstly regard the trained soft prompts as only embeddings in the vector space and calculate their *Euclidean similarity* and *cosine similarity*, among which cosine similarity is also explored by Vu et al. (2021).

Given two groups of trained prompts containing l virtual tokens: $P^{t_1} = \{\mathbf{p}_1^{t_1}, \ldots, \mathbf{p}_l^{t_1}\}$ and $P^{t_2} = \{\mathbf{p}_1^{t_2}, \ldots, \mathbf{p}_l^{t_2}\}$, which correspond to tasks t_1 and t_2. Firstly, we concatenate the l virtual tokens for each group and get two concatenation embeddings $\mathbf{P}^{t_1}, \mathbf{P}^{t_2} \in \mathbb{R}^{ld}$, then we compute Euclidean similarity and cosine similarity of them:

$$\begin{aligned} \text{E}_{\text{concat}}(P^{t_1}, P^{t_2}) &= \frac{1}{1 + \|\mathbf{P}^{t_1} - \mathbf{P}^{t_2}\|}, \\ \text{C}_{\text{concat}}(P^{t_1}, P^{t_2}) &= \frac{\mathbf{P}^{t_1} \cdot \mathbf{P}^{t_2}}{\|\mathbf{P}^{t_1}\|\|\mathbf{P}^{t_2}\|}. \end{aligned} \quad (3)$$

We further explore a simple way to make the metrics invariant to token positions. We compute Euclidean distances and cosine similarities for every virtual token pairs in the two groups and use the averaged results in the final similarity metrics:

$$\begin{aligned} \text{E}_{\text{average}}(P^{t_1}, P^{t_2}) &= \frac{1}{1 + \frac{1}{l^2}\sum_{i=1}^{l}\sum_{j=1}^{l}\|\mathbf{p}_i^{t_1} - \mathbf{p}_j^{t_2}\|}, \\ \text{C}_{\text{average}}(P^{t_1}, P^{t_2}) &= \frac{1}{l^2}\sum_{i=1}^{l}\sum_{j=1}^{l}\frac{\mathbf{p}_i^{t_1} \cdot \mathbf{p}_j^{t_2}}{\|\mathbf{p}_i^{t_1}\|\|\mathbf{p}_j^{t_2}\|}. \end{aligned} \quad (4)$$

Model Stimulation Similarity In the second way, we depict their similarities based on how they *stimulate the PLMs*, i.e., we examine the similarities between the responses of PLMs to the two soft prompts. Motivated by Geva et al. (2021) and Dai et al. (2021), which both find that the activation of the neurons in the feed-forward layers of Transformers (Vaswani et al., 2017) corresponds to specific model behaviors, we propose to use the *overlapping rate of activated neurons* as a similarity metric of prompts. Specifically, the feed-forward network $\text{FFN}(\cdot)$ in a Transformer layer is:

Model	Metric	Same Task	Different Tasks
$\text{RoBERTa}_{\text{LARGE}}$	E_{concat}	9.4	6.8
	$\text{E}_{\text{average}}$	41.6	37.6
	C_{concat}	47.6	31.7
	$\text{C}_{\text{average}}$	1.7	1.1
	ON	39.4	21.4
T5_{XXL}	E_{concat}	0.5	0.3
	$\text{E}_{\text{average}}$	4.0	3.4
	C_{concat}	29.4	3.4
	$\text{C}_{\text{average}}$	4.0	2.1
	ON	62.0	46.1

Table 3: The average values (%) of the 5 similarity metrics for prompt pairs of the same task (trained with 3 different random seeds) and different tasks.

$$\text{FFN}(\mathbf{x}) = \max(\mathbf{x}\mathbf{W}_1^\top + \mathbf{b}_1, \mathbf{0})\mathbf{W}_2 + \mathbf{b}_2, \quad (5)$$

where $\mathbf{x} \in \mathbb{R}^d$ is the input embedding, $\mathbf{W}_1, \mathbf{W}_2 \in \mathbb{R}^{d_m \times d}$ are trainable matrices, and $\mathbf{b}_1, \mathbf{b}_2$ are bias vectors. The $\max(\mathbf{x}\mathbf{W}_1^\top + \mathbf{b}_1, \mathbf{0})$ can be regarded as the non-negative activation values for d_m hidden neurons (Geva et al., 2021). We then change all the positive elements of $\max(\mathbf{x}\mathbf{W}_1^\top + \mathbf{b}_1, \mathbf{0})$ to 1 and get the one-hot activation state vector $\mathbf{s}$.

We feed an input sequence $\{P, \texttt{<s>}\}$ into the PLMs, where `<s>` is the special token indicating the start of a sentence. For RoBERTa, a `[MASK]` is additional prepended. This sequence is in the format of PT inputs but without specific input sentences.

We use the activation states of the positions used to decode outputs, which shall be more task-specific. Specifically, for T5, we use the decoder module's activation states at the first position. For RoBERTa, we use the activation states of `[MASK]`. Finally, we concatenate the activation states of PLM's L layers to get the overall activation states:

$$\text{AS}(P) = [\mathbf{s}_1; \mathbf{s}_2; ...; \mathbf{s}_L]. \quad (6)$$

We can only retrieve the activation states of a part of layers in the similarity computation. In experiments, we find that the higher layers tend to be more task-specific, which is consistent with the probing results (Liu et al., 2019a). Hence we use the activation states of the top 3 layers[5] in experiments below. We calculate the overlapping rate of activated neurons $\text{ON}(P^{t_1}, P^{t_2})$ between

---

[5] More results about the different layers's performance are left in appendix D.4.

Metric	RoBERTa$_{\text{LARGE}}$	T5$_{\text{XXL}}$
$\mathrm{E}_{\text{concat}}$	22.6	12.9
$\mathrm{E}_{\text{average}}$	2.8	-2.5
$\mathrm{C}_{\text{concat}}$	24.8	31.6
$\mathrm{C}_{\text{average}}$	44.7	33.5
ON	**49.7**	**36.9**

Table 4: The Spearman's rank correlation scores (%) between various similarity metrics and cross-task zero-shot transfer performance of soft prompts.

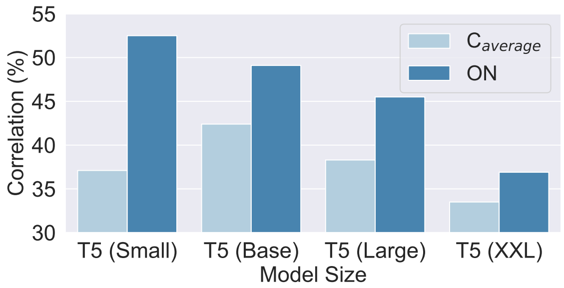

Figure 4: Spearman's correlation scores of ON and $\mathrm{C}_{\text{average}}$ with cross-task zero-shot transfer performance change along with the parameter size of T5.

the trained soft prompts of task t_1 and t_2 with the cosine similarity:

$$\mathrm{ON}(P^{t_1}, P^{t_2}) = \frac{\mathrm{AS}(P^{t_1}) \cdot \mathrm{AS}(P^{t_2})}{\|\mathrm{AS}(P^{t_1})\| \|\mathrm{AS}(P^{t_2})\|}. \quad (7)$$

6.2 Experimental Results

To evaluate the effectiveness of the above similarity metrics of soft prompts, we (i) test whether the similarity metrics can distinguish the trained prompts of the same tasks and different tasks, and (ii) examine whether these metrics align with the zero-shot transfer performance.

Regarding (i), we compare the similarities of the investigated metrics for two trained prompts within the same task (trained with different random seeds) and between different tasks in Table 3. From the results, we can observe that all the metrics work well to distinguish the prompts of the same task and different tasks. This suggests that the trained soft prompts of different tasks form distinguishable clusters in the embedding space and also stimulate different abilities within the PLM.

Moreover, to evaluate (ii), how well the similarity metrics align with the cross-task transfer performance, we quantify the correlations between the similarities and zero-shot transfer performance in Figure 3. Specifically, for each target task's prompt, we rank various source tasks' prompts with similarity scores and zero-shot transfer performance and then compute the Spearman's rank correlation (Spearman, 1987) between the two ranks generated by these two ways. The overall results are shown in Table 4[6]. We can see that: (1) The *overlapping rate of activated neurons* (ON) metric works better than all the embedding similarities, which suggests that model stimulation is more important for prompt transferability than embedding distances. (2) ON works much worse on T5$_{\text{XXL}}$ (11B parameters) than on RoBERTa$_{\text{LARGE}}$ (330M parameters). We guess this is because larger PLMs have higher redundancy (Aghajanyan et al., 2021), which means prompts can activate different redundant neurons to do similar jobs and thus influence the sensitivity of ON metric. This is supported by the experiments showing that the Spearman's correlation scores of ON drop with the increase of PLM scales (Figure 4), from which we can see $\mathrm{C}_{\text{average}}$ also exhibits a similar trend. We encourage future work to explore how to overcome the PLM redundancy for better transferrable PT. As a preliminary trial, we find that by taking the intersection of activation states of 3 prompts trained with different random seeds, ON's correlation score on T5$_{\text{XXL}}$ raises from 36.9% to 46.3%.

Projector	Task	$\mathrm{C}_{\text{average}}$	ON
Task Tuning (`laptop`)	`laptop`	3.8	52.4
	Same-Type Tasks	4.1	51.0
	Different-Type Tasks	3.4	46.0
Task Tuning (`MNLI`)	`MNLI`	2.7	70.7
	Same-Type Tasks	2.7	56.7
	Different-Type Tasks	4.1	53.4

Table 5: Similarities (%) between the prompts projected with **Task Tuning** projector and the original prompts trained on T5$_{\text{XXL}}$.

We further explore whether the prompt similarity metrics also work in the cross-model transfer setting by testing whether they work between the projected prompts and original prompts of the same task. In Table 5, we show the similarities of prompts projected with **Task Tuning** projectors by the two best metrics $\mathrm{C}_{\text{average}}$ and ON. We can see: (1) ON metric shows that the projected prompts are highly similar to the original prompts within the same type of projector-training tasks but are not so similar to different-type tasks, which is quite consistent with the cross-model zero-shot transfer

---

[6] The detailed results by task types are left in appendix D.2.

performance in Table 2. (2) However, C_{average} cannot reflect this phenomenon, which shows that the perspective of model stimulation is more promising for understanding transferability again.

7 Conclusion

We empirically investigate the transferability of prompts in this paper. In the cross-task setting, we find that soft prompts can transfer to similar tasks without training. In the cross-model setting, we successfully project prompts into the space of other PLMs. Further, we utilize trained prompts of other tasks or other PLMs as initialization to significantly accelerate training and improve effectiveness. Moreover, we explore various prompt transferability indicators and show that how the prompts stimulate PLMs is important to transferability. We hope the empirical analyses and the *model stimulation* idea can facilitate further research on transferable and efficient PT.

Author Contributions

Yusheng Su and Xiaozhi Wang mainly initiated and organized this research. First, Xiaozhi Wang proposed the research idea. Yusheng Su, Xiaozhi Wang, Yujia Qin and Yankai Lin discussed most of the investigation settings. Yusheng Su, Chi-Min Chan, and Kaiyue Wen conducted the experiments. Xiaozhi Wang and Yusheng Su wrote the paper. Yankai Lin, Yujia Qin, Huadong Wang, Zhiyuan Liu, Peng Li, Juanzi Li, and Lei Hou revised the paper. Maosong Sun and Jie Zhou provided valuable advice and proofread this paper.

A Basic Setup for Various Tasks

A.1 Dataset and Task

Sentiment Analysis (SA) SA is the task of classifying sentiment polarities for a given sentence. We select `IMDB` (Maas et al., 2011), `SST-2` (Socher et al., 2013), SemEval/`laptop` (Pontiki et al., 2014), SemEval/`restaurant` (Pontiki et al., 2014), Movie Rationales (`Movie`) (Zaidan et al., 2008), and TweetEval (`Tweet`) (Barbieri et al., 2020) for our experiments.

Natural Language Inference (NLI) NLI is the task of determining whether a hypothesis is entailed or contradicted by a given sentences (premise, hypothesis). We select `MNLI` (Williams et al., 2018), `QNLI` (Wang et al., 2019b), and `SNLI` (Bowman et al., 2015) for our experiments.

Ethical Judgment (EJ) EJ is the task of deciding whether a sentence is ethically acceptable. We select Ethics/`deontology` (Hendrycks et al., 2021) and Ethics/`justice` (Hendrycks et al., 2021) for our experiments.

Paraphrase Identification (PI) PI is the task of classifying whether a pair of sentences are semantically identical. We select `QQP` (Sharma et al., 2019) and `MRPC` (Dolan and Brockett, 2005) for our experiments.

Question Answering (QA) QA is the task of answering a question. We choose `SQuAD` (Rajpurkar et al., 2016) and `NQ-Open` (Lee et al., 2019) to analyze. For `SQuAD`, a PLM captures the answer from the content. As for `NQ-Open`, a PLM directly generates the answer without the content.

Summarization (SUM) SUM is the task of summarizing a given article and generating the abstract. We select `Multi-News` (Fabbri et al., 2019), and `SAMSum` (Gliwa et al., 2019) for our experiments.

A.2 Evaluation Metrics

For classification tasks (SA, NLI, EJ, and PI), we use accuracy (Acc.) as their evaluation metric. As for generation tasks (QA and SUM), we utilize F1 and ROUGE-L (Lin, 2004), respectively.

A.3 Prompt Tuning Setting

In the experiments, for all the investigated tasks, we use AdamW (Loshchilov and Hutter, 2019) as the optimizer and set the learning rate as 0.001. We set the length of soft prompts l as 100. All the soft prompts are randomly initialized and optimized with Equation 1. In the inference stage, RoBERTa predicts the label tokens at the [`MASK`] position and T5 directly uses its decoder to do generation. For the classification tasks (SA, NLI, EJ and PI), we obtaining answers in a ranking manner, i.e., we rank the label tokens by their likelihoods and regard the PLMs as predict the label of the label token with highest likelihood. For the conditional generation tasks (QA and SUM), we directly take the outputs of PLMs as their answers.

A.4 Label Tokens

The used label tokens for the classification tasks (SA, NLI, EJ, PI) are shown in Table 6. For generation tasks (QA, SUM), the desired output is just the annotated answers.

Task	Label Tokens
Sentiment Analysis (SA)	
`IMDB`	`positive, negative`
`SST-2`	`positive, negative`
`laptop`	`positive, moderate, negative`
`restaurant`	`positive, moderate, negative`
`Movie`	`positive, negative`
`Tweet`	`positive, moderate, negative`
Natural Language Inference (NLI)	
`MNLI`	`yes, neutral, no`
`QNLI`	`yes, no`
`SNLI`	`yes, neutral, no`
Ethical Judgment (EJ)	
`deontology`	`acceptable, un`
`justice`	`acceptable, un`
Paraphrase Identification (PI)	
`QQP`	`true, false`
`MRPC`	`true, false`

Table 6: Label tokens of classification tasks.

B Cross-Task Transfer

B.1 More Zero-shot transfer performance

In § 4.1, we report the zero-shot transfer performance (relative performance) on RoBERTa$_{\text{LARGE}}$ and T5$_{\text{XXL}}$. Here, we investigate the zero-shot transfer performance on other sizes of RoBERTa and T5, which are shown in Figure 5. According to these results, we can find that the transferability of soft prompts between the tasks of different types is generally poor, which is consistent with the conclusion in § 4.1.

(b) Unifying the label tokens (RoBERTa$_{\text{BASE}}$)

Figure 6: To exclude the poor transferability, which may result from the fact that different-type tasks use different label tokens, we unify the label tokens of different tasks into the same set of numbers (`1`, `2`, $\ldots$) and choose RoBERTa$_{\text{BASE}}$ for the experiments. From Figure (a) and (b), we observe that the transferability between different-type tasks are still generally not improved in this way. This indicates that different-type tasks surely require distinct abilities.

B.2 Unifying Label Tokens

We hypothesize that the poor transferability between different task types may result from the fact that different-type tasks usually use different label tokens, e.g., `yes` and `no` are for NLI tasks while `positive` and `negative` are for SA tasks. To verify whether this factor influences the transferability, we unify the label tokens of different tasks into the same set of numbers (`1`, `2`, $\ldots$) and choose RoBERTa$_{\text{BASE}}$ for the experiments. In Figure 6, we can observe that the transferability between different-type tasks are generally not improved in this way. This indicates that different-type tasks surely require distinct abilities, which prohibits reusing prompts between them.

B.3 Speedup Calculation

In this paper, we compute convergence speedup and comparable-result speedup as follows:

$$\text{Convergence Speedup(x)} = \frac{\text{PT convergence time}}{\text{TPT convergence time}},$$
$$\text{Comparable-result Speedup(x)} = \frac{\text{PT convergence time}}{\text{time of TPT achieving comparable result to PT}}. \quad (8)$$

We calculate the training loss and the evaluation score per 100 steps during the training. When the training loss stops dropping and the evaluation score stops increasing for 300 steps, we set the point as the convergence point. For the convergence speedup in Equation 8, the PT convergence time is divided by the TPT convergence time. As for the comparable-result speedup in Equation 8, the PT convergence time are divided by the time of TPT achieving comparable performance to PT.

C Cross-Model Transfer

C.1 Implementation Details of Projector

As mentioned in § 5.1, we give the prompt of the source PLM, $P^s = \{\mathbf{p}_1^s, \ldots, \mathbf{p}_l^s\}$, and concatenate its l virtual tokens into a unified vector $\mathbf{P}^s \in \mathbb{R}^{ld_s}$, where d_s is the hidden size of the source PLM. To transfer $\mathbf{P}^s$ to the target PLM whose hidden size is d_t, we design a projection function $\mathbf{Proj}(\cdot)$ parameterized by a two-layer perceptron as follows:

$$\tilde{\mathbf{P}}^s = \mathbf{Proj}(\mathbf{P}^s) = \mathbf{W}_2(\sigma(\mathbf{P}^s\mathbf{W}_1 + \mathbf{b}_1)) + \mathbf{b}_2, \quad (9)$$

where $\mathbf{W}_1 \in \mathbb{R}^{d_h \times ld_s}$, $\mathbf{W}_2 \in \mathbb{R}^{ld_t \times d_h}$ are trainable matrices, $\mathbf{b}_1 \in \mathbb{R}^{d_h}$, $\mathbf{b}_2 \in \mathbb{R}^{ld_t}$ are biases, σ is a non-linear activation function. For training configurations of projector, the optimizer is AdamW (Loshchilov and Hutter, 2019), the training batch size is 16, the learning rate is 0.005,

Table 7: We conduct experiments between various PLMs in different scales and heterogeneous frameworks: from BERT$_{\text{BASE}}$ to RoBERTa$_{\text{BASE}}$, from RoBERTa$_{\text{BASE}}$ to RoBERTa$_{\text{LARGE}}$, and from T5$_{\text{BASE}}$ to T5$_{\text{XXL}}$. Besides, we highlight the non-trivial zero-shot performance (%) of the cross-model setting with **bold**.

and the inner hidden size d_h is 768. In this paper, we investigate cross-model transfer among various PLMs including BERT$_{\text{BASE}}$, RoBERTa$_{\text{BASE}}$, RoBERTa$_{\text{LARGE}}$, T5$_{\text{SMALL}}$, T5$_{\text{BASE}}$, and T5$_{\text{XXL}}$, whose hidden sizes are 768, 768, 1024, 512, 768, and 1024, respectively. Besides, for non-linear activation functions, we have tried `tanh` and `LeakyReLU` (Xu et al., 2015), and find their performance on various PLMs are similar. The reported results are based on `LeakyReLU`.

C.2 More Zero-shot Transfer Performance

In § 5.2, we showed the zero-shot transfer performance of various projector-learning methods in the setting of transferring from RoBERTa$_{\text{LARGE}}$ to T5$_{\text{XXL}}$. We explore more cross-model transfer settings here, which are transferring between various PLMs in different scales and heterogeneous frameworks, including from BERT$_{\text{BASE}}$ to RoBERTa$_{\text{BASE}}$, from RoBERTa$_{\text{BASE}}$ to RoBERTa$_{\text{LARGE}}$, and from T5$_{\text{BASE}}$ to T5$_{\text{XXL}}$. We can find that the results in Table 7 are all consistent with § 5.2.

C.3 Technical Details of TPT$_{\text{MODEL}}$

In § 5.3, we demonstrate cross-model transferrable prompt tuning (TPT$_{\text{MODEL}}$) can well improve performance and reduce training time.

However, when we apply TPT$_{\text{MODEL}}$ to more PLMs, we find that the projected prompts may have quite different L_2 norm values with the original prompts, especially for the small-scale PLMs (e.g., from BERT$_{\text{BASE}}$ to RoBERTa$_{\text{BASE}}$). Specifically, we obtain the projected prompts with the trained Task Tuning projector, and find that the projected prompts are hard to optimize in some tasks as shown in Figure 7 `[Without LayerNorm]`. Thus, we attempt to add the layer normalization operation (Ba et al., 2016) `LayerNorm` into the projectors to regularize the norm of the projected prompt as follows:

$$\tilde{\mathbf{P}}^s = \texttt{LayerNorm}(\mathbf{Proj}(\mathbf{P}^s)). \quad (10)$$

By the `LayerNorm`, the projected prompts can work well on TPT$_{\text{MODEL}}$ and achieve better performance and speedup as shown in Figure 7 `[With LayerNorm]`. Interestingly, although prompts projected by the projectors `[Without LayerNorm]` are hard to be trained in TPT$_{\text{MODEL}}$, they can achieve similar zero-shot transfer performance with the prompts projected by the projectors `[With LayerNorm]` in Table 8.

Table 8: We find that the zero-shot performances of prompts projected by two Task Tuning projectors (`[With LayerNorm]` and `[Without LayerNorm]`) are close. **Bold** represents non-trivial performance.

D Transferability Indicator

D.1 Effectiveness of Similarity Metrics

We categorize all prompts into three groups: same tasks (prompts trained with different seeds on the same dataset), same-type tasks, and different-type tasks. Table 9 shows that all the similarity metrics successfully distinguish task types.

D.2 Correlation Between Prompt Transferability and Prompt Similarity

In § 6, we provide the overall averaged Spearman's rank correlation scores (%) between various similarity metrics and zero-shot transfer performance

Table 11: Spearman's rank correlation scores (%) between various similarity metrics and zero-shot transfer performance of soft prompts for various scales of RoBERTa.

of soft prompts for $\text{RoBERTa}_{\text{LARGE}}$ and T5_{XXL}.

Here, we further show Spearman's rank correlation scores grouped by the task types on more PLMs. The results are shown in Table 10 and Table 11.

D.3 PLMs' Redundancy Influence Indicators

From Table 10, we find that the correlation between prompt transferability and prompt similarity will drop with the increase of PLM size. We guess that this phenomena may result from PLMs' high redundancy (Aghajanyan et al., 2021).

To try to overcome this, we simultaneously utilize the prompts trained with three random seeds on the same dataset and take their intersection of activation states as the activated neurons into the similarity (ON) computation. This similarity is called ON_{I}. By using it, the correlation score of ON can significantly raise as shown in Table 10.

D.4 Overlapping Rate of Activated Neurons in Different Layers

To further understand model stimulation in PLMs, we investigate ON in different layers of PLMs. Specifically, on $\text{RoBERTa}_{\text{BASE}}$, we measure the similarity between different prompts with activation states of from 1 to 3 layers (Figure 8), from 4 to 6 layers (Figure 9), from 7 to 9 layers (Figure 10), from 10 to 12 layers (Figure 11), and all 12 layers (Figure 12), respectively.

We find that the activated neurons are common in the bottom layers but tend to be more task-specific in top layers, which is consistent with the findings of previous works (Liu et al., 2019a).

Abstract

Event extraction aims to identify an event and then extract the arguments participating in the event. Despite the great success in sentence-level event extraction, events are more naturally presented in the form of documents, with event arguments scattered in multiple sentences. However, a major barrier to promote document-level event extraction has been the lack of large-scale and practical training and evaluation datasets. In this paper, we present DocEE, a new document-level event extraction dataset including 27,000+ events, 180,000+ arguments. We highlight three features: large-scale manual annotations, fine-grained argument types and application-oriented settings. Experiments show that there is still a big gap between state-of-the-art models and human beings (41% Vs 85% in F1 score), indicating that DocEE is an open issue. DocEE is now available at `https://github.com/tongmeihan1995/DocEE.git`.

1 Introduction

Event Extraction (EE) aims to detect events from text, including event classification and event argument extraction. EE is one of the fundamental tasks in text mining (Feldman and Sanger, 2006) and has many applications. For instance, it can monitor political or military crises to generate real-time notifications and alerts (Dragos, 2013), and dig the links and connections (e.g., Who Met Whom and When) between dignitaries for portrait analysis (Zhan et al., 2020).

Most existing datasets (e.g., ACE2005 [1] and KBP2017 [2]) focus on sentence-level event extraction, while events are usually described at the document level, and event arguments are typically scattered across different sentences (Hamborg et al., 2019). Figure 1 shows an *Air Crash* event. To extract argument *Date*, we need to read sentence [1], while to extract argument *Cause of the Accident*, we need to integrate information in sentences [6] and [7]. Clearly, this requires reasoning over multiple sentences and modeling long-distance dependency, intuitively beyond the reach of sentence-level EE. Therefore, it is necessary to move EE forward from sentence-level to document-level.

Only a few datasets are curated for document-level EE. MUC-4(Grishman and Sundheim, 1996) provides 1,700 news articles annotated with 4 event types and 5 argument types. The 5 arguments are shared among different event types without further refinement. WikiEvents(Li et al., 2021) consists of only 246 documents with very few (22% of total) cross-sentences argument annotations. RAMS(Ebner et al., 2020) limits the scope of the arguments in a 5-sentence window around its event trigger, which is not in line with the actual application, and the number of the argument types in RAMS is only 65, which is quite limited. Doc2EDAG, TDJEE and GIT (Zheng et al., 2019; Wang et al., 2021; Xu et al., 2021) contain only 5 event types and 35 argument types in financial domain. In summary, existing datasets for document-level EE fail in the following aspects: small scale of data, limited coverage of domain and insufficient refinement of argument types. Therefore, it is urgent to develop a manually labeled, large-scale dataset to accelerate the research in document-level EE.

In the paper, we present DocEE, a large-scale human-annotated document-level EE dataset. Figure 1 illustrates an example of DocEE. DocEE focus on the extraction of the main event, that is *one-event-per-document*. We regard news headlines as the main event trigger and focus on main event arguments extraction throughout the article. We highlight the following three contributions of DocEE to this field: 1) Large-scale Manual Annotations. Do-

NAF Plane Crash: Military Takes Over Site, AIB To Commence Investigation

[1]Soldiers have cordoned off the site where the Nigerian Airforce plane crashed on Friday evening at the Kaduna International Airport.

[2]The plane which was carrying the Chief of Army Staff, Lieutenant General Ibrahim Attahiru, and other Senior Army Officers crashed near the airport's active runway, killing all the eleven people on board.

[3]Speaking on the incident, the Manager of Kaduna airport, Amina Salami told Channels Television that the military authorities have taken over the crash site. [4]She added that they have prevented civil aviation officials from gaining access to the crash site pending the arrival of officials from the Accident Investigation Bureau (AIB). [5]She explained that the military plane was initially scheduled to land at the Nigerian Airforce Base in Mando area, but was later diverted to the Kaduna airport due to poor weather conditions. The service life of the aircraft is three years.

[6]The incident happened as the plane was trying to land in bad weather, the military said. [7]President Muhammadu Buhari said that the lack of strict pre-flight inspections was also the cause of this disaster. [8]It was part of the government's plan to boost the military's efficiency in fighting a more than decade-long jihadist insurgency.

Event Type: Air Crash

Event Roles

- ● Date
- ● Location
- ● Casualties and Losses
- ○ Survivors
- ● Investigator of the Accident
- ● Cause of the Accident
- ● Passengers
- ○ Crew
- ● Aircraft Agency
- ○ Flight No.
- ● Service years
- ○ Taking-off Place
- ○ Scheduled Landing Place
- ○ Alternate Landing Place

Figure 1: An example from DocEE. Each document in DocEE is annotated with event type and involved event arguments. In the example, the document mainly describes a *Air Crash* event which contains the following arguments: *Data*,*Location*, *Causality and Losses* and etc. We use different colors to distinguish event arguments.

cEE contains 27,485 document-level events with 180,528 arguments, far exceeding the scale of existing document-level EE datasets. The large-scale annotations of DocEE can provide sufficient training and testing data, to fairly evaluate EE models. 2) Fine-grained argument types. DocEE has a total of 356 argument types, which is much more than the number of argument types in existing dataset (5 in MUC-5 and 65 in RAMS). Besides the general arguments, such as time and location, we design more personalized event arguments for each event type, such as *Water Level* for *Flood* event and *Magnitude* for *Earthquake* event. These fine-grained roles can bring more detailed semantics and pose a higher challenge to the semantic disambiguation ability of existing models. 3) Application-oriented settings. In the actual application, event extraction often face the problems of how to quickly adapt from the rich-resource domains to new domains. Therefore, we have added a cross-domain setting to better test the transfer capability of the EE models. In addition, DocEE removes the limitation that the arguments range should be within a certain window in RAMS, to better cope with realistic scenarios where the length of the article will be particularly long, and the argument of the event may appear in any corner of the article. With more scattered event arguments (see Table 1), DocEE poses a higher challenge to the long text processing capability of existing models.

To assess the challenges of DocEE, we implement 9 recent state-of-the-art EE models on DocEE along with human evaluation. Experiments demonstrate the high-quality of DocEE and show that even the performance of SOTA model is far lower than human performance, showing that the faintness of existing technology in processing document-level EE.

2 Related Datasets

Sentence-level Event Extraction Dataset Automatic Content Extraction (ACE2005)[1] consists of 599 documents with 8 event types and 33 subtypes. Text Analysis Conference (TAC-KBP)[2] also releases three benchmarks: TAC-KBP 2015/2016/2017, with 9/8/8 event types and 38/18/18 event subtypes. RED[3] annotates events from 95 English newswires. Chinese Emergency Corpus (CEC) focuses on Chinese breaking news, with a total of 332 articles in 5 categories. MAVEN (Wang et al., 2020) and LSEE (Chen et al., 2017) only annotate event triggers, with 168/21 types of trigger instances in 11,832/72,611 sentences. Based on them, various superior models have been proposed to improve the sentence-level EE and have achieved great success (Orr et al., 2018; Nguyen and Grishman, 2018; Tong et al., 2020).

Document-level Event Extraction Dataset Most of the existing document-level event datasets only focus on event classification, but lack event argument labelings, such as 20news [4] and THUCNews [5]. There are a few datasets annotated with cross-sentences event arguments. MUC-4 (Nguyen

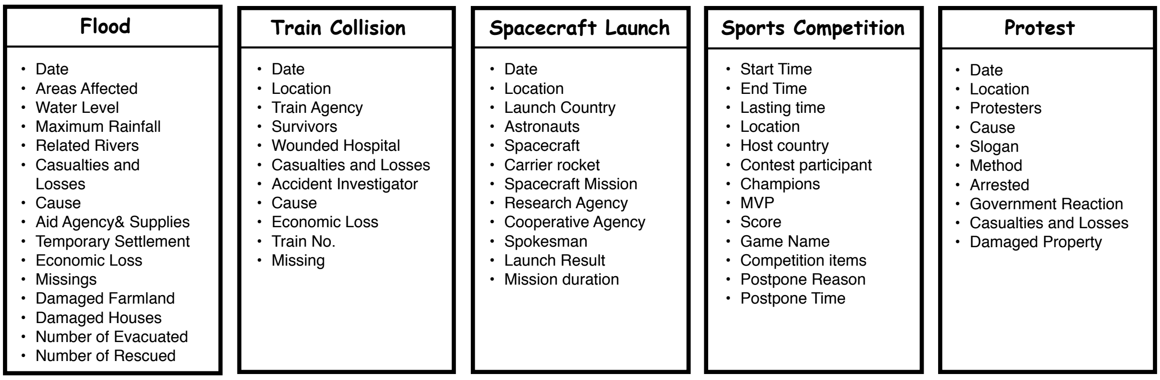

Figure 2: Five examples of event schema in DocEE.

et al., 2016) only contains 4 event types and 5 argument types, and the 4 event types are close to each other and limited to the terrorist attack topic[6]. WikiEvents (Li et al., 2021) and RAMS(Ebner et al., 2020) consist of 246/9,124 documents with only 59/65 argument types, and most of the arguments in the two datasets are shared among different event types without further refinement. Doc2EDAG, TDJEE and GIT (Zheng et al., 2019; Wang et al., 2021; Xu et al., 2021) only define 5 event types and 35 argument types in financial domain. Cancer Genetics, EPM, GENIA2011, GENIA2013, Pathway Curation and MLEE (Pyysalo et al., 2013; Ohta et al., 2011; Kim et al., 2011, 2013; Ohta et al., 2013; Van Landeghem et al., 2013) are limited to the biological domain. In summary, these datasets are either limited to specific domains, or have very limited data scale, or have not carefully refined event argument schema.

Open-domain Event Extraction Dataset To collect EE dataset in open domain, one way is to leverage semi-structured resources (Wikipedia) or existing knowledge bases (Freebase). The representative works are EventKG (Gottschalk and Demidova, 2018), Event Wiki (Ge et al., 2018) and Historical Wiki (Hienert and Luciano, 2012). The other way is to exploit open IE tools, such as dependency parsing, to extract events from unstructured text. The representative works are Event Logic Graph (Ding et al., 2019) and Giveme5W1H (Hamborg et al., 2019). The advantage of the open-domain EE dataset is its large scale, but the disadvantage is that it lacks manual review, and thus the quality cannot be guaranteed.

3 Constructing DocEE

Our main goal is to collect a large-scale dataset to promote the development of event extraction from sentence-level to document-level. In the following sections, we will first introduce how to construct the event schema, and then how to collect candidate data and how to label them through crowdsourcing.

3.1 Event Schema Construction

News is the first-hand source of hot events, so we focus on extracting events from news. Previous event schemas, such as FrameNet (Baker, 2014) and HowNet (Dong and Dong, 2003), pay more attention to trivial actions such as *eating* and *sleeping*, and thus is not suitable for document-level news event extraction.

To construct event schema, we gain insight from journalism. Journalism typically divides events into hard news and soft news (Reinemann et al., 2012; Tuchman, 1973). Hard news is a social emergency that must be reported immediately, such as earthquakes, road accidents and armed conflicts. Soft news refers to interesting incidents related to human life, such as celebrity deeds, sports events and other entertainment-centric reports. Based on the hard/soft news theory and the category framework in (Lehman-Wilzig and Seletzky, 2010), we define a total of 59 event types, with 31 hard news event types and 28 soft news event types. Detailed information is shown in Appendix Table 1. Our schema covers influential events of human concern, such as earthquakes, floods and diplomatic summits, which cannot be extracted at the sentence level and require multiple sentences to describe.

To construct argument schema, we leverage infobox in Wikipedia. As shown in Figure 3(a), the Wikipedia page describes an event, and the keys

---

[6] `https://www-nlpir.nist.gov/related_projects/muc/muc_data/muc_data_index.html`

in the infobox, such as *Date* and *Total fatalities*, can be regarded as the prototype arguments of the event. Based on this observation, we manually collect 20 wiki pages for each event type, and use their shared keys in infobox as our basic set of argument types. After that, we further expand the basic set. Specifically, for event type e, we first collect 20 news stories from New York Times, and then invited 5 students (native English-speaking, major in journalism) to summarize the key facts the public would like to learn from the news of e. For instance, in *Flood* event news, *Water Level* is a key fact, because it is an important factual basis for flood cause analysis and disaster relief decision-making, and can arouse widespread concern. Finally, by merging the key facts of the 5 students, we complete the argument types expansion. To ensure the quality, we further invite the above 5 students to make a trial labeling on the collected news, and filter argument types that appear less frequently in the article.

In total, we define 356 event arguments types for 59 event types. On average, there are 6.0 event arguments per class. Figure 2 illiterates some examples of event arguments types we defined. The complete schema and corresponding examples can be found *Event Schema.md* in the supplementary materials.

3.2 Candidate Data Collection

In this section, we introduce how to collect candidate document-level events. We choose wiki as our annotation source. Wiki contains two kinds of events: historical events and timeline events (Hienert and Luciano, 2012). Historical events refer to the events that have their own wiki page, such as *1922 Picardie mid-air collision*. Timeline events refer to the news events organized in chronological order, such as *A heatwave strikes India and South Asia* in wiki page *Portal:Current_events/June_2010*.[7] Figure 3 shows examples of two events. We adopt both kinds of events as our candidate data, because only using historical events will lead to uneven data distribution under our event schema, and timeline events can be a good supplement.

For a historical event, we adopt its Wikipedia article as the document of the event arguments to be annotated. For a timeline event, we use the URL to download the original news article as the document of the event arguments to be annotated. Because 22% of the timeline events do not have URLs (Wikipedia editors do not provide the URL when editing the entry), so we use Scale SERP[8] to find news articles and manually confirm their authenticity. For historical event, we adopt *templates+event type* as the query key to retrieve candidate events. The templates includes *"List of"+event type*, *event type+"in"+year*, *"Category:"+event type+"in"+country*, etc. More templates show in Appendix Table 7. For timeline event, we choose events between 1980 and 2021 as candidates, because there are very few events before 1980.

In order to balance the length of the article, we filtered out articles less than 5 sentences, and also truncated articles that were too long (more than 50 sentences). Finally, we select 44,000 candidate events from Wikipedia.

3.3 Crowdsourced Labeling

Given the candidate events and the predefined event schema, we now introduce how to annotate them through crowdsourcing. To ensure the quality of annotations, all annotators are either native English speakers or English-major students with TOEFL higher than 100 or IELTS higher than 7.5. The crowdsourced labeling process consists of two stages.

3.3.1 Stage 1: Event Classification

At this stage, annotators are required to classify candidate events into predefined event types. Following (Hamborg et al., 2018; Hsi, 2018), we focus on main event classification, so Stage 1 is a single-label classification task. Specifically, the main event refers to the event reflected in the title and mainly described in the article. Formally, given the candidate event $e =< t, a >$, where t represents the title and a represents the article, Stage 1 aims to obtain label y for each e, where y belongs to the 59 event types defined in subsection 3.1.

In total, we invite about 60 annotators to participate in Stage 1 annotation. The online annotation page is displayed in Appendix Figure 5. We first manually label 100 articles as standard answers to *pre-test* annotators, and weed out annotators with an accuracy rate of less than 70%, which left us 48 valid annotators. Then, we ask two independent annotators to annotate each candidate event. If the results of the two annotators are inconsistent

1922 Picardie mid-air collision

From Wikipedia, the free encyclopedia

Coordinates: 49°38′00″N 01°56′49″E

The **1922 Picardie mid-air collision** took place on 7 April 1922 over Picardie, France, involving British and French passenger-carrying biplanes. The midair collision occurred in foggy conditions. A British aircraft flying Croydon – Paris with only mail on board impacted a French aircraft flying three passengers Paris – Croydon, which resulted in seven deaths.

1922 Picardie mid-air collision

Accident	
Date	7 April 1922
Summary	Mid-air collision in fog
Site	Thieuloy-Saint-Antoine, Picardie, France 49°38′00″N 01°56′49″E
Total fatalities	7 (all)
Total survivors	0

June 3, 2007 (Sunday)

- A Paramount Airlines helicopter crashes in Sierra Leone, killing 22 people, with reports of at least one survivor. (BBC) (Reuters AlertNet)
- 2007 North Lebanon conflict: Soldiers and Islamist militants clash at a second Palestinian refugee camp in Lebanon. (BBC)

Sierra Leone air crash kills 19

A helicopter ferrying passengers to Freetown airport in Sierra Leone has crashed, killing 19 people, including Togo's Sports Minister Richard Attipoe.

The passengers were returning from watching Togo beat Sierra Leone 1-0 in an African Nations Cup qualifier.

The helicopter shuttle to the airport takes seven minutes

One of the two Ukrainian pilots survived when the helicopter burst into flames as it came into land.

Helicopters and ferries are the only way to reach the airport, which is located across a bay from Freetown.

The Togolese passengers had chartered the helicopter for the seven-minute flight from the city to the airport.

(a) Historical Event

(b) Timeline Event

Figure 3: Two sources of candidate events in DocEE. The left is a historical event, which has its own wiki page, and the right are two timeline events arranged in a wiki page by time unit. Each timeline event consists of a brief description and a URL pointing to original news.

(32.8% in this case), a third annotator will be the final judge. Due to the variety of event types in reality, a candidate event may not belong to any predefined class. We classify such event into the other class, which accounts for 23.6% of the total data.

3.3.2 Stage 2: Event argument Extraction

At this stage, annotators are required to extract event arguments from the whole article. Formally, given the candidate event $e =< t, a >$, its event type y and the predefined argument types R of y, Stage 2 aims to find all the arguments from the article a.

Due to the heavy workload in Stage 2, we invite more than 90 annotators. An example of the online annotation page is shown in Appendix Figure 6. We use a *preliminary annotation - multiple rounds inspection* method for labeling. In the preliminary annotation step, each article will be labeled by an annotator. We distribute no more than two event types to each annotator in this step to make the annotators more focused. Then, in the step of multiple rounds inspection, we first select high-precision annotators based on inter-annotator agreement to form a reviewer team (44.4% of the total), and then each article will go through three rounds of error correction by three independent annotators in the reviewer team. After each round, we will feed back annotation issues to the reviewers so that they can correct them in the next round of annotation. The accuracy rate has steadily increased from 56.24%, 76.83% to 85.96% after each round, which shows the effectiveness of our labeling method. We take the third round results as the final annotations.

We clarify some annotation details here. We do not include articles, prepositions in our annotations. For instance, we select "damaged car" among "damaged car", "damaged car belonging to the victim" and "the damaged car". For event arguments with multiple mentions in the document, for example, *Cause of the Accident* in Figure 1 that has two mentions, we will label all mentions to ensure the completeness of the extraction. For repeated mentions that refer to the same entity, we only label once.

3.3.3 Annotation Quality & Remuneration

Following (Artstein and Poesio, 2008; McHugh, 2012), we use Cohen's kappa coefficient to measure the Inter-Annotator Agreement(IAA). The IAA scores are 94% and 81% for State 1 Event Classification and Stage 2 Event Argument Extraction respectively, which are relatively high. The annotators spend an average of 0.5 minutes labeling a piece of data in Stage 1, so we pay them 0.1$ for each piece of data. It takes about 5 minutes to label a piece of data in Stage 2 , so we pay 0.8$ for each piece of data.

4 Data Analysis of DocEE

In the section, we analyze various aspects of DocEE to provide a deep understanding of the dataset and the task of document-level event extraction.

Overall Statistic In total, DocEE labels 27,485 valid document-level events and 180,528 event arguments. Each article is annotated with 6.6 event arguments on average. Event *Famous Person - Divorce* has the highest average number of event arguments per article (18.1), while event *Regime Change* has the lowest average number of event arguments per article (3.8). We compare DocEE to various representative event extraction datasets in Table 1, including sentence-level EE datasets

Datasets	#isDocEvent	#EvTyp.	#ArgTyp.	#Doc.	#Tok.	#Sent.	#ArgInst.	#ArgScat.
ACE2005	✗	33	35	599	290k	15,789	9,590	1
KBP2016	✗	18	20	169	94k	5,295	7,919	1
KBP2017	✗	18	20	167	86k	4,839	10,929	1
MUC-4	✓	4	5	1,700	495k	21,928	2,641	4.0
WikiEvents	✓	50	59	246	190k	8,544	5,536	2.2
RAMS	✓	139	65	9,124	957k	34,536	21,237	4.8
DocEE(ours)	✓	59	356	27,485	16,268k	749,568	180,528	10.2

Table 1: Statistics of EE datasets (isDocEvent: whether the event in the corpus at the document-level, EvTyp.: event type, ArgTyp.: event argument type, Doc.: document, Sent.: sentence, ArgInst.: event arguments, ArgScat.: the number of sentences in which event arguments of the same event are scattered)

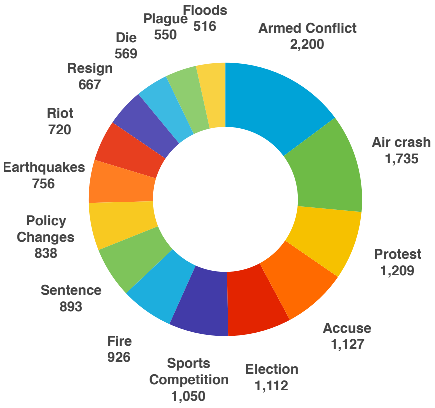

Figure 4: Top 15 event types in DocEE.

ACE2005, KBP and document-level EE dataset MUC-4, Wikievents, RAMS. We find that DocEE is much larger than existing datasets in many aspects, including the documents number and argument instances number. Compared to MUC-4, DocEE has far more event arguments (180,528 compared to 2,641). The reason is that among the 1,700 documents in MUC-4, 47.4% of articles are not labeled with any event argument, while DocEE guarantees that each article contains at least three event argument labels in crowdsourcing process, which greatly solves the problem of data scarcity of the event arguments in document-level EE.

Event Type Statistic Figure 4 shows the distribution of the top 15 frequent event types that have the most number of instances in DocEE. DocEE covers a variety of event types, including Armed Conflict (8.0%), Air crash (6.3%), Protest (4.4%), CommitCrime - Accuse (4.1%), Election (4.0%), Sports Competition (3.8%), Fire (3.4%), etc. Our annotated data follows a long-tailed distribution, which is due to the uneven distribution of class in the real data. According to statistics, there are 30.5% of classes with more than 500 instances and 83.1% of classes with more than 200 instances. More detailed information is shown in Appendix Table 6.

Event Arguments Statistic We randomly sample 1000 articles from DocEE for manual analysis, which contains a total of 4962 event arguments instances. We first classify event arguments based on their mention numbers. As shown in Table 2, 78.6% of the event arguments have a unique mention, and 21.4% of the event arguments have multiple mentions, which poses a great challenge to the model's recall capability. Then, we classify event arguments based on their mention lengths. 60.8% of the event arguments have no more than 3 words, and most of them are named entities such as person and location. While 30.8% event arguments have less than 10 words and 8.4% event arguments are answered by more than 10 words, such event arguments mainly include *Cause of the Accident*, *Investigation Results* , etc.

5 Experiments on DocEE

In this section, we show the challenges of DocEE by conducting comprehensive experiments on various SOTA models. We first introduce two benchmark settings, and then we conduct experiments on both event classification task and event argument extraction task. Finally, we discuss possible future research directions for document-level event extraction.

Benchmark Settings We design two benchmark settings for evaluation: normal setting and cross-domain setting. In the normal setting, we hope the training set and test set to be identically distributed. Specifically, for each event type, we randomly select 80% of the data as the training set, 10% of the data as the validation set, and the remaining 10% of the data as the test set.

Table 2: Answer types of event arguments in DocEE.

Answer Types	**%**	**Examples**
Single Answer	78.6	A masked man in a black hoodie showed a **gun** and was handed money before running east on Warren Street, according to the initial report. Argument Type: Bank Robbery Argument: Weapon Used
Multiple Answers	21.4	At around 6:20 a.m. **a lorry**, driven by David Fairclough of Wednesfield, rammed into the rear of **a tanker**, which then struck **a car** in front and exploded. The ensuing pile-up involved **160 vehicles** on a 400-yard (370 m) stretch of the motorway. Argument Type: Road Crash Argument: Number of Vehicles involved in the Crash

In order to be application-oriented, we design cross-domain setting to test the transfer capability of the SOTA models. We choose the event type under the subject of natural disasters as the target domain, including Floods, Droughts, Earthquakes, Insect Disaster, Famine, Tsunamis, Mudslides, Hurricanes, Fire and Volcano Eruption, and adopt the remaining 49 event types as source domains. The division reduces the overlap of argument types between the source domain and the target domain. In this setting, the models will first be pre-trained on the source domain, and then conduct 5-shot fine-tuning on the target domain. The detailed data split for each setting is shown in Table 3.

Method	Normal			Cross-Domain		
	Train	Dev	Test	Train	Dev	Test
#EvTyp.	59	59	59	59	10	10
#Doc.	22k	2.7k	2.7k	23.7k	1.6k	2.0k
#ArgInst.	141k	19k	19k	156k	11k	13k

Table 3: Statistics for two benchmark settings (Sec.5): normal and cross-domain.

Hyperparameters We use base version of pre-trained model for all the transformer-based methods, and set the learning rate to 2e-5. The batch size is 128 and the maximum document length is 512. All baselines are implemented by HuggingFace[9] with default parameters and all models can be fit into eight V100 GPUs with 16G memory. The training procedure lasts for about a few hours. For all the experiments, we report the average result of five runs as the final result. In human evaluation, we randomly select 1,000 document-level events and invite three students to label them. The final result is the average of their labeling accuracy.

5.1 Event Classification

Baselines We adopt a CNN-based method and various pre-trained transformer-based methods as our baselines, including: 1) **TextCNN** (Kim, 2014) uses different sizes CNN kernels to extract key information in text for classification. 2) **BERT** (Devlin et al., 2018) exploits unsupervised objective functions, masking language model (MLM) and next sentence prediction for pre-training. 3) **ALBERT** (Lan et al., 2020) proposes a self-supervised loss to improve inter-sentence coherence in BERT. 4) **DistilBert** (Sanh et al., 2019) combines language modeling, knowledge distillation and cosine-distance losses to improve BERT. 5) **RoBERTa** (Liu et al., 2019) is built on BERT and trains with much larger mini-batches and learning rates. Following (Kowsari et al., 2019), we use Precision(P), Recall(R) and Macro-F1 score as the evaluation metrics.

Method	Normal			Cross-Domain		
	P	R	F	P	R	F
TextCNN	78.6	75.4	76.2	8.5	2.1	2.6
BERT	89.3	89.8	89.5	72.6	78.4	75.4
ALBERT	88.8	88.9	88.1	25.5	21.3	23.2
DistilBert	89.6	90.7	90.1	79.8	79.6	79.7
RoBERTa	90.0	91.1	90.5	86.0	86.7	86.3
Human	98.4	97.7	98.0	-	-	-

Table 4: Overall Performance on Event Classification.

Overall Performance Table 4 shows the experimental results under the normal and cross-domain settings, from which we have the following observations: 1) Compared with TextCNN, transformer based models (BERT, ALBERT, DistillBert, RoBERTa) perform better, which are pre-trained on a large-scale unsupervised corpus and have more background semantic knowledge to rely on. 2) Humans have achieved high scores on DocEE, verifying the high quality of our annotated data sets. 3) There is still a gap between the performance of the current SOTA models and human beings, which indicates that more technological advances are needed in future work. Humans can connect and merge key information to form a knowledge

Table 5: Overall Performance on Event argument Extraction(%).

network to help them understand the main event, while deep learning models typically fail in long text perception. 4) There is a performance degradation from the normal setting to the cross-domain setting, which shows that domain migration is still a huge challenge for current SOTA models. Among the pre-trained baselines, ALBERT's performance drops the most. The reason may be that the parameter scale in ALBERT is relatively small, and the reserved source domain knowledge is limited.

5.2 Event argument Extraction

Baselines We introduce the following mainstream baselines for evaluation: 1) **BERT_Seq** (one of the baseline in Du and Cardie (2020a)) uses the pre-trained BERT model to sequentially label words in the article. Given the input article $A = \{w_1, w_2, \ldots, w_n\}$, the output of Sequence Labeling Methods is $O = \{r_1, r_2, \ldots, r_n\}$, where $r \in R$ and R is the set of the argument types. 2) **MG-Reader** (Du and Cardie, 2020a) improves document-level EE by proposing a novel multi-granularity reader to dynamically aggregate information in sentence and paragraph-level. 3) **DocEDAG** (Zheng et al., 2019) generates an entity-based directed acyclic graph for document-level EE. 4) **BERT_QA**(Du and Cardie, 2020c) uses the argument type as question to query the article for answer. Given the input article A, the argument type $r \in R$ as the question, the output is $O = \{start_r, end_r\}$. We give -1 for these not mentioned event arguments. 5) **Ontology_QA**. Following Vargas-Vera and Motta (2004), we refine the initial query in BERT_QA with argument ontology knowledge obtained from Oxford dictionary (Dictionary, 1989).

Considering the length limitation of pre-trained models, we split the article in three different ways. (Sent) means to split the article by sentence[10]. (Chunk) means to split the article by every 128 tokens (default). (Doc) means no splitting. We adopt Longformer (Beltagy et al., 2020) as encoder for the *(doc)* baseline, and BERT-base for the other baselines.

Following prior work (Du and Cardie, 2020b), we use Head noun phrase Match (HM) and Exact Match (EM) as two evaluation metrics. HM is a relatively relaxed metric. As long as the head noun of the predicted result is consistent with the golden label, it will be judged as correct. While EM requires that the prediction result is exactly the same as the gold label, which is relatively stricter.

Overall Performance As shown in Table 5, there is a big gap between the performance of SOTA models and human performance (41.0% Vs 85.9% in F score), indicating that document-level event argument extraction remains a challenge task.

The failure of existing baselines may be due to two reasons. One possible reason is the catastrophic forgetting in neural networks. Compared to NER and sentence-level EE, document-level EE (our task) highlights the model's capability to process long texts: the model has to read the entire text before determining the argument type of a span. Although a few models have been proposed to improve the long text capabilities of pre-trained models (such as longformer), and have achieved good results, (the performance of long-former (BERT_Seq(doc)) is superior to BERT_Seq(sent) and BERT_Seq(chunk) as shown in Table 5), but these models still have a big performance gap compared with human beings.

Another reason is that existing baselines suffer from the inferior capability in semantic understanding, which is reflected in two aspects: 1) EE models

---

[10] https://www.nltk.org/api/nltk.tokenize.html

fail to distinguish arguments of similar events. For instance, the article mainly describes *the 2021 U.S. Alaska Peninsula earthquake*, and also briefly mentions *2008 Wenchuan earthquake*. When asking the *Date* of the main event, EE models are easy to confuse the correct answer 2021 with the wrong answer 2008. 2) EE models often mistake unrelated entities for event arguments. For example, when extracting the event argument *Attack Target* in the *the 911 terrorist attack on the Pentagon* event, except to the correct answer *the New York Pentagon*, EE models often mistake other unrelated location entities in the article (such as *Mount Sinai Hospital*) as one of the answers.

We believe that the following research directions are worthy of attention: 1) Exploring pre-trained models with stronger long text processing capabilities. 2) Exploiting ontology and commonsense knowledge to improve the semantic understanding of EE models. In the future, we will focus on promote event extraction to a higher level, such as cross-document level.

6 Conclusion

In this paper, we present DocEE, a large-scale document-level EE dataset to promote event extraction from sentence-level to document-level. Comparing to existing datasets, DocEE greatly expands the data scale, with more than 27,000+ events and 180,000+ arguments, and contains more refined event arguments. Experiments show that DocEE remains an open issue.

Read the following news and classify the event

One killed, two injured in collapse at Knox County mine

KNOXVILLE, Tenn. (WATE) — One miner was killed and two other miners were injured in a collapse at a mine in Knox County Tuesday afternoon. Rural Metro Fire, Knox County Rescue, and American Medical Response responded to the Nyrstar Mine in Mascot on Tuesday. Rural Metro spokesperson Jeff Bagwell confirmed one person was killed in the collapse. Two injured workers were brought to the surface by mine rescue personnel. They were transported to a local hospital for treatment. The conditions of the injured miners were not immediately available. Nyrstar operates a processing plant and three underground zinc mines in East Tennessee: Young, Coy and Immel. The three mines are located in and around Knox and Jefferson Counties. Trailer tow hitch blamed for fatal mining accident in Jefferson County

参考文本 Pretoria Pit disaster

标注文本 The Pretoria Pit disaster was a mining accident on 21 December 1910, when an underground explosion occurred at the Hulton Colliery Bank Pit No. 3, known as the Pretoria Pit, in Over Hulton, Westhoughton, then in the historic county of Lancashire, in North West England. A total of 344 men and boys lost their lives. There were approximately 2,400 workers employed by the Hulton Colliery Company in 1910. On the morning of 21 December, approximately 900 workers arrived for the day shift. They were working five coal seams of the Manchester Coalfield; the Trencherbone, Plodder, Yard, Three-Quarters and Arley mines. [1] At 7:50am, there was an explosion in the Plodder Mine, which was thought to have been caused by an accumulation of gas from a roof collapse the previous day. [1] That day 349 workers descended the No 3 bank pit shaft to work in the Plodder, Yard and Three Quarters mines. Of those, only four survived to be brought to the surface. One died immediately and one the next day. The two survivors were Joseph Staveley and William Davenport. In addition one man died in the Arley Mine of No. 4 Pit, bringing the total to 344. There was a final fatality that day, William Turton, who died while fighting a fire in No. 3 pit. The men who were working the other mines in the pit worked from No.4 shaft were unharmed. [1] It was the second-worst mining accident in England, and the third-worst in Britain; after the Oaks Colliery explosion and Senghenydd Colliery Disaster. [citation needed] Many of the fatalities were from the same family. The worst affected was the Tyldesley family in which Mrs Miriam Tyldesley lost her husband, four sons and two brothers. A relief fund was established for the families and dependants and a total of £145,000 was raised. [1] In 1911, dependants were compensated and given annuities from a number of sources (including the fund). All the victims were members of Permanent Relief Societies to which they paid contributions weekly and most had private life insurance with friendly societies and all were covered by the Workmen's Compensation Act 1906 which brought together all (except the private insurance) the compensation to produce a lump sum and annuity for the dependants. [2] John Baxter was the last recipient of payments from the Hulton Colliery Explosion (1910) Relief Fund when he died in January 1973. [3] The fund was dissolved in 1975 and the remaining assets transferred to other miners' relief funds. [citation needed] There is a memorial to the victims in Westhoughton cemetery. A memorial service is held there each year and a selection of artifacts from the disaster is displa

Abstract

Cross-lingual natural language processing relies on translation, either by humans or machines, at different levels, from translating training data to translating test sets. However, compared to original texts in the same language, translations possess distinct qualities referred to as translationese. Previous research has shown that these translation artifacts influence the performance of a variety of cross-lingual tasks. In this work, we propose a novel approach to reducing translationese by extending an established bias-removal technique. We use the Iterative Null-space Projection (INLP) algorithm, and show by measuring classification accuracy before and after debiasing, that translationese is reduced at both sentence and word level. We evaluate the utility of debiasing translationese on a natural language inference (NLI) task, and show that by reducing this bias, NLI accuracy improves. To the best of our knowledge, this is the first study to debias translationese as represented in latent embedding space.

1 Introduction

"Translationese" refers to features in (professional human or machine) translated text that distinguishes it from non-translated, original text in the same language. Carriers of translationese include lexical and word order choices that are influenced by the source language (Gellerstam, 1986), as well the use of more explicit and standardised constructions (Baker et al., 1993) compared to original text. Translationese has a significant impact in machine translation evaluation. Toral et al. (2018) found that translating source sentences that are already the result of translation are easier to translate than original sentences. Similarly, Edunov et al. (2020) show that back-translation results in large BLEU scores when translationese is on the source side and original text is used as reference. To avoid such artifacts, it is advised to use original source sentences for machine translation evaluation (Zhang and Toral, 2019; Graham et al., 2020). Riley et al. (2020) train sentence-level classifiers to differentiate translationese from original target text, and then use this classifier to tag the training data for an NMT model to produce output that shows fewer translationese effects. Translation-inherited artifacts have been shown to have significant impact on other tasks as well. For example, Singh et al. (2019) show that substituting segments of original training samples by their translations from another language improves performance on natural language inference (NLI) tasks. Clark et al. (2020) introduce a translation-free Question Answering dataset to avoid having inflated gains from translation artifacts in transfer-learning tasks. Artetxe et al. (2020) show that cross-lingual models suffer from induced translation artifacts when evaluated on translated test sets. These examples motivate the need for reducing translation artifacts.

While a number of methods to remove or attenuate human-like biases (e.g., gender, race, etc.) in both static and contextualised word embeddings have recently been proposed (Bolukbasi et al., 2016; Gonen and Goldberg, 2019; Dev and Phillips, 2019; Ravfogel et al., 2020; Liang et al., 2020; Zhou et al., 2021), attenuating and eliminating a more implicit signal like translationese in embeddings has yet to be studied. Translationese signals are complex and multi-faceted and, unlike e.g. gender and profanity, can in general not be captured in terms of simple lists of contrastive word pairs (woman-man, she-he, etc.), but rather manifest as a complex mix of morphological, lexical, syntactic and semantic phenomena. Our study is a first attempt to directly debias translationese encoded as latent representations, based on the recently proposed Iterative Nullspace Projection (INLP) algorithm (Ravfogel et al., 2020).

The main contributions of our work are as follows. (i) We propose to reduce the bias induced

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics:
Human Language Technologies, pages 3983 - 3991
July 10-15, 2022

by translation by extending the INLP approach to translationese debiasing at both the word and sentence level, with findings demonstrating that our debiasing approaches can effectively attenuate translationese biases in both static word embedding spaces as well as sentence representations based on contextualised embeddings. (ii) We use the INLP method with a number of neural sentence-level translationese classification architectures (fastText, mBERT, XLM), and propose two alternative methods for detecting explicit translationese bias in word embeddings, and find that after debiasing, the models' performance on classifying translationese degrades to that of a random classifier. (iii) Finally, by integrating the proposed debiasing method within the NLI task, we show the effect of translation artifacts and their removal on the task.

2 Debiasing Strategies

Much previous research (Bolukbasi et al., 2016; Zhao et al., 2018; Dev and Phillips, 2019; Ravfogel et al., 2020) focuses on eliminating bias in word embeddings. However, existing models use lists of contrastive word pairs (e.g., woman-man, she-he) to detect, capture and mitigate specific biases (e.g., gender, profanity, etc.). While translationese cannot, in general, be captured in simple lists of contrastive word pairs, we do have labeled data at sentence level: translated (translationese) and original sentences. We use this data and the INLP algorithm to directly mitigate translationese at sentence level (Section 3). Additionally, we explore INLP at word level to debias translationese in Section 4. Only a few earlier studies (Dutta Chowdhury et al., 2020, 2021) deal with translationese at the level of word embedding spaces leveraging distances between graph-based representations of original and translationese data. For debiasing word embedding spaces, we adapt an idea from Gonen et al. (2020) to extract lists of pairs of identical words and examine how their use differs in translationese and original data (rather than contrasting word pairs). If a word is used very differently in translated and original data, this is reflected in differences in original and translated word embedding spaces, and is evidence of translationese in the embeddings. Alternatively, we propose a simpler approach that builds on a joint embedding space where words are tagged according to their origin (translationese or original) and without any need for a word list.

The **Iterative Nullspace Projection algorithm** (Ravfogel et al., 2020) focuses on removing linearly decipherable features from vector representations originally for gender bias mitigation. Given a set of labeled data with data points $X = x_1, ..., x_n$ and task labels $Y = y_1, ..., y_n$, we use a standard classification setup with a neural network and a simple classifier τ on top. An encoder h encodes x_k into a representation vector $h(x_k)$ and τ predicts y_k based on $h(x_k)$, i.e., $y_k = \tau(h(x_k))$. Let T be the trait to be mitigated, also known as the *protected attribute*. The goal of the INLP method is to neutralise the ability of the classifier τ to linearly predict T from h. τ is parameterised by a matrix W and trained to predict T from h. Using W, one can collapse the data onto its nullspace $N(W)$ with a projection matrix $P_{N(W)}$. This guarantees $WP_{N(W)}h(T) = 0$, i.e., the information used to classify T is linearly removed. By repeating this process i times until no classifier achieves above-majority accuracy, INLP can neutralise all features that W_i uses for predicting T from $\tilde{h}$:

$$\tilde{h} := P_{N(W_1)}P_{N(W_2)}...P_{N(W_i)}h \quad (1)$$

Details of the implementation are the same as in Ravfogel et al. (2020). [1]

3 Translationese in Sentence Embeddings

In our work, we are interested in adapting INLP to study the impact of removing the translationese attributes T from semantic representations, via a binary classification task. Specifically, the binary classifier learns to distinguish between original and translationese sentences. Therefore, in our setup, labels Y correspond to original and translationese and act as protected attributes.

Data. We use the Europarl corpus annotated with translationese information from Amponsah-Kaakyire et al. (2021). We focus on three languages: English (En), German (De) and Spanish (Es). The corpus provides originals in the three languages (L1) and translations into these three languages that come from original texts in the other two (L2). We use the notation L1–L2 to refer to the different sets in Table 1 and Table 2. For example, in En-De, L2 refers to English text translated from German. For each corpus, there is an equal number of translated and original sentences: 42k for

	fastText Text	**mBERT** `CLS`	**mBERT** *pool*	**XLM** `CLS`	**de-biased**
En-De	0.64	0.73	0.79	0.71	0.50
En-Es	0.71	0.78	0.83	0.77	0.50
De-En	0.68	0.78	0.84	0.77	0.50
De-Es	0.69	0.79	0.86	0.79	0.50
Es-De	0.71	0.77	0.85	0.77	0.50
Es-En	0.72	0.76	0.82	0.77	0.50

Table 1: Sentence Embedding Classification accuracy on original versus translationese using different models. After INLP debiasing, translationese classification reduces to random 50% accuracy in all cases.

De–En, De–Es, En–De, En–Es, Es–De and Es–En. We use 70% of the sentences for training, 15% for development and 15% for testing.

Classifier. We use a logistic classifier on top of sentence embeddings h obtained with 4 models without any additional fine-tuning to the translationese classification task. (i) fastText (Joulin et al., 2016): we compute an average of all token vectors in the sentence. (ii) mBERT$_{\texttt{CLS}}$ (Devlin et al., 2019): we use the `[CLS]` token in mBERT as sentence representation. (iii) mBERT$_{pool}$ (Devlin et al., 2019): we use mean pooling of mBERT's contextualised word embeddings. (iv) XLM$_{\texttt{CLS}}$ (Conneau et al., 2020): we use the `[CLS]` token from XLM-RoBERTa.

Results. The first four columns in Table 1 summarise the translationese classification accuracy achieved by the four models. mBERT$_{pool}$ achieves the best performance for all languages, while fastText trails the pack. The final column in Table 1 shows that INLP is close to perfection in removing translationse signals for the linear classifiers, reducing accuracy to a random 50%.

4 Translationese in Word Embeddings

Unlike sentence-level debiasing, word-level debiasing needs a seed translationese direction to obtain a debiased space. This is challenging for translationese as unlike, e.g. gender and profanity, translationese cannot in general be captured in terms of simple contrastive word pairs. In what follows, we introduce two approaches for debiasing translationese at the level of word embeddings.

Stepwise Aligned Space Projection. In order to estimate the seed translationese direction, we derive a list of words (G) used differently in translationese T and original O data using the *usage change* concept from Gonen et al. (2020). The same word used in different data sets (original and translated) is likely to have different neighbours in the two embedding spaces. We only use words from the intersection of both vocabularies O and T. We compute the score for context change across the embeddings $\mathcal{O}$ and $\mathcal{T}$ of the two data sets by considering the size of the intersection of two sets where each word in a corpus is represented as its top-k nearest neighbors (NN) in its embedding space:

$$score^k(w) = -|\mathrm{NN}^k_{\mathcal{O}}(w) \cap \mathrm{NN}^k_{\mathcal{T}}(w)| \qquad (2)$$

where $\mathrm{NN}^k_i(w)$ is the set of k-NN of word w in embedding space i. The smaller the size of the intersection, the more differently the word is used in the two data sets (and words with the smallest intersection can be seen as indicators of translationese). Given $\mathcal{O}$ and $\mathcal{T}$, we collect a ranked list of about 500 words with the smallest intersection as our translationese word list G. G allows us to identify the seed translationese direction for INLP. In our experiments we only consider words attested at least 200 times in the data. Appendix A.3 shows the top 50 elements for all the word lists. In our experiments, we use the translated and original parts of the data described in Section 3 to estimate the word embeddings $\mathcal{O}$ and $\mathcal{T}$ and use k=1000 nearest neighbours in Equation 2. Following Gonen et al. (2020), a large value of k results in large neighbors sets for each word in the two corpora, resulting in a more stable translationese wordlist G.

Next, we create a joint word embedding space $\mathcal{J}$ from the concatenation of the translated and original data, T and O. Since this joint space $\mathcal{J}$ includes both original and translationese signals, we then align the previously unrelated $\mathcal{O}$ and $\mathcal{T}$ spaces to this embedding space $\mathcal{J}$, using VecMap (Artetxe et al., 2018), producing aligned spaces $\tilde{\mathcal{O}}$ and $\tilde{\mathcal{T}}$, and resulting in an extended single embedding space where $\mathcal{T}$ and $\mathcal{O}$ are aligned to $\mathcal{J}$. Next, we compute the translationese direction v of the same word w in the two embeddings spaces, $\tilde{\mathcal{O}}$ and $\tilde{\mathcal{T}}$, using,

$$v := \tilde{\mathcal{T}}[w] - \tilde{\mathcal{O}}[w], \forall w \in G \qquad (3)$$

Finally, we compute the similarity of words in $\mathcal{J}$ along the directions v and $-v$, to divide them into two subspaces , translationese and non-translationese, respectively. Using Equation 3, we initialise the INLP algorithm in two ways: (i) **INLP.single**: with a direction vector created from the difference between two aligned spaces for the highest ranked word in G, and (ii) **INLP.avg**: by averaging the differences of all words in G.

	Direct Joint	Stepwise Aligned		de-biased
		INLP.Single	INLP.Avg	
En-De	0.98	0.99	1.00	0.50
En-Es	0.92	1.00	1.00	0.50
De-En	0.96	1.00	0.99	0.50
De-Es	0.91	1.00	1.00	0.50
Es-De	0.93	0.99	0.99	0.50
Es-En	0.95	1.00	1.00	0.50

Table 2: Classification accuracy on original versus translationese with word embeddings using our two approaches, before and after debiasing with INLP.

Direct Joint Space Projection. In this approach, we directly build the embeddings of a specific word w from $\mathcal{O}$ and $\mathcal{T}$ into the same space $\mathcal{J}'$ by annotating w as either w_o and w_t on surface in the O and T data. In this way we can easily track and distinguish the two embeddings of the same word w coming from O and T data in the same embedding space $\mathcal{J}'$ resulting from the simple concatenation of two datasets. This eliminates the need to compute the translationese direction vector v to group the subspaces and the complexity of maintaining and aligning $\mathcal{O}$, $\mathcal{T}$, $\mathcal{J}$, $\tilde{\mathcal{O}}$ and $\tilde{\mathcal{T}}$ spaces. Figure 1 in Appendix A.2.2 shows the t-SNE projection (Van der Maaten and Hinton, 2008) of the tagged tokens before and after debiasing.

Results. We compare the performance before and after debiasing using our two word-level debiasing methods in Table 2. As expected, debiasing reduces classification accuracy for all language pairs from ∼100% to ∼50% for both methods.

Translationese Word Lists. The content of our extracted translationese word lists depends on the language (see Appendix A.3). For Es, punctuation is clearly used differently in originals and translations into Es. For De, pronominal adverbs play an important role, especially when translations come from Es. For En, there is no clear trend but, interestingly, only one word in the top-50 list (*indeed*) overlaps with the words with a highest difference in frequency of usage in the original and translationese corpus as analysed for Europarl in Koppel and Ordan (2011). The number of times and the context where a word appears may reflect two different aspects of translationese.

5 Application to NLI

In order to investigate the impact of removing translationese artifacts from the translated data we analyse its impact on the NLI task, where machine translation is used. NLI predicts the relationship between two sentences, premise and hypothesis, and classifies it into one of the three categories —entailment, contradiction, or neutral. Recently, Artetxe et al. (2020) showed that, in the existing NLI datasets, there exists a significant lexical overlap between the premise and the hypothesis, which is utilised by neural NLI models to make predictions with high accuracies. However, when the premise and hypothesis are paraphrased independently using translation and back-translation, lexical overlap is reduced, negatively impacting the performance of the models.

Below we test whether and if so, to which extent our INLP-based translationese debiasing approach can avoid the observed performance loss in the back-translated NLI task. We generate Back-Translated (BT) NLI dataset by independently translating premise and hypothesis from the Original SNLI data. Then, we train two NLI models, one on Original and one on BT data. To reduce the translationese artifacts resulting from back-translation, we apply the sentence and word embedding debiasing strategies as described in Sections 3 and 4 over the embeddings generated from BT data, and use the resulting debiased-BT embeddings to train a third debiased NLI model in Table 3.

Finally, we consider two scenarios to evaluate translationese debiasing - (i) Symmetric `[Sym]`: where Original is tested with original test set, and BT and debiased NLI models are tested with BT test data and (ii) Asymmetric `[Asym]`: where all these models are tested with original test data. We use (i) to see whether debiasing the model trained on translated train-test can bring its performance closer to that of model trained on original train-test data. In (ii), we examine the asymmetry between original test data and BT-NLI training data, and whether our translationese debiasing of BT training data can offset this asymmetry and improve NLI performance. Table 3 shows the classification accuracies with respect to (i) and (ii).

Data. The large-scale SNLI dataset (Stanford Natural Language Inference) (Bowman et al., 2015) contains 570k sentence pairs in the training set manually classified as entailment, contradiction, or neutral. We use a subset of 10% of the training data for our experiments. The development and test data are used as in the original SNLI splits (each containing 10k examples). We generate a back-translated variant of the training and test data using German (De)

Approach	Test Data	SNLI Model		
		Original	Back-translated	debiased
Word-Joint	`Sym`	67.2±0.1	64.1±0.2	64.7±0.1
	`Asym`		64.4±0.2	65.1±0.1
Word-Aligned	`Sym`	67.8±0.1	64.3±0.2	64.8±0.2
	`Asym`		64.9±0.2	65.3±0.1
Sentence	`Sym`	65.6±0.0	58.4±0.0	60.1±0.0
	`Asym`		63.5±0.0	64.9±0.0

Table 3: Test set accuracies (3 runs mean) of our three NLI models in Symmetric and Asymmetric settings.

as the pivot language. For translation, we use the pre-trained models of Facebook-FAIR's WMT-19 news translation task submission (Ng et al., 2019).

Models. We train three different NLI models, each for original, back-translated and debiased versions of back-translated embeddings. For the word-level setup, we use a single hidden BiLSTM layer followed by a standard feedforward output layer on top of frozen fastText word embeddings for the 3-class NLI classification. The computation of word embeddings and debiasing follows the setup described in Section 4. For sentence-level debiasing, we use the BERT$_{pool}$ method explained in Section 3 with a linear SVC on top to predict the labels.

Results. Table 3 shows results consistent with Artetxe et al. (2020), in that models trained on Original data outperform models trained on BT data in both `Sym` and `Asym` scenarios. Table 3 also shows that, after translationese debiasing, classification accuracy on SNLI-debiased improves modestly for all models, with only a minor improvement at word-level, and larger improvement at the sentence level. Overall this may be due to the fact that translationese is a combination of lexical and syntactic phenomena that is better captured at sentence-level. Results in Table 3 suggest that debiasing translation artifacts helps in reducing the asymmetry between translated train and original test set. Therefore, rather than translating the entire test set to match the training set in transfer-learning tasks, debiasing the training set for translation artifacts is a promising direction for future work. Finally, for a complex task such as translationese debiasing, linear intervention alone may not be sufficient. As a result, non-linear guarding approaches need to be investigated further.

6 Conclusion

In this work, we remove translationese artifacts by extending the debiasing INLP approach at both word and sentence level. To the best of our knowledge, this is the first paper that attempts at debiasing sentence and word embeddings for translationese. We introduce two techniques for debiasing translationese at the word level: one (Stepwise Aligned Subspaces) is akin to the subspace construction approach of gender-debiasing proposed by Bolukbasi et al. (2016) and Ravfogel et al. (2020), the second (Direct Joint Subspace) is a simplified approach that operates directly on the joint space without the use of a separate translationese word list and multiple independently computed and subsequently aligned subspaces. Our word-based debiasing study provides a systematic view of translationese biases contained in static embeddings. We also explore translationese debiasing at sentence level embeddings computed from contextualised word embeddings. As expected, the INLP-based linear translationese debiasing results on static word embeddings are as "perfect" as our sentence level results, reducing the performance of a linear translationese classifier on the debiased data to chance, demonstrating that our debiasing strategies effectively attenuate translationese signals in both these spaces.

Further, we evaluate the effects of debiasing translation artifacts on a standard NLI task in two settings. Even though we achieve "perfect" performance for the translationese classification-based debiasing task with INLP, this translates into just modest improvements resulting from INLP-based debiasing translationese in neural machine translation in an NLI task, with slightly better results for sentence than word debiasing. This demonstrates that our debiasing approach is effective in reducing translation artifacts but that there is more to translationese than is visibe to a linear classifier.

Finally, we acknowledge that while this study is the first to debias translationese encoded as latent representation in (word and sentence) embedding space, the effect of this on the actual surface form of the generated output is not investigated. We hope to account for this in future work.

A Appendix

A.1 Experimental Setup and Hyperparameters

Each run in Table 1 took around 1.5 hours on a GTX1080Ti GPU. Each classification and debiasing step for SNLI sentence-level experiment in Table 3 took approximately 2 hours on V100-32GB GPU. Other hyperparameter settings are shown in the Table 4.

Model	Hyperparameters
fastText	minCount=5, dim=300
Logistic Regression	warm_start = True, penalty = ’l2’, verbose=5, solver="saga", random_state=23, max_iter=7
BiLSTM	hid_dim=300, dropout=0.2, batch_size=32, Adam optimizer with lr=0.0001, epochs=15
SNLI-sentence	nclfs=45, max_iter =1500
SNLI-Aligned (word)	nclfs=34 INLP.single,word=human
SNLI-Joint (word)	nclfs=35

Table 4: Hyperparameter settings.

A.2 Debiased Word Representations

A.2.1 Word Analogy Tests

To verify that debiasing does not hurt the quality of the word representations, we estimate the performance of the original and debiased embeddings on the word analogy task using the MultiSIMLEX benchmark (Vulić et al., 2020). As MultiSIMLEX does not cover German, we use German-Simlex from Leviant and Reichart (2015). After debiasing, Spearman’s ρ correlation coefficients show negligible decreases of 0.02 on En-De and En-Es, 0.01 on Es-En and Es-De, 0.3 on De-En and an increase of 0.01 for De-Es.

A.2.2 Visualisation

Figure 1 shows the t-SNE (Van der Maaten and Hinton, 2008) projection of the vectors in Direct Joint Space Projection before and after debiasing with INLP.

Abstract

Large pretrained language models (LMs) have become the central building block of many NLP applications. Training these models requires ever more computational resources and most of the existing models are trained on English text only. It is exceedingly expensive to train these models in other languages. To alleviate this problem, we introduce a novel method – called WECHSEL – to efficiently and effectively transfer pretrained LMs to new languages. WECHSEL can be applied to any model which uses subword-based tokenization and learns an embedding for each subword. The tokenizer of the source model (in English) is replaced with a tokenizer in the target language and token embeddings are initialized such that they are semantically similar to the English tokens by utilizing multilingual static word embeddings covering English and the target language. We use WECHSEL to transfer the English RoBERTa and GPT-2 models to four languages (French, German, Chinese and Swahili). We also study the benefits of our method on very low-resource languages. WECHSEL improves over proposed methods for cross-lingual parameter transfer and outperforms models of comparable size trained from scratch with up to 64x less training effort. Our method makes training large language models for new languages more accessible and less damaging to the environment. We make our code and models publicly available.

1 Introduction

Large LMs based on the Transformer architecture (Vaswani et al., 2017) have become increasingly popular since GPT (Radford et al., 2018) and BERT (Devlin et al., 2019) were introduced, prompting the creation of many large LMs pretrained on English text (Yang et al., 2019; Clark et al., 2020; Lewis et al., 2020; Ram et al., 2021). There is a tendency towards training larger and larger models (Brown et al., 2020; Fedus et al., 2021) while the main focus is on the English language. Recent work has called attention to the costs associated with training increasingly large LMs, including environmental and financial cost (Strubell et al., 2019; Bender et al., 2021). If training large LMs for English is already costly, it is prohibitively expensive to train new, similarly powerful models to cover other languages.

One approach to address this issue is creating massively multilingual models (Devlin et al., 2019; Conneau et al., 2020; Xue et al., 2021) trained on a concatenation of texts in many different languages. These models show strong natural language understanding capabilities in a wide variety of languages, but suffer from what Conneau et al. (2020) call the *curse of multilinguality*: beyond a certain number of languages, overall performance decreases on monolingual as well as cross-lingual tasks. Consistent with this finding, Nozza et al. (2020) observe that monolingual LMs often outperform massively multilingual models. This might be attributed to superior quality of monolingual tokenizers over their multilingual counterparts (Rust et al., 2021). It is thus desirable to train monolingual models in more languages. Training monolingual models in non-English languages is commonly done by training a new model with randomly initialized parameters (Antoun et al., 2020; Louis, 2020; Martin et al., 2020; Rekabsaz et al., 2019). However, to train a model with capabilities comparable to that of an English model in this way, presumably a similar amount of compute to what was used to train the English model would be required.

To address this issue, we introduce WECHSEL,[1] a novel method to transfer monolingual language models to a new language. WECHSEL uses multilingual static word embeddings between the source language and the target language to initialize model parameters. WECHSEL first copies all inner (non-

---

[1] Word Embeddings Can Help initialize Subword Embeddings in a new Language.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3992 - 4006
July 10-15, 2022

embedding) parameters of the English model, and exchanges the tokenizer with a tokenizer for the target language. Next, in contrast to prior work doing random initialization (de Vries and Nissim, 2021), the token embeddings in the target language are initialized such that they are close to semantically similar English tokens by mapping multilingual static word embeddings to subword embeddings. The latter step is particularly important considering that token embeddings take up roughly 31% of the parameters of RoBERTa (Liu et al., 2019) and roughly 33% of the parameters of GPT2 (Radford et al., 2019). Intuitively, semantically transferring embeddings instead of randomly initializing one third of the model should result in improved performance. Our parameter transfer provides an effective initialization in the target language, requiring significantly fewer training steps to reach high performance than training from scratch. As multilingual static word embeddings are available for many languages (Bojanowski et al., 2017), WECHSEL is widely applicable.

We conduct our experiments on RoBERTa and GPT-2 as representative models of encoder and decoder language models, respectively. We transfer the English RoBERTa model to four languages (French, German, Chinese and Swahili), and the English GPT-2 model to the same four plus another four very low-resource languages (Sundanese, Scottish Gaelic, Uyghur and Malagasy). We evaluate the transferred RoBERTa models on Named Entity Recognition (NER), and Natural Language Inference (NLI) tasks in the respective languages. The transferred GPT-2 models are evaluated in terms of Language Modelling Perplexity (PPL) on a held-out set. We compare WECHSEL with randomly initialized models (denoted as FullRand), as well as the recently proposed TransInner method which only transfers the inner (non-embedding) parameters (de Vries and Nissim, 2021). All mentioned models are trained under the same conditions (around 4 days on a TPUv3-8). We also compare our model with models of comparable size trained from scratch under significantly larger training regimes, in particular CamemBERT (Martin et al., 2020) (French), GBERT$_{\text{Base}}$ (Chan et al., 2020) (German), and BERT$_{\text{Base}}$-Chinese (Devlin et al., 2019).

Results show that models initialized with WECHSEL outperform randomly initialized models and models initialized with TransInner across all languages and all tasks, for both RoBERTa and GPT-2. In addition, strong performance is reached at a fraction of the training steps of other methods. Our contribution is summarized as follows.

- We propose WECHSEL, a novel method for transferring monolingual language models to a new language by utilizing multilingual static word embeddings between the source and the target language.
- We show effective transfer of RoBERTa and GPT-2 using WECHSEL to four and eight languages, respectively, achieved after minimal training effort.
- We release more effective GPT-2 and RoBERTa models than previously published non-English models, achieved under our more efficient training setting. Our code and models are publicly available at `github.com/cpjku/wechsel`.

In the following, we review related work in Section 2. We introduce the WECHSEL method in Section 3, followed by explaining the experiment setup in Section 4. We show and discuss results in Section 5.

2 Related Work

Large Language Models. Training Language Models is usually done in a self-supervised manner i. e. deriving labels from the training text instead of needing explicit annotations. One optimization objective is Masked Language Modelling (Devlin et al., 2019, MLM), where randomly selected tokens in the input are replaced by a special `[MASK]` token, and the task is to predict the original tokens. Another common objective is Causal Language Modelling (CLM), where the task is to predict the next token. These two objectives highlight a fundamental distinction between language models: models can be trained as encoders (e.g. with MLM) or as decoders (e.g. with CLM).

Instead of words, the vocabulary of recently proposed language models commonly consists of subwords (Clark et al., 2020; Liu et al., 2019; Devlin et al., 2019).

Multilingual representations. There has been a significant amount of work in creating multilingual static word embeddings. A common method is learning embeddings from scratch using data in multiple languages (Luong et al., 2015; Duong et al., 2016). Alternatively, multilinguality can be achieved by aligning existing monolingual word embeddings using a bilingual dictionary, so that the resulting embeddings share the same semantic space (Xing et al., 2015; Joulin et al., 2018). Recent studies improve on this by reducing (or completely removing) the need for bilingual data (Artetxe et al., 2017, 2018; Lample et al., 2018).

Beside static word embeddings, multilinguality is also well studied in the area of contextualized representations. One approach to learn multilingual contextualized representations is through training a model on a concatenation of corpora in different languages. Some models created based on this approach are mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020) and mT5 (Xue et al., 2021), trained on text in 104, 100, and 101 languages, respectively. As shown by Pires et al. (2019), a multilingual model such as mBERT can enable cross-lingual transfer by using task-specific annotations in one language to fine-tune the model for evaluation in another language. Despite the benefits, recent studies outline a number of limitations of massively multilingual LMs. Wu and Dredze (2020) empirically show that in mBERT "the 30% languages with least pretraining resources perform worse than using no pretrained language model at all". Conneau et al. (2020) report that beyond a certain number of languages in the training data, the overall performance decreases on monolingual as well as cross-lingual tasks. These studies motivate our work on introducing an efficient approach for creating effective monolingual LMs for more languages.

Cross-lingual transfer of monolingual LMs. Studies in this area can be divided into two categories:

- **Bilingualization of a monolingual LM** is concerned with extending a model to a new language while preserving its capabilities in the original language. Artetxe et al. (2020) approach this problem by replacing the tokenizer and relearning the subword embeddings, while freezing other (non-embedding) parameters. Such a model becomes bilingual, since the initial tokenizer and embeddings can be used for tasks in the source language, while the new tokenizer and embeddings can be used for tasks in the target language. Thus, a model can be finetuned on annotated task data in the source language, and then zero-shot transferred to the target language. Tran (2020) follow a similar approach, while instead of randomly initializing embeddings, they utilize static word embeddings to initialize embeddings in the target language close to semantically similar English tokens. They then continue training the model on an English text corpus as well as on the target language in order to preserve model capabilities in English.
- **Creating a new monolingual LM in the target language** is, in contrast, concerned with transferring a model from a source to a target language without the necessity to preserve its capabilities in the source language. Zoph et al. (2016) and Nguyen and Chiang (2017) show that cross-lingually transferring a machine translation model can improve performance, especially for low-resource languages. Zoph et al. (2016) use embeddings of random tokens in the original vocabulary to initialize token embeddings in the new vocabulary, while Nguyen and Chiang (2017) utilize vocabulary overlap between the source and target language. More recently, de Vries and Nissim (2021) follow a similar approach to the one of Artetxe et al. (2020) for transferring a GPT-2 model to a new language. de Vries and Nissim (2021) add an additional step, where they train the entire model for some amount of steps to allow adapting to the target language beyond the lexical level. We refer to the method of de Vries and Nissim (2021) as TransInner and consider it as a baseline in our experiments.

Our WECHSEL method belongs to the second category. WECHSEL can be seen as an extension to the method proposed by Tran (2020) with the goal of creating a new monolingual LM instead of bilingualizing the LM. This allows removing the constraints imposed by the need to preserve the model's capabilities in the source language. In addition, we generalize the semantic subword mapping done by Tran (2020) to consider an arbitrary number of semantically similar subword with an arbitrary temperature. We are the first to show that a cross-lingually transferred model can outperform monolingual models which have been trained extensively from scratch in the target language, while requiring substantially less computational resources.

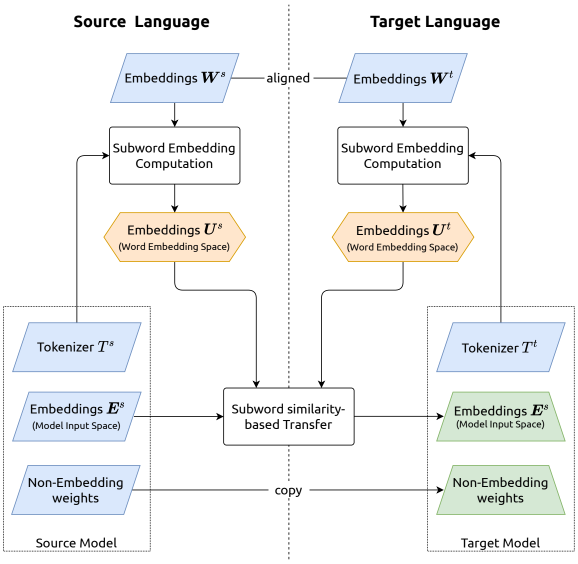

Figure 1: Summary of our WECHSEL method. We show inputs, intermediate results and outputs.

3 Methodology

To initialize the model in the target language, we copy the inner (non-embedding) parameters from the source model. Our goal, then, is given the tokenizer T^s in the source language with vocabulary $\mathbb{U}^s$, the corresponding token embeddings $\boldsymbol{E}^s$, and a tokenizer T^t in the target language with vocabulary $\mathbb{U}^t$, to find a good initialization of the embeddings $\boldsymbol{E}^t$ by using $\boldsymbol{E}^s$. To this end, we use existing bilingual word embeddings enriched with subword information, containing a set of words and subword n-grams in the source and target language and their aligned vectors. We denote the set of words and n-grams in the source and target language as $\mathbb{V}^s$ and $\mathbb{V}^t$ respectively, and the aligned static embeddings as $\boldsymbol{W}^s$ and $\boldsymbol{W}^t$. In Appendix D we consider an alternative method if no subword information is available in the bilingual word embeddings.

First, independently for both languages, we compute static subword embeddings for tokens in the tokenizer vocabulary in the same semantic space as the static word embeddings (Section 3.1). This results in subword embeddings $\boldsymbol{U}^s$ and $\boldsymbol{U}^t$ for the source and target language, respectively. Next, we use $\boldsymbol{U}^s$ and $\boldsymbol{U}^t$ to compute the semantic similarity of every subword in $\mathbb{U}^s$ to every subword in $\mathbb{U}^t$. Using these semantic similarities, we initialize the embeddings in $\boldsymbol{E}^t$ through a convex combination of embeddings in $\boldsymbol{E}^s$ (Section 3.2). By applying WECHSEL, the vectors of $\boldsymbol{E}^t$ are in the same semantic space as $\boldsymbol{E}^s$, where a subword in the target language is semantically similar to its counterpart(s) in the source language. These steps are summarized in Figure 1 and explained in more detail in the following.

3.1 Subword Embedding Computation

The process of mapping word embeddings to subword embeddings is done individually for the source and the target language. Given a tokenizer T with vocabulary $\mathbb{U}$ and embeddings $\boldsymbol{W}$, the goal is to find subword embeddings $\boldsymbol{U}$ for subwords in $\mathbb{U}$ in the same semantic space as $\boldsymbol{W}$. To this end, we decompose subwords in $\mathbb{U}$ into n-grams and compute the embedding by taking the sum of the embeddings of all occuring n-grams, equivalent to how embeddings for out-of-vocabulary words are computed in fastText (Bojanowski et al., 2017).

$$\boldsymbol{u}_x = \sum_{g \in \mathbb{G}^{(x)}} \boldsymbol{w}_g$$

where $\mathbb{G}^{(x)}$ is the set of n-grams occuring in the subword x and $\boldsymbol{w}_g$ is the embedding of the n-gram g. Subwords in which no known n-gram occurs are initialized to zero.

3.2 Subword similarity-based Transfer

Applying the previous step to both source and target language results in the subword embeddings $\boldsymbol{U}^s$ and $\boldsymbol{U}^t$ over the subword vocabularies $\mathbb{U}^s$ and $\mathbb{U}^t$, respectively. Our aim is to leverage these embeddings to find an effective transformation from $\boldsymbol{E}^s$ to $\boldsymbol{E}^t$. We first compute the cosine similarity of every subword $x \in \mathbb{U}^t$ to every subword $y \in \mathbb{U}^s$, denoted as $s_{x,y}$.

$$s_{x,y} = \frac{\boldsymbol{u}_x^t \boldsymbol{u}_y^{s\,T}}{\|\boldsymbol{u}_x^t\| \|\boldsymbol{u}_y^s\|}$$

We now exploit these similarities to initialize embeddings in $\boldsymbol{E}^t$ by a convex combination of embeddings in $\boldsymbol{E}^s$. In particular, each subword embedding in $\boldsymbol{E}^t$ is defined as the weighted mean of the k nearest embeddings in $\boldsymbol{E}^s$ according to the similarity values. The weighting is done by a softmax of the similarities with temperature τ.

$$\boldsymbol{e}_x^t = \frac{\sum_{y \in \mathcal{J}_x} \exp\left(s_{x,y}/\tau\right) \cdot \boldsymbol{e}_y^s}{\sum_{y' \in \mathcal{J}_x} \exp\left(s_{x,y'}/\tau\right)}$$

where $\mathcal{J}_x$ is the set of k neighbouring subwords in the source language. Subword embeddings for which $\boldsymbol{U}^t$ is zero are initialized from a random normal distribution $\mathcal{N}(\mathbb{E}[\boldsymbol{E}^s], \mathrm{Var}[\boldsymbol{E}^s])$.

4 Experiment Design

We evaluate our method by transferring the English RoBERTa (Liu et al., 2019) and the English GPT-2 model (Radford et al., 2019) to French, German, Chinese and Swahili. We refer to these languages as *medium-resource languages*. In addition, we study the benefits of our method on four *low-resource languages*, namely Sundanese, Scottish Gaelic, Uyghur and Malagasy.

We evaluate WECHSEL-RoBERTa by fine-tuning on XNLI (Conneau et al., 2018), and on the balanced train-dev-test split of WikiANN (Rahimi et al., 2019; Pan et al., 2017) to evaluate NLI and NER performance, respectively. The hyperparameters used for fine-tuning are reported in Appendix B. GPT-2 is evaluated by Perplexity (PPL) on a held-out set from the same corpus on which the model was trained on. Due to the difficulty of extrinsic evaluation on low-resource languages, we only train GPT-2 models in these languages, and evaluate their performance intrinsically via Language Modelling Perplexity on a held-out set. We use the pretrained models RoBERTa$_{\text{Base}}$ with 125M parameters, and the small GPT-2 variant with 117M parameters provided by HuggingFace's Transformers (Wolf et al., 2020) in all experiments.

Since under limited training regimes such as ours, using a smaller corpus does not in general degrade performance (Martin et al., 2020), we use a subset of 4GiB from the OSCAR corpus for German, French and Chinese. For the other languages, we use data from the CC-100 corpus (Conneau et al., 2020) which contains 1.6GiB, 0.1GiB, 0.1GiB, 0.4GiB and 0.2GiB for Swahili, Sundanese, Scottish Gaelic, Uyghur and Malagasy, respectively. To obtain aligned word embeddings between the source and the target language we use monolingual fastText word embeddings[2] (Bojanowski et al., 2017). We align these embeddings using the Orthogonal Procrustes method (Schönemann, 1966; Artetxe et al., 2016) with bilingual dictionaries from MUSE[3] (Conneau et al., 2017) for French, German and Chinese and a bilingual dictionary from FreeDict[4] (Bański and Wójtowicz, 2009) for Swahili. For the low-resource languages, we use bilingual dictionaries scraped from Wiktionary.[5]

Model	Tokens trained on	Factor
WECHSEL-RoBERTa	65.5B	1.0x
TransInner-RoBERTa	65.5B	1.0x
FullRand-RoBERTa	65.5B	1.0x
CamemBERT	419.4B	6.4x
GBERT$_{\text{Base}}$	255.6B	3.9x
BERT$_{\text{Base}}$-Chinese	131.1B	2.0x

Table 1: Tokens trained on in the target language between our models and previous monolingual models.

We choose temperature $\tau = 0.1$ and neighbors $k = 10$ for WECHSEL by conducting a parameter search over a grid with varying values for k and τ using linear probes (Appendix A). We train tokenizers in the target languages using a vocabulary size of 50k tokens and byte-level BPE (Radford et al., 2019). After applying WECHSEL, we continue training RoBERTa on the MLM objective and GPT-2 on the CLM objective. We compare against two baseline methods.

- **TransInner:** Randomly initializing $\boldsymbol{E}^t$ while transferring all other parameters from the English model as in de Vries and Nissim (2021). After training only embeddings for a fixed amount of steps while freezing other parameters, the entire model is trained for the remaining steps. In preliminary experiments reported in Appendix E, we compare the method by Zoph et al. (2016) with TransInner, observing superior performance of TransInner, so we choose TransInner as the baseline for cross-lingual transfer in all our experiments.

- **FullRand:** Training from scratch in the target language, as is commonly done when training BERT-like or GPT-like models in a new language (Antoun et al., 2020; Louis, 2020; Chan et al., 2020; Martin et al., 2020).

All models are trained for 250k steps with the same hyperparameters across all languages (reported in Appendix B). Training one model takes around 4 days on a TPUv3-8. For WECHSEL and FullRand we use a learning rate (LR) schedule with linear warmup from zero to the peak LR for the first 10% of steps, followed by a linear decay to zero. For TransInner, we perform two warmup phases from zero to peak LR, once for the first 10% of steps for training embeddings only, then again for the remaining steps while training the entire model.

In addition to the mentioned baselines trained under this setting, we compare the results of

Table 2: Results from fine-tuning RoBERTa models. We report accuracy for NLI on XNLI and micro F1 score for NER on WikiANN. Results are averaged over 3 runs. We report scores before training (**Score@0**), after 10% of steps (**Score@25k**) and after training (**Score@250k**). We also report results from fine-tuning prior monolingual models and XLM–R (**Score (more training)**), all trained on more tokens than our models. For each language, the best results in every column are indicated with underlines. The overall best results including the comparison with existing monolingual/multilingual models of comparable size are shown in bold.

RoBERTa models with existing comparable models trained from scratch with more training effort. We consider the total number of tokens the model has encountered in the target language, computed as the product of batch size × sequence length × train steps (shown in Table 1) as a proxy for training effort. We evaluate the performance of CamemBERT (Martin et al., 2020) (French), GBERT$_{\text{Base}}$ (Chan et al., 2020) (German), and BERT$_{\text{Base}}$-Chinese (Devlin et al., 2019) as existing monolingual LMs,[6] as well as XLM-R$_{\text{Base}}$ (Artetxe et al., 2020) as a high-performing multilingual LM.

5 Results

We present our results on transferring RoBERTa and GPT-2 from English to other languages, followed by analyzing training behavior. In Appendix C, we provide a qualitative assessment of how well subword tokens are mapped between the source and the target languages.

5.1 Transferring RoBERTa

Table 2 reports the evaluation results of RoBERTa. As shown, models initialized with WECHSEL outperform models trained from scratch and models initialized with TransInner across all languages. Surprisingly, close relatedness of the source and target language is not necessary to achieve effective transfer, as e. g. on NLI WECHSEL improves absolute accuracy by 7.15%, 6.31%, 6.94% and 4.71% over models trained from scratch for French, German, Chinese and Swahili, respectively.

We observe that our parameter transfer-based model consistently outperforms the previously released LMs on both monolingual and multilingual settings, while these models benefit from much larger training resources in terms of computation time and corpus size. In particular, the results show an improvement over XLM-R$_{\text{Base}}$ by an average 3.54% accuracy for NLI and 1.14% micro F1 score for NER. For NLI, we improve over the prior monolingual models by 1.55%, 3.15% and 1.77% absolute accuracy for French, German and Chinese, respectively. For NER, we observe improvements over monolingual models with 0.62% and 0.26% absolute micro F1 score improvement for French and German, respectively. For Chinese, the monolingual model BERT$_{\text{Base}}$-Chinese still outperforms our method by 1.5% absolute micro F1 score. We suspect that the discrepancy between NLI and NER is due to the limited training corpus size (max. 4GiB), while a larger corpus can potentially improve NER as more named entities appear (Martin et al., 2020).

---

[6] To the best of our knowledge there is no monolingual model available for Swahili.

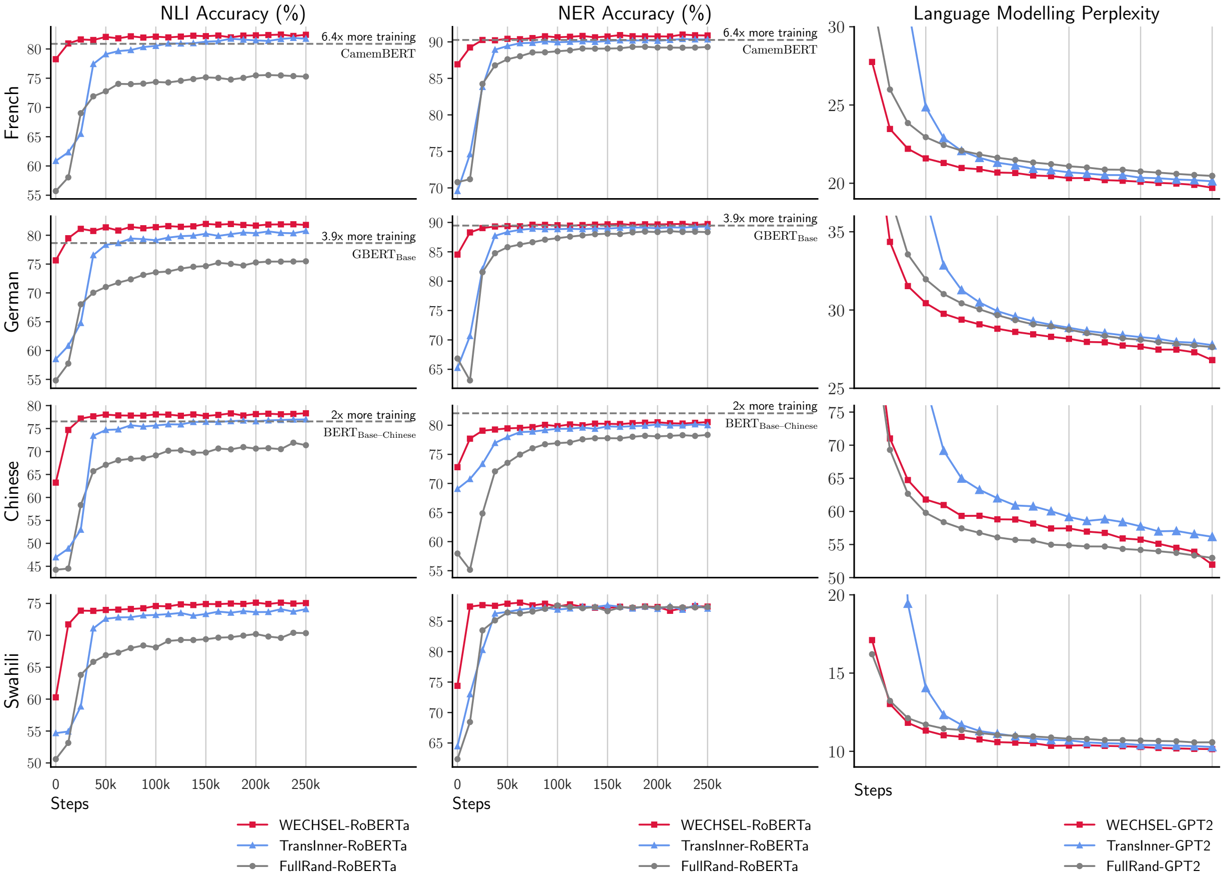

Figure 2: Test scores over training steps from fine-tuning RoBERTa models on NLI (using XNLI) and NER (using WikiANN). Perplexity on the held-out set over training steps of GPT-2 models. We evaluate every 12.5k steps.

Lang	**Model**	**PPL@0**	**PPL@25k**	**PPL@250k**
French	WECHSEL-GPT2	1.7e+3	23.47	**19.71**
	TransInner-GPT2	1.4e+5	67.97	20.13
	FullRand-GPT2	5.9e+4	25.99	20.47
German	WECHSEL-GPT2	3.7e+3	34.35	**26.80**
	TransInner-GPT2	1.5e+5	121.67	27.76
	FullRand-GPT2	5.8e+4	37.29	27.63
Chinese	WECHSEL-GPT2	2.4e+4	71.02	**51.97**
	TransInner-GPT2	1.5e+5	231.05	56.17
	FullRand-GPT2	5.8e+4	69.29	52.98
Swahili	WECHSEL-GPT2	1.4e+5	13.02	**10.14**
	TransInner-GPT2	1.4e+5	42.95	10.28
	FullRand-GPT2	5.8e+4	13.22	10.58

Table 3: Results of training GPT2 models. We report Perplexity before training (**PPL@0**), after 10% of steps (**PPL@25k**) and after training (**PPL@250k**).

Lang	**Model**	**Best PPL**
Sundanese	WECHSEL-GPT2	**111.72**
	TransInner-GPT2	151.86
	FullRand-GPT2	149.46
Scottish Gaelic	WECHSEL-GPT2	**16.43**
	TransInner-GPT2	18.62
	FullRand-GPT2	19.53
Uyghur	WECHSEL-GPT2	**34.33**
	TransInner-GPT2	39.06
	FullRand-GPT2	42.82
Malagasy	WECHSEL-GPT2	**14.01**
	TransInner-GPT2	14.85
	FullRand-GPT2	15.93

Table 4: Results of training GPT2 models on low-resource languages. We report the best Perplexity on the held-out set, evaluated every 2.5k steps. See Figure 3 for Perplexity throughout training.

The first two columns of Figure 2 show the performance of RoBERTa models on downstream tasks after each 12.5k training steps. Models initialized with WECHSEL reach high performance in significantly fewer steps than models initialized with FullRand or TransInner.

We expect FullRand-RoBERTa to approach performance of the respective prior monolingual models when trained on the same amount of tokens.[7]

---

[7] It would presumably be slightly worse because we restrict training corpus size to 4GiB.

For French, WECHSEL-RoBERTa outperforms CamemBERT after 10% of training steps, reducing training effort by 64x. For German, WECHSEL-RoBERTa outperforms $\text{GBERT}_{\text{Base}}$ after 10% of training steps, reducing training effort by 39x. For Chinese, WECHSEL-RoBERTa outperforms $\text{BERT}_{\text{Base}}$-Chinese on NLI, but does not outperform $\text{BERT}_{\text{Base}}$-Chinese on NER.

5.2 Transferring GPT-2

5.2.1 To Medium-Resource Languages

Results on medium-resource languages are shown in Table 3. Similar to the results for WECHSEL-RoBERTa, the GPT-2 models trained with WECHSEL consistently outperform the models trained from scratch and with TransInner across all languages.

The rightmost column of Figure 2 depicts the performance of GPT-2 models after each 12.5k training steps. Comparing the results across all languages throughout training, we observe a stronger dependence on similarity of the source to the target language than for downstream tasks such as NLI or NER. In particular, for French and German, WECHSEL is consistently better than TransInner and FullRand throughout the entire training, while for Chinese, a decrease in perplexity towards the end of training causes WECHSEL to surpass training from scratch.

5.2.2 To Low-Resource Languages

Table 4 reports the perplexity of Language Modelling on the low-resource languages. Again, we observe consistent improvements using WECHSEL on all languages. Furthermore, we find that the improvement from WECHSEL tends to increase as the amount of training data decreases by conducting a sensitivity analysis w. r. t. the amount of available training data (Appendix F).

In Figure 3 we report the performance of the low-resource LMs on the held-out set throughout training. One difference of the low-resource models with the ones trained on medium-resource languages is that the low-resource LMs are prone to overfitting, and require appropriate model selection even in the early steps of training. Notably, TransInner-GPT2 takes more steps to overfit since all non-embedding parameters are frozen for the first 25k steps (c. f. Section 4).

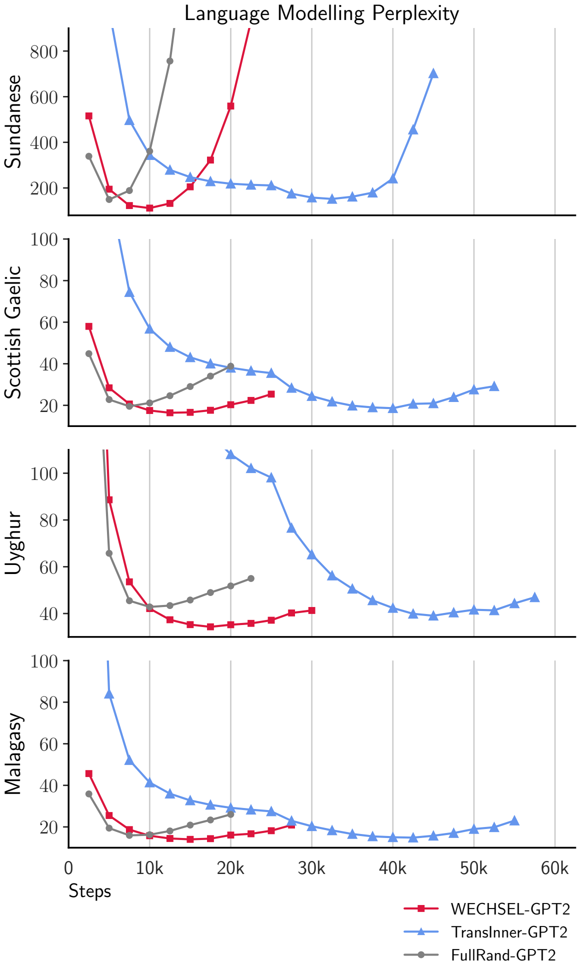

Figure 3: Perplexity throughout training on low-resource languages. We evaluate every 2.5k steps and stop training if Perplexity on the held-out set does not improve for 10k steps.

5.3 Is freezing necessary?

Previous work using the TransInner method freezes non-embedding parameters for a fixed amount of steps before training the entire model (de Vries and Nissim, 2021). This is done to prevent catastrophic forgetting at the beginning of training. To evaluate if freezing non-embedding parameters is still necessary with our method, we conduct an additional experiment. We train a German GPT-2 model with WECHSEL and a model with TransInner without freezing any parameters, and the same models with freezing of non-embedding parameters for the first 10% of steps. We match hyperparameters of the main experiments except training for 75k steps only. Based on the results shown in Figure 4, we conclude that freezing is necessary when using TransInner, but there is no need for freezing when using WECHSEL.

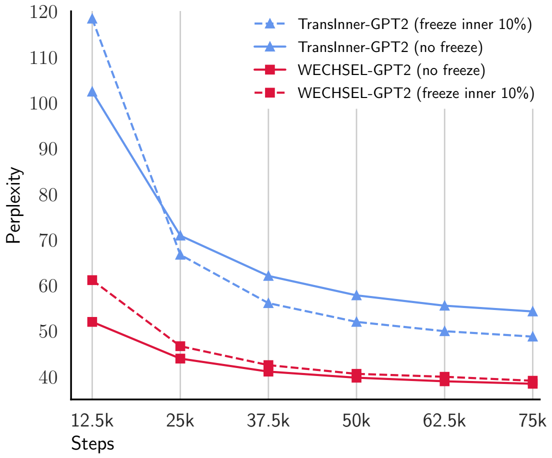

Figure 4: Comparison of German GPT-2 models trained with WECHSEL and TransInner between freezing non-embedding parameters at the start and not freezing any parameters.

6 Limitations and Potential Risks

6.1 Limitations

We conduct our experiments on up to eight languages, showing the benefits of our parameter transfer method to both medium- and low-resource languages. However, there are many more languages with diverse linguistic characteristics on which our WECHSEL method is not tested. This is a limitation forced by computational constraints, as we can not ascertain whether transfer to all other languages would result in similar improvements. In addition, our extrinsic evaluation is limited to two tasks (NLI and NER). While this choice is due to the limitations on the available collections in various languages, this evaluation does not necessarily provide a comprehensive view of language understanding tasks.

6.2 Risks

It is well-known that existing LMs trained on English text encode societal biases (Bolukbasi et al., 2016; Caliskan et al., 2017; Rekabsaz et al., 2021b) and stereotypes and using them in downstream tasks might lead to unfair treatment of various social groups (Zerveas et al., 2022; Krieg et al., 2022; Ganhör et al., 2022; Rekabsaz et al., 2021a; Melchiorre et al., 2021; Rekabsaz and Schedl, 2020; Elazar and Goldberg, 2018). Since we propose a method to transfer the English LMs to new languages, it is highly probable that the existing biases are also transferred to the target LMs. We therefore advocate a conscious and responsible use of the transferred LMs in practice.

7 Conclusion

We introduce WECHSEL, an effective method to transfer monolingual language models to new languages. WECHSEL exploits multilingual static word embeddings to compute an effective initialization of subword embeddings in the target language. We conduct experiments by transferring RoBERTa and GPT-2 models from English to French, German, Chinese and Swahili, as well as English GPT-2 to four low-resource languages. The evaluation results show that the transferred RoBERTa and GPT-2 models are more efficient and effective than strong baselines, and consistently outperform prior monolingual models that have been trained for a significantly longer time. WECHSEL facilitates the creation of effective monolingual LMs for new languages with medium to low resources, particularly in computationally-limited settings. In addition, our work provides strong evidence towards the hypothesis by Artetxe et al. (2020) that deep monolingual language models learn abstractions that generalize across languages.

A Grid search over k and τ

To choose number of neighbors k and temperature τ for WECHSEL we conduct a grid search over linear probes of models with different initialization shown in Table 7. For RoBERTa, we compute scores on NLI (using XNLI) and POS tagging (using the French, German and Chinese GSD corpora in Universal Dependencies) using linear probes of the last hidden state. We probe on NLI by taking a concatenation of the mean of all token representations in the premise with the mean of all token representations in the hypothesis. We probe on POS tagging by taking the mean of all token representations belonging to each word. For GPT2, we compute Language Modelling Perplexity on the held-out set also used to evaluate performance of the trained models.

B Hyperparameters

Hyperparameters used to fine-tune RoBERTa on downstream tasks are shown in Table 5. Hyperparameters used to train models in our main experiments are shown in Table 6.

Parameter	**NLI**	**NER**
peak learning rate	2e-5	2e-5
batch size	128	32
sequence length	128	128
Adam ϵ	1e-8	1e-8
Adam β_1	0.9	0.9
Adam β_2	0.999	0.999
train epochs	2	10
warmup	10% of steps	10% of steps
warmup schedule	linear	linear
LR decay	linear to zero	linear to zero

Table 5: Hyperparameters used to fine-tune RoBERTa models on NLI (XNLI) and NER (WikiANN).

Parameter	**RoBERTa**	**GPT2**
peak learning rate	1e-4	5e-4
batch size	512	512
sequence length	512	512
weight decay	0.01	0.01
Adam ϵ	1e-6	1e-6
Adam β_1	0.9	0.9
Adam β_2	0.98	0.98
train steps	250k	250k

Table 6: Hyperparameters of the models transferred from RoBERTa and GPT2.

C Qualitative subword correspondence

We show a small random sample of tokens in the target language and their closest English token (according to WECHSEL) in Table 8.

D Using Word Embeddings without subword information

As an alternative to n-gram decomposition, we introduce a method for mapping word embeddings to subword embeddings without using any subword information (shown in Figure 5). For this method, we require word frequency information in addition to the word embeddings. We apply the tokenizer T to every word v in $\mathbb{V}$ resulting in a set of subwords for each word. We define $\mathbb{V}^{(x)}$ as the set of words containing the subword x when tokenized. The embedding $\boldsymbol{u}_x$ of the subword x is then defined as the average of the embeddings of words in $\mathbb{V}^{(x)}$, weighted by the word frequencies.

$$\boldsymbol{u}_x = \frac{\sum_{v \in \mathbb{V}^{(x)}} \boldsymbol{w}_v \cdot f_v}{\sum_{v \in \mathbb{V}^{(x)}} f_v}$$

where $\boldsymbol{w}_v$ is the embedding and f_v is the frequency of word v.

Table 7: Grid search over the temperature τ and number of most similar tokens k parameters of WECHSEL.

We call this variant of our method WECHSEL$_{\text{TFR}}$. We evaluate WECHSEL$_{\text{TFR}}$ by training the same models as for WECHSEL. Results are shown in Table 9 for GPT2 and in Table 10 for RoBERTa. We find that, on average, performance is on par with WECHSEL.

E Choosing a transfer baseline

We consider two baseline methods to transfer models to a new language without using any language-specific information. One method copies non-embedding parameters to the target language and initalizes embeddings from a random normal distribution as done by de Vries and Nissim (2021). We refer to this method as TransInner. Another option copies non-embedding parameters and assigns the embedding of a random token in the source language to each embedding in the target language (effectively "shuffling" the embeddings) as done by Zoph et al. (2016) and Nguyen and Chiang (2017). We refer to this method as TransInnerShuffleEmb. We evaluate these two methods using a setup equivalent to the experiments in Section 5.3 and find that TransInner performs slightly better than TransInnerShuffleEmb (Figure 6), so we use TransInner for subsequent experiments.

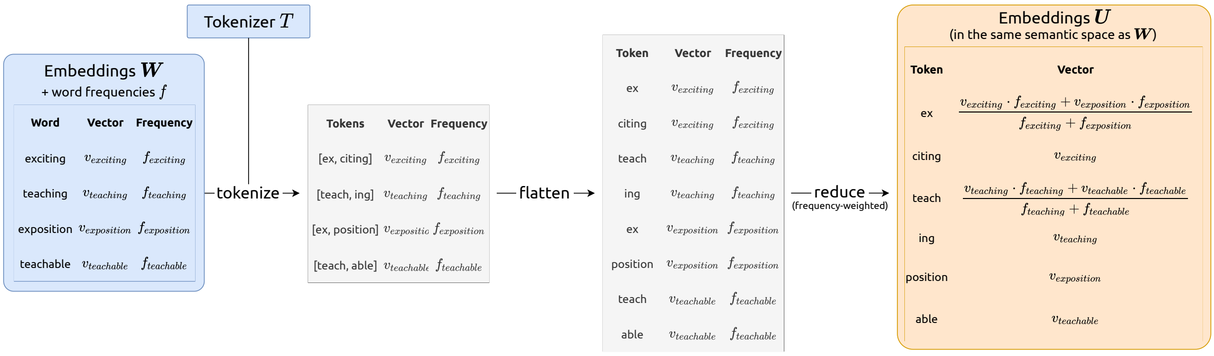

Figure 5: WECHSEL$_{\text{TFR}}$, an alternative subword embedding computation method. First, **tokenize** all words in the word embeddings. Then **flatten** the result by assigning the embeddings of the words in which it occured and their word frequencies to each subword. Finally, **reduce** the embeddings assigned to each subword by taking their mean, weighted by word frequency.

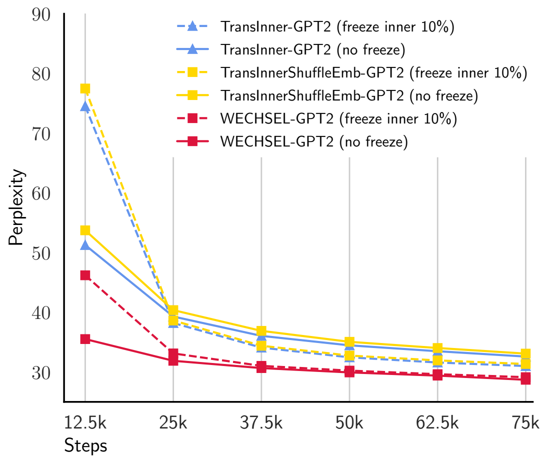

Figure 6: Comparison of German GPT-2 models trained with WECHSEL, TransInner and TransInnerShuffleEmb between freezing non-embedding parameters at the start and not freezing any parameters.

F Sensitivity Analysis w. r. t. training data size

Evaluating on languages with different amounts of available data only indirectly measures the effect of training data size on WECHSEL since other factors (e.g. language similarity to English) are also involved. We conduct a sensitivity analysis to make the relation to the amount of training data explicit (Table 11). Due to computational constraints we only do this for French. We find that the improvement from WECHSEL increases as the amount of training data decreases. In addition, we find that using fastText embeddings trained on less data deteriorates performance, but still leaves a clear margin to TransInner and FullRand.

We train models on random subsamples of 16MiB, 64MiB, 256MiB and 1024MiB of the original training data, and evaluate on the same held-out set. For WECHSEL-GPT2, we train two models. One using the original, publicly available fastText embeddings trained on Common Crawl data. The other using fastText embeddings trained only on the corresponding subsample of text.

A New Concept of Knowledge based Question Answering (KBQA) System for Multi-hop Reasoning

Yu Wang **Vijay Srinivasan** **Hongxia Jin**
Samsung Research America
{yu.wang1,v.srinivasan,hongxia.jin}@samsung.com

Abstract

Knowledge based question answering (KBQA) is a complex task for natural language understanding. Many KBQA approaches have been proposed in recent years, and most of them are trained based on labeled reasoning path. This hinders the system's performance as many correct reasoning paths are not labeled as ground truth, and thus they cannot be learned. In this paper, we introduce a new concept of KBQA system which can leverage multiple reasoning paths' information and only requires labeled answer as supervision. We name it as **M**utliple **R**easoning **P**aths KB**QA** System (MRP-QA). We conduct experiments on several benchmark datasets containing both single-hop simple questions as well as muti-hop complex questions, including WebQuestionSP (WQSP), ComplexWebQuestion-1.1 (CWQ), and PathQuestion-Large (PQL), and demonstrate strong performance.

1 Introduction

Knowledge-based question answering (KBQA) is the task of finding answers to questions by processing a structured knowledge base $\mathcal{KB}$. A $\mathcal{KB}$ consists of a set of entities $\mathcal{E}$, a set of relations $\mathcal{R}$, and a set of literals $\mathcal{S}$. A knowledge base fact is defined as (h, r, t), where $h \in \mathcal{E}$ is the head entity, $t \in \mathcal{E} \bigcup \mathcal{S}$ is the tail entity/literal, and $r \in \mathcal{R}$ is the directed relation between h and t. To answer a simple single-relation question (*i.e.* a 1-hop question) such as: *"Who is the president of the United States?"*, a typical KBQA system first identifies the entity (*i.e.* United States) and the relation (*i.e.* "president") asked in the question, and then searches for the answer entity by matching the entity-relation tuple <United States, president, ?> over $\mathcal{KB}$.

While a single-hop question can be answered by searching a predicate relation in $\mathcal{KB}$, it is much harder to answer more complex multi-hop questions containing multiple entities and relations with constraints. For instance, for complex compositional questions, it is not easy to extract all the relations correctly together with their head and tail entities in the right order. For complex conjunction questions that requires a conjunction of multiple evidences, it is even more difficult to correctly extract all the reasoning paths included.

Most prior works on multi-hop KBQA focus on learning a single given ground truth reasoning path for each question, and outputting the most possible reasoning path during prediction (Zhou et al., 2018; Zhang et al., 2018; Yu et al., 2018; Lan et al., 2019). However, it is common that $\mathcal{KB}$ has many alternative paths leading to the correct answer, of various reasoning qualities. These alternative reasoning paths are usually not provided as ground truth by the human annotators.

For example, Figure 1 shows 7 reasoning paths $\mathbf{p}^n = e_0^n \rightarrow r_1^n \rightarrow e_1^n \rightarrow \cdots \rightarrow e_{ans}^n$ $(n = \{1, \ldots, 7\})$ leading to an answer set containing the correct answer *"West Lafayette"* for a given question *"What city is home to the University that is known for Purdue Boilermakers men's basketball?"*, but only the reasoning path $\mathbf{p}^1$ is labeled as the correct path in the dataset. A model trained with only $\mathbf{p}^1$ as supervision is likely to miss other paths which are also valid. For example, it will probably map a similar question *"What city is home to the stadium that is known for Los Angeles Lakers?"* to path $\mathbf{p}^1$, but fail to associate it with $\mathbf{p}^3$ or $\mathbf{p}^4$, because $\mathbf{p}^3$ or $\mathbf{p}^4$ contain different types of relations. However, $\mathbf{p}^1$ is a wrong reasoning path for that test question.

As the example shown in Figure 1, there are four paths ($\mathbf{p}^1$,$\mathbf{p}^2$,$\mathbf{p}^3$,$\mathbf{p}^4$) pointing to the exact answer set containing only the answer entity, and thus can be treated as ground truth paths when training. Comparatively, reasoning paths $\mathbf{p}^5$ and $\mathbf{p}^6$ lead to a larger final entity set containing the correct answer

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4007 - 4017

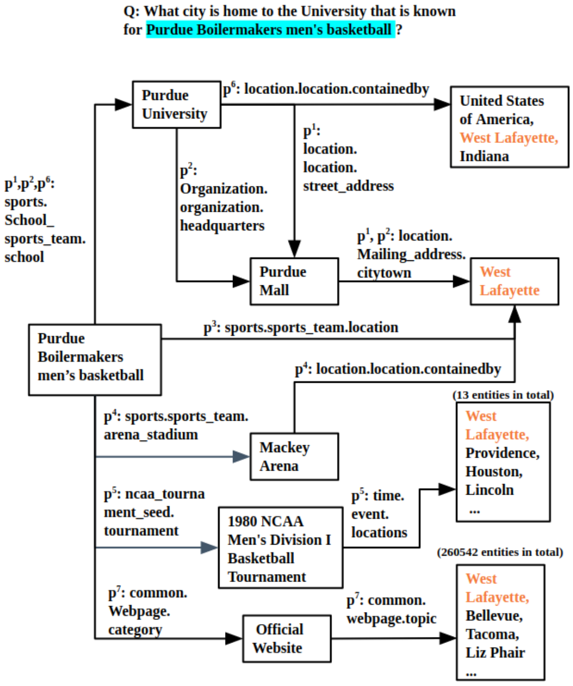

Figure 1: One QA example with Multiple Reasoning Paths (MRPs) from COMPLEXWEBQUESTION-1.1. The blue color highlighted is the extracted topic entity. Each square represents an entity, and the arrows represent the relations. Reasoning path $\mathbf{p}^1$ to $\mathbf{p}^4$ are the correct ones containing meaningful reasoning paths to the final answer. $\mathbf{p}^5$ and $\mathbf{p}^6$ are the "second choice" paths that generate a larger final answer set containing some wrong entities. $\mathbf{p}^7$ is the wrong one as its reasoning path is totally not interpretable and the answer set is huge.

"West Lafayette" but also other entities. These two paths can be considered as inferior to the top 4 paths; however, it is still worth including them in the training as a "second choice", as it is not difficult to extract the correct answer from final sets by additional post-processing. For example, a simple filter can be applied to filter out *"United States of America"* and *"Indiana"* from the predicted set, as they are not cities. Path $\mathbf{p}^7$ is bad because it is not interpretable, in addition to the final answer set being exaggeratedly large with invalid answers. Hence, path $\mathbf{p}^7$ should not be considered as a training path for this question. Unfortunately, it is not possible for any existing models to use multiple good/inferior paths, but not the bad ones, since current models are only trained with a single path for each question answer pair.

In this paper, we propose a novel multi-hop KBQA system, which can leverage the training information from multiple reasoning paths (MRPs) without using any path annotations, we name it as **M**utliple **R**easoning **P**aths KBQA System (MRP-QA). We model the reasoning path as a latent variable, and propose supporting training and prediction methods. The system can output diverse reasoning paths, and reward the "better" paths over the inferior ones by assigning "better" paths higher probabilities. Our method can be applied to most KBQA systems to predict the answer, and can be used with any model architecture. We achieve strong performance on three popular KBQA datasets. Experimental results show that our model performs especially well on multi-hop question, and in particular on complex questions that cannot be solved with a single reasoning path.

Our MRP-QA System does not need training paths annotation (only the question, and head and final entities), since it can sample the paths from the $\mathcal{KB}$ graph. This is of enormous pratical importance, because in practice questions and answers are easy to collect (sometimes for free), but path annotation is very labor-intensive and expensive.

2 Model

We first introduce some notations. For a given question q and its topic entity e_0 (identified by entity linking tool), a reasoning path is a sequence in the form $\mathbf{p} = (e_0, r_1, e_1, r_2, \cdots, e_{T-1}, r_T)$ that points to the answer entity $e_T = y$. That is, $\mathbf{p} \to e_T = y$. Each step (e_{t-1}, r_t, e_t) is a valid fact in the knowledge base $\mathcal{KB}$. Our goal is to build a model that can use multiple paths $\mathbf{p}$ to predict answer y given question q and topic entity e_0. In this section, we first present the design of our model architecture, and then explain the training and inference algorithms in detail.

2.1 MRP-QA Model Architecture

Figure 2 illustrates the architecture of our MRP-QA model. We model path probabilities using recurrent neural network with gated recurrent units (GRU). At a timestep t, the input hidden representations of GRU unit and predicted relation are denoted by h_{t-1} and r_t respectively. The model relies on the attention mechanism (Bahdanau et al., 2015) to produce a question context vector c_t. Specifically, all the words $w_0, w_1, \cdots, w_{|q|-1}$ in the given question q are first sent to a fixed embedding layer to acquire word embeddings $\varepsilon_w(w_0), \varepsilon_w(w_1), \cdots, \varepsilon_w(w_{|q|-1})$. Next we apply GRU to produce a temporary hidden state $h'_t =$

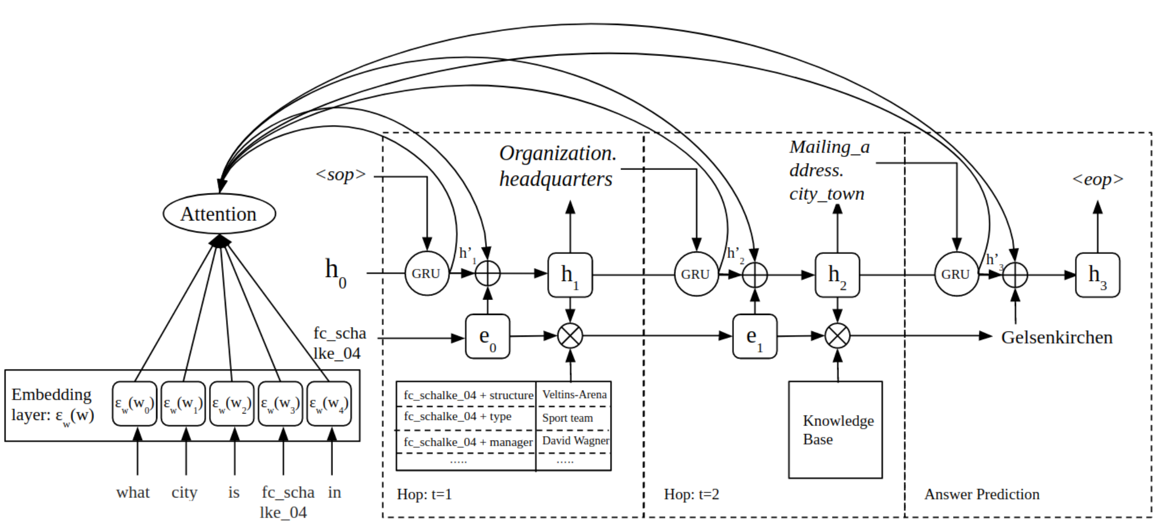

Figure 2: An illustration of how our MRP-QA model works with a QA pair *"What city is fc_schalke_04 in?"* and *Gelesenkirchen*. The entity linker extracts *fc_schalke_04* as the topic entity. We only show one possible paths here: r_1 is *Organization.headquarters* and r_2 is *Mailing_address.city_town*, our model can be used to output the probability of this given path. The symbol $\bigoplus$ represents concatenation, and $\bigotimes$ represents knowledge base lookup.

$GRU(h_{t-1}, r_{t-1})$, and then apply a parameterized feed-forward neural network a to calculate the similarity score $u_{tk} = a(h'_t, \varepsilon_w(w_k))$ of two inputs h'_t and $\varepsilon_w(w_k)$, and then these scores are normalized into attention weights $\alpha_{tk} = \frac{\exp(u_{tk})}{\sum_{0 \le j \le |q|-1} \exp(u_{tj})}$, which are used to produce the question context vector $c_t = \sum_{0 \le j \le |q|-1} \alpha_{tj} \varepsilon_w(w_j)$. In this fashion, word embeddings are combined in different ways based on attention weights to show different reasoning focuses at each timestep.

The model then concatenates temporary hidden state h'_t, entity representation $\varepsilon_e(e_{t-1})$, and question context c_t together, and passes the concatenation through a linear transformation f with ReLU activation to obtain the hidden state $h_t = ReLU(f([h'_t; \varepsilon_e(e_{t-1}); c_t]))$. This process is recurrently done until the model predicts a stop symbol <*eop*>[1]. Note that the vanilla RNN attention model only has h'_t and c_t when calculates h_t. We add entity representation into the calculation, since entity captures important information in the reasoning path.

2.2 Probabilities and Objective Function

The probability of predicting the k-th relation γ_k in $\mathcal{R}$ at timestep t is:

$$p(r_t = \gamma_k | q, e_0, r_1, \cdots, e_{t-1}) = \frac{\exp < h_t, \varepsilon_r(\gamma_k) >}{\sum_j \exp < h_t, \varepsilon_r(\gamma_j) >}$$

where ε_r is the embedding function, <> is the dot product between two inputs.

Given the previous entity e_{t-1} and relation r_t, the next matched entity may not be unique when we query the knowledge base. For example, if e_{t-1}="united states", and r_t = "president of", then the resulting entity has 45 possibilities. Since we do not have additional constraints, all of them are equally likely to be selected, and hence we define:

$$p(e_t | e_{t-1}, r_t) \tag{1}$$
$$= \begin{cases} 1/M & \text{if } e_t \text{ is one of the } M \text{ matched entities} \\ 0 & \text{if } e_t \text{ is not a matched entity} \end{cases}$$

Thus the probability of a path containing both entities and relations can be computed using the chain rule:

$$p(\mathbf{p}|q) = \prod_{t=1}^{T-1} p(e_t | e_{t-1}, r_t) \prod_{t=1}^{T} p(r_t | q, e_0, r_1, \cdots, e_{t-1}) \tag{2}$$

---

[1] This stop mechanism is the same as how it works in a vanilla RNN. Similarly, we also attach <sop> to the beginning of each sequence to denote the start state. We will omit these symbols in formulas for simplicity.

We assume that there are multiple valid paths $\mathbf{p} \in \mathcal{P}$ that can lead to the correct answer y and they are not given by the annotator in the dataset. We treat these paths as hidden variables and we marginalize them out to compute the probability of getting the answer y:

$$\begin{aligned} & p(y|q) \\ = & \sum_{\mathbf{p} \in \mathcal{P}} [p(e_{T(\mathbf{p})} = y | \mathbf{p}, q) p(\mathbf{p}|q)] \\ = & \sum_{\mathbf{p} \in \mathcal{P}} \prod_{t=1}^{T(\mathbf{p})} [p(e_t | e_{t-1}, r_t) p(r_t | q, e_0, r_1, \cdots, e_{t-1})] \end{aligned} \tag{3}$$

where $\mathcal{P}$ is a set of all valid paths leading to the answer y, and $T(\mathbf{p})$ is the number of hops in the path $\mathbf{p}$.

To train our model, we would like to maximize the answer probability $p(y|q)$ using only the given answer for each training instance. To make prediction on each test case, we would like to find the answer y with the highest probability.

It is a novel way that we define answer probability as in (3) in the KBQA task. Most of the existing methods assume the availability of a single ground truth path annotation and aim to maximize the probability of the given path (Zhou et al., 2018). As we will demonstrate later in the Section 3.3, considering multiple paths leads to a better model performance.

2.3 System Training

In order to train our MRP-QA model by maximizing the marginalized answer probability given in (3), it requires summing over all valid reasoning paths from the topic entity to the answer entity in knowledge base. Thus computing this objective exactly can be intractable. As shown in the early example, some reasoning paths (R_5, R_6, R_7 in Figure 1) are not very helpful for training, thus should be either removed from training or assigned low probabilities. To achieve this goal, we first apply depth first search (DFS) algorithm with maximum 3 hops to get valid path candidates. The algorithm starts the traversal from the topic entity node, and ends at the answer entity node. All possible paths between the topic entity and the answer entity within 3 hops are extracted as candidates. We then set a threshold to remove paths which point to too many entities at the last hop. To further filter out bad reasoning paths, we propose to dynamically choose reasoning paths deemed as most probable by the current model during training. The overall training procedure is summarized in Algorithm 1. Note that training with this algorithm does not require ground truth reasoning path label. Labeled reasoning path is a plus, but not necessary. If it is given, we can either include the ground truth paths in $\mathcal{P}$, or use them to initialize model training.

Algorithm 1: Training method for a MRP-QA System

```
Input  : KBQA dataset
         $(q^n, y^n, e_0^n), n = 1, 2, \cdots, N$,
         Knowledge Base $\mathcal{KB}$,
         Threshold $k_1$ and $k_2$.
Output : Trained model parameters
foreach instance $(q^n, y^n, e_0^n)$ do
    Use DFS algorithm to get a set of paths
      $\mathcal{P}^n$ from $e_0^n$ to $y^n$.
    Remove from $\mathcal{P}^n$ paths that point to
      more than $k_1$ entities.
end
foreach batch do
    foreach $(q^n, y^n, e_0^n)$ in the batch do
        Get top $k_2$ paths in $\mathcal{P}$ sorted by
          $p(\mathbf{p}|q)$ based on current model:
          $\tilde{\mathcal{P}}^n = \{\mathbf{p}_1^n, \cdots, \mathbf{p}_{k_2}^n\}$
    end
    Update model parameters by
      maximizing
      $\sum_{(q^n, y^n, e_0^n)} \log \sum_{\mathbf{p} \in \tilde{\mathcal{P}}^n} p(y^n | \mathbf{p}, q^n) P(\mathbf{p} | q^n)$
end
```

2.4 Prediction

During the prediction, we aim to select the answer y with the highest marginalized probability $p(y|q)$ as defined in (3). Similar to training, we need to approximate the sum with selected paths from $\mathcal{P}$. We use a modified beam search to find paths that have high probabilities. We add two constraints to standard beam search to only select the valid paths that match the knowledge base: (1) The first relation r_1 should connect to the topic entity e_0. (2) Each triple (e_{t-1}, r_t, e_t) should match a fact in KB. Given the set of paths collected as above, we can then collect a set of candidate answers that these paths point to. For each answer y, we evaluate its probability $p(y|q)$ approximately using the collected paths, and among them we output the answer with the highest probability.

Additionally, we observe that it could be beneficial to de-emphasize the impact of the topic entity during prediction, as noted in (Li et al., 2016), which can improve inference performance by avoiding generating generic predictions and reducing overfitting. Specifically, instead of searching y^* that maximizes $p(y|q)$, we can find an answer that maximizes $\frac{p(y|q)}{p(y|e_0)}$, where $p(y|e_0)$ is the probability of getting the answer y when the question only contains the topic entity word. Mathematically, one can show that this is equivalent to maximizing the point-wise conditional mutual information PMI$((y; q\backslash e_0)|e_0)$ between y and $q\backslash e_0$ given e_0, where $q\backslash e_0$ stands for the question with the topic entity term removed. Further discussion can be found in Section 4.

3 Results and Analysis

3.1 Experimental Setup

We conduct experiments on 3 multi-hop KBQA datasets, WebQuestionSP (WQSP) (Yih et al., 2015), ComplexWebQuestion-1.1 (CWQ) (Talmor and Berant, 2018), and PathQuestion-Large (PQL) (Zhou et al., 2018), and use the original train/dev/test split. WQSP is a dataset that has been widely used for relation extraction and end-to-end KBQA tasks, which contains 1 or 2 hops questions. CWQ dataset is designed to study complex questions by adding more constraints to questions in WebQuestionSP. PQL is a small dataset used to study sequential questions. Its original release contains two subsets: PQL2H and PQL3H, which contains only 2-hop and 3-hop questions correspondingly. Chen et al. (2019) then combined these two subsets and renamed the unified dataset as PQL+. All of the three datasets use Freebase (Google, 2013) as the supporting knowledge base. Table 1 contains statistics of these datasets.

	#train	#valid	#test	max_hops	>1 path
WQSP	2677	297	1639	2	79.4%
CWQ	27639	3519	3531	6	83.4%
PQL2H	1275	159	160	2	12.5%
PQL3H	1649	206	207	3	45.2%
PQL+	2924	365	367	3	30.6%

Table 1: Statistics of datasets. To count the data percentage with more than one path, *i.e.* >1 path, we use graph search algorithm to calculate what percentage of QA pairs can be solved with MRPs.

For questions with multiple answers, we use each answer to construct a question-answer (QA) pair. For WQSP and CWQ, we build a subgraph in a similar way as in (Sun et al., 2018), in order to generate the entity and relation candidates. For PQL, the original paper provides a subgraph of the Freebase. We implement our model using TensorFlow-1.11.0 and choose S-MART (Yang and Chang, 2016) and AllenNLP (Gardner et al., 2017) as our entity linking tools. If multiple topic entities are extracted, we use each topic entity to construct a question-answer pair. We test three different graph embedding methods Word2Vec (Mikolov et al., 2013), TransE (Bordes et al., 2013), and HolE (Trouillon and Nickel, 2017), and decide to use TransE in our final experiment based on validation performance. The threshold k_1 is set to be: 15 plus the number of answers in the ground truth answer set, and k_2 is top 50%. We adopt the average F1 score and the set accuracy as our main evaluation metrics. It is worth noticing that: except our methods' results, all other experimental results are obtained from early published papers. Details of these models can be found from our referenced papers.

3.2 Experimental Results

In Table 2 we compare our MRP-QA method to state-of-the-art models. All comparisons are divided into two groups based on different training supervisions. The upper block shows methods that are only trained with final answer as supervision, and the second block contains methods using extra annotations such as parsing results of the query. Experimental results show that our MRP-QA model performs better than all other methods on WQSP.

Also although NSM and NSM_{+h} (2nd best result) only relies on answers to train their model, it requires many prior knowledges, such as a big vocabulary to train word embeddings and graph embeddings, type label of the entity and of the relation, and pre-defined templates. The experiments from their papers show that these knowledge play a very important role in the system, *e.g.* F1 score drops from 69.0 to 60.7 by not using the pretrained embeddings for NSM.

In contrast, our model supports a training method that takes only raw QA pairs and the facts in knowledge base, and does not rely on any additional labels and pre-defined knowledge.

To further disentangle the contribution of differ-

Table 2: We report F1 (%) on WQSP and CWQ test sets. Methods labeled with $*$ only require the final answer as the supervision, and they are directly comparable to our MRP-QA model. As references, We also report the performance of methods that requires extra supervisions in the first block.

Setting	Δ F1 (std)
MRP-QA − $entity\_in\_RNN$	−2.1 (0.21)
MRP-QA − $marginal\_prediction$	−1.8 (0.32)
MRP-QA − $inference\_in\_training$	−3.4 (0.15)
MRP-QA − $mutual\_information$	−1.8 (0.16)

Table 3: Feature ablation study on the dev set with a mean of 5 runs.

ent factors in our MRP-QA method, we present a feature ablation test on WQSP dataset shown in Table 3. The vanilla RNN structure only maintains a hidden state and the previous prediction in the loop. Here, we show the performance boost by considering entity features in KBQA task. Instead of using greedy algorithm or beam search to output the top prediction with the highest joint probability $P(y, \mathbf{p})$, we propose to make the prediction based on marginalized probability $P(y)$, which also improves the performance by 1.8%. In addition, we show the benefits of using inference during training (line 6 and 7 in algorithm 1) and mutual information objective (Section (2.4)). More discussions can be found in the Section 4.

3.3 Choices of paths

In the second set of experiment, we test our MRP-QA model with different objective functions and compare their results correspondingly. The objective functions are as defined in Table 4, where the paths used for training are given in the last column. The detailed explanations are given as following:

Single ground truth path. When one reasoning path is given for each QA pair in addition to the answer, we can train the model to fit the given path and answer by maximizing $p(y, \mathbf{p}|q) = p(y|\mathbf{p}, q)p(\mathbf{p}|q)$. This objective ignores the fact that MRPs could be valid for the same answer (see Figure 1) and pushes all the probability mass to the single given one.

Single random path. Many existing methods require a ground truth path for each question in order to train the model. When only the ground truth answer but no path is given to each question, one can randomly sample a path that leads to the given answer and treat the sampled path as ground truth for training.

Multiple paths product. For many of the existing training methods which expect a single path leading to the answer as part of the input, it is also possible to make them incorporate multiple possible paths when no path annotation is given. The simplest way is to expand each (question, answer) pair into multiple training instances, each with a different path leading to the same answer, and then apply existing training method treating them as independent instances. This corresponds to the objective $\prod_{\mathbf{p}\in\mathcal{P}} p(y|\mathbf{p}, q)p(\mathbf{p}|q)$. This objective has an undesired consequence in practical model training: because of the multiplication operation, the model has to assign equally high probabilities to all given reasoning paths in order to maximize the product of the probabilities. If only some reasoning paths receive high probabilities while others receive low probabilities, the production will still be low. As a consequence, the model cannot differentiate bad reasoning paths from good ones by assigning distinguishable probabilities to them.

Multiple paths marginalization. Our proposed training objective replaces the multiplication operation by the summation operation, and this allows the model to concentrate only on good reasoning paths for each QA pair. It is easy to show that the model tends to assign high probability $p(\mathbf{p}|q)$ to a path $\mathbf{p}$ when the path leads to few possible answers and therefore the chance of getting the correct answer $p(y|\mathbf{p}, q)$ is high (see 2). Also, using Jensen's inequality, one can show that this marginal probability objective maximizes the answer probability directly which is the learning goal of KBQA task, while the previous one using product operation maximizes a lower bound.

We test different ways of choosing paths and defining training objectives on WQSP and CWQ datasets. We further divide the test samples into two groups, based on whether there exist multiple

Method	Objective	Path $\mathbf{p}$
single ground truth	$p(y\|\mathbf{p}, q)p(\mathbf{p}\|q)$	single ground truth path leading to y
single random	$p(y\|\mathbf{p}, q)p(\mathbf{p}\|q)$	single random path leading to y
multiple product	$\prod_{\mathbf{p}\in\mathcal{P}} p(y\|\mathbf{p}, q)p(\mathbf{p}\|q)$	all valid paths leading to y
multiple marginal (MRP-QA)	$\sum_{\mathbf{p}\in\mathcal{P}} p(y\|\mathbf{p}, q)p(\mathbf{p}\|q)$	all valid paths leading to y

Table 4: Different choices of paths and objectives.

	WQSP			CWQ		
	1 path	>1 path	all	1 path	>1 path	all
single ground truth	66.8	69.3	68.1	40.8	49.2	46.4
single random	65.7	64.1	64.8	40.8	46.9	44.9
multiple product	69.1	70.2	69.7	40.9	50.7	47.5
multiple marginal (MRP-QA)	73.0	76.3	74.9	43.7	53.0	49.9

Table 6: We report set accuracy (%) on PQL. Similar to Table 2, we use $*$ to highlight the methods which only requires the answer as supervision.

possible paths between the topic entity and the answer based on KB. Table 5 show that our proposed method gives the best performance on both scenarios. The models trained with single path perform consistently worse than those trained with multiple paths. Using random path is worse than using the given ground truth path. Between two models trained using multiple paths, the result shows the advantage of using our proposed objective.

3.4 PathQuestion-Large

In the third set of experiments, we test our MRP-QA model on PathQuestion-Large (PQL) dataset. This dataset contains synthetic questions generated by templates, and is supported by a very small knowledge base (500,000 times smaller than the full freebase). Not surprisingly, we can see the average performance on this dataset is much better than it is on the other two datasets. Recall that PQL2H and PQL3H represents two subsets with only 2 hops and 3 hops questions respectively. Table 6 shows that our MRP-QA method's performance beats all the other approaches on all three subsets of PQL from 1% to 7.8% in terms of test accuracy. Especially the gap between our method to the previous state-of-the-art approach (*i.e.* UHop) becomes larger when the number of hops increase from 2 to 3.

4 Case Study

Our model requires inference while using the current model to select training samples for next batch in training (see line 6 in Algorithm 1). This EM style training approach helps us filter out bad reasoning paths based on context information. For example, a sample question from WQSP is *who was the owner of kfc?*, the graph search algorithm can easily extract two "correct" paths starting from the topic entity *kfc* directing to the ground truth answer *Colonel Sanders*: *kfc* → *organization.organization.founders* → *Colonel Sanders* and *kfc* → *advertisingcharacters.product.advertising_characters* → *Colonel Sanders*. However, the second path is totally wrong given that the reasoning path is irrelevant to the given question. *Colonel Sanders* happens to be the advertising character of *kfc*, but this cannot be generalized to other cases. Without using the trained model to filter out this irreverent path, the model may learn incorrect map from *who is the owner...* to the relation *advertising_characters*. In our experiment, we observe that when we train our model with all reasoning paths generated from DFS algorithm without using this filtering strategy (*i.e.* $k_2 = inf$), the F1 score drops 3.4% as shown in Table 3. This shows the importance of using the filtering strategy.

Next we demonstrate the benefit of maximizing conditional mutual information instead of likelihood. A sample question in WQSP is *who did benjamin franklin get married to?*. We observe that there are 13 questions are using *Benjamin Franklin* as the topic entity in the training set, but most of them are related to his invention and none of them is about marriage. With such a strong prior on *Benjamin Franklin*, our experimental result shows that the model trained with maximum likelihood mistakingly maps this question to a path related to *invention*, while the model trained with mutual

Question: what state does romney live in? Answer: Massachusetts Topic entity: romney		
Single Ground truth	Multiple product	Multiple marginal (our)
.89:children	.29:education_institution/ state_province_region	.83:**places_lived/ location**
.06:**government_positions/ jurisdiction_of_office**	.25:**places_lived/ location**	.12:**government_positions/ jurisdiction_of_office**
.04:**government_positions/ office_position_or_title**	.25:**government_positions/ district_represented**	.04:**government_positions/ district_represented**
.00:**government_positions/ district_represented**	.01:**government_positions/ jurisdiction_of_office**	.01:place_of_birth/ state

Table 7: A running examples from WebQuestionSP dataset. We show the probability $P(r_0, \cdots, r_T|q)$ before the inferred relations. Paths that lead to the correct answers are highlighted in bold. We use / to split two relations. The three columns are corresponding to the results by using different training settings as it is in Table 4. Due to space limit, we only show the partial name of a relation in the example and the probability less than .01 is shown as .00. We do not show $P(e_0, \cdots, e_{T-1}|q)$ because they are not determined by our MRP-QA model.

information makes the correct prediction. Table 3 shows that we get a 1.8% performance boost by using mutual information.

We further show how generated probabilities look like with different choices of paths and objectives in Table 7. In the given example, only our MRP-QA method outputs the correct path, and one can also find that the top three results correspond to three different but correct reasoning processes. We observe that in many training questions *"live in"* co-occurs with word *"children"*, which explains why the first model makes wrong prediction. We can see that training with joint objective given a single relation path generates the most sharp relation path distribution, *i.e.* the gap between the top entity and the second one is larger than that using other objectives. It assigns most probability mass to the top relation path. In this case, the model does not have ability to identify multiple relation paths during inference. The other extreme is that the second model is trained with joint objective and MRPs, which distribute probabilities over many relation paths, hence the model cannot distinguish good relation paths from the bad ones. Between the above two extremes is the proposed marginal objective with MRPs, when the most probable path is assigned the largest probability, while the rest ones still get reasonable probability assignments.

5 Related Work

Most of the existing multi-hop KBQA systems approach this task by decomposing it into two subtasks: topic–entity linking and relation extraction. The topic–entity linking gives the system an entry point to start searching, and the relation extraction is used to search relation paths leading to the final answer. Following this track, a straightforward idea is to match the question to a candidate entity/relation directly via calculating the similarity between them (Zhang et al., 2018; Yu et al., 2018; Lan et al., 2019). This method is not ideal for multi-hop questions with long paths, because the number of candidate entity-relation combinations grows exponentially as the number of hops increases. To tackle this issue, methods are proposed to decompose the input question into several single-hop questions, and then use existing method to solve each simple question. The decomposition methods are based on semantic parsing (Abujabal et al., 2017; Luo et al., 2018) or templates (Ding et al., 2019). A similar idea is to encode the reasoning information hop by hop, and predict the final answer at the last hop (Miller et al., 2016; Zhou et al., 2018; Chen et al., 2019).

Another line of work has looked at solving KBQA task with only final answer as supervision. Liang et al. (2017) first propose to cast KBQA as a program generation task using neural program induction (NPI) techniques. They learn to translate the query to a program like logical form executable on the KB. As a follow up, Ansari et al. (2019) improves this idea by incorporating high level program structures. Both these NPI models do not require annotated relation path as supervision, but they need some prior knowledge to design the program templates. In other work, Min et al. (2019) recently proposed a latent variable approach which is similar to the one described here, but applied on text-based QA scenarios. The main difference between our work is that our method aims at finding multiple reasoning paths leading to the answer, while their method only focus on extracting single optimal solution. We employ inference during training to filter our irrelevant paths, while they use it to identify the optimal solution.

Besides knowledge based question answering models, there are also other question answering sytstems without using knowledge base/graph information. For examples, there are end-to-end question-answering models by using reinforcement learning(Wang and Jin, 2019), adversarial learning(Wang et al., 2021b, 2020b), and also the multi-model structure to handle the unknown entities in question answering(Wang et al., 2018, 2020a). Co-reference understanding (Wang et al., 2021a) is also another research direction in designing question-answering systems.

6 Conclusion

In this paper, We introduce a novel MRP-QA knowledge based question answering system which can leverage information from MRPs. To train our model, we use a marginalized probability objective function. Experimental results show that our model achieve strong performance on popular KBQA datasets.

Abstract

Existing research on Tabular Natural Language Inference (TNLI) exclusively examines the task in a monolingual setting where the tabular premise and hypothesis are in the same language. However, due to the uneven distribution of text resources on the web across languages, it is common to have the tabular premise in a high resource language and the hypothesis in a low resource language. As a result, we present the challenging task of bilingual Tabular Natural Language Inference (bTNLI), in which the tabular premise and a hypothesis over it are in two separate languages. We construct EI-INFOTABS: an English-Indic bTNLI dataset by translating the textual hypotheses of the English TNLI dataset INFOTABS into eleven major Indian languages. We thoroughly investigate how pre-trained multilingual models learn and perform on EI-INFOTABS. Our study shows that the performance on bTNLI can be close to its monolingual counterpart, with translate-train, translate-test and unified-train being strongly competitive baselines.

1 Introduction

Tabular Natural Language Inference (TNLI) is the task of classifying whether a textual hypothesis is an entailment, contradiction or a neutral extension of the given tabular premise. The task requires a broad range of reasoning abilities, including but not limited to the ability to make lexical, spatio-temporal, and semantic deductions. Recently published datasets, TabFact (Chen et al., 2020b) and INFOTABS (Gupta et al., 2020), have enabled the examination of the TNLI task. Moreover, sophisticated models based on deep contextual embeddings like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), etc. trained under supervision on heuristic adaptations of these datasets perform adequately.

Joe Strummer	
Birth Name	John Graham Mellor
Born	1952-08-21 Ankara, Turkey
Died	2002-12-22 Broomfield, Somerset, England
Genres	Punk Rock, Post Punk
Occupation(s)	Musician, Songwriter, Radio Host, Actor
Instruments	Vocals, Guitar, Piano
Years Active	1970-2002
Labels	CBS, Sony, Hellcat, Mercury
Associated Acts	The 101ers, The Clash

H1: John Graham Mellor plays less instruments than the number of labels he has worked for.

H2: Joe Strummer changed his surname after he became a guitar player.

H3: Joe Strummer was active in the sports industry for over three decades.

$H1_{hi-trl}$: jon grāham melar un lebaloan kī sankhyā kī tulanā mean kam vādya bajāte haian jinake lie unhoanne kām kiyā hai

$H2_{hi-trl}$: jo sṭramar ne ek giṭār vādak banane ke bād apanā upanām badal liyā

$H3_{hi-trl}$: jo sṭramar tīn dashakoan se khel udyog mean sakriya the

Figure 1: Tabular premise followed by human written hypotheses (H1, H2, H3). H1 is entailed entirely from the premise, H2 is neither entailed nor contradictory, and H3 is contradictory. $H1_{hi-trl}$, $H2_{hi-trl}$, and $H3_{hi-trl}$ are the transliterations of Hindi translations of the former, released as a part of our EI-INFOTABS dataset.

Typically, and to the authors' best knowledge, fact verification tasks, specifically TNLI, have been examined only in a monolingual setting wherein, the tabular premise and the textual hypothesis are in the same language. However, many semi-structured/tabular data sources exist only in English but require verification of hypotheses over those data sources in other languages, as discussed in §2. Therefore, we examine a modified tabular NLI task by introducing bilinguality within the premise

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4018 - 4037
July 10-15, 2022

and hypothesis pair. To understand this modified task, consider the example in Figure 1. The table presented in the figure has been extracted from the English Wikipedia article on *Joe Strummer*[1], a well known *musician*. Following which, are transliterated hypotheses in Hindi (hi) (and their English (en) translation) which are related to the information presented in the given table. We show transliterated hypotheses only for the ease of comprehension. We use native scripts for each language in the EI-INFOTABS dataset. For bilingual tabular NLI, a reasoning model should be able to predict the inference label entail for $H1_{hi}$, neutral for $H2_{hi}$ and contradict for $H3_{hi}$ given the English table as the primary context. In summary, our contributions are as follows:

- We introduce the task of bilingual tabular NLI (bTNLI) wherein the tabular premise is in a high resource language, while the textual hypothesis is in a low resource language. This is a practical, real world setting for fact verification on semi-structured tabular data which is further illustrated in §2.
- We create EI-INFOTABS, a dataset consisting of machine translated hypotheses in 11 Indian languages, while retaining the English tabular premises from the INFOTABS dataset. Through extensive studies shown in §3, we confirm that EI-INFOTABS is of good quality, and preserves properties important to study the bTNLI task.
- We explore several multilingual models for the bTNLI task, and establish strong baselines and share findings about their performance across multilingual models, languages, train-eval techniques, tabular reasoning categories, adversarial test splits, and both datasets (INFOTABS and EI-INFOTABS).

Overall, EI-INFOTABS dataset and our proposed train-eval strategies enable thorough examination of the challenging task of bTNLI. Furthermore, the former aslo serve as a quality benchmark for evaluating the robustness of multilingual models. The dataset and the associated scripts, are available at `https://enindicinfotabs.github.io`.

2 Motivation

Why Tabular NLI? Tabular data is termed as semi-structured as it is neither truly unstructured data like raw text, nor is it entirely structured like a database. Although semi-structured data is based on a structured scaffold, the content can be free-form text with variable length and type. Moreover, unlike a database, there is no homogeneity across various data points in a shared context. Such structural ambiguity imposes a significant cognitive load while reasoning about it. However, such data is ubiquitous in the real world (e.g. web pages, fact sheets, information tables) and we frequently make inferences from it.

Chen et al. (2020b) argue that reasoning about semi-structured data is broadly two-fold in nature. It consists of (a.) Linguistic Reasoning: a semantic deconstruction of the semi-structured data (b.) , and Symbolic Reasoning: a symbolic execution on the tabular structure.For instance, H_2 in Figure 1 requires linguistic reasoning over the phrase "*became a guitar player*" from the "*Occupation*", and the "*Instruments*" rows of the concerned table. H_1 requires symbolic reasoning in the form of conditional and arithmetic operations on the "*Labels*" and "*Instruments*" rows. Whereas, H_3 requires a combination of the two types of reasoning. Such interwoven reasoning criteria makes it challenging to model Tabular NLI task.

Why Indic Languages? Indian society is largely multilingual and consists of 122 major and 1599 other languages and dialects spanning 6 language families with over 1.3 billion native speakers[2]. Out of these, 30 languages have more than 1 million native speakers each and over 1 billion speakers cumulatively[3]. Moreover, India has the second largest online presence with over 749 million internet users and is expected to grow to over 1.5 billion users by 2040[4]. So, development of competent reasoning models for the Indic context is essential.

However, due to unfair linguistic bias on the web (Miquel-Ribé and Laniado, 2020; Joshi et al., 2020), there is a disproportionate distribution of text resources for Indian languages. Indian languages have a limited number of internet resources. Thus, they are often known as low web resource languages (LRL) (Khemchandani et al., 2021). For instance, Wikipedia entries in Hindi are just 2% of those in English, and Wikipedia entries in Assamese and Oriya are 7 times lesser than those in Hindi. This implies that a significant fraction of

---

[1] Joe Strummer Wikipedia

[2] Wikipedia Indian Languages

[3] 2011 Indian Census

[4] www.statista.com

articles and sometime even complete categories are discussed only in the English language Wikipedia (Bao et al., 2012).

Although, efforts have been made to bridge this gap (Adar et al., 2009; Kumaran et al., 2010), there still exist several limitations: (a.) **table extraction** for an article across languages is a challenge due to absence of Wikipedia page links, their infobox tables or important keys of tables, (b.) even if tabular data exists, infobox tables in Indian languages are not updated as regularly as their English equivalents (Minhas et al., 2022) which leaves us with **outdated and untrustworthy tabular data** for inference, (c.) and lastly, **table translation** while maintaining the intent, context, and the same quality of the source English language is difficult. Often, accurate translation requires the distinction of a language specific domain expert. Due to above reasons, tabular data is mostly absent from Indic Wikipedia articles.

Thus, fact verification in a bilingual setting wherein, the premise is in English and the claim/hypothesis is in an Indic language, is of great significance. Moreover, recent advances in multilingual language models (Khanuja et al., 2021a; Kunchukuttan, 2020), datasets (Roark et al., 2020; Ramesh et al., 2022), and translation systems (Ramesh et al., 2022) for Indian languages have enabled quality examination of several Indic NLU tasks which serves as additional motivation to evaluate the task of bTNLI for Indic languages before other low resource languages.

3 EI-INFOTABS Dataset

EI-INFOTABS is an English-Indic bTNLI extension of INFOTABS (Gupta et al., 2020), an English TNLI dataset. INFOTABS consists of 23,738 pairs of tabular premises and textual hypotheses. The hypotheses are human written short assertions with an accompanying NLI label, and the tabular premises are based on 2,540 Wikipedia infoboxes from 12 diverse categories. Moreover, it consists of additional adversarial test sets apart from α_1 which is the standard test set and is lexically and topically similar to the train set - α_2 is the lexically adversarial test set which maintains topical similarity and α_3 is the topically adversarial test set. The dev and test sets (α_1, α_2, α_3) cumulatively consist of 7200 table-hypothesis pairs equally splits on all four sets.

EI-INFOTABS extends it by providing machine translated hypotheses in 11 major Indic languages namely Assamese (*as*), Bengali (*bn*), Gujarati (*gu*), Hindi (*hi*), Kannada (*kn*), Malayalam (*ml*), Marathi (*mr*), Odia (*or*), Punjabi (*pa*), Tamil (*ta*), and Telugu (*te*) for each tabular premise. In this section, we discuss the EI-INFOTABS construction and verification.

3.1 EI-INFOTABS Construction

To construct EI-INFOTABS, we machine translated the English hypotheses provided in INFOTABS to 11 major Indian languages as described earlier. We use IndicTrans (Ramesh et al., 2022), an open-sourced state-of-the-art Indic NMT model. IndicTrans is trained on the Samanantar dataset (Ramesh et al., 2022), which is the largest publicly available parallel corpus for Indic languages. Moreover, it outperforms (a) commercial NMT systems like Google-Translate [5] and Bing Microsoft Translator [6], and (b) open-source multilingual models like OPUS-MT (Tiedemann and Thottingal, 2020), mBART50 (Liu et al., 2020) and mT5 (Xue et al., 2021).

3.2 EI-INFOTABS Verification.

Given the absence of Indic reference data, it becomes challenging to measure the quality of the translations, and subsequently, of EI-INFOTABS. In this section, we describe our robust quality estimation approach to validate EI-INFOTABS.

Automatic Evaluation. We use BERTScore (Zhang* et al., 2020), an automatic scoring metric for sentence similarity, between the source and back-translated English sentences. We use IndicTrans to generate Indic to English back-translated data.

BERTScore is known to correlate better with human judgment at the sentence level (Zhang* et al., 2020) compared to conventionally used MT evaluation metrics like BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004). BERTScore calculates word level semantic similarity whereas the conventional MT metrics focus on word overlap. The results are presented in Table 1. We notice high semantic similarity scores for all the languages. However, when we analyse the examples with low scores, we note that the scores are almost always low due to the error added during the back-translation phase. The back-translation introduces

---

[5] `https://translate.google.co.in/`

[6] `https://www.bing.com/translator`

errors due to incorrect transliteration of *Named Entities*. Consider the following example:

- Femme aux Bras Croisés is open for public viewing.
- Back-translated: The Ox Brass Crossox is open to the public
- Hindi Translation(Transliterated): fem auksa brās kroisaiksa janatā ke lie khulā hai

The Hindi translation of the original sentence is perfect, however, the named entity "*Femme aux Bras Croisés*" when back-translated becomes "*Ox Brass Crossox* "and yields a low BERTScore of 0.86. This is broadly identified as qualitative feedback for most of the sentences with low scores across all the languages. Around 20% of the examples yield a BERTScore of 1.0 and are deemed perfect translations when reviewed by native speakers.

Human Evaluation. Broadly, we follow the guidelines recommended in (Agirre et al., 2016) to conduct human evaluation. We (a.) diversely sample source-translation pairs in each language, (b.) prepare a common Direct Assessment (Graham et al., 2013) scoring strategy, and (c.) get the sampled data evaluated on the basis of that strategy.

Diverse Sampling. We sample 50 diverse hypotheses from the dev split of EI-INFOTABS for each Indic language. Using the k-DPP algorithm (Kulesza and Taskar, 2011) over the mBERT sentence representations, we're able to achieve syntactically and semantically diverse samples spanning the different table categories.

Direct Assessment. We adopt the human evaluation strategy for low resource machine translation laid out in (Guzmán et al., 2019). We ask native Indic language speakers proficient in English to score a source-translation pair from 0-100. The score highlights the perceived translation quality of the source-translation pair. For each language, we get the samples annotated by two different annotators. In Table 1, we report the average scores for each language along with the Pearson correlation coefficient (r) as a measure for inter-rater reliability. For more details on human evaluation strategy refer to Appendix §C.

Discussion. We report our evaluation results in Table 1. Automatic evaluation and our corresponding analysis on it shows that EI-INFOTABS consists of fluent, semantically accurate translations across all Indic languages. Moreover, we note competitive Direct Assessment scores for each language, and a positive r value which indicates that the native speakers agree on the good quality of EI-INFOTABS.

Language	DA	BS^{IT}	BS^{GT}	r
Bengali ('bn')	0.87	0.95	0.99	0.64
Marathi ('mr')	0.81	0.94	0.98	0.68
Gujarati ('gu')	0.89	0.95	0.98	0.38
Oriya ('or')	0.94	0.94	0.98	0.35
Hindi ('hi')	0.89	0.96	0.99	0.40
Punjabi ('pa')	0.86	0.95	0.98	0.34
Kannada ('kn')	0.87	0.95	0.98	0.70
Tamil ('ta')	0.85	0.94	0.98	0.59
Malayalam ('ml')	0.85	0.94	0.98	0.50
Telugu ('te')	0.84	0.94	0.98	0.39
Assamese ('as')	0.83	0.94	-	0.65

Table 1: Here, we compare the Average Direct Assessment (DA) scores provided by native speakers with Average BERTScore F1 scores for IndicTrans En-Indic-En back-translated data (BS^{IT}), and Average BERTScore F1 scores for Google-Translate En-Indic-En back-translated data (BS^{GT}). Additionaly, we also present the Pearson correlation coeffecient as a measure of inter-rater reliability. Higher score implies better quality for each of the metric.

4 Experimental Pipeline

We design our experimental pipeline along the lines of the research question: *How well do existing pre-trained multlilingual language models perform on the bTNLI task?* In this section, we propose various modeling strategies and examine how they might address the challenges and nuances of the proposed inference bTNLI task.

4.1 Table Representations

It is necessary to linearize semi-structured tabular data into a textual premise in order to reduce the task of Tabular Inferencing to a standard NLI task for which existing state-of-the-art language models can be adapted directly. We use and compare the previously proposed linearization methods (a.) Better Paragraph Representations (BPR) (Neeraja et al., 2021), (b.) and Premise as Structure - TabFact (Chen et al., 2020b; Gupta et al., 2020) (cf. Appendix §A). Henceforth, by premise, we refer to the linearized representation of the tabular premise i.e. the infobox table.

Table 2: Performance in terms of accuracy when evaluated on the α_1 test set. Higher value implies better performance. Here, LnAvg represents the average accuracy for a language across all models, while ModAvg represents the average accuracy of a model across all languages. A value in **Purple** represents the best accuracy for that model across all languages. An underlined value in **Blue** represents the best accuracy for that language across all models. A value in **Green** with an asterisk(*) represents the cases where language-wise and model-wise values coincide. As we fine-tune on a specific Indic language in the train-eval strategies Translate-Train-X and Bilingual-Train-X, we report the training average of accuracy on the remaining 10 Indic languages for them. We do not include the results of XLM-RoBERTa as the model fails to converge on these experiments on multiple runs with a distinct set of hyper-parameters as explained in Appendix §D. The results for the α_2 and α_3 sets are provided in Appendix §E.

4.2 Multilingual Models

Owing to the multilingual setting of this task, we utilise pre-trained multilingual models to encode the linearized English tabular premise along with the Indic hypothesis into contextual representations for classification. We consider two kinds of pre-trained multilingual models (a.) **Indic Specific** which includes IndicBERT and MuRIL due to their indic specific pre-training, and (b.) **Generic** which includes mBERT and XLM-Roberta due to their pre training in more than hundred languages. For more details refer to Appendix §B.

4.3 Training and Evaluation Strategies

In order to examine the inter-woven relationships among the 11 languages, and the corresponding impact on multilingual models' performance, we design a set of train-eval strategies for this task.

Translate-Train: We fine-tune and evaluate the models on EN-IN$_i$ premise-hypothesis pairs where IN$_i$ is one of the 11 Indic languages. This baseline evaluates the performance of the multilingual models on EI-INFOTABS when fine-tuned on Indic hypotheses. We also evaluated these models across all languages i.e. cross lingual zero-shot setting **Translate-Train-X**.

Translate-Test: We fine-tune the multilingual models on EN-EN premise-hypothesis pairs from the INFOTABS dataset and evaluate on EN-IN$_i$ premise-hypothesis pairs. This baseline evaluates the Zero-shot Cross-Lingual Transfer ability of the reasoning models from INFOTABS to EI-INFOTABS.

Bilingual-Train: We fine-tune the multilingual models on both EN-EN and EN-IN$_i$ premise-hypothesis pairs, and evaluate on EN-IN$_i$ premise-hypothesis pairs. This baseline evaluates whether addition of English hypotheses while fine-tuning aids the performance of the multilingual models prepared in Translate-Train. We also evaluated these models across all languages i.e. cross lingual zero-shot setting **Bilingual-Train-X**.

Multilingual-Train: We fine-tune the multilingual models on all available training data across all Indic languages and the English language. We evaluate the models on EN-IN$_i$ premise-hypothesis pairs on each 11 Indic languages. This baseline assesses if fine-tuning on several languages to produce a unified multilingual model improves performance.

EnTranslate-Test: We fine-tune the multilingual models on EN-EN premise-hypothesis pairs from INFOTABS and evaluate on EN-ENIN$_i$ premise-hypothesis pairs where ENIN$_i$ represents IN$_i$ to EN back-translated hypotheses. This approach evaluate the translate then test baseline on the EI-INFOTABS dataset.

5 Results and Analysis

In this section, we discuss and analyse the results obtained on conducting the experiments as per the various strategies laid out in §4. We present the results in Table 2 for each experiment on the α_1 test set using the BPR linearization algorithm. The values represent classification accuracy. We analyze the findings thoroughly across multilingual models, languages, train-eval techniques, tabular reasoning categories, adversarial test splits, and both datasets (INFOTABS and EI-INFOTABS).

5.1 Across Multilingual Models

We observe that MuRIL performs best across all languages and experiments except EnTranslate-Test, beating IndicBERT and mBERT. MuRIL's superior performance can be justified on the grounds of (a) the large size of the hidden layers, (b) Indic specific pre-training data, and (c) Indic specific pre-training objectives (Khanuja et al., 2021a). MuRIL's architecture consists of 237M parameters, compared to mBERT's 167M and IndicBERT's 33M, which makes it extremely competitive on any Indic NLU task. IndicBERT's relatively small size explains why it performs the worst, even though it is pre-trained on Indic specific data. mBERT comes in a close second to MuRIL, failing to perform adequately only on Odia (*or*). mBERT isn't pre-trained on Assamese (*as*) or Odia which justifies its extremely low performance on Odia. **However, we note competitive results on the Assamese language. This could be attributed to the fact that Assamese is closely related to Bengali (*bn*) linguistically. They both share the Bengali-Assamese script and are mutually intelligible** (Khemchandani et al., 2021).

#	dev	α_1	α_2	α_3
0	15.56%	16.33%	27.61%	25.67%
1-3	11.17%	10.83%	11.39%	14.22%
4-6	7.16%	7.5%	6.72%	9.61%
7-9	9.55%	10.67%	10.22%	12.67%
10-11	**56.56%**	**54.67%**	**44.06%**	**37.83%**

Table 3: Percentage of examples predicted correctly by our best performing model for the given number of Indic languages. For instance, 7.16% of examples in the dev set are predicted correctly for at least 4 and at max 6 Indic languages.

mBERT's performance gets boosted in EnTranslate-Test as mBERT is pre-trained on a significant amount of English data which makes it extremely competitive in modeling English NLU tasks. MuRIL performs similarly even though it is trained on lesser amount of English data. This could be due to Indic artifacts like sentence structure and inadequately transliterated named entities being present in the back-translated sentences which MuRIL has been trained to handle better than mBERT.

5.2 Across Languages

We observe that the models perform best on Hindi (*hi*) and Bengali. This is expected as they are high resource languages in the Indic context. **Additionally, as explained in §5.1, we note that pre-training or fine-tuning on Bengali aids the performance on Assamese due to their high degree of relatedness.** Table 3 shows the measure of agreement across the languages. We note that almost all languages agree on 55% of the predictions on the dev set and the α_1 test set. This reduces to 38% on the α_3 test set. **This indicates that for a majority of examples from the non-adversarial test sets, MuRIL performs uniformly across languages. However, its performance across languages starts varying more on the adversarial test sets (α_2 and α_3).**

5.3 Train-Eval Strategies

Translate-Train's results show that the multilingual models converge and perform adequately when fine-tuned on EI-INFOTABS. Moreover, when fine-tuned along with English data - as described

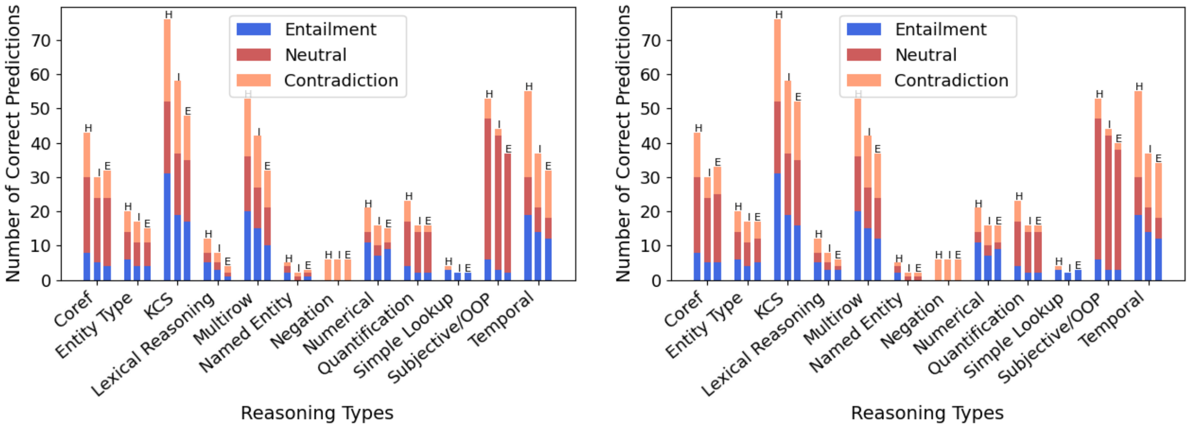

Figure 2: Here, we compare human benchmarks (H), predictions of the best performing model trained on INFOTABS from (Neeraja et al., 2021) (I) and predictions of our best performing model (E), MuRIL (Multilingual-Train), on the examples annotated with reasoning category in the dev split for Oriya (left) and Hindi (right).

in Bilingual-Train - mBERT and IndicBERT perform marginally better while MuRIL doesn't report a change in performance. **MuRIL, when fine-tuned on all languages as described in Multilingual-Train, performs best on** EI-INFOTABS **and forms the benchmark for this task**. mBERT and IndicBERT, however, perform worse on Multilingual-Train when compared to Bilingual-Train. This indicates that these models fail to generalise their reasoning ability across all languages and aren't as multilingually robust as MuRIL. The results on Translate-Test are the lowest across all train/eval strategies which indicates a poor Zero-shot Cross-Lingual Transfer from INFOTABS to EI-INFOTABS. However, the performance of MuRIL on Translate-Test is comparable with its performance on Translate-Train unlike mBERT and IndicBERT. This indicates that MuRIL can generalize well across English and Indic languages which are linguistically distinct.

Translate-Train-X and Bilingual-Train-X evaluate the average Cross-Lingual Transfer performance of the models trained in Translate-Train and Bilingual-Train. **We observe higher performance in Bilingual-Train-X over Translate-Train-X which indicates that addition of English training data aids the Cross Lingual Transfer from one Indic language to another. Moreover, the average performance of MuRIL on Bilingual-Train-X is comparable to that on Translate-Train which suggests that MuRIL robustly generalises across Indic languages.** Both, Bilingual-Train-X and Translate-Train-X perform better than Translate-Test due to high language relatedness among Indic languages when compared with English. The results on EnTranslate-Test are extremely promising for both MuRIL and mBERT. Their performance is very close to that of the best performing model, MuRIL, on Translate-Train. This indicates that back-translation doesn't lead to a significant loss in information required for the bTNLI task.

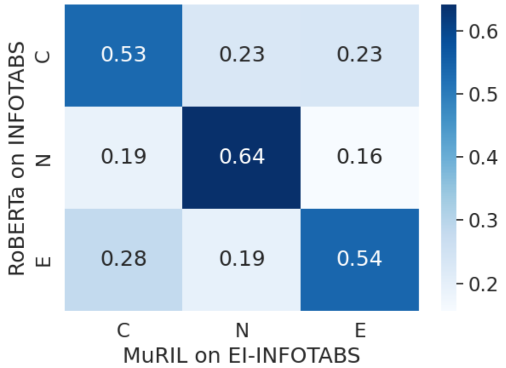

Figure 3: Consistency Matrix which measures the deviation of our best performing model, MuRIL (Multilingual-Train)'s predictions on the α_1 test set for Hindi as compared to that of RoBERTa$_{\text{LARGE}}$ on the α_1 test set of INFOTABS.

5.4 Tabular Reasoning Categories

We conduct a fine-grained analysis on how our best model, MuRIL (Multilingual-Train), performs on various reasoning categories. We present the results in Figure 2 for Hindi and Odiya. We observe that MuRIL performs similarly on EI-INFOTABS as RoBERTa$_{\text{LARGE}}$ does on INFOTABS for entity type, named entity, negation, numerical, quantification and simple lookup reasoning types. Additionally, MuRIL performs better for the co-reference resolution reasoning type. This is broadly

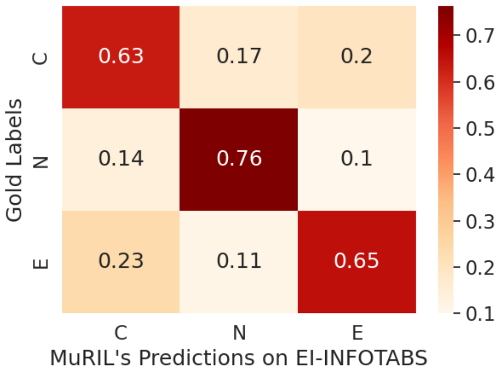

Figure 4: Confusion Matrix for the predictions of our best performing model, MuRIL (Multilingual-Train), on the Hindi α_1 set from EI-InfoTabs.

observed across all the Indic languages. Both RoBERTa$_{\text{LARGE}}$ and MuRIL perform poorly for knowledge and common sense, multi-row, co-reference, and temporal reasoning types.

5.5 Across Adverserial Test Splits

The results for the other evaluation sets α_2 and α_3 are provided in Appendix §E. Across all the experiments, we note that the fine-tuned models perform best on α_1, followed by α_2 and α_3 respectively. **Moreover, we note that on most baselines, the average performance of a fine-tuned model drops by roughly 10% when tested on α_2 or α_3.** This is similar to the observations reported on InfoTabs (Neeraja et al., 2021) and presented in Table 4. Low performance of the multilingual models on the α_2 test set of EI-InfoTabs indicates that (a.) multilingual models learn shallow lexical features to make inferences on EI-InfoTabs just like the monolingual models do on InfoTabs, (b.) and IndicTrans carefully captures the lexical adversity in the α_2 test set of InfoTabs.This commends the ability of IndicTrans to handle lexical nuances. Low performance on α_3 test set of EI-InfoTabs suggests that the multilingual models learn categorical features and perform adversely when evaluated on unseen category.

5.6 EI-InfoTabs v/s InfoTabs

Table 4 reports the human benchmarks and the baselines with the BPR linearization algorithm on each validation set in InfoTabs. We observe that the baselines on EI-InfoTabs are within an absolute margin of 10% when compared to those on InfoTabs. **This suggests that EI-InfoTabs is more challenging than InfoTabs which was expected due to the presence of (a.) bilinguality within the premise-hypothesis pair, and (b.) the low resource nature of Indic languages.**

Figure 3 reports the consistency of predictions of MuRIL on the α_1 test set of Hindi EI-InfoTabs when compared against that of RoBERTa$_{\text{LARGE}}$ on the α_1 test set of InfoTabs. We observe that MuRIL behaves noticeably different than RoBERTa$_{\text{LARGE}}$. MuRIL disagrees with RoBERTa$_{\text{LARGE}}$ on 47% of examples with the Contradiction and Entailment labels. However, for Neutral labels, it only disagrees on around 36% of the examples. Moreover, from our discussion in §5.4, we observe that MuRIL outperforms RoBERTa$_{\text{LARGE}}$ on certain reasoning categories.

Model (Rep)	Dev	α_1	α_2	α_3
BERT$_B$ (BPR)	63.00	63.54	52.57	48.17
RoBERTa$_B$ (TabFact)	68.06	66.7	56.87	55.26
RoBERTa$_L$ (BPR)	76.42	75.29	66.50	64.26
RoBERTa$_L$ (TabFact)	77.61	75.06	69.02	64.61
Human	**79.78**	**84.04**	**83.88**	**79.33**

Table 4: The human benchmarks and several baselines on evaluation set of InfoTabs as reported in Gupta et al. (2020) (TabFact) and Neeraja et al. (2021) (BPR). Here subscript X$_L$ and X$_B$ represent X model L: Large and B: Base versions respectively.

However, the models fine-tuned on EI-InfoTabs broadly mimic the performance of RoBERTa$_{\text{LARGE}}$ on InfoTabs. Figure 4 presents the confusion matrix of MuRIL's predictions on the α_1 test set of Hindi. We observe a similar distribution across all Indic languages. As noted in Gupta et al. (2020), MuRIL also tends to predict Neutral hypotheses with the highest confidence as they mostly contain out of table or subjective information terms. Moreover, both models confuse Entailment with Contradiction inference label and vice-versa. We observe that the model predictions on EI-InfoTabs is similar to RoBERTa$_{\text{LARGE}}$ predictions on InfoTabs.

6 Further Discussion

EI-InfoTabs is the first Tabular NLI dataset in the Indic context which enables preliminary studies in this field. Moreover, it introduces bilinguality for fact verification scenarios which is of huge significance in low resource contexts. It motivates the development of cross-lingual reasoning models, and helps in evaluation of robustness of multilingual models. For instance, our experiments on EI-InfoTabs clearly indicate that MuRIL is a significantly more robust multilingual model when compared to mBERT as it is able to generalize its reasoning ability across all Indic languages.

Although, we explain how machine translation doesn't affect the semantics of the hypotheses, it does come with a few challenges. We identified a few instances wherein the IndicTrans model translates named entities, instead of transliterating them. This is observed only, but not always, when a named entity has an English dictionary word in it. For instance, "*Death Proof*", name of a movie, gets translated and not transliterated in two out of nine hypotheses containing the phrase. This is mostly observed in the *Movies* category. However, this doesn't affect our reasoning models and they perform on par on this category when compared with RoBERTa$_{\text{LARGE}}$'s performance on INFOTABS. This is so because such translations when shallow parsed indicate that the translated entity still acts as the Noun Phrase in the sentence. This helps the translation, though technically imperfect, retain the intended semantic structure.

7 Related Work

Tabular Reasoning. Tabular NLI has been of keen interest recently. Datasets like TabFact (Chen et al., 2020b), INFOTABS (Gupta et al., 2020) were the first resources on TNLI and they enabled a fine-grained examination of the task. Beyond NLI, there has been a thorough examination of various other NLP tasks on semi-structured data. For instance, question answering (Abbas et al., 2016; Chen et al., 2020c; Zayats et al., 2021; Oguz et al., 2020; Chen et al., 2021, and others), semantic parsing and retrieval (Krishnamurthy et al., 2017; Sun et al., 2016; Pasupat and Liang, 2015; Lin et al., 2020, and others), tabular probing (Gupta et al., 2021), generative tasks including table-to-text (Parikh et al., 2020; Nan et al., 2021; Yoran et al., 2021; Chen et al., 2020a,d, and others). Other works have explored creating task-independent representations for Wikipedia infoboxes (Herzig et al., 2020; Yin et al., 2020; Zhang et al., 2020; Iida et al., 2021; Pramanick and Bhattacharya, 2021; Glass et al., 2021, and others), and boosting tabular reasoning by pre-training and external knowledge incorporation (Neeraja et al., 2021; Varun et al., 2022, and others).

Multilingual Models. Multilingual, and specifically Cross-Lingual transfer (Deshpande et al., 2021; Patil et al., 2022, and other), has been widely discussed in the context of low resource languages. Several datasets (Conneau et al., 2018; Yang et al., 2019; Ponti et al., 2020; Artetxe et al., 2020; Nivre et al., 2016; Lewis et al., 2021, and others), benchmarks and leaderboards (Hu et al., 2020; Liang et al., 2020; Ruder et al., 2021; Khanuja et al., 2021b, and others), and evaluation frameworks (Tarunesh et al., 2021; K et al., 2021; Srinivasan et al., 2021) have emerged which focus entirely on evaluation of multilingual NLU. Further, multilingual language models have been developed for (a.) Natural Language Understanding (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020; Chi et al., 2021; Chung et al., 2021, and others), (b.) and Natural Language Generation (Xue et al., 2021; Fan et al., 2021, and others).

Indic Resources. Indic NLP, recently, has seen a recent surge in the number of datasets (Ramesh et al., 2022; Roark et al., 2020; Haddow and Kirefu, 2020a; Abadji et al., 2022; Kolluru et al., 2021, and others), multilingual models (Dabre et al., 2021; Kakwani et al., 2020; Khanuja et al., 2021a, and others), toolkits (Arora, 2020; Bhat et al., 2015; Jain et al., 2020, and others), translation systems (Ramesh et al., 2022), and dedicated benchmarks for evaluation (Kakwani et al., 2020; Krishna et al., 2021). This has enabled the Indian NLP research community to construct competent models for a variety of challenging NLP tasks.

8 Conclusion

We motivate and introduce the bilingual tabular NLI for fact verification tasks, and release EI-INFOTABS- a first of its kind tabular NLI dataset for making inferences in 11 Indic languages over English tabular data. Our robust quality estimation experiments show that the machine translated datasets closely preserve the semantics of the source and are fluent. We show that pre-trained multilingual models find this task challenging, however, still perform close to the benchmarks on INFOTABS with Translate-test and Translate-train providing good performance. The analysis also shows the similarity of inference capabilities across languages. The dataset offers immense potential as it opens up avenues in (a) multilingual tabular NLI, (b) bilingual claim verification, (c) and evaluation of multilingual models.

9 Ethical Considerations

In terms of demographic and socioeconomic characteristics, we attempted to establish a balanced, bias-free dataset. The EI-INFOTABS dataset is derived from the INFOTABS dataset, which is devoid of bias. The only possible source of prejudice can be the translation pipeline. Our qualitative analysis indicates that translation quality is reasonably good and there aren't any observable biases like gender in the translation. The dataset is intended and useful for studying language model representations in a cross-lingual and structured data setting. The paper points out that low-resource languages can benefit from reasoning over structured data in other languages. This is a relatively new research topic and further work will help understand limitations as well as uncover new directions. Hence, we recommend the use of this dataset at this point exclusively for scholarly, non-commercial purposes.

Acknowledgement

We thank members of the Utah NLP group for their valuable insights and suggestions at various stages of the project; and reviewers their helpful comments. The authors also thank Manila Devaraj, Arka Singha, Anagh Chattopadhyay, Maitrey Mehta, Souvik Banerjee, Rupambara Padhi, Jayant Duneja, Nithila Prakash, Tanvi Kamble, Anirudh Palutla for helping with annotations for quality estimation. A Details: Table Representation

1. **Premise as Paragraph**: (Chen et al., 2020b), (Gupta et al., 2020) employ universal templates to construct close to natural language sentences for isolated cells in a

Hyper Parameter	XLM-RoBERTa	IndicBERT	MuRIL-base-cased	mBERT-cased
Initial Learning Rate	[1e-4,1e-9]	5e-5	5e-5	5e-5
Batch Size	128	128	128	128
Weight Decay	0.01	0.01	0.01	0.01
Max Seq Length	128	128	128	128
Model Size	278M	33.7M	237M	177M
Warmup Steps	500	500	500	500

Table 5: Hyper Parameters used for Fine-Tuning the corresponding multilingual models.

row, and then, concatenate them to obtain a single paragraph representation. (Gupta et al., 2020) suggest constructing sentences of the form *"The* `k` *of* `t` *is* `v`*"* for a cell having key `k`, value `v` in a table with title `t`. E.g. in figure 1 for the row *Born* the premise sentence would be *"The* `born` *of* `Joe Strummer` *is* `21 August 1952 (1952-08-21) Ankara, Turkey`*"*

However, (Neeraja et al., 2021) identify that such templates can often lead to ungrammatical sentences and propose the ***B****etter* ***P****aragraph* ***R****epresentation* (BPR) approach. BPR utilises type specific templates based on the entity type of a key, and the overall category of the table itself resulting in grammatical sentences. (Neeraja et al., 2021) note a significant increase in performance while employing BPR over the universal template. We adopt BPR as one of our representation approaches. E.g. for same *Born* key in figure 1 the premise sentence with BPR representation would be *"*`Joe Strummer` *was born on* `August 21, 1952 (1952-08-21)` *at* `Ankara, Turkey`*"*

2. **Premise as Structure**: Unlike the natural language like *Premise as Paragraph* representations, here, we try to represent the row as structural text as proposed by (Chen et al., 2020b). Every isolated cell in a row is represented as *"*`k` *:* `v`*"* where `k` is the key, and `v` is the value of the cell. A row's structural representation is a semi-colon ";" separated sequence of the structural representations of all the isolated cells in that row. E.g. for the same *Born* key in figure 1 the premise sentence will be represented as *"*`Born : August 21, 1952 (1952-08-21), Ankara, Turkey`*"*

B Details: Multilingual Models

Indic Specific: This class of multilingual models are pre-trained entirely on Indic language data along with English. We use *MuRIL Base* (Khanuja et al., 2021a), and *IndicBERT* (kak) pre-trained multilingual models. *MuRIL* is a *BERT* (Devlin et al., 2019) based model trained with *Masked Language Modeling* (Taylor, 1953) and *Translation Language Modeling* (CONNEAU and Lample, 2019) objectives. It is trained on (a.) Common Crawl OSCAR corpus[7] and Wikipedia[8] monolingual data for 16 Indic languages along with the English language, (b.) PMIndia (Haddow and Kirefu, 2020b) along with other in-house parallel corpora, (c.) and the Dakshina Dataset (Roark et al., 2020) along with other parallel in-house transliterated corpora. *IndicBERT* is an *ALBERT* (Lan et al., 2019) based model trained on *IndicCorp* (kak).

Generic: This class of multilingual models are pre-trained on a wide array of languages from around the world. We use *mBERT-cased* (Devlin et al., 2019) and *XLM-RoBERTa* (con) pre-trained multilingual models.

C Human Evaluation Strategy

We requested our colleagues who are native speakers and are proficient in English to help us with this task while disclosing the intentions. We provide them with instructions adopted from the Direct Assessment (Graham et al., 2013) strategy for low resource machine translation in (Guzmán et al., 2019). We sample 50 pairs of source, translation pairs and ask the annotators to provide a continuous score between 0 to 100. 0–10 range represents a translation that is completely incorrect and inaccurate. 70–90 range represents a translation that closely preserves the meaning of the source sentence while the 90–100 range represents a perfect translation.

---

[7] Oscar Corpus [8] Tensorflow Datasets

D Model Hyper-Parameters

Table 5 reports the hyper-parameters used for fine-tuning the multilingual models on EI-InfoTabs. We use the Huggingface Transformers[9] library to script these experiments. We were unable to successfully converge XLM-RoBERTa in multiple runs spanning a distinctive set of hyper-parameters. Figure 5 shows the loss plots for XLM-RoBERTa and mBERT when fine-tuned on EI-InfoTabs. It is distinctively visible that XLM-RoBERTa is unable to converge on EI-InfoTabs on a significant amount of steps unlike mBERT.

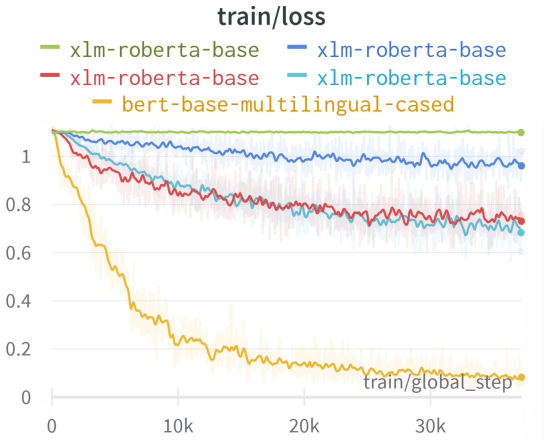

Figure 5: Train Loss for multiple runs of XLM-RoBERTa with distinct set of hyper-parameters compared with that of mBERT. Each run spans roughly 37,000 steps.

Fine-Tuning Settings. We follow the conventionally used pipeline for fine-tuning *BERT* for Sequence Classification (Jiang and de Marneffe, 2019). We concatenate the premise and the hypothesis strings using a `[SEP]` token in between them, prepend this sequence with a `[CLS]` token, tokenize this sequence using the pre-trained tokenizer for the respective model, and provide the obtained sequence as input to the pre-trained model. We attach a three-way classification head with cross-entropy loss on top of the pooled output obtained from the previous step. With an initial learning rate of 5e-05 with AdamW optimizer (Loshchilov and Hutter, 2018), we fine-tune each model on 4 1080Ti GPUs with a batch size of 32 per GPU over 10 epochs.

E Performance on the α_2 and α_3 Adversarial Sets

Tables 6 and 7 report the results for the adverserial test sets α_2 and α_3 respectively using the BPR linearization method.

F Zero Shot Cross-Lingual Transfer

Tables 8 and 9 report the performance of MuRIL on Translate-Train-X and Bilingual-Train-X. We note that models trained on linguistically closer pairs of languages are able to admirably transfer their performance to each other. Notably, Assamese (‘as’) and Bengali (‘bn’) being immensely closely related, support this hypothesis. Moreover, we note the same for closely related Indo-European languages Bengali, Hindi, Gujarati (‘gu’), and Marathi (‘mr’). Models trained on these languages distinctively transfer their performance better on each other compared to languages from the Dravidian language family - Malayalam (‘ml’), Telugu (‘te’), Tamil (‘ta’), Kannada (‘kn’). Dravidian languages are not as closely related due to differences in scripts and sentence structures which is observed in the results as well.

Table 6: Performance in terms of accuracy when evaluated on the α_2 test set. Higher value implies better performance. Here, LnAvg represents the average accuracy for a language across all models, while ModAvg represents the average accuracy of a model across all languages. A value in **Purple** represents the best accuracy for that model across all languages. An underlined value in **Blue** represents the best accuracy for that language across all models. A value in **Green** with an asterisk(*) represents the cases where language-wise and model-wise values coincide. As we fine-tune on a specific Indic language in the fine-tuning strategies Translate-Train-X and Bilingual-Train-X, we report the training average of the concerned language. We do not include the results of XLM-RoBERTa as the model fails to converge on these experiments on multiple runs with a distinct set of hyper-parameters as explained in Appendix §D.

Table 7: Performance in terms of accuracy when evaluated on the α_3 test set. Higher value implies better performance. Here, LnAvg represents the average accuracy for a language across all models, while ModAvg represents the average accuracy of a model across all languages. A value in **Purple** represents the best accuracy for that model across all languages. An underlined value in **Blue** represents the best accuracy for that language across all models. A value in **Green** with an asterisk(*) represents the cases where language-wise and model-wise values coincide. As we fine-tune on a specific Indic language in the fine-tuning strategies Translate-Train-X and Bilingual-Train-X, we report the training average of the concerned language. We do not include the results of XLM-RoBERTa as the model fails to converge on these experiments on multiple runs with a distinct set of hyper-parameters as explained in Appendix §D.

Abstract

Entities lie in the heart of biomedical natural language understanding, and the biomedical entity linking (EL) task remains challenging due to the fine-grained and diversiform concept names. Generative methods achieve remarkable performances in general domain EL with less memory usage while requiring expensive pre-training. Previous biomedical EL methods leverage synonyms from knowledge bases (KB) which is not trivial to inject into a generative method. In this work, we use a generative approach to model biomedical EL and propose to inject synonyms knowledge in it. We propose KB-guided pre-training by constructing synthetic samples with synonyms and definitions from KB and require the model to recover concept names. We also propose synonyms-aware fine-tuning to select concept names for training, and propose decoder prompt and multi-synonyms constrained prefix tree for inference. Our method achieves state-of-the-art results on several biomedical EL tasks without candidate selection which displays the effectiveness of proposed pre-training and fine-tuning strategies. The source code is available at Github.com/Yuanhy1997/GenBioEL.

1 Introduction

Biomedical entity linking (EL) refers to mapping a biomedical mention (i.e., entity) in free texts to its concept in a biomedical knowledge base (KB) (e.g., UMLS (Bodenreider, 2004)). This is one of the most concerned tasks of research in medical natural language processing which is highly related to high-throughput phenotyping (Yu et al., 2015), relation extraction (Li et al., 2016), and automatic diagnosis (Yuan and Yu, 2021).

Recent methods in biomedical EL mainly used neural networks to encode mentions and each concept name into the same dense space, then linked mentions to corresponding concepts depending on embedding similarities (Sung et al., 2020; Lai et al., 2021; Bhowmik et al., 2021; Ujiie et al., 2021; Agarwal et al., 2021). Synonyms knowledge has been injected into these similarity-based methods by contrastive learning (Liu et al., 2021a; Yuan et al., 2022). For example in UMLS, concept **C0085435** has synonyms: *Reiter syndrome*, *Reactive arthritis* and *ReA* which help models to learn different names of a concept entity. However, similarity-based methods requires large memory footprints to store representation for each concept which are hard to deploy.

In general domain, GENRE (Cao et al., 2021a) viewed EL as a seq2seq task which inputs mentions with contexts and outputs concept names token-by-token. Mentions, contexts and concepts can be mingled due to the power of transformers, and the model does not need to store representations for each concept during inference. GENRE pre-trained on Wikipedia EL datasets to boost performances. However, directly implementing GENRE on biomedical EL cannot harvest satisfying results. The gap occurs in two aspects: (1) There are no such large-scale human-labeled biomedical EL datasets for pre-training. (2) Biomedical concepts may have multiple synonyms. We find the results are sensitive to the synonyms selection for training, and simply using a 1-to-1 mapping between names and concepts as Cao et al. (2021a,b) may hurt performances.

To address the above issues, we propose KB-guided pre-training and synonyms-aware fine-tuning to improve generative EL. For **pre-training**, we construct pre-training samples using synonyms and definitions collected from KBs and sentence templates. KB-guided pre-training has the same format as seq2seq EL, which fills the gap of loss of pre-training corpus. Compared to the method introduced in Cao et al. (2021a), ours performs better in biomedical EL with fewer resources. For **fine-**

tuning, we propose decoder prompts to highlight mentions. We find the model tends to generate textually similar names to mentions. Hence textual similar criterion is proposed for selecting concept names during fine-tuning. During inference, we propose a multi-synonyms constrained prefix tree, which results in significantly improved performance. The overview of our approach is illustrated in Figure 1.

We conduct experiments on various biomedical EL datasets and achieve SOTA results on COMETA, BC5CDR, and AskAPatient (AAP) even without candidate selection. Extensive studies show the effectiveness of our proposed pre-training and fine-tuning schemes.

2 Approach

Define a set of concepts $\mathcal{E}$ as target concepts (i.e. concepts from target KBs). For each concept $e \in \mathcal{E}$, we have a set of synonyms names $f(e) = \{s_e^i | i \in \{1, \dots, n_e\}\}$. All the synonyms forms a name set $\mathcal{S} = \bigcup_{e \in \mathcal{E}} \{s_e^i | i \in \{1, \dots, n_e\}\}$. Names-to-concept mappings can be defined by:$\sigma(s_e^i) = e$ where $\sigma = f^{-1}$. For mention m with left and right contexts c_l and c_r which gold label is $e_m \in \mathcal{E}$, we need to find the target concept $\hat{e}_m \in \mathcal{E}$. m, c and s comprise a sequence of tokens.

2.1 Seq2seq EL

Our model applies an encoder-decoder transformer architecture following Cao et al. (2021a). The encoder input is: `[BOS]`c_l`[ST]`m`[ET]`c_r`[EOS]`, where `[ST]` and `[ET]` are the special tokens marking m[1]. For the decoder side, unlike GENRE decoding target names directly, we use simple prefix prompts P_m =<m `is`> to strengthen the interaction between mentions and make the decoder side output resemble a natural language sentence: `[BOS]` m `is` s, where s is a target name belong to label concept e. The training objective of Seq2Seq EL is to maximize the likelihood:

$$p_\theta(s|P_m, c, m) = \prod_{i=1}^{N_s} p_\theta(y_i|y_{<i}, P_m, c, m),$$

where N_s is the number of tokens of s and y_i indicates the ith token. The inference of Seq2seq EL applies beam search (Sutskever et al., 2014) with targets constrained to the name set $\mathcal{S}$ by a prefix tree (constructed by name set $\mathcal{S}$). Unlike mGENRE Cao et al. (2021b) using provided candidates to decrease the size of the prefix tree, we use the whole name set $\mathcal{S}$ instead.

2.2 KB-Guided Pre-training

As the training data of EL is tiny compared to the vast number of concepts in KB, thus it makes EL for some mentions zero-shot problems. We want to leverage synonyms knowledge from KB to enhance the model's performance. Injecting synonyms knowledge to the encoder-only models can be done by contrastive learning (Liu et al., 2021a; Yuan et al., 2022). However, such a paradigm cannot directly apply to encoder-decoder architecture as entities are not represented by dense embeddings. To mitigate this problem, we construct a pre-training task that shares a similar form as Section 2.1. We manually define a set of clause templates to splice with synonyms and definitions in KB to form input synthetic language discourses. Concretely, we select two synonyms s_e^a and s_e^b and definition c_e of a concept $e \in \mathcal{E}$. Then we randomly pick a template to concatenate them to form the encoder input, here we give two examples:

`[BOS][ST]`s_e^a`[ET]` **is defined as** c_e`[EOS]`
`[BOS]`c_e **describes** `[ST]`s_e^a`[ET][EOS]`

For the decoder: `[BOS]` s_e^a `is` s_e^b. c_e is the simulated context and s_e^b is for model to predict. If definitions are absent in KB, we will use other synonyms to construct c_e. All templates we used can be found in Appendix E.2.

2.3 Synonyms-Aware Fine-tuning

We propose and validate by experiments in Section 4 that seq2seq EL is profoundly influenced by the textual similarity between mentions and concept names. It tends to generate textually similar names. We select the target name by calculating the character 3-gram TF-IDF similarity (Neumann et al., 2019) between mention m and all synonyms $\{s_e^i\}$ and choosing the most similar one as

$$s = \arg\max_{s \in \{s_e^i\}} \cos(\text{TFIDF}(m), \text{TFIDF}(s)).$$

By the textual similarity criterion, we manually reduce the difficulty of fine-tuning. We do not use this criterion for pre-training since we want it to learn various synonyms to improve generalization.

---

[1] We use words **Start** and **End** as `[ST]` and `[ET]` respectively.

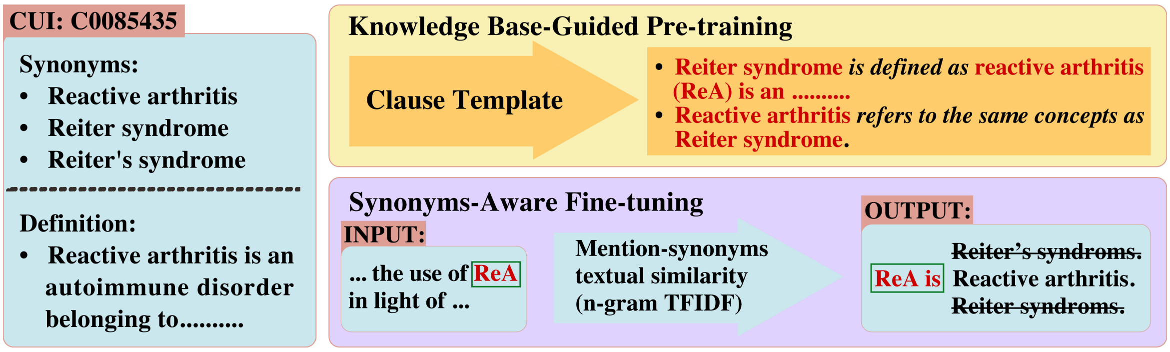

Figure 1: Overview of our approach.

Model	BC5CDR
Bhowmik et al. (2021)	84.8
Angell et al. (2021)	91.3
Varma et al. (2021)	$91.9_{\pm0.2}$
FT (Ours)	$92.6_{\pm0.1}$
PT + FT (Ours)	**93.3**$_{\pm0.2}$

Table 1: Recall@1 on BC5CDR test dataset. Sung et al. (2020); Liu et al. (2021a); Lai et al. (2021) evaluate it by splitting into two subsets which is a easier setting and we do not compare to them. FT corresponds to fine-tuning and PT corresponds to pre-training.

Model	NCBI	COMETA	AAP
Sung et al. (2020)	91.1	71.3	82.6
Liu et al. (2021a)	92.3	75.1	89.0
Lai et al. (2021)	92.4	80.1	-
FT (Ours)	$91.6_{\pm0.1}$	$80.7_{\pm0.2}$	$88.8_{\pm0.1}$
PT + FT (Ours)	**91.9**$_{\pm0.2}$	**81.4**$_{\pm0.1}$	**89.3**$_{\pm0.1}$

Table 2: Recall@1 on NCBI-disease, COMETA and AskAPatient test datasets.

Different from GENRE using only one canonical name for each concept for prefix tree, we use multi-synonym names (i.e. $\mathcal{S}$) to construct prefix tree. During inference, we apply prefix tree constrained beam search to decode the name $\hat{s}_m$, and map to the concept $\hat{e}_m = \sigma(\hat{s}_m)$ via N-to-1 names-to-concept mapping σ.

3 Experiments

3.1 Datasets and KBs

Pre-training We use a subset of UMLS *st21pv* (Mohan and Li, 2019) as $\mathcal{E}$ for pre-training. It contains 2.37M concepts, where 160K concepts contain definitions and 1.11M concepts have multiple synonyms. While pre-training, we iterate concepts and synonyms to construct inputs and outputs.

Fine-tuning We evaluate our model on BC5CDR (Li et al., 2016), NCBI (Doğan et al., 2014), COMETA (Basaldella et al., 2020) and AAP (Limsopatham and Collier, 2016). These benchmarks focus on different entity types, including disease, chemicals, and colloquial terms. For fair comparison, we follow Varma et al. (2021) in BC5CDR, Lai et al. (2021) in NCBI and COMETA, and Limsopatham and Collier (2016) in AAP to construct dataset splits and target KB concepts $\mathcal{E}$. Name set $\mathcal{S}$ is constructed by synonyms from UMLS and original KB which is detailed in Appendix E.1. Datasets summaries are shown in Appendix A. We use recall@1/@5 as metrics for performance illustration, and recall@5 results are listed in Appendix C.

3.2 Implementation Details

We use `BART-large` (Lewis et al., 2020) as the model backbone. We pre-train and fine-tune our model using teacher forcing (Williams and Zipser, 1989) and label smoothing (Szegedy et al., 2016) which are standard in seq2seq training. The hyperparameters can be found in Appendix E.3.

3.3 Main Results

Table 1 and 2 compare the recall@1 with state-of-the-art(SOTA) methods. Our method with KB-guided pre-training exceeds the previous SOTA on BC5CDR, COMETA and AAP, which is up to 1.4 on BC5CDR, 1.3 on COMETA and 0.3 on AAP. Our method also shows superiority over previous SOTA on BC5CDR and COMETA without pre-training. Besides, our method shows competitive results on NCBI compared to SOTA, and we further analyse the results of NCBI through case studies in Appendix D.

4 Discussion

Does pre-training help? On all datasets, KB-guided pre-training improves fine-tuning consis-

Init	BC5CDR	COMETA
Not Fine-tune		
BART	6.2	4.1
GENRE	38.3	23.8
KB-guided	42.4	33.1
Synonyms-aware Fine-tune		
BART	92.5	80.9
GENRE	92.9	80.8
KB-guided	**93.3**	**81.4**

Table 3: Recall@1 for BC5CDR and COMETA test dataset using different initial checkpoints. We only use left context for BART in decoding and omit decoding prompts for GENRE when not fine-tuning which are consistent with their pre-training.

tently, which is 0.7 on BC5CDR, 0.3 on NCBI, 0.7 on COMETA, and 0.5 on AAP. To better understand KB-guided pre-training, we conduct ablation studies. We compare different pre-trained models without fine-tuning in Table 3. BART fails to link mentions due to the mismatch of the pre-training task. GENRE has been pre-trained on the large-scale BLINK dataset (Wu et al., 2020), and it obtains a decent ability to disambiguate biomedical mentions. Our pre-trained model shows improvement on BC5CDR and COMETA compared to GENRE with fewer pre-training resources (6 GPU days vs. 32 GPU days). We then conduct synonyms-aware fine-tuning on different pre-trained models in Table 3. Our pre-trained model outperforms BART (+0.8 on BC5CDR, +0.5 on COMETA) and GENRE (+0.4 on BC5CDR, +0.6 on COMETA) which proves the effectiveness of pre-training.

Selection of Names We ablate the selection of target names s for fine-tuning: (a) proposed TF-IDF similarity; (b) the shortest name in a concept; (c) randomly sampled name in a concept. We also compare how to construct $\mathcal{S}$ for inference: (i) using all synonyms from UMLS and target KB; (ii) using the shortest name for a concept; (iii) using randomly sampled name for a concept. We note (i) establish an N-to-1 mapping from synonym name to concept, while (ii) and (iii) establish a 1-to-1 mapping. We conduct experiments on available combinations. From Table 4, we conclude that (1) N-to-1 mapping performs better than 1-to-1 mappings during inference, which means synonyms can boost performances. Using one synonym like GENRE degrades performances. (2) Textual similarity criterion performs better than shortest or sampled names when training.

We also check the accuracies of different TF-IDF similarity sample groups on COMETA trained with using all synonyms as $\mathcal{S}$ and TF-IDF for selecting target names s. From Figure 2, we find the distribution of TF-IDF similarity between mentions and selected names is polarized, and the accuracy increases along with textual similarities which prove textually similar targets are easy to generate. This phenomenon validates the advantage of selecting textually similar names for fine-tuning.

s	$\mathcal{S}$	Prompt	BC5CDR	COMETA
TF-IDF	All	√	**93.3**	**81.4**
Shortest	All	√	87.2	80.6
Sample	All	√	86.9	80.8
Shortest	Shortest	√	76.3	77.5
Sample	Sample	√	72.4	77.8
TF-IDF	All	×	93.0	80.9

Table 4: Recall@1 for BC5CDR and COMETA test dataset using different s for training, different $\mathcal{S}$ for inference and applying decoder prompts or not.

Decoder Prompting One difference between GENRE and ours is using prompt tokens on the decoder side. Prompting has shown improvement on various NLP tasks (Liu et al., 2021b). Here, prompt tokens serve as informative hints by providing additional decoder attention queries and making the outputs resemble language models' pre-training tasks. We test dropping the prompt tokens, and Table 4 shows degraded performances (-0.3 on BC5CDR and -0.5 on COMETA). The results illustrate the improvement brought by decoder prompting.

Sub-population Analysis We list several sub-populations of the BC5CDR benchmark to illustrate the model's performance on different fine-grained categories of mentions. The details of sub-populations are shown in Appendix C.2

Our model's performance on different sub-populations of BC5CDR is shown in Table 9. Through the results, we have several findings:

1. Compared with Varma et al. (2021), our method shows superiority over most of the sub-populations of BC5CDR. Our method without pre-training outperforms the data-augmented version of Varma et al. (2021).

2. Our method surpasses Varma et al. (2021) by the largest margin on **Unseen Concepts**. One possible explanation is that our generative method learns the linkage between mentions and contextual information better, thus gaining superior zero-shot performance.

Subset	Varma et al. (2021)		Ours		Sample Size
	Baseline	Full	FT	PT + FT	
Overall	89.5	91.3	92.5	**93.4**	9.65k
Single Word Mentions	91.4	92.9	95.8	**96.6**	7.04k
Multi-Word Mentions	84.5	**86.8**	85.3	84.8	2.62k
Unseen Mentions	75.3	79.6	81.8	**83.3**	3.28k
Unseen Concepts	69.7	77.5	86.3	**86.9**	2.16k
Not Direct Match	89.4	**91.9**	83.0	84.3	3.83k
Top 100	97.3	97.2	97.9	**98.1**	3.31k

Table 5: Accuracy over sub-populations on BC5CDR of our proposed methods and Varma et al. (2021). The best results are presented in bold letters and the second best results are highlighted by underlines.

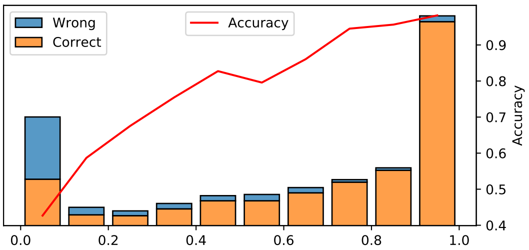

Figure 2: The accuracy of our model on COMETA dataset. The X-axis represents the TF-IDF similarities between mention m and the selected target names s.

3. Our KB-guided pre-training gains improvement universally on most subsets. This reflects the effectiveness of the pre-training task.

4. Popular concepts and single-word mentions are more easily resolved compared to unseen mentions or concepts and multi-word mentions, respectively. Unsurprisingly, mentions with less training resources and longer textual forms are more difficult. The lengths of mentions may challenge the generative model.

5 Related Work

Biomedical EL is an important task in biomedical NLP. Classification-based methods used a softmax layer for classification (Limsopatham and Collier, 2016; Miftahutdinov and Tutubalina, 2019) which consider concepts as category factors and lost information of concept names. Recent methods (Sung et al., 2020; Liu et al., 2021a; Lai et al., 2021; Bhowmik et al., 2021; Ujiie et al., 2021; Agarwal et al., 2021; Yuan et al., 2022) encoded mentions and names into a common space and disambiguated mentions by nearest neighbors. Angell et al. (2021) and Varma et al. (2021) adopted a retrieve-and-rerank framework to boost performances. Varma et al. (2021) emphasized the lack of training samples in EL and augmented data using Wikipedia and PubMed, while our pre-training corpus constructed by KB and templates can serve as good supplementary training data.

Generative EL Cao et al. (2021a) proposed to view EL as a seq2seq problem that got rid of hard negative sampling during training and required less memory at inference. The shortage is it demanded vast training sources (11 GB training data and 32 GPU days) to achieve competitive performance. Cao et al. (2021b) explored dealing synonyms in multilingual generative EL by adding language identifiers that cannot be directly implemented in biomedical EL.

6 Conclusion

To the best of our knowledge, our work is the first to explore generative EL in the biomedical domain. We inject synonyms and definition knowledge into the generative language model by KG-guided pre-training. We emphasize the synonym selection issue and propose synonyms-aware fine-tuning by considering the textual similarity. Decoding prompts are also introduced to improve the model's performance. Our model sets new state-of-the-art on different biomedical EL benchmarks. GENRE shows that well-selected candidate sets can improve seq2seq EL, and we believe this will further boost our performances.

A Dataset Summary and Statistics

We pre-process the datasets by the following procedures: (1) the abbreviations in the texts are expanded using AB3P (Sohn et al., 2008); (2) the texts are lower-cased, and the beginning and ending of a mention are marked by two special tokens `[ST]` and `[ET]`; (3) the overlapping mentions and mentions absent from the target KB are discarded.

BC5CDR (Li et al., 2016) is a benchmark for biomedical entity recognition and disambiguation. The dataset annotates 1500 PubMed article abstracts with 4409 chemicals, 5818 diseases entities, and 3116 chemical-disease interactions. All the annotated entities are mapped to MeSH ontology, which is a smaller medical vocabulary that comprises a subset of UMLS (Bodenreider, 2004). In this work, in consideration of fairness, we follow two most recent works (Angell et al., 2021; Varma et al., 2021) that use MeSH contained in UMLS 2017 AA release to construct the target knowledge base.

NCBI (Doğan et al., 2014) contains a corpus of 793 PubMed abstracts. It consists of 6892 annotated disease mentions of 790 unique disease concepts. All the mentions are labeled with concepts in MELIC ontology (Davis et al., 2012). MELIC is a medical dictionary that merges the diseases concepts, synonyms, and definitions in MeSH and OMIM and is composed of 9700 unique diseases. In our work, we used the processed data and the target ontology provided by BioSyn (Sung et al., 2020) and ResCNN (Lai et al., 2021). We followed their works to construct our training, developing, and testing data.

COMETA (Basaldella et al., 2020) consists of 20k English biomedical entity mentions from publicly available and anonymous health discussions on Reddit. All the mentions are expert-annotated with concepts from SNOMEL CT. We use the “stratified (general)” split and follow the evaluation protocol of SapBert (Liu et al., 2021a) and ResCNN (Lai et al., 2021).

AskAPatient (Limsopatham and Collier, 2016) is a dataset containing 8,662 phrases of social media language. Each phrase can be mapped to one of the 1,036 medical concepts from SNOMEL-CT and AMT (the Australian Medicines Terminology). The samples in AskAPatient do not include contextual information and mentions can only be disambiguated by phrases per se. We follow the experimental settings from works of Sung et al. (2020) and Limsopatham and Collier (2016) and apply the 10-fold evaluation protocol.

Statistics of above-mentioned datasets are listed in Table 6.

	NCBI	BC5CDR	COMETA	AskAPatient
Target names $\|\mathcal{S}\|$	108,071	809,929	904,798	3,381
Target concepts$\|\mathcal{E}\|$	14,967	268,162	350,830	1,036
Train samples	5784	9,285	13,489	16,826
Dev samples	787	9,515	2,176	1,663
Test samples	960	9,654	4,350	1,712

Table 6: Basic statistics of NCBI-disease, BC5CDR, COMETA, AskAPatient datasets and the corresponding target knowledge bases.

Dataset	NCBI	BC5CDR	COMETA	AAP
FT	$95.6_{\pm 0.1}$	$95.3_{\pm 0.1}$	$88.7_{\pm 0.2}$	$95.6_{\pm 0.1}$
PT+FT	$96.3_{\pm 0.1}$	$95.8_{\pm 0.2}$	$88.2_{\pm 0.1}$	$96.0_{\pm 0.1}$

Table 7: The Recall@5 results of our proposed method on different benchmarks.

B License and Availability of Resources

BC5CDR, NCBI, COMETA, and AskAPatients are all publicly available datasets on the Internet. Their target KBs MeSH, MELIC, and SNOMEL CT are covered by UMLS Metathesaurus License. One can require such a license by signing up for a UMLS terminology services account to access KBs mentioned above.

C Additional Experiment Results

C.1 Recall@5 Results

We show the Recall@5 result of our method with and without pre-training in Table 7.

C.2 Sub-population Analysis

Following Varma et al. (2021), we split test samples into different sub-populations. The details of different sub-population categories we use is shown in Table 8.

D Case Study

We provide case studies on the NCBI-disease benchmark to give an insight and justification of the performance of our method. For the case of mention ***colorectal adenomas*** which is annotated with **D018256 adenomatous polyp**, the mention exists for 6 times in the test set (account for 0.63 score of Recall@1). Our model fails to correctly disambiguate all such mentions while linking the mention to other concepts **D000236 colorectal adenomas** or **D003123 hereditary nonpolyposis colorectal cancer**. In the training set, the mention *colorectal adenomas* exists for two times and is annotated with **D003132** and **D000236** respectively. Thus, through this case, we can see (1) our model learns the information contained in the training set; (2) such inconsistent test samples are hard to disambiguate correctly.

E Implementation Details

In this section, we provide more details of our experiments.

E.1 Knowledge Base Pre-processing

Given different knowledge bases, we pre-process their content by the following procedure:

1. For each concept, we include all its synonyms from the original target KB. We also expand the synonym set for each concept using UMLS. We use the 2017 AA Active Release of UMLS.

2. For synonyms in the expanded name set $\mathcal{S}$, we lowercase them and remove the symbols (e.g., dash line - or comma ,).

3. There may exist a name as a synonym for multiple concepts. We de-duplicate these overlapped synonyms by removing the synonym from the concept with more other synonyms to avoid the unbalanced number of synonyms in each concept.

It is worth noticing that we do not de-duplicate the synonyms in the target KB of NCBI in consideration of comparison fairness. In the previous works, a mention link to multiple concepts, and correct disambiguation is claimed if the target concept is hit by one of the predicted concepts in NCBI.

E.2 Pre-training Clause Templates

We list pre-training clause templates we used in Table 10. For those concepts containing only 2 synonyms, s_e^a and s_e^b are the two synonyms respectively and c_e is the same as s_e^b. For those concepts containing only 1 sole synonym, s_e^a, s_e^b and c_e are the same.

Subset	Definition
Overall	Full set of the data
Single Word Mentions	Mentions that have one sole word.
Multi-Word Mentions	Mentions that have multiple words(Separated by blank spaces).
Unseen Mentions	Mentions not existing in fine-tuning set.
Unseen Concepts	Concepts not existing in fine-tuning set.
Not Direct Match	Mentions that are not a synonym of the target concept in KB.
Top 100	Mentions that mapped to the top 100 concepts in existing frequency in fine-tuning set.

Table 8: Accuracy over sub-populations on BC5CDR of our proposed methods and Varma et al. (2021).

Subset	Varma et al. (2021)		Ours		Sample Size
	Baseline	Full	FT	PT + FT	
Overall	89.5	91.3	$\underline{92.5}$	**93.4**	9.65k
Single Word Mentions	91.4	92.9	$\underline{95.8}$	**96.6**	7.04k
Multi-Word Mentions	84.5	**86.8**	$\underline{85.3}$	84.8	2.62k
Unseen Mentions	75.3	79.6	$\underline{81.8}$	**83.3**	3.28k
Unseen Concepts	69.7	77.5	$\underline{86.3}$	**86.9**	2.16k
Not Direct Match	$\underline{89.4}$	**91.9**	83.0	84.3	3.83k
Top 100	97.3	97.2	$\underline{97.9}$	**98.1**	3.31k

Table 9: Accuracy over sub-populations on BC5CDR of our proposed methods and Varma et al. (2021). The best results are presented in bold letters and the second best results are highlighted by underlines.

Concepts		Templates	
Definition	>2 synonyms	Encoder Side	Decoder Side
√	√ / ×	s_e^a <is defined as> c_e. s_e^a <is described as> c_e. c_e <are the definitions of> s_e^a. c_e <describe> s_e^a. c_e <define> s_e^a.	s_e^a is s_e^b.
×	√	c_e <are the synonyms of> s_e^a. c_e <indicate the same concept as> s_e^a. s_e^a <has synonyms such as> c_e. s_e^a <refers to the same concepts as> c_e.	s_e^a is s_e^b.
×	×	c_e <is> s_e^a. c_e <is the same as> s_e^a. s_e^a <is> c_e. s_e^a <is the same as> c_e.	s_e^a is s_e^b.

Table 10: The templates used for constructing pre-training samples for different kinds of concepts. s_e^a is the selected synonym as the input mention, s_e^b is the synonym selected as the decoding target. c_e is the contextual information comprised by definition, other synonyms, or mention itself. The template words are between <>, and we omit the special tokens for marking mentions for conciseness.

E.3 Experiment Parameters

Our model contains 406M parameters with 12-layer transformer encoders and 12-layer transformer decoders. We list the hyper-parameters of our model for KB-guided pre-training and synonyms-aware fine-tuning on different benchmarks in Table 11. For pre-training, we heuristically select our parameters. For fine-tuning, we tune training steps among $\{20000, 30000, 40000\}$ on development set. For BC5CDR and COMETA, we use learning rate as $1e-5$ and warmup steps as 500. For AskAPatient and NCBI, we search learning rate among $\{5e-6, 8e-7, 3e-7\}$, and do not use warmup. We only evaluate our model at the end of training. For each benchmark, we run three times to calculate means and standard deviations.

E.4 Computational Resource

For our KB-guided pre-training, we implement our model on 6 A100 GPU with 40 GB memory with the help of DeepSpeed ZeRO 2 (Rajbhandari et al., 2020) and train for 1 day. For fine-tuning on different benchmarks, we implement our model on 1 A100 GPU.

Parameters	Pre-train	BC5CDR	COMETA	AskAPatient	NCBI
Training Steps	80,000	20,000	40,000	30,000	20,000
Learning Rate	4e-5	1e-5	1e-5	5e-6	3e-7
Weight Decay	0.01	0.01	0.01	0.01	0.01
Batch Size	384	8	8	8	8
Adam ϵ	1e-8	1e-8	1e-8	1e-8	1e-8
Adam β	(0.9,0.999)	(0.9,0.999)	(0.9,0.999)	(0.9,0.999)	(0.9,0.999)
Warmup Steps	1,600	500	500	0	0
Attention Dropout	0.1	0.1	0.1	0.1	0.1
Clipping Grad	0.1	0.1	0.1	0.1	0.1

Abstract

Self-augmentation has received increasing research interest recently to improve named entity recognition (NER) performance in low-resource scenarios. Token substitution and mixup are two feasible heterogeneous self-augmentation techniques for NER that can achieve effective performance with certain specialized efforts. Noticeably, self-augmentation may introduce potentially noisy augmented data. Prior research has mainly resorted to heuristic rule-based constraints to reduce the noise for specific self-augmentation methods individually. In this paper, we revisit these two typical self-augmentation methods for NER, and propose a unified meta-reweighting strategy for them to achieve a natural integration. Our method is easily extensible, imposing little effort on a specific self-augmentation method. Experiments on different Chinese and English NER benchmarks show that our token substitution and mixup method, as well as their integration, can achieve effective performance improvement. Based on the meta-reweighting mechanism, we can enhance the advantages of the self-augmentation techniques without much extra effort.

1 Introduction

Named entity recognition (NER), which aims to extract predefined named entities from a piece of unstructured text, is a fundamental task in the natural language processing (NLP) community, and has been studied extensively for several decades (Hammerton, 2003; Huang et al., 2015; Chiu and Nichols, 2016; Ma and Hovy, 2016). Recently, supervised sequence labeling neural models have been exploited most popularly for NER, leading to state-of-the-art (SOTA) performance (Zhang and Yang, 2018; Li et al., 2020a; Ma et al., 2020).

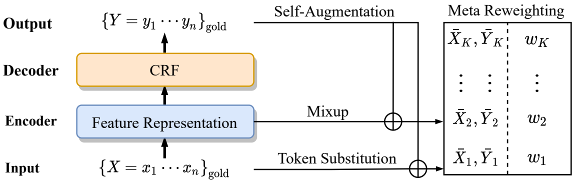

Figure 1: The main idea of our work, where the two heterogeneous self-augmentation methods (i.e., token substitution and mixup) are integrated by a unified meta reweighting framework.

Although great progress has been made, developing an effective NER model usually requires a large-scale and high-quality labeled training corpus, which is often difficult to be obtained in real-world scenarios due to the expensive and time-consuming annotations by human experts. Moreover, it would be extremely serious because the target language, target domain, and the desired entity type could all be infinitely varied. As a result, the low-resource setting with only a small amount of annotated corpus available is far more common in practice, even though it may result in significant performance degradation due to the overfitting problem.

Self-augmentation is a prospective solution to this problem, which has received widespread attention (Zhang et al., 2018; Wei and Zou, 2019; Dai and Adel, 2020; Chen et al., 2020; Karimi et al., 2021). The major motivation is to generate a pseudo training example set deduced from the original gold-labeled training data automatically. For NER, a token-level task, the feasible self-augmentation techniques include token substitution (Dai and Adel, 2020; Zeng et al., 2020) and mixup (Zhang et al., 2020a; Chen et al., 2020), which are deformed at the ground-level inputs and the high-level hidden representations, respectively.

Nonetheless, there are still some limitations currently for the above token substitution and mixup methods. For one thing, both of them require some specialized efforts to improve their effectiveness due to the potential noise introduced by the self-augmentation, which may restrict the valid seman-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4049 - 4060
July 10-15, 2022

tic representation of the augmented data. For instance, token substitution is typically limited to the named entities in the training corpus (Wu et al., 2019), and the mixup tends to be imposed on the example pairs with small semantic distance gaps (Chen et al., 2020). For another thing, though the two techniques seem to be orthogonal and probably complementary to each other, it remains a potential challenge to effectively and naturally integrate them.

In this work, we revisit the token substitution and mixup methods for NER, and investigate the two heterogeneous techniques under a unified meta reweighting framework (as illustrated in Figure 1). First, we try to relax the previous constraints to a broader scope for these methods, allowing for more diverse and larger-scale pseudo training examples. However, this would inevitably produce some low-quality augmented examples (i.e., noisy pseudo data) in terms of linguistic correctness, which may negatively affect the model performance. To this end, we present a meta reweighting strategy for controlling the quality of the augmented examples and leading to noise-robust training. Also, we can naturally integrate the two methods by using the example reweighting mechanism, without any specialization in a specific self-augmentation method.

Finally, we carry out experiments on several Chinese and English NER benchmark datasets to evaluate our proposed methods. We mainly focus on the low-resource settings, which can be simulated by using only part of the standard training set when the scale is large. Experimental results show that both our token substitution and mixup method coupled with the meta-reweighting can effectively improve the performance of our baseline model, and the combination can bring consistent improvement. Positive gains become more significant as the scale of the training data decreases, indicating that our self-augmentation methods can handle the low-resource NER well. In addition, our methods can still work even with a large amount of training data. The code is available at `https://github.com/LindgeW/MetaAug4NER`.

2 Our Approach

In this section, we firstly describe our baseline model. Then, we present our self-augmentation methods to enhance the baseline model in the low-resource settings. Finally, we elaborate on our meta reweighting strategy, which aims to alleviate the negative impact of the noisy augmented examples caused by the self-augmentation while also elegantly combining these augmentation methods.

2.1 Baseline Model

NER task is typically formulated as a sequence labeling problem, which transforms entities/non-entities into token-level boundary label sequence by using the BIO or BIOES schema (Huang et al., 2015; Lample et al., 2016). In this work, we adopt BERT-BiLSTM-CRF as our basic model architecture which consists of four components: (1) input representation, (2) BiLSTM encoding, (3) CRF decoding, and (4) training objective.

Input Representation Given an input sequence $X = (x_1, \cdots, x_n)$ of length n, we first convert it into sequential hidden vectors using the pre-trained BERT (Devlin et al., 2019):

$$\boldsymbol{e}_1, \cdots, \boldsymbol{e}_n = \text{BERT}(X), \tag{1}$$

where each token is mapped to a contextualized representation correspondingly.

Encoding We use a bidirectional LSTM layer to further extract the contextual representations, where the process can be formalized as:

$$\boldsymbol{h}_1, \cdots, \boldsymbol{h}_n = \text{BiLSTM}(\boldsymbol{e}_1, \cdots, \boldsymbol{e}_n), \tag{2}$$

where $\boldsymbol{h}_i$ is the hidden state output of the i-th token in the sequence ($i \in [1, n]$).

Decoding First, a linear transformation layer is used to calculate the initial label scores. Then, a label transition matrix $\boldsymbol{T}$ is used to model the label dependency. Let $Y = (y_1, \cdots, y_n)$ be a label sequence, the score $s(Y|X)$ can be computed by:

$$\begin{aligned} \boldsymbol{o}_i &= \boldsymbol{W}\boldsymbol{h}_i + \boldsymbol{b}, \\ s(Y|X) &= \sum_{i=1}^{n}(\boldsymbol{T}_{y_{i-1},y_i} + \boldsymbol{o}_i[y_i]), \end{aligned} \tag{3}$$

where $\boldsymbol{W}$, $\boldsymbol{b}$ and $\boldsymbol{T}$ are the model parameters. Finally, we employ the Viterbi algorithm (Viterbi, 1967) to find the best label sequence Y.

Training Objective We exploit the sentence-level cross-entropy objective for training. Given a gold-labeled training example (X, Y), we have the conditional probability $p(Y|X)$ based on the

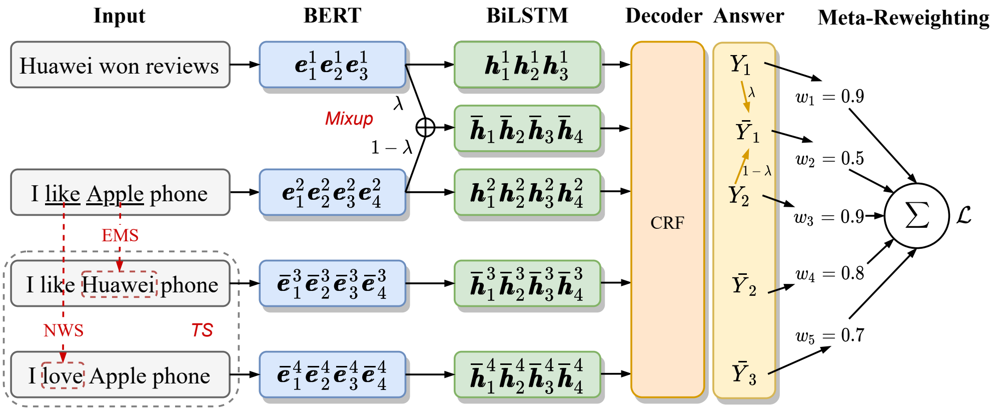

Figure 2: An overview of the self-augmentation framework for NER.

scoring function defined in Equation 3, and then apply a cross-entropy function to calculate the single example loss:

$$p(Y|X) = \frac{\exp\big(s(Y|X)\big)}{\sum_{\widetilde{Y}} \exp\big(s(\widetilde{Y}|X)\big)}, \qquad (4)$$
$$\mathcal{L}(X,Y) = -\log p(Y|X).$$

where $\widetilde{Y}$ denotes the candidate label sequences.

2.2 Self-Augmentation

Self-augmentation methods can reduce the demand for abundant manually-annotated examples, which can be implemented at the input level and representation level. Token substitution and mixup are two popular methods for NER that correspond to these two distinct levels. Here, we try to extend these two self-augmentation methods.

Token Substitution Token substitution aims to generate pseudo examples based on the original gold-labeled training data by replacing the tokens of input sentence with their synonym alternatives (Wu et al., 2019; Dai and Adel, 2020). For NER, Wu et al. (2019) adopted this method to obtain performance gains on Chinese datasets where the substituted objects are limited to named entities. Dai and Adel (2020) empirically demonstrated the superiority of synonym replacement among various augmentation schemes where the synonyms are retrieved from the off-the-shelf WordNet thesaurus.

Our token substitution is performed by building a synonym dictionary, which covers the named entity synonyms as well as numerous normal word synonyms. Following Wu et al. (2019), we treat all entities of the same type from the training set as synonyms, which are added to the entity dictionary. We name it as entity mention substitution (EMS). Meanwhile, we extend the substitution to non-entity tokens (i.e., the corresponding label is 'O'), which is named as normal word substitution (NWS). Since unlabeled data in a specific domain is easily accessible, we adopt the word2vec-based algorithm (Mikolov et al., 2013; Pennington et al., 2014) to mine tokens with similar semantics on Wikidata via distributed word representation (Yamada et al., 2020), and build a normal word synonym dictionary from the k-nearest token set based on cosine similarity distance. Note that this scheme does not require access to thesaurus for a specific domain in order to obtain synonyms.

Figure 2 presents an example of token substitution, where EMS and NWS are both involved. Specifically, for a given gold-labeled training example (X, Y), we replace the entity token of X with a sampled entity from the entity dictionary which has the same entity type, and meanwhile replace the non-entity token of X with a sampled synonym. Then, we can obtain a pseudo example $(\bar{X}, \bar{Y})$. Especially, we balance the EMS and NWS strategies based on a ratio γ by adjusting the percentage of EMS operations, aiming for a good trade-off between entity diversity and context diversity. And, we refer to this method as TS in the rest of this paper for short.

Mixup for CRF Unlike token substitution performed at the ground input, the mixup technique (Zhang et al., 2018) generates virtual examples at the feature representation level in the NLP field (Guo et al., 2019). The main idea is to perform linear interpolations on both the input and ground-truth output between randomly sampled example pairs from the given training set. Chen et al. (2020) presented the first work based on the token classification framework for the NER task, and their mixup strategy is constrained to the examples pairs where the input sentences are semantically similar by using specific heuristic rules. Different from their method, we extend the mixup technique to the CRF decoding.

Formally, give an example pair (X_1, Y_1) and (X_2, Y_2) randomly sampled from the gold-labeled training set, we firstly obtain their vector representations through Equation 1, resulting in $\boldsymbol{e}_{1,1} \cdots \boldsymbol{e}_{1,n_1}$, and $\boldsymbol{e}_{2,1} \cdots \boldsymbol{e}_{2,n_2}$, respectively. Then we apply the linear interpolation to obtain a new virtual training example $(\bar{X}, \bar{Y})$. Here we assume a regularization of pair-wise linear interpolation over the input representations and the output scores, where the following attributes should be satisfied:

$$\bar{X}\colon \begin{cases} \mathrm{BERT}(\bar{X}) = \bar{\boldsymbol{e}}_1 \cdots \bar{\boldsymbol{e}}_n \\ \bar{\boldsymbol{e}}_i = \lambda \boldsymbol{e}_{1,i} + (1-\lambda)\boldsymbol{e}_{2,i}, i \in [1, n] \end{cases} \quad (5)$$
$$\bar{Y}\colon s(\bar{Y}|\bar{X}) = \lambda s(Y_1|\bar{X}) + (1-\lambda) s(Y_2|\bar{X}),$$

where $n = \max(n_1, n_2)$ [1] and λ is sampled from a $\mathrm{Beta}(\alpha, \alpha)$ distribution ($\lambda \in [0, 1]$ and $\alpha > 0$). According to this formulation, the loss function can be reformulated as:

$$\begin{aligned} \mathcal{L}(\bar{X}, \bar{Y}) &= -\log \frac{\exp\left(s(\bar{Y}|\bar{X})\right)}{\sum_{\widetilde{Y}} \exp\left(s(\widetilde{Y}|\bar{X})\right)} \\ &= \lambda \mathcal{L}(\bar{X}, Y_1) + (1-\lambda)\mathcal{L}(\bar{X}, Y_2). \end{aligned} \quad (6)$$

which aligns with the training objective of Equation 4. In this way, our mixup method can fit well with the structural decoding.

2.3 Meta Reweighting

Although the self-augmentation techniques can efficiently generate numerous pseudo training examples, how to control the quality of augmented examples is a potential challenge that cannot be overlooked. In particular, unlike sentence-level classification tasks, entity recognition is highly sensitive to the semantics of the context. While positive augmented examples can help our model advance, some low-quality augmented examples that are inevitably introduced during self-augmentation may hurt the final model performance.

In this paper, we leverage a meta reweighting mechanism to dynamically and adaptively assign the example-wise weights to each mini-batch of training data, motivated by Ren et al. (2018). The key idea is that a small and clean meta-data set is applied to guide the training of model parameters, and the loss produced by the mini-batch of meta-data is exploited to reweight the augmented examples in each batch online. Intuitively, if the data distribution and gradient-descent direction of the augmented example are similar to those of the sample in the meta-data set, our model could better fit this *positive* augmented sample and increase its weight, and vice versa. In other words, the clean and valid augmented examples are more likely to be fully trained.

Algorithm 1 The training procedure of the meta reweighting strategy

```
Input: Initial model parameters $\Theta^{(0)}$, clean training dataset $\mathcal{D}$, augmented training dataset $\hat{\mathcal{D}}$, batch size $m, n$, training steps $T$
Output: Updated model parameters $\Theta^{(T)}$
for $t = 1$ to $T$ do
    Initialize the trainable parameter $\epsilon$.
    $\{x_c, y_c\} \leftarrow$ SampleMiniBatch($\mathcal{D}$, $m$).
    $\{x_a, y_a\} \leftarrow$ SampleMiniBatch($\hat{\mathcal{D}}$, $n$).
    $\mathcal{L}_a \leftarrow \sum_{i=1}^{n} \epsilon_i \mathcal{L}(f(x_{a,i}; \Theta^{(t)}), y_{a,i})$.
    $\nabla\Theta^{(t)} \leftarrow$ Grad($\mathcal{L}_a, \Theta^{(t)}$).
    $\hat{\Theta}^{(t)} \leftarrow \Theta^{(t)} - \beta\nabla\Theta^{(t)}$.
    $\mathcal{L}_c \leftarrow \frac{1}{m}\sum_{i=1}^{m} \mathcal{L}(f(x_{c,i}; \hat{\Theta}^{(t)}), y_{c,i})$.
    $\nabla\epsilon \leftarrow$ Grad($\mathcal{L}_c, \epsilon$).
    $\hat{w} \leftarrow$ Sigmoid($-\nabla\epsilon$).
    $w \leftarrow \frac{\hat{w}}{\sum_j \hat{w}_j + \delta}$.
    $\hat{\mathcal{L}}_a \leftarrow \sum_{i=1}^{n} w_i \mathcal{L}(f(x_{a,i}; \Theta^{(t)}), y_{a,i})$.
    $\nabla\Theta^{(t)} \leftarrow$ Grad($\hat{\mathcal{L}}_a, \Theta^{(t)}$).
    $\Theta^{(t+1)} \leftarrow$ OptimizerStep($\Theta^{(t)}, \nabla\Theta^{(t)}$).
end for
```

More specifically, suppose that we have a set of N augmented training examples $\hat{\mathcal{D}} = \{(X_i, Y_i)\}_{i=1}^{N}$, our final optimizing objective can be formulated as a weighted loss as follows:

$$\Theta^*(w) = \arg\min_{\Theta} \sum_{i=1}^{N} w_i \mathcal{L}(f(X_i; \Theta), Y_i), \quad (7)$$

where $w_i \geq 0$ is the learnable weight for the loss of i-th training example. $f(\cdot; \Theta)$ represents the forward process of our model (with parameter Θ). The optimal parameter w is further determined by minimizing the following loss computed on the meta example set $\mathcal{D} = \{(X_i^m, Y_i^m)\}_{i=1}^{M}$ ($M \ll$

---

[1] Special zero-vector pads are used to align two sequences with different lengths.

N):

$$w^* = \arg\min_w \frac{1}{M}\sum_{i=1}^{M}\mathcal{L}(f(X_i^m;\Theta^*(w)),Y_i^m), \tag{8}$$

Accordingly, we need to calculate the optimal Θ^* and w^* in Equation 7 and 8 based on two nested loops of optimization iteratively. For simplicity and efficiency, we take a single gradient-descent step for each training iteration to update them via an online-approximation manner. At every training step t, we sample a mini-batch augmented examples $\{(X_i,Y_i)\}_{i=1}^n$ initialized with the learnable weights ϵ. After a single optimization step, we have:

$$\hat{\Theta}^{(t+1)}(\epsilon) = \Theta^{(t)} - \beta\nabla_\Theta\sum_{i=1}^{n}\epsilon_i\mathcal{L}(f(X_i;\Theta),Y_i), \tag{9}$$

where β is the inner-loop step size. Based on the updated parameters, we then calculate the loss of the sampled mini-batch meta examples $\{(X_j^{meta},Y_j^{meta})\}_{j=1}^m$:

$$\mathcal{L}^{meta}(\hat{\Theta}) = \frac{1}{m}\sum_{j=1}^{m}\mathcal{L}(f(X_j^{meta};\hat{\Theta}^{(t+1)}),Y_j^{meta}), \tag{10}$$

To generalize the parameters $\hat{\Theta}$ well to the meta-data set, we take the gradients of ϵ w.r.t the meta loss to produce example weights and normalize it along mini-batch:

$$\begin{aligned}\hat{w}_i &= \sigma(-\nabla_{\epsilon_i}\mathcal{L}^{meta}(\hat{\Theta})\Big|_{\epsilon_i=0}),\\ w_i &= \frac{\hat{w}_i}{\sum_j\hat{w}_j+\delta}.\end{aligned} \tag{11}$$

where $\sigma(\cdot)$ is the sigmoid function and δ is a small value to avoid division by zero. Finally, we optimize the model parameters over augmented examples with the calculated weights.

Algorithm 1 illustrates the detailed training procedure of the meta reweighting strategy. It is noteworthy that the augmented training examples contain the original clean training examples, which serve as the unbiased meta-data. Since the algorithm execution just requires a clear definition of the training objective for the input examples, it is also well adaptable for the virtual augmented examples generated by our mixup method.

3 Experiments

3.1 Settings

Datasets To validate our methods, we conduct experiments on Chinese benchmarks: OntoNotes 4.0 (Weischedel et al., 2011) and Weibo NER (Peng and Dredze, 2015), as well as English benchmarks: CoNLL 2003 (Sang and Meulder, 2003) and OntoNotes 5.0[2] (Pradhan et al., 2013). The Chinese datasets are split into training, development and test sections following Zhang and Yang (2018) while we take the same data split as Benikova et al. (2014) and Pradhan et al. (2012) on the English datasets. We follow Lample et al. (2016) to use the BIOES tagging scheme for all datasets. The detailed statistics can be found in Table 4.

Dataset	Type	Train	Dev	Test
OntoNotes 4	#sent	15.7k	4.3k	4.3k
	#char	491.9k	200.5k	208.1k
	#entity	12.6k	6.6k	7.3k

	#entity	23.5k	5.9k	5.6k
OntoNotes 5	#sent	59.9k	8.5k	8.3k
	#token	1088.5k	147.7k	152.7k
	#entity	81.8k	11.1k	11.3k

Table 4: Statistics of datasets. #sent and #entity stand for the number of sentences and entity words, respectively.

Implementation Details We use one-layer BiLSTM and the hidden size is set to 768. The dropout ratio is set to 0.5 for the input and output of BiLSTM. Regarding BERT, we adopt BERT-base model[3] (BERT-base-cased for the English NER) and fine-tune the inside parameters together with all other module parameters. We use the AdamW(Loshchilov and Hutter, 2019) optimizer to update the trainable parameters with β_1=0.9 and β_2=0.99. For the BERT parameters, the learning rate is set to $2e{-}5$. For other module parameters excluding BERT, a learning rate of $1e{-}3$ and weight decay of $1e{-}4$ are used. Gradient clipping is used to avoid gradient explosion by a maximum value of 5.0. All the models are trained on NIVIDIA

Tesla V100 (32G) GPUs. The `higher` library[4] is utilized for the implementation of second-order optimization involved in Algorithm 1.

For the NWS, we use the word vectors trained on Wikipedia data[5] based on the GloVe model (Pennington et al., 2014) and build the synonym set for any given non-entity word based on the top-5 cosine similarity, where stop-words are excluded.

As mentioned in Section 2.2, we defined two core hyper-parameters for our self-augmentation methods, one for TS (i.e., γ) and the other for mixup (i.e., λ). Specifically, we set $\gamma = 20\%$ and λ by sampled from the $\text{Beta}(\alpha, \alpha)$ distribution with $\alpha = 7$, where the details will be shown in the analysis section. Meanwhile, we conduct the augmentation up to 5 times corresponding to the original training data.

Evaluation We conduct each experiment by 5 times and report the average F1 score. The best-performing model on the development set is then used to evaluate on the test set.

3.2 Main Results

The main results are presented in Table 1, 2 and 3, verifying the effectiveness of our method under the low-resource setting and the standard full-scale setting, respectively. Since Weibo is a small-scale dataset, we do not consider its partial training set for the low-resource setting.

Low-Resource Setting We randomly sample 5%, 10%, and 30% of the original training data from OntoNotes and CoNLL03 for simulation studies. Table 1 shows the results where F1 scores of the baseline, +TS, +Mixup, and +Both are reported. We can observe that: (1) the baseline performance will drop significantly as the size of training data get reduced gradually, which demonstrates the performance of the supervised NER model relies heavily on the scale of the labeled training data. (2) although the number of training examples has increased, vanilla self-augmentation (without meta reweighting) might degrade the model performance due to potentially unreliable pseudo-labeled examples. The meta reweighting strategy helps to adaptively weight the augmented examples during training, which combats the negative impact and leads to a stable and positive performance boost.

In addition, as the scale of the training data decreases, the effectiveness of the augmentation methods can be more significant, indicating that our self-augmentation methods are highly beneficial for the low-resource settings, and the two-stage combination of the two heterogeneous methods can yield better performance consistently.

Full-Scale Setting Table 2 and 3 show the results using full-scale training data. The results demonstrate that our baseline model is already strong. The model after vanilla augmentation could perform slightly worse since each training example is treated equally even if it is noisy. This also implies our meta reweighting makes great sense. Furthermore, our final model (+Both) can further achieve performance gains by integrating these self-augmentation methods with the meta reweighting mechanism. The overall trend is similar to the low-resource setting, but the gains are relatively smaller when the training data is sufficient. That may be attributed that the size of training data is large enough to narrow the performance gap between the baseline and augmented models. It also suggests that our method does not hurt the model performance even when using enough training data.

Comparison with Previous Work We also compare our method with previous representative SOTA work, where all referred systems exploit the pre-trained BERT model. As shown, compared to Dai and Adel (2020) and Chen et al. (2020), our method either outperforms or performs on par with theirs when using limited training data. For Chen et al. (2020), the pure mixup performs slightly better due to the well-designed example sampling strategy, but our overall framework outperforms theirs. Moreover, our method can match the performance of the semi-supervised setting that uses additional 10K unlabeled training data. Besides, our final model, without utilizing much external knowledge, can achieve very competitive results on the full training set in comparison to most previous systems.

3.3 Analysis

In this subsection, we further conduct detailed experimental analyses on the CoNLL03 dataset for a better understanding of our method. Our main concern is on the low-resource setting, therefore the models based on 5%, 10% and 30% of the original training data are our main focus.

Augmentation Times The size of augmented examples is an essential factor in final model performance. Typically, we examine the 5% CoNLL03 training data. As illustrated in Figure 3, the larger pseudo examples can obtain better performance in a certain range. However, as the times of augmentation increases, the uptrend of performance slows down. The improvement tends to be stable when the pseudo samples are increased to about 5 times the original training data. Excessively increasing the augmentation times does not necessarily bring consistent performance improvement. And we select an appropriate value for training data of different sizes from a range [1, 8].

Influence of γ for Token Substitution Regarding our TS strategy, we take both NWS and EMS into account simultaneously. The two parts are blended by a percentage parameter γ, namely γ for EMS and $1 - \gamma$ for NWS. Here we examine the influence of γ in the sole self-augmentation model by TS. Figure 4 shows the results, where $\gamma = 0$ and $\gamma = 100\%$ denote the model with only NWS and EMS, respectively. As shown, our model can achieve the overall better performance when $\gamma = 20\%$, indicating that both of them are helpful

Method	**5%**	**10%**	**30%**
Baseline	85.12	87.11	89.24
Mixing on BiLSTM	86.15	87.66	89.41
Mixing on BERT	**86.33**	**88.03**	**89.75**

Table 5: Performance comparison of the mixup strategy on BERT or BiLSTM layer.

for the TS strategy, and NWS can be slightly better. One possible reason is that the entity words in original training examples are relatively sparse (i.e., the ‘O’ label is dominant), allowing the NWS to produce more diverse pseudo examples.

Mixup Parameter We further inspect the model with the mixup strategy alone so as to understand the important factors of the mixup model. First, we analyze the influence of the mixing parameter α. As depicted in Figure 5, we can see that α indeed affects the effectiveness of the mixup method greatly. Considering the feature of Beta distribution, the sampled λ will be more concentrated around 0.5 as the α value becomes large, resulting in a relatively balanced weight between the mixed example pairs. The model performance remains stable when α is around 7. Second, we study where to conduct the mixup operation since there are two main options in our framework, i.e., the hidden representations of either the BERT or BiLSTM for linear interpolation. Table 5 reports the comparison results, demonstrating the former is a better choice.

Case Study To further understand the effectiveness of the meta-reweighting mechanism, we present several high-quality and low-quality examples in Table 6. As shown, the difference between the positive and negative examples for TS could be reflected in the syntactic and semantic validity of the augmented examples. Similarly, for the mixup, it seems that the valid example pairs are more likely to generate positive augmented examples.

4 Related Work

In recent years, research on NER has concentrated on either enriching input text representations (Zhang and Yang, 2018; Nie et al., 2020b; Ma et al., 2020) or refining model architectures with various external knowledge (Zhang and Yang, 2018; Ye and Ling, 2018; Li et al., 2020a; Xuan et al., 2020; Li et al., 2020b; Yu et al., 2020; Shen et al., 2021). Particularly, NER model, with the aid of large pre-trained language models (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2019), has achieved impressive performance gains. However, these models mostly depend on rich manual annotations, making it hard to cope with the low-resource challenges in real-world applications. Instead of pursuing a sophisticated model architecture, in this work, we exploit the BiLSTM-CRF model coupled with the pre-trained BERT as our basic model structure.

Self-augmentation methods have been widely investigated in various NLP tasks (Zhang et al., 2018; Wei and Zou, 2019; Dai and Adel, 2020; Zeng et al., 2020; Ding et al., 2020). The mainstream methods can be broadly categorized into three types: (1) token substitution (Kobayashi, 2018; Wei and Zou, 2019; Dai and Adel, 2020; Zeng et al., 2020), which performs local substitution for a given sentence, (2) paraphrasing (Kumar

Table 6: Case study on positive and negative augmentation with respect to the TS and mixup.

et al., 2019; Xie et al., 2020; Zhang et al., 2020b), which involves sentence-level rewriting without significantly changing the semantics, and (3) mixup (Zhang et al., 2018; Chen et al., 2020; Sun et al., 2020), which carries out the feature-level augmentation. As a data-agnostic augmentation technique, mixup can help improve the generalization and robustness of our neural model acting as an useful regularizer (Verma et al., 2019). For NER, token substitution and mixup are very suitable and have been exploited successfully with specialized efforts (Dai and Adel, 2020; Chen et al., 2020; Zeng et al., 2020), while the paraphrasing strategy may result in structure incompleteness and token-label inconsistency, thus there has not been widely concerned yet. In this work, we mainly investigate the token substitution and mixup techniques for NER, as well as their integration. Despite the success of various self-augmentation methods, quality control may be an issue easily overlooked by most methods.

Many previous studies have explored the example weighting mechanism in domain adaption (Jiang and Zhai, 2007; Wang et al., 2017; Osumi et al., 2019). Xia et al. (2018) and Wang et al. (2019) looked into the example weighting methods for cross-domain tasks. Ren et al. (2018) adapted the MAML algorithm (Finn et al., 2017) and proposed a meta-learning algorithm to automatically weight training examples of the noisy label using a small unbiased validation set. Inspired by their work, we extend the meta example reweighting mechanism to the NER task, which is exploited to adaptively reweight mini-batch augmented examples during training. The main purpose is to mitigate the potential noise effects brought by the self-augmentation techniques, advancing a noise-robust model, especially in low-resource scenarios.

5 Conclusion

In this paper, we re-examine two heterogeneous self-augmentation methods (i.e., TS and mixup) for NER, extending them into more unrestricted augmentations without heuristic constraints. We further exploit a meta reweighting strategy to alleviate the potential negative impact of noisy augmented examples introduced by the aforementioned relaxation. Experiments conducted on several benchmarks show that our self-augmentation methods along with the meta reweighting mechanism are very effective in low-resource settings, and still work when enough training data is used. The combination of the two methods can lead to consistent performance improvement across all datasets. Since our framework is general and does not rely on a specific model backbone, we will further investigate other feasible model structures.

Unsupervised Stem-based Cross-lingual Part-of-Speech Tagging for Morphologically Rich Low-Resource Languages

Abstract

Unsupervised cross-lingual projection for part-of-speech (POS) tagging relies on the use of parallel data to project POS tags from a source language for which a POS tagger is available onto a target language across word-level alignments. The projected tags then form the basis for learning a POS model for the target language. However, languages with rich morphology often yield sparse word alignments because words corresponding to the same citation form do not align well. We hypothesize that for morphologically complex languages, it is more efficient to use the stem rather than the word as the core unit of abstraction. Our contributions are: 1) we propose an unsupervised stem-based cross-lingual approach for POS tagging for low-resource languages of rich morphology; 2) we further investigate morpheme-level alignment and projection; and 3) we examine whether the use of linguistic priors for morphological segmentation improves POS tagging. We conduct experiments using six source languages and eight morphologically complex target languages of diverse typologies. Our results show that the stem-based approach improves the POS models for all the target languages, with an average relative error reduction of 10.3% in accuracy per target language, and outperforms the word-based approach that operates on three-times more data for about two thirds of the language pairs we consider. Moreover, we show that morpheme-level alignment and projection and the use of linguistic priors for morphological segmentation further improve POS tagging.

1 Introduction

Low-resource languages lack annotated data even for basic syntactic information such as parts of speech (POS). To address this problem, two main unsupervised approaches have been adopted: zero-shot model transfer (Pires et al., 2019) and cross-lingual POS tagging via alignment and projection (Yarowsky et al., 2001; Fossum and Abney, 2005; Das and Petrov, 2011; Duong et al., 2013; Täckström et al., 2013; Agić et al., 2015, 2016; Buys and Botha, 2016; Eskander et al., 2020b). Eskander et al. (2020b) show that the alignment and projection approach is less sensitive to the morphological dissimilarities between the source and target languages than zero-shot model transfer.

In annotation projection, the word structure in the source and target languages impacts the quality of the alignment and projection phases, and hence affects the overall performance of the ultimate POS model. This becomes a concern for languages with rich word structure where affixation is common as they usually suffer from sparse alignment models that often fail to align words corresponding to the same citation form due to the extensive paradigms and translation inconsistencies. Sparse alignment hinders the ability of a system to project the tags properly and results in null tags on the target side. These null tags then reduce the number of qualifying training examples and impact the POS model by introducing non-continuous labeled sequences. Adding to these practical issues, the concept of word as a unit of structure has long been questioned in language sciences (Marantz, 2001).

We hypothesize that using the stem as the core unit of abstraction results in better POS models for low-resource languages of rich morphology. Our contribution is three-fold.

Unsupervised stem-based cross-lingual approach for POS tagging for morphologically complex low-resource languages, where we use the stem as the core unit of abstraction. In order to adapt a fully-unsupervised approach, we use a state-of-the-art unsupervised morphological segmenter, MorphAGram (Eskander et al., 2016, 2020a), to derive the stems and morphemes. We follow the setup of Eskander et al. (2020b) using the Bible as the only source of parallel data in order to emulate a low-resource scenario. We experiment with

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4061 - 4072
July 10-15, 2022

the same six source languages, namely English, Spanish, French, German, Russian and Arabic, but choose six morphologically complex target languages, namely Amharic, Basque, Finnish, Indonesian, Telugu and Turkish and add two new target languages, namely Georgian and Kazakh, where we contribute a small POS-annotated dataset for the former. We show that the stem-based approach outperforms the word-based one in 43 language pairs out of 48, with an average relative error reduction of 10.3% in accuracy per target language, up to 21.0% in the case of Kazakh. We also show that the stem-based approach outperforms the word-based approach which operates on three-times more data for about two thirds of the experimental pairs.

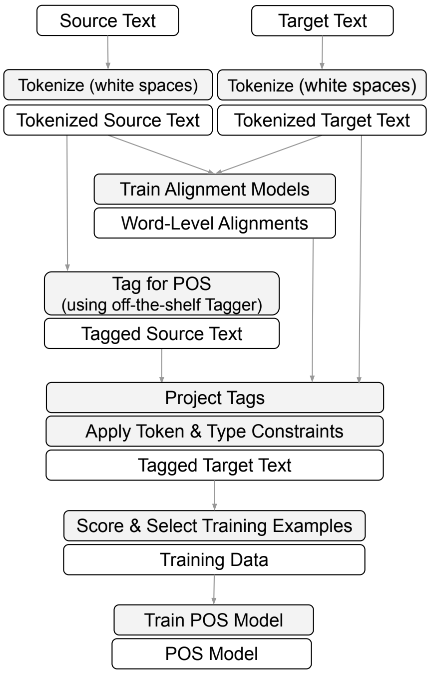
Morpheme-level alignment and projection, which allows for abstracting away from how the morphemes are combined in the source and target languages. We test the setup with Arabic as the source language and show improvements for seven out of the eight target languages.

Using linguistic priors in morphological segmentation, which results in better segmentation models towards better alignment and projection. Using Georgian as a case study, we show that the use of linguistic priors, in the form of a set of affixes provided by an expert in the target language, improves the ultimate POS models.

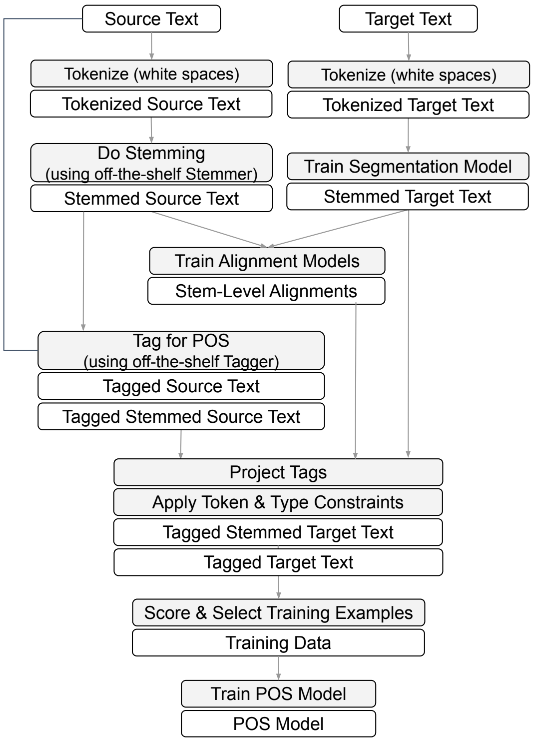
Finally, we make our code publicly available to encourage further research [1].

2 Approach

We perform fully unsupervised cross-lingual POS tagging via alignment and projection. We follow the main architecture presented by Eskander et al. (2020b) (Section 2.1). A primary difference is that we harness unsupervised morphological segmentation to use the stems as the core unit of abstraction for both alignment and projection (Section 2.2). In addition, we experiment with morpheme-level alignment and projection (Section2.3) and examine the use of linguistic priors towards better morphological segmentation and POS tagging (Section 2.4). This allows for less sparse alignment models and denser projections, which in turn produces larger POS training data of a better quality.



(a) Word-based approach (Eskander et al., 2020b)



(b) Our proposed stem-based approach

Figure 1: Unsupervised cross-lingual POS tagging via alignment and projection

2.1 Word-based Alignment and Projection

Figure 1a shows the pipeline presented by Eskander et al. (2020b). The only input to the process is a parallel text between the target language and a source one for which a POS tagger is accessible. First,

---

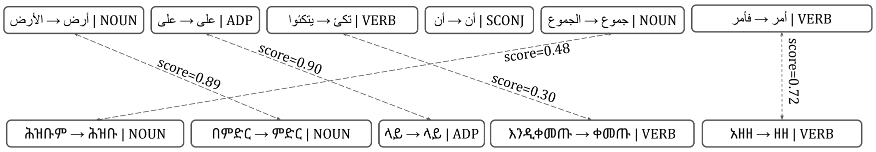
(a) Word-based alignment and projection



(b) Stem-based alignment and projection

Figure 2: An example of alignment and projection from Arabic onto Amharic. The alignment models are trained on the New Testament. Arabic reads right to left.

the parallel text gets white-space tokenized and is used to train two word-alignment models (source-to-target and target-to-source) using GIZA++ (Och and Ney, 2003). The alignment models are then applied to align the source and target sides on the word level. Next, the source side is tagged for POS using an off-the-shelf tagger (e.g., Stanza (Qi et al., 2020)). The source tags are then projected onto the target across the word-based alignments, where only those bidirectional alignments whose confidence is above a particular threshold are considered in order to eliminate one-to-many and many-to-one alignments and those alignments of low confidence.

The projected tags for each token represent what are called token constraints, while the tag distribution of each word type across the whole target side forms type constraints. The token and type constraints are then coupled by nullifying those tag assignments whose type-level probabilities are below some threshold. The target text, along with its projected tags, then constitutes the training data for a neural POS tagger, where only the top scoring sentences, in terms of tag-assignment density and alignment confidence, are considered.

The neural tagger is a bidirectional long short-term memory (BiLSTM) model (Hochreiter and Schmidhuber, 1997) that uses a custom softmax activation to handle the null tags. It uses word embeddings, both randomly initialized and the contextual multilingual embeddings *XLM-R* (Conneau et al., 2019); prefix and suffix n-gram character embeddings, where n is in $\{1, 2, 3, 4\}$; and hierarchical Brown-cluster (Brown et al., 1992) embeddings.

The architecture can benefit from parallel data of multiple source languages, where either the projections from multiple source languages (Mul_proj) or the decoded outputs that are based on multiple single-source models (Mul_out) can be combined through maximum-voting mechanisms.

2.2 Stem-Based Alignment and Projection

While the architecture by Eskander et al. (2020b) yields the state-of-the-art results for unsupervised POS tagging when evaluated on 12 languages of diverse typologies, the complexity of word structure in the source and target languages has a direct impact on the quality of both alignment and projection. Rich word structure where affixation is common increases the ratio of word types to word tokens, which in turn results in sparse alignment models and incomplete projections that form null tags on the target side. Null tags result in a score that is too low for the underlying sentence to qualify as a training example and introduce missing information for the training of the POS model, which negatively impacts the overall quality of POS tagging.

An example is shown in Figure 2a, where Arabic and Amharic are the source and target languages, respectively. The example corresponds to verse *MAT 15:35*, *“He commanded the multitude to sit down on the ground”*, where the word-alignment models are trained on the New Testament. As shown, the two Arabic-Amharic pairs {ሕዝቡም, الجموع} (*and the people*, *the people*) and {አዘዘ, فأمر} (*he commanded*, *then he commanded*) are not aligned, resulting in null tags. The sparse word-

Verse	Amharic Word		Arabic Word	
MAT 15:35	ሕዝቡም	(*and the people*)	الجموع	(*the people*)
MAT 26:55	ለሕዝቡ	(*to the people*)	للجموع	(*to the people*)
LUK 9:11	ሕዝቡም	(*and the people*)	فالجموع	(*and the people*
LUK 23:4	ለሕዝቡ	(*to the people*)	والجموع	(*and the people*)
MAT 1:24	እንዳዘዘው	(*as he commanded*)	أمره	(*he commanded him*)
MAT 15:35	አዘዘ	(*he commanded*)	فأمر	(*then he commanded*)
b.LUK 5:14	እንዳዘዘ	(*as he commanded*)	أمر	(*he commanded*)
b.ACT 21:34	አዘዘ	(*he commanded*)	أمر	(*he commanded*)

Table 1: Paired inflected forms that correspond to the same citation form across Arabic and Amharic parallel verses in the New Testament

alignment models are simply unable to properly align words that correspond to the same citation form because of the extensive paradigms, which, along with translation inconsistencies, leads to the loss of the one-to-one correspondence between word structures across parallel texts (examples are shown in Table 1). Using the stem instead of the word as the core unit of abstraction is more productive; the stem is usually shared by all the members of a paradigm, which reduces misalignment.

Figure 2b shows that stemming the Arabic and Amharic texts yields complete one-to-one alignments and projections, which in turn eliminates the word-based null assignments and assigns each word on the Amharic side a valid POS tag.

Figure 1b illustrates our overall stem-based approach. We first stem the source and target sides and train two stem-level alignment models, one in each direction. Next, we assign the stems of the source side the POS tags of their corresponding words, which are then projected onto the target stems through the stem-level alignments. We then apply the token and type constraints on the labeled stems on the target side. However, since we train the ultimate POS model on the word level, we replace each target stem by its corresponding word and assign that word the stem-based projected POS tag. The rest of the pipeline for sentence selection and training the POS model are the same as in the word-based architecture described in Section 2.1.

We assume that the source language is a high-resource one for which an off-the-shelf stemmer is accessible. On the other hand, for the target languages, we use MorphAGram[2] (Eskander et al., 2020a) to train an unsupervised morphological segmentation model using the target side of the parallel text. MorphAGram is a state-of-the-art framework for unsupervised morphological segmentation based on Adaptor Grammars (AGs) (Johnson et al., 2007), nonparametric Bayesian models that generalize Probabilistic Context Free Grammars (PCFGs). We run MorphAGram in a cascaded setup of two learning rounds. In the first round, we train a segmentation model using a language-independent high-precision grammar (PrStSu2a+SM [3]) to obtain a list of morphemes. We then seed these morphemes into the best performing language-independent grammar (PrStSu+SM) for the second round of learning as described by Eskander et al. (2016, 2020a). Both PrStSu2a+SM and PrStSu+SM grammars model the word as a sequence of prefixes, a stem and suffixes, where the affixes are recursively defined in order to model multiple consecutive items.

2.3 Morpheme-Based Alignment and Projection

Next, we perform morpheme-based alignment and projection in a similar fashion as in the stem-based approach (Section 2.2). This approach abstracts away from whether the morphemes in the source and target languages are free-standing or not.

On the source side, each morpheme receives a separate POS tag using an off-the-shelf POS tagger. These tags are then projected onto the target morphemes through bidirectional morpheme-level alignments. We obtain the target morphemes using MorphAGram, where the output of the PrStSu+SM grammar yields prefixes, a stem, and suffixes for each word. However, since we train the POS model on the word level, we replace each sequence of morphemes on the target side by its corresponding word and assign that word the POS tag of the representative morpheme. We define the representative morpheme either as the morpheme whose POS tag ranks the highest among those of the other morphemes[4] (RANK) or as the stem morpheme (STEM).

2.4 Using Linguistic Priors for Segmentation

We hypothesize that better detection of stems yields more robust alignment and projection towards improved POS tagging. Accordingly, instead of conducting morphological segmentation on the target side in a fully unsupervised manner, we follow Eskander et al. (2021) by seeding affix morphemes into the grammar tree prior to training the segmentation model textcolorbluein a minimally super-

---

[3] See Eskander et al. (2020a) for grammar definitions.

[4] We use the default POS ranking at `https://github.com/coastalcph/ud-conversion-tools`

vised fashion; these affixes are generated manually by an expert in the target language. With Georgian as a case study, we examine this setup in the stem-based approach using the PrStSu+SM grammar.

2.5 Featurizing Segmented Data

In this setup, we utilize the unsupervised morphological-segmentation model that is trained on the target side of the parallel text to produce stem, complex-prefix and complex-suffix features, and leverage these features as part of the neural POS model. For training, we use these features as randomly initialized embeddings that we concatenate with the existing word, affix and words-cluster embeddings prior to applying the BiLSTM encoding layer.

3 Experiments and Evaluation

3.1 Languages and Data

We conduct our experiments on six source languages and eight target ones [5], for a total of 48 language pairs. We use the same source languages used by Eskander et al. (2020b), namely English, Spanish, French, German, Russian, and Arabic [6], and experiment with eight typologically diverse target languages: six morphologically rich languages that are largely agglutinative, namely Basque, Finnish, Georgian, Kazakh, Telugu, and Turkish; morphologically rich Amharic, where many morphological alterations rely on consonantal roots; and less morphologically rich Indonesian.

We conduct the experiments in a truly low-resource scenario, where we use the New Testament as the source of our parallel data (unless noted otherwise): limited in size and out-of-domain with respect to the evaluation sets. We use the Multilingual Parallel Bible Corpus [7] (Christodouloupoulos and Steedman, 2015) as the source of data for all the languages, except for Georgian and Kazakh [8].

3.2 Experimental Settings

For the tagging of the source languages, we use the same off-the-shelf taggers as in Eskander et al. (2020b): Stanza [9] (Qi et al., 2020) for English, Spanish, French, German and Russian and MADAMIRA (Pasha et al., 2014) for Arabic. We also use MADAMIRA for Arabic morphological segmentation. For the stemming of the other source languages, we use the *Snowball* Stemmer (Porter, 2001) as part of *NLTK* [10] (Bird and Loper, 2004). On the other hand, we use MorphAGram [11] (Eskander et al., 2020a) to train and apply the morphological-segmentation models for the target languages as described in Section 2.2.

We follow Eskander et al. (2020b) by using the same thresholds for alignment and projection, along with the same neural hyperparameters of the POS tagger. We also evaluate our models in terms of POS accuracy on the same Universal Dependencies (UD) v2.5 (Zeman et al., 2019) test datasets. However, since the UD project does not currently contain Georgian datasets, we developed a small POS dataset for Georgian (100 sentences) following the UD-tagging scheme. The sentences are taken from the Modern Georgian and Political texts sub-corpora of the Georgian National Corpus [12], and they are hand-tagged and carefully revised by a linguist who specializes in and speaks Georgian as a second language [13]. Finally, all the results are averaged over three runs.

3.3 System Performance

Table 2 reports the POS accuracy for the baseline word-based approach and our stem-based approach for all the 48 target-source language pairs using the New Testament as the source of parallel data. In addition, we report the results for the two multilingual setups Mul_out and Mul_proj per target language. The stem-based approach outperforms the word-based one in 43 language pairs and all the multilingual setups except Mul_proj in the case of Indonesian, which stands out in our language sample as the least complex in terms of morphology. The biggest improvement in the stem-based approach is achieved in the cases of Russian → Turkish, Russian → Kazakh, Spanish → Kazakh and Arabic → Georgian, with relative error reductions of 33.8%, 30.2%, 28.6% and 27.2%, respectively. When averaging across the sources (includ-

---

[5] Although most of our target languages are high-resource ones, we use them in a simulated low-resource setup.

[6] The source languages are commonly spoken ones as the assumption is that translations that involve those languages are easily accessible.

Turkish	64.7	71.9	73.2	**73.4**

Table 3: POS-tagging performance (accuracy) of the word-based, stem-based and morpheme-based approaches when projecting from Arabic using the New Testament as the source of parallel data. The best result per target language is in **bold**. All the morpheme-based improvements are statistically significant for $p\text{-}value < 0.01$.

ing the multilingual ones), Kazakh, Telugu and Turkish experience the highest relative error reductions of 21.0%, 12.1% and 12.1%, respectively. On the other hand, Russian and Arabic yield the highest relative error reductions of 16.3% and 15.6%, respectively, when averaging across the target languages, which is in line with the morphological complexity of the two languages.

Eskander et al. (2020b) show that related languages transfer best across each other. This results in efficient word-based baselines for related language pairs, which in turn limits the corresponding gains in the stem-based approach. On the other hand, a low word-based baseline makes room for improvement when operating on the stem level. For instance, both Georgian and Telugu witness the highest stem-based gains when transferring from Arabic, their lowest performing source language in the word-based approach. For more information about the correlation between language relatedness and cross-lingual learning, see Eskander (2021).

Next, we evaluate the morpheme-based approach (Section 2.3). Table 3 reports the performance of the word-based, stem-based and morpheme-based approaches using Arabic as the source language since it is more morphologically complex than the other sources. The morpheme-based approach results in dense training instances as both alignment and projection are performed in a more fine-grained level compared to the word-based and stem-based approaches. It therefore improves POS tagging for all the target languages except Amharic, where Telugu benefits the most with relative error reductions of 23.9% and 15.3% over the stem-based approach using the RANK and STEM mechanisms, respectively. The difference in the performance of the RANK and STEM mechanisms is only statisti-

Target	Approach	Source for Unsupervised Learning								Ave. Error Reduction

Table 4: POS-tagging performance (accuracy) of the word-based and stem-based (with and without linguistic priors (LP)) approaches when using the New Testament as the source of parallel data. The best result per source language is in **bold**. The improvements in the LP stem-based approach that are not statistically significant for $p\text{-}value < 0.01$ are between parentheses.

cally significant for $p\text{-}value < 0.01$ in the cases of Amharic and Basque, where the STEM mechanism yields better performance, and in the case of Telugu, where the RANK mechanism is superior. Finally, we hypothesize that the quality of morphological segmentation highly affects the efficiency of the morpheme-based setups, which explains the variation in the performance across the different target languages and mechanisms.

As mentioned earlier, we use Georgian as a case study to examine the impact of using linguistic priors for morphological segmentation on the quality of POS tagging (Section 2.4). The results are listed in Table 4. The use of linguistic priors improves the stem-based approach except when projecting from Arabic. The lack of improvement in the case of Arabic can be explained by over-segmentation that produces incorrect POS tags for the common conjunction და (*and*). The characters და also correspond to a verbal prefix that is manually seeded as a prior. This seeding causes erroneous projections labeling და as a verb or an adverb when projecting from Arabic.

Finally, we experiment with the use of the stem and affix information as training features in the POS neural model (Section 2.5). However, most of the improvements due to the use of these features are not statistically significant (See Appendix A for full results) since such features are surpassed by the prefix and suffix n-gram character embeddings.

3.4 Analysis of the Stem-Based Approach

Upon alignment and projection, the highest scoring target sentences are selected as training examples, where sentence score is defined as the harmonic mean of the percentage of tokens with projected tags and the average alignment probability of those tokens. The fine-grained stem-level alignments allow for better alignment confidence and more dense sentences, which in turn increases sentence scores and the number of training examples, and hence reduces the number of out-of-vocabulary words (OOVs). Table 5 lists the average number of training examples, average relative increase in the number of training examples, average relative increase in sentence scores and average relative decrease in the number of OOVs for each target language in the stem-based approach with respect to the word-based one. We witness improvements in the examined aspects for each target language, which explains the considerable improvements in the stem-based approach.

Next, we examine the average relative error reduction in the detection of open-class tags (nouns, verbs and adjectives) in the stem-based approach as compared to the word-based one per target language (Table 6) and per source language (Table 7). Kazakh benefits the most from the stem-based approach at the detection of nouns and adjectives, while Amharic receives the highest gains for verbs. On the other hand, projecting from Russian in the stem space achieves the highest gains for nouns, while the stem-based projection from Arabic yields the highest gains for both verbs and adjectives.

Finally, Figure 3 illustrates the absolute improvements in POS tagging when applying the stem-based approach using the New-Testament as the source of parallel data compared to the word-based approach using the entire Bible as the source of parallel data (three-times more data). As illustrated, the stem-based approach achieves better performance in about two thirds of the language pairs with an average absolute gain of 1.7%. This means using the stem as the core unit of abstraction compensates for the lack of adequate parallel data.

4 Related Work

The line of work most closely related to ours is unsupervised cross-lingual POS tagging via alignment and projection, which was first introduced

by Yarowsky et al. (2001). They applied noise-reduction techniques to improve the alignments and used the resulting transition and emission probabilities to define an HMM POS tagger.

Exploiting multiple source languages via maximum voting was then explored by Fossum and Abney (2005), by voting among the outputs of different single-source models, and by Agić et al. (2015), by projecting the annotations from multiple languages before training the POS tagger.

In order to increase the size of the training data, Das and Petrov (2011) proposed graph-based label propagation, while Duong et al. (2013); Agić et al. (2015) applied self-training and revision. On another hand, Täckström et al. (2013) and Buys and Botha (2016) investigated the use of token and type constraints to reject projections of low confidence.

Eskander et al. (2020b) derived a cross-lingual POS-tagging pipeline that utilizes the best practices in alignment and projection. In addition, they examined the use of pretrained multilingual contextual embeddings, along with affix embeddings and Brown clusters, within a rich neural architecture, which achieves the state-of-the-art results for unsupervised POS tagging. We follow their approach by presenting stem-based alignment and projection for morphologically complex low-resource languages.

Regarding unsupervised morphological segmentation, several generative and discriminative frameworks have been developed over the last two decades. The two most notable frameworks are: 1) Morfessor (Creutz and Lagus, 2007; Grönroos et al., 2014), a commonly-used HMM framework that utilizes the MDL principle to segment into morphemes of a hierarchical structure; and 2) MorphAGram (Eskander et al., 2020a), a segmentation framework that is based on Adaptor Grammars (AGs) (Johnson et al., 2007), Bayesian models that utilize Probabilistic Context Free Grammars (PCFGs). We use MorphAGram to train morphological-segmentation models as it achieves the state-of-the-art performance and allows for deriving affix and stem information (as opposed to a sequence of unlabeled morphemes).

5 Conclusion and Future Work

We presented a fully unsupervised stem-based approach for cross-lingual POS tagging via alignment and projection, where we use the stem as the core unit of abstraction to abstract away from complex affixation. Our experiments using six source languages and eight morphologically rich target lan-

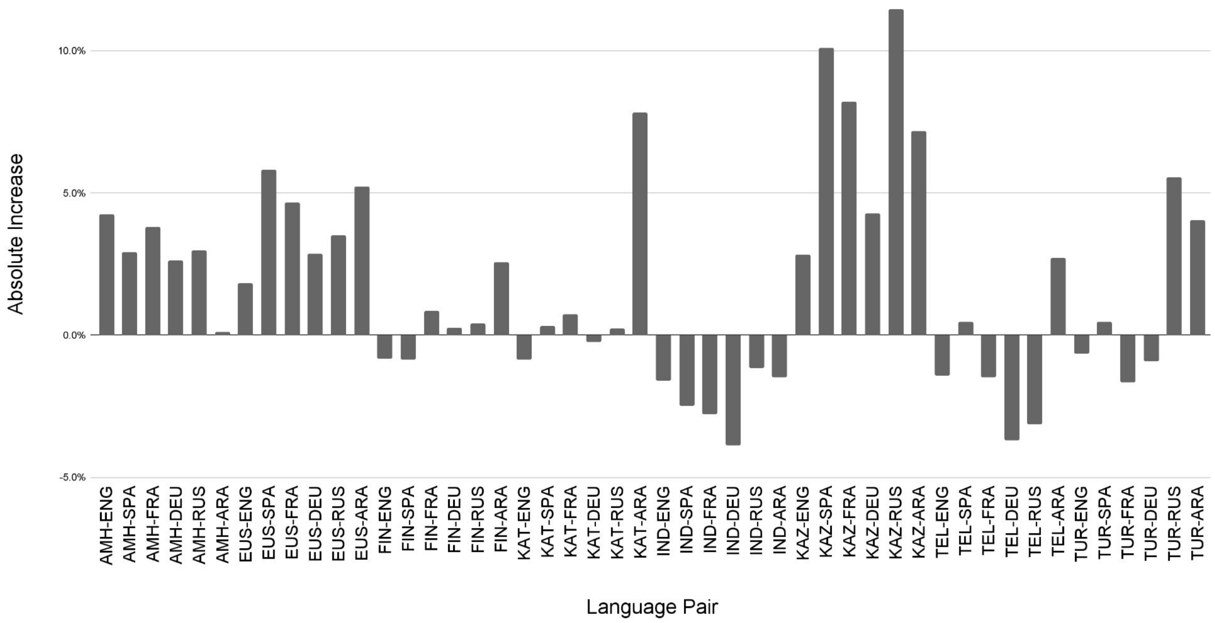

Figure 3: Absolute performance increases (accuracy) when applying the stem-based approach using the New Testament as the source of parallel data as compared to the word-based approach using the entire Bible as the source of parallel data

guages in low-resource setups show improvements over the word-based approach in 43 language pairs out of 48, with an average relative error reduction of 10.3% in accuracy per target language. In addition, we examined morpheme-based alignment and projection and the use of linguistic priors in morphological segmentation, which further improve POS tagging.

In the future, we plan to study the role of morphological typology in cross-lingual learning. This allows for deriving disciplined guidelines for the selection of an appropriate source language that transfers well to the target language of interest.

Acknowledgements

This research is based upon work supported by the Intelligence Advanced Research Projects Activity (IARPA), (contract #FA8650-17-C-9117) and the National Science Foundation (awards #1941742 and #1941733). 6 Ethical Considerations

The Georgian annotations were done by a linguist with appropriate compensation after educating them about the research purpose and the annotation process. We claim ownership of the Georgian dataset for open distribution as the text is taken from the Modern Georgian and Political texts subcorpora of the Georgian National Corpus, which is an open-sourced work that allows for modifications, derived work and redistribution. The quality of the annotations was examined manually and empirically. The source code and the data will be released open-source. Finally, the limitations of the work lay within the reported performance. There should be no potential risks given these stated limitations.

Abstract

Real-world datasets often encode stereotypes and societal biases. Such biases can be implicitly captured by trained models, leading to biased predictions and exacerbating existing societal preconceptions. Existing debiasing methods, such as adversarial training and removing protected information from representations, have been shown to reduce bias. However, a disconnect between fairness criteria and training objectives makes it difficult to reason theoretically about the effectiveness of different techniques. In this work, we propose two novel training objectives which directly optimise for the widely-used criterion of *equal opportunity*, and show that they are effective in reducing bias while maintaining high performance over two classification tasks.

1 Introduction and Background

Modern neural machine learning has achieved great success across a range of classification tasks. However, when applied over real-world data, especially in high-stakes settings such as hiring processes and loan approvals, care must be taken to assess the fairness of models. This is because real-world datasets generally encode societal preconceptions and stereotypes, thereby leading to models trained on such datasets to amplify existing bias and make biased predictions (i.e., models perform unequally towards different subgroups of individuals). This kind of unfairness has been reported over various NLP tasks, such as part-of-speech tagging (Hovy and Søgaard, 2015; Li et al., 2018; Han et al., 2021b), sentiment analysis (Blodgett et al., 2016; Shen et al., 2021), and image activity recognition (Wang et al., 2019; Zhao et al., 2017).

Various methods have been proposed to mitigate bias, including adversarial training, and pre- and post-processing strategies. Adversarial training aims to make it difficult for a discriminator to predict protected attribute values from learned representations (Han et al., 2021c; Elazar and Goldberg, 2018; Madras et al., 2018). Pre- and post-processing strategies vary greatly in approach, including transforming the original dataset to reduce protected attribute discrimination while retaining dataset utility (du Pin Calmon et al., 2017), iteratively removing protected attribute information from (fixed) learned representations (Ravfogel et al., 2020), or reducing bias amplification by injecting corpus-level constraints during inference (Zhao et al., 2017).

However, training strategies and optimisation objectives are generally disconnected from fairness metrics which directly measure the extent to which different groups are treated (in)equitably. This makes it difficult to understand the effectiveness of previous debiasing methods from a theoretical perspective. In this work, we propose to explicitly incorporate equal opportunity into our training objective, thereby achieving bias reduction. This paper makes the following contributions:

1. We are the first to propose a weighted training objective that directly implements fairness metrics.
2. Observing that model performance for different classes can vary greatly, we further propose a variant of our method, taking both bias reduction among protected attribute groups and bias reduction among different classes into consideration.
3. Experimental results over two tasks show that both proposed methods are effective at achieving fairer predictions, while maintaining performance.

Our code is available at: `https://github.com/AiliAili/Difference_Mean_Fair_Models`.

2 Related Work

2.1 Fairness Criteria

Various criteria have been proposed to capture different types of discrimination, such as group fairness (Hardt et al., 2016; Zafar et al., 2017a; Cho et al., 2020; Zhao et al., 2020), individual fairness (Sharifi-Malvajerdi et al., 2019; Yurochkin et al., 2020; Dwork et al., 2012), and causality-based fairness (Wu et al., 2019; Zhang and Bareinboim, 2018a,b). In this work, we focus on group fairness, whereby a model should perform equally across different demographic subgroups.

To quantify how predictions vary across different demographic subgroups, demographic parity (Feldman et al., 2015; Zafar et al., 2017b; Cho et al., 2020), equal opportunity (Hardt et al., 2016; Madras et al., 2018), and equalised odds (Cho et al., 2020; Hardt et al., 2016; Madras et al., 2018) are widely used to measure fairness. *Demographic parity* ensures that models achieve the same positive rate for each demographic subgroup, oblivious the ground-truth target label. *Equal opportunity* requires that a model achieves the same true positive rate (TPR) across different subgroups, considering only instances with a positive label. *Equalised odds* goes one step further in requiring not only the same TPR but also the same false positive rate (FPR) across groups.

Demographic parity, equal opportunity, and equalised odds only focus on the prediction outcome for one specific target label (i.e. a "positive" class) in a binary classification setting, but does not apply fairness directly to multi-class settings, when fairness for different subgroups across all classes is required. Equal opportunity can be generalised by extending the "positive" class to each target class, as we do in our work.

2.2 Debiasing Methods

A broad range of methods has been proposed to learn fair models. Based on where debiasing occurs, in terms of dataset processing, model training, and inference, we follow Cho et al. (2020) in categorising methods into: (1) pre-processing, (2) post-processing, and (3) in-processing.

Pre-processing methods manipulate the original dataset to mitigate discrimination (Wang et al., 2019; Xu et al., 2018; Feldman et al., 2015; du Pin Calmon et al., 2017; De-Arteaga et al., 2019). For example, du Pin Calmon et al. (2017) transform the original dataset to reduce discrimination while retaining dataset utility. Class imbalance methods used in bias reduction, such as dataset sampling (Kubat and Matwin, 1997; Wallace et al., 2011), instance reweighting (Cui et al., 2019; Li et al., 2020; Lin et al., 2017), and weighted max-margin (Cao et al., 2019), also belong to this category. For example, Lahoti et al. (2020), Subramanian et al. (2021b), and Han et al. (2021a) reweight instances by taking the (inverse of) joint distribution of the protected attribute classes and main task classes into consideration. Wang et al. (2019) and Han et al. (2021a) down-sample the majority protected attribute group within each target class, and train on the resulting balanced dataset.

Post-processing methods calibrate the prediction outcome or learned representations of models to achieve fair predictions (Hardt et al., 2016; Pleiss et al., 2017; Zhao et al., 2017; Ravfogel et al., 2020). For example, Zhao et al. (2017) enforce a corpus-level constraint during inference to reduce bias. Ravfogel et al. (2020) iteratively remove protected attribute information from representations generated by an fixed encoder, by iteratively training a discriminator over the projected attribute and projecting the representation into the discriminator's null space.

In-processing methods learn fair models during model training. One family of approaches is based on constrained optimisation, incorporating fairness measures as regularisation terms or constraints (Zafar et al., 2017b; Subramanian et al., 2021a; Donini et al., 2018; Narasimhan, 2018; Cho et al., 2020). For example, Zafar et al. (2017a) translate equalised odds into constraints on FPR and FNR across groups, and solve using constraint programming. Cho et al. (2020) adopt kernel density estimation to quantify demographic parity and equalised odds, but in a manner which is limited to low-dimensional data and binary classification tasks. Another line of work is to use adversarial training to obtain fair models, in jointly training an encoder and discriminator(s) over the encoded representations such that the discriminator(s) are ineffective at predicting the protected attribute values from learned representations (Han et al., 2021c; Elazar and Goldberg, 2018; Madras et al., 2018; Zhang et al., 2018; Agarwal et al., 2018; Roh et al., 2020). Elsewhere, Shen et al. (2021) use contrastive learning to learn fair models by simultaneously pushing instances belonging to the same target class closer and pulling instances belonging to the same protected attribute class further apart.

The most relevant work to ours is *FairBatch* (Roh et al., 2021). It proposes to formulate the original task as a bi-level optimisation problem, where the inner optimiser is the standard training algorithm and the outer optimiser is responsible for adaptively adjusting the sampling probabilities of instances with a given target class and protected attribute value, based on the equal opportunity metric achieved by the intermediate inner model. That is, they adaptively adjust the instance *resampling* probability during training to reduce bias. However, different from FairBatch, whose resampling strategy is bound by the sampling probability $[0, 1]$, our proposed method achieves bias reduction by *reweighting* instances during training, where the reweighting range is unbounded, leading to greater flexibility in trading off performance and fairness.

3 Methodology

3.1 Preliminaries

Suppose we have some data $X \in \mathbb{R}^n$, target labels $Y \in C$, and protected attribute values $A = \{0, 1\}$, where C is the number of target classes for a given task.

Equal opportunity A classifier is said to satisfy equal opportunity if its prediction is conditionally independent of the protected attribute A given the target label Y, $\{P(\hat{y} = y|Y = y, A = 0) = P(\hat{y} = y|Y = y, A = 1)\}$ for $\forall y \in Y$. Here, $\hat{y}$ is a prediction outcome, $y \in Y$ and $a \in A$. As mentioned above, we slightly modify the definition of equal opportunity by allowing y to be each candidate target class, accommodating multi-class settings. We explicitly address the fairness criterion across *all* target classes by promoting comparable true positive rates across protected classes.

3.2 Optimising Equal Opportunity

Instead of using a fairness proxy (Zafar et al., 2017b) or kernel density estimation to quantify fairness (Cho et al., 2020), we propose to optimise equal opportunity by directly minimising the absolute difference in loss between different subsets of instances belonging to the same target label but with different protected attribute classes,

$$\mathcal{L}^{\text{class}}_{\text{eo}} = \mathcal{L}_{ce} + \lambda \sum_{y=\in C} \sum_{a \in A} |\mathcal{L}^{y,a}_{ce} - \mathcal{L}^{y}_{ce}| \qquad (1)$$

Here, $\mathcal{L}_{ce}$ denotes the average cross-entropy loss based on instances in the batch; $\mathcal{L}^{y,a}_{ce}$ denotes the average cross-entropy loss computed over instances with the target label y and the protected attribute label a; and $\mathcal{L}^{y}_{ce}$ denotes the average cross-entropy loss computed over all instances with target label y. Our proposed loss $\mathcal{L}^{\text{class}}_{\text{eo}}$ is the weighted sum of the overall cross-entropy and the sum of the cross-entropy difference for each target label overall and that conditioned on the target label, thereby capturing both performance and fairness. This method is denoted as $\mathsf{EO}_{\mathrm{CLA}}$, as it captures class-wise equal opportunity.

3.3 Equal Opportunity across Classes

One drawback of $\mathsf{EO}_{\mathrm{CLA}}$ is that it only focuses on optimising equal opportunity, ignoring the fact that the performance for different classes can vary greatly, especially when the dataset is skewed. To learn fair models not only towards demographic subgroups but also across target classes, we propose a variant of Equation 1, by introducing one additional constraint on top of equal opportunity to encourage the label-wise cross entropy loss terms to align. Formally: $\mathcal{L}^{y_1}_{ce} \approx \mathcal{L}^{y_2}_{ce}$, where $y_1 \neq y_2$, and $y_1 \in Y$, $y_2 \in Y$. This objective encourages equal opportunity not only for demographic subgroups but also across different target classes:

$$\mathcal{L}^{\text{global}}_{\text{eo}} = \mathcal{L}_{ce} + \lambda \sum_{y=\in C} \sum_{a \in A} |\mathcal{L}^{y,a}_{ce} - \mathcal{L}_{ce}| \qquad (2)$$

This method is denoted as $\mathsf{EO}_{\mathrm{GLB}}$, short for global equal opportunity.

3.4 Theory

In this section, we show how our training objective is related to equal opportunity in the binary classification and binary protected attribute setting. Note that our proof naturally extends to cases where the numbers of target classes and/or protected attribute values are greater than two as described in Equations 1 and 2.

Let $m_{y,a}$ be the number of training instances with target label y and protected attribute a in a batch. For example, $m_{1,0}$ denotes the number of instances with target label 1 and protected attribute 0 in the batch. Let $\mathcal{L}^{y,a}$ be the average loss for instances with target label y and protected attribute a. For example, $\mathcal{L}^{1,0}$ is the average loss for instances with target label 1 and protected attribute 0.

3.4.1 Cross-Entropy Loss

The vanilla cross-entropy loss is computed as:

$$\frac{1}{N}(m_{0,0}\mathcal{L}^{0,0} + m_{0,1}\mathcal{L}^{0,1} + m_{1,0}\mathcal{L}^{1,0} + m_{1,1}\mathcal{L}^{1,1}) \qquad (3)$$

which is the average loss over different subsets of instances with a given target label and protected attribute class.

3.4.2 Difference Loss

The EO$_{\text{CLA}}$ method defined in Equation 1 can be written as:

$$\begin{aligned}\mathcal{L}^{\text{class}}_{\text{eo}} &= \mathcal{L}_{ce} + \lambda \sum_{y,a} |\mathcal{L}^{y,a}_{ce} - \mathcal{L}^{y}_{ce}| \\ &= \sum_{y,a} \Big[\frac{m_{y,a}}{N} \mathcal{L}^{y,a}_{ce} + \lambda \, \text{sign}_{y,a} \, (\mathcal{L}^{y,a}_{ce} - \mathcal{L}^{y}_{ce}) \Big], \\ &= \sum_{y,a} \Big[(\frac{m_{y,a}}{N} + \lambda \, \text{sign}_{y,a}) \mathcal{L}^{y,a}_{ce} \\ &\qquad - \lambda \, \text{sign}_{y,a} \, \mathcal{L}^{y}_{ce} \Big], \end{aligned} \tag{4}$$

where sign is a sign function, and $\text{sign}_{y,a} = \text{sign}\,(\mathcal{L}^{y,a}_{ce} - \mathcal{L}^{y}_{ce})$. Noting that for binary protected attributes, $\text{sign}_{y,a} = -\,\text{sign}_{y,\neg a}$, and $\sum_{y,a} \mathcal{L}^{y}_{ce} = 0, \forall y$ in this case:

$$\mathcal{L}^{\text{class}}_{\text{eo}} = \sum_{y,a} (\frac{m_{y,a}}{N} + \lambda \, \text{sign}_{y,a}) \mathcal{L}^{y,a}_{ce} \tag{5}$$

By comparing Equations 3 and 5, we can see that for target label y, our method dynamically increases the weight for poorly-performing subsets (i.e. $\text{sign}_{y,g} = 1$) by λ, and decreases the weight for well-performing subsets ($\text{sign}_{y,g} = -1$) by λ, thereby leading to fairer predictions by adjusting the weight for instances with different protected attribute classes conditioned on a given target label.

3.4.3 From Binary Cross-Entropy to True Positive Rate

Using the definition of binary cross-entropy

$$-[y_i \cdot \log(p(y_i)) + (1 - y_i) \cdot \log(1 - p(y_i))],$$

the loss for a certain subset, e.g., the subset of instances with target label 1 and protected attribute class 0, can be simplified as:

$$\begin{aligned}\mathcal{L}^{1,0} = &- \frac{1}{m_{1,0}} \sum_{j=1}^{m_{1,0}} \Big(y_j \cdot \log(p(\hat{y}_j)) \\ &+ (1 - y_j) \cdot \log(1 - p(\hat{y}_j)) \Big) \\ = &- \frac{1}{m_{1,0}} \sum_{j=1}^{m_{1,0}} \log(p(\hat{y}_j)) \end{aligned} \tag{6}$$

Notice that $p(\hat{y}_j)$ is equivalent to $p(\hat{y}_j = 1)$, making $\mathcal{L}^{1,0} = -\frac{1}{m_{1,0}} \sum_{j=1}^{m_{1,0}} \log(p(\hat{y}_j))$ an unbiased estimator of $-\log p(\hat{y} = 1 | y = 1)$, which approximates $-\log$ TPR.

Minimising the expectation of the absolute difference between $\mathcal{L}^{1,0}$ and $\mathcal{L}^{1,1}$ can approximate the true positive rate difference between two groups with the same target label 1:

$$\begin{aligned} &\text{argmin}_\theta \, \mathbb{E}(|\mathcal{L}^{1,0} - \mathcal{L}^{1,1}|) \\ &= \text{argmin} \, | - \log p(\hat{y} = 1 | y = 1, g = 0) \\ &\qquad - (-\log p(\hat{y} = 1 | y = 1, g = 1))| \\ &\approx \text{argmin} \, | \log \frac{TPR_{1,0}}{TPR_{1,1}} | \\ &= \text{argmin} \, |TPR_{1,0} - TPR_{1,1}| \end{aligned}$$

This demonstrates that minimising the absolute difference between $\mathcal{L}^{1,0}$ and $\mathcal{L}^{1,1}$ is roughly equivalent to minimising the TPR difference between two groups with the same target label, which is precisely the formulation of equal opportunity, as described in Section 4.3. Therefore, the second term in our proposed method (Equation 1) is optimising directly for equal opportunity.

4 Experiments

Our experiments compare the performance and fairness of our methods against various competitive baselines, and across two classification tasks.

4.1 Baselines

We compare our proposed methods EO$_{\text{CLA}}$ and EO$_{\text{GLB}}$ against the following seven baselines:

1. CE: train the model with cross-entropy loss and no explicit bias mitigation.
2. INLP: first train the model with cross-entropy loss to obtain dense representations, and iteratively apply null-space projection to the learned representations to remove protected attribute information (Ravfogel et al., 2020). The resulting representations are used to make predictions.
3. Adv: jointly train the model with cross-entropy loss and an ensemble of three adversarial discriminators for the projected attribute, with an orthogonality constraint applied to the discriminators to encourage diversity (Han et al., 2021c).
4. DS: downsample the dataset corresponding to the protected attribute conditioned on a given target label (Han et al., 2021a).
5. RW: reweight instances based on the (inverse) joint distribution of the protected attribute classes and target classes (Han et al., 2021a).

6. Constrained: formulate the task as a constrained optimisation problem, where equal opportunity is incorporated as constraints (Subramanian et al., 2021a).
7. FairBatch: formulate the model training as a bi-level optimisation problem, as described in Section 2.2 (Roh et al., 2021).

4.2 Experiment Setup

For each task, we first obtain document representations from their corresponding pretrained models, which are not finetuned during training. Then document representations are fed into two fully-connected layers with a hidden size of 300d. For all experiments, we use the Adam optimiser (Kingma and Ba, 2015) to optimise the model for at most 60 epochs with early stopping and a patience of 5. All models are trained and evaluated on the same dataset splits, and models are selected based on their performance on the development set. We finetune the learning rate, batch size, and extra hyperparameters introduced by the corresponding debiasing methods for each model on each dataset (see the Appendix for details). Noting the complexity of model selection given the multi-objective accuracy–fairness tradeoff and the absence of a standardised method for selecting models based on both criteria in fairness research, we determine the best-achievable accuracy for a given model, and select the hyperparameter settings that reduce bias while maintaining accuracy as close as possible to the best-achievable value (all based on the dev set). We leave the development of a fair and robust model selection method to future work.

4.3 Evaluation Metrics

To evaluate the performance of models on the main task, we adopt $\mathrm{F}_1^{\mathrm{micro}}$ and $\mathrm{F}_1^{\mathrm{macro}}$ for all our datasets, taking class imbalance into consideration, especially in the multi-class setting.

To evaluate fairness, we follow previous work (De-Arteaga et al., 2019; Ravfogel et al., 2020) and adopt root mean square TPR gap over all classes, which is defined as

$$\mathrm{GAP} = \sqrt{\frac{1}{|C|}\sum_{y\in Y}(\mathrm{GAP}_y^{\mathrm{TPR}})^2},$$

where $\mathrm{GAP}_y^{\mathrm{TPR}} = |\mathrm{TPR}_{y,a} - \mathrm{TPR}_{y,\neg a}|,\ \ y \in Y$, and $\mathrm{TPR}_{a,y} = \mathbb{P}(\hat{y} = y|y,a)$, indicating the proportion of correct predictions among instances with target label y and protected attribute label a. $\mathrm{GAP}_y^{\mathrm{TPR}}$ measures the absolute performance difference between demographic subgroups conditioned on target label y, and a value of 0 indicates that the model makes predictions independent of the protected attribute.

4.4 Twitter Sentiment Analysis

4.4.1 Task and Dataset

For our first dataset, the task is to predict the binary sentiment for a given English tweet, where each tweet is also annotated with a binary protected attribute indirectly capturing the ethnicity of the tweet author as either African American English (AAE) or Standard American English (SAE). Following previous studies (Ravfogel et al., 2020; Han et al., 2021c; Shen et al., 2021), we adopt the dataset of Blodgett et al. (2016) (**Moji** hereafter), where the training dataset is balanced with respect to both sentiment and ethnicity but skewed in terms of sentiment–ethnicity combinations (40% HAPPY-AAE, 10% HAPPY-SAE, 10% SAD-AAE, and 40% SAD-SAE, respectively). The number of instances in the training, dev, and test sets are 100K, 8K, and 8K, respectively. The dev and test set are balanced in terms of sentiment–ethnicity combinations.

4.4.2 Implementation Details

Following previous work (Elazar and Goldberg, 2018; Ravfogel et al., 2020; Han et al., 2021c), we use DeepMoji (Felbo et al., 2017), a model pretrained over 1.2 billion English tweets, as the encoder to obtain text representations. The parameters of DeepMoji are fixed in training. Hyperparameter settings are provided in Appendix A.2.

4.4.3 Experimental Results

Table 1 presents the results over the **Moji** test set. Compared to CE, INLP and Adv moderately reduce model bias while simultaneously improving model performance. Surprisingly, both DS and RW reduce GAP substantially and achieve the joint best $\mathrm{F}_1^{\mathrm{micro}}$, indicating that the biased prediction is mainly due to the imbalanced distribution of protected attribute classes conditioned on a given target label, and the imbalanced distribution of sentiment–ethnicity combinations.[1] However,

---

[1] However, it does not hold the other way around as demonstrated by previous studies (Wang et al., 2019), indicating that a balanced dataset either in terms of target label and protected attribute combination, or in terms of protected attribute class distribution conditioned on target classes, can still lead to biased predictions.

Model	$\text{F}_1^{\text{micro}}$ ↑	GAP ↓

EO_{CLA}	75.03±0.25	**10.83**±1.40†
EO_{GLB}	75.20±0.20	11.49±1.07

Table 1: Experimental results on the **Moji** test set (averaged over 10 runs); **Bold** = Best Performance; ↑= the higher the better; ↓= the lower the better. The best result is marked with "†" if the difference over the next-best method is statistically significant (based on a one-tailed Wilcoxon signed-rank test; $p < 0.05$), noting that if the best method is one of our methods, we compare it to the next-best method which is not our own.

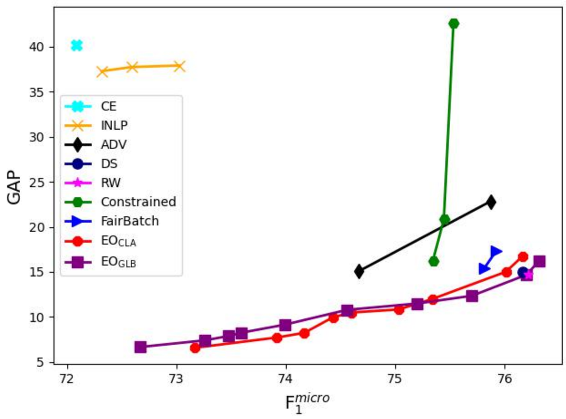

Figure 1: $\text{F}_1^{\text{micro}}$ vs. GAP of different models on the **Moji** test set, as we vary the most sensitive hyperparameter for each model.

the drawback of dataset imbalance methods is that they lack the flexibility to control the performance–fairness tradeoff. Both Constrained and FairBatch also effectively reduce bias and achieve improved performance. Both of our methods, EO_{CLA} and EO_{GLB}, achieve competitive performance on the main task with the largest bias reduction. For all models except INLP, we can see that incorporating debiasing techniques leads to improved performance on the main task. We hypothesise that incorporating debiasing techniques (either in the form of adversarial training, data imbalance methods, or optimising towards equal opportunity) acts as a form of regularisation, thereby reducing the learned correlation between the protected attribute and main task label, and encouraging models to learn task-specific representations.

Performance–Fairness tradeoff. We plot the tradeoff between $\text{F}_1^{\text{micro}}$ and GAP for all models on the **Moji** test set in Figure 1. In this, we vary the most-sensitive hyperparameter for each model: the number of iterations for INLP, the λ weight for adversarial loss for Adv, the step size of adjusting resampling probability for FairBatch, and the weight for minimising the loss difference for EO_{CLA} and EO_{GLB}.[2] As we can see, INLP has limited capacity to reduce bias, and the performance for the main task is slightly worse than the other methods. Compared with Adv, Constrained, and FairBatch, our proposed methods EO_{CLA} and EO_{GLB} achieve fairer predictions while maintaining competitive performance (bottom right). Another advantage of our methods is that they allow for greater variability in the performance–fairness tradeoff, demonstrating the effectiveness and superiority of our proposed method. Note that only the pareto points for each model are plotted. For example, for Adv, we experimented with 7 values of λ, but the results are captured by only two pareto points.

4.5 Profession Classification

4.5.1 Task and Dataset

For our second dataset, the task is to predict a person's occupation given their biography (De-Arteaga et al., 2019), where each short online biography is labelled with one of 28 occupations (main task label) and binary gender (protected attribute). Following previous work (De-Arteaga et al., 2019; Ravfogel et al., 2020), the number of instances in the training, dev, and test sets are 257K, 40K, and 99K, respectively.[3]

4.5.2 Implementation Details

Following the work of Ravfogel et al. (2020), we use the "CLS" token representation of the pretrained uncased BERT-base (Devlin et al., 2019) to obtain text representations, and keep BERT fixed during training. Hyperparameter settings for all models are provided in Appendix A.3.

---

[2] For CE, DS, and RW, there is no hyperparameter that controls the tradeoff between model performance and bias reduction.

[3] There are slight differences between our dataset and that used by previous studies (De-Arteaga et al., 2019; Ravfogel et al., 2020) as a small number of biographies were no longer available on the web when we crawled them.

Model	$\mathrm{F}_1^{\mathrm{macro}} \uparrow$	$\mathrm{F}_1^{\mathrm{micro}} \uparrow$	GAP ↓
CE	**75.95**$\pm$0.10†	**82.19**$\pm$0.04†	16.68$\pm$0.46
INLP	71.44$\pm$0.40	79.54$\pm$0.18	13.52$\pm$1.54
Adv	70.88$\pm$2.31	79.72$\pm$1.02	16.78$\pm$0.87
DS	67.73$\pm$0.26	78.48$\pm$0.10	9.17$\pm$0.41
RW	69.21$\pm$0.36	76.18$\pm$0.32	**8.58**$\pm$0.49†
FairBatch	75.14$\pm$0.28	81.82$\pm$0.07	10.80$\pm$1.04
$\mathrm{EO_{CLA}}$	72.07$\pm$0.18	81.52$\pm$0.06	12.80$\pm$0.42
$\mathrm{EO_{GLB}}$	75.11$\pm$0.18	81.74$\pm$0.07	12.72$\pm$0.51

Table 2: Experimental results on the **Bios** test set (averaged over 10 runs). The best result is marked with "†" if the difference over the next-best method is statistically significant (based on a one-tailed Wilcoxon signed-rank test; $p < 0.05$), noting that if the best method is one of our methods, we compare it to the next-best method which is not our own.

4.5.3 Experimental Results

Table 2 shows the results on the **Bios** test set.[4] We can see that Adv is unable to reduce GAP even at the cost of performance in terms of $\mathrm{F}_1^{\mathrm{micro}}$ and $\mathrm{F}_1^{\mathrm{macro}}$. Both DS and RW reduce bias in terms of GAP, at the cost of a drop in performance, in terms of $\mathrm{F}_1^{\mathrm{micro}}$ and $\mathrm{F}_1^{\mathrm{macro}}$. We attribute this to the dramatic decrease in the number of training instances for DS, and the myopia of RW in only taking the ratio of occupation–gender combinations into consideration but not the difficulty of each target class. Among INLP, FairBatch, $\mathrm{EO_{CLA}}$, and $\mathrm{EO_{GLB}}$, we can see that FairBatch achieves a reasonable bias reduction with the least performance drop. This is due to it dynamically adjusting the resampling probability during training. Comparing $\mathrm{EO_{CLA}}$ and $\mathrm{EO_{GLB}}$, we can see that $\mathrm{EO_{GLB}}$ is better able to deal with the dataset class imbalance (reflected in $\mathrm{F}_1^{\mathrm{macro}}$), while reducing bias.

Performance–Fairness tradeoff. Figure 2 shows the $\mathrm{F}_1^{\mathrm{micro}}$–GAP tradeoff plot for the **Bios** test set. We can see that INLP and Adv reduce bias at the cost of performance, as do DS and RW. Compared with FairBatch, $\mathrm{EO_{CLA}}$ and $\mathrm{EO_{GLB}}$ provide greater control in terms of performance–fairness tradeoff, such as achieving a smaller GAP with a slight decrease of $\mathrm{F}_1^{\mathrm{micro}}$. A similar trend is also observed for the $\mathrm{F}_1^{\mathrm{macro}}$–GAP tradeoff as shown in Figure 3. Although $\mathrm{EO_{CLA}}$ is outperformed by FairBatch, $\mathrm{EO_{GLB}}$ provides greater control in terms of performance–fairness tradeoff, suggesting an advantage of $\mathrm{EO_{GLB}}$ in enforcing fairness across target classes, especially for the imbalanced dataset.

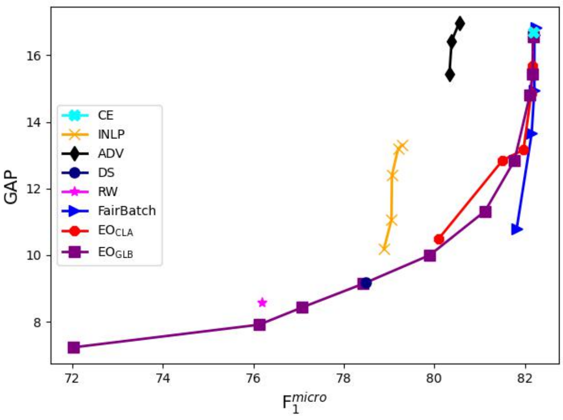

Figure 2: $\mathrm{F}_1^{\mathrm{micro}}$ vs. GAP of different models on the **Bios** test set, as we vary the most sensitive hyperparameter for each model.

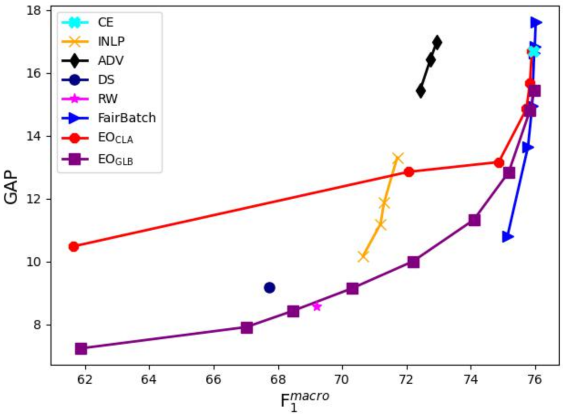

Figure 3: $\mathrm{F}_1^{\mathrm{macro}}$ vs. GAP of different models on the **Bios** test set, as we vary the most sensitive hyperparameter for each model.

5 Analysis

To better understand the effectiveness of our proposed methods, we perform two sets of experiments: (1) an ablation study, and (2) an analysis of training efficiency.

5.1 Ablation Study

$\mathrm{EO_{CLA}}$ can be reformulated as $\mathcal{L}_{ce} + \lambda \sum_{y \in C}\{\max(\mathcal{L}_{ce}^{y,a}, \mathcal{L}_{ce}^{y,\neg a}) - \min(\mathcal{L}_{ce}^{y,a}, \mathcal{L}_{ce}^{y,\neg a})\}$, effectively assigning more weight to worse-performing instances (argmax loss) and less weight to better-performing instances (argmin loss). To explore the impact of adjusting weights on model performance,

---

[4] We omit results for Constrained as it did not converge on this data set, presumably because of its brittleness over multi-class classification tasks.

we experiment with two versions: (1) $\mathcal{L}_{ce} + \lambda \sum_{y \in C} \max(\mathcal{L}_{ce}^{y,a}, \mathcal{L}_{ce}^{y,\neg a})$, denoted as $\mathrm{EO}_{\mathrm{CLA}}^{\max}$, where we assign higher weights to worse-performing instances without changing the weights assigned to better-performing instances; and (2) $\mathcal{L}_{ce} - \lambda \sum_{y \in C} \min(\mathcal{L}_{ce}^{y,a}, \mathcal{L}_{ce}^{y,\neg a})$, denoted as $\mathrm{EO}_{\mathrm{CLA}}^{\min}$, where we assign smaller weights to better-performing instances without changing the weights assigned to worse-performing instances. Correspondingly, for $\mathrm{EO}_{\mathrm{GLB}}$, we have $\mathrm{EO}_{\mathrm{GLB}}^{\max}$ and $\mathrm{EO}_{\mathrm{GLB}}^{\min}$. Hyperparameter settings for each model can be found in Appendix B.1.

Tables 3 and 4 show the results for the different models on **Moji** and **Bios**. We can see that the full $\mathrm{EO}_{\mathrm{CLA}}$ and $\mathrm{EO}_{\mathrm{GLB}}$ both achieve better bias reduction than ablated *min* and *max* counterparts on **Moji**, while maintaining similar levels of performance in terms of $\mathrm{F}_1^{\mathrm{micro}}$.[5] On **Bios**, we can see that $\mathrm{EO}_{\mathrm{CLA}}^{\max}$ outperforms $\mathrm{EO}_{\mathrm{CLA}}$ in bias reduction and model performance except for $\mathrm{F}_1^{\mathrm{micro}}$, indicating that it is beneficial for bias reduction to increase the weight for worse-performing instances. On the other hand, $\mathrm{EO}_{\mathrm{CLA}}^{\min}$ is inferior to $\mathrm{EO}_{\mathrm{CLA}}$ in terms of both bias reduction and performance. We conjecture that reducing the weights for better-performing instances is harmful for model performance (especially for minority classes) over datasets with imbalanced distributions, as is the case for **Bios**.[6] Among the three variants of $\mathrm{EO}_{\mathrm{GLB}}$, $\mathrm{EO}_{\mathrm{GLB}}^{\max}$ slightly improves performance on the main task and maintains the same level of bias reduction as $\mathrm{EO}_{\mathrm{GLB}}$, while $\mathrm{EO}_{\mathrm{GLB}}^{\min}$ improves performance on the main task but does not reduce bias. Overall, these results show that our two methods perform best in their original formulations.

5.2 Training Efficiency

To understand the training efficiency of the different models, we perform experiments with varying training data sizes on both **Moji** and **Bios**. Based on results from Tables 1 and 2, we provide results for CE, FairBatch, $\mathrm{EO}_{\mathrm{CLA}}$, and $\mathrm{EO}_{\mathrm{GLB}}$.

Model	$\mathrm{F}_1^{\mathrm{micro}} \uparrow$	GAP $\downarrow$
$\mathrm{EO}_{\mathrm{CLA}}$	75.03±0.25	10.83±1.40
$\mathrm{EO}_{\mathrm{CLA}}^{\max}$	75.92±0.10	13.79±1.64
$\mathrm{EO}_{\mathrm{CLA}}^{\min}$	75.33±0.19	14.50±1.78
$\mathrm{EO}_{\mathrm{GLB}}$	75.20±0.20	11.49±1.07
$\mathrm{EO}_{\mathrm{GLB}}^{\max}$	76.31±0.10	16.47±0.90
$\mathrm{EO}_{\mathrm{GLB}}^{\min}$	76.27±0.13	18.01±0.40

Table 3: Ablation results over **Moji** test set (averaged over 10 runs).

Model	$\mathrm{F}_1^{\mathrm{macro}} \uparrow$	$\mathrm{F}_1^{\mathrm{micro}}$	GAP $\downarrow$
$\mathrm{EO}_{\mathrm{CLA}}$	72.07±0.18	81.52±0.06	12.80±0.42
$\mathrm{EO}_{\mathrm{CLA}}^{\max}$	72.09±0.19	79.95±0.12	8.98±0.43
$\mathrm{EO}_{\mathrm{CLA}}^{\min}$	53.17±0.53	76.66±0.23	19.22±1.68
$\mathrm{EO}_{\mathrm{GLB}}$	75.11±0.18	81.74±0.07	12.72±0.51
$\mathrm{EO}_{\mathrm{GLB}}^{\max}$	75.37±0.06	81.89±0.03	12.47±0.51
$\mathrm{EO}_{\mathrm{GLB}}^{\min}$	75.95±0.12	82.19±0.05	16.74±0.42

Table 4: Ablation results over **Bios** test set (averaged over 10 runs).

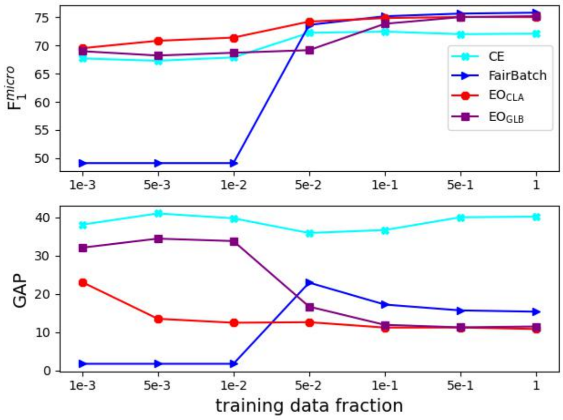

Figure 4: $\mathrm{F}_1^{\mathrm{micro}}$ vs. GAP of different models on the **Moji** test set. The full training set is 100K instances.

Figure 4 presents the results for **Moji**. When the proportion of training data is no larger than 1K, FairBatch is unable to learn a decent model, while both $\mathrm{EO}_{\mathrm{CLA}}$ and $\mathrm{EO}_{\mathrm{GLB}}$ are still effective. As we increase the number of training instances, improved performance on the main task can been observed for all models, and larger bias reduction is achieved for all models except CE. Overall, $\mathrm{EO}_{\mathrm{CLA}}$ and $\mathrm{EO}_{\mathrm{GLB}}$ perform well in low-resource settings and achieve better bias reduction for larger volumes of training instances, demonstrating their superiority.

Figure 5 presents the results for **Bios**. We see that FairBatch outperforms $\mathrm{EO}_{\mathrm{CLA}}$ and $\mathrm{EO}_{\mathrm{GLB}}$, especially in terms of $\mathrm{F}_1^{\mathrm{macro}}$ and GAP. Our explanation is that FairBatch adopts a resampling strategy, while our method adopts a reweighting strategy. Although statistically equivalent, resampling outper-

---

[5] For the max and min versions of both $\mathrm{EO}_{\mathrm{CLA}}$ and $\mathrm{EO}_{\mathrm{GLB}}$, we finetune with the corresponding best-performing λ, respectively. A smaller GAP value cannot be achieved by further adjusting/increasing the value of λ.

[6] This is in line with previous research (Swayamdipta et al., 2020), which shows that easy-to-learn instances are important in optimising models.

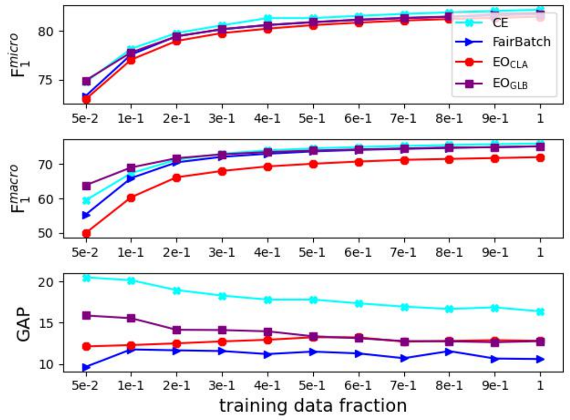

Figure 5: F_1^{micro} and F_1^{macro} vs. GAP of different models on the **Bios** test set. The full training set is 257K.

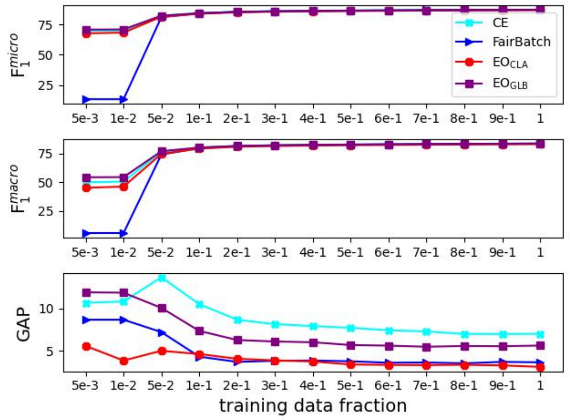

Figure 6: F_1^{micro}, F_1^{macro}, vs. GAP of different models on the subset of **Bios** data. Here, instances are from the top-8 most common classes, whose proportion is greater than 4% in the original dataset, resulting into a full training dataset size of 188K.

forms reweighting when combined with stochastic gradient algorithms (An et al., 2021). The data imbalance in **Bios** exacerbates this effect. To verify this, we generated a version of **Bios** with only instances belonging to the top-8 most common classes, whose ratio in the original training set is bigger than 4%. Figure 6 presents results with the subset of dataset consisting of the top-8 most common classes. The plots show a similar trend as observed for the **Moji** dataset on this relatively balanced dataset. Specifically, when the training dataset is small, FairBatch is unable to learn a decent model, while both EO_{CLA} and EO_{GLB} are still effective.

5.3 Limitations

Consistent with previous work, we did not finetune the underlying pretrained models in obtaining document representations in this work. Finetuning may further remove biases encoded in the pretrained models, which we leave to future work. This work focused only on datasets with binary protected attributes, and future experiments should explore the methods' generalization to higher-arity attributes. For both INLP and Adv, we follow experimental setup from the original papers, noting that the `fairlib` (Han et al., 2022) debiasing framework[7] — which was developed after this work was done — recently showed that both models can obtain better performance and fairness scores with a larger budget for hyperparameter finetuning.

6 Conclusion

We proposed to incorporate fairness criteria into model training, in explicitly optimising for equal opportunity by minimising the loss difference over different subgroups conditioned on the target label. To deal with data imbalance based on the target-label, we proposed a variant of our method which promotes fairness across all target labels. Experimental results over Twitter sentiment analysis and profession classification tasks show the effectiveness and flexibility of our proposed methods.

Ethical Considerations

Our works aims to achieve fairer models, contributing to equal treatment for different demographic subgroups. However, its usage in the real world should be carefully calibrated/auditioned as debiasing for one projected attribute does not guarantee fairness for other protected attributes. In this work, due to the limitations of the dataset, we treat gender as binary, which is not perfectly aligned with the real world.

Acknowledgements

We thank anonymous reviewers for their helpful feedback. This research was supported by The University of Melbourne's Research Computing Services and the Petascale Campus Initiative. This work was funded in part by the Australian Research Council.

A Experimental Settings

A.1 Adv Setup

For Adv, we use 3 sub-discriminators as Han et al. (2021c), where each sub-discriminator consists of two MLP layers with a hidden size of 256, followed by a classifier layer to predict the protected attribute. Sub-discriminators are optimised for at most 100 epochs after each epoch of main model training, leading to extra training time.

A.2 Hyperparameter Settings for Twitter Sentiment Analysis

For all models except for Adv, the learning rate is $3e-3$, and the batch size is 2,048. For INLP, following Ravfogel et al. (2020), we use 300 linear SVM classifiers. For Adv, the learning rate is $1e-3$, and the batch size is 2,048, the number of discriminators is 3, λ_{adv} is 0.5, and λ_{diff} is $1e-3$. For FairBatch, α is set as 0.1. For both EO_{CLA} and EO_{GLB}, λ is set as 0.5. All hyperparameters are finetuned on the **Moji** dev set.

A.3 Hyperparameter Settings for Profession Classification

For all models except for Adv, the learning rate is $3e-3$, and the batch size is 2,048. For INLP, following Ravfogel et al. (2020), we use 300 linear SVM classifiers. For Adv, the learning rate is $1e-2$, and the batch size is 1,024, the number of discriminators is 3, λ_{adv} is $1e-2$, and λ_{diff} is $1e4$. For FairBatch, α is set as $5e-2$. For EO_{CLA}, λ is set as $1e-2$, and for EO_{GLB}, λ is set as $5e-3$. All hyperparameters are finetuned on the **Bios** dev set.

B Analysis

B.1 Ablation Study hyperparameter Settings

For all models, we have tuned the hyperparameter λ and selected model based on performance on the dev set. On the **Moji** dataset, for $\text{EO}_{\text{CLA}}^{\text{max}}$, $\lambda = 2$, for $\text{EO}_{\text{CLA}}^{\text{min}}$, $\lambda = 0.4$, for $\text{EO}_{\text{GLB}}^{\text{max}}$, $\lambda = 2$, for $\text{EO}_{\text{GLB}}^{\text{min}}$, $\lambda = 0.2$. On the **Bios** dataset, for $\text{EO}_{\text{CLA}}^{\text{max}}$, $\lambda = 0.05$, for $\text{EO}_{\text{CLA}}^{\text{min}}$, $\lambda = 0.005$, for $\text{EO}_{\text{GLB}}^{\text{max}}$, $\lambda = 0.005$, for $\text{EO}_{\text{GLB}}^{\text{min}}$, $\lambda = 1e-4$.

Leaner and Faster: Two-Stage Model Compression for Lightweight Text-Image Retrieval

Siyu Ren **Kenny Q. Zhu**[*]

Abstract

Current text-image approaches (e.g., CLIP) typically adopt dual-encoder architecture using pre-trained vision-language representation. However, these models still pose non-trivial memory requirements and substantial incremental indexing time, which makes them less practical on mobile devices. In this paper, we present an effective two-stage framework to compress large pre-trained dual-encoder for lightweight text-image retrieval. The resulting model is smaller (39% of the original), faster (1.6x/2.9x for processing image/text respectively), yet performs on par with or better than the original full model on Flickr30K and MSCOCO benchmarks. We also open-source an accompanying realistic mobile image search application.

1 Introduction

Text-image retrieval is the task aiming at retrieving a list of relevant images from a large set of images given a textual query specified by the user. Recently, large-scale vision-language pre-training (VLP) has spawned models (Tan and Bansal, 2019; Li et al., 2020; Radford et al., 2021) that established state-of-the-art results in various vision-language tasks (Antol et al., 2015; Suhr et al., 2019), including text-image retrieval. Existing VLP models for text-image retrieval can be divided into two categories: cross-encoder architecture and dual-encoder architecture. Cross-encoder models show better retrieval accuracy by allowing fine-grained cross-modal attention among image and text. However, they are prohibitively slow to apply to the entire image pool because each image has to go through the deep Transformer again whenever a new text query comes in. Moreover, most cross-encoder models rely on external object detection models (Ren et al., 2015) to extract visual features, which further increase memory consumption. On the other hand, dual-encoder models are more scalable in that they allow pre-computing image representations as reusable vectors independent of the text queries. These image vectors can be indexed and efficiently retrieved at runtime using Approximate Nearest Neighbor (ANN) search (Johnson et al., 2017). As long as the image pool remains unchanged, the image encoder is not required.

However, a more practical scenario calls for dynamic indexing of new images into the pool (e.g., private photo collections on mobile devices), which requires both the image encoder and the text encoder to be resident in memory. This makes the above approach less practical on mobile devices with limited memory and processing power. Unfortunately, little attention has been paid to fulfill this need. In this paper, we show that a large dual-encoder model can be compressed into a much smaller and faster counterpart while retaining its retrieval accuracy using a novel two-stage compression framework. In the first stage, we make use of abundant non-paired texts/images to separately compress text or image encoder with an effective intra-modal contrastive knowledge distillation scheme. In the second stage, we sequentially fine-tune the distilled image or text encoder on paired text-image data with comprehensive learning objectives. Using CLIP (Radford et al., 2021) as the target model, our compressed models deliver comparable performance on MSCOCO and Flickr30K while being just 39% of the original size and 1.6x/2.9x times faster for processing image/text. Detailed ablation study shows the effectiveness of each component in the compression framework and their synergistic effects.

Our contributions are three-folds: 1) an effective compression framework tailored for lightweight text-image retrieval; 2) a leaner and faster model with competitive accuracy; 3) open-sourced models and text-to-image search mobile applications

2 Related Work

Cross-encoder. Cross-encoder architecture (Tan and Bansal, 2019; Chen et al., 2019; Li et al., 2020) adopts a single Transformer network (Vaswani et al., 2017) which is able to process inputs from different modalities, e.g., images and texts. Benefitting from the self-attention mechanism, the hidden states of images and texts interact with each other at the patch/token-level, therefore yielding state-of-the-art retrieval accuracy. Though effective, these models suffer from huge memory consumption and inference latency, making them inpractical in time-sensitive real-world scenarios.

Dual-encoder. In contrast to cross-encoder, dual-encoder architecture (Radford et al., 2021; Jia et al., 2021) trains two seperate encoders for vision and language modalities. The exact choices of encoder architecture may be different. For example, CLIP utilizes Transformers for both visual and text encoders, while ALIGN (Jia et al., 2021) uses pre-trained BERT as text encoder and EfficientNet as visual encoder. In dual encoder, interactions between different modalities take place only at the final encoder layer, resulting in slightly worse performance compared to cross-encoders. Nevertheless, this late-interaction scheme of dual-encoder allows for efficient similarity computation, thus rendering it suitable for prividing real-time searching.

3 Approach

3.1 Background on Dual-Encoder

Dual-encoder architecture employs two separate neural networks to encode inputs from different modalities and map them to a shared space.

We denote the image encoder as f_v and the text encoder as f_t in the context of text-image retrieval. To train f_v and f_t, it is common to adopt an objective that pushes the embeddings of matched text-image pairs closer while pushing those of non-matched text-image pairs apart. Specifically, **C**ontrastive **L**anguage-**I**mage **P**retraining (CLIP) (Radford et al., 2021) optimizes an InfoNCE (van den Oord et al., 2018) loss:

$$\mathcal{L}_{t2v} = -\frac{1}{N}\sum_{i=1}^{N}\log\frac{e^{f_t(x_i)^\top f_v(y_i)/\tau}}{\sum_{j=1}^{N} e^{f_t(x_i)^\top f_v(y_j)/\tau}} \quad (1)$$

Here, $f_t(x_i)$ and $f_v(y_j)$ are the L2-normalized embeddings of text in the i-th pair and image in the j-th pair. N is the mini-batch size and τ is the temperature to scale the logits. The final objective is the sum of L_{t2v} and its symmetric version L_{v2t}.

3.2 Two-Stage Model Compression

Despite good retrieval accuracy, models like CLIP still pose non-trivial memory footprint and inference time, which is undesirable for low-resource devices such as smart phones.

To tackle this issue, we propose a two-stage compression framework to make large dual-encoder model smaller and faster while retaining its accuracy. A schematic overview is illustrated in Figure

1. The first stage is *task-agnostic*, where we leverage massively available non-paired texts/images to separately compress the text/image encoder using an intra-modal contrastive knowledge distillation scheme. The second stage is *task-specific*, where we sequentially fine-tune the distilled image and text encoder using a combination of multiple techniques. We denote the image and text encoder of the large dual-encoder as f_v^T and f_t^T and those of the compressed model as f_v^S and f_t^S.

3.2.1 Stage-1

The extremely large scale of text-image pairs (e.g., 400 million used to train CLIP) makes it possible to make up for the noise in data and train over-parametrized large dual-encoder (i.e., f_v^T and f_t^T) from scratch to learn aligned visual and language representations. However, it is difficult to train small model (i.e., f_v^S and f_t^S) with lower capacity using the same *inter-modal* learning scheme.

To circumvent this issue, we propose to exploit massively available non-paired data from the web and optimize an *intra-modal* contrastive objective that aligns the output embeddings of f^S and pretrained f^T, which can be seen as a form of knowledge distillation (Hinton et al., 2015). Here we take visual modality as an example. Given a collection of images $\{y_i\}_{i=1}^N$, we feed them to both f_v^S and f_v^T to produce two sets of image embeddings $\{f_v^S(y_i)\}_{i=1}^N$ and $\{f_v^T(y_i)\}_{i=1}^N$. Then we optimize the following contrastive objective for updating f_v^S:

$$\mathcal{L}_{v2v} = -\frac{1}{N}\sum_{i=1}^{N}\log\frac{e^{f_v^S(y_i)^\top f_v^T(y_i)/\tau}}{\sum_{j=1}^{N} e^{f_v^S(y_i)^\top f_v^T(y_j)/\tau}} \tag{2}$$

The same formulation is symmetrically applied to language modality to obtain L_{t2t} for updating f_t^S:

$$\mathcal{L}_{t2t} = -\frac{1}{N}\sum_{i=1}^{N}\log\frac{e^{f_t^S(x_i)^\top f_t^T(x_i)/\tau}}{\sum_{j=1}^{N} e^{f_t^S(x_i)^\top f_t^T(x_j)/\tau}} \tag{3}$$

Essentially, f_v^S/f_t^S is trained to recover the representation power of f_v^T/f_t^T in a decoupled manner.

3.2.2 Stage-2

After training f_v^S and f_t^S using general-domain data, it is necessary to adapt the learned representations to downstream tasks using in-domain data. First, we fine-tune f_v^T and f_t^T on paired text-image data $D = \{(x_i, y_i)\}_{i=1}^N$ using standard InfoNCE loss (Section 3.1). In the experiments, we found that jointly fine-tuning image and text encoder results in retrieval performance even worse than no fine-tuning at all. Therefore, we choose to sequentially fine-tune f_v^T/f_t^T by fixing the other one. The resulting fine-tuned encoders are denoted as $f_v^{T'}$ and $f_t^{T'}$ and are henceforth kept fixed. Next, for training f_v^S and f_t^S, we propose several techniques essential to successful compression:

Knowledge Distillation (KD). In addition to the standard InfoNCE loss, we design two kinds of knowledge distillation objectives to learn from $f_v^{T'}$ and $f_t^{T'}$. One is the Kullback-Leibler divergence between image-text matching distribution predicted by $f_v^{T'}$ and $f_t^{T'}$ and the one predicted by f_v^S and f_t^S. This resembles previous response-based knowledge distillation (Hinton et al., 2015). The other is the same contrastive objective defined in Section 3.2.1. It indirectly encourages the alingment between visual and language representations.

Sequential Finetuning (SF). Similar to how we get $f_v^{T'}$ and $f_t^{T'}$, we also fine-tune f_v^S and f_t^S in a sequential manner. Concretely, we first let the compressed model share the same text encoder with the target dual-encoder and only fine-tune its image encoder. After that, we then fix the image encoder and fine-tune its text encoder in the same way.

Hard Negative Mining (HN). Prior works on contrastive representation learning (Chen et al., 2020; Gao et al., 2021) typically exploit in-batch negative samples. Though efficient, image-text pairs in a batch are randomly sampled and are likely to be trivially unrelated. Models trained in such a way may fail in cases where candidates are similar. To achieve more accurate retrieval, we mine hard negatives from the entire corpus. In our sequential fine-tuning setting, we first use $f_t^{T'}$ to compute embeddings of all texts in the corpus and index them with Faiss (Johnson et al., 2017). During training f_v^S, for each image y_i we use $f_v^S(y_i)$ as query to the index and obtain its top-k texts as negative samples. Afterward, we use the trained f_v^S to compute embeddings of all images in the corpus and build the index. During training f_t^S, for each text x_i we use $f_t^S(x_i)$ as query to the index and get its top-k images as negative samples.

The complete training objective of stage-2 is defined as $\mathcal{L} = \mathcal{L}_{t2v} + \mathcal{L}_{v2t} + \mathcal{L}_{KD} + \mathcal{L}_{HN}$.

4 Experiment

4.1 Setup

Dataset. We use Conceptual Caption (Sharma et al., 2018) for stage-1 compression. It consists of 3M noisy image alt-text pairs. However, we do not

Table 3: Comparisons of disk space and QPS.

use the image-text alignment information but only treat it as a reservoir of general-domain images and texts. In stage-2, we use MSCOCO (Lin et al., 2014) and Flickr30K (Plummer et al., 2015) as the benchmarks. For MSCOCO, there are 113,287 images for training, 5,000 images for validation, and both 5K and 1K for testing. For Flickr30K, there are 28,783 images for training, 1,000 images for validation, and 1k for testing.

Evaluation Metrics. Following previous work, we use recall R@K (K=1,5,10) as the main metric of task performance. We also report the disk space (MB) and how many image/text queries can be encoded per second (QPS_v for image and QPS_t for text) to evaluate model's memory footprints and inference speed.

Target Model. We use the open-sourced ViT-B/32 CLIP as the target dual-encoder model to compress. The image encoder f_v^T is a 12-layer Vision Transformer (Dosovitskiy et al., 2020) with 768 hidden dimension and 12 attention heads. The text encoder f_t^T is a 12-layer Transformer with 512 hidden dimention and 8 attention heads. Note that this is the largest publically available version according to OpenAI's official repository.

Compression Configuration. For image encoder f_v^S, we use a ViT-S/16 with 384 hidden dimension. We initialize it with weights pretrained on ImageNet-21K (Ridnik et al., 2021)for faster convergence and better performance. For text encoder f_t^S, we experiment with both 6-layer and 4-layer Transformer (marked as $f_t^{S_6}$ and $f_t^{S_4}$), of which the weights are initialized from corresponding layers in f_t^T. We also compare with a baseline compression method that directly fine-tunes pre-trained ViT-S/16 and 4-layer TinyBERT (Jiao et al., 2019) f_t^{TinyBERT} using InfoNCE loss throughout both stages.

Implementation Detail. In stage-1, we train 1 epoch using AdamW (Loshchilov and Hutter, 2017) with a batch size of 84 for both images and texts, learning rate of 3e-4, and weight decay of 0.1. In stage-2, we use the same optimization setting except that we train with batch size 96 for 5 epochs. We employ a cosine learning rate scheduler with 10,000 warm-up steps for both stages. All reported results are calculated on the test set using checkpoints with the highest validation performance.

4.2 Results

Main Results. Table 1 summarizes the main results. As can be observed, the pre-trained CLIP model can already deliver moderately good retrieval performance. The performance is further improved after fine-tuning. Fine-tuning pre-trained ViT-S/16 and TinyBERT underperforms the zero-shot CLIP, showing that training with *inter-modal* InfoNCE is not effective without extremely large-scale paired data. On most evaluation metrics, models compressed by our proposed two-stage pipeline perform on par with or better than the fine-tuned target model. We also found that the capacity of text encoder has limited affect on the performance.

Ablation Study. We perform extensive ablations to study the importance of each proposed technique. Due to the computational budget, we only conduct ablation on the image encoder and fix the text encoder as $f_t^{T'}$. We evaluate *w/o stage-1*, *stage-1*$_{MSE}$ (mean-square-error between f_v^S and f_v^T), and *stage-1*$_{InfoNCE}$ (identical to the loss in Section 3.1) for stage-1 ablation. We also study the effectiveness of KD/SF/HN by removing them separately or together. We made several observations based on Table 2: 1) SF makes fine-tuning stable and is essential for convergence. 2) both KD and HN improve retrieval accuracy and are complementary to each other. 3) intra-modal contrastive distillation helps when image-text pairs are noisy and outperforms inter-modal infoNCE loss.

Efficiency. In Table 3, we compare the disk space and QSP used by models on a RTX 2080Ti of 12GB memroy. The compressed image encoder f_v^S takes 85MB disk space (39% of f_v^T) meanwhile being 1.51x times faster. Our compressed text encoder can achieve up to x2.77 inference speed-up and 40% size reduction (from 243MB to 146MB). We further benchmark models' memory and runtime performance on a real iPhone X with 1,000 images in the gallery for testing. It takes 870MB and 295MB for loading CLIP and our compressed model into main memory respectively. After indexing, the response time for a single text query is 0.4s for CLIP while it is only 0.1s for our compressed model. Although the results are hardware-dependent, our compressed model still shows an evident improvement in efficiency.

5 Conclusion

In this paper, we present a two-stage framework for lightweight text-image retrieval. Experiments on two benchmarks show the effectiveness of each component in the framework and the best performance is achieved when combining them together. It holds the merit of reducing model size and accelerating inference time, making memory/response-sensitive applications more practical.

Abstract

Previous studies on the timeline summarization (TLS) task ignored the information interaction between sentences and dates, and adopted pre-defined unlearnable representations for them. They also considered date selection and event detection as two independent tasks, which makes it impossible to integrate their advantages and obtain a globally optimal summary. In this paper, we present a *joint learning-based heterogeneous graph attention network for TLS* (HeterTLS), in which date selection and event detection are combined into a unified framework to improve the extraction accuracy and remove redundant sentences simultaneously. Our heterogeneous graph involves multiple types of nodes, the representations of which are iteratively learned across the heterogeneous graph attention layer. We evaluated our model on four datasets, and found that it significantly outperformed the current state-of-the-art baselines with regard to ROUGE scores and date selection metrics.

1 Introduction

Timeline summarization (TLS) is designed to extract sentences that describe an evolutionary story from a massive amount of web articles with respect to a specific topic in chronological order. TLS has drawn much attention in recent years (Chen et al., 2019; Martschat and Markert, 2018; You et al., 2021b; Ghalandari and Ifrim, 2020; Yu et al., 2021) since it releases people from burdensome manual creation of summaries and gives readers a faster but comprehensive access to track events from many aspects, such as start and end, causality, and the main protagonists involved.

Most studies on TLS seek ways to combine two individual subtasks: date selection and event detection. Depending on different strategies for them, current methods are generally divided into three categories (Ghalandari and Ifrim, 2020): 1) *direct summarization* approaches (Chieu and Lee, 2004; Tran et al., 2013; Martschat and Markert, 2018; Duan et al., 2020) directly identify topic-related sentences from a collection of news articles to form a timeline; 2) *date-wise summarization* methods (Wang et al., 2016; Ghalandari and Ifrim, 2020; Li et al., 2021; Quatra et al., 2021) first select salient dates then construct a timeline for each date individually with sentences of the highest score; and 3) *event detection* algorithms (Steen and Markert, 2019; Duan et al., 2020; Yu et al., 2021) detect events by clustering sentences from multi-timeline news articles then identify several of the most important events and summarize them separately.

Although great successes have been achieved in conducting TLS, several issues remain unsolved. First, current TLS methods mainly adopt statistical hand-designed features to represent dates, e.g., the number of published articles and topic-related sentences in a specific time duration (Yu et al., 2021; Ghalandari and Ifrim, 2020), and employ sentence-BERT (Reimers and Gurevych, 2019) and other pre-defined unchangeable representations for sentences. The low-level or unlearnable representations tend to ignore the semantic and temporal information interaction between sentences and dates, which significantly degrades the performance of downstream tasks. Secondly, traditional approaches focus on either date selection or event detection. Although excellent date selection algorithms can pinpoint accurate timeline dates, they usually extract topic-irrelevant sentences. While event detection algorithms are capable of avoiding redundant summaries by various clustering strategies, they sometimes capture wrong timeline dates. To the best of our knowledge, there is no framework that jointly learns the advantages of the above two subtasks to accurately capture salient dates and eliminate topic-irrelevant sentences in a timeline.

To circumvent the above dilemma, we propose to jointly learn date/sentence representations and event detection-based sentence clustering in a het-

erogeneous graph attention network (HAN) for TLS. Specifically, we construct a heterogeneous graph with dates, words, and sentences as semantic units to solve the first problem. In this graph, words act as a bridge between dates and sentences, enabling date nodes to learn different granularities (word- and sentence-level) of semantic information and sentence representations to be complemented with a date-related intra- and cross-sentence message. As for the second issue, semi-supervised date prediction and event detection-based clustering are integrated into an overall objective, where labeled dates guide and facilitate sentence clustering, and sentence-level clustering information indicating main events improves the accuracy of unlabeled date prediction. Note that we create a new way beyond the above-mentioned three categories as a *joint end-to-end* approach since we no longer have to handle each subtask step by step.

We highlight our contributions as follows:

- This study is the first to construct a model for automatic TLS as a HAN that propagates heterogeneous information with different granularities, of *date-word-sentence*, to effectively learn flexible and accurate representations for both date and sentence nodes.
- Date selection and event detection subtasks are incorporated into an overall objective so that they can be jointly optimized to obtain a globally optimal solution.
- We have empirically shown that HeterTLS outperformed all existing competitors on four benchmark datasets. Its effectiveness and robustness were further confirmed via ablation studies and parameter analysis.

2 Related Work

2.1 Timeline summarization

Unlike multi-document summarization (MDS), TLS executes both date selection and summary extraction (Zhou et al., 2021). In accordance with different strategies for defining the two subtasks, available approaches are categorized into three classes, whose major methods are reviewed as follows.

Direct summarization approaches (Allan et al., 2001; Yan et al., 2011a; Li and Li, 2013; Zhao et al., 2013; Suzuki and Kobayashi, 2014) treat the task as MDS with time-stamped textual summaries. Chieu and Lee (2004) directly rank and extract sentences relevant to a query from a collection of documents and place them along a timeline. As the current state-of-the-art method for direct summarization, revised submodular-function optimization, which is commonly used for MDS, is applied to search for a combination of sentences from an entire document collection (Martschat and Markert, 2018).

Date-wise summarization methods (Li et al., 2021) first select dates then extract sentences corresponding to the dates. Tran et al. (2013, 2015b) propose a supervised graphical model for selecting salient dates and tracking events on each date. In another study, text and image embeddings are jointly learned using a scalable low-rank approximation approach to generate a more readable timeline summary (Wang et al., 2016).

Event detection algorithms (Tran et al., 2015c; Pasquali et al., 2019; Duan et al., 2020) usually cluster documents by affinity propagation to detect events and summarize them individually along a timeline (Steen and Markert, 2019) or implement multi-timeline summarization (Yu et al., 2021).

2.2 Heterogeneous graph for summarization

A heterogeneous graph contains different types of nodes and multiple relationships between nodes (Xu et al., 2021; Hu et al., 2021). Wang et al. (2020) present a HAN for single or multiple document extractive summarization to enrich cross-sentence relations through additional semantic units. Jia et al. (2020) leverage a sentence-level redundancy layer into a HAN to remove excessive phrases. Although much research has gone into constructing source documents as heterogeneous graphs and using graph attention network-based first-order neighbors during information dissemination, longer-distance heterogeneous paths have not been considered. Inspired by Wang et al. (2019), we extended a HAN to TLS and developed HeterTLS to learn better node representations for downstream tasks.

3 Methodology

3.1 Problem definition and preliminaries

Given a collection of news documents $\mathcal{D}$ within $\mathcal{T}$ dates, TLS involves 1) predicting a sequence of date labels $\{y_1, \cdots, y_{\mathcal{T}} | y_i \in \{0, 1\}\}$, where $y_t = 1$ represents the t-th date included in the timeline; and 2) ranking and extracting sentences from candidates for each selected date. The number of dates as well as the length of the daily summaries are typically controlled by the user.

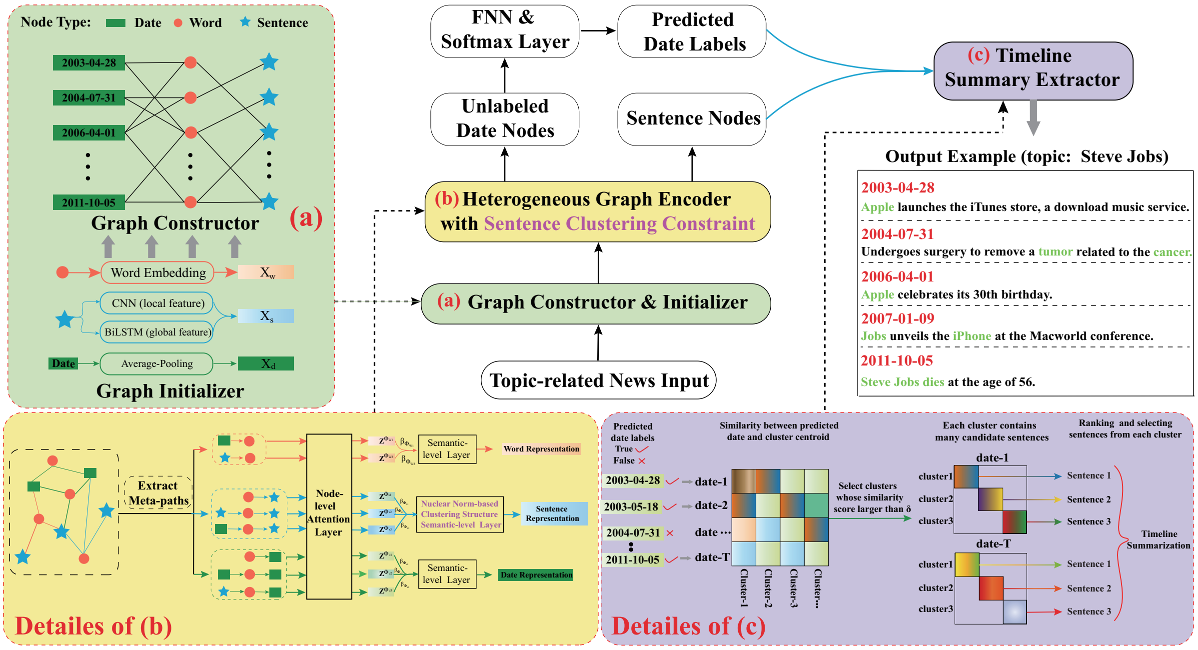

Figure 1: Model overview. HeterTLS consists of three chief components: (a) graph constructor and initializer, (b) heterogeneous graph encoder with sentence clustering constraint, and (c) timeline summary extractor. We first construct heterogeneous network for date, sentence, and word nodes with two initialization strategies. We then extract meta-paths and iteratively update node representations via HAN under nuclear norm constraint on sentence nodes. Finally, we predict unlabeled date nodes and extract sentences from candidate clusters.

Given a graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$ with $\mathcal{V} = V_d \cup V_w \cup V_s$ and $\mathcal{E} = E_{w-d} \cup E_{w-s}$, where V_d, V_w, and V_s respectively denote a node set for dates, words, and sentences and E_{w-d} and E_{w-s} are a set of undirected edges between word-date and word-sentence. Specifically, $V_d = \{d_1, \cdots, d_{\mathcal{T}}\}$, $V_w = \{w_1, \cdots, w_m\}$, and $V_s = \{s_1, \cdots, s_n\}$ correspond to $\mathcal{T}$ dates, m unique words, and n sentences within $\mathcal{D}$. $e_{ij} \neq 0$ $(i \in \{1, \cdots, m\}, j \in \{1, \cdots, n\})$ of E_{w-s} indicates that the i-th word appears in the j-th sentence. $e_{ij} \neq 0$ $(i \in \{1, \cdots, m\}, j \in \{1, \cdots, \mathcal{T}\})$ of E_{w-d} signifies the i-th word appears in the articles published on the j-th date. No edge exists between nodes of the same type, e.g., word pairs. We then define a meta-path and meta-path-based neighbors for disseminating information among heterogeneous nodes.

Definition 1 Meta-path Φ is defined as a path in the form of $v_1 \xrightarrow{e_1} \cdots \xrightarrow{e_q} v_{q+1}$, which describes a composite edge relation $e = e_1 \circ \cdots \circ e_q$ between nodes v_1 and v_{q+1}, where $\circ$ denotes the composition of relations.

Definition 2 Meta-path-based neighbors $\mathcal{N}_i^{\Phi}$ of the i-th node are defined as all nodes in a single meta-path Φ.

Figure 1 exhibits an overview of HeterTLS, which consists of three main components: (a) *graph constructor and initializer*, (b) *heterogeneous graph encoder with sentence clustering constraint*, and (c) *timeline summary extractor*. Each component is introduced subsequently in detail in the following subsections.

3.2 Graph constructor and initializer

Let $\mathbf{X}_d \in \mathbb{R}^{\mathcal{T} \times r_d}$, $\mathbf{X}_w \in \mathbb{R}^{m \times r_w}$, and $\mathbf{X}_s \in \mathbb{R}^{n \times r_s}$ respectively denote input feature matrices for date, word, and sentence nodes, where r_d, r_w, and r_s are dimensions of date representations, word embeddings, and sentence representations. We initialize the j-th sentence node in Figure 1 (a) by concatenating its local n-gram feature p_j and sentence-level global feature q_j as $X_{s_j} = [p_j; q_j]$. p_j is captured by a convolutional neural network (CNN) (LeCun et al., 1998) with different kernel sizes, and q_j is gripped by a bidirectional long short-term memory (Bi-LSTM) (Hochreiter and Schmidhuber, 1997). Considering the success of transformer-based pretrained models, we also provide another initialization strategy: using BERT (Devlin et al., 2019) and sentence-BERT (Reimers and Gurevych, 2019) as word and sentence encoders. Date nodes take the average-pooling of their connected sentences as initialization for both aforementioned strategies.

To leverage the saliency of each word in different sentences or dates, we propose term frequency-inverse sentence frequency (TF-ISF) and term frequency-inverse date frequency (TF-IDATEF) weights to initialize edges in E_{w-s} and E_{d-w}. Specifically, TF is the number of occurrences of w_i in s_j or d_t, and ISF/IDATEF is determined by dividing the total number of sentences or dates in $\mathcal{D}$ by the number of sentences or dates containing w_i (refer to Appendix D for more details).

3.3 Heterogeneous graph encoder with sentence clustering constraint

As Figure 1 (b) illustrates, we first iteratively update node representations via meta-paths in heterogeneous graph attention layers. We then introduce how we constrain sentence representations to reserve a low-rank-based clustering structure, which helps sentence nodes learn better event-related information. Finally, the semi-supervised date classification and sentence clustering structure are jointly learned in an overall objective.

3.3.1 Heterogeneous graph attention layer

Node representations are updated by hierarchical heterogeneous graph attention layers, where the node-level attention layer ensures information propagation and aggregation in a single meta-path, while the semantic-level one is committed to merging messages from multiple meta-paths. Specifically, referring to $\mathbf{h}_i$ as the hidden state of the i-th node, the node-level attention layer is calculated as

$$e_{ij}^{\Phi_p} = LeakyReLU(\mathbf{W}_a[\mathbf{W}_{\phi_i}\mathbf{h}_i; \mathbf{W}_{\phi_j}\mathbf{h}_j]), \quad (1)$$

$$\alpha_{ij}^{\Phi_p} = \frac{exp(e_{ij}^{\Phi_p})}{\sum_{l \in \mathcal{N}_i^{\Phi_p}} exp(e_{il}^{\Phi_p})}, \quad (2)$$

$$\mathbf{z}_i^{\Phi_p} = \Big\|_{k=1}^{K} \sigma\Big(\sum_{j \in \mathcal{N}_i^{\Phi_p}} \alpha_{ij}^{\Phi_p}\mathbf{W}_{\phi_j}\mathbf{h}_j\Big), \quad (3)$$

where $\mathbf{W}_a$, $\mathbf{W}_{\phi_i}$, and $\mathbf{W}_{\phi_j}$ are trainable parameters, $\mathbf{z}_i^{\Phi}$ is the representation of the i-th node learned from the node-level attention layer by Φ, α_{ij}^{Φ} measures the importance of the j-th node to the i-th node via Φ, $\mathcal{N}_i^{\Phi}$ contains all nodes in single meta-path Φ, and K is the number of multi-heads.

Afterwards, the semantic-level attention layer fuses all the meta-path information for the i-th node. We extract meta-paths $\hat{\Phi}_{d_{1\sim3}}$={date-word, date-word-date, date-word-sent} for date nodes, $\hat{\Phi}_{w_{1\sim2}}$={word-sent, word-date} for word nodes, and $\hat{\Phi}_{s_{1\sim3}}$={sent-word, sent-word-sent, sent-word-date} for sentence nodes (Figure 1 (b)), while long-distance meta-paths are discarded due to their limited impact. With the assumption that the i-th node has P meta-paths as $\{\Phi_1, \cdots, \Phi_P\}$, the representation of the i-th node is updated as

$$w_{\Phi_p} = \frac{1}{|\mathcal{V}|}\sum_{i \in \mathcal{V}} \mathbf{q}^T tanh(\mathbf{W}\mathbf{z}_i^{\Phi_p} + \mathbf{b}), \quad (4)$$

$$\beta_{\Phi_p} = \frac{exp(w_{\Phi_p})}{\sum_{l=1}^{P} exp(w_{\Phi_l})}, \quad (5)$$

$$\mathbf{z}_i = \sum_{p=1}^{P} \beta_{\Phi_p}\mathbf{z}_i^{\Phi_p}, \quad (6)$$

where $\mathbf{q}$, $\mathbf{W}$, and $\mathbf{b}$ are learnable parameters and β_{Φ_p} represents the importance of the p-th meta-path for the final embedding of the i-th node.

In the same manner described by Wang et al. (2020), to avoid gradient vanishing after certain iterations, a residual connection and position-wise feed-forward network (FFN) layer with two linear transformations (Vaswani et al., 2017) are added after the semantic-level attention layer.

Iterative update: We alternately update each type of node to realize information propagation and aggregation. The updating process for the t-th iteration is measured as

$$Z_{w_{1\sim2}}^{t+1} = NLevel(H_d^t, H_s^t, H_w^t), \quad (7)$$

$$H_w^{t+1} = FFN(SLevel(Z_{w_{1\sim2}}^{t+1}) + H_w^t), \quad (8)$$

$$Z_{d_{1\sim3}}^{t+1} = NLevel(H_d^t, H_s^t, H_w^{t+1}), \quad (9)$$

$$H_d^{t+1} = FFN(SLevel(Z_{d_{1\sim3}}^{t+1}) + H_d^t), \quad (10)$$

$$Z_{s_{1\sim3}}^{t+1} = NLevel(H_d^{t+1}, H_s^t, H_w^{t+1}), \quad (11)$$

$$H_s^{t+1} = FFN(SLevel(Z_{s_{1\sim3}}^{t+1}) + H_s^t), \quad (12)$$

where $NLevel$ and $SLevel$ respectively indicate node-level and semantic-level attention layers, and H^t is the stacked hidden state of a certain type of node at the t-th timestep. Eqs. 8, 10, and 12 represent the residual connection and FFN layer.

3.3.2 Sentence clustering constraint

Detecting main events from $\mathcal{D}$ can effectively reduce the redundancy when generating summaries. Current TLS methods (Yu et al., 2021) identify major events by applying K-means directly to sentence representation matrix H_s, which has two limitations. First, K-means is sensitive to initialization and outliers, resulting in unstable outputs (Ding and Li, 2007). Furthermore, the clustering performance is undesirable due to the independence of sentence representation learning and sentence clustering. Even though structure learning has the potential to address the above issues by co-clustering on a newly created bipartite graph to extract the clustering structure (You et al., 2021a; Nie et al., 2017), it is not suitable for our framework to make H_s a block-diagonal matrix with k components. Theorem 1 paves the way to detect the clustering structure of H_s by adding a low-rank constraint.

Theorem 1 (Chung and Graham, 1997) The multiplicity of eigenvalue 0 of the normalized Laplacian matrix of H_s is equal to the number of clusters in H_s.

Theorem 1 indicates that the block-diagonal clustering structure relies on newly constructing an adjacency network of sentence nodes, which increases the complexity of the model. Haeffele and Vidal (2020); Piao et al. (2019) propose the nuclear norm and prove that the constraint on the Laplace matrix of H_s is mathematically equal to the constraint on sentence representation matrix H_s as

$$\mathcal{L}_{cluster} = \|H_s\|_*, \tag{13}$$

where $\|H_s\|_*$ is defined as the sum of the k smallest eigenvalues, i.e., $\sum_{i=n-k}^{n} \lambda_i$ with λ_i as the i-th smallest eigenvalue (Piao et al., 2019). When $\|H_s\|_*$ is set to 0, we obtain k clusters in H_s by reorganizing its columns or rows and converting it into a block-diagonal form with k blocks, as shown in Figure 1 (c). We also determine parameter k by the elbow method (Bholowalia and Kumar, 2014).

3.3.3 Joint learning framework

Past work considered date selection and sentence clustering-based event detection as independent tasks. In HeterTLS, they are jointly trained to combine their advantages into an overall objective:

$$\mathcal{L} = \mathcal{L}_{classify} + \lambda \mathcal{L}_{cluster}, \tag{14}$$

where $\mathcal{L}_{classify}$ minimizes the cross-entropy over all labeled date nodes between the ground-truth during training, and λ serves as a weighted coefficient to balance $\mathcal{L}_{classify}$ with $\mathcal{L}_{cluster}$. Eq. 14 can be optimized via stochastic gradient descent (SGD) (Zinkevich et al., 2010) in an end-to-end manner. Readers can also refer to (Piao et al., 2019; Liu and Vandenberghe, 2009) for the detailed nuclear norm optimization strategy of $\mathcal{L}_{cluster}$.

Our date classification is trained in a transductive learning-based semi-supervised manner. We iterate all node representations in the heterogeneous graph simultaneously with 50% labeled date nodes (40% for training and 10% for verification) and 50% unlabeled date nodes as the test set. The joint learning model is able to effectively find event-based candidate clusters (see Figure 1 (c)), thereby save much running time and improve the accuracy of TLS.

Table 1: Basic dataset statistics. Avg.X demonstrates average X for each topic, and Timelines refers to number of ground-truths in each dataset.

3.4 Timeline summary extractor

With l selected dates and their corresponding representations $\{\mathbf{h}_{d_1}, \cdots, \mathbf{h}_{d_l}\}$, we represent the k clusters as $\{\mathbf{h}_{c_1}, \cdots, \mathbf{h}_{c_k}\}$ by averaging sentence representations inside that cluster. As shown in Figure 1 (c), candidate clusters for the t-th selected date are determined by calculating the cosine similarity between the date representation with all cluster representations as $cos(\mathbf{h}_{d_t}, \mathbf{h}_{c_j})(j \in \{1, \cdots, k\})$. If the cosine similarity is larger than the pre-defined threshold δ (see Section 5.4), the corresponding cluster is considered a candidate for the date. Finally, we apply CENTROID-OPT (Ghalandari, 2017) as a sentence ranking algorithm within a cluster and summarize each date individually by selecting one sentence per cluster with the highest ranking score.

4 Experiments

4.1 Datasets

We carried out our experiments on the four most widely used benchmark datasets, i.e., 17 Timelines (T17) (Tran et al., 2013), Crisis (Tran et al., 2015a), Entities (Ghalandari and Ifrim, 2020), and CovidTLS (Quatra et al., 2021). All contain human-written timelines concerning certain topics, the source news articles of which are retrieved from the web at a given point in time.

Using these datasets makes it possible to comprehensively verify the effectiveness and generalization of HeterTLS because both the number of

Table 2: Concatenation- and alignment-based ROUGE-1/2 F1-scores for T17, Crisis, and Entities datasets. Best results among model-generated timelines are marked in bold. Symbol † indicates that our results significantly surpass all baselines using bootstrap test (Dror et al., 2018) with $p < 0.005$.

topics and their time spans are completely different. Specifically, the Entities dataset contains dozens of topics and spans decades per topic, while the others involve only a few topics within two years. The basic statistics are summarized in Table 1.

4.2 Evaluation metrics

In our experiments, the evaluation of model-generated timelines depended on the ROUGE metric and its variants as follows (Yu et al., 2021):

Concatenation-based ROUGE F1 Similar to conventional ROUGE, it compares a concatenated system summary with its corresponding ground-truth by referring only to the textual overlap while ignoring all time stamps of the timeline (Yan et al., 2011b; Nguyen et al., 2014; Wang et al., 2016).

Alignment-based ROUGE F1 On the basis of the above concatenation metric, it linearly penalizes the ROUGE score by the distance of date alignments (Martschat and Markert, 2017).

Date selection F1 It only measures how well the model selects dates contained in the ground-truth (Martschat and Markert, 2018).

4.3 Experimental settings

Since each topic has at least one ground-truth timeline, we considered each timeline independently if multiple ground-truths exist, and the final evaluation results were obtained by averaging scores over all timelines. We split training/verification/test sets in accordance with the ratio of 40%/10%/50% mentioned to Sec. 5.5. All experiments for a dataset were subject to leave-one-out cross-validation, and significant differences were determined by bootstrap test (Dror et al., 2018) with p-value of 0.005.

For our heterogeneous network, the vocabulary size was limited to $50,000$ and tokens were initialized with 400-dimensional GloVe embeddings (Pennington et al., 2014). We truncated an input document to a maximum length of 40 sentences and removed 10% of vocabulary with the lowest TF-IDATEF values to eliminate noise. Date/sentence nodes and edge features individually included $r_d = r_s = 128$ and 40-dimensional vectors for initialization. We set the learning rate and regularization hyper parameter λ to $5e-4$ and 1.5, respectively. Each HAN layer had 8 heads and 64-dimensional hidden size. The inner hidden size of the FFN layer was set to 512. An early stop was carried out when the validation loss did not descend for three continuous epochs. We trained all baselines as well as HeterTLS on a single Titan RTX GPU.

4.4 Baselines

The following excellent baselines were used for comparison and to demonstrate the effectiveness of HeterTLS: *direct summarization* including CHIEU (Chieu and Lee, 2004) and MARTSCHAT (Martschat and Markert, 2018); *date-wise summarization* such as TRAN (Tran et al., 2013), DATEWISE (Ghalandari and Ifrim, 2020), and SDF (Quatra et al., 2021); and *event detection* method DASG (Liu et al., 2021). We additionally follow Ghalandari and Ifrim (2020) to obtain full oracle.

5 Results and Discussion

5.1 Performance of HeterTLS

According to Tables 2 and 3, HeterTLS outperformed all baselines in terms of all metrics. Con-

Table 3: Date F1-scores on T17, Crisis, and Entities datasets. Bold-faced characters and † indicate best results and significant improvements over all baselines.

sidering that DASG ignores date information, we excluded it from the Date F1 experiment. We noticed that HeterTLS with pre-trained initial node representations surpassed HeterTLS only on Crisis and CovidTLS (refer to Appendix A) datasets. This indicates that pre-trained models require larger downstream datasets (Crisis or CovidTLS datasets) to escape from the local optimum, while CNN- and Bi-LSTM-based initialization can better capture the characteristics of small-scale datasets and reach the globally optimal solution in a few epochs.

We consider three possible reasons for the excellent performance of HeterTLS. First, the HAN is configured to learn multi-level semantic features for date representations. Compared with hand-designed statistical low-level features, these features are much more distinguishable, so they improve the accuracy of date selection. Second, regarding the improvement of ROUGE scores, the introduction of low-rank-based regularization helps sentence representations learn a diagonal clustering structure, which enables HeterTLS to effectively capture the topic-related events and informative sentences. Third, date selection and sentence clustering-based event detection are jointly learned and optimized to obtain a globally optimal solution.

5.2 Ablation study

We investigated the contribution of each module to HeterTLS via ablation studies using each dataset.

HeterTLS-HAN To verify the interaction within heterogeneous connections, we show the ablation performance in Table 2 by removing the HAN and simply using unlearnable semantic features with nuclear norm constraint. We suspect that the HAN layer plays a critical role in facilitating date selection with semantic messages and providing sentence nodes with temporal clustering information, which cannot be replaced with fixed features. Meta-paths also provide abundant iterative patterns to pass semantic and temporal information.

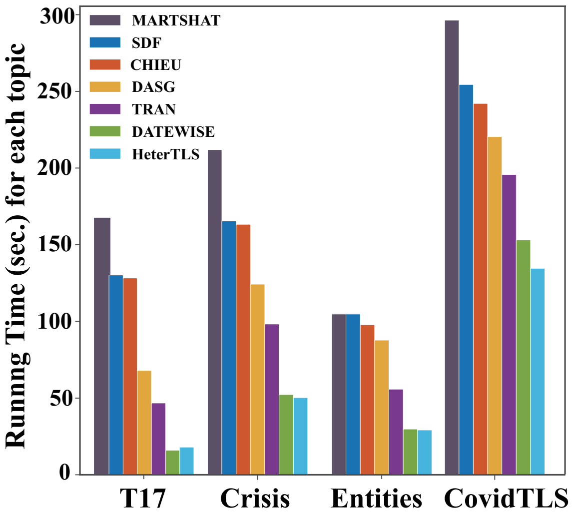

Figure 2: Comparison of running time of current state-of-the-art models and HeterTLS

However, sentence nodes initialized by CNN and Bi-LSTM layers help capture local and global sentence relationships, which has been proved predominant with regard to the extractive summarization task (Wang et al., 2020). Furthermore, the nuclear norm constraint can effectively reduce the redundancy between selected summary sentences. The above two components ensure the promising performance of the ablation model.

HeterTLS-joint learning Based on the assumption that the remarkable improvement of HeterTLS compared with baselines is due to jointly training node representations and clustering regularization, we show the performance in a separate learning pattern. Date representations are first learned using a HAN to predict which date should be selected to form a timeline. We then cluster sentence nodes in the graph to produce center cluster representations.

From the last block in Tables 2 and 3, implementing the subtasks individually degrades the performance to a great extent. We consider that in the joint learning framework of HeterTLS, vertices learn more discriminative features under the guidance and constraint of sentence clustering and in turn improve clustering accuracy, which cannot be imitated by separate learning. This result further indicates the superiority of HeterTLS, implying that

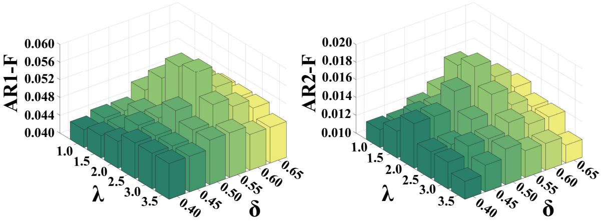

Figure 3: Impact of parameters on Entities dataset

the combination of node representations and clustering structure is promising for identifying salient dates and sentence candidates simultaneously.

5.3 Running time

We conducted an investigation of running time with all models being trained with the same device and show the results in Figure 2. HeterTLS ran up to an order of magnitude faster than most baselines, while it achieved comparable running efficiency to the current fastest baseline DATEWISE (2020).

The following two reasons may explain the efficiency of HeterTLS. 1) Accurate node initialization enables the model to converge to a globally optimal solution in less than eight epochs. Since transductive semi-supervised learning requires fewer labeled date nodes, it can simplify the scale of the training model and reduce the training time caused by parameter updates. 2) Previous methods rank all candidates by measuring informativeness, redundancy, coherence, and diversity (Yan et al., 2011b). In contrast, our strategy reduces the time complexity by measuring the similarity between date and cluster representations to select candidate clusters that exceed a pre-defined threshold. It can thus extract the most informative sentence in each candidate cluster as a summary without consuming time on the multi-index optimization problem.

5.4 Impact of parameters

There are two essential hyper parameters in our experiments: λ is adopted to balance the importance between $\mathcal{L}_{classify}$ and $\mathcal{L}_{cluster}$ in Eq. 14, and δ acts as a threshold to decide the most related clusters for selected dates (Figure 1(c)). Several sets of λ and δ were tested in terms of AR1-F and AR2-F. We can clearly see the best performance from Figure 3 when $\lambda \in [2.0, 2.5]$ and $\delta = 0.55$ on Entities dataset. It is explicit that a larger δ works better. A plausible reason is that a relatively high threshold can effectively filter irrelevant clusters and reduce the redundancy of generated timelines. However, the gradual changes in histograms indicate that our method rarely fails to converge as parameters vary because it is robust and insensitive to parameters. The parameter impact on other datasets is discussed in Appendix B due to limited space.

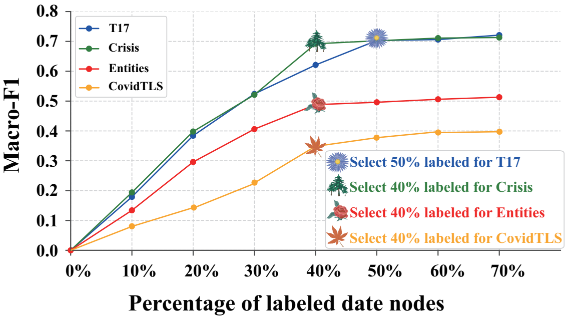

Figure 4: Ratio of labeled date nodes on training set vs. corresponding accuracy on test set

5.5 Ratio of labeled dates

Figure 4 shows that our model achieved promising Macro-F1 scores for date classification on test sets when the ratio of labeled dates was set to 40 or 50% in the training phase. Therefore, we reasonably believe that our HAN-based transductive learning earns high-quality date classification even with small-scale labeled data, so it can be effectively applied to real TLS tasks. Specifically, HeterTLS learns high-order semantic features implied in a small amount of labeled dates, which can help predict critical time stamps that should be preserved.

5.6 Consecutive dates and redundancy

The proportions of consecutive dates in chronologically ordered model-generated timelines and ground-truth timelines were experimentally measured according to Ghalandari and Ifrim (2020). News articles and sentences published on adjacent dates tend to refer to the same story, especially in a long-time-span dataset such as Entities.

	T17	Crisis	Entities	CovidTLS
Ground-truth	0.45	0.18	0.03	0.48
MARTSCHAT	0.63	-	0.18	0.68
DATEWISE	0.62	0.52	0.30	0.66
HeterTLS	0.48	0.23	0.10	0.56

Table 4: Proportions of consecutive dates of timelines produced with different methods and ground-truths

Combining with Table 1, Table 4 reveals that because the time duration of Entities dataset is the longest, up to 12 years, the proportion of adjacent dates is the lowest among all datasets. Therefore, we reasonably believe that the trend of adjacent

Figure 5: Partial timelines on topic of *Steve Jobs* from Entities dataset produced with ground-truth and HeterTLS

date proportion is the same as that of redundancy. The results in Table 4 indicate that HeterTLS is the closest to the ground-truth, thereby proving its ability to predict salient dates.

5.7 Case study

We now show the quality of timelines generated by HeterTLS through a cases study. The topic *Steve Jobs* is taken from Entities dataset with the time duration from 2003-04-28 to 2011-08-24. In Figure 5, parts of the ground-truth timeline of certain dates are shown on the left, while the right side lists the HeterTLS-generated timeline with similar period coverage as the ground-truth. We manually colored some keywords to illustrate consistent contents in both timeline summaries. The examples demonstrate different levels of detail in describing particular events. Three advantages of HeterTLS are explicit by comparing it with the ground-truth:

- The semi-supervised date prediction component of HeterTLS can accurately position salient dates as the ground-truth, which is the very principle for extracting TLS sentences.
- Our model can capture the major object of each event or topic well (marked in orange) in a daily summary. For example, the subject of the ground-truth on 2003-04-28 is *Apple launches*, and HeterTLS also generates the same phrase as the subject. On 2009-06-29, *Steve Dowling announces* and *Steve Dowling said* serve as subjects in the ground-truth and model-generated summary, respectively.
- Although HeterTLS generates timelines in an extractive manner, the generated summaries are short and accurate. Current extractive methods always adopt greedy or beam search to extract an uncertain number of sentences as timelines, which greatly increases redundancy. We use clustering-based constraints and intra-class extraction to ensure that HeterTLS generates short but accurate sentences.

6 Conclusion

We addressed several fundamental problems concerning TLS and proposed a joint learning model called HeterTLS, which trains a HAN by utilizing clustering structure learning-based event detection. The proposed model facilitates node representations with information of different semantic units. Meanwhile, the sentence representations with clustering structure are rich in date- and semantic-level features, which significantly reduce redundancy and improve clustering accuracy. Experimental results, including those of the ablation studies of each part of the overall architecture, demonstrated the effectiveness of HeterTLS.

Table 5: Concatenation- and alignment-based ROUGE-1/2 F1-score for CovidTLS dataset. Best results among model-generated timelines are marked in bold. Symbol † indicates that our results significantly surpass all baselines using bootstrap test (Dror et al., 2018) with $p < 0.005$.

The newly released CovidTLS dataset [1] describes the outbreak and evolution of the Covid-19 pandemic since the beginning of 2020. Because it is undoubtedly one of the most important worldwide events and affects all aspects of people's lives and work, it has been reported by an unprecedented amount and variety of news articles. The whole corpus was crawled from well-known English journals, while it is annotated with a ground-truth timeline retrieved from a public, authoritative website.

Table 5 shows the excellent performance of HeterTLS on this new dataset. Since CovidTLS is a large-scale dataset containing 26,376 documents and 791,280 sentences per topic, the pre-trained node representations can escape from the local optimal solution through massive iteration processes and converge to its globally optimal solution. We are convinced that the lightweight HeterTLS is more effective for small-scale datasets while HeterTLS initialized using pre-trained language models attains better results on large-scale datasets.

B Impact of parameters on T17, Crisis, and CovidTLS Datasets

We selected several sets of λ and δ to test the performance of HeterTLS and give a general overview in Figure 6 as in Sec. 5.4. HeterTLS performed the best when $\lambda = 1.5$ and $\delta = 0.6$ on T17 dataset, while $\lambda \in [2.0, 2.5]$ and $\delta \in [0.5, 0.55]$ on Crisis and CovidTLS datasets. Even though a larger δ coupled with a smaller λ works better, HeterTLS seldom failed to converge as the parameters changed. Therefore, we reasonably believe that our proposed model is not sensitive to parameters.

C Attach date labels for sentences

Since it is a difficult problem to correctly extract the chronological order of events from time stamped-free texts, we therefore attempt to only attach dates to the sentences extracted from news articles. We assume that the first date expression detected in a sentence s is the date of the event mentioned in s. We further craft simple rules to detect date expressions in sentences and resolve them to absolute dates using the date of the article as a reference. For example, with "today" parsed as the publication date of the article, "September" and "Sunday" indicate the last September and Sunday before the article date. In the case that no date expression is detected in the entire sentences s, $date(s)$ is taken to be the publication date of the article containing s. Although this assumption is frequently incorrect in document types such as biographies, literary writings, or historical texts, we find it is reasonable for news articles. News, by definition, reports up-to-date events.

D Edge Initialization

We give a more detailed description of the edge initialization in the main body. To leverage the saliency of each word in different sentences and dates, we propose using term frequency-inverse sentence frequency (TF-ISF) and term frequency-inverse date frequency (TF-IDATEF) weights to initialize edges in E_{w-s} and E_{d-w}.

$$TF_{i,j} = \frac{n_{i,j}}{\sum_k n_{k,j}}, \tag{15}$$

$$ISF_i = \log \frac{|S|}{|\{j : w_i \in s_j\}|}, \tag{16}$$

$$I\textsc{Date}F_i = \log \frac{|D|}{|\{j : w_i \in d_j\}|}, \tag{17}$$

where $n_{i,j}$ indicates the number of occurrences of word w_i in sentence s_j (for edges in E_{w-s}) or date d_j (for edges in E_{d-w}), and the denominator of Eq. 15 is the sum of the number of occurrences of all words in s_j or d_j. In Eqs. 16 and 17, $|S|$ and $|D|$ respectively denote the total number of sentences

and dates in the corpus, and $|\{j : w_i \in s_j\}|$ and $|\{j : w_i \in d_j\}|$ are the numbers of sentences or dates where term w_i appears.

Intuitively, some words, e.g., articles such as *"the"* and *"a"*, appear in many sentences and dates, while other words, e.g., *"Harry Potter"*, are not so frequent. Therefore, words with lower ISF/IDateF values are not so important and usually have no specific meaning. Conversely, words with higher ISF/IDateF values might be important and indicate salient information or the topic of the article. This assumption allows HeterTls to distinguish key points from non-key points.

Early Rumor Detection Using Neural Hawkes Process with a New Benchmark Dataset

Abstract

Little attention has been paid on EArly Rumor Detection (EARD), and EARD performance was evaluated inappropriately on a few datasets where the actual early-stage information is largely missing. To reverse such situation, we construct BEARD, a new Benchmark dataset for EARD, based on claims from fact-checking websites by trying to gather as many early relevant posts as possible. We also propose HEARD, a novel model based on neural Hawkes process for EARD, which can guide a generic rumor detection model to make timely, accurate and stable predictions. Experiments show that HEARD achieves effective EARD performance on two commonly used general rumor detection datasets and our BEARD dataset.

1 Introduction

The proliferation of online rumors has aroused widespread concerns. Many studies have been conducted for automatic rumor detection in social media and achieved high detection accuracy (Ma et al., 2016, 2017; Yu et al., 2017; Ruchansky et al., 2017; Ma et al., 2018; Guo et al., 2018; Bian et al., 2020). However, these generic detection methods lack in-depth modeling of temporality, which can cause tremendous delay in detection given the instantaneous and sporadic nature of rumor propagation.

While a few EArly Rumor Detection (EARD) models have been proposed (Liu and Wu, 2018; Zhou et al., 2019; Song et al., 2019; Xia et al., 2020), they have been designed with oversimplification and evaluated inappropriately using the datasets constructed for generic rumor detection. Widely used rumor detection datasets, such as TWITTER (Ma et al., 2016) and PHEME (Zubiaga et al., 2016), are generally limited in covering relevant posts in the early stage as there was no mechanism ensuring to gather information that is further away from the official debunking time of a rumor. For this reason, the generalizability of EARD cannot be effectively trained nor be genuinely reflected using a general rumor detection dataset. As an example, we showcase two rumors from TWITTER and PHEME datasets in Table 1. We manually trace Twitter conversations about each claim and recollect as many early posts relevant to it as we could. It is observed that the original posts in both datasets are clearly delayed as compared to our recollected posts. Also, the rumor indicative patterns in the recollected posts unfold differently, where dissenting voices, a common indicator of rumor, appear much earlier and may last for many hours or even years, evolving from vaguely opposing the claim (e.g., ‘like bubbles’, ‘someone’) to firmly refuting it with evidence (e.g., ‘Photoshop contest’). The original “early” posts in PHEME clearly fail to cover such useful patterns reflecting the early dynamics, and the posts in TWITTER do not cover any early indicative signals before the rumor was officially debunked by Snopes. Given the unavailability of EARD-specific dataset, it is necessary to construct a Benchmark dataset for EARD (BEARD) consid-

ering the earliness of relevant posts to gather.

Meanwhile, EARD methods have not been well studied either in the literature. Prior works claimed as being able to do early detection can be divided into two categories, both of which are sub-optimal: 1) Methods that are unable to automatically determine a time point for confirming the detection (Zhao et al., 2015b; Nguyen et al., 2017; Wu et al., 2017; Liu and Wu, 2018; Xia et al., 2020). Typically, such methods apply a generic rumor detection model to report a decision of classification (e.g., rumor or non-rumor) at each of the *pre-determined* checkpoints while leaving the determination of the best detection point to human judge. This is subject to a delayed decision as the results at the later checkpoints also need to be examined. 2) Methods that are trained to automatically determine an early detection point, but cannot guarantee the stability of decision (Zhou et al., 2019; Song et al., 2019). For example, CED (Song et al., 2019) decides an early detection point using a fixed probability threshold to assess if the current prediction is credible or not. However, prediction probability does not really reflect model's confidence (Guo et al., 2017), and such decision without properly modeling the *uncertainty beyond the decision point* may fail to give a timely and reliable detection because the prediction could flip over and over again afterwards with new posts flow in.

In this work, we propose a new method called Hawkes EArly Rumor Detection (HEARD) to model the stabilization process of rumor detection based on a Neural Hawkes Process (NHP) (Mei and Eisner, 2017), which can automatically determine when to make a timely and stable decision of detection. The basic idea is to construct a detection stability distribution over the *expected future* predictions based on a sequence of *prior and current* predictions, such that an optimal time point can be fixed without any delay for awaiting and checking the upcoming data beyond that point. Our main contributions can be summarized as follows[1]:

- We introduce BEARD, the first EARD-oriented dataset, collected by covering as much as possible the early-stage information relevant to the concerned claims.
- We propose HEARD, a novel EARD model based on the NHP to automatically determine an optimal time point for the stable decision of early detection.
- Extensive experiments show that HEARD achieves more effective EARD performance as compared to strong baselines on BEARD and two commonly used general rumor detection datasets.

2 Related Work

2.1 Early Rumor Detection

Despite extensive research on general rumor detection, early detection has not been studied well. Many studies claimed that their general detection models can be applied to early detection by simply fed with data observed up to a set of pre-determined checkpoints (Ma et al., 2016; Yu et al., 2017; Ma et al., 2017, 2018; Guo et al., 2018; Bian et al., 2020). Nevertheless, how to determine an optimal early detection point from many checkpoints is missing and non-trivial, as deciding when to stop often needs to check the data or model's outputs after the current checkpoint, causing delays of detection.

Some methods were claimed further as designed for early detection. Zhao et al. (2015b) proposed to gather related posts with skeptical phrases, and performed detection with cluster-based classifiers over real-time posts. Nguyen et al. (2017) developed a hybrid neural model for post-level representation and credit classification, which were incorporated with the temporal variations of handcrafted features for detecting rumors. Wu et al. (2017) clustered relevant posts and selected key features from clusters to train a topic-independent classifier for revealing emergent rumors. Xia et al. (2020) employed burst detection to segment an event into sub-events and trained an encoder for each sub-event representation for incremental prediction. None of the above methods really address the key issues of early detection as they lack mechanisms enforcing the earliness, and they cannot automatically fix an optimal detection point either.

ERD (Zhou et al., 2019) used deep reinforcement learning to enforce model to focus on early time intervals for the trade-off between accuracy and earliness of detection, and is the first EARD method that can automatically decide to stop or continue at a checkpoint. Song et al. (2019) proposed another EARD method called Credible Detection Point

---

[1] Dataset and source code are released at `https://github.com/znhy1024/HEARD`

(CED) using a fixed probability threshold to determine if detection process should stop depending on the credibility of current prediction. However, these models are unstable or of low confidence because the uncertainty of future predictions is not taken into account in training.

2.2 Rumor Detection Datasets

Quite a few rumor detection datasets based on social media posts relevant to a set of claims were released, such as TWITTER (Ma et al., 2016), PHEME (Zubiaga et al., 2016), RumourEval-2017/19 (Derczynski et al., 2017; Gorrell et al., 2019), FakeNewsNet (Shu et al., 2020), etc.. RumourEval-2017/19 are minor variants of PHEME while FakeNewsNet is never used for EARD. These datasets were built for general detection of rumors without much consideration on the earliness of information. Thus, the actual early-stage social engagements may not be covered by different data collection mechanisms used, such as applying a rigid time cut-off in Search API or launching a real-time gathering with Streaming API *after* a news outbreak. To our best knowledge, there is no dataset specifically built for early rumor detection task.

3 BEARD Corpus Construction

We scrape the text of title, claim, debunking time and veracity label in the articles on the fact-checking website `snopes.com`. Our goals are two-fold: 1) The collected posts are not only relevant to the claim but can diversely cover copious variations of relevant text expressions; 2) The collection can cover posts of early arrival, possibly ahead of the pertinent news exposure on the mainstream media.

To this end, we firstly construct high-quality search queries for Twitter search. An original query is formed from the title and claim of each article, with stop words removed. Since the lengthy query might harm the diversity of search results, we utilize some heuristics to obtain a substantial set of variants of each query potentially with better result coverage in Twitter search: i) We preform synonym replacement to create a set of variants of the query; ii) We shorten each variant by removing its words one by one with carefully crafted rules to maintain useful information, e.g., named entities, for good search quality, while keeping the remaining words after each removal as a new variant. As a result, we obtain a substantial set of variants of the original query and merge the Twitter search results of each query and all its variants.

To cover early posts, each Twitter search is performed in an iterative fashion. To avoid ground-truth leakage, we first obtain the possible earliest official debunking time of the given claim by cross-checking its similar claims in a range of fact-checking websites (see Appendix A.1). From the earliest debunking time, we search backward for the relevant posts within M days *prior to* debunking, and then push back further N days earlier than before in each iteration until the number of newly gathered posts in an iteration becomes less than 1% of the posts obtained from the previous iteration.

Finally, for each retrieved post, we use its conversation ID to find the root post of the conversation it is engaged in. We utilize Sentence-BERT (Reimers and Gurevych, 2019) to retain those root posts with cosine similarities to the claim being higher than an empirical threshold. Thus far, we have obtained a set of conversation IDs for each claim which are led by different root posts (see Appendix A.4 for post-processing). Then we fetch from Twitter all the posts in the detected conversations along with the root posts into our final collection as an instance, and label the conversation as rumor if the corresponding claim is from the "Fact Checks" category on the Snopes or non-rumor if it is from the "News" category.

Due to space limit, we provide the details of search queries construction in Appendix A.2, and the settings of iterative Twitter search in Appendix A.3.

4 Problem Definition

Let $\mathbf{C} = \{C\}$ denote a set of instances, where each $C = \{y, S\}$ consists of the ground-truth label $y \in \{0, 1\}$ and a set of relevant posts in chronological order $S = \{(\mathbf{m}_1, \tau_1), ..., (\mathbf{m}_i, \tau_i), ..., (\mathbf{m}_{|S|}, \tau_{|S|})\}$. y indicates C is a rumor if $y = 1$ or a non-rumor otherwise. $|S|$ is the number of relevant posts in S. Each tuple $(\mathbf{m}_i, \tau_i) \in S$ includes the text content $\mathbf{m}_i$ and the timestamp τ_i of the i-th post, where τ_i is defined as the time difference between the first and the i-th post, such that $\tau_1 = 0$ and $\tau_{i-1} \leq \tau_i$ for $i > 1$. In other words, τ_i can be regarded as the elapsed time relative to the earliest post so that the timelines of different instances are aligned.

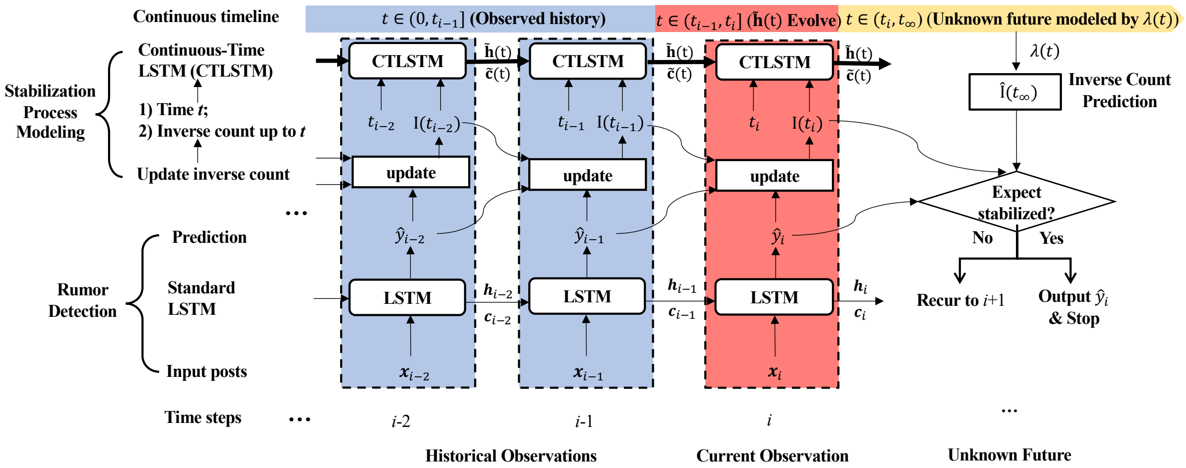

Figure 1: The architecture of HEARD. When the current observation arrives at time t_i, rumor detection predictions from LSTM $\hat{y}_i$ and $\hat{y}_{i-1}$ are used to update PI count $I(t_i)$. Then the intensity function $\lambda(t)$ is computed by CTLSTM for $t > t_i$. HEARD will determine t_i as the earliest time point with stable prediction $\hat{y}_i$ and stop if the stability prediction $\hat{I}(t_\infty)$ equals to $I(t_i)$, or continue otherwise.

Following the pre-processing method in most prior studies (Ma et al., 2016; Song et al., 2019; Zhou et al., 2019), we divide each posts sequence into a sequence of intervals to avoid excessively long sequence. We chop a sequence S into intervals based on three strategies: 1) fixed posts number, 2) fixed time length and 3) variable length in each interval (Zhou et al., 2019). Hence S is converted to $X = \{(\mathbf{x}_i, t_i)\}_{i=1}^{|X|}$, where $|X|$ is the number of intervals, $\mathbf{x}_i = \{\mathbf{m}_{i,1}, \mathbf{m}_{i,2}, ..., \mathbf{m}_{i,|\mathbf{x}_i|}\}$ and $t_i = \tau_{i,|\mathbf{x}_i|}$ which is the timestamp of the *last* post $\mathbf{m}_{i,|\mathbf{x}_i|}$ in the i-th interval. Then, we merge the posts falling into the same interval as a single post.

We define the EARD task as automatically determining the *earliest* time $\hat{t} \in \{t_i\}$, such that the prediction $\hat{y} \in \{0, 1\}$ at $\hat{t}$ for a given claim is *accurate and remains unchanged* afterwards with time goes by. It is worthwhile to mention that since t_i relates to the granularity of intervals, it might affect the precision of a decision point based on the formed intervals. In practice, however, we will try to make the intervals small for keeping such impact marginal.

5 HEARD Model

Figure 1 shows the architecture of HEARD, which contains two components: 1) the rumor detection component predicts rumor/non-rumor label at each time step/interval; 2) the stabilization component models the prediction stabilization process and determines when to stop at the earliest detection point. We will describe them with detail in this section.

5.1 Rumor Detection Modeling

A standard LSTM cell (Hochreiter and Schmidhuber, 1997) followed by a fully-connected layer is utilized for rumor detection in each interval. For any $(\mathbf{x}_i, t_i) \in X$, $\mathbf{x}_i$ can be turned into a vector $\mathbf{e}_i$ by a text representation method, e.g., TF-IDF (Salton and Buckley, 1988), CNN (Kim, 2014), BERT (Devlin et al., 2019), etc.. Taking $\mathbf{e}_i$ as input, the LSTM cell gets the hidden state $\mathbf{h}_i = \mathrm{LSTM}(\mathbf{e}_i)$ and forwards it through the fully-connected layer to perform prediction. The predicted class probability distribution of an instance at t_i is calculated as $\mathbf{p}_i^r = \sigma(\mathbf{W}\mathbf{h}_i + \mathbf{b})$ and thus the predicted class is $\hat{y}_i = \mathrm{argmax}(\mathbf{p}_i^r)$, where $\sigma(\cdot)$, $\mathbf{W}$ and $\mathbf{b}$ are sigmoid function, weight matrix and bias, respectively.

5.2 Stabilization Process Modeling

Prediction Inverse (PI). Our rumor detection component keeps observing the posts stream and outputs a prediction sequence $\hat{y}_1, \hat{y}_2, \hat{y}_3, \ldots$ along the time steps. During the process, newly arrived posts may provide updated features rendering the next decision of rumor detection to invert from rumor to non-rumor or the other way round. Presumably, the predictions would get stabilized when sufficient clues are accumulated over time. By modeling such a process, we aim to fix the earliest time t_i when the model can produce a stable prediction, meaning that there will be no expected inverses of prediction occurring from t_i onward. Thus, we need to train the model for learning the expected future PIs to maximize its stability of prediction.

As a future PI can occur unforseeably at any time, we introduce $I(t)$ as a cumulative count of PIs up to any time point t in a *continuous* time space to accommodate the uncertainty. Then a PI counts sequence $I(t_1), I(t_2), I(t_3)\dots$ can be obtained from the prediction sequence. Clearly, we have $I(t_1) = 0$, and $I(t_i) = I(t_{i-1}) + 1$ if $\hat{y}_i \neq \hat{y}_{i-1}$ or $I(t_i) = I(t_{i-1})$ otherwise. Additionally, we denote $\mathcal{H}_{t_i} = \{(I(t_1), t_1), \dots, (I(t_{i-1}), t_{i-1})\}$ the history of PI counts up to $t \in (t_{i-1}, t_i]$, and denote $\Delta I(t_i, t_j) = I(t_j) - I(t_i)$ the difference of PI counts between t_i and t_j for $j > i$.

Neural Hawkes Process (NHP). General Hawkes process (Hawkes, 1971) is a doubly stochastic point process for modeling sequence of discrete events in continuous time, which has been successfully applied in social media research, such as modeling the popularity of tweets (Zhao et al., 2015a), rumor stance classification (Lukasik et al., 2016), fake retweeter detection (Dutta et al., 2020), and extracting temporal features for fake news detection (Murayama et al., 2020). Given a sequence of events $E_1, E_2, E_3, \dots$ which occur at the corresponding time points $t_1, t_2, t_3, \dots$ and $N(t)$ that is the number of events occurring up to time t, a univariate Hawkes process with a conditional intensity that indicates expected arrival rate of future events at t is defined as (Yang and Zha, 2013):

$$\lambda(t) = \mu + \int_{-\infty}^{t} \kappa(t-s)\mathrm{d}N(s) \tag{1}$$

where $\mu \geq 0$ is the base intensity of event and $\kappa(\cdot)$ is a *manually specified monotonic kernel function* that shows how the excitation from history decays with time. It assumes that arrived events can temporarily raise the probability of future events but the influence monotonically decays over time. However, this assumption is very strong which limits its ability for modeling complex dynamic point processes. In rumor diffusion, prediction inverse is the event influenced by many factors, such as what users express in historical and upcoming posts, which may bring tremendous uncertainty of prediction invalidating the monotonic decay assumption. Thus, we propose to adopt an NHP (Mei and Eisner, 2017) to capture the complex effects by utilizing a RNN with continuous-time LSTM (CTLSTM) to *learn* the intensity function. CTLSTM extends the vanilla LSTM with an interpolation-like mechanism so that its hidden state for controlling intensity can be updated *discontinuously* with each event occurrence and also evolves *continuously* as time elapses towards the next upcoming event.

Intensity Function Estimation. We use NHP to model the dynamics of PI (i.e., event) and approximate a detection stability distribution over the expected future predictions based on the sequence of historical and current predictions. As shown in Figure 1, CTLSTM reads the current observation $(I(t_i), t_i)$ to obtain $\lambda(t)$ for any $t > t_i$, so that the distribution over the expected PI counts can be approximated. The intensity function $\lambda(t)$ is controlled by a hidden state $\widetilde{\mathbf{h}}(t)$ as follow:

$$\lambda(t) = f(\widetilde{\mathbf{W}} \cdot \widetilde{\mathbf{h}}(t)) \tag{2}$$

where $\widetilde{\mathbf{W}}$ is a weight matrix and $f(x) = \beta \log(1 + \exp(x/\beta))$ is the softplus function to obtain a positive intensity with a scale parameter β (Mei and Eisner, 2017).

To model the unknown future for $t > t_i$ based on historical representation $\widetilde{\mathbf{h}}(t_i)$, a new hidden cell vector $\widetilde{\mathbf{c}}(t)$ is introduced to control how $\widetilde{\mathbf{h}}(t)$ *continuously* evolves over time. Specifically, $I(t_i)$ is firstly transformed to a vector at t_i by a fully-connected layer to join the updates in CTLSTM. Then, CTLSTM updates the hidden state $\widetilde{\mathbf{h}}(t)$ that has been evolving towards $\widetilde{\mathbf{h}}(t_i)$ based on $\widetilde{\mathbf{c}}(t)$ for $t \in (t_{i-1}, t_i]$. Thus, a richer representation of history can be learned by taking into account the dynamics of impact between the two consecutive observations. Meanwhile, to model the expected future PI count, $\widetilde{\mathbf{c}}(t)$ is updated to a new state with the current cell input, which is analogous to how vanilla LSTM updates hidden cell[2], and from the new state, $\widetilde{\mathbf{c}}(t)$ begins to continually approximate a target state that is defined by CTLSTM to represent an expected state of $\widetilde{\mathbf{c}}(t)$ for $t \to \infty$.

Expected Stabilization. $\lambda(t)$ indicates the expected instantaneous rate of future PIs from t onward. We can predict the value of $I(t_\infty)$ (t_∞ denotes $t \to \infty$) and further determine an expected earliest stabilized observation $(I(t_{i^*}), t_{i^*})$, such that $t_{i^*} = \min\{t_i \mid \Delta I(t_i, t_\infty) = 0, i \in \{1, \dots, |X|\}\}$. Hence, t_{i^*} indicates the expected

---

[2] The difference is that vanilla LSTM updates the hidden cell based on that of the previous time step while the update here is based on $\widetilde{\mathbf{c}}(t)$ for $t \to t_i$.

earliest time that the predictions remain unchanged after it. We approximate $\Delta I(t_i, t_\infty)$ by

$$\Delta \hat{I}(t_i, t_\infty) = \int_{t_i}^{\infty} \lambda(t)\mathrm{d}t \tag{3}$$

where $\hat{I}(\cdot)$ constantly denotes a predicted PI count. We use Monte Carlo trick to handle all integral estimations (Mei and Eisner, 2017). Given t_{i^*}, HEARD finally outputs $\hat{y}_{i^*}$ as the stable prediction for early rumor detection.

5.3 HEARD Model Training

We utilize a next observation $(I(t_{i+1}), t_{i+1})$ prediction task to train CTLSTM. With PIs as the indicator of model stability, CTLSTM aims to fit the sequence of observations $\mathcal{H}_{t_{i+1}}$ obtained from the predictions of the rumor detection module.

Specifically, $\hat{I}(t_{i+1})$ can be obtained from $I(t_i) + \Delta\hat{I}(t_i, t_{i+1})$, and the difference value $\Delta\hat{I}(t_i, t_{i+1})$ is either 1 or 0 which can be predicted as $\Delta\hat{I}(t_i, t_{i+1}) = \mathrm{argmax}(\mathbf{p}_i^c)$, where we infer $\mathbf{p}_i^c = \sigma(\mathbf{W}'\widetilde{\mathbf{h}}(t_i) + \mathbf{b}')$ with trainable parameters $\mathbf{W}'$ and $\mathbf{b}'$. For predicting t_{i+1}, a density $p_i(t)$ is formulated as

$$p_i(t) = \lambda(t) \exp\left(-\int_{t_i}^{t} \lambda(s)\mathrm{d}s\right) \tag{4}$$

Then we use the minimum Bayes risk predictor for time prediction (Mei and Eisner, 2017):

$$\hat{t}_{i+1} = \mathbb{E}[t_{i+1} | t_i, \mathcal{H}_{t_i}] = \int_{t_i}^{\infty} p_i(t) t \mathrm{d}t \tag{5}$$

where $\mathbb{E}[\cdot]$ is an estimator for choosing an optimal time point t to minimize the expectation of risks.

The overall loss consists of three terms on rumor detection, expected earliest stable time and CTLSTM. Concretely, given an instance C with input sequence $X = \{(\mathbf{x}_i, t_i)\}$, let $\mathbf{y}$ be the one-hot encoding of ground-truth label (i.e., rumor or not). At each time of observation t_i, the cross-entropy loss between prediction and ground truth is defined as $L_i^r = -\mathbf{y} \cdot \log \mathbf{p}_i^r$. For the expected earliest stable time, the loss at t_i is defined as

$$L_i^e = |\Delta\hat{I} - \Delta I| - \log\left(1 - \frac{i}{|X|}\right) \tag{6}$$

where the first term is the loss of $\Delta I(t_i, t_\infty)$[3] approximation in Eq. 3, and the second term encourages the model to select an earliest time possible.

Dataset		Instances #	Posts #	AvgLen (hrs)
TWITTER	R	498	182,499	2,538
	N	494	466,480	1,456
PHEME	R	1,972	31,230	10
	N	3,830	71,210	19
BEARD	R	531	2,644,807	1,432
	N	667	657,925	1,683

Table 2: Statistics of datasets. R: Rumor; N: Non-rumor.

The loss incurred from CTLSTM is given as

$$L_i^c = -\mathbf{\Delta I} \cdot \log \mathbf{p}_i^c + |\hat{t}_{i+1} - t_{i+1}| \tag{7}$$

where $\mathbf{\Delta I}$ is the one-hot encoding of target $\Delta I(t_i, t_{i+1})$, the first term is the loss of next prediction inverse and the second term is the loss of time prediction for next observation.

Our objective is to minimize the cumulative loss up to t_{i^*} when the early detection decision is made: $L = \frac{1}{i^*}\sum_{i=1}^{i^*} L_i$, where $L_i = L_i^r + L_i^e + L_i^c$. We use stochastic gradient decent (SGD) mini-batch training over all training instances.

6 Experiments and Results

6.1 Experimental Setup

Datasets. We use BEARD, TWITTER (Ma et al., 2016) and PHEME (Zubiaga et al., 2016) datasets in the evaluation. BEARD contains 1,198 rumors and non-rumors reported during 2015/03-2021/01 with around 3.3 million relevant posts. We hold out 20% of instances for tuning, and the rest are randomly split with a ratio of 3:1 for training/test. Results are averaged over 5 splits. In Table 2, we show the statistics of TWITTER, PHEME and BEARD datasets.

Baselines. We compare HEARD with four state-of-the-art baselines using their original source codes: 1) **BERT** (Devlin et al., 2019) is fine-tuned on the "earliest rumor detection" task (Miao et al., 2021), in which the early detection strategy is to output a prediction using only the *first* post of each instance. 2) **CED** (Song et al., 2019) uses a fixed probability threshold to check if the prediction is credible for determining the early detection point. 3) **ERD** (Zhou et al., 2019) uses a Deep Q-Network (DQN) to enforce the model to focus on early posts for determining the time point to stop and output the detection result. 4) **STN** (Xia et al., 2020) use a time-evolving network to represent

---

[3] For simplicity, $\Delta I(t_i, t_\infty)$ and $\Delta\hat{I}(t_i, t_\infty)$ are denoted as ΔI and $\Delta\hat{I}$ in Eq. 6, respectively.

state-independent sub-events in posts sequence for classifying claims at each checkpoint.

6.2 Experimental Settings

To balance the sequence length and granularity of time intervals, we pre-process posts sequences in the three datasets differently. We merge every 10 posts in BEARD and every 2 posts in TWITTER while we only merge the posts with the same timestamp in PHEME due to its generally short sequences. For each interval, both ERD and STN use pre-trained word embeddings to initialize the embedding matrix and fine-tune it in the training, while CED uses the TF-IDF method (Salton and Buckley, 1988), all of which follow the settings in the original papers (Song et al., 2019; Zhou et al., 2019; Xia et al., 2020). We also follow the original CED setting by using TF-IDF with 1,000 dimensions for representing the posts in each time interval.

The hidden size of standard LSTM is set to 128 with the dropout rate of 0.1, and the size of CTL-STM is set to 64. We pad all the sequences in a batch to the same length as the longest one, with the batch size of 16. We use the Adam (Kingma and Ba, 2015) with a learning rate of $2e$-4 for optimization. To avoid overfitting, we add a L2 regularization with the weight of $1e$-4. All values are fixed based on the validation set.

Our model HEARD is implemented using Pytorch[4]. We use the original source codes of all the baselines: CED[5] and ERD[6] are implemented with TensorFlow; BERT[7] are implemented with Pytorch, and we use the base uncased pre-trained model; The code of STN is obtained directly from the authors of the original paper (Xia et al., 2020) which is implemented with Pytorch. All the experiments are conducted on a server with 4*12GB NVIDIA GeForce RTX 2080 Ti GPUs.

6.3 Evaluation Metrics

We use the general classification evaluation metrics accuracy and F1-score together with several EARD-specific metrics (see below) for evaluation.

Early Rate (ER) (Song et al., 2019) is defined as the utilization ratio of posts: $ER = \frac{1}{|\mathbf{C}|}\sum_{C\in\mathbf{C}}\frac{i_C}{|C|}$ where $\mathbf{C}$ is the test set, i_C implies the early detection decision is made at the i-th post in instance C and $|C|$ is the number of posts in it. *Lower* ER means the model can detect rumors *earlier*.

Early Detection Accuracy Over Time (EDAOT). The metric of detection accuracy over time widely used (Ma et al., 2016; Zhou et al., 2019; Xia et al., 2020) is unsuitable for EARD models as it enforces a model to output a decision at each checkpoint whereas an EARD model can decide its own optimal decision point which may be earlier and more accurate than its output at the checkpoint. Our variant requires a model output result *only* when it cannot make an early decision before a given checkpoint while both accuracy and average time of decisions will be presented. Specifically, given a set of checkpoints at time $\{t_1, ..., t_k\}$, at the j-th checkpoint, the detection accuracy is $Acc_{t_j} = \sum_{C\in\mathbf{C}}\frac{\mathbb{1}_{\hat{y}_{i^*}=y}}{|\mathbf{C}|}$, where the binary function $\mathbb{1}$ takes 1 if $\hat{y}_{i^*} = y$ or 0 otherwise. And the average time of decisions is $AvgT_{t_j} = \sum_{C\in\mathbf{C}}\frac{t_{i^*}}{|\mathbf{C}|}$, where $t_{i^*} \leq t_j$, and $t_{i^*} = t_j$ if the model cannot make a decision before t_j.

Stabilized Early Accuracy (SEA) is a newly defined comprehensive metric considering accuracy, earliness and stabilization:

$$SEA = \frac{1}{3|\mathbf{C}|}\sum_{C\in\mathbf{C}}\Bigg[\mathbb{1}_{\hat{y}_{i^*}=y} + \left(1 - \frac{i_C}{|C|}\right) + \left(1 - \frac{\Delta I(t_{i^*}, t_{|X|})}{|X| - i^*}\right)\Bigg]$$

where the first term is the ratio of correctly predicted instances at the predicted time point t_{i^*} indicating accuracy, the second term is the ratio of posts after t_{i^*} indicating earliness, and the third term is the ratio of unchanged predictions after t_{i^*} indicating stability. The value of SEA is bounded in $[0, 1]$ and higher SEA means better performance.

6.4 Results and Analysis

The main results are provided in Table 3. We show the EDAOT results in Figure 2.

Results of Classification. STN uses the entire timeline of each instance since it cannot automatically determine an early detection point. As shown in Table 3, however, it only achieves comparable Accuracy and F1 as ERD and CED and is much worse than HEARD, even though it was reported much better than CED on TWITTER in previous

Table 3: Early rumor detection results.

work (Xia et al., 2020)[8]. This implies that the early detection models are promising which can use a prior fraction of posts to achieve similar or much better results. It also suggests that capturing early-stage features is important to more accurate rumor detection. Only using the source post for detection, BERT gives worst Accuracy and F1 on TWITTER and BEARD, but it gets unexpectedly high performance on PHEME. We inspect this issue by following the prior analysis (Schuster et al., 2019) based on Local Mutual Information (LMI) (Evert, 2005) and Pointwise Mutual Information (PMI) (Church and Hanks, 1990). We find that the source posts in PHEME have spuriously much stronger correlation with the class labels. Appendix B.1 discusses such bias and the possible cause. This observation suggests data sampling bias exists in the existing dataset, and thus the model's decision based on the source post only can be misleading and insufficient.

Results of ER and SEA. Table 3 also shows that HEARD consistently outperforms ERD and CED in large margin based on ER and SEA, indicating HEARD is more effective and stable. HEARD considerably improves CED by 57%, 68% and 27% in ER and by 27%, 32% and 11% in SEA on TWITTER, PHEME and BEARD, respectively. ERD's high ER scores entails that it can hardly make early decision, as this DQN-based model seems weak on its reward function, which gives a small penalty to continuation but a large one to termination with wrong predictions (Zhou et al., 2019), discouraging it from stopping early. BERT only uses the first post for detection which thus obtains the lowest ER. Note that a model being *expectantly* stable at the time of decision means the prediction will remain unchanged even though new data could be seen by the model after that. To probe its stability, we enforce model to continue outputting predictions at the checkpoints later than its decision point. We can see that HERAD still outperforms BERT on SEA on all the datasets indicating it is more stable.

Results of EDAOT. Figure 2 shows that HEARD is clearly superior over the baselines in accuracy, earliness and stability at the checkpoints. ERD looks relatively stable but it hardly makes early detection due to aforementioned reason. Our conjecture is that its DQN module forces it to overly focus on the first few intervals while deferring the decision to the end due to the weak reward design, resulting in nearly no improvement even with more data. Note that in EDAOT evaluation a model should stop once it outputs a prediction for a given checkpoint (i.e., deadline). Thus, BERT reports all the predictions using only the first post, rendering the same accuracy at checkpoints. Interestingly, HEARD can make especially fast decisions on PHEME which only uses a little less than 6 hours given a 48-hour deadline. The reason might be the average length

---

[8] The CED performance reported in (Xia et al., 2020) is an excerpt from (Song et al., 2019) based on half of the TWITTER data, while they experimented STN using the full data.

(a) Germanwings

(b) Darkest baby

Figure 3: (a) A rumor in PHEME on “The co-pilot of Germanwings flight 9525 was Muslim convert”; (b) A rumor in TWITTER on “A photograph shows the darkest baby in the world”. Y-axis: the number of collected posts; X-axis: timeline in minutes (m)/days (d); Colored bar: the semantic similarity between the posts in any time step and the posts in the decision time step, where the red bar denotes recollected data and the blue one denotes original data. The similarity ranges from 0.7 to 1.0, and the darker the color the more similar the posts are.

of instances in PHEME is only around 14 hours as compared to over 1,000 hours in other two datasets, which HEARD can especially benefit from in the training. However, considering the fact that the PHEME (and TWITTER) dataset may fail to cover the real early information, such a very quick detection on it could be an illusion since the patterns the model actually uses for the decision are from the midst of rumor propagation.

7 Case Study

In this section, we give an intuitive illustration to reveal 1) why BEARD is more suitable for EARD task; and 2) how HEARD is more advantageous than the state-of-the-arts with automatic early time point determination. Specifically, we recollect the relevant posts of rumor cases in PHEME and TWITTER using our data construction method for BEARD. To analyze the first question, we inspect the posts before and after the recollection as shown in Figure 3. In the original posts, the actual early-stage timelines of both cases are largely missing. Our recollected data can cover the important denial and questioning posts signaling rumors in the early stage. This observation indicates that our data collection method has improved coverage by recalling these actual early information which is not available in the existing datasets.

To analyze the second question, we display the detection outputs of different models before and after the recollection. HEARD consistently detects rumors with less time than CED and ERD since it automatically terminates when stabilization process estimates the expected future prediction inverse will not change. The correctness of such expectation could be reflected by the value of semantic similarity, which almost has no change with new posts coming in after the detection point, implying the future prediction results are expected stable.

8 Conclusion and Limitation

We introduce BEARD, a new benchmark dataset collected for early rumor detection, and propose a model called HEARD to perform stable early rumor detection based on neural Hawkes process. Experiments show that HEARD achieves overall better performance than state-of-the-art baselines. Analysis entails BEARD is more suitable for the early rumor detection task.

There are some cases that a rumor seems to be stable over an extended time period but is eventually refuted by an authoritative source later. It is because sensational discussions are more attractive to some social media users than facts, which leads to signals in support of the rumor are usually much stronger in social media, and the final correction often has only small engagement. In such cases, our model HEARD based on social media alone could be misled by the signals of only one source. In future, we plan to study incorporating authoritative sources of information to alleviate this phenomenon on social media, such as statements of official platforms, scientific sources, etc..

A Corpus Construction Protocols

A.1 Claims Collection

Snopes[9] is a well-known fact-checking website where fact-checkers manually collect check-worthy claims from multiple sources (e.g., social media, e-mail, news, etc.) and review each claim to report a decision in terms of "Fact Checks" (i.e., rumors being fact-checked) or "News" (i.e., non-rumors of no need to check). Further, the checkers verify the rumors and compose detailed fact-checking articles for justifying the veracity of rumors.

We utilize Snopes to collect the claims for constructing our data instances in terms of rumors and non-rumors. There are around 10k+ claims on Snopes in total (up to the end of 2021), but majority of them have very limited exposure on Twitter. Specifically, we include the claims into our collection based on the following principles: (1)

---

[9] `https://www.snopes.com/`

We only include the claims that were published in recent 6 years since they have relatively more complete exposure on Twitter (e.g., aged posts might be more likely to get deleted); (2) We only include the claims that have relevant posts on Twitter before the claim was officially debunked. As a result, we collect 531 rumor and 667 non-rumor claims reported during 2015/03-2021/01. For each claim, we scrape the text of article title, the claim, the debunking time and the veracity label.

We also try to exclude posts that may leak the ground truth since a claim might have been fact-checked by other fact-checking websites, thus the truth might have been referenced in the social media posts, such as the rumor example in TWITTER shown in Table 1. To minimize the chance of ground truth leakage, therefore, we match each claim from Snopes across the claims from a handful set of fact-checking websites including FactCheck.org[10] and PolitiFact.com[11] to get the possible earliest official debunking time, from which we begin collecting the relevant posts backwards in time.

A.2 Query Construction

For each claim, we construct a set of high-quality search queries for Twitter search to diversely cover relevant posts. Firstly, we concatenate the title and claim of an article followed by stop words removal to filter out noise, resulting in an original query. Since the original query might be long and harm the diversity of search results, we carry out the following ad hoc operations to shorten the query for maintaining maximum useful information and possibly broadening the coverage of retrieved posts: (1) We perform synonym replacement with Natural Language Toolkit (NLTK) (Bird et al., 2009) to create a variant of the query for each replacement; (2) For each variant obtained in (1), we use Google Search API[12] to search for this altered query and rank by the frequencies of the *highlighted words* that are hit in the top-100 searched snippets; (3) We then shorten the original query and its variants obtained in (2) by removing the highlighted words that are contained in the queries one by one starting from the low-frequency words, while keeping the remaining words after each removal as a variant of the query, until the shortest variant is left with three words. Note that here we perform named entity recognition by NLTK on the original query and the words that are parts of named entities will not be removed as they are useful for search.

A.3 Iterative Twitter Search

To prevent early quit of iteration caused by the intermittent sparse distribution of posts along the timeline, we manually adjust the values of M and N by trial and error with different instances to gather as much early posts as we can. We also manually check the search results based on a sample of instances using different settings of the termination threshold, i.e., the ratio of the number of gathered posts in each iteration over that in the previous iteration. We observe that too high threshold hinders early posts to be searched out, but too low threshold tends to introduce more noise. We finally set 1% as the termination threshold by trading off earliness and noise.

A.4 Posts Collection

Rather than merging the conversations led by different root posts regarding the same claim into a large conversation, it is more realistic to remain them naturally separated since the conversations originate from different sources and the merge may introduce unnecessary bias. And we drop all the posts that are published after the official debunking time of each claim to avoid ground truth leakage.

B Experimental Details

B.1 Bias Evaluation on Datasets

As mentioned in Section 6.4, we utilize LMI and PMI to examine the data sampling bias in the existing datasets and BEARD. The top-5 LMI-ranked words of PHEME, TWITTER and BEARD are shown in Table 4. The top-5 LMI-ranked words of PHEME have much higher LMI and PMI than the other two datasets indicating the high correlations between the words of source posts and the label. Meanwhile, the words in PHEME, e.g., 'breaking', 'hostages', 'shot', etc., are more eyes-catching comparing to the top ranked words in other two datasets. These idiosyncrasies might be introduced by the construction method of PHEME in a sense that journalists might see a timeline of posts about the breaking news and then annotate source posts of conversations, which are easily utilized by BERT to obtain high classification performance. Some

Table 4: Top-5 LMI-ranked words of source posts correlated with class label in three datasets.

salient bias also exists in TWITTER dataset evidenced as some top words with high LMI and PMI, such as ‘black (lives)’, ‘flag’ and ‘trump’, while we do not observe such bias among the top words in BEARD.

Emp-RFT: Empathetic Response Generation via Recognizing Feature Transitions between Utterances

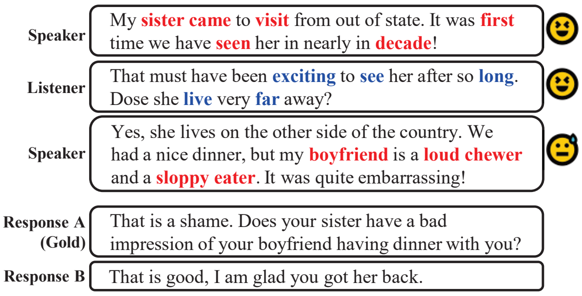
Wongyu Kim[1]**, Youbin Ahn**[2]**, Donghyun Kim**[2]**, and Kyong-Ho Lee**[2]
[1]Department of Artificial Intelligence, [2]Department of Computer Science
Yonsei University, Seoul, Republic of Korea
`{rladnjsrb9999, ybahn, dhkim92, khlee98}@yonsei.ac.kr`

Abstract

Each utterance in multi-turn empathetic dialogues has features such as emotion, keywords, and utterance-level meaning. Feature transitions between utterances occur naturally. However, existing approaches fail to perceive the transitions because they extract features for the context at the coarse-grained level. To solve the above issue, we propose a novel approach of recognizing feature transitions between utterances, which helps understand the dialogue flow and better grasp the features of utterance that needs attention. Also, we introduce a response generation strategy to help focus on emotion and keywords related to appropriate features when generating responses. Experimental results show that our approach outperforms baselines and especially, achieves significant improvements on multi-turn dialogues.

1 Introduction

Humans have empathy which is the ability to understand situations others have experienced and emotions they have felt from the situations (Eisenberg and Strayer, 1987). That ability also enables to interest and console others while sharing a conversation. Thus, empathetic response generation task has been considered noteworthy. Figure 1 shows an example of a multi-turn empathetic dialogue dataset, EmpatheticDialogues (Rashkin et al., 2019) constructed to solve the task. A speaker talks about one of 32 emotion labels and a situation related to the emotion label, and a listener empathizes, responding to the speaker. Existing approaches (Rashkin et al., 2019; Lin et al., 2019; Majumder et al., 2020; Li et al., 2020; Kim et al., 2021) for the task achieve promising results but show limitations when dialogues become long because they extract features from the concatenation of all tokens in the context at the coarse-grained level.



Speaker My **sister came** to **visit** from out of state. It was **first** time we have **seen** her in nearly in **decade**!

Listener That must have been **exciting** to **see** her after so **long**. Dose she **live** very **far** away?

Speaker Yes, she lives on the other side of the country. We had a nice dinner, but my **boyfriend** is a **loud chewer** and a **sloppy eater**. It was quite embarrassing!

Response A (Gold) That is a shame. Does your sister have a bad impression of your boyfriend having dinner with you?

Response B That is good, I am glad you got her back.

Figure 1: An example of EmpatheticDialogues with response A and B. Response B is from one of state-of-the-art models. Highlighted words are keywords.

However, at the fine-grained level, each utterance in multi-turn empathetic dialogues has features such as emotion, keywords that each denote what an interlocutor feels and primarily says, and utterance-level meaning that can be known when looking at the entire utterance. In addition, it is a natural phenomenon that features of each utterance differ from the previous, as the dialogue is prolonged. Hence, we humans instinctively recognize these feature transitions, which helps us understand how the dialogue flows and grasp the features of utterance that needs attention. Also, humans respond to others, focusing on emotion and keywords related to appropriate features. Take the example in Figure 1. In the first turn, the speaker is excited to see the speaker's sister in a long time by mentioning keywords (e.g., 'sister', 'visit', 'decade'), and the listener reacts to the excitement and asks about her by mentioning keywords (e.g., 'exciting', 'see', 'live'). However, in the second speaker utterance, the speaker becomes embarrassed because of the speaker's boyfriend's bad table manners by mentioning keywords (e.g., 'boyfriend', 'loud', 'eater'). We humans recognize that the features of second speaker utterance have changed compared to those of previous utterances, and usually decide to be attentive to the features of the second utterance. Then, by focusing on information such as keywords of that utterance and emotion and keywords (e.g., 'bad', 'impression') related to the features of that utterance, humans generate empathetic, coherent,

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4118 - 4128
July 10-15, 2022 ©2022 Association for Computational Linguistics

and non-generic responses like response A. However, the model which produces non-empathetic and incoherent response like response B, considers that the features of the first speaker utterance represent the context from the coarse-grained view.

In this paper, we first propose to annotate features on each utterance at the fine-grained level (§4). Then, we introduce a novel **Emp**athetic response generator based on **R**ecognizing **F**eature **T**ransitions (Emp-RFT), which has two essential parts: Feature Transition Recognizer and Response Generation Strategy. The first part recognizes feature transitions between utterances, utilizing comparison functions of Wang and Jiang (2017), which makes Emp-RFT understand the dialogue flow and grasp appropriate features of utterance that needs attention. The second part helps Emp-RFT focus on emotion and keywords related to appropriate features. Specifically, by fusing context with keywords, such keywords are emphasized within each utterance and get more attention when generating responses. Then, Emp-RFT detects next emotion and keywords that denote emotion and keywords of the response, which helps figure out proper emotion and keywords for generation. Lastly, inspired by Dathathri et al. (2020); Chen et al. (2020), a new mechanism of Plug and Play Language Model(PPLM), contrastive PPLM using contrastive loss, is introduced, which controls Emp-RFT to actively use the keywords detected to be next keywords when generating responses.

We conduct experiments on EmpatheticDialogues. Emp-RFT outperforms strong baselines, particularly, when dialogues are multi-turn.

Our main contributions are as follows. (1) We introduce a novel approach that recognizes feature transitions between utterances, which results in understanding how the dialogue flows and grasping the features of utterance that the model should be attentive to. (2) We propose a response generation strategy including fusing context with keywords, next emotion and keywords detection, and contrastive PPLM. The strategy makes our model focus on emotion and keywords related to appropriate features when generating responses. (3) In the experiments, Emp-RFT outperforms baselines, especially, when dialogues are prolonged.

2 Related Work

Since Rashkin et al. (2019) release EmpatheticDialogues, many approaches have been proposed to generate empathetic responses. Lin et al. (2019) propose mixture of emotional experts. Majumder et al. (2020) propose emotion grouping, emotion mimicry, and stochastic sampling. Li et al. (2020) extract emotional words through lexicon and propose an adversarial generative model. Shen et al. (2021) apply dual-learning with unpaired data for the bidirectional empathy. Gao et al. (2021) integrate emotion cause into response generation process through gated mechanism. Sabour et al. (2021); Li et al. (2022) use implicit commonsense for context modelling. Kim et al. (2021) train a model to extract words that cause the speaker's emotion and attach RSA Framework (Frank and Goodman, 2012) to any generative models to generate responses, focusing on emotion cause words.

Recently, many studies have shown remarkable improvements through recognizing transitions of features between utterances in open-domain multi-turn dialogues. Qiu et al. (2020) perceive transitions of emotion states for context modelling. Zou et al. (2021) propose a module to manage keyword transitions. Zhan et al. (2021) model external knowledge transitions to select a knowledge used for generation. In multi-turn empathetic dialogues, we consider emotions, keywords, and utterance-level meaning (Gu et al., 2021) as important features of each utterance and propose a novel approach of recognizing feature transitions between utterances.

3 Task Formulation

Given context $con = [u^1, \dots, u^{n-1}]$, where an utterance $u^i = [u^i_1, \dots, u^i_{|u^i|}]$ consists of $|u^i|$ words, we can obtain $e = [e^1, \dots, e^{n-1}]$ and $k = [k^1, ..., k^{n-1}]$, where e^i and $k^i = [k^i_1, ..., k^i_{|k^i|}]$ each denote emotion and $|k^i|$ keywords of u^i through data preparation (§4). To conduct next keywords detection, we construct keyword pairs kps (§4.2) whose each pair has two keywords each from keywords of the speaker utterance and keywords of the listener utterance in the same turn. Finally, given con, e, k, and kps, we detect next emotion e^y and next keywords $k^y = [k^y_1, \dots, k^y_{|k^y|}]$, and generate an empathetic response $y = [y_1, \dots, y_m]$.

4 Data Preparataion

In this section, we introduce feature annotation in the speaker and listener utterances.

Feature	Top-1 Acc	Top-5 Acc	macro-F1
EofSU	46.77	81.26	43.55
EofLU	58.44	89.96	53.25
Feature	**TL-P**	**TL-R**	**TL-F1**
KofSU	41.53	66.58	51.15
KofLU	52.31	60.97	56.30

Table 1: Performances of feature annotations. When we evaluate annotations of **EofSU/KofSU**, EMOCAUSE (Kim et al., 2021) made based on EmpatheticDialogues, is used to verify emotion and emotion cause words detection models. For evaluations of keyword annotations, we use the metrics, Token-Level(**TL**) Precision(**P**), Recall(**R**), and **F1** (DeYoung et al., 2020), usually used in token extraction tasks.

4.1 Feature Annotation in Speaker Utterances

Emotion and Keywords of Speaker Utterance (EofSU/KofSU). Speakers try to say an emotional experience that causes a certain emotion in the utterance. Thus, we leverage a model (Kim et al., 2021) which is trained to jointly detect an emotion and emotion cause words of the speaker utterance, using EmpatheticDialogues. We regard top-6 emotion cause words as keywords and remove stopwords and punctuations in keywords.

4.2 Feature Annotation in Listener Utterances

Emotion of Listener Utterance (EofLU). We finetune RoBERTa (Liu et al., 2019) to detect an emotion given a situation description in EmpatheticDialogues. Then, the model predicts an emotion of the listener utterance.

Keywords of Listener Utterance (KofLU). Listeners express empathy in the utterance through three Communication Mechanisms (CMs) (Sharma et al., 2020) including emotional reaction, interpretation, and exploration. Thus, three models are leveraged, where each model is trained to detect words that cause one of three CMs, using another dialogue dataset for mental health support [1]. Then, three models predict such words in the listener utterance. Since predicted words take up slightly a lot in the listener utterance, these words are filtered out in the keyword pairs construction.

Keyword Pairs Construction. Inspired by Zou et al. (2021), keyword pairs kps are constructed not only to filter out above predicted words, but also to conduct next keyword detection. Given a dialogue corpus, all pairs are extracted, where each pair has a head word and a tail word each from keywords in the speaker utterance and predicted words in the listener utterance in the same turn. Then, all pairs are filtered out to obtain high-frequency pairs through pointwise mutual information (PMI)[2] (Church and Hanks, 1990) which can measure the association between two words in a corpus. Filtered pairs become kps. A tail word of a kp is regarded as a keyword of the listener utterances joined to extract that keyword pair.

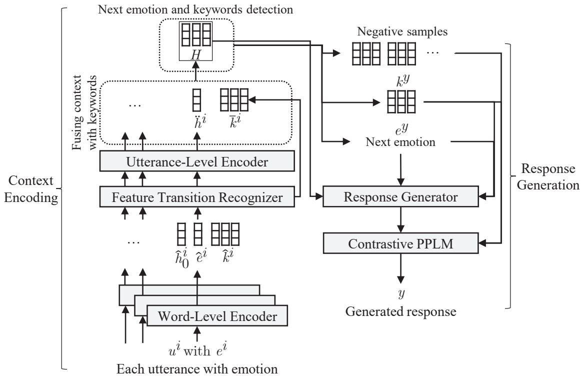


Figure 2: Overall architecture of Emp-RFT.

Performances of feature annotations are summarized in Table 1 and show reliable results. However, test sets for **KofLU** based on EmpatheticDialogues, don't exist. Thus, we randomly sample 100 test dialogues in EmpatheticDialogues and ask 3 human workers to annotate whether each word plays important role for empathizing in the listener utterances. By majority voting, the final verdict on each annotation is decided. We compute the inter-annotator agreement on annotation of test sets for **KofLU** through Fleiss' kappa ($\boldsymbol{\kappa}$) (Fleiss and Cohen, 1973), and result in 0.55, where $0.4 < \boldsymbol{\kappa} < 0.6$ indicates moderate agreement.

5 The Emp-RFT Model

In this section, we detail Emp-RFT whose overall architecture is shown in Figure 2.

5.1 Context Encoding

Word-Level Encoder. Emp-RFT contains an encoder $f_\theta(\cdot)$ which has the six-layer encoder of BART (Lewis et al., 2020) as the backbone and extracts feature vectors of each u^i. Inspired by BERT (Devlin et al., 2019), we prefix each utterance with a $[SEN]$ token, so $u_0^i = [SEN]$. Then, each token

---

[1] A dialogue has a (post, response) pair, and words which cause each CM are annotated on each dialogue.

[2] We use pairs whose PMI ≥ 1. The pairs whose tail words are stopwords or punctuations, are removed.

is represented as emb_j^i, the sum of the following four embeddings: word embedding, position embedding, role embedding and emotion embedding $M_e \in \mathbb{R}^{n_{emo} \times d}$ [3]. Then, the encoder transforms each utterance into a list of output hidden states:

$$[\hat{h}_0^i, ..., \hat{h}_{|u^i|}^i] = f_\theta([emb_0^i, ..., emb_{|u^i|}^i]), \qquad (1)$$

where $\hat{h}_j^i \in \mathbb{R}^d$. For each utterance, we can obtain utterance-level meaning vector $\hat{h}_0^i$ derived from the token $[SEN]$, concatenated keyword vectors $\hat{k}^i \in \mathbb{R}^{|k^i| \times d}$ derived from the tokens corresponding to k_p^i (p is the index for keywords.), and emotion vector $\hat{e}^i = M_e \hat{h}_0^i$.

Feature Transition Recognizer. Emp-RFT has a component that operates as the process illustrated in Figure 3. The component computes feature transition information between feature vectors, utilizing two comparison functions, subtraction and multiplication of Wang and Jiang (2017). Each feature vector is compared to previous two feature vectors [4]. First, emotion transition information eti^i is computed:

$$eti^i = \text{ReLU}(W_{eti}(f_{com}(\hat{e}^i, \hat{e}^{i-1}, \hat{e}^{i-2}))), \qquad (2)$$

$$f_{com}(\hat{e}^i, \hat{e}^{i-1}, \hat{e}^{i-2}) = \begin{bmatrix} (\hat{e}^i - \hat{e}^{i-1}) \odot (\hat{e}^i - \hat{e}^{i-1}) \\ \hat{e}^i \odot \hat{e}^{i-1} \\ (\hat{e}^i - \hat{e}^{i-2}) \odot (\hat{e}^i - \hat{e}^{i-2}) \\ \hat{e}^i \odot \hat{e}^{i-2} \end{bmatrix}, \qquad (3)$$

where f_{com} and $\odot$ each denote our transition information computing function and Hadamar product, and $W_{eti} \in \mathbb{R}^{d \times 4n_{emo}}$. Next, utterance-level meaning transition information uti^i is computed:

$$uti^i = \text{ReLU}(W_{uti}(f_{com}(\hat{h}_0^i, \hat{h}_0^{i-1}, \hat{h}_0^{i-2}))), \qquad (4)$$

where $W_{uti} \in \mathbb{R}^{d \times 4d}$. We then obtain enhanced utterance vector of each utterance by integrating utterance-level meaning vector, and emotion and utterance-level meaning transition information:

$$\bar{h}^i = \text{FC}_{utt}([\hat{h}_0^i; eti^i; uti^i]), \qquad (5)$$

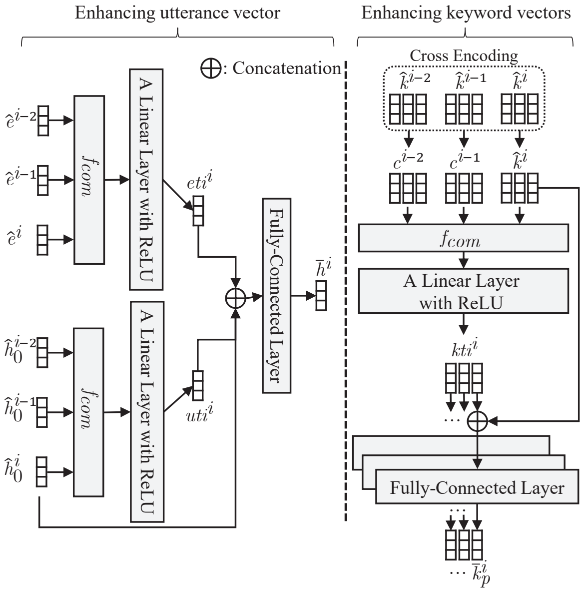

Figure 3: Operation process of feature transition recognizer.

where FC_{utt} is a fully-connected layer with size of d. In addition, keyword transition information kti^i is computed between concatenated keyword vectors and cross-encoded vectors c^t, where $t \in \{i-1, i-2\}$:

$$kti^i = \text{ReLU}(W_{kti}(f_{com}(\hat{k}^i, c^{i-1}, c^{i-2}))^T), \qquad (6)$$

$$c^t = \text{softmax}(Q^i (K^t)^T) \hat{k}^t, \qquad (7)$$

$$Q^i = \hat{k}^i W_Q, K^t = \hat{k}^t W_K, \qquad (8)$$

where $W_{kti} \in \mathbb{R}^{d \times 4d}$, W_Q and $W_K \in \mathbb{R}^{d \times d}$. We can obtain enhanced keyword vector of each keyword by integrating keyword vector, and keyword transition information:

$$\bar{k}_p^i = \text{FC}_{key}([\hat{k}_p^i; kti_p^i]), \qquad (9)$$

where FC_{key} is a fully-connected layer with size of d. Consequently, the enhanced feature vectors guide Emp-RFT to accurately grasp the features of utterance that the model should be attentive to when given feature transition information.

Utterance-Level Encoder. Emp-RFT contains another encoder $g_\phi(\cdot)$ which has the six-layer encoder of BART, and transforms enhanced utterance vectors with global position embeddings (GPE) into a context representation to capture relationships between utterances (Gu et al., 2021):

$$[\ddot{h}^1, ..., \ddot{h}^{n-1}] = g_\phi([\bar{h}^1, ..., \bar{h}^{n-1}]). \qquad (10)$$

Emp-RFT consists of hierarchical structures of encoders through word-level and utterance-level encoders. This structure makes Emp-RFT comprehend each utterance at the fine-grained level, and

---

[3] j, d, and n_{emo} each denote the index for words, hidden size, and the number of emotion classes. The role and emotion embbedings are each for distinguishing two interlocutors and for incorporating the emotion into each utterance.

[4] If there aren't previous feature vectors, we can obtain those by regarding first output hidden state of a padded utterance as utterance and keyword vectors (Qiu et al., 2020).

understand the context by integrating information based on comprehension of each utterance.

Fusing Context with Keywords. Emp-RFT fuses context with keywords as the process illustrated in Figure 4. We first dynamically build keyword graph for each context. Keywords in each context become nodes and are initialized by corresponding enhanced keyword vectors with GPE. Edges are built across the below cases: (1) between two keywords from the same utterance and (2) between a keyword from a certain utterance and another keyword from the previous two utterances. Also, a tail word in a kp whose head word is k_p^{n-1} is appended as a node and connected with k_p^{n-1} node. Appended nodes (ANs) are initialized through BART decoder whose parameters are frozen with GPE, and used for next keywords detection. To obtain keyword representation $\hat{v}_o^i$ from the keyword graph(o is the index for nodes.), nodes are updated based on multi-head graph-attention mechanism (Veličković et al., 2018; Li et al., 2022). This mechanism makes Emp-RFT not only capture relationships between nodes but also manage influences of each appended node through attention architecture:

$$\hat{v}_o^i = v_o^i + \overset{MH}{\underset{mh=1}{\Big\|}} \sum_{z \in A_o^i} \alpha_{oz}^{i,mh}(W_v^{mh} v_z), \tag{11}$$

$$\alpha_{oz}^{i,mh} = \frac{\exp((W_q^{mh} v_o^i)^T W_{key}^{mh} v_z)}{\sum_{s \in \mathcal{A}_o^i} \exp((W_q^{mh} v_o^i)^T W_{key}^{mh} v_s)}, \tag{12}$$

where v_o^i, $\|$, A_o^i, and $\alpha_{oz}^{i,mh}$ each denote a node representation, the concatenation of MH attention heads, the neighbours of v_o^i in the adjacency matrix A, and self-attention weight and W_v^{mh}, W_q^{mh}, $W_{key}^{mh} \in \mathbb{R}^{d_{mh} \times d}$ ($d_{mh} = d/MH$). Lastly, we can obtain the fused context representation $H = [h^1, ..., h^{n-1}]$ by fusing the context representation with the sum of keyword representations:

$$h^i = \mathrm{FC}_{fuse}([\ddot{h}^i; \mathrm{sum}([\hat{v}_1^i, ..., \hat{v}_{|k^i|}^i])]), \tag{13}$$

where FC_{fuse} is a fully-connected layer with size of d. Consequently, keywords are emphasized within each utterance and get greater attention when generating responses.

Next Emotion and Keywords Detection. Emp-RFT detects next emotion e^y and keywords k^y, which helps figure out proper emotion and keywords for generation. First, based on the max-pooled fused context representation, next emotion distribution is predicted:

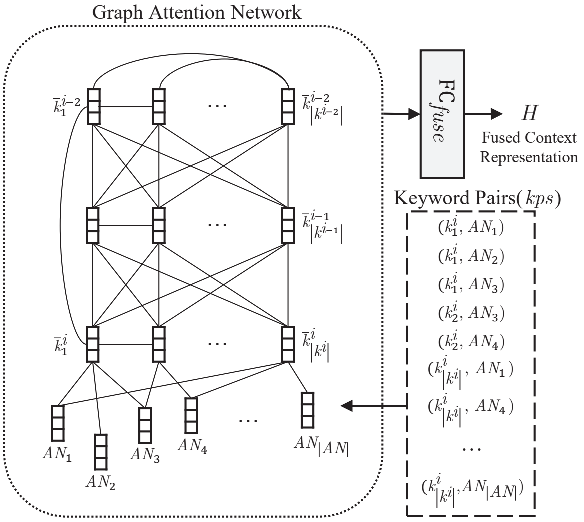

Figure 4: Operation process of fusing context with keywords. AN_o is the appended node. Some symbols and edges are omitted for simplicity.

$$P_e = \mathrm{softmax}(M_e \mathrm{MP}(H)), \tag{14}$$

where MP denotes maxpooling. We use the emotion with the highest probability ($\hat{e}^y$) for generation. Also, Emp-RFT predicts whether the word of each AN belongs to the next keywords through the binary classification, where the true label denotes the word belongs to:

$$P_k = \prod_{o=1}^{|ANs|} \mathrm{softmax}(W_{AN}[\hat{v}_o^n; \mathrm{MP}(H)]), \tag{15}$$

where $W_{AN} \in \mathbb{R}^{2 \times 2d}$. We consider the words of ANs whose probabilities for the true label ≥ 0.8 as the keywords ($\hat{k}^y$) for generation.

5.2 Response Generation

Response Generator. Emp-RFT includes a response generator (RG) which has the six-layer decoder of BART as the backbone. Through the four embeddings with $\hat{e}^y$, explained previously, we can obtain the input sequence embedding for RG. We prefix it with the sum of node representations corresponding to $\hat{k}^y$. Then, RG is fed to predict probability distribution on each next token y_t based on the fused context representation:

$$P(y|con, e, k, kps) = \prod_{t=1}^{m} P(y_t|y_{<t}, H). \tag{16}$$

Training. We apply cross-entropy loss to three objectives (eq. 14, 15, 16), and train parameters of

Emp-RFT in end-to-end manner through the sum of all losses .

Contrastive PPLM. Analysis on the generated responses of the trained Emp-RFT shows that an active reflection of $\hat{k}^y$ is demanded. Thus, inspired by Dathathri et al. (2020); Chen et al. (2020), we propose Contrastive PPLM with a discriminator using contrastive loss. Existing discriminators (Dathathri et al., 2020; Majumder et al., 2021) are trained to predict whether a sentence contains a certain attribute, using cross-entropy loss. Then, the gradient of the loss is passed to the generative model to generate a sentence containing such attribute during inference. However, since keywords are not attributes but objects, we train a discriminator to predict whether a response in EmpatheticDialogues is more similar to the keyword set of the response(positive sample) than the keyword sets of another responses(negative samples) in the same batch, using contrastive loss based on the similarity between objects:

$$L^{a}_{pplm} = -\log \frac{\exp(r_a^T ks_a/\tau)}{\sum_{b=1}^{B} \exp(r_a^T ks_b/\tau)}, \tag{17}$$

where r,ks,τ and B each denote response and keyword set representations, a temperature parameter and batchsize. During inference, we repeatedly sample three random ANs except for nodes of $\hat{k}^y$, and consider the sum of such AN representations as one of negative samples and the sum of node representations corresponding to $\hat{k}^y$ as a positive sample. Then, the gradient of the contrastive loss is passed to Emp-RFT.

6 Experiments

6.1 Dataset and Baselines

Dataset. Experiments were conducted on EmpatheticDialogues (Rashkin et al., 2019) which contains 24,850 multi-turn dialogues. For each dialogue, we can extract a certain number of instances corresponding to the number of turns within the dialogue. This totals to 47,611 instances, where 22,761 are multi-turn. In one turn of a dialogue, a speaker talks about one of 32 evenly distributed emotion labels and a situation related to the emotion label and a listener empathizes by responding to the speaker. Following the instructions of the dataset, we use 8:1:1 train/valid/test split.

Baselines. We compared Emp-RFT to the following five baseline models: (1) **MoEL** (Lin et al., 2019) is a transformer-based generative model, which has decoders for each emotion and integrates outputs of the decoders according to predicted emotion distribution. (2) **EmpDG** (Li et al., 2020) uses emotional words and consists of an adversarial framework including a generator and discriminators which reflect the user feedback. (3) **MIME** (Majumder et al., 2020) is also a transformer-based generative model which mimics user emotion based on emotion grouping and uses stochastic sampling for varied responses. (4) **MIME+Focused S1** and (5) **Blender+Focused S1** (Kim et al., 2021) attach RSA Framework to MIME and Blender (Roller et al., 2021). Blender is a pretrained model with 90M parameters size, using an immense number of dialogues. It is finetuned on EmpatheticDialogues. Using distractors and Bayes' Rules, RSA Framework makes the models focus on certain parts of the post, such as emotion cause words when generating responses in the single-turn dialogues [5]. Implementation details about Emp-RFT and baselines are covered in Appendix A.1.

6.2 Evaluation Metrics

Automatic Evaluation. We evaluated the models, using the following three metrics: (1) Perplexity (**PPL**) (Vinyals and Le, 2015) measures how highly likely tokens are generated, which evaluates the overall quality of the model. (2) Distinct-n (**Dist-n**) (Li et al., 2016) measures how diverse the generated response is via the unique words within its n-gram. (3). We use BERTscore (**$\mathbf{F_{BERT}}$**) (Zhang et al., 2019) which measures token-level semantic similarities between the generated response and the gold response based on embeddings from BERT (Devlin et al., 2019).

Human Ratings. Human evaluations for the dialogues models are essential because of insufficient reliability on automatic metrics. We randomly sampled 100 test dialogues and asked 3 human workers to score models' generated responses on 1 to 5 point scale, following the four metrics (Rashkin et al., 2019): (1) **Empathy** measures whether the generated response understands the speaker's emotion and situation. (2) **Relevance** measures whether the generated response is coherent to the context. (3) **Fluency** measures whether the generated response is grammatically correct and readable. (4) Since we conclude that models generating generic responses are not empathizing to the speaker, we

---

[5] To make the models work in the multi-turn dialogues, the models are converted to take several utterances and to focus on emotion cause words of the last utterance.

Method	Automatic Evaluation				Human Evaluation

Table 3: Results of human A/B test. The results in front of and behind '/' are each on all instances and multi-turn instances. Fleiss' kappa (κ) denotes agreements among human workers, where $0.4 < \kappa < 0.6$ and $0.6 < \kappa < 0.8$ indicate moderate and substantial agreements, respectively.

use **Diversity** to measure whether the generated response is non-generic.

Human A/B Test. We further conducted a human A/B test which provides stronger intuitions and higher agreements than human ratings, because this is carried with 3 human workers selecting the better response when given two generated responses (Sabour et al., 2021).

6.3 Analysis of Response Generation

We abbreviate feature transition recognizer, contrastive PPLM, next emotion and keywords detection, and fusing context with keywords as FTR, CP, NEKD, and FCK, respectively.

Automatic Evaluation Results. The overall automatic evaluation results are shown in the left part of Table 2. Emp-RFT performed exceedingly on all metrics except for PPL, which was nearly the same as Blender+Focused S1. The improvements on other metrics indicated that our approach was effective for generating generally high quality and non-generic responses which were also semantically similar with the gold response. While the utilization of pretrained models yielded significant improvements compared to models only trained on EmpatheticDialogues, Emp-RFT showed even greater performance when compared to Blender+Focused S1 endowed with more significant number of dialogues. In addition, due to utilization of FTR, Emp-RFT obtained remarkable results even on multi-turn instances, whereas, other models suffered due to their means of utilizing features for the context at the coarse-grained level.

Human Evaluation Results. In the right part of Table 2, Emp-RFT acquired the highest scores on all metrics, which demonstrated that all components of Emp-RFT helped generate responses that are empathetic, coherent to the context, and non-generic. Also, utilizing pretrained models showed significant improvements, especially on Fluency and Diversity scores. In Table 3, the generated responses from Emp-RFT were more preferred, which indicated Emp-RFT consistently outperformed other methods in various experiments. When observing at the models' performance difference between multi-turn instances and all instances, only Emp-RFT continued to perform consistently, whereas other models showed significant perfor-

Method	Top-1 Acc	Top-5 Acc	macro-F1
CoMAE	41.12	80.09	39.61
Emp-RFT	**42.08**	**80.78**	**40.39**

Method	TL-P	TL-R	TL-F1
ConceptFlow	37.68	48.27	42.32
CG-nAR	44.62	61.94	51.87
Emp-RFT	**45.35**	**63.15**	**52.78**

Table 4: The results of next emotion(top) and keywords(bottom) detection. We used the metrics introduced in Table 1.

mance drops under multi-turn instances. From this, we concluded that Emp-RFT continuously understood the dialogue flow.

Ablation Study. To better understand effects of each component in Emp-RFT, we conducted the ablation study. We gradually ablated each component within the response generation strategy in a hierarchical manner. (1) **w/o FTR**: Feature transition recognizer was disabled, which resulted in considerable drops on all metrics, especially on PPL, $\mathrm{F_{BERT}}$, Empathy, and Relevance scores on multi-turn instances, because Emp-RFT could not grasp the attention-needed features of utterance within multi-turn instances through FTR. (2) **w/o CP**: Contrastive PPLM was removed, which caused lower Dist-n and Diversity scores, because Emp-RFT could not actively use various $\hat{k}^y$ when generating responses through CP. (3) **w/o (CP+NEKD)**: Next emotion and keywords detection were disabled, which interfered with Emp-RFT's utilization of the next emotion and keyword. It droped not only Dist-n and Diversity scores but also other metrics. (4) **w/o (CP+NEKD+FCK)**: Fusing the context representation with keyword representations was disregarded. Since keywords were no longer emphasized for context modelling, such information could not get more attention when generating responses. It caused drops on all metrics, particularly on $\mathrm{F_{BERT}}$, Dist-n, and Diversity.

6.4 Analysis of Next Emotion and Keywords

We report the results in terms of NEKD in Table 4. Since all baselines have not conducted NEKD, we trained models showing promising results such as **CoMAE** (Zheng et al., 2021), **ConceptFlow** (Zhang et al., 2020) and **CG-nAR** (Zou et al., 2021) with EmpatheticDialogues. (More details are covered in Appendix A.2). Then, we compared Emp-RFT to those models. Emp-RFT outperformed other models on all metrics, which proved Emp-RFT figured out which emotion and keywords were proper for generation.

Emotion Label: Furious
Annotated Emotion: Annoyed → Apprehensive → Confident → Hopeful
u^1: My roommate eats my food sometimes. This makes me so angry!
u^2: You should get a mini fridge and put it in your room, with a lock on it.
u^3: I think that's a great idea. I know where to get those fridges for cheap.
Gold: Yea man go for it, don't procrastinate.

MoEL: I am sorry you have to hear that. I hope it works out for you.
EmpDG: I agree with you. I think it isn't worth before you get it back.
MIME: I am sorry to hear that. I hope you don't have to deal with that.
MIME+Focused S1: I agree. I have a friend who is not to be a parent.
Blender+Focused S1: Roommates can be so annoying.

$\hat{e}^y$: Trusting, $\hat{k}^y$: procrastinate, safety, profit
Emp-RFT: Don't procrastinate. It makes your foods safety.
w/o FTR: I agree. I have a safety but pricy fridge.

Emotion Label: Proud
Annotated Emotion: Trusting → Proud → Grateful→ Sentimental → Disappointed → Sentimental
u^1: Hi, My girlfriend was recently let go of her job, but she put so much work in to finding a new job and got one with better pay!
u^2: That's great! It was meant to happen then.
u^3: Yes I agree, she was so happy when she found out the job was hers.
u^4: I would have been too. I've never been fired. I always quit.
u^5: She wasn't really fired, her position was no more. Schools don't have much room left for Home Ec teachers. Sad.
Gold: I remember taking Home Ec. I loved that class.

MoEL: I am sorry to hear that. I hope you can find a new job.
EmpDG: I am sorry you had that. I am not a fan of the past few years ago. I am not sure she had a close relationship.
MIME: I am sorry to hear that. I hope you find a new job.
MIME+Focused S1: I am sorry to hear that. I hope you find a new job.
Blender+Focused S1: She was paid for her hard work.

$\hat{e}^y$: Sentimental, $\hat{k}^y$: Ec, class, jobs, solution, remember
Emp-RFT: I remember the Ec class. It's a relief for her to find the job.
w/o FTR: I'm glad she found the solution to the job problem.

Emotion Label: Caring
Annotated Emotion: Annoyed → Caring → Sad→ Caring
u^1: My poor neighbor is suffering a lot without her husband.
u^2: I suffer a lot too when my wife is gone. What happened to him?
u^3: He passed away from cancer.
Gold: Ah, the evil cancer. Took my grandmother as well. I am sure he's off in a better place now.

$\hat{e}^y$: Sad, $\hat{k}^y$: condolences, cancer, grandmother, evil, lost
Emp-RFT: My condolences. I lost my grandmother because of the cancer.
w/o CP: I'm sorry to hear that. It's so hard to lost someone.
w/o (CP+NEKD): Oh no. I'm scary to get the cancer.
w/o (CP+NEKD+FCK): Oh no. I'm sorry to hear that.

Table 5: Model generations. The words marked in red and blue are keywords of the speaker utterance and listener utterance, respectively.

6.5 Case Study

The cases from the models are shown in Table 5. In the first case, MoEL and MIME expressed regret, which was emotionally inappropriate to the context. All baselines except for MoEL failed to grasp the proper features within the context, and therefore generated incoherent responses. Especially, Blender+Focused S1 ignored the features of u^3. Since Emp-RFT understood the dialogue flow, it became attentive to not only the features of u^3 but also those of u^1, u^2, mentioning ('procrastinate', 'foods', 'safety'), which led to empathy and coherence. In the second case, all baselines couldn't understand the longer context, which resulted in improper empathy. Also, Blender+Focused S1 disregarded the features of u^5, and therefore overlooked the speaker's sadness. Emp-RFT fully comprehended why the speaker's happiness changed to the sadness. In both cases, without FTR, the responses of Emp-RFT were non-empathetic and incoherent because of dismissing appropriate features. In the third case, we report the case in terms of the response generation strategy. Without CP, NEKD, and FCK, Emp-RFT produced a generic response. With the utilization of FCK, Emp-RFT perceived the word 'cancer' in u^3 but expressed excessive emotion by mentioning 'scary'. When Emp-RFT additionally conducted NEKD, Emp-RFT generated emotionally appropriate responses by mentioning 'sorry' and 'hard', and utilized the keyword 'lost'. Lastly, with CP, Emp-RFT generated a diverse response, actively using $\hat{k}^y$.

7 Conclusion

We proposed a novel approach that recognizes feature transitions between utterances, which led to understanding the dialogue flow and grasping the features of utterance that needs attention. Also, to make our model focus on emotion and keywords related to appropriate features, we introduced a response generation strategy including fusing context with keywords, next emotion and keywords detection, and contrastive PPLM. Experimental results showed that our model outperformed baselines, and especially, achieved significant improvements on multi-turn instances, which proved our approach was effective for empathetic, coherent, and non-generic response generation.

8 Ethical Considerations

We expect that our proposed approach does not suffer from ethical problems. The dataset we use in our work is EmpatheticDialogues which is English-based. The dataset is constructed by crowdsourcing with Amazon Mechanical Turk, which protects private user information (Rashkin et al., 2019). In addition, the dialogue dataset is anticipated not to have responses which include discrimination, abuse, bias, etc, because the robust collection procedure of EmpatheticDialogues ensures the quality of the dataset. Thus, we expect that models trained using the dataset, do not generate inappropriate responses which harm the users. However, we inform that our model utilizes a pretrained language model, which may produce inappropriate responses. Lastly, we anticipate our model make potential users be interested and consoled by generating empathetic responses.

A Implementation Details

A.1 Empathetic Response Generation Models

We use the official codes of all baselines, and follow the implementations (MoEL [6], EmpDG [7], MIME [8], MIME+Focused S1 and Blender Focused S1 [9]). Our model is implemented by Pytorch [10], and based on two encoders of BART-base and a decoder of BART-base [11]. Hidden size d is 768 and the number of emotion classes n_{emo} is 32. MH and the number of layers of graph attention network are each 4. Using Adam optimization (Kingma and Ba, 2015), our model is trained on single RTX 3090 GPU with a batch size of 4. We apply early-stopping and select a model showing the best performance through perplexity on the valid set. For contrastive PPLM, we utilize the official code of PPLM [12]. We set a temperature parameter τ and batch size to 0.5 and 64, respectively. Through represenations derived from the last token of BART decoder whose parameters are frozen, we can obtain each response representation r_a and each keyword set representation ks_a, where the keyword set corresponds to the response. Thus, ks_a becomes a positive sample for r_a, and keyword set representations for other responses in the same batch become negative samples.

A.2 Next Emotion and Keywords Detection

We utilize the repositories and follow implemetation details of CoMAE [13], ConceptFlow [14], and CG-nAR [15]. We train three models, using EmpatheticDialogues instead of originally used datasets.

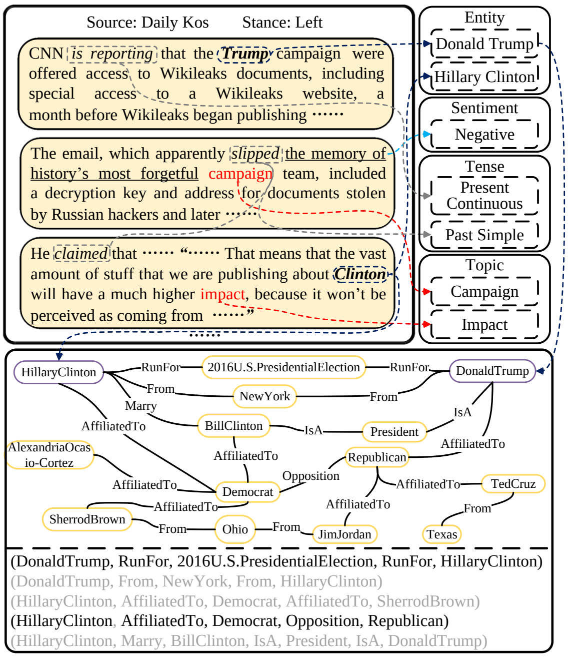
Abstract

Political perspective detection has become an increasingly important task that can help combat echo chambers and political polarization. Previous approaches generally focus on leveraging textual content to identify stances, while they fail to reason with background knowledge or leverage the rich semantic and syntactic textual labels in news articles. In light of these limitations, we propose KCD, a political perspective detection approach to enable multi-hop knowledge reasoning and incorporate textual cues as paragraph-level labels. Specifically, we firstly generate random walks on external knowledge graphs and infuse them with news text representations. We then construct a heterogeneous information network to jointly model news content as well as semantic, syntactic and entity cues in news articles. Finally, we adopt relational graph neural networks for graph-level representation learning and conduct political perspective detection. Extensive experiments demonstrate that our approach outperforms state-of-the-art methods on two benchmark datasets. We further examine the effect of knowledge walks and textual cues and how they contribute to our approach's data efficiency.

1 Introduction

Political perspective detection aims to identify ideological stances of textual data such as social media posts and news articles. Previous approaches generally leverage the textual content of news articles with various text modeling techniques to identify political stances. Those works (Jiang et al., 2019; Li and Goldwasser, 2019, 2021; Feng et al., 2021a) leveraged diversified text models, such as recurrent neural networks (Yang et al., 2016), word embedding techniques (Pennington et al., 2014; Peters et al., 2018), convolutional neural networks (Jiang et al., 2019), and pre-trained language models (Devlin et al., 2019; Liu et al., 2019), to encode news paragraphs and classify them into different perspective labels. Later approaches incorporate information sources beyond text to facilitate argument mining and boost task performance. News discussion on social networks (Li and Goldwasser, 2019), social and linguistic information about news articles (Li and Goldwasser, 2021), media sources and information (Baly et al., 2020) as well as external knowledge from knowledge graphs (Feng et al., 2021a) are introduced in the task of political perspective detection and achieve better performance.



CNN *is reporting* that the ***Trump*** campaign were offered access to Wikileaks documents, including special access to a Wikileaks website, a month before Wikileaks began publishing ……

The email, which apparently *slipped* the memory of history's most forgetful campaign team, included a decryption key and address for documents stolen by Russian hackers and later ……

He *claimed* that …… "…… That means that the vast amount of stuff that we are publishing about ***Clinton*** will have a much higher impact, because it won't be perceived as coming from ……"

article from Daily Kos[1]. This article discusses remarks from the Trump campaign team about Wikileaks and its effect on Hillary Clinton's bid for president. Individuals often rely on the multi-hop reasoning that Clinton and Trump are from opposite political parties and run against each other to inform their perspective analysis process. Besides, the negative sentiment expressed in satiric tones and the quotation of Trump campaign staff also give away the author's denial and left-leaning perspective. That being said, knowledge reasoning and implicit textual indicators are essential in the news bias detection process.

In light of these limitations, we propose a political perspective detection framework **KCD** (**K**nowledge Walks and Textual **C**ues Enhanced Political Perspective **D**etection). Specifically, KCD generates multi-hop knowledge walks, aggregates them based on semantic relevance and incorporates them in textual representations with multi-head attention. KCD then constructs a heterogeneous information network to jointly model knowledge-enriched news content and diversified textual cues as paragraph-level labels. Finally, KCD learns graph representations with relational graph neural networks and conduct perspective detection with different aggregation strategies. Our main contributions are summarized as follows:

- We propose knowledge walks, a strategy to incorporate multi-hop knowledge reasoning in textual representations for knowledge-aware political perspective detection.
- We propose to construct a heterogeneous information network to represent news articles, which jointly models knowledge-enriched news content and implicit textual cues in news articles.
- Extensive experiments demonstrate that our approach consistently outperforms state-of-the-art methods on two widely adopted benchmarks. Further analysis bears out the necessity of knowledge walks and textual cues in our approach.

2 Related Work

2.1 Political Perspective Detection

Political perspective detection aims to identify the ideological stances of news articles, which is widely studied to help strengthen the online information landscape (Li and Goldwasser, 2019) and mitigate ideological echo chambers (Li and Goldwasser, 2021; Feng et al., 2021a). Early approaches leverage text analysis techniques for bias detection, such as sentiment analysis (Jiang et al., 2011; Wang et al., 2017), bias feature extraction (Horne et al., 2018), word embeddings (Jiang et al., 2019; Li and Goldwasser, 2019), and different neural network architectures (Augenstein et al., 2016; Du et al., 2017; Xu et al., 2018; Yang et al., 2016; Jiang et al., 2019; Feng et al., 2021b; Li and Goldwasser, 2021; Feng et al., 2021a). In addition to textual content of news articles, social media users also become the focus of perspective detection research (Bel-Enguix et al., 2021). User interactions (Magdy et al., 2016), user clustering (Darwish et al., 2020), and label propagation (Stefanov et al., 2020) are leveraged to identify the ideological preferences on social media. Fusing both news text and social network analysis directions, Li and Goldwasser (2019) propose to enrich news text with the content and structure of social media discussions about these news articles. Recent state-of-the-art approaches chart a new path by incorporating social and political external knowledge into stance detection. Baly et al. (2020) propose adversarial media adaptation and leverage source background knowledge for political perspective detection. Li and Goldwasser (2021) combine language encoders with pre-training tasks of social and linguistic information. Feng et al. (2021a) propose to construct and leverage political knowledge graphs as domain-specific external knowledge. In this paper, we build on these works to examine and explore the effect of multi-hop knowledge reasoning and diversified textual cues in the task of political perspective detection.

2.2 Knowledge Graph in NLP

Knowledge graphs (KGs) are effective representations of real-world entities, relations, and knowledge. Generic (Fellbaum, 2010; Pellissier Tanon et al., 2020; Bollacker et al., 2008; Speer et al., 2017) and domain-specific KGs (Feng et al., 2021a; Chang et al., 2020) are widely adopted in NLP tasks as external knowledge sources. These approaches could mainly be categorized into feature extraction, language model and graph-based methods. For feature extraction approaches, KG embedding technique TransE (Bordes et al., 2013) is leveraged to learn features for knowledge injecton (Ostendorff et al., 2019; Hu et al., 2021). For language model approaches, the adapter architecture is leveraged

---

[1] https://www.dailykos.com/

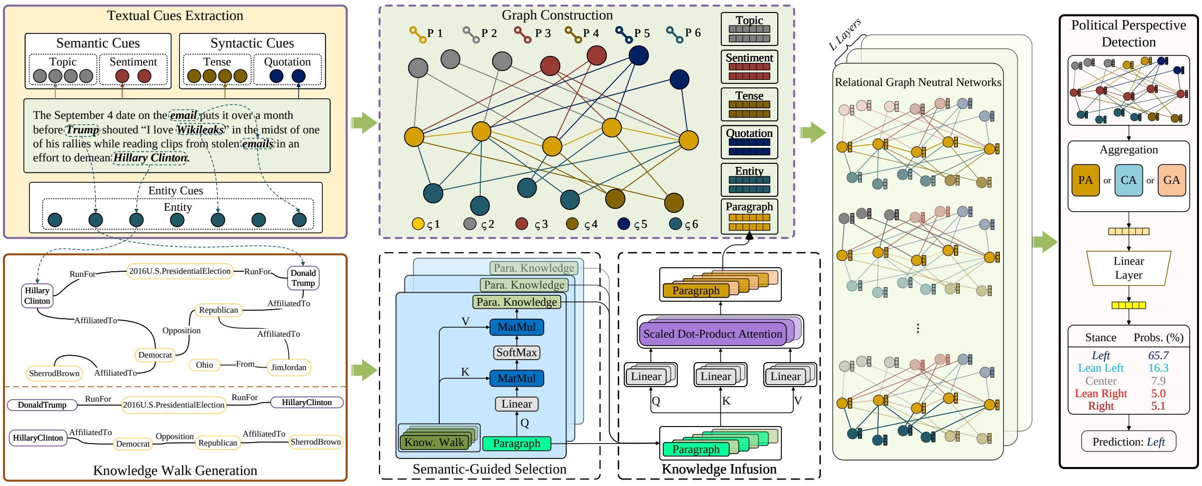

Figure 2: Overview of our proposed framework KCD.

to fine-tune on KG-related tasks (Majewska et al., 2021; Meng et al., 2021; Wei et al., 2021). In addition, Wang et al. (2021) propose a unified model to combine knowledge embedding with language representation pre-training. For graph-based approaches, KG entities and relations are injected into graphs and heterogeneous information networks (Hu et al., 2021; Feng et al., 2021a; Lu et al., 2021). Graph neural networks are then adopted to learn knowledge-aware text representations. In this paper, we propose knowledge walk, a novel strategy to infuse multi-hop knowledge reasoning into language representations and apply them in political perspective detection.

3 Methodology

Figure 2 presents an overview of our proposed political perspective detection framework **KCD** (**K**nowledge Walks and Textual **C**ues Enhanced Political Perspective **D**etection). We firstly generate knowledge walks on the external knowledge graph. These knowledge walks are then selected based on semantic relevance and injected into textual representations with multi-head attention. We then construct a heterogeneous information network to jointly model knowledge-enriched news content and diversified textual cues as paragraph-level labels and supernodes. Finally, we adopt relational graph neural networks and different aggregation strategies to learn graph-level representation and conduct political perspective detection.

3.1 Knowledge Walks and Infusion

We firstly propose the novel strategy of knowledge walks and combine them with textual representations to enable multi-hop knowledge reasoning. We partition an n-paragraph news document into different paragraphs and denote them as $\mathcal{S} = \{s_1, ..., s_n\}$. We encode each paragraph by averaging the the embeddings of words from pre-trained RoBERTa (Liu et al., 2019):

$$v_i^s = RoBERTa(s_i), \quad 1 \leq i \leq n \qquad (1)$$

We use a political knowledge graph[2] as external knowledge for perspective detection. Let the i-th triple in the knowledge graph be (e_{ih}, r_i, e_{it}), where e_{ih} and e_{it} denote the head and tail entity and r_i represents the relation of the i-th triple.

3.1.1 Knowledge Walk Generation

We firstly use TagMe (Ferragina and Scaiella, 2012) to identify mentioned KG entities in each paragraph s_i. For each mentioned entity, we use it as the starting point $e_{(0)}$ in a K-hop knowledge walk:

$$kw_i = \{e_{(0)}, r_{0,1}, e_{(1)}, ..., r_{K-1,K}, e_{(K)}\} \qquad (2)$$

where $e_{(i-1)}$ and $r_{i-1,i}$ denote the i-th triple's head entity and relation. Specifically, a knowledge walk is generated by adopting biased random walk of length K starting from $e_{(0)}$. The conditional probability of arriving at $e_{(i)}$ from $e_{(i-1)}$ through $r_{i-1,i}$ is formulated as

$$P(e_{(i)}|e_{(i-1)}, r_{i-1,i}) = \frac{exp(p(r_{i-1,i}))}{\sum_{j=1}^{|N_r(i-1)|} exp(p(r_j))} \qquad (3)$$

---

[2] https://github.com/BunsenFeng/news_stance_detection

where $N_r(i-1)$ denotes the neighboring relations of $e_{(i-1)}$, $p(r)$ is the importance score of KG relation r, which could be tuned by domain experts for human-in-the-loop knowledge walk generation. In this way, we generate multiple knowledge walks for each paragraph based on its mentioned entities, which models the multi-hop reasoning process with external knowledge.

3.1.2 Semantic-Guided Selection

After obtaining multiple knowledge walks for a single news paragraph, we propose a selection and aggregation process guided by textual content to differentiate essential knowledge walks from the irrelevant ones. We firstly transform each knowledge walk kw_i into a sentence t_i by concatenating the textual description of entities and relations. We then encode the knowledge walk sentence t_i with pre-trained RoBERTa (Liu et al., 2019):

$$v_i^k = RoBERTa(t_i) \tag{4}$$

Suppose a total of m knowledge walks $\{kw_{i,j}\}_{j=1}^m$ are generated for paragraph s_i, we then aggregate their knowledge walk sentence embeddings $\{v_{i,j}^k\}_{j=1}^m$ as follows:

$$v_i^p = \sum_{j=1}^{m} \frac{exp(\alpha \cdot v_{i,j}^k)}{\sum_{q=1}^m exp(\alpha \cdot v_{i,q}^k)} v_{i,j}^k \tag{5}$$

where α denotes the learnable attention vector guided by paragraph semantics:

$$\alpha = \phi(W_a v_i^s + b_a) \tag{6}$$

where W_a and b_a are learnable parameters of the attention module and we use Leaky-ReLU for ϕ. v_i^s is the sentence embedding from equation 1. In this way, we aggregate m knowledge walks based on semantic relevance to the paragraph to filter and retain important knowledge reasoning paths.

3.1.3 Knowledge Infusion

After representing multi-hop knowledge reasoning for paragraph s_i with v_i^p, we conduct document-wise multi-head self-attention to infuse knowledge walks into textual representations v_i^s. We concatenate knowledge walk and text representations:

$$T = concat([v_1^s, v_1^p, ..., v_n^s, v_n^p]) \tag{7}$$

where T is the input for multi-head self-attention:

$$\tilde{T} = MultiHead(Q, K, V) \tag{8}$$

where $Q = K = V = T$ and the output $\tilde{T} = concat([\tilde{v_1^s}, \tilde{v_1^p}, ..., \tilde{v_n^s}, \tilde{v_n^p}])$. In this way, we obtain language representations of news paragraphs $\{\tilde{v_i^s}\}_{i=1}^n$, which jointly models textual content and related multi-hop knowledge reasoning paths.

3.2 Textual Cues and Graph Construction

We construct a heterogeneous information network (HIN) as in Figure 2 “Graph Construction“ to jointly represent knowledge-enriched news content and diversified textual cues in news articles. Specifically, we use paragraph nodes to represent the news content and connect them with different paragraph-level labels with heterogeneous edges. Firstly, for paragraph nodes:

$\mathcal{V}1$ and $\mathcal{R}1$: Paragraph Nodes We use one node in $\mathcal{V}1$ to represent each paragraph in the news article to partition the entire document and allow fine-grained analysis. We adopt the knowledge-enriched representations $\{\tilde{v_i^s}\}_{i=1}^n$ in Section 3.1 as initial node features for $\mathcal{V}1$. We then use relation $\mathcal{R}1$ to connect adjacent paragraphs to preserve the original flow of the news article.

3.2.1 Semantic Cues

We further analyze the topic and sentiment of news paragraphs, extract paragraph-level labels and inject them into our news HIN structure.

$\mathcal{V}2$ and $\mathcal{R}2$: Topic Cues The topics and frequent topic switching in news articles often give away the stance and argument of authors. We train LDA to extract the topics in each political perspective detection corpus and use one node to represent each topic. We then encode the topic text with pre-trained RoBERTa as node attributes. We then use $\mathcal{R}2$ to connect each paragraph node in $\mathcal{V}1$ with its affiliated topic node in $\mathcal{V}2$ with the help of BertTopic (Grootendorst, 2020).

$\mathcal{V}3$ and $\mathcal{R}3$: Sentiment Cues The sentiment of news articles signal the authors’ approval or denial, which helps identify their stances towards individuals and issues. We use two nodes to represent positive and negative sentiment and we make their node attributes learnable. We then conduct sentiment analysis (Wolf et al., 2020) to identify paragraph sentiment and use $\mathcal{R}3$ to connect $\mathcal{V}1$ with their corresponding sentiment nodes in $\mathcal{V}3$.

3.2.2 Syntactic Cues

Apart from semantic cues, syntactic information in news articles also contribute to the perspective analysis process (Dutta et al., 2022). In light of this, we analyze the tense of news paragraphs and whether it contains direct quotation and use them as paragraph-level labels in our constructed HIN.

$\mathcal{V}4$ and $\mathcal{R}4$: Tense Cues The tense of news paragraphs helps separate facts from opinions. For example, simple past tense often indicates factual statements while simple future tense suggests opinions and projections that might not be factual. We use 17 nodes in $\mathcal{V}4$ to represent 17 possible tenses in our constructed news HIN. We use NLTK (Bird et al., 2009) to extract paragraph tenses and use $\mathcal{R}4$ to connect paragraph nodes in $\mathcal{V}1$ with $\mathcal{V}4$.

$\mathcal{V}5$ and $\mathcal{R}5$: Quotation Cues It is common for authors to directly quote others' words in news articles, which helps to identify the basis of the author's argument. We use two nodes to differentiate between whether a news paragraph quotes someone or not. Specifically, we identify quotation marks in news paragraphs and use $\mathcal{R}6$ to connect $\mathcal{V}1$ with $\mathcal{V}6$ based on whether direct quotation is detected.

3.2.3 Entity Cues

$\mathcal{V}6$ and $\mathcal{R}6$: Entity Cues We follow previous works (Feng et al., 2021a; Hu et al., 2021) to use one node to represent each entity in the external knowledge graph. We adopt TransE (Bordes et al., 2013) to learn knowledge graph embeddings and use them as initial node features for $\mathcal{V}6$. We then adopt entity linking tool TagMe (Ferragina and Scaiella, 2012) to align news paragraphs with their mentioned entities and use $\mathcal{R}6$ to connect $\mathcal{V}1$ with $\mathcal{V}6$ correspondingly.

In this way, we obtain a heterogeneous information network for news articles that jointly models knowledge-enriched news content and diversified textual cues in news articles. Our approach could be similarly extended to other textual cues and paragraph-level labels that would be helpful in political perspective detection and related tasks.

Hyperparameter	**Value**

lr_scheduler_step	0.1
# early stop epoch	40
Optimizer	Adam

Table 1: Hyperparameter settings of KCD. SE and AS denote the datasets SemEval and Allsides.

3.3 Learning and Optimization

Upon obtaining the news HINs, we adopt relational graph neural networks for representation learning and conduct political perspective detection as graph-level classification. Specifically, we follow Feng et al. (2021a) and use gated R-GCN to ensure a fair comparison and highlight the effectiveness of knowledge walks and textual cues. After L layers of gated R-GCN, we denote the learned node representations as $\overline{v}$ and obtain graph-level representation v_g with three different aggregation strategies: Paragraph Average (PA), Cue Average (CA) and Global Average (GA):

$$v_g = \begin{cases} \frac{1}{|\mathcal{V}1|}\sum_{v \in \mathcal{V}1} \overline{v} & \text{if Paragraph Average;} \\ \frac{1}{|\mathcal{V}-\mathcal{V}1|}\sum_{v \notin \mathcal{V}1} \overline{v} & \text{if Cue Average;} \\ \frac{1}{|\mathcal{V}|}\sum_{v \in \mathcal{V}} \overline{v} & \text{if Global Average.} \end{cases} \tag{9}$$

where $\mathcal{V} = \bigcup_{i=1}^{6} \mathcal{V}i$ represents the set of all nodes in our HIN. We then transform the graph-level representation v_g with a softmax layer and classify news articles into perspective labels:

$$\hat{y} = softmax(W_o \cdot v_g + b_o) \tag{10}$$

where W_o and b_o are learnable parameters and $\hat{y}$ is our model's prediction. We optimize the end-to-end process with cross entropy loss and L_2 regularization.

4 Experiments

4.1 Dataset

We make use of two real-world political perspective detection datasets SemEval (Kiesel et al., 2019) and Allsides (Li and Goldwasser, 2019), which are widely adopted in various previous works (Li and Goldwasser, 2019, 2021; Feng et al., 2021a). We follow the same evaluation settings as in previous works so that our results are directly comparable. Section B in the appendix provides more dataset details to facilitate reproduction.

4.2 Baselines

We compare KCD with the following competitive baselines and state-of-the-art methods:

- **CNN** (Jiang et al., 2019) is the first-place solution in the SemEval 2019 Task 4 contest (Kiesel et al., 2019). It combines convolutional neural networks with Glove (Jiang et al., 2019) and ELMo (Peters et al., 2018) for political perspective detection on the SemEval dataset.
- **HLSTM** (Yang et al., 2016) is short for hierarchical long short-term memory networks. Li and Goldwasser (2019) uses HLSTMs and different word embeddings for news bias detection.
- **HLSTM_Embed** and **HLSTM_Output** (Li and Goldwasser, 2021) leverage entity information with masked entity models in addition to news content for political perspective detection.
- **Word2Vec** (Mikolov et al., 2013), **GloVe** (Pennington et al., 2014), **ELMo** (Peters et al., 2018), pre-trained **BERT** (Devlin et al., 2019) and **RoBERTa** (Liu et al., 2019) are leveraged by Feng et al. (2021a) as textual features and political perspective detection is further conducted with two fully connected layers.
- **MAN** (Li and Goldwasser, 2021) incorporates social and linguistic information with pre-training tasks and conducts fine-tuning on the task of political perspective detection.
- **KGAP** (Feng et al., 2021a), short for **K**nowledge **G**raph **A**ugmented **P**olitical perspective detection, leverages knowledge graphs and graph neural networks for a knowledge-aware approach. We compare our gated R-GCN based approach with KGAP's gated R-GCN setting.

4.3 Implementation

We implement our KCD framework with pytorch (Paszke et al., 2019), pytorch lightning (Falcon and The PyTorch Lightning team, 2019), pytorch geometric (Fey and Lenssen, 2019), and the transformers library (Wolf et al., 2020). We present our hyperparameter settings in Table 1 to facilitate reproduction. We adhere to these settings throughout all experiments in the paper unless stated otherwise. Our implementation is trained on a Titan X GPU with 12GB memory. We make our code and data publicly available[3].

	- w/o KW	87.29	81.77	85.51	85.00

Table 2: Political perspective detection performance on two benchmark datasets. Acc and MaF denote accuracy and macro-averaged F1-score. N/A indicates that the result is not reported in previous works. TC and KW indicate textual cues and knowledge walks respectively.

4.4 Experiment Results

We present model performance on two benchmark datasets in Table 2, which demonstrates that

- KCD, especially with the PA aggregation strategy, consistently outperforms state-of-the-art methods on both benchmark datasets.
- KGAP and KCD, which incorporate knowledge graphs, outperform other baselines. This indicates that external knowledge is essential in providing background information and political context to analyze ideological perspectives. KCD without textual cues performs better than baseline methods except KGAP and performs close to KGAP. These suggests that KGAP's method of infusing knowledge as HIN nodes and our method of infusing knowledge as knowledge walks are both effective.
- PA outperforms CA and GA on both datasets, which suggests that the aggregation strategy is important since subsidiary nodes like textual cues may result in noise. As a result, we should focus on paragraph nodes in our heterogeneous information networks.

---

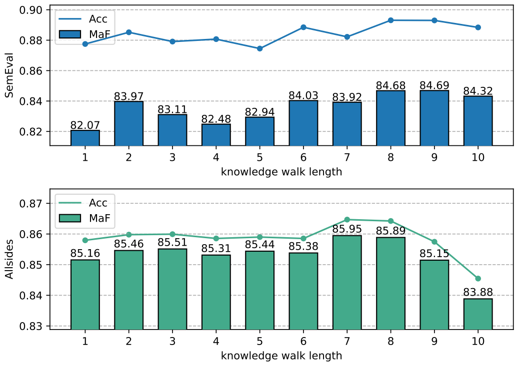

Figure 3: Our approach's performance when the maximum length of knowledge walk generation is specified from 1 to 10 knowledge graph triples.

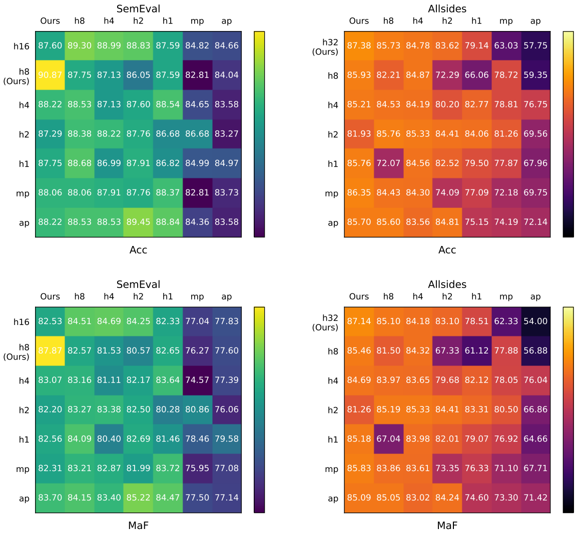

Figure 4: Model performance with different knowledge infusion strategies at two aggregation steps. The horizontal and vertical axis represent the first and second aggregation. h_k denotes multi-head attention with k heads, mp and ap stand for max and average pooling.

- Removing textual cues and knowledge walks in KCD result in substantial performance drop, which demonstrates the effectiveness of textual cues and knowledge walks.

In the following, we examine the effect of knowledge walks and textual cues in our approach. We also explore how our approach performs with limited data compared to baseline methods.

4.5 Knowledge Walks Study

We propose knowledge walks, an approach to conduct multi-hop reasoning on knowledge graphs and inject them into textual representations. We study the effect of knowledge walk length and knowledge infusion strategies on our model's performance.

4.5.1 Knowledge Walks Length

Our proposed knowledge walks could be of any length, where shorter walks provide more condensed knowledge and longer walks provide more diverse knowledge. To examine the effect of knowledge walk length, we generate 5,088[4] knowledge walks of 1 to 10 triples and present model performance in Figure 3. It is illustrated that longer knowledge walks (8 or 9 for SemEval, 7 or 8 for Allsides) perform better than shorter ones, indicating the necessity of multi-hop knowledge reasoning in the task of political perspective detection.

4.5.2 Knowledge Infusion Strategy

We propose a two-step approach to infuse multi-hop knowledge reasoning into textual representations of news articles:

- First Aggregation: We firstly aggregate different generated knowledge walks based on semantic relevance in Equ. (5) and Equ. (6).
- Second Aggregation: We then use multi-head attention to aggregate all paragraphs and knowledge representations with Equ. (7) and Equ. (8).

To examine the effect of our knowledge infusion strategy, we substitute these two aggregation steps with different multi-head attention settings as well as max and average pooling. Results in Figure 4 demonstrate significant performance difference on the horizontal axis. This suggests that our semantic relevance-based knowledge walks aggregation strategy in Equ. (5) and Equ. (6) successfully filters out irrelevant knowledge reasoning and contributes to model performance. Besides, according to the vertical axis, our adopted multi-head attention in Equ. (7) and Equ. (8) is generally effective and does not rely on specific attention head settings.

4.6 Textual Cues Study

We propose to leverage semantic, syntactic and entity textual cues as paragraph-level labels to leverage implicit indicators in news articles for political perspective detection. To examine the effectiveness of these textual cues, we randomly remove them with probability p and present model performance in Figure 5. It is illustrated that:

---

[4] so that there is a knowledge walk beginning with every possible (entity, relation) in the knowledge graph.

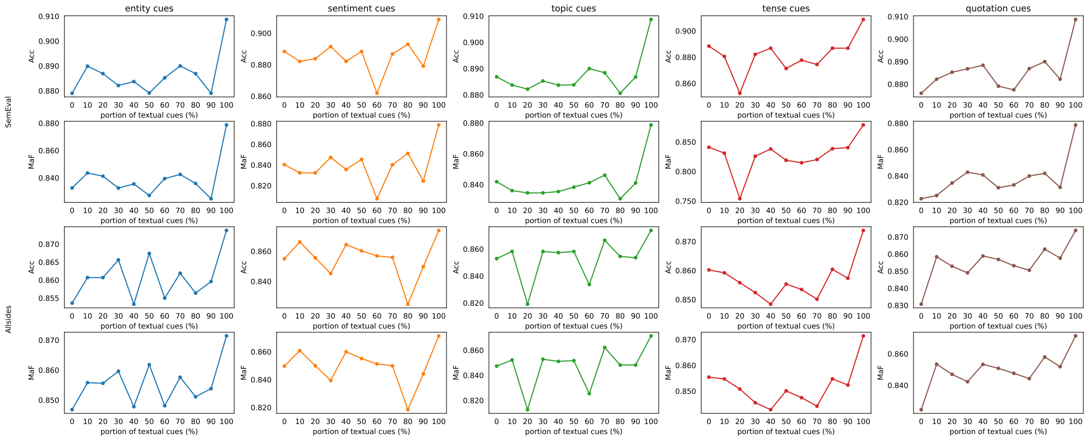

Figure 5: Model performance when five different types of textual cues are gradually removed.

- A performance boost is observed between 0% and 100% for all five textual cues, suggesting the necessity of modeling implicit textual indicators. Besides, adding only part of textual cues sometimes leads to a decrease in performance, which implies that incomplete cues may be counter-productive and introduce noise.

- Among five different cues, entity and quotation cues contribute more to model performance than others. This suggests some implicit textual cues are more important than others in analyzing the ideological perspectives of news articles.

- The effect of textual cues is larger on the dataset SemEval, which is significantly smaller than Allsides. This suggests that we alleviate the data-hungry problem by introducing diversified textual cues as paragraph-level labels and contribute to model performance.

4.7 Data Efficiency Study

As Li and Goldwasser (2021) point out, supervised data annotations could be difficult and expensive to obtain for the task of political perspective detection in news media. Our proposed knowledge walks and textual cues serve as additional information and might help mitigate this issue. To examine whether we have achieved this end, we train KCD, KGAP (Feng et al., 2021a) as well as various text models with reduced training sets of SemEval and Allsides. Results in Figure 6 demonstrate that

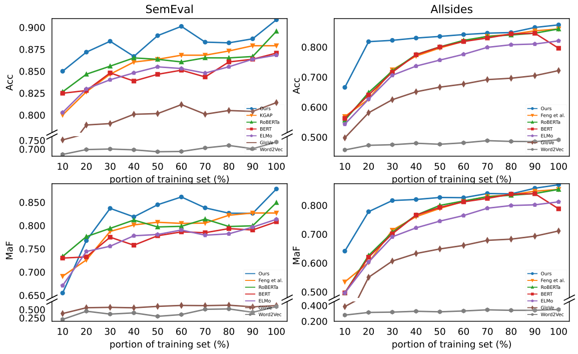

Figure 6: Model performance when KCD and various competitive baselines are trained with 10% to 100% of the training set on SemEval and Allsides.

- KCD has better data efficiency and achieves steady performance with smaller training sets. This observation is especially salient on Allsides where the news articles are longer (Li and Goldwasser, 2021), thus more knowledge walks and textual cues could be extracted and incorporated to alleviate data dependence.

- Both KCD and KGAP leverage external knowledge and are more robust to reduced datasets. Our approach further leverages textual cues and has better data deficiency. This suggests that a solution to limited data could be incorporating information in addition to news content.

- With only 10% training set, KCD outperforms all baselines by at least 5.68% and 9.71% in accuracy on two datasets. This suggests that our approach is simple, effective, and not data-hungry under limited data settings.

5 Conclusion

In this paper,we propose KCD, a political perspective detection approach that reasons with multi-hop external knowledge and leverages diversified implicit textual indicators. We firstly generate multi-hop knowledge walks, dynamically aggregate them based on semantic relevance and infuse into news text representations. We then construct a heterogeneous information network to jointly model knowledge-enriched news content and diversified textual cues as paragraph-level labels. Finally, we learn graph representations with relational graph neural networks under different aggregation settings and conduct political perspective detection as graph-level classification. Extensive experiments demonstrate that our approach consistently outperforms state-of-the-art baselines on two benchmark datasets. Further experiments also bear out the necessity of knowledge walks and textual cues in modeling political perspectives in news media.

A Limitations

Our proposed model has two minor limitations:

- We propose to model news articles with heterogeneous information networks. This graph-based approach might not fit well with shorter news articles with only a few paragraphs. This issue might be addressed by using sentence nodes instead of paragraph nodes for shorter articles.

- For very large knowledge graphs with many different types of relations, it might be hard for domain experts to help set $p(r)$ for every knowledge graph relation. This issue might be addressed by only setting a larger $p(r)$ for several important rs according to domain expert.

Dataset	**# Articles**	**# Class**	**Class Distribution**
SemEval	645	2	407 / 238
Allsides	10,385	3	4,164 / 3,931 / 2,290

Table 3: Details of two datasets SemEval and Allsides.

Datasets	**Setting**	**Acc**	**MaF**
SemEval	GA	88.62 ± 0.32	83.86 ± 0.27
	CA	89.30 ± 0.24	84.85 ± 0.30
	PA	89.90 ± 0.68	86.11 ± 1.18
AllSides	GA	84.88 ± 2.90	84.31 ± 2.96
	CA	79.85 ± 2.58	79.41 ± 2.56
	PA	87.17 ± 0.24	86.72 ± 0.35

Table 4: Average performance and standard deviation of three different aggregation strategies for five runs.

B Dataset Details

We used the same datasets as in previous works (Li and Goldwasser, 2019, 2021; Feng et al., 2021a), namely SemEval (Kiesel et al., 2019) and Allsides (Li and Goldwasser, 2019). We follow the same 10-fold setting for SemEval and 3-fold setting for Allsides (Li and Goldwasser, 2021). We use the exact same folds so that the results are directly comparable. A minor difference would be that we have to discard a few news articles on Allsides since their urls have expired and we could not retrieve their original news article. We report the statistical information of SemEval and Allsides in Table 3.

C Computation Details

C.1 Computational Resources

Our proposed approach has a total of 7.8M learnable parameters. It takes approximately 0.7 and 1.6 GPU hours to train our approach on two datasets respectively. We train our model on one Titan X GPU with 12GB memory.

C.2 Experiment Runs

We run our approach with three different aggregation strategies **five times** and report the average accuracy and macro F1-score with standard deviation in Table 4. For experiments in Section 4.5, 4.6 and 4.7, we do not have enough computational resources to run five times, thus we report the performance of a single run.

D Scientific Artifact Usage

We provide additional details about used scientific artifacts and specifically how we used them.

- NLTK (Bird et al., 2009): We use NLTK to extract the tense of news articles. Specifically, we first use NLTK POS-tagger to process new paragraphs and attach speech tag to each word. Then we align verb tags with NLTK tagset to identify the tense of paragraphs.

- BertTopic (Grootendorst, 2020): We use BertTopic to mine the topics of news corpus. Specifically, we use BertTopic topic model to learn dataset-specific topic models. For SemEval we obtained 197 topics and for Allsides we obtained 1225 topics. Next, we predict topics for each news paragraph. Each topic consists of ten topic words with scores and we select the top five to serve as the news paragraph's topic.

- Huggingface Transformers (Wolf et al., 2020): We use the pipeline module for sentiment analysis. Specifically, we use the sentiment analysis API in the text classification pipeline to generate a sentiment label and score for news paragraphs. We then use the sentiment label as the sentiment cues for news paragraphs.

- TagMe (Ferragina and Scaiella, 2012): We use TagMe to align news articles with entities in the knowledge graph. Specifically, we use TagMe to annotate named entities in news paragraphs and save the entities with a score higher than 0.1 for further alignment. We then calculate the similarity score between TagMe annotated entities and political knowledge graph entities. We recognize the entities with a score higher than 0.9 as entity cues in our constructed HIN.

- Political knowledge graph (Feng et al., 2021a): We use the political knowledge graph collected in Feng et al. (2021a) for external knowledge in political perspective detection.

- OpenKE (Han et al., 2018): We use OpenKE to train TransE (Bordes et al., 2013) knowledge graph embeddings for the political knowledge graph. Specifically, we set the TransE hidden size to 768 and train the model with other default hyperparameters in OpenKE.

Collective Relevance Labeling for Passage Retrieval

Abstract

Deep learning for Information Retrieval (IR) requires a large amount of high-quality query-document relevance labels, but such labels are inherently sparse. Label smoothing redistributes some observed probability mass over unobserved instances, often uniformly, uninformed of the true distribution. In contrast, we propose knowledge distillation for informed labeling, without incurring high computation overheads at evaluation time. Our contribution is designing a simple but efficient teacher model which utilizes collective knowledge, to outperform state-of-the-arts distilled from a more complex teacher model. Specifically, we train up to ×8 faster than the state-of-the-art teacher, while distilling the rankings better. Our code is publicly available at `https://github.com/jihyukkim-nlp/CollectiveKD`.

1 Introduction

Facilitated by recent developments in pre-trained language models (PLM) such as BERT (Devlin et al., 2019), neural ranking models have seen significant improvements in effectiveness (Yates et al., 2021). Neural ranking models can be categorized into two major groups: Cross-encoders and bi-encoders, which jointly or separately encode a query q and a passage p, respectively. While the former shows stronger performance, the latter makes the passage representations indexable and thus enables efficient retrieval supported by approximated nearest neighbor (ANN) search, e.g., FAISS (Johnson et al., 2019). In this work, targeting web-scale retrieval, we follow the bi-encoder design and adopt the state-of-the-art bi-encoder, ColBERT (Khattab and Zaharia, 2020) as our target retriever.

While label supervision has a critical role in training bi-encoders, only **incomplete labels** are available in benchmark training datasets due to the prohibitive cost of exhaustive human annotation of large-scale passage corpora. As a prominent example, in MSMARCO (Nguyen et al., 2016) training dataset, the number of labeled relevant passages per query averages only 1.1, among 8.8M passages. In contrast, in TREC-DL 2019 (Craswell et al., 2020) which provides complete annotations for a select number of queries on the same passage collection, the same value is 58.2, indicating that significant amounts of relevant passages can remain unlabeled in MSMARCO. Meanwhile, we stress that the problem of incomplete labels observed from benchmark datasets gets worse in real-life retrieval tasks, where new relevant documents are constantly added without annotation.

Training strategy	KD capacity	Efficiency
Standard KD	✔(cross-encoder)	✘
Self-KD	✘(bi-encoder)	✔
Ours **Collective Self-KD**	✔(collective bi-enc)	✔

Table 1: Comparison of existing KD approaches with ours. Teacher for each method denoted in parentheses.

Existing work addressing incomplete labels can be categorized into uninformed smoothing and informed labeling. **Uninformed smoothing** redistributes the observed probability mass uniformly over the unobserved, and has been shown to improve model calibration and prediction (Szegedy et al., 2016; Müller et al., 2019). However, given diverse topics in the passage corpora, uniform smoothing does not accurately reflect the true distribution. Alternatively, **informed labeling** distills knowledge from a trained model, evaluating the relevance of a q-p pair, to assign a higher probability to an unlabeled pair with a higher estimated relevance, also known as knowledge distillation (KD) (Hinton et al., 2015).

Table 1 contrasts two existing KD strategies with different teachers – cross- and bi-encoders – and

positions our proposed KD approach. Standard KD approaches adopt a high-capacity teacher, e.g., cross-encoder, to teach a bi-encoder student, e.g., ColBERT (Hofstätter et al., 2020). However, the cross-encoder teacher sacrifices efficiency, requiring BERT encodings to be recomputed for each possible q-p pair. Alternatively, student and teacher can have equal capacity (Furlanello et al., 2018), by adopting a bi-encoder teacher, i.e., in a self-knowledge distillation setting (self-KD). However, while increasing efficiency due to independent encoding of q and p, the bi-encoder teacher provides little additional knowledge to the student. Our contribution is devising a more informed bi-encoder teacher achieving both high capacity and efficiency.

To augment capacity without sacrificing efficiency, our distinction is utilizing a set of relevant passages from the bi-encoder teacher as **collective knowledge**. To illustrate, in Table 2, we show a query q, along with a set of three passages $\mathcal{F}_q = \{p_1, p_2, p_3\}$, labeled as relevant by ColBERT. Considered individually, each passage may be mistakenly judged as relevant to the query, e.g., p_3. Instead, we consider $\mathcal{F}_q$ collectively, identifying their *representative semantics*, or collective centroid $\tilde{q}$. Next, we treat $q \cup \tilde{q}$ as if it were a query, and *redistribute* relevance labels based on the similarity to $q \cup \tilde{q}$, such that relevant passages (e.g., $\{p_1, p_2\}$) and non-relevant passages (e.g., $\{p_3\}$) can be discriminated. We henceforth denote our ColBERT teacher leveraging collective knowledge as **collective bi-encoder**.

We validate the effectiveness of our proposed collective bi-encoder for KD, comparing retrieval efficacy with existing models on the TREC and MSMARCO datasets. While achieving the state-of-the-art performance, we train up to ×8 times faster than existing KD that uses cross-encoder teachers.

2 Approach

Taking the state-of-the-art bi-encoder ColBERT as our target retriever (§2.1), our goal is to tackle the problem of incomplete labels during training (§2.2). To do so, we devise a stronger ColBERT teacher that leverages collective knowledge to refine relevance labels that are transferred to the ColBERT student via KD (§2.3).

2.1 Baseline: ColBERT

While following a bi-encoder design to enable p to be indexed offline, ColBERT additionally models term-level interactions between separately encoded q, p term representations (called **late-interaction**) to leverage exact-match signals as in cross-encoder.

Specifically, terms in q, p are first encoded using BERT, as contextualized representations $\mathbf{q}, \mathbf{p} \in \mathbb{R}^{768}$, then q-p relevance $\phi_q(p)$ is computed by aggregating similarity between the terms in q, p:

$$\phi_q(p) = \sum_{i \in [1,|q|]} \max_{j \in [1,|p|]} (\mathbf{W}\mathbf{q}_i)^\top (\mathbf{W}\mathbf{p}_j), \quad (1)$$

where $|q|$, $|p|$ denote the number of tokens in q, p respectively, and $\mathbf{W} \in \mathbb{R}^{128 \times 768}$ compresses features for efficient inner-product computation.

Our goal is to improve training by addressing the challenge of incomplete labels, which we discuss in the following subsection.

2.2 Challenge: Incomplete Labels

We formally revisit the challenge of incomplete labels in IR. Given complete labels on true relevance, ϕ_q^*, the correlation between ϕ_q and ϕ_q^* can be increased via an objective $\mathcal{L}$ using KL-divergence.

$$\mathcal{R}_q(p) = \text{softmax}(\phi_q(p)) \quad (2)$$

$$\mathcal{L} = -\sum_{p' \in \mathcal{P}} \mathcal{R}_q^*(p') \log \frac{\mathcal{R}_q(p')}{\mathcal{R}_q^*(p')}, \quad (3)$$

where $\mathcal{R}_q^*$ denotes a probability distribution obtained by normalizing ϕ_q^*. Let us now consider the scenario of incomplete label supervision: The standard training approach would approximate $\mathcal{R}_q^*$ as $\mathcal{R}_q^*(p^+)$ = 1 for a labeled positive p^+, and $\mathcal{R}_q^*(p^-)$ = 0 for the others by assuming them to be negatives

$\{p^-\}$:

$$\mathcal{L} = -\log \mathcal{R}_q(p^+) \tag{4}$$

$$= -\log \frac{e^{\phi_q(p^+)}}{e^{\phi_q(p^+)} + \sum_{p^-} e^{\phi_q(p^-)}}, \tag{5}$$

where, in the official train samples of MSMARCO, p^- is randomly sampled from the top-1000 ranked passages by BM25 given q as a query. Our claim is that, in the case of *incomplete* labels, where the number of unlabeled p^+ becomes larger, this assumption causes $\mathcal{R}_q^*$ to be poorly approximated.

2.3 Proposed: Collective Self-KD

To better estimate $\mathcal{R}_q^*(p)$, we utilize collective knowledge, introduced in Section §1. Collective knowledge makes it possible to distill residual relevance knowledge between teacher and student, leading to a high degree of efficiency.

As illustrated in Table 2, our collective bi-encoder teacher first obtains the collective centroid $\tilde{q}$ from top-ranked passages to expand q to $q \cup \tilde{q}$. Given $q \cup \tilde{q}$, the collective knowledge of the teacher is reflected in the updated $\mathcal{R}_q^*(p)$, which is now approximated as $\mathcal{R}_{q\cup\tilde{q}}(p)$, the similarity between p and $q \cup \tilde{q}$. In practice, we implement our teacher using the recently proposed ColBERT-PRF (Wang et al., 2021), which uses **PRF for *query expansion*** (at test time) by using top-ranked passages from ColBERT as pseudo-relevance feedback (PRF).

Our distinction is leveraging **PRF for *labeling*** (at train time) to augment the capacity of bi-encoder teacher. This is an important distinction, as it provides substantial benefits as follows: (1) Train-time PRF is more reliable than test-time PRF, since at test time, the initial ranking is less accurate for novel queries that have not been observed during training. (2) Train-time PRF additionally provides hard negatives (Xiong et al., 2021) (e.g., p_3 in Table 2), as by-products of the initial ranking from ColBERT, producing better $\{p^-\}$ for training. With the goal of distilling collective knowledge while preserving test time efficiency, we now describe in detail the operation of our collective bi-encoder teacher, and $\mathcal{R}_q^*(p)$ estimation process.

2.3.1 Collective Knowledge Extraction

As a preliminary, we pre-train a ColBERT model using Eq (5) and use it to rank passages in the collection for each q, producing a ranking $\Pi_q = \{p^l\}_{l=1}^{|\mathcal{P}|}$ where l and $|\mathcal{P}|$ denotes the rank of each passage and the size of the passage collection, respectively. From these, we obtain the top-f_p ranked passages, as feedback passages $\Pi_q^{l\leq f_p} = \{p^l\}_{l=1}^{f_p}$.

To extract collective knowledge present in $\Pi_q^{l\leq f_p}$, we apply k-means clustering on the token embeddings in $\Pi_q^{l\leq f_p}$, i.e., $\{\mathbf{W}\mathbf{p}_i^l\}_{\forall l\in\{1,f_p\},\forall i\in\{1,|p^l|\}}$, producing f_c centroid embeddings $\mathcal{C}_q = \{\mathbf{c}_{q,m}\}_{m=1}^{f_c}$. Then, in order to sift out trivial knowledge, discriminative embeddings among $\mathcal{C}_q$ are further filtered. More precisely, we sort the centroids in $\mathcal{C}_q$, by the IDF score of the token that is the nearest neighbor, among the entire passage collection, to each $\mathbf{c}_{q,m}$. According to these IDF scores, we select the top-f_e embeddings among $\mathcal{C}_q$ as the final collective centroid embeddings, i.e., vector representations for $\tilde{q}$, denoted by $\mathcal{E}_q = \{\mathbf{e}_{q,n}\}_{n=1}^{f_e} \subset \mathcal{C}_q$.

Finally, to obtain the improved approximation of $\mathcal{R}_q^*$ via $\mathcal{R}_{q\cup\tilde{q}}(p)$, the similarity between $\mathcal{E}_q$ and p is added to $\phi_q(p)$ in Eq (1):

$$\mathcal{R}_q^*(p) \approx \text{softmax}(\phi_q(p) + \beta \sum_{n\in[1,f_e]} \sigma_{q,n} \max_{j\in[1,|p|]} \mathbf{e}_{q,n}^\top(\mathbf{W}\mathbf{p}_j)), \tag{6}$$

where $\sigma_{q,n}$ is the IDF of the nearest neighbor token of $\mathbf{e}_{q,n}$, weighing the contribution of each $\mathbf{e}_{q,n}$ in terms of discriminability, and β is a hyperparameter controlling overall contribution. Note that, we can reuse the collective centroids for estimating the $\mathcal{R}_q^*(p)$ of any p, avoiding redundant BERT encoding.

2.3.2 Collective Knowledge Distillation

We now propose efficient distillation strategies for teaching $\mathcal{R}_q^*$ to the student, where we leverage the fact that the student and the teacher share the identical architecture design. For efficient KD, we let our student inherit most of the knowledge through the parameters of the teacher, by initializing the student's parameters with those of the pre-trained ColBERT, denoted by θ. Since θ already captures $\mathcal{R}_q$, the knowledge distillation of $\mathcal{R}_{q\cup\tilde{q}}$ can be simplified as distilling residual relevance, i.e., $\mathcal{R}_{\tilde{q}}$, to the student.

Meanwhile, when using θ for initialization, p^- sampled by BM25 now becomes a trivial negative that can be easily discriminated by θ. To learn additional knowledge, we introduce hard negatives, by utilizing the initial ranking Π_q from the pre-trained ColBERT. Specifically, we replace the pool of p^- with top-100 ranked passages $\Pi_q^{l\leq 100}$, so as to improve top-ranking performance of the student.

Table 3: "CE" and "CE-3" denote a single and an ensemble of three cross-encoder teachers, respectively. MRT denotes Mean Response Time (ms) per query. Those outperforming all baselines except ColBERT-PRF are underlined, and the best shown in **bold**. Superscripts denote statistical significance with paired t-test over the indicated baselines ($p < 0.05$).

3 Experiments

3.1 Experimental Settings

We conduct our experiments by trainining retrievers using the MSMARCO training dataset, and evaluating on the MSMARCO Dev and TREC-DL 2019/2020 datasets, which provide binary and graded relevance labels, respectively. For TREC-DL datasets, we adopt grade 2 as the binary cut-off. For evaluation metrics, we report MRR@10 for MSMARCO and NDCG@10 for TREC-DL, and Recall@1000 for both. We also report the per query mean response time (MRT) of retrievers. The results are from a single run.

3.2 Dataset Details

MSMARCO (Nguyen et al., 2016)[1] is a passage ranking dataset initially introduced for reading comprehension and subsequently adopted for retrieval. The collection consists of 8.8M passages, obtained from the top-10 search results retrieved by the Bing search engine, in response to 1M real-world queries. The training and evaluation sets contain approximately 500,000 queries and 6,980 queries, respectively, with roughly one relevant positive passage label per query, with binary relevance labels.

TREC-DL 2019/2020 (Craswell et al., 2020, 2021) datasets are provided by the passage ranking task of the 2019 and 2020 TREC Deep Learning tracks, providing densely-judged annotations of 43 and 54 queries, respectively. They share the same passage pool as MSMARCO, and there are 215/211 human relevance annotations per query. The relevance judgments are graded on a four-point scale: Irrelevant, Related, Highly Relevant, and Perfectly Relevant.

3.3 Results

In this section, we validate the effectiveness of our collective self-KD with ColBERT as our target retriever. The results of ranking experiments are reported in Table 3.

Baselines We compare several different training strategies: training using incomplete labels (i.e., by Eq (5)) or using better approximation of $\mathcal{R}^*$ from a teacher. For the former, we report results from different $\{p^-\}$: ColBERT trained using top-1000 ranked passages by BM25 (**ColBERT**) and ColBERT further fine-tuned using $\Pi_q^{l \leq 100}$ (**ColBERT-HN**). For the latter, we compare different teachers: (1) an identically parameterized teacher (**Self-KD**), (2) a cross-encoder adopting BERT-Base encoder (**Standard KD; CE**), (3) an ensemble of three cross-encoders with different PLMs, i.e., BERT-Base, BERT-Large, and ALBERT-Large (Lan et al., 2019), (**Standard KD; CE-3**), and finally (4) our collective bi-encoder teacher (**Collective Self-KD**). For relevance labels from cross-encoder teachers, we used open-sourced data by (Hofstätter et al., 2020)[2]. Analysis on estimated $\mathcal{R}^*$ from different teachers can be found in Appendix A.1. For values of (f_p, f_c, f_e, β), we set (f_p=3, f_c=24, f_e=10) and ran experiments with $\beta = 0.5$ and $\beta = 1.0$, by referring to the reported results in Wang et al. (2021). For further analysis on (f_p, f_c, f_e, β), see Appendix A.2. In addition, we also compare ColBERT-PRF Ranker with $\beta = 0.5$ and $\beta = 1.0$.

---

[1] MSMARCO is intended for non-commercial research purposes. Refer to https://microsoft.github.io/msmarco for further details.

[2] https://zenodo.org/record/4068216

Ranking Performance By leveraging PRF to augment query contexts, ColBERT-PRF shows strong performance, outperforming the others on TREC-DL datasets. Meanwhile, on MSMARCO Dev queries, ColBERT-PRF shows comparable or higher recall but lower MRR@10, compared to ColBERT. This is a well-known limitation of PRF for sparse query datasets, such as MSMARCO evaluation dataset with a few relevant documents (1.1 per query) (Amati et al., 2004).

Among ColBERT retrievers, as expected, basic self-KD fails to improve performance. For ColBERT students distilled from cross-encoder teachers, Recall@1k shows marginal difference on MSMARCO Dev, and decreases on the TREC-DL datasets. Our teacher is the most effective for KD, where our student outperforms the others on all metrics. As a result, our student shows closest performance to ColBERT-PRF. This indicates collective knowledge from PRF helps to better labeling relevance and our collective self-KD effectively transfers collective knowledge to our student.

Importantly, our method produces a much more efficient student than ColBERT-PRF, by distilling collective knowledge into the parameters of the student, resulting in a 3-fold reduction of MRT. More specifically, recall that ColBERT-PRF performs PRF at *evaluation time*, and thus performs two rounds of retrieval (one using q and the other using $q \cup \tilde{q}$), increasing latency approximately two fold. Furthermore, obtaining $\tilde{q}$ from PRF requires additional online computation at evaluation time. In contrast, we transfer such computations to training time for relevance labeling, eliminating all overheads at evaluation time.

Training Efficiency We compare training efficiency between our collective self-KD and standard KD using cross-encoder teachers. On the same device[3], we measured elapsed times for the annotation phase of relevance labels via teacher, and student training phase using the labels.

In annotation phase, for a single cross-encoder teacher using a BERT-Base encoder, obtaining $\mathcal{R}^*$ takes roughly 40 hours. For a teacher using a BERT-Large encoder, this time increases to 90 hours, and for ALBERT-Large encoder, to 110 hours. When ensembling cross-encoder teachers, the cost is compounded. In contrast, our teacher takes only 15 hours for obtaining collective knowledge, i.e., $\mathcal{E}_q$ along with σ_n in Eq 6, indicating a speedup between $\times 2.67 \sim \times 16$. Such efficiency gain comes from the difference in the encoding phase. More precisely, given $|Q|$ queries and $|D|$ documents, cross-encoder spends quadratic complexity for encoding, e.g., $|Q| \times |D|$ BERT encoding, while our teacher adopting bi-encoder design only spends linear complexity, e.g., $|Q| + |D|$ BERT encoding. As a result, cross-encoder teachers do not scale to real-world retrieval tasks, for labeling large numbers of queries/documents.

For training student, we enable efficient training via informed initialization. As a result, time consumed for training student only takes 20 hours, whereas the same value was around 50 hours in standard KD, indicating an overall speedup of $\times 2.5$. In total, our collective self-KD is at least $\times 2.5$ faster and up to $\times 8$ faster than standard KD approaches.

4 Conclusion and Future Work

We study collective relevance labeling to overcome incomplete labels in passage retrieval. Our approach bypasses the computational overhead associated with PRF, leading to a state-of-the-art student retriever without sacrificing efficiency. We validate the effectiveness of our method over existing approaches on the MSMARCO and TREC-DL Passage Ranking datasets.

As future work, we consider zero-shot transfer. While our collective self-KD effectively distills knowledge, one requirement we have is to bootstrap the collective knowledge with a good initial ranking model. As it usually requires some form of label supervision to train such a model, the case where no initial supervision is available, may be considered a limitation of our method. We believe bootstrapping an effective self-KD without any supervision is a promising direction.

A Appendix

A.1 Analysis on $\mathcal{R}_q^*$ approximated by different teachers

Given the top-100 passages ranked by the pretrained ColBERT, i.e., $\Pi_q^{l\leq 100}$, the goal of our teacher is to obtain better relevance boundary through collective knowledge, by which unlabeled positives can be discriminated from true negatives. To analyze the reliability of relevance boundary from the teacher, we evaluate how well the teacher classifies positives among the top-100 passages, using TREC 2019 that provides complete relevance labels.

Figure 1 shows trade-offs between precision and recall when applying different thresholds on ϕ_q. We set different cut-offs on graded relevance for deciding positive passages. For example, in the left most figure with boundary 1, we treat passages with labeled relevance 1,2,3 as positives and 0 as negatives. As baselines, we compare our collective bi-encoder teacher with the pretrained ColBERT, and a cross-encoder teacher, monoBERT[4] (Nogueira

Performance Metric	f_p			f_c		f_e		β	
	1	3	5	12	24	5	10	0.5	1.0
NDCG@10	0.651	0.703	0.702	0.717	0.703	0.700	0.703	0.710	0.703
Recall@1k	0.843	0.842	0.849	0.846	0.842	0.844	0.842	0.848	0.842

Table 4: Ranking performance of our collective bi-encoder teacher under different configurations.

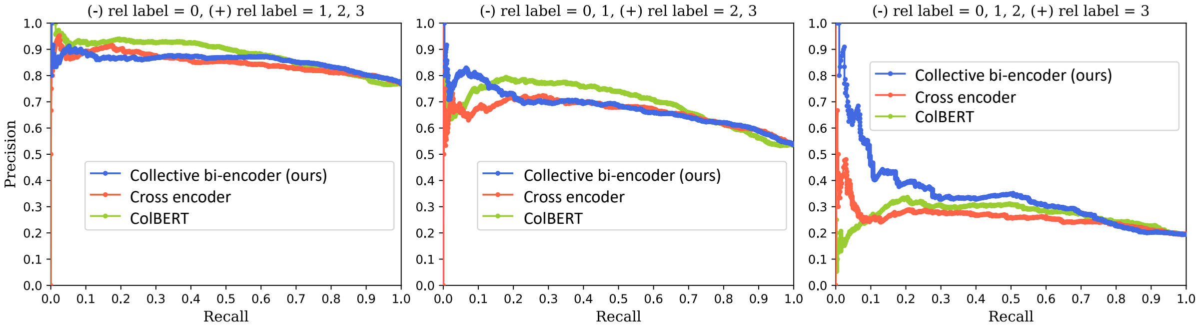

Figure 1: Precision-recall curves on TREC 2019 with different thresholds on predicted/labeled relevance scores. From the left to the right, we gradually increase the threshold of the labeled relevance that decides which passages are positive passages.

et al., 2019). Better precision-recall curves should bow towards the top right corner.

For the cut-offs of 1 and 2, we observed little differences between retrievers. For example, when retrievers are tasked to classify non-relevant passages with relevance label 0 and the others (the left most figure), all retrievers show 100% recall with near 80% precision. In contrast, for the cut-off of 3 (the rightmost figure), our teacher shows much better trade-offs compared to the others. For example, collective bi-encoder teacher shows near 50% precision to achieve 10% recall, while the others show 20% precision to achieve the same recall. The noticeable drop of precision for both ColBERT and cross-encoder in low (<0.5) recall regimes indicate that these models have difficulty distinguishing moderate relevance (1, 2) from perfect relevance (3), that is, they are not well calibrated to distinguish between those two groups. On the other hand, our teacher's refinement of q through collective knowledge is effective in calibrating relevance, to finely reflect the distinction between perfectly relevant passages and the others.

A.2 Analysis on (f_p, f_c, f_e, β)

Exploring ranking performance of students under all different configurations of (f_p, f_c, f_e, β) is expensive. Instead, the optimal configuration can be decided by ranking performance of the teacher. Here, we explore $f_p \in \{1, 3, 5\}$, $f_c \in \{12, 24\}$, $f_e \in \{5, 10\}$, and $\beta \in \{0.5, 1.0\}$. Meanwhile, according to reported results by (Wang et al., 2021), $(f_p = 3, f_c = 24, f_e = 10, \beta \in \{0.5, 1.0\})$ shows strong performance. Thus, instead of testing all different configurations, we set $(f_p = 3, f_c = 24, f_e = 10, \beta = 1.0)$ as default values, and change one variable at a time. When evaluating teachers using TREC-DL 2019 dataset, We found similar results to (Wang et al., 2021) (Table 4).

COGMEN: COntextualized GNN based Multimodal Emotion recognitioN

Abstract

Emotions are an inherent part of human interactions, and consequently, it is imperative to develop AI systems that understand and recognize human emotions. During a conversation involving various people, a person's emotions are influenced by the other speaker's utterances and their own emotional state over the utterances. In this paper, we propose COntextualized Graph Neural Network based Multimodal Emotion recognitioN (COGMEN) system that leverages local information (i.e., inter/intra dependency between speakers) and global information (context). The proposed model uses Graph Neural Network (GNN) based architecture to model the complex dependencies (local and global information) in a conversation. Our model gives state-of-the-art (SOTA) results on IEMOCAP and MOSEI datasets, and detailed ablation experiments show the importance of modeling information at both levels.

1 Introduction

Emotions are intrinsic to humans and guide their behavior and are indicative of the underlying thought process (Minsky, 2007). Consequently, understanding and recognizing emotions is vital for developing AI technologies (e.g., personal digital assistants) that interact directly with humans. During a conversation between a number of people, there is a constant ebb and flow of emotions experienced and expressed by each person. The task of multimodal emotion recognition addresses the problem of monitoring the emotions expressed (via various modalities, e.g., video (face), audio (speech)) by individuals in different settings such as conversations.

Emotions are physiological, behavioral, and communicative reactions to cognitively processed stimuli (Planalp et al., 2018). Emotions are often a result of internal physiological changes, and these physiological reactions may not be noticeable by others and are therefore intra-personal. For example, in a conversational setting, an emotion may be a communicative reaction that has its origin in a sentence spoken by another person, acting as a stimulus. The emotional states expressed in utterances correlate with the context directly; for example, if the underlying context is about a happy topic like celebrating a festival or description of a vacation, there will be more positive emotions like joy and surprise. Consider the example shown in Figure 1, where the context depicts an exciting conversation. Speaker-1 being excited about his admission affects the flow of emotions in the entire context. The emotion states of Speaker-2 show the dependency on Speaker-1 in $\mathcal{U}_2, \mathcal{U}_4$ and $\mathcal{U}_6$, and maintains intra-personal state depicted in $\mathcal{U}_8$ and $\mathcal{U}_{10}$ by being curious about the responses of Speaker-1. The example conversation portrays the effect of global information as well as inter and intra dependency of speakers on the emotional states of the utterances. Moreover, emotions are a multimodal phenomenon; a person takes cues from different modalities (e.g., audio, video) to infer the emotions of others, since, very often, the in-

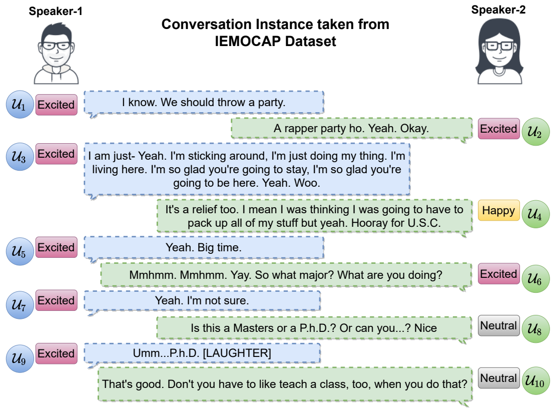

Figure 1: An example conversation between two speakers, with corresponding emotions evoked for each utterance.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4148 - 4164
July 10-15, 2022

formation in different modalities complement each other. In this paper, we leverage these intuitions and propose **COGMEN**: **CO**ntextualized **G**raph neural network based **M**ultimodal **E**motion recognitio**N** architecture that addresses both, the effects of context on the utterances and inter and intra dependency for predicting the per-utterance emotion of each speaker during the conversation. There has been a lot of work on unimodal (using text only) prediction, but our focus is on multimodal emotion prediction. As is done in literature on multimodal emotion prediction, we do not focus on comparison with unimodal models. As shown via experiments and ablation studies, our model leverages both the sources (i.e., local and global) of information to give state-of-the-art (SOTA) results on the multimodal emotion recognition datasets IEMOCAP and MOSEI. In a nutshell, we make the following contributions in this paper:

- We propose a Contextualized Graph Neural Network (GNN) based Multimodal Emotion Recognition architecture for predicting per utterance per speaker emotion in a conversation. Our model leverages both local and global information in a conversation. We use GraphTransformers (Shi et al., 2021) for modeling speaker relations in multimodal emotion recognition systems.
- Our model gives SOTA results on the multimodal Emotion recognition datasets of IEMOCAP and MOSEI.
- We perform a thorough analysis of the model and its different components to show the importance of local and global information along with the importance of the GNN component. We release the code for models and experiments: `https://github.com/Exploration-Lab/COGMEN`

2 Related Work

Emotion recognition is an actively researched problem in NLP (Sharma and Dhall, 2021; Sebe et al., 2005). The broad applications ranging from emotion understanding systems, opinion mining from a corpus to emotion generation have attracted active research interest in recent years (Dhuheir et al., 2021; Franzen et al., 2021; Vinola and Vimaladevi, 2015; Kołakowska et al., 2014; Colombo et al., 2019; Janghorbani et al., 2019; Goswamy et al., 2020; Singh et al., 2021a; Agarwal et al., 2021; Singh et al., 2021b). Availability of benchmark multimodal datasets, such as CMU-MOSEI (Zadeh et al., 2018b), and IEMOCAP (Busso et al., 2008), have accelerated the progress in the area. Broadly speaking, most of the existing work in this area can be categorized mainly into two areas: *unimodal* approaches and *multimodal* approaches. Unimodal approaches tend to consider the text as a prominent mode of communication and solve the emotion recognition task using only text modality. In contrast, multimodal approaches are more naturalistic and consider multiple modalities (audio+video+text) and fuse them to recognize emotions. In this paper, we propose a multimodal approach to emotion recognition. Nevertheless, we briefly outline some of the prominent unimodal approaches as some of the techniques are applicable to our setting.

Unimodal Approaches: COSMIC (Yu et al., 2019) performs text only emotion classification problem by leveraging commonsense knowledge. DialogXL (Shen et al., 2021a) uses XLnet (Yang et al., 2019) as architecture in dialogue feature extraction. CESTa (Wang et al., 2020) captures the emotional consistency in the utterances using Conditional Random Fields (Lafferty et al., 2001) for boosting the performance of emotion classification. Other popular approaches parallel to our work use graph-based neural networks as their baseline and solve the context propagation issues in RNN-based architectures, including DialogueGCN (Ghosal et al., 2019), RGAT (Ishiwatari et al., 2020), ConGCN (Zhang et al., 2019), and SumAggGin (Sheng et al., 2020). Some of the recent approaches like DAG-ERC (Shen et al., 2021b) combine the strengths of conventional graph-based neural models and recurrence-based neural models.

Multimodal Approaches: Due to the high correlation between emotion and facial cues (Ekman, 1993), fusing modalities to improve emotion recognition has drawn considerable interest (Sebe et al., 2005). Some of the initial approaches include Datcu and Rothkrantz (2014), who fused acoustic information with visual cues for emotion recognition. Wollmer et al. (2010) use contextual information for emotion recognition in a multimodal setting. In the past decade, the growth of deep learning has motivated a wide range of approaches in multimodal settings. The Memory Fusion network (MFN) (Zadeh et al., 2018a) proposes synchronizing multimodal sequences using multi-view gated memory storing intra-view and cross-view interactions through time. Graph-MFN (Bagher Zadeh et al., 2018) extends the idea of MFN and introduces Dynamic Fusion Graph (DFG), which learns to model the n-modal interactions and alter its structure dynamically to choose a fusion graph based on the importance of each n-modal dynamics during inference. Conversational memory network (CMN) (Hazarika et al., 2018b) leverages contextual information from the conversation history and uses gated recurrent units to model past utterances of each speaker into memories. Tensor fusion Network (TFN) (Zadeh et al., 2017) uses an outer product of the modalities. Other popular approaches include DialogueRNN (Majumder et al., 2019) that proposes an attention mechanism over the different utterances and models emotional dynamics by its party GRU and global GRU. B2+B4 (Kumar and Vepa, 2020), use a conditional gating mechanism to learn cross-modal information. bc-LSTM (Poria et al., 2017) proposes an LSTM-based model that captures contextual information from the surrounding utterances. Multilogue-Net (Shenoy and Sardana, 2020) proposes a solution based on a context-aware RNN and uses pairwise attention as a fusion mechanism for all three modalities (audio, video, and text). Recently, Delbrouck et al. (2020) proposed TBJE, a transformer-based architecture with modular co-attention (Yu et al., 2019) to encode multiple modalities jointly. CONSK-GCN (Fu et al., 2021) uses graph convolutional network (GCN) with knowledge graphs. Lian et al. (2020) use GNN based architecture for Emotion Recognition using text and speech modalities. Af-CAN (Wang et al., 2021a) proposes RNN based on contextual attention for modeling the transaction and dependence between speakers.

3 Proposed Model

In a conversation involving different speakers, there is a continuous ebb and flow in the emotions of each of the speakers, usually triggered by the context and reactions of other speakers. Inspired by this intuition, we propose a multimodal emotion prediction model that leverages contextual information, inter-speaker and intra-speaker relations in a conversation.

In our model, we leverage both the context of dialogue and the effect of nearby utterances. We model these two sources of information via two means: **1) Global Information**: How to capture the impact of underlying context on the emotional state of an utterance? **2) Local information**: How to establish relations between the nearby utterances that preserve both inter-speaker and intra-speaker dependence on utterances in a dialogue?

Global Information: We want to have a unified model that can capture the underlying context and handle its effect on each utterance present in the dialogue. A transformer encoder (Vaswani et al., 2017) architecture is a suitable choice for this goal. Instead of following the conventional sequential encoding by adding positional encodings to the input, in our approach, a simple transformer encoder without any positional encodings leverages the entire context to generate distributed representations (features) efficiently corresponding to each utterance. The transformer facilitates the flow of information from all utterances when predicting emotion for a particular utterance.

Local Information: The emotion expressed in an utterance is often triggered by the information in neighboring utterances. We establish relations between the nearby utterances in a way that is capable of capturing both inter-speaker and intra-speaker effects of stimulus over the emotion state of an utterance. Our approach comes close to DialogueGCN (Ghosal et al., 2019), and we define a graph where each utterance is a node, and directed edges represent various relations. We define relations (directed edges) between nodes $\mathcal{R}_{ij} = u_i \rightarrow u_j$, where the direction of the arrow represents the spoken order of utterances. We categorize the directed relations into two types, for self-dependent relations between the utterances spoken by the same speaker $\mathcal{R}_{intra}$, and interrelations between the utterances spoken by different speakers $\mathcal{R}_{inter}$. We propose to use Relational GCN (Schlichtkrull et al., 2018) followed by a GraphTransformer (Shi et al., 2021) to capture dependency defined by the relations.

3.1 Overall Architecture

Figure 2 shows the detailed architecture. The input utterances go as input to the **Context Extractor** module, which is responsible for capturing the global context. The features extracted for each utterance by the context extractor form a graph based on interactions between the speakers. The graph goes as input to a **Relational GCN**, followed by **GraphTransformer**, which uses the formed graph to capture the inter and intra-relations between the utterances. Finally, two linear layers acting as an **emotion classifier** use the features obtained for all

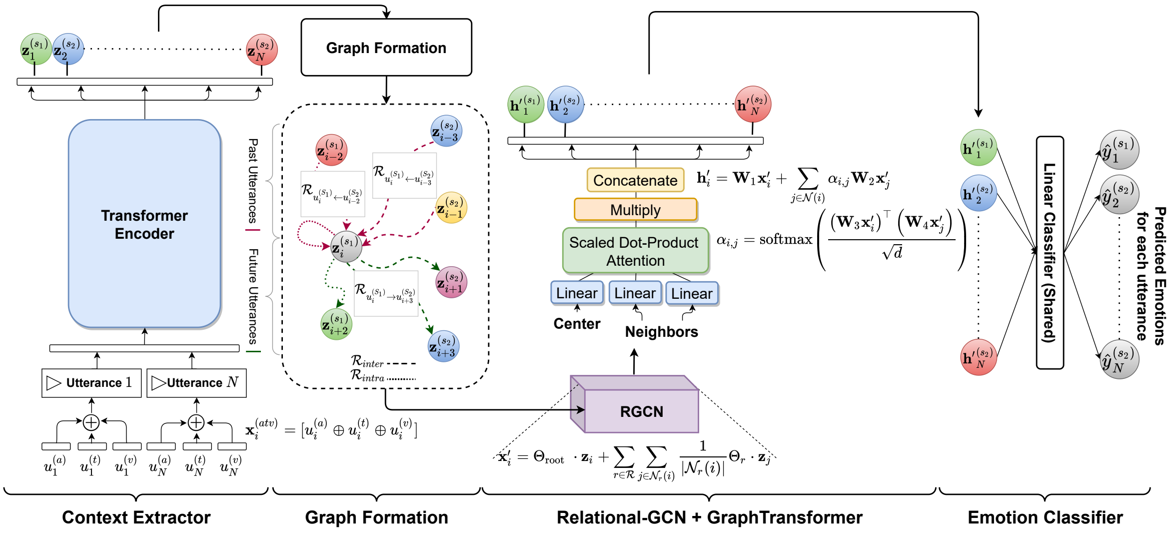

Figure 2: The proposed model (**COGMEN**) architecture.

the utterances to predict the corresponding emotions.

Context Extractor: Context Extractor takes concatenated features of multiple modalities (audio, video, text) as input for each dialogue utterance ($u_i; i = 1, \ldots, n$) and captures the context using a transformer encoder. The feature vector for an utterance u_i with the input features corresponding to available modalities, audio ($u_i^{(a)} \in \mathbb{R}^{d_a}$), text ($u_i^{(t)} \in \mathbb{R}^{d_t}$) and video ($u_i^{(v)} \in \mathbb{R}^{d_v}$) is:

$$\mathbf{x}_i^{(atv)} = [u_i^{(a)} \oplus u_i^{(t)} \oplus u_i^{(v)}] \in \mathbb{R}^d$$

where $d = d_a + d_t + d_v$. The combined features matrix for all utterances in a dialogue is given by:

$$\mathbf{X} = \mathbf{x}^{(atv)} = [\mathbf{x}_1^{(atv)}, \mathbf{x}_2^{(atv)} \ldots, \mathbf{x}_n^{(atv)}]^T$$

We define a Query, a Key, and a Value vector for encoding the input features $\mathbf{X} \in \mathbb{R}^{n\times d}$ as follows:

$$\begin{aligned} Q^{(h)} &= \mathbf{X}W_{h,q}, \\ K^{(h)} &= \mathbf{X}W_{h,k}, \\ V^{(h)} &= \mathbf{X}W_{h,v}, \end{aligned}$$

where, $W_{h,q}, W_{h,k}, W_{h,v} \in \mathbb{R}^{d\times k}$

The attention mechanism captures the interaction between the Key and Query vectors to output an attention map $\alpha^{(h)}$, where σ_j denotes the softmax function over the row vectors indexed by j:

$$\alpha^{(h)} = \sigma_j\left(\frac{Q^{(h)}(K^{(h)})^T}{\sqrt{k}}\right)$$

where $\alpha^{(h)} \in \mathbb{R}^{n\times n}$ represents the attention weights for a single attention head (h). The obtained attention map is used to compute a weighted sum of the values for each utterance:

$$\begin{aligned} \text{head}^{(h)} &= \alpha^{(h)}(V^{(h)}) \in \mathbb{R}^{n\times k} \\ \mathbf{U}' &= [\text{head}^{(1)} \oplus \text{head}^{(2)} \oplus \ldots \text{head}^{(H)}]W^o \end{aligned}$$

where, $W^o \in \mathbb{R}^{kH\times d}$ and H represents the total number of heads in multi-head attention. Note $\mathbf{U}' \in \mathbb{R}^{n\times d}$. We add residual connection $\mathbf{X}$ and apply LayerNorm, followed by a feed forward and Add & Norm layer:

$$\begin{aligned} \mathbf{U} &= \text{LayerNorm}\left(\mathbf{X} + \mathbf{U}'; \gamma_1, \beta_1\right); \\ \mathbf{Z}' &= \text{ReLU}\left(\mathbf{U}W_1\right)W_2; \\ \mathbf{Z} &= \text{LayerNorm}\left(\mathbf{U} + \mathbf{Z}'; \gamma_2, \beta_2\right); \end{aligned}$$

where, $\gamma_1, \beta_1 \in \mathbb{R}^d$, $W_1 \in \mathbb{R}^{d\times m}$, $W_2 \in \mathbb{R}^{m\times d}$, and $\gamma_2, \beta_2 \in \mathbb{R}^d$. The transformer encoder provides features corresponding to every utterance in a dialogue ($[\mathbf{z}_1, \mathbf{z}_2, \ldots, \mathbf{z}_n]^T = \mathbf{Z} \in \mathbb{R}^{n\times d}$).

Graph Formation: A graph captures inter and intra-speaker dependency between utterances. Every utterance acts as a node of a graph that is connected using directed relations (past and future relations). We define relation types as speaker to speaker. Formally, consider a conversation between M speakers defined as a dialogue $\mathcal{D} = \{\mathcal{U}^{S_1}, \mathcal{U}^{S_2}, \ldots, \mathcal{U}^{S_M}\}$, where $\mathcal{U}^{S_1} = \{u_1^{(S_1)}, u_2^{(S_1)}, \ldots, u_n^{(S_1)}\}$ represent the set of utterances spoken by speaker-1. We define intra relations between the utterances spoken by the same speaker, $\mathcal{R}_{intra} \in \{\mathcal{U}^{S_i} \rightarrow \mathcal{U}^{S_i}\}$, and inter relations between the utterances spoken by different speakers, $\mathcal{R}_{inter} \in \{\mathcal{U}^{S_i} \rightarrow \mathcal{U}^{S_j}\}_{i \neq j}$. We further consider a window size and use $\mathcal{P}$ and $\mathcal{F}$ as hyperparameters to form relations between the past $\mathcal{P}$ utterances and future $\mathcal{F}$ utterances for every utterance in a dialogue. For instance, $\mathcal{R}_{intra}$ and $\mathcal{R}_{inter}$ for utterance $u_i^{(S_1)}$ (spoken by speaker-1) are defined as:

$$\begin{aligned}
\mathcal{R}_{intra}(u_i^{(S_1)}) = \{\, & u_i^{(S_1)} \leftarrow u_{i-\mathcal{P}}^{(S_1)} \ldots u_i^{(S_1)} \leftarrow u_{i-1}^{(S_1)}, \\
& u_i^{(S_1)} \leftarrow u_i^{(S_1)}, u_i^{(S_1)} \rightarrow u_{i+1}^{(S_1)} \ldots u_i^{(S_1)} \rightarrow u_{i+\mathcal{F}}^{(S_1)} \,\} \\
\mathcal{R}_{inter}(u_i^{(S_1)}) = \{\, & u_i^{(S_1)} \leftarrow u_{i-\mathcal{P}}^{(S_2)}, \ldots, u_i^{(S_1)} \leftarrow u_{i-1}^{(S_2)}, \\
& u_i^{(S_1)} \rightarrow u_{i+1}^{(S_2)}, \ldots, u_i^{(S_1)} \rightarrow u_{i+\mathcal{F}}^{(S_2)} \,\}
\end{aligned}$$

where ← and → represent the past and future relation type respectively (example in Appendix F).

Relational Graph Convolutional Network (RGCN): The vanilla RGCN (Schlichtkrull et al., 2018) helps accumulate relation-specific transformations of neighboring nodes depending on the type and direction of edges present in the graph through a normalized sum. In our case, it captures the inter-speaker and intra-speaker dependency on the connected utterances.

$$\mathbf{x}'_i = \Theta_{\text{root}} \cdot \mathbf{z}_i + \sum_{r \in \mathcal{R}} \sum_{j \in \mathcal{N}_r(i)} \frac{1}{|\mathcal{N}_r(i)|} \Theta_r \cdot \mathbf{z}_j$$

where $\mathcal{N}_r(i)$ denotes the set of neighbor indices of node i under relation $r \in \mathcal{R}$, Θ_{root} and Θ_r denote the learnable parameters of RGCN, $|\mathcal{N}_r(i)|$ is the normalization constant and $\mathbf{z}_j$ is the utterance level feature coming from the transformer.

GraphTransformer: For extracting rich representation from the node features, we use a GraphTransformer (Shi et al., 2021). GraphTransformer adopts the vanilla multi-head attention into graph learning by taking into account nodes connected via edges. Given node features $H = \mathbf{x}'_1, \mathbf{x}'_2, \ldots, \mathbf{x}'_n$ obtained from RGCN,

$$\mathbf{h}'_i = \mathbf{W}_1 \mathbf{x}'_i + \sum_{j \in \mathcal{N}(i)} \alpha_{i,j} \mathbf{W}_2 \mathbf{x}'_j$$

where the attention coefficients $\alpha_{i,j}$ are computed via multi-head dot product attention:

$$\alpha_{i,j} = \text{softmax}\left(\frac{(\mathbf{W}_3 \mathbf{x}'_i)^\top \left(\mathbf{W}_4 \mathbf{x}'_j\right)}{\sqrt{d}} \right)$$

Dataset	Number of dialogues [utterances]

Table 1: Dataset Statistics.

Emotion Classifier: A linear layer over the features extracted by GraphTransformer ($\mathbf{h}'_i$) predicts the emotion corresponding to the utterance.

$$h_i = \text{ReLU}(W_1 \mathbf{h}'_i + b_1)$$

$$\mathcal{P}_i = \text{softmax}(W_2 h_i + b_2)$$

$$\hat{y}_i = \arg\max(\mathcal{P}_i)$$

where $\hat{y}_i$ is the emotion label predicted for the utterance u_i.

4 Experiments

We experiment for the Emotion Recognition task on the two widely used datasets: **IEMOCAP** (Busso et al., 2008) and **MOSEI** (Zadeh et al., 2018b). The dataset statistics are given in Table 1. IEMOCAP is a dyadic multimodal emotion recognition dataset where each utterance in a dialogue is labeled with one of the six emotion categories: anger, excited, sadness, happiness, frustrated, and neutral. In literature, two IEMOCAP settings are used for testing, one with 4 emotions (anger, sadness, happiness, neutral) and one with 6 emotions. We experiment with both of these settings. MOSEI is a multimodal emotion recognition dataset annotated with 7 sentiments (-3 (highly negative) to +3 (highly positive)) and 6 emotion labels (happiness, sadness, disgust, fear, surprise, and anger). Note that the emotion labels differ across the datasets. We use weighted F1-score and Accuracy as evaluation metrics (details in Appendix C).

Implementation Details: For IEMOCAP, audio features (size 100) are extracted using OpenSmile (Eyben et al., 2010), video features (size 512) are taken from Baltrusaitis et al. (2018), and text features (size 768) are extracted using sBERT (Reimers and Gurevych, 2019). Audio features for the MOSEI dataset were taken from Delbrouck et al. (2020), which are extracted using librosa (McFee et al., 2015) with 80 filter banks, making the feature vector size of 80. The video features (size 35) are taken from Zadeh et al. (2018b). The textual features (size 768) are obtained using sBERT. The textual features are

Table 2: Results on IEMOCAP (6-way) multimodal (A+T+V) setting. Avg. denotes weighted average.

sentence-level static features. For Audio and Visual modalities, we use sentence/utterance level features by averaging all the token level features. We fuse the features of all the available modalities (A(audio)+T(text)+V(video): ATV) via concatenation. We also explored other fusion mechanisms (Appendix G.1). However, concatenation gave the best performance. We conduct a hyper-parameter search for our proposed model using Bayesian optimization techniques (details in Appendix A).

Baselines: We do a comprehensive evaluation of **COGMEN** by comparing it with a number of baseline models. For IEMOCAP, we compare our model with the existing multimodal frameworks (Table 2), which includes DialogueRNN (Majumder et al., 2019), bc-LSTM (Poria et al., 2017), CHFusion (Majumder et al., 2018), memnet (Sukhbaatar et al., 2015), TFN (Zadeh et al., 2017), MFN (Zadeh et al., 2018a), CMN (Hazarika et al., 2018b), ICON (Hazarika et al., 2018a), and Af-CAN (Wang et al., 2021b). For MOSEI, **COGMEN** is compared (Table 4) with multimodal models, including Multilogue-Net (Shenoy and Sardana, 2020) and TBJE (Delbrouck et al., 2020) (details and analysis of baselines in §6).

Model	**F1-score (%)**
bc-LSTM	75.13
CHFusion	76.80
COGMEN	**84.50**

Table 3: Results on IEMOCAP dataset for 4 emotion classes in multimodal setting (weighted F1-score).

5 Results and Analysis

IEMOCAP: Table 2 shows the results for IEMOCAP (6-way) multimodal setting. Overall, **COGMEN** performs better than all the previous baselines as measured using accuracy and F1-score. We also see an improvement in the class-wise F1 for happy, sad, neutral, and excited emotions. This improvement is possibly due to the GNN architecture (described in analysis later) that we are using in our model, and none of the previous multimodal baselines uses GNN in their architecture. Results for IEMOCAP (4-way) setting are in Table 3. In this setting, **COGMEN** achieves 7.7% improvement over the previous SOTA model.

MOSEI: For emotion classification across 6 emotion classes, we used two settings (as done in previous works): *Binary Classification* across each emotion label where a separate model is trained for every emotion class, and *Multi-label Classification* in which the sentence is tagged with more than 1 emotion and single model predicts multiple classes. The reason for doing this was that Multilogue-Net provides results on binary classification setting and TBJE provides results on Multi-label setting. We ran both models on these settings. For a fair comparison, we use the same utterance level textual features similar to our setting (extracted from sBERT) and train Multilogue-Net architecture on both the settings. Originally, Multilogue-Net used GloVe embeddings (Pennington et al., 2014) for textual features, and actual results in the paper are different than reported here. For TBJE, we use the features provided by the paper as it uses token-level features. **COGMEN** outperforms (Table 4) the baseline models in most of the cases. For 2 class sentiment classification, **COGMEN** outperforms the previous baselines with the highest accuracy score of 85% for A+T. For 7 class, our model shows comparable performance. All the multimodal approaches tend to perform poorly when

		Sentiment Class Accuracy(%)		Emotion Class (weighted) F1-score (%)						Multi-label Emotion Class (weighted) F1-score (%)					
Model		**2 Class**	**7 Class**	**Happiness**	**Sadness**	**Angry**	**Fear**	**Disgust**	**Surprise**	**Happiness**	**Sadness**	**Angry**	**Fear**	**Disgust**	**Surprise**

	T + A + V	81.5	44.4	-	-	-	-	-	-	64.0	67.9	74.7	84.0	83.6	86.1
COGMEN	T	84.42	43.50	69.28	70.49	73.04	87.80	83.69	85.83	69.92	72.16	77.34	86.39	**86.00**	88.27
	A + T	**85.00**	44.31	68.39	**73.28**	74.98	88.08	**83.90**	85.35	69.62	72.67	76.93	86.39	85.35	88.21
	T + A + V	84.34	43.90	**70.42**	72.31	**76.20**	**88.17**	83.69	85.28	**72.74**	**73.90**	**78.04**	86.71	85.48	**88.37**

Table 4: Results on MOSEI dataset. For emotion classification, a weighted F1-score is used. For Sentiment Classification, the results are reported using accuracy. 2 class sentiment consists of only positive and negative sentiment. 7 class sentiment consists of sentiments from highly negative (-3) to highly positive (+3). For the cells showing '-', the results were not provided in the paper, and we were not able to reproduce the results since *TBJE* used token level features, and we are using sentence-level features.

# Utterances in Context	**F1-score (%)**

Table 7: Comparison with unimodal architectures on IEMOCAP dataset.

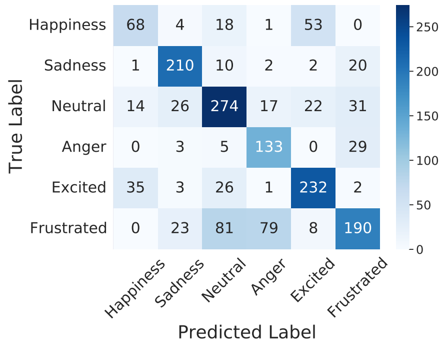
adding visual modality, possibly because of noise present in the visual modality and lack of alignment with respect to other modalities. In contrast, our model can capture rich relations across the modalities and show a performance boost while adding visual modality.

We conducted further analysis on our model. Although due to space limitations, the results below mainly describe experiments over IEMOCAP, similar trends were observed for MOSEI as well.

Effect of Local and Global Info.: We test our architecture in two information utilization settings: global and local. To test the importance of context in our architecture, we create a sub-dataset using the IEMOCAP (4-way) setting by splitting each dialogue into n utterances and training our architecture. Table 5 shows the decrease in performance with number of utterances present in a dialogue (more details on effect of window size in Appendix G.2). This experiment helps understand the importance of context in a dialogue. Moreover, it points towards challenges in developing a real-time system (details in §6). We test the local information hypothesis by removing the GNN module and directly passing the context extracted features to the emotion classifier. Table 6 shows the drop in performance across modalities when the GNN component is removed from the architecture, making our local information hypothesis more concrete.

Effect of Relation Types: We also test the effect of inter and intra-relations in the dialogue graph by making all relations of the same type and training the architecture. We observe a drop in performance (Table 6) when the relations are kept the same in the graph formation step. The explicit relation formation helps capture the local dependencies present in the dialogue.

Effect of Modalities: The focus of this work is multimodal emotion recognition. However, just for the purpose of comparison, we also compare with unimodal (text only) approaches. We compare (Table 7) with EmoBERTa (Kim and Vossen, 2021), DAG-ERC (Shen et al., 2021b), CESTa (Wang et al., 2020), SumAggGIN (Sheng et al., 2020), DialogueCRN (Hu et al., 2021), DialogXL (Shen et al., 2021a) and DialogueGCN (Ghosal et al., 2019). Text-based models are specifically optimized for text modalities and incorporate changes to architectures to cater to text. It is not fair to compare with our multimodal approach from that perspective. As shown in results, **COGMEN**, being a fairly generic architecture, still gives better (for IEMOCAP (4-way)) or comparable performance with respect to the SOTA unimodal architectures. In the case of our model, adding more information via other modalities helps to improve the performance. Results on different modality combinations are in Appendix D.



True Label \ Predicted Label	Happiness	Sadness	Neutral	Anger	Excited	Frustrated
Happiness	68	4	18	1	53	0
Sadness	1	210	10	2	2	20
Neutral	14	26	274	17	22	31
Anger	0	3	5	133	0	29
Excited	35	3	26	1	232	2
Frustrated	0	23	81	79	8	190

Figure 3: Confusion Matrix for IEMOCAP (6-way)

Error Analysis: After analysing the predictions made across the datasets, we find that our model falls short in distinguishing between similar emotions, such as *happiness* vs *excited* and *anger* vs *frustration* (Figure 3). This issue also exists in previous methods as reported in Shen et al. (2021b), and Ghosal et al. (2019). We also find that our model misclassifies the other emotion labels as neutral because of a more significant proportion of neutral labeled examples. Moreover, we observe the accuracy of our model when classifying examples having emotion shift is 53.6% compared to 74.2% when the emotion remains the same (more details in Appendix B).

Efficacy of the GNN Layer: For observing the effect of the GNN component in our architecture, we also visualize the features before and after the GNN component. Figure 4 clearly shows the better formation of emotion clusters depicting the importance of capturing local dependency in utterances for better performance in emotion recognition (more in Appendix E and Appendix Figure-9).

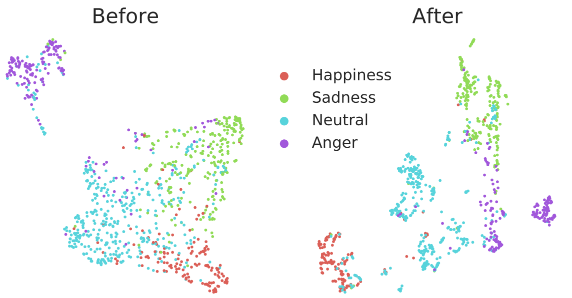


Figure 4: UMAP (Becht et al., 2019) representation of IEMOCAP (4-way) features before and after GNN.

Importance of utterances: To verify the effect of utterances and their importance in a prediction for a dialogue, we infer the trained model on dialogues by masking one utterance at a time and calculating the F1-score for prediction. Figure 5 shows the obtained results for a dialogue (Appendix Table 10) instance taken randomly from IEMOCAP (4-way) (more in Appendix E). For the first 4 utterances, emotions state being neutral, the effect of masking the utterances is significantly less. In contrast, masking the utterances with emotion shift (9, 10, 11) completely drops the dialogue's F1-score, showing that our architecture captures the effects of emotions present in the utterances.

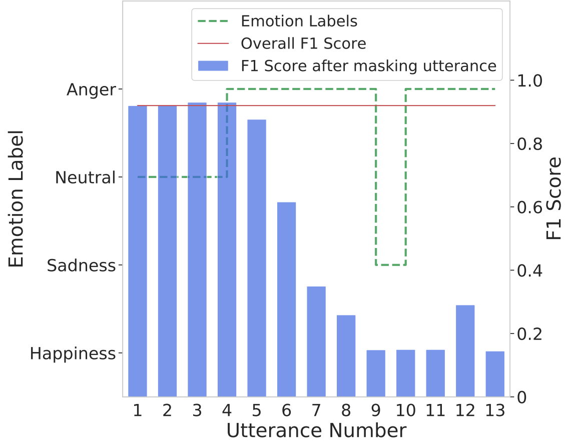

Figure 5: Importance of utterances in IEMOCAP (4-way). Performance drop is observed while masking 9^{th}, 10^{th} and 11^{th} utterances during inference.

6 Discussion

Comparison with Baselines: Emotion recognition in a multimodal conversation setting comes with two broadly portrayed research challenges (Poria et al., 2019), first, the ability of a model to capture global and local context present in the dialogues, and second, the ability to maintain self and interpersonal dependencies among the speakers. All the popular baselines like Dialogue-GCN (Ghosal et al., 2019), DialogueRNN (Majumder et al., 2019), bc-LSTM (Poria et al., 2017) Af-CAN (Wang et al., 2021a), etc., try to address these challenges by proposing various architectures. bc-LSTM (bi-directional contextual LSTM (Poria et al., 2017)) uses LSTM to capture the contextual information and maintain long relations between the utterances from the past and future. Another contemporary architecture Af-CAN (Wang et al., 2021a) utilizes recurrent neural networks based on contextual attention to model the interaction and dependence between speakers and uses bi-directional GRU units to capture the global features from past and future. We propose to address these issues using a unified architecture that captures the effect of context on utterances while maintaining the states for self and interpersonal dependencies. We make use of transformers for encoding the global context and make use of GraphTransformers to capture the self and interpersonal dependencies. Our way of forming relational graphs between the utterances comes close to DialogueGCN (unimodal architecture). We further use a shared Emotion classifier for predicting emotions from all the obtained utterance level features. Moreover, our unified architecture handles multiple modalities effectively and shows an increase in performance after adding information from other modalities.

Limitations (Offline Setting): A noteworthy limitation of all the proposed Emotion Recognition approaches (including the current one) is that they use global context from past and future utterances to predict emotions. However, baseline systems compared in this paper are also offline systems. For example, bc-LSTM (bi-directional contextual LSTM) and Af-CAN use utterances from the past and future to predict emotions. Other popular baselines like DialogueGCN and DialogueRNN (BiDialogueRNN) also peek into the future, assuming the presence of all the utterances during inference (offline setting). All such systems that depend on future information can only be used in an offline setting to process and tag the dialogue. An Emotion Recognition system that could work in an online setting exhibits another line of future work worth exploring due to its vast use cases in live telecasting and telecommunication. A possible approach to maintain the context in an online setting would be to take a buffer of smaller context size, where the model can predict emotions taking not the complete dialogue but a smaller subset of it as input in real-time. We tried exploring this setting for our architecture with an online buffer of maintaining a smaller context window. For experimenting with it, we created a sub-dataset using the IEMOCAP (4-way) setting by splitting each dialogue into n utterances and training our architecture. Our results in Table 5 show the decrease in performance with the number of utterances present in a dialogue depicting the importance of context in a conversation. Performance improvements in these settings where the system can work in real-time are worth exploring and are an interesting direction for future research.

7 Conclusion and Future Work

We present a novel approach of using GNNs for multimodal emotion recognition and propose **COGMEN: COntextualized GNN based Multimodal Emotion recognitioN**. We test **COGMEN** on two widely known multimodal emotion recognition datasets, IEMOCAP and MOSEI. **COGMEN** outperforms the existing state-of-the-art methods in multimodal emotion recognition by a significant margin (i.e., 7.7% F1-score increase for IEMOCAP (4-way)). By comprehensive analysis and ablation studies over **COGMEN**, we show the importance of different modules. **COGMEN** fuses information effectively from multiple modalities to improve the performance of emotion prediction tasks. We perform a detailed error analysis and observe that the misclassifications are mainly between the similar classes and emotion shift cases. We plan to address this in future work, where the focus will be to incorporate a component for capturing the emotional shifts for fine-grained emotion prediction.

Appendix

A Hyperparameter Setting

Hyperparameters used to train our model are described in Table 8 for IEMOCAP (4-way and 6-way) and Table 9 for MOSEI dataset.

Dropout	GNNHead	SeqContext	ILR
0.1	7	4	1e-4

Table 8: **Hyperparameter values for our model on IEMOCAP dataset.** *ILR: Initial learning rate.*

Modalities	Dropout	GNNHead	SeqContext	ILR
T	0.399	3	5	3.3e-3
A+T	0.103	1	2	6.9e-3
A+T+V	0.337	2	1	1.1e-3

Table 9: **Hyperparameter value on MOSEI dataset**. *ILR: Initial learning rate.*

We use PyTorch (Paszke et al., 2019) for training our architecture and PyG (PyTorch Geometric) (Fey and Lenssen, 2019) for the GNN component in our architecture. We use comet (Comet.ML, 2021) for logging all our experiments and its Bayesian optimizer for hyperparameter tuning. Our architecture trained on the IEMOCAP dataset has 55,932,052 parameters and takes around 7 minutes to train for 50 epochs on the NVIDIA Tesla K80 GPU. Comparison of the model with baselines in terms of the number of parameters is challenging, as the baselines parameters vary depending on the hyperparameter setting. Moreover, many baselines do not provide information about the number of parameters.

B Dataset Analysis

We study IEMOCAP dataset in detail for error analysis of our model. We observe the emotion transition at Utterance level (Figure 6) and Speaker level (Figure 7). We find a high percentage of transitions between similar emotions, causing the models to confuse between the similar classes of emotion. Considering the emotion transition between states that are opposite, like from happy to sad, we deduce the poor performance of emotion recognition architectures for such cases. We plan to address this issue in future work where we target a model which performs better in fine-grained emotion recognition and is robust towards the shifts in emotions.

	happiness	sadness	neutral	anger	excited	frustrated
happiness	277	22	65	2	104	7
sadness	25	594	105	21	6	73
neutral	79	110	544	176	87	308
anger	1	19	158	446	7	277
excited	109	9	92	10	489	22
frustrated	5	71	311	267	24	768

C Evaluation Metrics

Weighted F1 Score: The F1 score can be interpreted as a harmonic mean of the precision and recall, where an F1 score reaches its best value at 1 and worst score at 0. The relative contribution of precision and recall to the F1 score are equal. The formula for the F1 score is:

$$F1 = 2 * \frac{(precision * recall)}{(precision + recall)}$$

For weighted F1 score, we calculate metrics for each label, and find their average weighted by support (the number of true instances for each label).
Accuracy: It is defined as the percentage of correct predictions in the test set.

D Results on Modality Combinations

Table 11 shows results on the IEMOCAP dataset for all the modality combinations for our architectures. Figure 8 shows the confusion matrix for prediction on IEMOCAP 4-way dataset.

Speaker	Utterance Text	Emotion
M	’Why does that bother you?’	neutral
F	"She’s been in New York three and a half years. Why all of the sudden?"	neutral
M	’Well maybe. Maybe she just wanted to see her again.’	neutral
F	"What did you mean? He lived next door to the girl all of his life, why wouldn’t he want to see her again? Don’t look at me like that, he didn’t tell me any more than he told you."	neutral
M	"She’s not his girl. She knows she’s not."	angry
F	"I want you to pretend like he’s coming back!"	angry
M	"Because if he’s not coming back, then I’ll kill myself."	angry
F	’Laugh. Laugh at me, but what happens the night that she goes to sleep in his bed, and his memorial breaks in pieces?"	angry
M	’Only last week, another boy turned up in Detroit, been missing longer than Larry, you read it yourself, ’	angry
F	"You’ve got to believe. You’ve got to–"	sad
M	"What do you mean me above all? Look at you. You’re shaking!"	angry
F	"I can’t help it!"	angry
M	’What have I got to hide? What the hell is the matter with you, Kate?’	angry

E Additional Analysis

Efficacy of the GNN Layer: We observe the efficacy of the GNN component in our architecture and visualize the features before GNN and after the GNN component (Figure 9) explained in section 5.

Importance of utterances: Figure 10 shows the obtained results for a dialogue instance taken randomly from IEMOCAP 4-way. For the first 15 utterances, emotions state being sadness, the effect of masking the utterances is more negligible for the first 5 utterances. This drop depicts the importance of utterances 5-15 that affect future utterances. Further, masking the utterances with high

7	$u^{(S_2)}$	$u^{(S_1)}$	Future	$u^{(S_2)} \rightarrow u^{(S_1)}$
8	$u^{(S_2)}$	$u^{(S_2)}$	Future	$u^{(S_2)} \rightarrow u^{(S_2)}$

Table 13: Unique Relation types for a conversation between two speakers

emotion shift (15 to 30) drops the F1 score of the dialogue, showing the importance of fluctuations for predicting the emotion states for other utterances.

F Graph Formation

To give a clear picture of the graph formation procedure, we describe the process for utterances spoken in a dialogue. As an illustration, let's consider two speakers, S_1 and S_2, present in a conversation of 7 utterances. Features corresponding to each utterance is shown as a node in Figure 11. Speaker 1 speaks utterances $u_{i-3}, u_{i-1}, u_{i+1}, u_{i+3}$ and Speaker 2 speaks u_{i-2}, u_i, u_{i+2}. After creating the graphs with relations, the constructed graph would look like shown in Figure 11, and the corresponding relations for each instance would be as shown in Table 12. Since there are two speakers in the conversation ($S_N = 2$), the total number of unique relations would be:

$$\begin{aligned} \text{number of relations} &= 2 \times (S_N)^2 \\ &= 2 \times (2)^2 \\ &= 8 \end{aligned}$$

Table 13 shows the number of possible unique relations for a conversation between two speakers.

G Discussion

G.1 Modality Fusing Mechanisms

While experimenting with the model architecture, we explored various mechanisms for mixing information from multiple modalities. Some of the mechanisms include pairwise attention inspired from Ghosal et al. (2018), bimodal attention present in Multilogue-Net (Shenoy and Sardana, 2020), and crossAttention layer proposed in HKT (Hasan et al., 2021). However, in our case, none of these fusing mechanisms shows significant performance improvement over simple concatenation. Moreover, all these fusing mechanisms require extra computation steps for fusing information. In contrast, a simple concatenation of modality features works well with no additional computational overhead.

G.2 Effect of window size in Graph Formation

To explore the effect of window size in the Graph Formation module of our architecture, we conduct experiments with multiple window sizes. The obtained results are present in Table 14. The window size can be treated as a hyperparameter that could be adjusted while training our architecture. Moreover, the freedom of setting the window size makes our architecture more flexible in terms of usage. A larger window size would result in better performance for cases where the inter and intra speaker dependencies are maintained for longer sequences. In contrast, setting a lower window size would be better in a use case where the topic frequently changes in dialogues and speakers are less affected by another speaker. In the future, we plan to explore a dynamic and automatic selection of window size depending on the dialogue instance.

Modalities	Window Past	Window future	F1 Score (%)
atv	1	1	81.72
atv	2	2	83.21

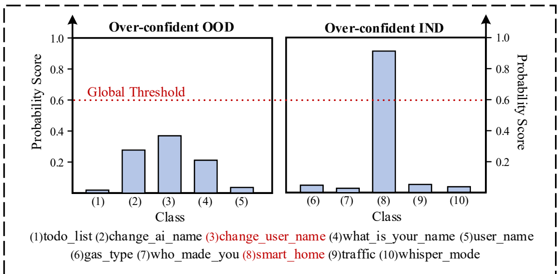
Abstract

Detecting Out-of-Domain (OOD) or unknown intents from user queries is essential in a task-oriented dialog system. A key challenge of OOD detection is the overconfidence of neural models. In this paper, we comprehensively analyze overconfidence and classify it into two perspectives: over-confident OOD and in-domain (IND). Then according to intrinsic reasons, we respectively propose a novel reassigned contrastive learning (RCL) to discriminate IND intents for over-confident OOD and an adaptive class-dependent local threshold mechanism to separate similar IND and OOD intents for over-confident IND. Experiments and analyses show the effectiveness of our proposed method for both aspects of overconfidence issues.[1]

1 Introduction

Out-of-domain (OOD) detection is a key component of the task-oriented dialogue system(Gnewuch et al., 2017; Akasaki and Kaji, 2017; Shum et al., 2018; Tulshan and Dhage, 2019). It aims to decide whether a user query falls outside the range of predefined supported intents and avoid performing wrong operations (Lin and Xu, 2019; Xu et al., 2020; Zeng et al., 2021a). Due to the complexity of annotating OOD intents, most work focus on unsupervised OOD detection where there is no labeled OOD data but only labeled in-domain (IND) data (Xu et al., 2020). No prior knowledge about OOD intents makes it challenging to identify these unknown samples in the dialog system.



Error Type	Input Sentence	Ground Truth	Baseline Predict
Over-confident OOD	can you call me a different name	change_user_name(IND)	OOD
Over-confident IND	please clean the car windows	OOD	smart_home(IND)

Figure 1: Examples of two kinds of overconfidence.

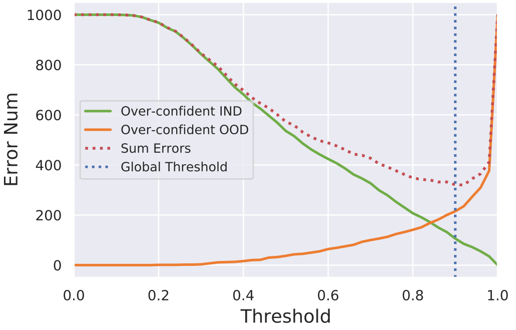


Figure 2: Number of error cases comparing over-confident IND and OOD. Global threshold denotes the best overall performance.

Existing unsupervised OOD detection methods mostly follow the same framework: firstly learn intent representations via labeled in-domain (IND) data then employ detecting algorithms, such as Maximum Softmax Probability (MSP) (Hendrycks and Gimpel, 2017), Local Outlier Factor (LOF) (Lin and Xu, 2019), Gaussian Discriminant Analysis (GDA) (Xu et al., 2020) to compute the similarity of features between OOD samples and IND samples. For example, Hendrycks and Gimpel (2017) simply uses a fixed threshold on the IND classifier's probability estimate and predicts a query as OOD only if its max logit is below the threshold. Lin and Xu (2019) employs an unsupervised density-based novelty detection algorithm, local outlier factor (LOF) to detect OOD intents. Further, Zeng et al. (2021a) proposes a supervised contrastive learning objective to learn discriminative intent features.

However, these methods ignore the key challenge of OOD detection, over-confidence. Guo et al. (2017); Liang et al. (2017, 2018) have theoretically proved that deep neural networks with the softmax classifier are prone to produce highly

---

July 10-15, 2022

over-confident posterior distributions even for such abnormal OOD samples. In this paper, we define the over-confidence issue from two aspects. (1) IND → OOD: Given an in-domain test sample, the pre-trained IND classifier predicts a lower confidence score than a fixed threshold[2] and incorrectly regards it as an OOD intent, which we name as **over-confident OOD**. We argue it's because IND classes have high semantic similarity then scatter and lower the max confidence score. For example, in Figure 1, the IND test query "can you call me a different name" is wrongly detected as OOD intent because its ground-truth IND label *change_user_name* is similar to the other IND categories *what_is_your_name* and *change_ai_name*. Thus the query gets comparable probability scores among the three IND classes, resulting in a lower max probability score than the threshold. (2) OOD → IND: Given an OOD test sample, the same classifier instead predicts a higher confidence score than the threshold and wrongly regards it as an IND, which we name as **over-confident IND**. The reason is the spurious correlation between OOD and IND intents, such as similar syntactic structure, entities, etc. For example, the OOD query "please clean the car windows" is classified into the IND category *smart_home* because plausibly similar examples like "please lock the doors" also exist in this category. The spurious correlation is frequent since humans define OOD without a clear and standard principle. Existing models (Lee et al., 2018; Ren et al., 2019; Zheng et al., 2020; Xu et al., 2020) mainly focus on the latter aspect over-confident IND, but we find the former over-confident OOD also makes a side effect on OOD detection. As Figure 2 shows, as the threshold rises, the number of negative OOD samples also increases which denotes the over-confident OOD issue gets worse but the over-confident IND issue gets better. We need to consider both two aspects of overconfidence.

In this paper, we propose a novel reassigned contrastive learning (RCL) to discriminate intent representations between semantically similar IND categories and an adaptive class-dependent local threshold mechanism to separate similar IND and OOD intents. Specifically, for over-confident OOD, we first construct hard contrastive pairs among easily misclassified IND types using a pre-trained intent classifier. Then we train a new model to learn discriminative intent representations for similar IND categories via supervised contrastive learning (Khosla et al., 2020; Gunel et al., 2020). We aim to sample hard contrastive batches where anchors and positives have the same class label but different classifier outputs (hard positives), and anchors and negatives have the same classifier output but different class labels (hard negatives). For over-confident IND, we propose an adaptive class-dependent local threshold mechanism to separate similar IND and OOD intents. Traditional detection methods like MSP, GDA, Energy (Liu et al., 2020) use a global threshold to identify the confidence score of a test query, ignoring the difference between each IND class with OOD samples. We aim to adjust the class-dependent local threshold so that semantically correlated OOD and IND classes have a higher threshold to mitigate the model's overconfidence to IND.

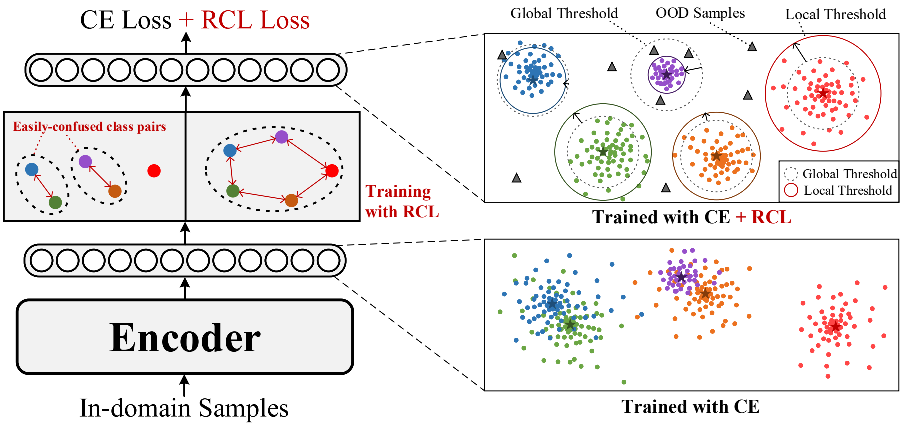
Our contributions are three-fold: (1) We perform a comprehensive study on the overconfidence issue of OOD detection and analyze two-aspect reasons. (2) We propose a novel reassigned contrastive learning (RCL) to discriminate IND intents for over-confident OOD and an adaptive class-dependent local threshold mechanism to separate similar IND and OOD intents for over-confident IND. (3) Experiments and detailed analyses demonstrate the effectiveness of our proposed method for both aspects of overconfidence issues.

2 Related Work

OOD Detection Unsupervised models use only IND data for OOD detection following the threshold-based protocol, including modeling the probability density (Pidhorskyi et al., 2018), reconstruction (Golan and El-Yaniv, 2018), using classifier ensembles (Vyas et al., 2018; Shu et al., 2017), Bayesian models (Malinin and Gales, 2018), likelihood ratios (Ren et al., 2019). Note that all these methods require a dev set of labeled OOD intents to tune a fixed global threshold hyperparameter. We propose a more robust and efficient local threshold mechanism both to improve OOD performance and reduce the need for a large dev set of labeled OOD data. Another type of OOD detection model aims to utilize a set of OOD data in the training phase, including N+1 classifier (Fei and Liu, 2016; Zhan et al., 2021), entropy regularization (Zheng et al., 2020), adversarial augmentation (Zeng et al., 2021c).

---

[2] The threshold is tuned via the dev set. We will discuss it later.



a) The overall architecture b) The representation space

Figure 3: The overall architecture of our proposed approach. Reassigned contrastive learning (RCL) discriminates intent representations between semantically similar IND categories for over-confident OOD and adaptive class-dependent local threshold separates similar IND and OOD intents for over-confident IND.

Contrastive Learning Recent contrastive learning methods (Chen et al., 2020; He et al., 2020) have proven effective to learn unsupervised representations for downstream tasks. Winkens et al. (2020); Zeng et al. (2021b) combine cross-entropy loss on labeled IND data and instance-wise contrastive learning (CL) loss on unlabeled data (including unlabeled IND and OOD intents). They require a large amount of unlabeled corpus and can't explicitly distinguish different intent types. Further, Zeng et al. (2021a) uses supervised contrastive learning (SCL) (Khosla et al., 2020) to learn discriminative intent representations only using labeled IND data. Compared to CL, SCL regards all the IND intents from the same class as positive pairs and samples from different classes as negative pairs. However, we find intents within similar categories are still easily misclassified (see Section E). Thus, we propose a simple but strong reassigned contrastive learning (RCL) framework to give more penalty on these easily-confused IND classes to explicitly distinguish them. RCL aims to learn discriminative intent representations for OOD detection. Zhuang et al. (2019); Wang and Liu (2021) mines negatives close to the anchor sample as hard negatives by computing representation cosine similarity, but RCL uses the model's wrong predictions as supervised positives and negatives. Our method is more accurate because estimating representation similarity may be biased and we can construct both hard positives and negatives.

3 Methodology

Figure 3 shows the overall architecture of our proposed RCL and class-dependent local threshold where RCL discriminates easily-confused IND intents and local threshold separates similar IND and OOD intents. We follow a two-stage framework: first train an in-domain intent classifier in the training stage, then extract the intent feature of a test sample and employ the detection methods in the test stage.

3.1 Reassigned Contrastive Learning

Traditional models (Hendrycks and Gimpel, 2017) use cross-entropy (CE) loss to train an IND intent classifier which does not explicitly distinguish the margins between IND categories. Later, Lin and Xu (2019) and Zeng et al. (2021a) respectively propose a large margin cosine loss (LMCL) and a supervised contrastive learning (SCL) loss to minimize intra-class variance and maximize inter-class distance. However, we find IND intents within similar categories are still easily misclassified (see Section E). Therefore, we aim to give more penalty on these easily-confused IND classes to learn discriminative intent representations.

We first review the original contrastive learning (CL) and supervised contrastive learning (SCL) then introduce our RCL framework. Given an IND sample x_i and its intent label y_i, we adopt a BiLSTM (Hochreiter and Schmidhuber, 1997) or BERT (Devlin et al., 2019) encoder to get the intent representation z_i. Following Chen et al. (2020); Zeng et al. (2021b), we formulate CL loss for a positive pair of examples (i, j) as:

$$\ell_{i,j} = -\log \frac{\exp\left(\operatorname{sim}\left(z_i, z_j\right)/\tau\right)}{\sum_{k=1}^{2N} \mathbb{1}_{[k\neq i]} \exp\left(\operatorname{sim}\left(z_i, z_k\right)/\tau\right)} \tag{1}$$

where $\mathbb{1}_{[k\neq i]} \in \{0, 1\}$ is an indicator function evaluating to 1 if $k \neq i$. τ denotes a temperature parameter. The final loss is computed across all positive pairs, both (i, j) and (j, i) in a mini-batch of N examples. CL regards two augmented [3] views of a sample as positive pairs and views of different samples as negative pairs. Further, SCL extends the positive set by adding views of different samples from the same IND intent class and vice versa. However, these methods ignore easily-confused relations between semantically similar IND classes and can't separate them in the latent space. Therefore, we add more penalty to these easily-confused IND classes to learn discriminative intent representations. Specifically, our proposed reassigned contrastive learning (RCL) framework includes three stages.

IND classifier training First, we train an initial intent classification model M_{init} on the labeled IND dataset $\{(x_i, y_i)\}_{i=1}^{n}$ using CE, and save its predictions $\{\hat{y}_i\}_{i=1}^{n}$ on the training IND datapoints. We will use these outputs to train a more discriminated model.

Confused-label pair contrasting Here we aim to separate easily misclassified IND types. Thus we use the M_{init} outputs to obtain confused label pairs of the training data. For example, if class A and B have misclassified error cases, we use all the A and B's samples to construct contrastive batches. Then we perform SCL on these batches to train a new intent model M from scratch [4]. The intuition is that we treat samples that have the same class label but different classifier outputs as hard positives, and samples that have the same classifier output but different class labels as hard negatives. We display an example as Figure 4. Essentially, we restrict the new model to focus on misclassified intent classes by adding hard positives and negatives, further to learn discriminative intent representations. Different from existing hard CL work (Zhuang et al., 2019; Wang and Liu, 2021) which only consider close negatives as hard negatives using representation similarity, RCL uses the model's wrong predictions as supervised positives and negatives. Our method is more accurate because estimating representation similarity may be biased and we can construct both hard positives and negatives. We also perform SCL on other clean IND types.

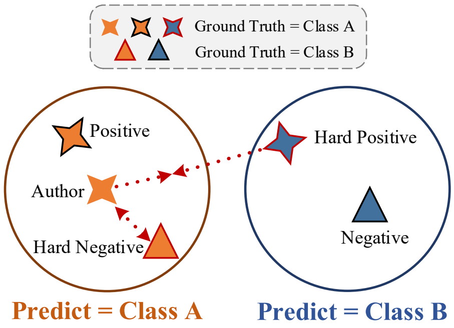


Figure 4: An example of confused label pair (A, B) where the same color denotes the same prediction class of the initial model.

In the experiments, we iteratively repeat the two processes for 5 epochs.

Global contrasting Apart from the confused label pairs, we also employ SCL on all the IND samples to avoid knowledge forgetting. Following Zeng et al. (2021a), we regard views of different samples from the same IND intent class as positives and views of different samples from the different IND intent class as negatives. Finally, we use CE to fine-tune the model M. In the experiments, we set the training epoch of SCL and CE to 10 and 20.

3.2 Adaptive Class-Dependent Local Threshold

Previous detection methods usually use a global threshold to identify the confidence score of a test query, ignoring the difference between individual IND classes with OOD samples. For example, if a test OOD query is similar to an IND type, it may obtain a high confidence score on this IND category and be wrongly regarded as IND. Therefore, we aim to set adaptive class-dependent local thresholds to avoid over-confident IND.

Previous methods using global threshold (Xu et al., 2020; Zeng et al., 2021a) first compute the max confidence scores of all the OOD and IND intents on the dev set, like max probability score, then adjust the threshold to maximize OOD F1 on the dev set. Notice it's a general and standard setting where a few labeled OOD data exists in the dev set for hyperparameter tuning for the OOD detection task.[5] For the local threshold, we input all OOD and IND queries to the pre-trained classifier and then get the confidence scores belonging to each IND type. Here we can use existing detection

---

[3] In this paper, we use adversarial augmentation as Zeng et al. (2021a). Please see more details in the original paper.

[4] We find training a new model M from scratch is much better than continual finetuning M_{init}. We argue it's hard to remove intrinsic knowledge existing in a model.

[5] Section 5.4 shows our local threshold requires only 20 OOD intents on CLINC to achieve excellent metrics compared to 15, 000 IND intents in the training set, which is more robust and efficient.

	CLINC-Full		CLINC-Small		Snips	
	IND	OOD	IND	OOD	IND	OOD
Vocabulary size	6240		5725		11241	
Avg utterance length	9		9		9	
Intents	150	-	150	-	5	2

Samples per class	20	-	20	-	20	-
Testing Set Size	5500	1000	5500	1000	500	200
Samples per class	30	-	30	-	100	-

Table 1: Full statistics of OOD datasets, CLINC-Full, CLINC-Small and Snips.

methods to get confidence scores, such as MSP, GDA, Energy, etc. Taking MSP as an example, we get probability scores of all the intents. Then we group all the OOD samples into the corresponding IND type according to the max probability. So in each group, we have both OOD and IND intents and learn the class-dependent threshold by maximizing OOD F1 on each group. If no OOD sample is grouped into an IND type, we simply select the global threshold as the local threshold for this IND type. For inference, we select the local threshold of corresponding IND category where the test query gets the max probability score and predict it as OOD if the score is below the local threshold, Otherwise IND. Note that tuning local threshold doesn't increase too much computation cost but only multiple judgments and no extra cost in the inference. Local threshold achieves the best performance on CLINC and Snips even only using 20 OOD intents and is robust to different datasets and different number of OOD intents.

4 Experiments

4.1 Datasets

We perform experiments on three public benchmark OOD datasets, including CLINC-Full, CLINC-Small (Larson et al., 2019) and Snips (Coucke et al., 2018). We show the detailed statistic of these datasets in Table 1. Snips is a personal voice assistant dataset which contains 7 types of user intents across different domains. We randomly sample two classes among all classes in Snips, regarding them as OOD classes and the rest as IND classes. CLINC-Full and CLINC-Small both contain 150 IND intents across 10 domains. CLINC-Full has 100 training samples for each IND type, while CLINC-Small contains 50. We follow the standard dataset split Larson et al. (2019) and use the collected OOD test queries for evaluation. Note that all the datasets we used have a fixed set of labeled OOD data but we don't use it for training. We notice some work (Zhang et al., 2021) use a different split in CLINC-Full dataset where they sample 25%, 50%, 75% of all IND classes as IND, the other IND classes as OOD. The simulated split makes OOD data similar to IND data which class clusters are more compact thus get higher metrics. In this paper, we mainly follow the standard dataset split unless otherwise stated. For fair comparison, we also perform the same dataset split 25%, 50%, 75% in Table 3 and Table 10.

4.2 Metrics

We report both OOD metrics: Recall and F1-score (F1) and in-domain metrics: F1-score (F1). Since, we aims to improve the performance of detecting out-of-domain intents from user queries, OOD Recall and F1 are the main evaluation metrics in this paper.

4.3 Baselines

In training stage, we compare RCL with CE and SCL. In detection stage, we compare local threshold with global threshold. To verify the generalization of our proposed models, we use three OOD detection algorithms MSP (Maximum Softmax Probability)(Hendrycks and Gimpel, 2017), GDA (Gaussian Discriminant Analysis)(Xu et al., 2020) and Energy(Ouyang et al., 2021). Besides, we compare our models with the following state-of-the-art baselines, OpenMax(Bendale and Boult, 2016a), DeepUnk(Lin and Xu, 2019), Energy(Ouyang et al., 2021), SCL(Zeng et al., 2021a) and ADB(Zhang et al., 2021). We provide a more comprehensive comparison and implementation details of these models in the Appendix.

4.4 Implementation Details

To conduct a fair comparison, we follow a similar evaluation setting as (Zeng et al., 2021a) and (Zhang et al., 2021). We use the public pre-trained GloVe embeddings (Pennington et al., 2014) and BERT-uncased (Devlin et al., 2019) (with 12-layer transformer, implemented in PyTorch) to embed tokens. We set the learning rate to 1e-03 for LSTM and 2e-05 for BERT. To speed up the traning procedure and achieve better performance, we freeze all but the last transformer layer parameters of BERT. We use Adam optimizer (Kingma and Ba, 2014) to train our model and set the dropout rate to 0.5. We use the best F1 scores on the development set to calculate the MSP, GDA and Energy thresholds adaptively. Each result of the experiments is tested

for 10 times under the same setting and reports the average value. In the training stage, for our model, we conduct 5 epochs of confused-label pair contrasting on designative batches of IND data, and then 10 epochs of global contrasting on randomly sampled IND data. Finally, we used CE to finetune the previous model with the epoch to 20. For the baselines in Table 2, we set the training epoch to 20 for CE and 15 for SCL. For fair comparison, we adopt the same data augmentation method as (Zeng et al., 2021a). Specifically, we apply adversarial attack to generate pseudo positive samples to increase the diversity of views for contrastive learning. The training time for CE is about 1.6 minutes using Glove+LSTM, and 12 minutes using BERT. The training stage of our model lasts about 2 minutes using Glove+LSTM, and 15 minutes using BERT on single Tesla T4 GPU (16 GB of memory) in CLINC-Full dataset which has 15,000 training samples. And the test stage of our model lasts about 1 second using Glove+LSTM, and 3 seconds using BERT. We have similar training time with SCL. And the test time of RCL is the same as that of CE and SCL.

4.5 Main Results

Table 2 displays our experimental results on datasets of CLINC-full and Snips with three different OOD detection algorithms: MSP, GDA and Energy. We show similar results on CLINC-Small dataset in the Appendix Table 7. From Table 2, we can make the following observations.

Our method achieves the best results under all detection algorithms. Using RCL+Local threshold significantly outperforms all the baselines under different OOD detection algorithms. Specifically, our method achieves 10.44%, 5.84%, 4.20% improvements over SCL+Global threshold on OOD F1 under three OOD detection algorithms on CLINC-full dataset and 7.30%, 7.64% and 7.49% on Snips dataset. We also observe that F1 score of IND classification with our approaches can keep comparable or slightly outperform the baselines, showing that RCL and class-dependent local threshold effectively improve OOD detection without harming the performance of IND classification. We show similar results on CLINC-Small dataset in the Appendix Table 7.

RCL consistently outperforms CE and SCL. On CLINC-Full, RCL achieves 4.73%, 4.57% and 4.18% improvements over SCL on OOD F1 under three OOD detection settings and 4.77%, 4.97% and 4.69% on Snips dataset, respectively. It demonstrates that RCL can stably discriminate the representation space by separating easily-confused classes and thus improve the performance of OOD detection. We also find compared with local threshold, RCL improved more significantly on global threshold. We argue this is due to the local threshold has alleviated part of overconfidence problem.

Local threshold consistently outperforms global threshold. We find the local threshold consistently wins the global one with a significant margin, especially in MSP. We argue MSP suffers from more serious over-confident IND issue than GDA and energy. This reveals that the local threshold can alleviate the over-confident IND issue by assigning an adaptive threshold for each IND class.

Comparing with previous baselines. To make a

Models	Min	Median	Max	Mean
CE	162.9	252.6	445.5	261.1
SCL	125.0	228.8	408.7	235.9
RCL(ours)	**96.4**	**177.9**	**390.2**	**190.6**

Table 4: Intra-class variance statistics.

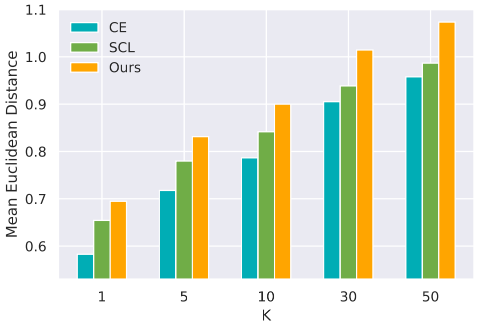

Figure 5: Inter-class distance statistics with different number of the nearest class centers.

fair comparison with previous baselines, we follow the same setting as Zhang et al. (2021). Specifically, we use the BERT as the backbone of the model, and sample 25%, 50%, 75% or 100% (Full) classes of the CLINC-Full dataset as the IND classes, the other as OOD. From Table 3 and 10 (in the Apendix), we can observe that our approach outperforms previous baselines on F1 scores of both OOD detection and IND classification. We achieve 4.56%, 3.51%, 4.03%, and 5.51% performance gain on OOD F1 for the 25%, 50%, 75% and Full settings.

5 Analysis

5.1 Analysis of IND Representations

To analyse how our RCL method affects the representation space and improves the performance of OOD detection, we perform a statistical analysis of the intra-class variance within each class as well as the inter-class distance between multiple classes.

RCL leads to smaller intra-class variance. To calculate the intra-class variance, we first compute the class center by averaging all samples representation corresponding to same class, then we calculate the variance of all samples to corresponding class center as the corresponding intra-class variance. In Table 4, we show the intra-class variance statistics among all classes with different training strategies: CE, SCL and our proposed RCL. We can find that all of the minimum, median, mean and maximum values of our approach are lower than CE and SCL, demonstrating that the RCL makes the representations within a single class tighter.

Type 1	Type 2	Models	Inter-class Distance
change_user_name	change_ai_name	CE	0.526
		SCL	0.573
		Ours	**0.900**
change_user_name	payday	CE	1.023
		SCL	1.151
		Ours	**1.181**
what_is_your_name	user_name	CE	0.449
		SCL	0.466
		Ours	**0.789**
change_speed	play_music	CE	0.774
		SCL	0.925
		Ours	**1.094**
rewards_balance	redeem_rewards	CE	0.511
		SCL	0.572
		Ours	**0.666**

Table 5: Inter-class distance statistics between Confused Pairs.

RCL leads to larger inter-class distance. We calculate the inter-class distance by averaging the euclidean distance from the center class to its K nearest classes. For each class, we take the class center by averaging all representations that belong to this class. Figure 5 show that our RCL approach consistently obtains larger inter-class distance compared to CE and SCL. This phenomena shows that our approach improves the OOD detection performance by separating among classes while maintaining intra-class high cohesion. It effectively improves the uniformity of the representation space.

5.2 Analysis of Confusing IND Categories

To further verify the effect of RCL on easily-confused classes, we select 4 label pairs that are easily confused by the baseline model (*change user name* v.s. *change ai name*, *what is your name* v.s. *user name*, *change speed* v.s. *play music*, and *rewards balance* v.s. *redeem rewards*). In addition, we also select one label pair that is semantically unrelated (*change user name* v.s. *payday*). For each class pair, we compare the inter-class of models that are trained with CE, SCL and our RCL.

We can observe from the group that training with RCL greatly increases the inter-class distance between confusable classes in Table 5. Take the first class pair as an example, our RCL achieves 57% gain of inter-class distance over the SCL baseline, while the SCL only achieves 9% gain based on CE. On the other hand, when comparing between the group 1 and 2, we can conclude that our method works better on pushing away confusable class pairs, while for semantically unrelated ones, the effect is not obvious (+ 57% v.s. + 2.6%).

5.3 Effect of Local Threshold

As we discussed above, setting a general global threshold for OOD detection is a straightforward

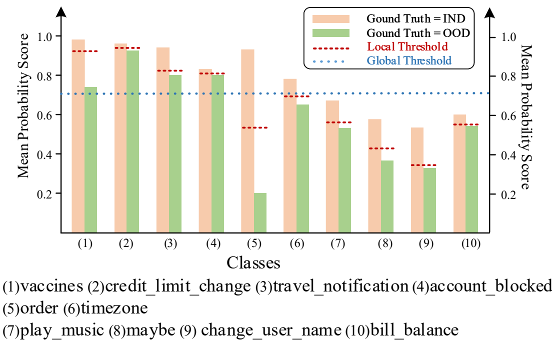

Figure 6: Local Threshold vs Global Threshold.

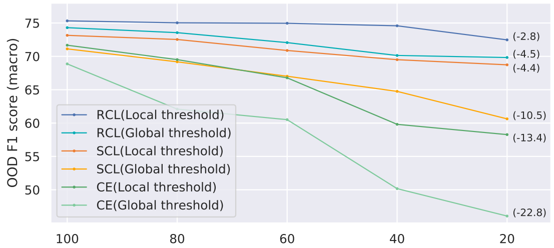
idea and the common practice in reality. However, it can not be applied to the situation where the variance of each IND class is various. If the global threshold is not suitable for some specific IND classes, the probability of true OOD samples may exceed the global threshold, resulting in over-confident IND samples.

To show the effect of class-dependent local threshold, we randomly select 20 IND classes, and give the mean softmax probability of the IND samples of each class as well as the OOD samples that have the same class with maximum softmax probability (i.e., these samples may be misclassified to this IND class or correctly identified as OOD, depending on the threshold). Then, we give the global threshold and the class-dependent local threshold for each IND class. For simplicity, we only show the mean value but variance. Note that the threshold between IND and OOD means most of the judgments are correct, but not necessarily all of them. We show half of results in Figure 6 and the rest in the Appendix(Figure 10).

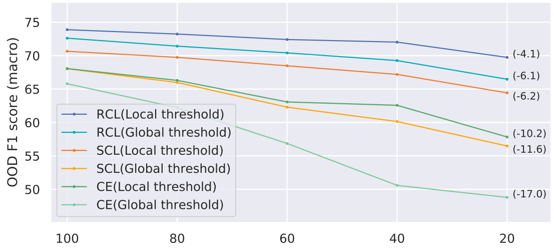
For IND classes (1) - (4), the averaged maximum softmax probabilities of OOD samples are all beyond the threshold, indicating that a large proportion of the OOD samples are over-confident and will be classified to the corresponding IND class. However, with our class-dependent local threshold, the threshold is greater than the global threshold and can distinguish the IND and OOD samples more precisely.

For IND classes (5) - (6), the global threshold is lucky to distinguish the IND and OOD samples. However, we find these classes only make up a small proportion of all IND classes (about 20% since only 2 classes among 10 belong to this case).

For IND classes (7) - (10), we find even the averaged maximum softmax probability of IND samples is below the global threshold. It means that these IND classes can be easily confused with other semantically related IND classes, and thus degrades their maximum softmax probabilities, resulting in over-confident OOD samples. In contrast, our local threshold can automatically select the proper threshold, adaptively degrading the threshold correspondingly so that the threshold can exactly separate the IND and OOD samples.



(a) Energy



(b) GDA

Figure 7: Effect of out-of-domain data size in development set.

5.4 Effect of Development Set Size

Figure 7 shows the effect of development set size. Using a small amount of OOD samples in development set to get a more suitable threshold is inevitable in OOD detection task. To show the effect of development set size, we randomly choose development data with a certain proportion from CLINC-Full OOD labeled development set and use the original test set for evaluation. We use the LSTM+Energy and LSTM+GDA settings.

Compare local and global thresholds. We find that the local threshold consistently outperforms global threshold with a significant margin, regardless of the OOD detection methods and training strategies we applied. Specifically, the performance drops are -4.5%(-2.8%), -10.5%(-4.4%) and -22.8%(-13.4%) over global(local) thresholds with three training strategies, respectively. Besides, we also find that the CE+Global collapses in performance when there are only 20 samples in dev set, while CE+Local is much better. We speculate that this phenomenon occurs because the OOD samples in the CLINC-Full dataset are diverse and the global threshold tends to overfit the data. It confirms that our proposed local threshold method can alleviate the reliance on development size by

Models	IND<->OOD			IND<->IND	All Errors
	IND->OOD	OOD->IND	SUM		
MSP	156	576	732	290	1022
MSP + RCL	**122**	542	664	233	897
MSP + Local Threshold	284	**378**	662	234	896
MSP + RCL + Local Threshold	229	390	**619**	**194**	**813**

Table 6: Statistics of different error types using RCL and Local Threshold.

assigning a specific threshold for each class.

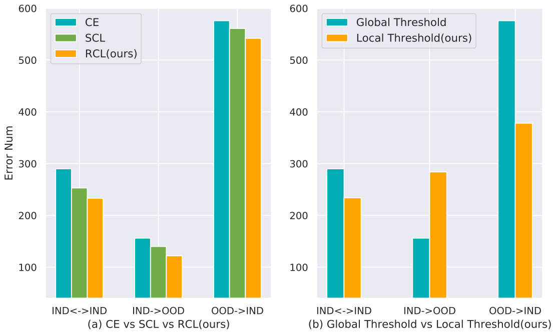
Compare RCL with other training strategies. We find that the RCL consistently outperforms SCL and CE. Specifically, under CE, SCL and RCL, the performance drops are -22.8%, -10.5% and -4.5%, respectively. Besides, with the decrease of development data size, the corresponding difference gradually increases. It demonstrates that RCL can effectively relieve the dependence on development size by separating easily misclassified classes.

We also observe that in the range of 40-100, the performance of RCL hardly degrades. To be more specific, when only 40 OOD labeled data provided, the OOD F1 score of RCL+Local threshold model is still 74.58(-0.74%). And even when only 20 OOD labeled data are available(about 0.13% training data), our proposed model still outperforms the best baseline(SCL+Global threshold) with 100 OOD labeled data by 1.35%. This reveals that our model is more robust and less dependent on development set size. And the result of our model is significantly improved under four datasets further proves that our proposed methods have strong robustness and generalization capability.

5.5 Analysis of Error Types

In order to explore the effect of our method on different error types. We divide all the error samples into three categories: **confusion between IND**(IND<->IND), **over-confident OOD**(IND<->OOD) and **over-confident IND**(OOD<->IND).

Figure 8(a) indicates that RCL can achieve consistently improvements in all the three error types. Figure 8(b) indicates that local threshold outperforms global threshold both in error of IND<->IND and OOD->IND. While greatly reducing OOD->IND errors, local threshold inevitably increases IND->OOD errors (explained by Figure 2). We hypothesize this is due to the high semantic similarity between IND classes and labeling noise in dataset, which can be mitigated by RCL(see Table 6). We will leave more possible solutions for future work. Combined with Table 6, compared to global threshold, our local threshold can obtain smaller overall errors. In general, local threshold is better for the overall performance.



(a) CE vs SCL vs RCL(ours)

(b) Global Threshold vs Local Threshold(ours)

Figure 8: Statistics of different error types using different training objectives and different thresholds.

Table 6 displays the comparison between RCL and local threshold. We find our RCL and local threshold both outperform MSP baseline and RCL+local threshold achieves the best performance. Comparing RCL and local threshold, RCL targets at IND->OOD errors (from 156 to 122) for over-confident OOD, while local threshold helps reduce OOD->IND errors (from 576 to 378) for over-confident IND. Besides, they both help reduce overall IND&OOD errors. On the other hand, the performance improvement on OOD detection always helps IND classification.

6 Conclusion

In this paper, we focus on the overconfidence issue of unsupervised OOD detection. We find the reasons for overconfidence arise from two aspects: (1) IND classes have high semantic similarity. (2) IND and OOD intents have spurious correlations. According to the two reasons, we respectively propose a novel reassigned contrastive learning (RCL) to discriminate IND intents for over-confident OOD and an adaptive class-dependent local threshold mechanism to separate similar IND and OOD intents for over-confident IND. We perform extensive experiments and comprehensive analyses to demonstrate the effectiveness of our approach. We hope to provide new guidance for future work.

A Comparison of CL, SCL and RCL

Contrastive learning (CL) methods (Chen et al., 2020; He et al., 2020) have been proven effective to learn unsupervised representations for downstream tasks. Winkens et al. (2020); Zeng et al. (2021b) propose to apply contrastive learning (CL) to OOD detection task. They first perform CL on unlabeled data (including unlabeled IND and OOD intents) to learn OOD representations, then use cross-entropy loss on labeled IND data to learn an IND intent classifier. But the unlabeled data is not always available. More importantly, CL can only independently learn the OOD and IND representations (because the CL loss is built in an instance-wise way), but not explicitly distinguish different intent types in a class-wise way. Further, Zeng et al. (2021a) uses supervised contrastive learning (SCL) (Khosla et al., 2020) to learn discriminative intent representations only using labeled IND data. Compared to CL, SCL regards all the IND intents from the same class as positive pairs and samples from different classes as negative pairs. SCL aims to learn tight intent representations for each intent type and tries to distinguish different intent types. However, we find intents within similar categories

are still easily misclassified (see Section E). Intuitively, these easily-confused IND classes can be regarded as hard examples (Zhuang et al., 2019) for existing CL-based methods. Inspired by the idea, we propose a simple but strong reassigned contrastive learning (RCL) framework to give more penalty on these easily-confused IND classes to explicitly distinguish them. The main difference is the confused-label pair contrasting process (we provide an example to show how to construct hard positives and negatives in Figure 4) and please see details in the Confused-label pair contrasting section(line 241-267). Generally, RCL aims to learn discriminative intent representations for OOD detection, especially for these easily-confused intent classes. Compared to Zhuang et al. (2019); Wang and Liu (2021), these work only mines negatives close to the anchor sample as hard negatives by computing representation cosine similarity, but RCL uses the model's wrong predictions as supervised positives and negatives. Our method is more accurate because estimating representation similarity may be biased and we can construct both hard positives and negatives. Note that RCL only increases the training cost for a little but requires no extra inference budget and uses the same model size as SCL. Please see the following section for details.

B Comparison of time complexity and space complexity

We discuss the time and space complexity of RCL and Local threshold in Table 8 and Table 9. In terms of time complexity, we set the epoch of SCL and RCL to 15. The training time for RCL is about 15 minutes using BERT in CLINC-Full dataset which has 15,000 training samples. RCL have similar training time with SCL. And the test stage of global threshold lasts about 3 seconds using BERT. The local threshold has almost the same test time as the global threshold, while the performance can even be increased by 9%. From the perspective of space complexity, RCL and SCL utilize the same encoder structure. The size of the model parameters of RCL is equal to that of SCL. Besides, the global threshold and the local threshold are only the differences of the algorithm, and there are no extra parameters.

C Algorithm

We show the training procedure of RCL in Algorithm 1. E_0, E_1 and E_2 are the training epochs of confused-label pair contrasting, global contrasting and cross-entropy classification processes, respectively. In practice, we set E_0, E_1 and E_2 to 5, 10 and 20, respectively. n is the number of training samples. First, we construct a set of confused la-

Algorithm 1 : Reassigned Contrastive Learning

for epoch = 1 to $E_2$ do
    random sample batches $B_2 = \{(x_i, y_i)\}_{i=1}^{N}$ from $D_0$
    compute cross-entropy loss
end for
```

bel pairs by combining the ground truth labels y and predicted labels $\hat{y}$ of the training data. Taking Figure 4 as an example, (A, B) is one of confusing label pairs in P. m is the number of confusing label pairs. And the remaining labels that never confused with other labels, called clean labels, are collected in the set S. k is the number of clean labels. Then, we sample confused mini-batch $\hat{B}$ following P restrainedly. Note that a mini-batch $\hat{B}_j$ will only contain the samples with ground truth y_j or $\hat{y}_j$. We also sample clean mini-batch B following S restrainedly. Different from the confused mini-batch, a clean mini-batch B_j can contain any sample whose label belongs to S. We will compute the supervised contrastive loss iteratively, on confused mini-batch or clean mini-batch. Apart from confused-label pair contrasting, we also employ global contrasting by randomly sampling batches on all IND samples to avoid knowledge forgetting. Finally, we compute cross-entropy loss to fine-tune the model.

D Baselines

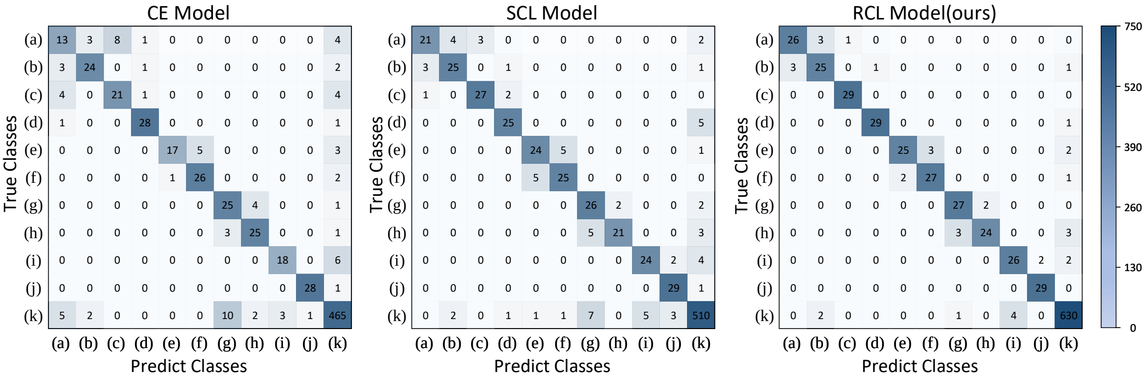
We compare many types of unsupervised OOD detection models. For feature extractor, we use LSTM(Long Short Term Memory)(Hochreiter and Schmidhuber, 1997) or BERT(Bidirectional Encoder Representations from Transformers)(Devlin et al., 2019). For training objection, we compare RCL with CE and SCL. For detection algorithms, to verify the generalization of our proposed models, we use MSP(Maximum Softmax Probability)(Hendrycks and Gimpel, 2017), GDA(Gaussian Discriminant Analysis)(Xu et al., 2020) and Energy(Ouyang et al., 2021). Besides, we compare our models with the following state-of-the-art baselines, OpenMax(Bendale and Boult, 2016a), DeepUnk(Lin and Xu, 2019), Energy(Ouyang et al., 2021), SCL(Zeng et al., 2021a), ADB(Zhang et al., 2021). We supplement the relevant baseline details as follows:

MSP (Maximum Softmax Probability)(Hendrycks and Gimpel, 2017) applies a threshold on the maximum softmax probability. We use the best F1 scores on the validation set to calculate the threshold adaptively.

GDA (Gaussian Discriminant Analysis)(Xu et al., 2020) is a generative distance-based classifier for out-of-domain detection with Euclidean space. It estimates the class-conditional distribution on feature spaces of DNNs via Gaussian discriminant analysis to avoid over-confidence problems and use Mahalanobis distance to measure the confidence score of whether a test sample belongs to OOD.

Energy(Ouyang et al., 2021) maps a sample $\mathbf{x}$ to a single scalar called the *energy*. We use the threshold on the energy score to consider whether a test query belongs to OOD.

OpenMax(Bendale and Boult, 2016b) is an open set detection method in computer vision, we adapt



(a)change_user_name (b)user_name (c)change_ai_name (d)what_is_your_name (e)redeem_rewards

Figure 9: Confusion matrix of CE, SCL and RCL based on MSP.

it for OOD. We firstly use the CE loss to train a classifier on in-domain intents, then fit a Weibull distribution to the classifier's output logits.

DeepUnk(Lin and Xu, 2019) learns the deep intent features with the margin loss and detects the unknown intent with local outlier factor.

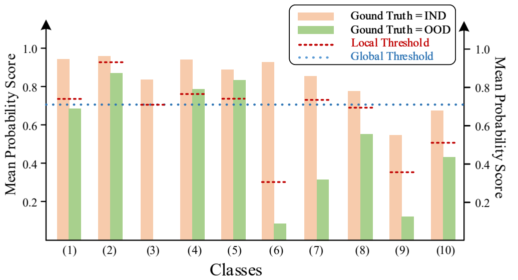
SCL(Zeng et al., 2021a) uses a supervised contrastive learning objective to learn discriminative intent features. We conduct many experiments and from multiple perspectives prove that our method can consistently outperform SCL.

ADB(Zhang et al., 2021) learns adaptive decision boundary using a loss function to balance both the empirical risk and the open space risk. It is still a time-consuming process. Compare with ADB, our method can achieve the best performance.

E IND Confusion Matrix

To demonstrate how our proposed RCL approach improves the performance by decreasing the number of error cases, we show the confusion matrix among 10 IND classes as well as the unseen OOD class. Specially, we pick 10 easily-confused classes by the baseline model as the IND classes, and show the confusion matrices of CE, SCL and RCL in Figure 9. From the figure, we can make the following observations.

On the one hand, we find the confusion of easily-confused IND classes is significantly mitigated. Take the beginning four IND classes *change user name* (a), *user name* (b), *change ai name* (c) and *what is your name* (d) as an example, when training with CE, there are totally 34 misclassified samples. However, after applying our RCL approach, the number misclassified samples decreases to 11, which is a 68% reduction. It indicates that the confusion among those semantically close IND classes is effectively alleviated by our RCL training strategy.



(1)calories (2)interest_rate (3)pto_balance (4)uber (5)update_playlist
(6)order_checks (7)definition (8)timezone (9)distance (10)restaurant_reviews

Figure 10: Local Threshold vs Global Threshold.

On the other hand, we focus on the confusion between the unseen OOD and the IND classes. The last row of the confusion matrix indicates the over-confident IND (truly OOD sample, but predicted as IND), while the last column of the confusion matrix indicates the over-confident OOD (truly IND sample, but predicted as OOD). We can find that our RCL model reduces the number of over-confident IND samples by 69.6% and 70.0% compared to the CE and SCL models, respectively. Meanwhile, our RCL model also reduces the number of over-confident OOD samples by 60.0% and 47.4% compared to the CE and SCL models, respectively. This phenomena proves that our RCL model improves the OOD detection performance through solving the over-confident IND and OOD issues.

F Effect of Local Threshold

Figure 10 shows the result of the additional 10 IND classes. Limited by the degree of semantic similarity between OOD and IND, there may be no OOD samples on some classes. In this case, we will set the local threshold to be the same as the global threshold, as IND class (3).

For IND classes (1), (6), (7) and (8), both the global threshold and local threshold are between the mean softmax probability of the IND samples and OOD samples. Analyze with specific examples, we find that the probability of OOD samples in (6) is more concentrated on small probability values, while (7) and (8) have greater variance. Compared with the global threshold, the local threshold can better alleviate the over-confident problem by choosing a more appropriate threshold boundary.

For IND classes (2), (4) and (5), the mean maximum softmax probabilities of OOD samples are all beyond the global threshold. For category (2), the local threshold falls exactly between IND and OOD while global does not. For (4) and (5), although both the local threshold and the global threshold are below OOD, it is clear that the local threshold is more reasonable.

For IND classes (9) and (10), both the averaged max softmax probability of IND and OOD are lower than the global threshold, which means that a large portion of IND samples will be misclassified as OOD. On the contrary, our local threshold method can adaptively select more appropriate thresholds, which largely eliminates the problem of overconfident OOD.

AISFG: Abundant Information Slot Filling Generator

Yang Yan[*], **Junda Ye**[*], **Zhongbao Zhang, Liwen Wang**
Beijing University of Posts and Telecommunications, Beijing, China
`{yanyang42,jundaye,zhongbaozb,w_liwen}@bupt.edu.cn`

Abstract

As an essential component of task-oriented dialogue systems, slot filling requires enormous labeled training data in a certain domain. However, in most cases, there is little or no target domain training data is available in the training stage. Thus, cross-domain slot filling has to cope with the data scarcity problem by zero/few-shot learning. Previous researches on zero/few-shot cross-domain slot filling focus on slot descriptions and examples while ignoring the slot type ambiguity and example ambiguity issues. To address these problems, we propose **A**bundant **I**nformation **S**lot **F**illing **G**enerator (**AISFG**), a generative model with a novel query template that incorporates domain descriptions, slot descriptions, and examples with context. Experimental results show that our model outperforms state-of-the-art approaches in zero/few-shot slot filling task.[1]

1 Introduction

Slot filling is a critical part of downstream tasks in natural language understanding (NLU) such as dialogue systems. Recently, some supervised slot filling models have achieved state-of-the-art results within deep learning (Mesnil et al., 2013; Yao et al., 2013; Louvan and Magnini, 2018; Kim et al., 2019).Nonetheless, these methods have a strong dependency on the domain-specific labels, which is not capable of transferring to new domains that always contain little or no data.

To alleviate the problem of resource gap between source and target domains, cross-domain zero-shot has become an important research direction in slot filling. However, most researches on slot filling utilize token-level classification frameworks, which means they either convert it to a BIO tag labeling task (Shah et al., 2019; Bapna et al., 2017; Du et al., 2021) or predict the start and end position as QA task in the sentence (Du et al., 2021; Yu et al., 2021a), to extract spans. Recently, prompt learning methods reformulate the downstream tasks to a similar form with the pre-training tasks, which can fully utilize the knowledge encoded in PLMs and improve the performance of the downstream tasks in the scenarios of data scarcity. Motivated by this, we consider making the slot filling task consistent with PLMs pre-training tasks.

In this paper, we propose a generative template-based zero-shot slot filling framework named Abundant Information Slot Filling Generator (AISFG), which utilizes pre-trained generative model as the backbone and generates responses in natural language style. Thus, the slot filling task is consistent with the pre-training task of the PLM. In particular, we notice that shared cross-domain slot types sometimes refer to totally different entities across different domains. For example, in the SNIPS dataset (Coucke et al., 2018), domains *RateBook* and *SearchScreeningEvent* share a common slot type *object_type*, but it refers to book type and movie schedule, respectively. We call this slot type ambiguity issue. Moreover, we argue that incorporating slot examples only is far from fully utilizing the example information. For instance, for sentence *give 5 out of 6 stars to creatures of light and darkness*, we give the slot description to find *best rating* with examples *like 6 and 5*, the model produces the wrong answer 5 but not 6. We conjecture that, the model just learn that predicting a number is satisfying from these two examples but does not understand what is the best rating means. We call this example ambiguity issue. Thus, we attach our attention to domain-specific descriptions and examples with context to alleviate the above two issues. Specifically, we design the query template by incorporating domain descriptions, slot descriptions and examples with context.

The contribution of this paper can be summarized in three aspects:

July 10-15, 2022

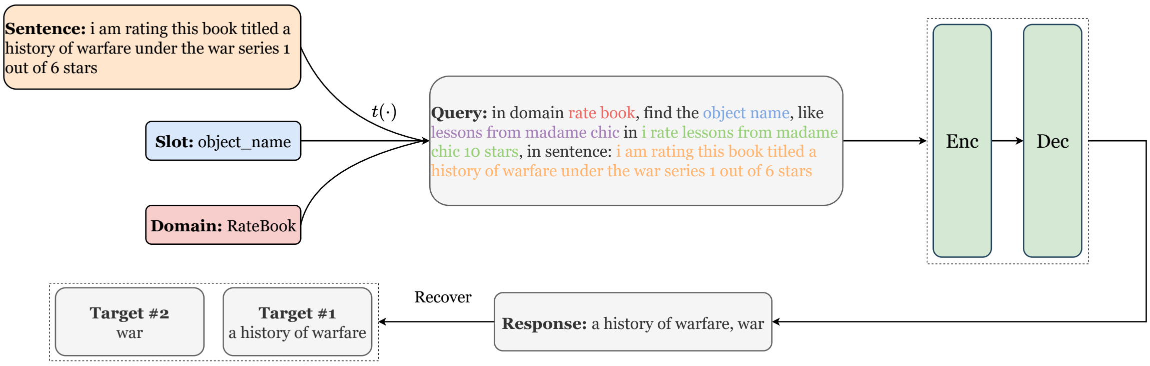

Figure 1: Illustration of our proposed AISFG.

- We propose a generative template-based zero-shot slot filling framework. To the best of our knowledge, we are the first to apply the generative framework to perform the zero-shot cross-domain slot filling task.
- We focus on slot type ambiguity and example ambiguity, which is ignored by previous researches. We incorporate domain-specific descriptions and examples with context to the query template to handle these two issues.
- The experimental results show that AISFG achieves better performance than the existing methods on the setting of zero/few-shot.

2 Methodology

2.1 Slot Filling as Generation

Given a sentence x from domain $d \in \mathcal{D}$, slot filling aims to predict a set of (slot type, span) pairs (s, y), where $s \in \mathcal{S}$ is a specific entity type from a fixed set of slot types, and $y = \{y_1, y_2, \ldots, y_i\}$ is a set of spans in sentence x. Most work on slot filling utilizes token-level classification frameworks, which means they either convert it to BIO tag labeling or predict the start and end position in the sentence, to extract spans.

In contrast to this convention, we frame slot filling as a conditional sequence generation task and solve it in a sequence-to-sequence manner. As shown in Figure 1, given a sentence x, domain d, slot type s and target y, we construct natural language query $q = t_q(x, d, s)$ and response $r = t_r(y)$ based on the predefined template. The generative model takes q as input and directly predicts r in a generation manner.

Leveraging the rich knowledge in the pre-trained generative model is important for cross-domain slot filling, especially in zero/few-shot setting. Thus, we construct query and response as natural language sentences to naturally utilize them.

Query Construction To solve the slot type ambiguity and example ambiguity, we synthesize the query by incorporating domain descriptions, slot descriptions and examples with context. Specifically, query construction template is formulated as:

in domain $\underline{①}$, find the $\underline{②}$, like $\underline{③}$
in $\underline{④}$, in sentence: x.

where the blank ①, ②, ③, ④ are filled with domain description, slot description, example entity and context for example, respectively. To avoid data leakage, we construct examples and contexts manually to ensure the example entities are not appeared in the dataset. The predefined specific mappings between domain/slot and description/example/context are reported in Appendix A.1 and A.3. Moreover, a query example is illustrated in Figure 1.

Response Construction Ideally, the response should be as simple as possible to alleviate the generation difficulty. Besides, an explicit template is easily converted to the original format for compatibility. Thus, we construct response by concatenating target entities with commas:

$$y_1, y_2, \ldots, y_i.$$

where y_i is the i-th entity span in sentence x. A response example is illustrated in Figure 1.

2.2 Train and Inference

The sequence-to-sequence model is instantiated as a pre-trained generative language model, such as BART (Lewis et al., 2020). In the training stage, for the input sentence x with multiple slots, we build a training pair, which consists of a query and a response based on the templates above for each slot. We further fine-tune the parameters based on these training pairs to maximize the log likelihood for predicting gold responses just like in an ordinary generation task. In the inference stage, we

also build a query for each candidate slot, and the response $\hat{r}$ is generated in an auto-regressive manner, which means selecting the token as the next token with the highest probability over the vocabulary set at each time step. Note that, although we do not explicitly restrict the response tokens should originate from the input sentence x, AISFG can always do it (but there are exceptions, we show some cases in Section 3.4). Then, the response $\hat{r}$ is split by commas to recover to the original format $\hat{y}$ for evaluation.

3 Experiments

3.1 Setup

Dataset We evaluate our method on SNIPS (Coucke et al., 2018), a public spoken language understanding dataset which contains 7 domains and 39 slots. To simulate the cross-domain scenarios, we choose one domain as the target domain for test and the left six domains as the source domains for training following the setup of Liu et al. (2020).

However, domains in SNIPS are not completely independent with each other. To achieve a real cross-domain scenario, we use another commonly used dataset namely ATIS (Price, 1990) as the target domain to test our model which is trained on SNIPS.

Baselines We compare our method against a number of representative baselines as follows:

- **Concept Tagger (CT)** A slot-filling framework proposed by Gobbi et al. (2018), which utilizes original slot descriptions to generalize to unseen slot types.
- **Robust Zero-shot Tagger (RZT)** Besides leveraging slot descriptions like CT, RZT (Shah et al., 2019) further introduces examples to improve the robustness of zero-shot slot filling.
- **Coarse-to-fine Approach (Coach)** Coach (Liu et al., 2020) is a two-step coarse-to-fine model for slot-filling, which performs coarse-grained BIO labeling task in the first step and performs fine-grained slot type classification task in the second step. It also encodes slot descriptions to help recognize unseen slot types.
- **QA-driven slot filling (QASF)** QASF (Du et al., 2021) uses a linguistically motivated question generation strategy for converting slot descriptions and example values into natural questions and solves the slot filling by extracting spans from utterances with a span-based QA model.

3.2 Main Results

Cross-Domain Slot Filling The cross-domain slot filling results are reported in Table 1. In SNIPS dataset, AISFG outperforms the state-of-the-art models (QASF for zero-shot and Coach for few-shot) by 7.47% on the average F1 under zero-shot setting, 13.57% under 20-shot setting and 8.88% under 50-shot setting, which demonstrates the superiority of our method. We train AISFG on SNIPS dataset and test it on the ATIS dataset for simulating a real cross-domain scenario, results are reported in the bottom of Table 1. AISFG consistently outperforms the existing state-of-the-art approaches, especially in zero-shot setting, where AISFG achieves 32.31% F1 score improvement. The significant performance improvement proves that utilizing rich domain information to prompt knowledge in PLMs may be a shortcut for solving data scarcity issue.

Analysis on Seen versus Unseen Slots We divide the samples in each target domain into "seen" and "unseen" categories in the SNIPS dataset for further understanding the transferring ability of our model. Following Liu et al. (2020), an example is categorized as "unseen" as long as the slot does not

Coach	9.31	46.22	68.59	74.55
QASF	41.73	56.23	-	-
AISFG	**63.96**	**76.11**	**85.09**	**88.77**

Table 3: Averaged F1-scores (%) over all target domains on SNIPS dataset for “seen” and “unseen” slots. ‘-’ represents the result is missed in published papers

exist in the remaining six source domains. Otherwise, it is tagged as “seen”.

Table 3 shows the average F1 results on seen and unseen slots in target domains under zero-shot and 50-shot settings. From this table, AISFG achieves the best results in both seen and unseen slots, especially on unseen slots in zero-shot scenario, which indicates our method is more effective for transferring knowledge from source to the target domain. Besides, approaches leverage PLMs (*i.e.*, QASF and AISFG) have significant advantages over others, which demonstrates utilizing knowledge encoded in PLMs can enhance the transferring ability.

3.3 Ablation Studies

To solve the slot type ambiguity issue and example ambiguity issue, we incorporate domain description and context for example to the query template, respectively. To understand the influence of these components in the query template, we perform ablation studies on the SNIPS dataset and report results in Table 2. In this table, SD, DD, E, EC refers to Slot Description, Domain Description, Example and Example with Context, respectively. For example, “SD+EC” represents the query template is built by domain description plus example with context.

The Effect of Domain Description Comparing SD versus SD+DD and SD+EC versus AISFG, we observe that incorporating domain descriptions can improve the performance under few-shot setting but not for zero-shot setting. We conjecture the reason is that, the domain description we used (shown in Table 4) is simply converted from the domain name and contains limited information, which is not enough to provide domain knowledge. However, when some target domain examples are given (*i.e.*, few-shot), the meaning of domain descriptions can be enhanced by these training examples. Then, the domain description becomes a domain indicator and can be used to distinguish the slot types shared by different domains, resulting in improved performance.

The Effect of Context Example Comparing SD versus SD+EC and SD+DD versus AISFG, we observe that incorporating examples with contexts can further boost the performance in both zero-shot and few-shot settings, which demonstrates these examples with contexts are helpful for cross-domain slot filling. Moreover, SD+EC outperforms SD+E in both zero-shot and few-shot settings. Especially, for the zero-shot setting in domain *RateBook*, which contains plenty of ambiguity examples, SD+EC achieves 8.06% improvement over SD+E, which indicates contexts are useful to alleviate example ambiguity.

3.4 Error Analysis and Case Study

To better understand our proposed model, we analyze the error predictions in all cross-domain experiments on SNIPS dataset (Table 1) and categorize them into three types: boundary mistakes, vocabu-

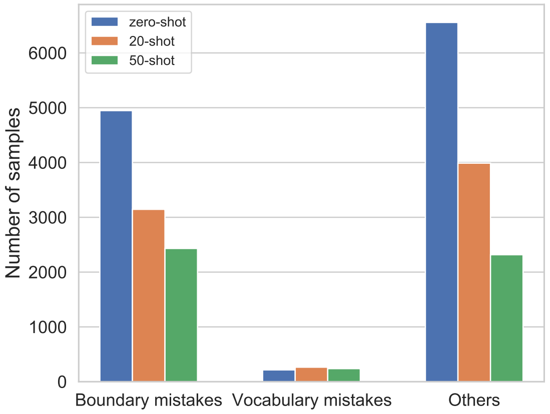

Figure 2: Number of samples against mistake types.

Boundary mistake example
Sentence: i want the complete global albums collection.
Slot: object_name
Gold Label: the complete global albums collection.
Prediction: global albums collection.

Vocabulary mistake example (synonym)
Sentence: find a picture called blink of an eye.
Slot: object_name
Gold Label: blink of an eye.
Prediction: wink of an eye.

Vocabulary mistake example (tense)
Sentence: show schedule for loved by thousands.
Slot: object_name
Gold Label: loved by thousands.
Prediction: love by thousands.

Figure 3: Examples for boundary mistake and vocabulary mistake.

lary mistakes and others. Boundary mistakes indicate that AISFG predicts the main body of the gold label while missing/adding other words, which may lead to an inaccurate boundary (top example in Figure 3). Vocabulary mistakes refer to the predictions that i) some words in the gold label are replaced by synonyms (middle example in Figure 3); ii) some words in the gold label are substituted by different tenses (bottom example in Figure 3).

As shown in Figure 2, the most common mistakes are the boundary mistakes. Especially, in 50-shot experiment, the amount of boundary-mistake predictions reaches almost half of all mistakes. We find that the model often struggles to detect the exact same span as the ground truths, as shown in the top example in Figure 3. When the shot number increases from 0 to 20 and from 20 to 50, the amount of boundary mistakes reduces by 36.4% and 22.7%, respectively, indicating that increasing shot number is beneficial for addressing the boundary mistakes.

Vocabulary mistakes such as synonyms or tenses replacement are the least common. Since the proposed AISFG is a generative model, we carry no restriction on what the model produces, therefore it may come with the vocabulary mistakes. However, most of these mistakes can be solved by post-processing the outcome of the model (*i.e.*, comparing the prediction with the original sentence and replacing the wrong words), which is one of the improvements of our future AISFG. Moreover, as shown in Figure 2, increasing shot number is useless for tackling the vocabulary mistakes.

4 Related Work

The main challenge of cross-domain slot filling is to handle domain-specific slot types which have few or no supervision signals during the training stage. To handle the unseen slots, previous methods introduce slot descriptions (Lee and Jha, 2019; Liu et al., 2020; Bapna et al., 2017) and slot examples (Guerini et al., 2018; Shah et al., 2019) to capture the semantic relationship between unseen slots and input sentences. Based on these researches, we incorporate more information, like domain description and example context, to boost the performance on unseen slots.

Typically, traditional methods formulate the slot filling task as a token-level classification task (Liu et al., 2020; Bapna et al., 2017; Shah et al., 2019; Wang et al., 2021). To leverage the knowledge encoded in pre-trained language models, RCSF (Yu et al., 2021b) utilizes BERT (Devlin et al., 2019) to predict the start/end position of the target slot entity. However, the downstream task (*i.e.*, token/position prediction) is inconsistent with the pre-training task (*i.e.*, Masked LM and NSP for BERT), which may limit the expressiveness of the PLM (Mehri and Eskenazi, 2021). To bridge the gap, we treat the slot filling as a generative task and utilize a PLM whose pre-training task is also a generative task.

5 Conclusion & Discussion

In this paper, we introduce a novel zero-shot cross-domain slot filling model named AISFG, which can adapt to unseen domains seamlessly with the help of domain and slot description and together with full context examples. Experiments show that our model significantly outperforms existing zero-shot cross-domain slot filling approaches. Moreover, we conduct error analysis and case study to better understand our proposed model and leave solving boundary mistakes and vocabulary mistakes as our future work.

A.2 Implementation Details

For a fair comparison with QASF, which is based on BERT (Du et al., 2021), we instantiate the sequence-to-sequence model as BART-base, which contains a similar parameter size as BERT. Following Liu et al. (2020), we reserve 500 samples in target domain as the validation set and regard the rest as the test set. We use Adam optimizer (Kingma and Ba, 2015) with a learning rate 2e-5 to fine-tune all parameters. The batch size is set to 16 and the decoding beam search size for BART is set to 2. The early stop strategy with patience of 5 is used to save the best checkpoint based on validation set.

Similar to the baselines, we use F1 score as the evaluation metric. For a given query, the true positive is the prediction with exactly matched entity extraction boundaries.

Abstract

Negation is a common linguistic feature that is crucial in many language understanding tasks, yet it remains a hard problem due to diversity in its expression in different types of text. Recent work has shown that state-of-the-art NLP models underperform on samples containing negation in various tasks, and that negation detection models do not transfer well across domains. We propose a new negation-focused pre-training strategy, involving targeted data augmentation and negation masking, to better incorporate negation information into language models. Extensive experiments on common benchmarks show that our proposed approach improves negation detection performance and generalizability over the strong baseline NegBERT (Khandelwal and Sawant, 2020).

1 Introduction

Negation is an important linguistic phenomenon that appears commonly in natural language but is underrepresented in common NLP benchmarks (Hossain et al., 2020). Furthermore, the Checklist benchmark (Ribeiro et al., 2020) shows that most sentiment analyzers and machine comprehension models struggle with samples containing negation. Negation is even more important in biomedical domain text, where patients are carefully defined as having/not having specific characteristics. Even within the biomedical domain, there are many types of text such as clinical notes, lab reports, or research publications, each with particular characteristics in relation to the use of negation. A recent study on English texts found that negation detection models do not transfer well across domains, due to variations in expression of negation (Khandelwal and Sawant, 2020). It remains a challenge to solve negation in general, even with state-of-the-art NLP models.

Negation detection is typically defined as consisting of the two sub-tasks of: (1) cue detection, detecting the cue phrase that triggers the negation; and (2) scope resolution, determining the affected spans that are negated. There are three primary datasets that have been used to evaluate negation: (1) the *BioScope* corpus (Vincze et al., 2008) includes full papers and abstracts of biological papers; (2) the *SFU* corpus (Konstantinova et al., 2012) is a collection of product reviews; and (3) the *Sherlock* dataset (Morante and Blanco, 2012) consists of short literary works. There are differences in annotation schemes across the datasets, such as whether or not the cues are included inside scope annotation, and sub-optimal cross-dataset results have been observed, providing clear indications that the datasets are highly divergent in language use and negation types.

In this work, we aim to extend the transfer learning capability of NegBERT (Khandelwal and Sawant, 2020) through additional pre-training with task-related augmented training data, and a new masking objective. Our contributions are:

- We introduce an approach to augmenting data to emphasize negation in pre-training.
- We propose a novel extension to the standard random masked language model objective in pre-training to explicitly mask negation cues, to make the models more robust to negation.
- We conduct extensive experiments on different benchmarks to evaluate cross-domain performance of large pre-trained language models as well as the effectiveness of the proposed pre-training strategies; code is available at `https://github.com/joey234/negation-focused-pretraining`.

2 Related work

To date, negation detection has been heavily reliant on rule-based systems. Chapman et al. (2001) proposed a simple system, NegEx, based on regular expressions to detect negation cues in a sentence given a concept of interest (the scope). NegEx re-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4188 - 4193

mains the most popular approach to negation detection, especially in the clinical domain to determine the polarity of clinical concepts (e.g., as sourced from MetaMap (Aronson and Lang, 2010)). Further research has extended NegEx with syntactic information (Mehrabi et al., 2015; Peng et al., 2018), and shown that rule-based systems can achieve relatively good performance for detecting negation, especially in the biomedical domain, but do not generalize well to other domains or datasets.

To approach negation cue and negation scope detection with supervised machine learning, two classification tasks are defined: (1) finding negation tokens, and (2) classifying tokens as the first or last (or neither) token within the scope of negation. Most work follows a common scheme in extracting various features from the sentence, and using a classifier to classify each token as the beginning, inside, or outside of a negation cue or scope span (Morante and Daelemans, 2009; Ou and Patrick, 2015; Cruz et al., 2016). Recently, research has shifted to applying deep learning methods to the task. Most approaches make use of RNN-based architectures to encode the input sentences, combined with a softmax layer for classification (Lazib et al., 2019; Chen, 2019). Despite the high performance on common benchmarks, results are biased by the fact that negation scope is often delimited by punctuation and other dataset artefacts (Fancellu et al., 2017). As such, they are potentially only learning domain-specific surface features rather than capturing the true semantics of negation. NegBERT applies a large pre-trained language model to the problem of negation detection, outperforming previous deep learning methods on negation detection, with especially high gains on scope resolution.

3 Method

Our proposed pre-training strategy consists of two main components: (1) negation-focused data collection in which we first collect relevant data that contains negation; and (2) negation-focused pre-training that makes use of the negation-focused data to emphasize negation instances, and adopts a novel negation-specific masking strategy.

3.1 Negation-focused data collection

We aim to construct a dataset that is enriched with negation information, to support negation-sensitized pre-training of large language models. To obtain sentences with negations, we extend the NegEx lexicon with additional negation cues obtained from biomedical texts (Morante, 2010), and apply it to sentences extracted from a corpus using the SpaCy English sentence tokenizer, keeping only those sentences with at least one identified negation cue.

For the biomedical domain, we use texts in the TREC-CDS 2021 snapshot[1] of the clinical trials registry.[2] Clinical trials are documents describing the protocols and relevant patient characteristics of a clinical research study. Descriptions of clinical trials can be quite long, but a core aspect of the trial description is the patient inclusion/exclusion criteria, specifying what types of characteristics or conditions a patient must have/not have in order to be suitable for the trial. The reasons for choosing this data are that: (1) it is in-domain for the biomedical domain; (2) the texts are well-formed sentences with proper grammatical structure; and (3) the texts contain many negations, especially in the inclusion/exclusion criteria sections. For the general domain, we apply this approach to *wikitext* (Merity et al., 2016), a set of verified articles in Wikipedia. We sample the data equally from these two sets, obtaining $1,381,948$ negation sentences.

3.2 Negation-focused pre-training

Adaptive pre-training on target domain data has been shown to be an effective strategy for domain adaptation (Gururangan et al., 2020). We therefore hypothesize that pre-training language models on text with negations will help the model incorporate information about negation, and learn better representations for sentences containing negation. Using the negation-focused data, we first apply the standard random word masking strategy (Devlin et al., 2019) and train the model with the masked language model objective.

As part of the collection of the negation-focused data, we obtain predictions of negation cues in all the sentences, which can be explicitly incorporated to make the model more robust to negation. Inspired by work on entity and span masking (Joshi et al., 2020; Yamada et al., 2020), we explore explicitly incorporating information about negation cues into the model by masking these cues, and targeting prediction of the masked cue in the pre-training stage. Below is an example of how a sentence is tokenized under our masking scheme:

---

[1] `http://www.trec-cds.org/2021.html`

[2] `http://clinicalTrials.gov`

No serious complications such as hypertension, diabetes. ⇒ ***[CUE]*** *serious complications such as* ***[MASK]****, diabetes.*

A new type of token ***[CUE]*** is introduced under this masking scheme, and the model needs to reconstruct the original sentence by predicting both the ***[CUE]*** token to be *No*, and the randomly-masked token ***[MASK]*** to be *hypertension*. By always masking negation cues in all the sentences, we force the model to focus more on this type of token, and thus, aim to learn better embeddings incorporating information of how a negation cue is represented in the context of the sentence. Moreover, by using a different token to mask negation cues, we ensure that the model learns to distinguish between different types of tokens. In this work, we replace the BERT encoder of NegBERT with RoBERTa (Liu et al., 2019) and apply whole-word masking, meaning that all the sub-word tokens that constitute a word will be masked.

4 Experiments

4.1 Experimental settings

Following the experimental settings in NegBERT, we use the three standard benchmarks for negation cue detection and scope resolution tasks, i.e. BioScope (Vincze et al., 2008) (separated into two subsets, sourced from abstracts and full-text papers, resp.), the SFU product reviews dataset (Konstantinova et al., 2012), and the Sherlock dataset (Morante and Blanco, 2012). In addition, we use the negation-annotated subset of VetCompass UK[3] (Cheng et al., 2017), consisting of clinical notes in the veterinary domain, which are very informal compared to BioScope. It also contains abbreviations and shortening of terms, as well as certain unique negation cues. To investigate cross-domain performance, we perform cue detection and scope resolution for all 4 datasets, based on training on one dataset and evaluating on all datasets. Detailed statistics of these datasets are presented in Table 1. Note that we do not experiment with the setting of training with all the combined training data from the corpora as it has been pointed out by previous work that doing so hurts the performance of the models (Jiménez-Zafra et al., 2020; Barnes et al., 2021) due to differences in annotation schemes between the corpora introducing noise during training. Re-annotating all the datasets using a common annotation scheme would be a potential solution here, which we leave for future work.

Dataset	#sentences	#negations	#unique cues
BioScope-Abstract	11871	1719	28
BioScope-FullPaper	2670	376	18
SFU	17263	3527	53
Sherlock	5520	1421	30
VetCompass	6582	724	26

Table 1: Dataset statistics

We formulate the two tasks as sequence labeling problems, where each token is tagged with a corresponding label. For cue detection, we use the annotation scheme *{0: Affix, 1: Normal Cue, 2: Part of multiword cue, 3: Not part of cue}*. For scope resolution, we use gold cue information and two labels *{0: Outside negation scope, 1: Part of negation scope}*. We adopt the same hyper-parameters as NegBERT. Following the standard evaluation scheme in previous negation detection works, all systems are evaluated using token-level F_1-score, based on whether it is inside or outside of any negation cue or scope. Methods evaluated include: (1) **NegBERT**; (2) **AugNB** = NegBERT plus pre-training on negation-focused data; and (3) **CueNB** = NegBERT plus pre-training on negation-focused data and the negation cue masking objective. Note that for NegBERT, we also replace the BERT encoder with RoBERTa to ensure results are comparable between the models.

4.2 Main results

Tables 2 and 3 report the performance of negation cue detection and negation scope resolution, respectively. Results reported are the average of 5 runs with different random seeds. NegBERT results are produced using the official implementation.[4] To provide a more general view, we summarize the results in Table 4. In general, we observe gains in both the same-dataset setting (training and test set belongs to one corpus) and cross-dataset setting (training one one training set and testing on all others test sets) for both of the proposed models, with CueNB achieving the largest gains.

We observe similar trends across all datasets for

Table 4: Aggregated results

both cue detection and scope resolution. Regarding the in-dataset setting, AugNB outperforms the baseline NegBERT on all datasets except for Sherlock. Gains are more noticeable over the biomedical datasets (BioScope, VetCompass). For Sherlock, however, we observe a slight degradation in performance with the proposed pre-training scheme. This is likely due to the fact that Sherlock has major differences in annotation scheme compared to other corpora, specifically including scopes to the left of cues, while in BioScope and SFU, the scope is usually annotated only to the right of cues. Also, the cue itself is not considered to be part of the scope in Sherlock or SFU, unlike in BioScope.

In the cross-dataset setting, we record gains across all benchmarks. The largest cross-dataset improvements over NegBERT are for SFU, perhaps due to SFU being the largest dataset in size, containing a relatively large number of unique cues. CueNB further improves the performance of AugNB, confirming our hypothesis that explicitly masking the cue helps the model learn better representations for negation cues and thus, better distinguish between cues and normal words. These results show that our negation-focused pre-training strategy is effective for improving the transfer learning performance of pre-trained language models on the negation detection task.

4.3 Discussion

We conducted an error analysis on the VetCompass validation set to see what qualitative improvement CueNB makes over NegBERT. For cue detection, there are two main types of errors that CueNB helps alleviate. First, CueNB can detect more unique cues such as *negative*, *won't*, and also multiword cues like *no longer*. Second, CueNB is able to recognize cases when the negations are actually just speculative. For example, in the sentence *O reports has smelled for past week,* ***not sure*** *if anal glands . . .* , the word *not* is part of the speculation phrase *not sure*, indicating that this is not truly a negation phrase but rather expresses uncertainty. For scope resolution, CueNB mostly helps in recognizing the correct scope boundary. One common case is when the cue relates to multiple spans in a sentence. In the sentence *Examination: QAR, thorac ausc and abdo palp NAD,*[5] NegBERT only recognizes the nearest span *abdo palp NAD* to be the scope, whereas CueNB recognizes the full correct span *thorac ausc and abdo palp NAD*. It also helps in cases where there are multiple separate negations in the same sentence. For instance, in the

---

[5] *NAD* is the negation cue *no abnormality detected*, *QAR*, *thorac ausc* (thoracic ausculation), *abdo palp* (abdonimal palpation), are different types of physical examinations.

Model	Cue	Scope
NegBERT	94.46	95.34
+ negation-focused data	95.36	95.94
+ explicit cue masking	95.58	96.03
CueNB	**95.87**	**96.76**

Table 5: Ablation study on BioScope validation set.

sentence *No V+ or no D+.*, the phrases *No V+* and *no D+* are two independent negation scope spans, while NegBERT would recognize the whole sentence as a single span. Another interesting case is when there are exceptions in the sentence, e.g. the *No … other than …* construction. For *No probs detected other than the skin lesions*, CueNB is able to recognize the correct scope *No probs detected* while NegBERT considers the whole sentence to be the scope.

We also conduct an ablation study to understand the impact of each component of the proposed pre-training strategy. Table 5 presents the results of different variations of the proposed pre-training scheme on the BioScope-Abstract validation split. We consider two variations, pre-training with: (1) only the negation-focused data (equivalent to the AugNB model); and (2) only the cue masking objective. To model the latter variation, we explicitly mask the cue in the BioScope training set, then pre-train on this training set. From the results, we see that both strategies help improve the baseline NegBERT on cue detection and scope resolution, with explicitly masking the cues being the most important. Combining both strategies (CueNB) further improves the overall results.

5 Conclusion

In this work, we propose a new negation-focused pre-training strategy to explicitly incorporate negation information into pre-trained language models. Empirical results on common benchmarks show that the proposed strategy helps improve the performance of pre-trained language models on the negation detection task when evaluating on the same source dataset, as well as their transferability to target data in different domains. Despite the gains over previous methods, the sub-optimal results on some benchmarks show that negation remains a big challenge in NLP.

Abstract

Existing Math Word Problem (MWP) solvers have achieved high accuracy on benchmark datasets. However, prior works have shown that such solvers do not generalize well and rely on superficial cues to achieve high performance. In this paper, we first conduct experiments to showcase that this behaviour is mainly associated with the limited size and diversity present in existing MWP datasets. Next, we propose several data augmentation techniques broadly categorized into *Substitution* and *Paraphrasing* based methods. By deploying these methods we increase the size of existing datasets by five folds. Extensive experiments on two benchmark datasets across three state-of-the-art MWP solvers shows that proposed methods increase the generalization and robustness of existing solvers. On average, proposed methods significantly increase the state-of-the-art results by over five percentage points on benchmark datasets. Further, the solvers trained on the augmented dataset performs comparatively better on the challenge test set. We also show the effectiveness of proposed techniques through ablation studies and verify the quality of augmented samples through human evaluation.

Original Problem
Problem: Nancy grew 8 potatoes. Sandy grew 5 potatoes. How many potatoes did they grow in total ?
True Equation: X = 8+5

Paraphrasing Method
Problem: How many potatoes did they grow in all given that nancy grew 8 potatoes and sandy grew 5 potatoes.
Equation Label: X = 8+5

Substitution Method
Problem: Dwight grew 8 potatoes. Juliette grew 5 potatoes. How many potatoes did they grow together ?
Equation Label: X = 8+5

Table 1: A MWP and its augmentation examples generated by our methods with preserved equation labels. Blue and Violet colours denote the changes made after the primary stage and secondary stage respectively.

1 Introduction

A Math Word Problem (MWP) consists of natural language text which describes a world state involving some known and unknown quantities, followed by a question text to determine the unknown values. The task is to parse the problem statement and generate equations that can help find the value of unknown quantities. An example of a simple MWP is shown in Table 1. In recent years, the challenge of solving MWP has gained much attention in the NLP community as it needs the development of commonsense multi step reasoning with numerical quantities. With the rise of deep learning, performance of math solvers has also increased significantly over the years (Wang et al.; Zhang et al.). However, recent analysis conducted in (Kumar et al., 2021) and (Patel et al., 2021) show that these deep learning based solvers rely on shallow heuristics to solve vast majority of problems. They curated adversarial examples and SVAMP challenge set respectively to infer that MWP solvers (1) do not understand the relationship between numbers and their associated entities, (2) do not focus on the question text and (3) ignore word order information. In this paper, we first conduct experiments to establish that the above drawbacks are due to the limited size and diversity of problems present in the existing MWP datasets. Next, we propose various augmentation methods to create diverse and large number of training examples to mitigate these shortcomings. Our methods are focused on: (1) Increasing the number of problems in the existing datasets and (2) enhancing the diversity of the problem set.

Training deep neural models effectively requires large number of data points (Longpre et al., 2020). Constructing large datasets which are annotated, labeled and have MWPs of similar difficulty level is a very expensive and tedious task. To address these key challenges, we resort to data augmenta-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4194 - 4206
July 10-15, 2022

tion techniques. Our motivation behind generating augmentations is that humans require sufficient practice to understand MWPs. Humans learn to solve MWPs by going through a variety of similar examples and slowly become capable enough to tackle variations of similar difficulty levels. We aim to generate augmentations such that sufficient linguistic variations of a similar problem are present in the dataset. These variations will make the solver more robust in tackling MWP, increase their reasoning ability and numerical understanding.

Data augmentation for MWPs is a challenging task as we need to preserve the equation labels while generating new samples (Kumar et al., 2021). The generated samples should be (1) semantically similar to their original counterpart, (2) must have the same numerical values and preserve relationship with their respective entities and (3) should maintain the same sequence of events in the problem text. Existing augmentation methods (Wei and Zou) cannot be directly applied due to the above mentioned reasons. Our methods can be broadly classified as follows:

- **Paraphrasing Methods:** It generates variations of the question text by re-statement such that the semantic and syntactic meaning along with the equation labels is preserved.
- **Substitution Methods:** These methods generate variations of the problem statement by identifying and substituting some of the keywords such that the augmentations are semantically and syntactically correct.

To ensure high quality augmentations [1], we propose a selection algorithm which selects samples that have high similarity with original problem and incur high loss values when tested on existing solvers. This algorithm helps selecting only those samples that can make existing solvers more robust. Further, we also verify the validity and the quality of generated augmentations through human evaluation.

Most of the existing MWP datasets are either in languages other than English or contain problems of varying difficulty levels (Koncel-Kedziorski et al., 2016; Wang et al.; Huang et al., 2016; Amini et al., 2019; Miao et al., 2020). We focus on strengthening existing English language datasets which can facilitate the development of better MWP solvers. We consider datasets containing MWP that can be solved using linear equations in one variable. These datasets include MaWPS (Koncel-Kedziorski et al., 2016) and ASDiv-A (Miao et al., 2020) both having $2,373$ and $1,213$ problems respectively. Following are the key contributions made in this paper:

- To the best of our knowledge, this is the first work that extensively evaluates data augmentation techniques for MWP solving. This is the first attempt to generate MWP problems automatically without manual intervention.
- Accuracy of the state of the art solvers increases after training on the proposed augmented dataset. This demonstrates the effectiveness of our methods. To verify the validity of generated augmentations we conduct human evaluation studies.
- We increase the diversity of the training dataset through augmentations and obtain comparatively better results than state-of-the-art solvers on the SVAMP challenge set.

2 Related Work

Math Word Solvers: Many research efforts have been undertaken in the recent past to solve the challenging MWP task. Broadly, these solvers can be categorized into statistical learning based and deep learning based models. Traditional approaches focused more on statistical machine learning (Kushman et al., 2014; Hosseini et al., 2014) with the aim of categorizing equations into templates and extracting key patterns in the problem text. Recently, due to the advent of deep learning in NLP, solvers have witnessed a considerable increase in their performances. (Wang et al.) modelled MWP task as a sequence to sequence task and used LSTM's (Hochreiter and Schmidhuber, 1997) for learning problem representations. (Chiang and Chen, 2018) focused on learning representations for operators and operands.(Wang et al., 2019; Xie and Sun, 2019) used tree structures for decoding process. (Zhang et al.) modelled question as a graph to map quantities and their attributes. Existing datasets which have been used as benchmark for english language includes MaWPS (Koncel-Kedziorski et al., 2016) and Chinese language dataset Math23K (Wang et al.). These datasets although constrained by

---

[1] Codebase and augmented datasets are available at: https://github.com/kevivk/MWP-Augmentation

their size deal with algebraic problems of similar difficulty levels. Recently, ASDiv (Miao et al., 2020) has been proposed, which has diverse problems which includes annotations for equations, problem type and grade level. Other large datasets in English language include MathQA (Amini et al., 2019) and Dolphin18k (Huang et al., 2016). Although, these datasets have larger problem set but they are noisy and contain problems of varied difficulty levels.

Text Data Augmentation: To effectively train deep learning models, large datasets are required. Data augmentation is a machine learning technique that artificially enlarges the amount of training data by means of label preserving transformations (Taylor and Nitschke, 2018). (Longpre et al., 2020) hypothesize that textual data augmentation would only be helpful if the generated data contains new linguistic patterns that are relevant to the task and have not been seen in pre-training. In NLP, many techniques have been used for generating augmentations, (Wei and Zou) introduced noise injection, deletion, insertion and swapping of words in text. (Rizos et al., 2019) used recurrent neural networks and generative adversarial networks for short-text augmentation (Maheshwary et al., 2021b). Recently, hard label adversarial attack models have also been used (Maheshwary et al., 2021a). Other frequently used methods include inducing spelling mistakes (Belinkov and Bisk, 2018), synonym replacement (Zhang et al., 2016), identifying close embeddings from a defined search space (Alzantot et al., 2018), round trip translations (Sennrich et al., 2016), paraphrasing techniques (Kumar et al., 2019) and words predicted by language model (Kobayashi, 2018) among many others. These methods are specific to the task at hand and needs to be adapted such that the generated augmentations bring diversity in the concerned dataset.

3 Proposed Augmentation Approach

Data augmentation generates new data by modifying existing data points through transformations based on prior knowledge about the problem domain. We introduce carefully selected transformations on well known text augmentation techniques to develop examples suited for the task of MWP. These transformations help in increasing the diversity and size of problem set in existing datasets.

3.1 Problem Definition

A MWP is defined as an input of n tokens, $\mathcal{P} = \{w_1, w_2..w_n\}$ where each token w_i is either a numeric value or a word from a natural language. The goal is to generate a valid mathematical equation $\mathcal{E}_\mathcal{P}$ from $\mathcal{P}$ such that the equation consists of numbers from $\mathcal{P}$, desired numerical constants and mathematical operators from the set $\{/, *, +, -, =, (,)\}$. Let $\mathcal{F} : \mathcal{P} \to \mathcal{E}_\mathcal{P}$ be an MWP solver where $\mathcal{E}_\mathcal{P}$ is the equation to problem $\mathcal{P}$. Our task is to generate augmented problem statement $\mathcal{P}^*$ from the original input $\mathcal{P}$ such that $\mathcal{P}^*$ is: (1) semantically similar to the initial input $\mathcal{P}$, (2) preserves the sequence of events in the problem statement, (3) keeps the numerical values intact and (4) the solution equation is same as $\mathcal{E}_\mathcal{P}$.

3.2 Deficiencies in Existing Models

As showcased by (Patel et al., 2021), existing MWP solvers trained on benchmark datasets like MaWPS and ASDiv-A focus their attention only on certain keywords in the problem statement and do not pay much heed to the question text. We further show that even after performing significant transformations on the test set such as (1) dropping the question text, (2) randomly shuffling the sequence of sentences, (3) random word deletion, and (4) random word reordering, the solvers are still able to produce correct equations. Upon introducing these transformations we should expect a very high drop in accuracy values as the transformed problems are now distorted. Surprisingly, the decrease in accuracy scores is relatively very less than expected as shown in Table 2. We only observe a relatively moderate drop for word reordering. From this analysis, we can say that instead of focusing on the sequence of events, question text and semantic representation of the problem, solvers pick word patterns and keywords from the problem statement. We hypothesize that the drop in accuracy for word reordering experiment indicates that the solvers try to identify a contiguous window of words having some keywords and numbers in them, and generates equation based on these keywords. We further probe on this hypothesis by visualizing the attention weights in the experiment section.

3.3 Augmentation Methods

A MWP can also be expressed as $\mathcal{P} = (S_1, S_2..S_k, Q)$ where Q is the question and $(S_1, S_2..S_k)$ are the sentences constituting the prob-

Dataset	Eval Type	Seq2Seq	GTS	Graph2Tree
MaWPS	True	84.6	87.5	88.7
	WD	**80.2**	**81.5**	**77.3**
	QR	**77.4**	**82.0**	**80.2**
	SS	**77.0**	**60.4**	**66.4**
	WR	**54.9**	**34.8**	**39.3**
ASDiv-A	True	70.6	80.3	82.7
	WD	**60.2**	**61.3**	**56.7**
	QR	**58.7**	**52.4**	**54.1**
	SS	**56.2**	**59.3**	**60.7**

Table 2: Performance of solvers on modified test sets. True represents unaugmented test set. WD,QR,SS,WR represent word deletion, question reordering, sentence shuffling and word reordering respectively.

lem description. To mitigate the deficiencies in MWP solvers, we propose a two stage augmentation paradigm consisting of primary and secondary stage. In primary stage, we generate base augmentation candidates which then proceed to the secondary stage and get modified accordingly to become potential candidates. After identifying the potential candidates, we filter out the best candidates using proposed candidate selection algorithm. Table 1 shows changes in MWP after primary and secondary stage. Following are the details:

- **Primary Stage:** In the primary stage, our focus is on inducing variations in the question text Q of a given problem statement $\mathcal{P}$. For this, we first generate n base candidates $\{b_1, b_2, ..., b_n\}$ from Q using $T5$ paraphrasing model (Raffel et al., 2020). The key intuition behind this step is to ensure that each augmentation of a given problem has a different question text. This will empower the solver to learn variations from the question text as well.

- **Secondary Stage:** After the generation of base candidates, we implement augmentation methods to generate potential candidates. These methods although well known, require careful tuning to adapt for MWP generation. Table 3 showcases MWP examples and their generated augmentations. Detailed description of these techniques follow.

3.3.1 Paraphrasing Methods

Paraphrasing has proved to be an effective way of generating text augmentations (Witteveen and Andrews). It generates samples having diverse sentence structures and word choices while preserving the semantic meaning of the text. These additional samples guide the model to pay attention to not only the keywords but its surroundings as well. This is particularly beneficial for the task of MWP solving, where most of the problem statements follow a general structure.

Problem Reordering: Given original problem statement $\mathcal{P} = (S_1, S_2, ...S_k, Q)$, we alter the order of problem statement such that $\mathcal{P}^* = (Q, S_1, S_2, ..., S_k)$. To preserve the semantic and syntactic meaning of problem statement we use filler phrases like ’Given that’ and ’If-then’. To make these paraphrases more fluent, we use named entity recognition and co-reference resolution to replace the occurrences of pronouns with their corresponding references. Please note that this method is better than random shuffling of sentences as it preserves the sequence of events in the problem statement.

Round Trip Translations: Round trip translations, more commonly referred as back-translation is an interesting method to generate paraphrases. This idea has evolved as a result of the success of machine translation models (Wu et al., 2016). In this technique, sentences are translated from their original language to foreign languages and then translated back to the original language. This round trip can be between multiple languages as well. The motivation behind using this technique is to utilize the different structural constructs and linguistic variations present in other languages.
Back-translation is known to diverge uncontrollably (Tan et al., 2019) for multiple round trips. This may lead to change in the semantics of the problem statement. Numerical quantities are fragile to translations and their order and representation may change. To overcome these challenges, we worked with languages that have structural constructs similar with English. For instance, languages like Finnish which are gender neutral, can become problematic as they can lead to semantic variance in augmented examples. To preserve numerical quantities, we replace them with special symbols and keep a map to restore numerical quan-

Category	Augmentation Method	Example
Paraphrasing Methods	**Round trip Translation**	**Original:** The schools debate team had 4 boys and 6 girls on it. If they were split into groups of 2, how many groups could they make ? **Augmented:** The school discussion group consisted of 4 boys and 6 girls. If they are divided into groups of 2 . How many groups could they have created ?
	Problem Reordering	**Original:** Lucy has an aquarium with 5 fish . She wants to buy 1 more fish . How many fish would Lucy have then ? **Augmented:** If lucy has an aquarium with 5 fish and she wants to buy 1 more fish then how many fish would lucy have ?
Substitution Methods	**Fill Masking**	**Original:** There are 8 walnut trees currently in the park . Park workers will plant 3 more walnut trees today . How many walnut trees will the park have when the workers are finished ? **Augmented:** There are 8 walnut trees currently in the park . Park workers will plant 3 more walnut trees soon . How many walnut trees will the park have after the workers are finished ?
	Named-Entity Replacement	**Original:** Sally found 7 seashells , Tom found 12 seashells , and Jessica found 5 seashells on the beach . How many seashells did they find together ? **Augmented:** Edd found 7 seashells , Alan found 12 seashells , and Royal found 5 seashells on the beach . How many seashells were found together ?
	Synonym Replacement	**Original:** Katie 's team won their dodgeball game and scored 25 points total . If Katie scored 13 of the points and everyone else scored 4 points each , how many players were on her team ? **Augmented:** Katie's group won their rumble game and scored 25 points total . If Katie scored 13 of the points and all else scored 4 points each, How many players was on her group ?

Table 3: Augmentation examples from all proposed methods. Coloured text represents the changes in problem statement.

tities in the generated paraphrases. We have used the following round trips:

English - Russian - English: Although Russian is linguistically different from English, we still chose it as word order does not affect the syntactic structure of a sentence in Russian language (Voita et al., 2019). For single round trip, we preferred Russian as it has the potential to generate different paraphrase structures.

English - German - French - English: German and french are structurally similar to English language (Kim et al., 2019), we chose them for multiple round trips to both maintain semantic in-variance and induce minor alterations in the paraphrases.

3.3.2 Substitution Methods

In this class of methods, the focus is on generating variations of the problem statement by identifying and substituting some of the keywords such that the augmentations are semantically and syntactically correct, with the equation labels preserved. Substitution is effective for MWP solving as it guides the solvers focus away from certain keywords, allowing it to distribute its attention and generalize better. We propose the following methods:

Fill-Masking: In this technique, we model the challenge of generating candidates as a masked language modelling problem. Instead of randomly choosing words for masking, we use part of speech tags to focus on nouns and adjectives, preferably in the vicinity of numerical quantities. We replace these identified keywords with mask tokens. These masked candidate sentences are then passed through a masked language model (Devlin et al., 2019a) and suitable words are filled in masked positions to generate our candidate sentences.

Synonym Replacement: In this method, after stop-word removal, we select keywords randomly for substitution. Unlike fill-mask technique, where masked language models were deployed, here we use Glove embeddings (Pennington et al., 2014) to find the top k candidates that are close synonyms of the keywords. To ensure syntactic correctness in candidates, we maintain the part of speech tags for the substitute candidates. These synonyms are then used to substitute the keywords in the problem statement and generate augmented candidates.

Named-Entity Replacement: A common occurrence in MWP is the usage of named entities. These entities play a crucial role in stating the problem statement, but the solution equations do not change on altering these entities. Following this insight, we first identify the named entities[2] such as person, place and organizations present in the problem statement. Then we replace these named entities with their corresponding substitutes, like a person's name is replaced by another person's name to generate the potential candidates. Table 4 reports the statistics of augmented datasets on both MaWPS and ASDiv-A. All the techniques described in paraphrasing and substitution methods are used for generating the potential candidates for a problem statement. After generation of the potential candidates for augmenting a problem statement, the best possible candidate is selected by using Algorithm 1. Key motivation behind developing this algorithm is to select candidates on which the solver does not perform well and which are similar to the original problem statement.

Algorithm 1 MWP Candidate Selection Algorithm

```
Requires: $\mathcal{M}$ is augmentation method, $\mathcal{S}$ is similarity model, $\mathcal{F}$ is solver model, $\mathcal{L}$ is Loss function.
Input: Problem text $\mathcal{P}$
Output: Augmented Text $\mathcal{P}^*$
1: $\mathcal{E}_P \leftarrow \mathcal{F}(\mathcal{P})$
2: $Candidates \leftarrow \mathcal{M}(\mathcal{P})$
3: for $C_j$ in $Candidates$ : do
4:     $S_j \leftarrow \mathcal{S}(C_j, \mathcal{P})$
5:     $L_j \leftarrow (\mathcal{L}(C_j) - \mathcal{L}(P))/\mathcal{L}(P)$
6:     $CandidateScore.add(S_j * L_j)$
7: $\mathcal{P}^* = \arg\max_{C_j} CandidateScore(C_j)$
8: end
```

We use negative log likelihood as the loss function $\mathcal{L}$ and Sentence-BERT (Reimers and Gurevych, 2019) fine tuned on MWP equation generation task as sentence embedding generator $\mathcal{S}$. We calculate the similarity of each candidate embedding with the original problem representation using cosine similarity as shown in Line 3 of the algorithm. Further, for each candidate sentence, we evaluate their loss values and select the candidate with the maximum mean normalized loss and similarity score.

Dataset	Problem Size	Vocabulary Size
MaWPS	2,373	2,632
ASDiv-A	1,213	2,893
Paraphrase	5,909	3,832
Substitution	6,647	3,923
Combined-MaWPS	**10,634**	**5,626**
Combined-ASDiv	**5,312**	**6,109**

Table 4: Statistics of augmented dataset compared with MaWPS and ASDiv-A. Combined-Dataset represents combination of Paraphrase and Substitution methods.

4 Experiments

Datasets and Models: To showcase the effectiveness of proposed augmentation methods, we select three state-of-the-art MWP solvers: (1) *Seq2Seq* (Wang et al.) having an LSTM encoder and an attention based decoder. (2) *GTS* (Xie and Sun, 2019) having an LSTM encoder and a tree based decoder and (3) *Graph2tree* (Zhang et al.) consists of a both tree based encoder and decoder. *Seq2Seq* serves as our base model for experimentation. Many existing datasets are not suitable for our analysis as either they are in Chinese (Wang et al.) or they have problems of higher complexities (Huang et al., 2016) . We conduct experiments across the two largest available English language datasets satisfying our requirements: (1) *MaWPS* (Koncel-Kedziorski et al., 2016) containing $2,373$ problems (2) *ASDiv-A* (Miao et al., 2020) containing $1,213$ problems. Both datasets have MWPs with linear equation in one variable.

Experiment Setup: We train and evaluate the three solvers on both MaWPS and ASDiv-A using five fold cross validation. Evaluation is conducted on both original and augmented datasets. We use the same hyperparameter values as recommended in the original implementation of these solvers. Further, each solver has been trained from scratch and by using BERT embeddings (Devlin et al., 2019b). We also evaluate the models on *SVAMP* (Patel et al., 2021) challenge set. This test set has been designed specifically to examine the robustness and adaptability of the solvers. Ablation studies have been conducted to assess the effectiveness of candidate selection algorithm and augmentation techniques.

Problem 1: Ricardo was making baggies of cookies with 5 cookies in each bag. If he had 7 chocolate chip cookies and 3 oatmeal cookies, how many baggies could he make ?
Solution Equation: X = (7+3)/5
Pre Augmentation Equation: X = (7/3)/3
Post Augmentation Equation: X = (7+3)/5

Problem 2: For halloween Destiny bought 9 pieces of candy. She ate 3 pieces the first night and then her sister gave her 2 more pieces. How many pieces of candy does Destiny have now ?
Solution Equation: X = 9-3+2
Pre Augmentation Equation: X = ((9+3-3
Post Augmentation Equation: X = (9+3-2)

Problem 3 : Audrey needs 6 cartons of berries to make a berry cobbler. She already has 2 cartons of strawberries and 3 cartons of blueberries. How many more cartons of berries should Audrey buy ?
Solution Equation: X = 6-2-3
Pre Augmentation Equation: X = (6-(2)+3)
Post Augmentation Equation: X = 6-(2+3)

Table 6: Examples illustrating equation results before and after training on the full augmented dataset.

4.1 Results and Analysis

Table 5 shows the result of proposed methods. These results have been reported on BERT embeddings. Table 11 shows a comparison between training from scratch and using BERT embeddings. By training these state-of-the-art models on the augmented dataset we achieve better results for both MaWPS and ASDiv-A. On average, we were able to increase the accuracy significantly by more than five percentage points. Both paraphrasing and substitution methods have performed well independently and in combination. Further, we conduct ablation studies to analyze the performance of each augmentation method. In Table 6 we illustrate some examples on which existing models generate incorrect equations. However, after being trained with augmented dataset they generate correct equations. Additionally, in Problem 2 the base model generates syntactically incorrect solution, but post augmentation it generates syntactically correct equation. These examples show the increased robustness and solving abilities of solvers.

Problem: There are 3 pencils in the drawer. Sara placed 7 more pencils in the drawer. How many pencils are there in all ?
Mean attention values: 0.45 0.11 0.05

Problem: There are 3 pencils in the drawer. Sara placed 7 more pencils in the drawer. How many pencils are there in all ?
Augmented mean attention values : 0.31 0.16 0.09

Table 7: Examples illustrating distribution of top three attention weights before and after training on the full augmented dataset.

Attention Visualizations: Through this investigation, we aim to ascertain our hypothesis that to generate equations MWP solvers focus only on certain keywords and patterns in a region. They ignore essential information like semantics, sequence of events and content of the question text present in the problem statement. In Table 7, we show some sample problem statements with their attention weights. These weights are generated during the decoding process using Luong attention mechanism (Luong et al., 2015). Moreover, to illustrate the effectiveness of our augmentation techniques, we show the distribution of attention weights for models trained on the augmented dataset. We can infer from the examples showcased in Table 7 that before augmentation the focus of the solver is limited to a fixed region around numerical quantities and it does not pay heed to the question text. However, after training on the augmented dataset the solver has a better distribution of attention weights, the weights are not localised and and the model is also able to pay attention on the question text.

Ablation Studies: To assert the effectiveness of our methods, we conduct the following ablations:

Method	Eval Type	Seq2Seq	GTS	Graph2Tree
RSA	True	84.6	87.5	88.7
	Paraphrasing	**85.3**	**88.1**	**89.2**
	Substitution	**86.8**	**87.3**	**87.9**
	Combined	**87.0**	**89.2**	**89.5**
CSA	True	84.6	87.5	88.7
	Paraphrasing	**88.3**	**90.4**	**92.6**
	Substitution	**89.2**	**89.7**	**91.7**
	Combined	**91.3**	**92.6**	**93.5**

Table 8: Ablation Study for Random Selection Algorithm (RSA) and Candidate Selection Algorithm (CSA).

Candidate Selection Algorithm: For testing the usefulness of candidate selection algorithm, we compare it with a random selection algorithm. In this, we randomly select one of the possible candidates as augmented problem statement. We evaluate the accuracy of models trained on the augmented datasets, generated using both the algorithms. Result in Table 8, shows that candidate selection algorithm performs better than random selection algorithm and this demonstrates the effectiveness of our algorithm.

Augmentation Methods: To examine the effectiveness of proposed augmentation techniques, we evaluate the models on each of the proposed techniques independently and report the results in Table 9. Although, all the methods contribute towards increase in accuracy but Round trip translations and synonym replacement perform marginally better than others. This behaviour can be linked to the structural diversity and keyword sensitivity that round trip translations and synonym replacement bring respectively (Feng et al., 2021).

Augmentation	Seq2Seq	GTS	Graph2Tree
True	84.6	87.5	88.7
RRT	**86.5**	89.1	**91.6**
PR	85.9	88.4	90.7
FM	84.8	87.2	89.1
SR	85.2	**90.1**	91.2
NER	86.1	88.3	89.7

Table 9: Result of Ablation study for each augmentation method. True represents unaugmented MaWPS dataset, RRT, PR, FM, SR, NER represents round trip translations, problem reordering, fill masking,synonym replacement and named entity replacement respectively.

Augmentation	Seq2Seq	GTS	Graph2Tree
True	37.5	39.6	41.2
MaWPS(P+S)	39.2	40.1	42.3
ASDiv-A(P+S)	37.8	40.4	42.1
Combined	**40.2**	**41.3**	**43.8**

Table 10: Result of augmentations on SVAMP Challenge Set. P and S represent paraphrasing and substitution methods. Combined represents augmented MaWPS and ASDiv-A. True is combined MaWPS and ASDiv-A.

SVAMP Challenge Set: SVAMP (Patel et al., 2021) is a manually curated challenge test set consisting of $1,000$ math word problems. These problems have been cherry picked from MaWPS and ASDiv-A, then altered manually to modify the semantics of question text and generate additional equation templates. This challenge set is suitable for evaluating a solver's performance as it modifies problem statements such that solver's generalization can be checked. The results are shown in Table 10. Although, our proposed augmented dataset has very limited equation templates, still it performs comparatively better than state-of-the-art models on SVAMP challenge set. This result signifies the need for a larger and diverse dataset with enhanced variety of problems. Further, it demonstrates the effectiveness of our method which is able to perform better on SVAMP test set and increase model's accuracy despite the challenges.

Augmentation Method	MaWPS		ASDiv-A	
	Scratch	BERT	Scratch	BERT
True	77.2	**84.6**	53.2	**70.6**
Paraphrasing	79.8	**88.3**	58.1	**75.6**
Substitution	81.3	**89.2**	57.3	**73.2**
Combined	82.7	**91.3**	60.4	**78.2**

Table 11: Performance comparison of baseline model trained from scratch and trained using BERT embeddings. True represents unaugmented dataset.

BERT Embeddings: We train the solvers in two different settings, using pre-trained BERT embeddings and training from scratch. We chose BERT specifically as we require contextual embeddings which could be easily adapted for the task of MWP. Moreover, existing models have also shown results using BERT and it would be fair to compare their performances when trained using similar embeddings. Results obtained are shown in Table 11. We observe that for solver's trained using BERT, accuracy is higher than models trained from scratch.

Human Evaluation: To verify the quality of augmented examples, we conduct human evaluation. The focus of this evaluation is: (1) To check if the augmentations will result in the same linear equation as present in the original problem statement, (2) To evaluate if the numerical values for each augmentation example is preserved, (3) Evaluate each sample in the range 0 to 1 for its semantic similarity with the original problem statement, (4) On a scale of 1 to 5 rate each augmented example for its grammatical correctness. We conduct the human evaluations on randomly shuffled subsets consisting of around 40% of the total augmented examples for both the datasets. This process is repeated three times with different subsets, five human evaluators evaluate each example in all subsets, and the mean results are computed as shown in Table 12.

Evaluation Criteria	**MaWPS**		**ASDiv-A**	
	Para	Sub	Para	Sub
Preserves Equation	92.3%	89.5%	93.6%	90.1%
Preserves Numbers	88.4%	91.2%	87.3%	90.3%
Semantic Similarity	0.96	0.89	0.91	0.87
Syntactic Similarity	4.67	4.36	4.59	4.33

Table 12: Human Evaluation scores on augmentated dataset. Para and Sub represents paraphrasing and substitution methods respectively.

5 Future Work and Conclusion

We showcase that the existing MWP solvers are not robust and do not generalize well on even simple variations of the problem statement. In this work, we have introduced data augmentation techniques for generation of diverse math word problems. We were able to enhance the size of existing dataset by 5 folds and significantly increase the performance of state-of-the-art solvers by over 5 percentage points. Future works could focus on developing techniques to generate data artificially and making robust MWP solvers.

7 Appendix

7.1 Implementation Details

For conducting our experiments we have used two Boston SYS-7048GR-TR nodes equipped with NVIDIA GeForce GTX 1080 Ti computational GPU's having 11GB of GDDR5X RAM. All implementations of training and testing is coded in Python with Pytorch framework. The number of parameters range from 20M to 130M for different models. We use negative log likelihood as the loss criterion. Hyper-parameter values were not modified, and we follow the recommendations of the respective models. To reduce carbon footprint from our experiments, we run the models only on a single fold for searching hyperparameter values. We chose the number of base candidates after primary stage n as 7. Generating augmentation examples using Paraphrasing Methods took around 12 minutes on average for MaWPS and 8 minutes for ASDiv-A datasets. Substitution methods took around 5 minutes on average for both MaWPS and ASDiv-A dataset. The experiments conducted by us are not computation heavy. Each of the state-of-the-art models get trained within 5 hrs of time, with Graph2Tree taking the maximum time.

7.2 Additional Augmented Examples

In this section, we present some additional valid as well as invalid augmented examples. Additionally, we also show some more examples with their attention weights. Table 13 shows some additional examples with their attention weight distribution. These weights have been shown for the base model trained before augmentation and after augmentation on MaWPS dataset. Table 14 illustrates some additional problem statements for all the techniques in paraphrasing methods and substitution methods. In Table 15, we present some invalid augmented examples which do not satisfy our human evaluation criteria. These examples are such that they alter the semantics of the original problem statement.

Problem: A magician was selling magic card decks for 2 dollars each . If he started with 25 decks and by the end of the day he had 4 left, how much money did he earn ?
Mean attention values: 0.34 0.11 0.09

Abstract

We propose DiffCSE, an unsupervised contrastive learning framework for learning sentence embeddings. DiffCSE learns sentence embeddings that are sensitive to the difference between the original sentence and an edited sentence, where the edited sentence is obtained by stochastically masking out the original sentence and then sampling from a masked language model. We show that DiffSCE is an instance of equivariant contrastive learning (Dangovski et al., 2021), which generalizes contrastive learning and learns representations that are insensitive to certain types of augmentations and sensitive to other "harmful" types of augmentations. Our experiments show that DiffCSE achieves state-of-the-art results among unsupervised sentence representation learning methods, outperforming unsupervised SimCSE[1] by 2.3 absolute points on semantic textual similarity tasks. [2]

1 Introduction

Learning "universal" sentence representations that capture rich semantic information and are at the same time performant across a wide range of downstream NLP tasks without task-specific finetuning is an important open issue in the field (Conneau et al., 2017; Cer et al., 2018; Kiros et al., 2015; Logeswaran and Lee, 2018; Giorgi et al., 2020; Yan et al., 2021; Gao et al., 2021). Recent work has shown that finetuning pretrained language models with *contrastive learning* makes it possible to learn good sentence embeddings without any labeled data (Giorgi et al., 2020; Yan et al., 2021; Gao et al., 2021). Contrastive learning uses multiple augmentations on a single datum to construct positive pairs whose representations are trained to be more similar to one another than negative pairs. While different data augmentations (random cropping, color jitter, rotations, etc.) have been found to be crucial for pretraining vision models (Chen et al., 2020), such augmentations have generally been unsuccessful when applied to contrastive learning of sentence embeddings. Indeed, Gao et al. (2021) find that constructing positive pairs via a simple dropout-based augmentation works much better than more complex augmentations such as word deletions or replacements based on synonyms or masked language models. This is perhaps unsurprising in hindsight; while the training objective in contrastive learning encourages representations to be *invariant* to augmentation transformations, direct augmentations on the input (e.g., deletion, replacement) often change the meaning of the sentence. That is, ideal sentence embeddings should *not* be invariant to such transformations.

We propose to learn sentence representations that are *aware* of, but not necessarily invariant to, such direct surface-level augmentations. This is an instance of *equivariant* contrastive learning (Dangovski et al., 2021), which improves vision representation learning by using a contrastive loss on *insensitive* image transformations (e.g., grayscale) and a prediction loss on *sensitive* image transformations (e.g., rotations). We operationalize equivariant contrastive learning on sentences by using dropout-based augmentation as the insensitive transformation (as in SimCSE (Gao et al., 2021)) and MLM-based word replacement as the sensitive transformation. This results in an additional cross-entropy loss based on the *difference* between the original and the transformed sentence.

We conduct experiments on 7 semantic textual similarity tasks (STS) and 7 transfer tasks from SentEval (Conneau and Kiela, 2018) and find that this difference-based learning greatly improves over standard contrastive learning. Our DiffCSE approach can achieve around 2.3% absolute improve-

---

[1] SimCSE has two settings: unsupervised and supervised. In this paper, we focus on the unsupervised setting. Unless otherwise stated, in this paper we use SimCSE to refer to unsupervised SimCSE.

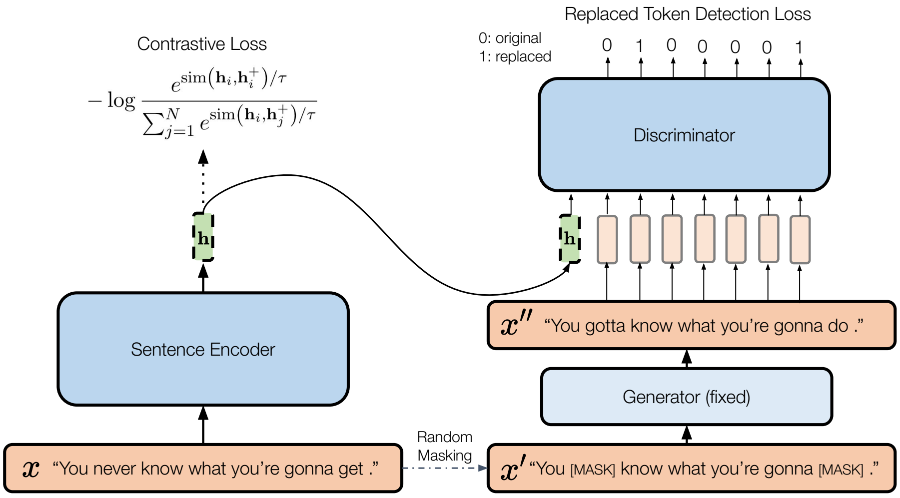

Figure 1: Illustration of DiffCSE. On the left-hand side is a standard SimCSE model trained with regular contrastive loss on dropout transformations. On the right hand side is a conditional difference prediction model which takes the sentence vector $\mathbf{h}$ as input and predict the difference between x and x''. During testing we discard the discriminator and only use $\mathbf{h}$ as the sentence embedding.

ment on STS datasets over SimCSE, the previous state-of-the-art model. We also conduct a set of ablation studies to justify our designed architecture. Qualitative study and analysis are also included to look into the embedding space of DiffCSE.

2 Background and Related Work

2.1 Learning Sentence Embeddings

Learning universal sentence embeddings has been studied extensively in prior work, including unsupervised approaches such as Skip-Thought (Kiros et al., 2015), Quick-Thought (Logeswaran and Lee, 2018) and FastSent (Hill et al., 2016), or supervised methods such as InferSent (Conneau et al., 2017), Universal Sentence Encoder (Cer et al., 2018) and Sentence-BERT (Reimers and Gurevych, 2019). Recently, researchers have focused on (unsupervised) contrastive learning approaches such as SimCLR (Chen et al., 2020) to learn sentence embeddings. SimCLR (Chen et al., 2020) learns image representations by creating semantically close augmentations for the same images and then pulling these representations to be closer than representations of random negative examples. The same framework can be adapted to learning sentence embeddings by designing good augmentation methods for natural language. ConSERT (Yan et al., 2021) uses a combination of four data augmentation strategies: adversarial attack, token shuffling, cut-off, and dropout. DeCLUTR (Giorgi et al., 2020) uses overlapped spans as positive examples and distant spans as negative examples for learning contrastive span representations. Finally, SimCSE (Gao et al., 2021) proposes an extremely simple augmentation strategy by just switching dropout masks. While simple, sentence embeddings learned in this manner have been shown to be better than other more complicated augmentation methods.

2.2 Equivariant Contrastive Learning

DiffCSE is inspired by a recent generalization of contrastive learning in computer vision (CV) called equivariant contrastive learning (Dangovski et al., 2021). We now explain how this CV technique can be adapted to natural language.

Understanding the role of input transformations is crucial for successful contrastive learning. Past empirical studies have revealed useful transformations for contrastive learning, such as random resized cropping and color jitter for computer vision (Chen et al., 2020) and dropout for NLP (Gao et al., 2021). Contrastive learning encourages representations to be insensitive to these transformations, i.e. the encoder is trained to be invariant to a set of manually chosen transformations. The above studies in CV and NLP have also revealed transformations that are *harmful* for contrastive learning. For example, Chen et al. (2020) showed that making the representations insensitive to rotations decreases the ImageNet linear probe accuracy, and Gao et al. (2021) showed that using an MLM to replace 15% of the words drastically reduces performance on

STS-B. While previous works simply omit these transformations from contrastive pre-training, here we argue that we should still make use of these transformations by learning representations that are *sensitive* (but not necessarily invariant) to such transformations.

The notion of (in)sensitivity can be captured by the more general property of equivariance in mathematics. Let T be a transformation from a group G and let $T(x)$ denote the transformation of a sentence x. Equivariance is the property that there is an induced group transformation T' on the output features (Dangovski et al., 2021):

$$f(T(x)) = T'(f(x)).$$

In the special case of contrastive learning, T''s target is the identity transformation, and we say that f is trained to be "invariant to T." However, invariance is just a trivial case of equivariance, and we can design training objectives where T' is not the identity for some transformations (such as MLM), while it is the identity for others (such as dropout). Dangovski et al. (2021) show that generalizing contrastive learning to equivariance in this way improves the semantic quality of features in CV, and here we show that the complementary nature of invariance and equivariance extends to the NLP domain. The key observation is that the encoder should be equivariant to MLM-based augmentation instead of being invariant. We can operationalize this by using a conditional discriminator that combines the sentence representation with an edited sentence, and then predicts the *difference* between the original and edited sentences. This is essentially a conditional version of the ELECTRA model (Clark et al., 2020), which makes the encoder equivariant to MLM by using a binary discriminator which detects whether a token is from the original sentence or from a generator. We hypothesize that conditioning the ELECTRA model with the representation from our sentence encoder is a useful objective for encouraging f to be "equivariant to MLM."

To the best of our knowledge, we are the first to observe and highlight the above parallel between CV and NLP. In particular, we show that equivariant contrastive learning extends beyond CV, and that it works for transformations even without algebraic structures, such as diff operations on sentences. Further, insofar as the canonical set of useful transformations is less established in NLP than is in CV, DiffCSE can serve as a diagnostic tool for NLP researchers to discover useful transformations.

3 Difference-based Contrastive Learning

Our approach is straightforward and can be seen as combining the standard contrastive learning objective from SimCSE (Figure 1, left) with a *difference prediction* objective which conditions on the sentence embedding (Figure 1, right).

Given an unlabeled input sentence x, SimCSE creates a positive example x^+ for it by applying different dropout masks. By using the BERT$_{\texttt{base}}$ encoder f, we can obtain the sentence embedding $\mathbf{h} = f(x)$ for x (see section 4 for how $\mathbf{h}$ is obtained). The training objective for SimCSE is:

$$\mathcal{L}_{\text{contrast}} = -\log \frac{e^{\operatorname{sim}\left(\mathbf{h}_i, \mathbf{h}_i^{+}\right)/\tau}}{\sum_{j=1}^{N} e^{\operatorname{sim}\left(\mathbf{h}_i, \mathbf{h}_j^{+}\right)/\tau}},$$

where N is the batch size for the input batch $\{x_i\}_{i=1}^{N}$ as we are using in-batch negative examples, $\operatorname{sim}(\cdot,\cdot)$ is the cosine similarity function, and τ is a temperature hyperparameter.

On the right-hand side of Figure 1 is a conditional version of the difference prediction objective used in ELECTRA (Clark et al., 2020), which contains a generator and a discriminator. Given a sentence of length T, $x = [x_{(1)}, x_{(2)}, ..., x_{(T)}]$, we first apply a random mask $m = [m_{(1)}, m_{(2)}, ..., m_{(T)}], m_{(t)} \in [0, 1]$ on x to obtain $x' = m \cdot x$. We use another pretrained MLM as the generator G to perform masked language modeling to recover randomly masked tokens in x' to obtain the edited sentence $x'' = G(x')$. Then, we use a discriminator D to perform the Replaced Token Detection (RTD) task. For each token in the sentence, the model needs to predict whether it has been replaced or not. The cross-entropy loss for a single sentence x is:

$$\begin{aligned}\mathcal{L}_{\text{RTD}}^{x} = \sum_{t=1}^{T} \Big(& -\mathbb{1}\left(x''_{(t)} = x_{(t)}\right) \log D\left(x'', \mathbf{h}, t\right) \\ & - \mathbb{1}\left(x''_{(t)} \neq x_{(t)}\right) \log\left(1 - D\left(x'', \mathbf{h}, t\right)\right) \Big)\end{aligned}$$

And the training objective for a batch is $\mathcal{L}_{\text{RTD}} = \sum_{i=1}^{N} \mathcal{L}_{\text{RTD}}^{x_i}$. Finally we optimize these two losses together with a weighting coefficient λ:

$$\mathcal{L} = \mathcal{L}_{\text{contrast}} + \lambda \cdot \mathcal{L}_{\text{RTD}}$$

The difference between our model and ELECTRA is that our discriminator D is *conditional*, so it can use the information of x compressed in a fixed-dimension vector $\mathbf{h} = f(x)$. The gradient of D can be backward-propagated into f through $\mathbf{h}$. By doing so, f will be encouraged to make $\mathbf{h}$ informative enough to cover the full meaning of x, so that D can distinguish the tiny difference between x and x''. This approach essentially makes the conditional discriminator perform a "diff operation", hence the name DiffCSE.

When we train our DiffCSE model, we fix the generator G, and only the sentence encoder f and the discriminator D are optimized. After training, we discard D and only use f (which remains fixed) to extract sentence embeddings to evaluate on the downstream tasks.

4 Experiments

4.1 Setup

In our experiment, we follow the setting of unsupervised SimCSE (Gao et al., 2021) and build our model based on their PyTorch implementation.[3] We also use the checkpoints of BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) as the initialization of our sentence encoder f. We add an MLP layer with Batch Normalization (Ioffe and Szegedy, 2015) (BatchNorm) on top of the `[CLS]` representation as the sentence embedding. We will compare the model with/without BatchNorm in section 5. For the discriminator D, we use the same model as the sentence encoder f (BERT/RoBERTa). For the generator G, we use the smaller DistilBERT and DistilRoBERTa (Sanh et al., 2019) for efficiency. Note that the generator is fixed during training unlike the ELECTRA paper (Clark et al., 2020). We will compare the results of using different size model for the generator in section 5. More training details are shown in Appendix A.

4.2 Data

For unsupervised pretraining, we use the same 10^6 randomly sampled sentences from English Wikipedia that are provided by the source code of SimCSE.[3] We evaluate our model on 7 semantic textual similarity (STS) and 7 transfer tasks in SentEval.[4] STS tasks includes STS 2012–2016 (Agirre et al., 2016), STS Benchmark (Cer et al., 2017) and SICK-Relatedness (Marelli et al., 2014). All the STS experiments are fully unsupervised, which means no STS training datasets are used and all embeddings are fixed once they are trained. The transfer tasks are various sentence classification tasks, including MR (Pang and Lee, 2005), CR (Hu and Liu, 2004), SUBJ (Pang and Lee, 2004), MPQA (Wiebe et al., 2005), SST-2 (Socher et al., 2013), TREC (Voorhees and Tice, 2000) and MRPC (Dolan and Brockett, 2005). In these transfer tasks, we will use a logistic regression classifier trained on top of the frozen sentence embeddings, following the standard setup (Conneau and Kiela, 2018).

4.3 Results

Baselines We compare our model with many strong unsupervised baselines including SimCSE (Gao et al., 2021), IS-BERT (Zhang et al., 2020), CMLM (Yang et al., 2020), DeCLUTR (Giorgi et al., 2020), CT-BERT (Carlsson et al., 2021), SG-OPT (Kim et al., 2021) and some post-processing methods like BERT-flow (Li et al., 2020) and BERT-whitening (Su et al., 2021) along with some naive baselines like averaged GloVe embeddings (Pennington et al., 2014) and averaged first and last layer BERT embeddings.

Semantic Textual Similarity (STS) We show the results of STS tasks in Table 1 including BERT$_{\texttt{base}}$ (upper part) and RoBERTa$_{\texttt{base}}$ (lower part). We also reproduce the previous state-of-the-art SimCSE (Gao et al., 2021). DiffCSE-BERT$_{\texttt{base}}$ can significantly outperform SimCSE-BERT$_{\texttt{base}}$ and raise the averaged Spearman's correlation from 76.25% to 78.49%. For the RoBERTa model, DiffCSE-RoBERTa$_{\texttt{base}}$ can also improve upon SimCSE-RoBERTa$_{\texttt{base}}$ from 76.57% to 77.80%.

Transfer Tasks We show the results of transfer tasks in Table 2. Compared with SimCSE-BERT$_{\texttt{base}}$, DiffCSE-BERT$_{\texttt{base}}$ can improve the averaged scores from 85.56% to 86.86%. When applying it to the RoBERTa model, DiffCSE-RoBERTa$_{\texttt{base}}$ also improves upon SimCSE-RoBERTa$_{\texttt{base}}$ from 84.84% to 87.04%. Note that the CMLM-BERT$_{\texttt{base}}$ (Yang et al., 2020) can achieve even better performance than DiffCSE. However, they use 1TB of the training data from Common Crawl dumps while our model only use 115MB of the Wikipedia data for pretraining. We put their scores in Table 2 for reference. In SimCSE, the authors propose to use MLM as an auxiliary task for the sentence encoder to further boost the performance of transfer tasks. Compared with

the results of SimCSE with MLM, DiffCSE still can have a little improvement around 0.2%.

5 Ablation Studies

In the following sections, we perform an extensive series of ablation studies that support our model design. We use BERT$_{\text{base}}$ model to evaluate on the development set of STS-B and transfer tasks.

Removing Contrastive Loss In our model, both the contrastive loss and the RTD loss are crucial because they maintain what should be sensitive and what should be insensitive respectively. If we remove the RTD loss, the model becomes a SimCSE model; if we remove the contrastive loss, the performance of STS-B drops significantly by 30%, while the average score of transfer tasks also drops by 2% (see Table 3). This result shows that it is important to have insensitive and sensitive attributes that exist together in the representation space.

Next Sentence vs. Same Sentence Some methods for unsupervised sentence embeddings like Quick-Thoughts (Logeswaran and Lee, 2018) and CMLM (Yang et al., 2020) predict the next sentence as the training objective. We also experiment with a variant of DiffCSE by conditioning the ELECTRA loss based on the next sentence. Note that this kind of model is not doing a "diff operation" between two similar sentences, and is not an instance of equivariant contrastive learning. As shown in Table 3 (use next sent. for x'), the score of STS-B decreases significantly compared to DiffCSE while transfer performance remains similar. We also tried using the same sentence and the next sentence at the same time for conditioning the ELECTRA objective (use same+next sent. for x'), and did not observe improvements.

Other Conditional Pretraining Tasks Instead of a conditional binary difference prediction loss, we can also consider other conditional pretraining tasks such as a conditional MLM objective proposed by Yang et al. (2020), or corrective language modeling,[5] proposed by COCO-LM (Meng et al., 2021). We experiment with these objectives instead of the difference prediction objective in Table 3. We observe that conditional MLM on the same sentence does not improve the performance either on STS-B or transfer tasks compared with DiffCSE. Conditional MLM on the next sentence performs even worse for STS-B, but slightly better than using the same sentence on transfer tasks. Using both the same and the next sentence also does not improve the performance compared with DiffCSE. For the corrective LM objective, the performance of STS-B decreases significantly compared with DiffCSE.

Augmentation Methods: Insert/Delete/Replace In DiffCSE, we use MLM token replacement as the equivariant augmentation. It is possible to use other methods like random insertion or deletion instead of replacement.[6] For insertion, we choose to

---

[5] This task is similar to ELECTRA. However, instead of a binary classifier for replaced token detection, corrective LM uses a vocabulary-size classifier with the copy mechanism to recover the replaced tokens.

[6] Edit distance operators include *insert, delete* and *replace*.

w/o BatchNorm	81.47	83.91

Table 5: Development set results of STS-B and transfer tasks for DiffCSE and SimCSE with and without BatchNorm.

randomly insert mask tokens to the sentence, and then use a generator to convert mask tokens into real tokens. The number of inserted masked tokens is 15% of the sentence length. The task is to predict whether a token is an inserted token or the original token. For deletion, we randomly delete 15% tokens in the sentence, and the task is to predict for each token whether a token preceding it has been deleted or not. The results are shown in Table 4. We can see that using either insertion or deletion achieves a slightly worse STS-B performance than using MLM replacement. For transfer tasks, their results are similar. Finally, we find that combining all three augmentations in the training process does not improve the MLM replacement strategy.

Pooler Choice In SimCSE, the authors use the pooler in BERT's original implementation (one linear layer with tanh activation function) as the final layer to extract features for computing contrastive loss. In our implementation (see details in Appendix A), we find that it is better to use a two-layer pooler with Batch Normalization (BatchNorm) (Ioffe and Szegedy, 2015), which is commonly used in contrastive learning framework in computer vision (Chen et al., 2020; Grill et al., 2020; Chen and He, 2021; Hua et al., 2021). We show the ablation results in Table 5. We can observe that adding BatchNorm is beneficial for either DiffCSE or SimCSE to get better performance on STS-B and transfer tasks.

Size of the Generator In our DiffCSE model, the generator can be in different model size from BERT$_{\texttt{large}}$, BERT$_{\texttt{base}}$ (Devlin et al., 2019), DistilBERT$_{\texttt{base}}$ (Sanh et al., 2019), BERT$_{\texttt{medium}}$, BERT$_{\texttt{small}}$, BERT$_{\texttt{mini}}$, BERT$_{\texttt{tiny}}$ (Turc et al., 2019). Their exact sizes are shown in Table 6 (L: number of layers, H: hidden dimension). Notice that although DistilBERT$_{\texttt{base}}$ has only half the number of layers of BERT, it can retain 97% of

	STS-B	Avg. transfer
SimCSE	81.47	83.91
DiffCSE w/ generator:		
BERT$_{\texttt{large}}$ (L=24, H=1024)	82.93	85.88
BERT$_{\texttt{base}}$ (L=12, H=768)	83.63	85.85
DistilBERT$_{\texttt{base}}$ (L=6, H=768)	**84.56**	**85.95**
BERT$_{\texttt{medium}}$ (L=8, H=512)	82.25	85.80
BERT$_{\texttt{small}}$ (L=4, H=512)	82.64	85.66
BERT$_{\texttt{mini}}$ (L=4, H=256)	82.12	85.90
BERT$_{\texttt{tiny}}$ (L=2, H=128)	81.40	85.23

Table 6: Development set results of STS-B and transfer tasks with different generators.

Ratio	*15%*	*20%*	*25%*	*30%*	*40%*	*50%*
STS-B	84.48	84.04	84.49	**84.56**	84.48	83.91

Table 7: Development set results of STS-B under different masking ratio for augmentations.

BERT's performance due to knowledge distillation.

We show our results in Table 6, we can see the performance of transfer tasks does not change much with different generators. However, the score of STS-B decreases as we switch from BERT-medium to BERT-tiny. This finding is not the same as ELECTRA, which works best with generators 1/4-1/2 the size of the discriminator. Because our discriminator is conditional on sentence vectors, it will be easier for the discriminator to perform the RTD task. As a result, using stronger generators (BERT$_{\texttt{base}}$, DistilBERT$_{\texttt{base}}$) to increase the difficulty of RTD would help the discriminator learn better. However, when using a large model like BERT$_{\texttt{large}}$, it may be a too-challenging task for the discriminator. In our experiment, using DistilBERT$_{\texttt{base}}$, which has the ability close to but slightly worse than BERT$_{\texttt{base}}$, gives us the best performance.

Masking Ratio In our conditional ELECTRA task, we can mask the original sentence in different ratios for the generator to produce MLM-based augmentations. A higher masking ratio will make more perturbations to the sentence. Our empirical result in Table 7 shows that the difference between difference masking ratios is small (in 15%-40%), and a masking ratio of around 30% can give us the best performance.

Coefficient λ In Section 3, we use the λ coefficient to weight the ELECTRA loss and then add it with contrastive loss. Because the contrastive learning objective is a relatively easier task, the scale of contrastive loss will be 100 to 1000 smaller than ELECTRA loss. As a result, we need a smaller λ to balance these two loss terms. In the Table 8 we show the STS-B result under different λ values. Note that when λ goes to zero, the model becomes a SimCSE model. We find that using $\lambda = 0.005$ can give us the best performance.

λ	*0*	*0.0001*	*0.0005*	*0.001*
STS-B	82.22	83.90	84.40	84.24
λ	*0.005*	*0.01*	*0.05*	*0.1*
STS-B	**84.56**	83.44	84.11	83.66

Table 8: Development set results of STS-B under different λ.

6 Analysis

6.1 Qualitative Study

A very common application for sentence embeddings is the retrieval task. Here we show some retrieval examples to qualitatively explain why DiffCSE can perform better than SimCSE. In this study, we use the 2758 sentences from STS-B testing set as the corpus, and then use sentence query to retrieve the nearest neighbors in the sentence embedding space by computing cosine similarities. We show the retrieved top-3 examples in Table 9. The first query sentence is "you can do it, too.". The SimCSE model retrieves a very similar sentence but has a slightly different meaning ("you can use it, too.") as the rank-1 answer. In contrast, DiffCSE can distinguish the tiny difference, so it retrieves the ground truth answer as the rank-1 answer. The second query sentence is "this is not a problem". SimCSE retrieves a sentence with opposite meaning but very similar wording, while DiffCSE can retrieve the correct answer with less similar wording. We also provide a third example where both SimCSE and DiffCSE fail to retrieve the correct answer for a query sentence using double negation.

6.2 Retrieval Task

Besides the qualitative study, we also show the quantitative result of the retrieval task. Here we also use all the 2758 sentences in the testing set of STS-B as the corpus. There are 97 positive pairs in this corpus (with 5 out of 5 semantic similarity scores from human annotation). For each positive pair, we use one sentence to retrieve the other one, and see whether the other sentence is in the top-1/5/10 ranking. The recall@1/5/10 of the retrieval task are shown in Table 10. We can observe that DiffCSE can outperform SimCSE for

SimCSE-BERT$_{\text{base}}$	**DiffCSE-BERT$_{\text{base}}$**
Query: you can do it, too.	
1) you can use it, too. 2) can you do it? 3) yes, you can do it.	1) yes, you can do it. 2) you can use it, too. 3) can you do it?
Query: this is not a problem.	
1) this is a big problem. 2) you have a problem. 3) i don 't see why that should be a problem.	1) i don 't see why this could be a problem. 2) i don 't see why that should be a problem. 3) this is a big problem.
Query: i think that is not a bad idea.	
1) i do not think it's a good idea. 2) it's not a good idea . 3) it is not a good idea .	1) i do not think it's a good idea . 2) it is not a good idea. 3) but it is not a good idea.

recall@1/5/10, showing the effectiveness of using DiffCSE for the retrieval task.

6.3 Distribution of Sentence Embeddings

To look into the representation space of DiffCSE, we plot the cosine similarity distribution of sentence pairs from STS-B test set for both SimCSE and DiffCSE in Figure 2. We observe that both SimCSE and DiffCSE can assign cosine similarities consistent with human ratings. However, we also observe that under the same human rating, DiffCSE assigns slightly higher cosine similarities compared with SimCSE. This phenomenon may be caused by the fact that ELECTRA and other Transformer-based pretrained LMs have the problem of squeezing the representation space, as mentioned by Meng et al. (2021). As we use the sentence embeddings as the input of ELECTRA to perform conditional ELECTRA training, the sentence embedding will be inevitably squeezed to fit the input distribution of ELECTRA. We follow prior studies (Wang and Isola, 2020; Gao et al., 2021) to use *uniformity* and *alignment* (details in Appendix C) to measure the quality of representation space for DiffCSE and SimCSE in Table 11. Compared to averaged BERT embeddings, SimCSE has similar alignment (0.177 v.s. 0.172) but better uniformity (-2.313). In contrast, DiffCSE has similar uniformity as Avg. BERT (-1.438 v.s. -1.468) but much better alignment (0.097). It indicates that SimCSE and DiffCSE are optimizing the representation space in two different directions. And the improvement of DiffCSE may come from its better alignment.

Model	**Alignment**	**Uniformity**	**STS**
Avg. BERT$_{\text{base}}$	0.172	-1.468	56.70
SimCSE-BERT$_{\text{base}}$	0.177	**-2.313**	76.16
DiffCSE-BERT$_{\text{base}}$	**0.097**	-1.438	**78.49**

Table 11: *Alignment* and *Uniformity* (Wang and Isola, 2020) measured on STS-B test set for SimCSE and DiffCSE. The smaller the number is better. We also show the averaged STS score in the right-most column.

7 Conclusion

In this paper, we present DiffCSE, a new unsupervised sentence embedding framework that is aware of, but not invariant to, MLM-based word replacement. Empirical results on semantic textual similarity tasks and transfer tasks both show the effectiveness of DiffCSE compared to current state-of-the-art sentence embedding methods. We also conduct extensive ablation studies to demonstrate the different modeling choices in DiffCSE. Qualitative study and the retrieval results also show that DiffCSE can produce a better embedding space for sentence retrieval. One limitation of our work is that we do not explore the supervised setting that uses human-labeled NLI datasets to further boost the performance. We leave this topic for future work. We believe that our work can provide researchers in the NLP community a new way to utilize augmentations for natural language and thus produce better sentence embeddings.

A Training Details

We use a single NVIDIA 2080Ti GPU for each experiment. The averaged running time for DiffCSE is 3-6 hours. We use grid-search of batch size $\in \{64, 128\}$ learning rate $\in$ {2e-6, 3e-6, 5e-6, 7e-6, 1e-5} and masking ratio $\in \{0.15, 0.20, 0.30, 0.40\}$ and $\lambda \in \{0.1, 0.05, 0.01, 0.005, 0.001\}$. The temperature τ in SimCSE is set to 0.05 for all the experiments. During the training process, we save the checkpoint with the highest score on the STS-B development set. And then we use STS-B development set to find the best hyperparameters (listed in Table 12) for STS task; we use the averaged score of the development sets of 7 transfer tasks to find the best hyperparameters (listed in Table 13) for transfer tasks. All numbers in Table 1 and Table 2 are from a single run.

hyperparam	**BERT$_{\text{base}}$**	**RoBERTa$_{\text{base}}$**
learning rate	7e-6	1e-5
masking ratio	0.30	0.20
λ	0.005	0.005
training epochs	2	2
batch size	64	64

Table 12: The main hyperparameters in STS tasks.

hyperparam	**BERT$_{\text{base}}$**	**RoBERTa$_{\text{base}}$**
learning rate	2e-6	3e-6
masking ratio	0.15	0.15
λ	0.05	0.05
training epochs	2	2
batch size	64	128

Table 13: The main hyperparameters in transfer tasks.

Method	**BERT$_{\text{base}}$**	**RoBERTa$_{\text{base}}$**
SimCSE	110M	125M
DiffCSE (train)	220M	250M
DiffCSE (test)	110M	125M

Table 14: The number of parameters used in our models.

During testing, we follow SimCSE to discard the MLP projector and only use the `[CLS]` output to extract the sentence embeddings.

The numbers of model parameters for BERT$_{\text{base}}$ and RoBERTa$_{\text{base}}$ are listed in Table 14. Note that in training time DiffCSE needs two BERT models to work together (sentence encoder + discriminator), but in testing time we only need the sentence encoder, so the model size is the same as the SimCSE model.

Method	**STS-B**	**Avg. transfer**
SimCSE	81.47	83.91
+ *Additional positives*		
MLM 15%	73.59	83.33
random insert 15%	80.39	83.92
random delete 15%	78.58	81.80
+ *Additional negatives*		
MLM 15%	83.02	84.49
random insert 15%	55.65	79.86
random delete 15%	55.13	82.56
+ *Equivariance (Ours)*		
MLM 15%	**84.48**	85.95
randomly insert 15%	82.20	85.96
randomly delete 15%	82.59	**85.97**

Table 15: Development set results of STS-B and transfer tasks for using three types of augmentations (replace, insert, delete) in different ways.

Projector with BatchNorm In Section 5, we mention that we use a projector with BatchNorm as the final layer of our model. Here we provided the PyTorch code for its structure:

```
class ProjectionMLP(nn.Module):
   def __init__(self, hidden_size):
      super().__init__()
      in_dim = hidden_size
      middle_dim = hidden_size * 2
      out_dim = hidden_size
      self.net = nn.Sequential(
      nn.Linear(in_dim, middle_dim,
          bias=False),
      nn.BatchNorm1d(middle_dim),
      nn.ReLU(inplace=True),
      nn.Linear(middle_dim, out_dim,
          bias=False),
      nn.BatchNorm1d(out_dim,
          affine=False))
```

B Using Augmentations as Positive/Negative Examples

In Section 5, we try to use different augmentations (e.g. insertion, deletion, replacement) for learning equivariance. In Table 15 we provide the results of using these augmentations as additional positive or negative examples along with the SimCSE training paradigm. We can observe that using these augmentations as additional positives only decreases the performance. The only method that can improve the performance a little bit is to use MLM 15% replaced examples as additional negative examples. Overall, none of these results can perform better than our proposed method, e.g. using these augmentations to learn equivariance.

C Uniformity and Alignment

Wang and Isola (2020) propose to use two properties, *alignment* and *uniformity*, to measure the quality of representations. Given a distribution of positive pairs p_{pos} and the distribution of the whole dataset p_{data}, *alignment* computes the expected distance between normalized embeddings of the paired sentences:

$$\ell_{\text{align}} \triangleq \underset{(x,x^+)\sim p_{\text{pos}}}{\mathbb{E}} \left\| f(x) - f\left(x^+\right) \right\|^2 .$$

Uniformity measures how well the embeddings are uniformly distributed in the representation space:

$$\ell_{\text{uniform}} \triangleq \log \underset{x,y \overset{i.i.d.}{\sim} p_{\text{data}}}{\mathbb{E}} e^{-2\|f(x)-f(y)\|^2} .$$

The smaller the values of uniformity and alignment, the better the quality of the representation space is indicated.

D Source Code

We build our model using the PyTorch implementation of SimCSE[7] Gao et al. (2021), which is based on the HuggingFace's Transformers package.[8] We also upload our code[9] and pretrained models (links in `README.md`). Please follow the instructions in `README.md` to reproduce the results.

E Potential Risks

On the risk side, insofar as our method utilizes pretrained language models, it may inherit and propagate some of the biases present in such models. Besides that, we do not see any other potential risks in our paper.

Generative Cross-Domain Data Augmentation for Aspect and Opinion Co-Extraction

Junjie Li, Jianfei Yu*, **and Rui Xia***
School of Computer Science and Engineering,
Nanjing University of Science and Technology, China
`{jj_li, jfyu, rxia}@njust.edu.cn`

Abstract

As a fundamental task in opinion mining, aspect and opinion co-extraction aims to identify the aspect terms and opinion terms in reviews. However, due to the lack of fine-grained annotated resources, it is hard to train a robust model for many domains. To alleviate this issue, unsupervised domain adaptation is proposed to transfer knowledge from a labeled source domain to an unlabeled target domain. In this paper, we propose a new Generative Cross-Domain Data Augmentation framework for unsupervised domain adaptation. The proposed framework is aimed to generate target-domain data with fine-grained annotation by exploiting the labeled data in the source domain. Specifically, we remove the domain-specific segments in a source-domain labeled sentence, and then use this as input to a pre-trained sequence-to-sequence model BART to simultaneously generate a target-domain sentence and predict the corresponding label for each word. Experimental results on three datasets demonstrate that our approach is more effective than previous domain adaptation methods. The source code is publicly released at `https://github.com/NUSTM/GCDDA`.

1 Introduction

Aspect and opinion co-extraction is a fundamental task in opinion mining. It aims to extract aspect terms and opinion terms from review sentences. Given a review "*the keyboard is great*", the aspect term is *keyboard* and the opinion term is *great*. Most existing works formulate aspect and opinion co-extraction as a sequence labeling task. With the support of deep learning, many supervised methods have achieved remarkable results (Liu et al., 2015; Yin et al., 2016; Wang et al., 2017; Wu et al., 2020). However, owing to the high cost of fine-grained annotations, the scarcity of labeled data in many new domains makes them fail to obtain a robust performance.

To alleviate the deficiency of labeled data, unsupervised domain adaptation is proposed to transfer knowledge from a labeled source domain to an unlabeled target domain. The main difficulty of unsupervised domain adaptation lies in the distribution discrepancy between data from different domains. Specifically, reviews from different domains may have distinct aspect terms, opinion terms, and expression patterns. To tackle the distribution discrepancy problem, many domain adaptation methods were proposed for coarse-grained sentiment classification (Blitzer et al., 2007; Yu and Jiang, 2016; Ziser and Reichart, 2018; Ghosal et al., 2020). However, due to the complexity of fine-grained domain adaptation for aspect and opinion extraction, only a handful of studies attempt to address this issue. Most of them are based on the following three paradigms:

- **rule-based adaptation**, which iteratively extracts aspects and opinions in sentences based on domain-independent syntactic rules and opinion dictionary (Li et al., 2012; Ding et al., 2017).
- **feature-based adaptation**, which incorporates the general syntactic information to learn a domain-invariant word representation across domains (Wang and Pan, 2018; Li et al., 2019; Pereg et al., 2020; Chen and Qian, 2021).
- **data augmentation-based adaptation**, which utilizes the labeled data in the source domain to directly generate high-quality target-domain data with fine-grained annotation (Yu et al., 2021).

However, the paradigms mentioned above suffer from the following problems. For rule-based adaptation methods, it is difficult to design high-quality manual rules and opinion set, which may bring low precision results. For feature-based adaptation methods, although they can bridge the domain gap by using the unlabeled data from both domains, the

---

July 10-15, 2022

main task classifier is only trained by the source labeled data, which fails to exploit the important supervision signals in the target domain. Although our recent work (Yu et al., 2021) has shown the superiority of data augmentation-based adaptation methods, its main limitation lies in that it only replaces source-specific aspects and opinions in the source domain review with target-specific aspects and opinions, but ignoring other domain-specific attributes such as collocations and expression styles, which limits the quality and diversity of generated target-domain data.

To this end, we propose a Generative Cross-Domain Data Augmentation framework for unsupervised domain adaptation, which generates target labeled data from source labeled data based on a pre-trained sequence-to-sequence model, i.e., BART (Lewis et al., 2020). Specifically, given the labeled samples in the source domain, we first train a classifier to assign pseudo labels for each unlabeled sample in the target domain. With the labeled and pseudo labeled samples from both domains, we then remove their domain-specific features to obtain domain-independent samples. Next, we employ the BART model by feeding the domain-independent samples and their token labels to the encoder and reconstructing their original texts and corresponding labels in the decoder. In the inference stage, given a source-domain sentence in which the domain-specific features are removed, the model can generate a target-domain sentence by integrating target-specific features into the source context while predicting its token-level labels. Compared with the previous method (Yu et al., 2021), our new approach generates high-quality target-domain data with more flexible syntactic patterns by making full use of the knowledge from the domain-invariant source contexts. With the label prediction, our approach can easily obtain the adaptive token labels for each generated target-domain sample.

Our main contributions in this work can be summarized as follows:

- We propose a Generative Cross-Domain Data Augmentation framework for unsupervised domain adaptation, which exploits the pre-trained sequence-to-sequence model BART to generate the target-domain data with fine-grained annotation based on the labeled source-domain data.
- Extensive experiments on three datasets of aspect and opinion co-extraction demonstrate the effectiveness of our generative framework. Further analysis shows that our framework is able to generate more fluent and diversified target-domain samples than previous approaches.

2 Related Work

2.1 Aspect and Opinion Extraction

Aspect and opinion extraction is an fundamental task in opinion mining, which is widely studied in the literature. Unsupervised learning methods have been proposed to extract aspect and opinion terms by association rule and extended opinions (Hu and Liu, 2004) or by manual syntactic rules and predefined opinion dictionary (Qiu et al., 2011). With the constant attention on deep learning, many supervised approaches have achieved remarkable results (Liu et al., 2015; Zhang et al., 2015; Yin et al., 2016; Wang et al., 2017; Yu et al., 2018; Wu et al., 2020). However, the deficiency of annotated data in many domains make them fail to achieve desired results.

2.2 Domain Adaptation

To solve the issue mentioned above, many domain adaptation methods proposed for coarse-grained sentiment classification either align the domain-specific feature space with domain-independent pivot words (Blitzer et al., 2007; Pan et al., 2010; Yu and Jiang, 2016) or learn a domain-invariant representation based on auto-encoder (Glorot et al., 2011; Yin et al., 2016) and domain adversarial learning (Li et al., 2018b). However, only a few fine-grained domain adaptation approaches are proposed for ABSA (Li et al., 2019; Gong et al., 2020) or aspect and opinion extraction. Most of them can be categorized into two types: 1) rule-based methods (Li et al., 2012; Ding et al., 2017) exploit manual syntactic rules and opinion seeds to extract aspects and opinions, which usually obtains less satisfactory results due to the quality of rules; 2) feature representation-based methods focus on learning a domain-invariant word representation (Wang and Pan, 2018; Pereg et al., 2020; Chen and Qian, 2021) based on the unlabeled data. However, the main task classifier fails to exploit the important supervision signals in the target domain.

2.3 Data Augmentation

Data augmentation is another solution for the scarcity of annotation data. Many previous works mainly focus on the sentence-level task (Guo

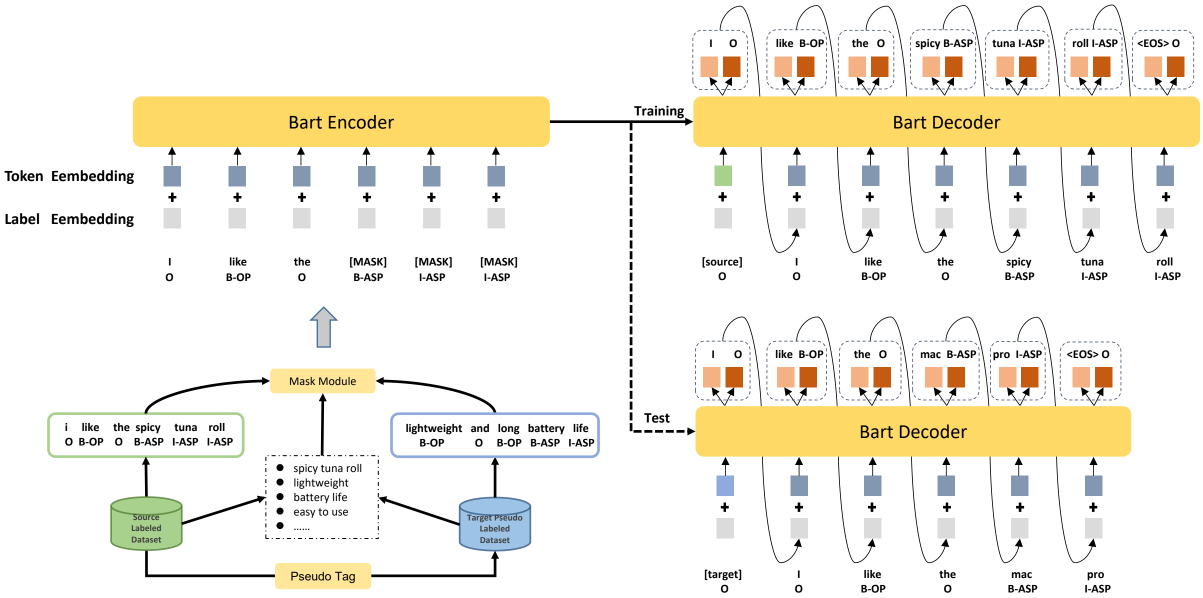

Figure 1: Overview of our proposed Generative Cross-Domain Data Augmentation framework.

et al., 2019; Min et al., 2020) and the token-level task (Gao et al., 2019; Chen et al., 2020) . For aspect/opinion extraction, Ding et al. (2020) designed a data augmentation method with language models trained on the linearized labeled sentences to generate considerable labeled data. Hsu et al. (2021) exploited a masked language model BERT to substitute unimportant words in sentences to enhance the data diversity. Li et al. (2020) proposed to generate a new review while preserving its original labels and aspect terms with a masked sequence-to-sequence model. However, all the studies above follow the in-domain setting, which fails to exploit the rich contexts from other domains. Our recent work (Yu et al., 2021) proposed a cross-domain review generation method, which replaces source-specific aspects and opinions in labeled source-domain reviews with target-specific aspect and opinions based on the masked language model BERT. However, it fails to consider other domain-specific attributes such as collocations and expression styles in cross-domain review generation. Based on our previous work, we propose a Generative Cross-Domain Data Augmentation framework for unsupervised domain adaptation, which can generate more flexible target data with fine-grained annotation in this paper.

3 Problem Formulation

In this paper, we focus on the aspect and opinion co-extraction task and formulate it as a sequence labeling problem. We denote a review as a sequence of tokens $x = [x_1, x_2, ..., x_n]$, and the task aims to predict the label sequence of the review $y = [y_1, y_2, ..., y_n]$, where $y_i \in \{B{-}ASP, I{-}ASP, B{-}OP, I{-}OP, O\}$. For unsupervised domain adaptation, we are given a set of source-domain labeled reviews $D_S = \{(x_i^s, y_i^s)\}_{i=1}^{N^s}$ and a set of unlabeled data from the target domain $D_U = \{x_i^u\}_{i=1}^{N^u}$. The goal is to predict token-level labels on the test set from the target domain $D_T = \{x_i^t\}_{i=1}^{N^t}$.

4 Methodology

In this paper, we propose a Generative Cross-Domain Data Augmentation framework, which generates target-domain reviews with fine-grained annotation from source-domain labeled reviews. Figure 1 illustrates the overall architecture of our generative framework. Specifically, we leverage the labeled samples in the source domain to train a classifier, and then assign pseudo labels for each unlabeled sample in the target domain. Given the labeled and pseudo labeled sentences from both domains, we employ a segment mask module to remove their domain-specific features while preserving their context and original labels. Next, a pre-trained sequence-to-sequence model BART concatenates the domain-invariant context and original labels as the input of the encoder, followed by recovering the original sentences and predicting their token-level labels via the decoder. During the inference stage, given a labeled source-domain sentence, the model removes its domain-specific features, and then employs the fine-tuned BART model to generate a target-domain sentence with its token-level labels.

4.1 Pseudo Label Annotation

First, we train a base classifier on the labeled data from the source domain D_S, which employs a pre-trained BERT model (Devlin et al., 2019) to obtain the contextualized word representation and a Conditional Random Field (CRF) layer for sequence labeling. The trained classifier is then applied to assign pseudo labels on the unlabeled data from the target domain D_U to achieve the pseudo labeled target-domain data D_{TP}. However, the label quality of D_{TP} tends to be relatively low due to the distribution discrepancy between the source and target domains. Therefore, it is crucial to generate high-quality target-domain data by combining the contexts from the labeled source-domain data D_S with the weak supervision in the pseudo labeled target-domain data D_{TP}.

4.2 Domain-Specific Feature Mask and Reconstruction

To automatically generate the target-domain data with fine-grained annotation, we propose a two-step approach as follows. First, a domain-specific segment set is extracted from the labeled and pseudo labeled datasets in both domains. Next, given a labeled sentence, we replace the domain-specific segments with $[mask]$ tokens, followed by feeding the masked domain-independent review to a pre-trained BART model (Lewis et al., 2020) to reconstruct its original text, domain prompt, and token-level labels.

4.2.1 Domain-Specific Segment Mask

Because reviews in different domains contain different aspects, opinions, and expression patterns, we define the text segments occurring more frequently in one domain as domain-specific segments or features. To obtain these domain-specific features, we introduce a frequency-ratio method based on (Li et al., 2018a). Specifically, we segment all sentences into word segments of different lengths, and then calculate the relative frequency of the n-gram segment w in the dataset D_v as follows:

$$s(w, D_v) = \frac{count(w, D_v) + \lambda}{\left(\sum_{v' \in V, v' \neq v} count(w, D_{v'})\right) + \lambda}, \tag{1}$$

where $count(w, D_v)$ denotes the frequency of an n-gram w in D_v, $v \in V$, $V = \{S, TP\}$, and λ is the smoothing parameter.

Next, we filter these n-gram w based on the relative frequency as follows:

$$s(w, D_v) \geq \delta, \tag{2}$$

where δ is a specified threshold.

We regard the filtered n-gram segments as the domain-specific segment set M. Given a review, we exploit the Forward Maximum Matching algorithm to match the segments that appear in M, and then replace each matched word with a special token $[mask]$. For example, in Figure 1, given a sentence "*i like the spicy tuna roll*", if the matched segment is "*spicy tuna roll*", we obtain a corresponding masked sentence "*i like the* $[mask]$ $[mask]$ $[mask]$". It is worth noting that as long as one word of a domain-specific aspect phrase or opinion phrase is masked, we will mask the whole aspect or opinion phrase.

4.2.2 Reconstruction and Label Generation

According to the above steps, for each sample $(X, L) \in D_S \cup D_{TP}$, a corresponding masked tuple $(\tilde{X}, L)$ can be obtained as the model input, where the masked sentence is $\tilde{X} = [\tilde{x}_1, \tilde{x}_2, ..., \tilde{x}_n]$ and the label sequence for each word is $L = [l_1, l_2, ..., l_n]$. To reconstruct the original text as well as its corresponding labels, we implement several modification on BART.

Encoder: In addition to the word embedding and position embedding layers in BART, we also establish a label embedding layer:

$$E_x = TokenEmb([\tilde{x}_1, \tilde{x}_2, ..., \tilde{x}_n]), \tag{3}$$

$$E_l = LabelEmb([l_1, l_2, ..., l_n]), \tag{4}$$

where $E_x \in R^{n \times d}$, $E_l \in R^{n \times d}$, and d is the dimension of the embedding. The output of the hidden state can be formulated as:

$$H = BartEncoder(E_x + E_l), \tag{5}$$

where $H \in R^{n \times d'}$, d' denotes the hidden dimension.

Decoder: To inform the BART model to distinguish the features from different domains, we insert a domain label tuple $([source], O)$ or $([target], O)$ at the beginning of the decoder, which can be regarded as a domain prompt. For each time step t, the decoder takes the previous decoder predictions

Algorithm 1 Training Procedure

```
Require: $D_S$: source labeled dataset; $D_U$: target unlabeled
    dataset; $K$: number of training iterations for BART;
Train a base classifier on dataset $D_S$
Get the target pseudo labeled dataset $D_{TP}$ by assigning
    pseudo labels on $D_U$
Extract and construct domain-specific n-gram segments
    set $M$ from $D_S \cup D_{TP}$ using Eq.(1),Eq.(2)
for $i \leftarrow 1$ to $K$ do
    Select an example$(X, L)$,$d$ from $D_S \cup D_{TP}$,where
        $d \in \{[source], [target]\}$
    $(\tilde{X}, L) \leftarrow SegmentMask(X, L, M)$
    $(X^{'}, L^{'}) \leftarrow ([d] + X, [O] + L)$
    $\theta \leftarrow BART((\tilde{X}, L), (X^{'}, L^{'}))$
end for
Return $\theta$
```

($x_{<t}$, $l_{<t}$) and the encoder output H as inputs to get the possibility of the next token and the next token label with two separate linear layers:

$$P(x_t|x_{<t}, l_{<t}, H) = \text{Softmax}(W_x z_t + b_x), \quad (6)$$

$$P(l_t|l_{<t}, x_{<t}, H) = \text{Softmax}(W_l z_t + b_l), \quad (7)$$

where $W_x \in R^{|V_x|\times d}$, $W_l \in R^{|V_l|\times d}$, and $|V_x|$ and $|V_l|$ refer to the dictionary size and the number of label types, respectively. The hidden layer vector z_t for the time step t is as follows:

$$z_t = BartDecoder(E_t), \quad (8)$$

$$E_t = TokenEmb(x_{t-1}) + LabelEmb(l_{t-1}). \quad (9)$$

For each sample, we calculate the negative log-likelihood loss for tokens and the label sequence, respectively:

$$\mathcal{L}_x = -\sum_{t=1}^{n+1} \log(P(x_t|x_{<t}, l_{<t}, H)), \quad (10)$$

$$\mathcal{L}_l = -\sum_{t=1}^{n+1} \log(P(l_t|l_{<t}, x_{<t}, H)). \quad (11)$$

The final training loss consists of the addition of two parts:

$$\mathcal{L} = \mathcal{L}_x + \mathcal{L}_l. \quad (12)$$

Algorithm 1 details the training procedure of our method.

4.3 Cross-Domain Data Generation

During the inference stage, given a source-domain labeled sentence $(X, L) \in D_S$, we employ the same mask strategy to remove its domain-specific features. Then, the masked tuple $(\tilde{X}, L)$ is fed to the BART encoder. Different from the decoder in the training phase, we only provide $([target], O)$ as the domain prompt to decode a target-domain sentence based on the auto-regressive way and jointly predict its token-level labels. To generate more samples and further increase the diversity of generated samples, we introduce several strategies as follows. For each sample $(X, L) \in D_S$, we repeat the mask step three times to get three masked tuple $(\tilde{X}, L)$ with different seeds. Specifically for the matched segments without any aspects or opinions, we randomly mask them with a probability of 60%. Thus, we can obtain three different target reviews from one source labeled review.

Dataset	Domain	Sentence	Train	Test
R	Restaurant	5841	4381	1460
L	Laptop	3845	2884	961
D	Device	3836	2877	959

Table 1: The statistics of our datasets.

4.4 Post-Processing

We post-process our generated target labeled data with the following steps: 1) Delete sentences with incorrect labels that do not follow the BIO schema; 2) Use a base classifier trained on the labeled source-domain data to assign labels on the generated target-domain data. Delete sentences whose assigned tags are inconsistent with generated ones.

4.5 Training for the Main Task

Finally, we can obtain the high-quality target-domain data with fine-grained annotation generated from our approach. We then use these generated samples for the main task of aspect and opinion co-extraction. Similar to Section 4.1, we employ a pre-trained BERT model (Devlin et al., 2019) with a CRF layer as the main task classifier, and train it on the generated data only. Based on the trained classifier, we evaluate its performance on the test set of the target domain.

5 Experiments

5.1 Datasets

We use three benchmark datasets from different domains, namely Restaurant (R), Laptop (L) and Device (D). R and L are two combination datasets from SemEval 2014 and 2015 (Pontiki et al., 2014, 2015). D consists of reviews from digital device collected by (Hu and Liu, 2004). Following previous works (Wang and Pan, 2018; Pereg et al., 2020; Chen and Qian, 2021), we use three different seeds to split the dataset from each domain into training set and testing set by a ratio of 3:1. The statistics are shown in Table 1. We report the average results on different splits.

5.2 Experimental Setting

5.2.1 Cross-Domain Data Augmentation

For domain-specific segment mask module, we set the length of n-gram segment w to $n \in [1, 4]$ and the relative frequency threshold δ to 10. A pre-trained sequence-to-sequence model BART is fine-tuned on $D_S \cup D_{TP}$ for 3 training epochs with batch size set to 8. We use Adam as the optimizer with a learning rate of 5e-5. The fine-tuned BART is used to generate triple target-domain labeled data conditioned on the source-domain labeled data.

5.2.2 Aspect and Opinion Co-Extraction

As mentioned in Section 3, we formulate aspect and opinion co-extraction as a sequence labeling task. We use BERT_E+CRF as the base classifier to assign pseudo labels in Section 4.1 and Section 4.4, which consists of the uncased BERT_{base} (Devlin et al., 2019) model post-trained on a combined data of E-commerce reviews from the Amazon Electronics dataset and the Yelp Challenge (Xu et al., 2019) and a CRF layer (Lafferty et al., 2001). For the main task, we also use the BERT_E+CRF classifier and train it on our generated data. We use the Adam optimizer fro both BERT and CRF with different learning rates of 3e-5 and 0.02, respectively. Moreover, we employ the early stopping strategy, and stop the training procedure of the BERT_E+CRF classifier after 2 epochs in both pseudo label annotation and main task training stages. We finally report the average Micro-F1 of three different splits for aspect and opinion co-extraction.

5.3 Compared Methods

We divide all comparison systems into four parts:

Part 1 denotes hand-built feature-based methods. CrossCRF (Jakob and Gurevych, 2010) uses a linear-chain CRF with some manual features including POS tags and dependency relations to bridge the domain gap. RAP (Li et al., 2012) proposes a Relational Adaptive bootstraPping method to extract aspects and opinions based on source labeled data and pre-defined syntactic rules.

Part 2 denotes word2vec-based methods. Hier-Joint (Ding et al., 2017) is a cross-domain RNN model, which exploits auxiliary labels consisting of aspect terms extracted by manually designed syntactic rules and opinion seeds. RNSCN (Wang and Pan, 2018) and TRNN-GRU (Wang and Pan, 2020) integrate syntactic relations by constructing the dependency tree. TIMN (Wang and Pan, 2019) proposes a Transferable Interactive Memory Network that can learn shared representations across domains effectively. SemBridge (Chen and Qian, 2021) is a CNN-based model, which links the source and target domains with semantic bridges by retrieving transferable semantic prototypes based on syntactic roles.

Part 3 denotes pre-trained model-based methods. BERT_B+CRF consists of the uncased BERT_{base} model and a CRF layer. SA-EXAL (Pereg et al., 2020) achieves domain adaptation by combining the pre-trained BERT model with a syntactic-aware attention mechanism. BERT_E+CRF is the base classifier introduced in Section 5.2.2. Both the BERT_B+CRF and BERT_E+CRF are only trained on the labeled source-domain data. CDRG (Yu et al., 2021) is a data augmentation-based adaptation method, which generates labeled target-domain data by replacing source-specific aspects and opinions in source domain reviews with target-specific aspects and opinions. CDRG-Merge trains the BERT_E+CRF classifier on the combination of labeled source-domain data and generated target-domain data for aspect and opinion co-extraction.

Part 4 denotes the proposed Generative Cross-Domain Data Augmentation Framework, i.e., GCDDA, which designs a BART-based generative model (Lewis et al., 2020) to convert the labeled source-domain review to a target-domain review while predicting its corresponding token-level labels. We train the BERT_E+CRF classifier on the generated target-domain data for aspect and opinion co-extraction.

5.4 Main Results

The comparison results of all methods are shown in Table 2. We can clearly observe that our approach achieves the best performance in terms of the average Micro-F1. Specifically, GCDDA outperforms the baseline approach BERT_E+CRF by 4.90% and 0.36% for aspect extraction and opinion extraction, respectively. Compared with the significant improvement on aspect extraction, we achieve a relatively low result on opinion term extraction. We attribute it to the following reasons: 1) the aspect terms across two domains tend to be quite different and have small overlaps; and

Model	R->L		R->D		L->R		L->D		D->R		D->L		AVE

Table 2: Comparison results of different methods for aspect and opinion extraction on Micro-F1. The AVE above means averaged scores on all domain pairs. The best scores are in bold. All methods are grouped into four parts. The last part is our approach.

Model	F1		BLEU	Perplexity
	ASP	OP		
Source	52.49	73.82	100.00	27.48
CDDA-MLM	56.66	73.66	90.59	28.49
GCDDA	**57.39**	**74.18**	**89.72**	**28.14**

Table 3: Comparison results of two different Cross-Domain Data Augmentation methods on several evaluation metrics for generated data. Source denotes the source-domain labeled data. CDDA-MLM denotes the data generated by BERT. GCDDA is our method.

2) the opinion terms across two domains tend to have a significant overlap, e.g., great, good, terrible usually occurring in both domains. The similar trend can also be observed in the state-of-the-art approach SemBridge (Chen and Qian, 2021). Moreover, compared with SemBridge which is based on static word vectors, our method GCDDA improves its performance by 4.86% and 2.10%, which proves the effectiveness of the pre-trained language model. Lastly, GCDDA outperforms our recent data augmentation-based method CDRG-Merge by 2.27% and 1.13% on the two tasks, respectively. All these observations show the effectiveness of our proposed approach.

5.5 Evaluation on Generated Samples

In this section, we conduct several experiments to evaluate the quality of our generated target labeled data. For better comparison, we construct another cross-domain data augmentation approach (CDDA-MLM), which can be regarded as a variant of our GCDDA approach based on the masked language model BERT. CDDA-MLM adopts the same mask strategy and post-processing as GCDDA, and we post-train BERT on the unlabeled data from the target domain with the standard MLM objective. Moreover, we employ it to replace the $[mask]$ token with target words. Unlike GCDDA, there is no label embedding and label prediction in CDDA-MLM. In addition, the original labels can be directly transferred to the target sentence due to the word-to-word generation.

As shown in Table 3, we evaluate the generated data with three metrics including F1-score, BLEU[1], and Perplexity[2], and report the average results on six cross-domain pairs. For F1-score, we observe that our proposed model GCDDA achieves the best result. It is due to the fact that we add the label embedding for GCDDA to capture the consistency between tokens and labels, which leads to more precise and controllable generation of target aspects or opinions in the appropriate place conditioned on the source-domain context and its labels. Additionally, compared with only using source labeled data, the significant improvement shows that our method GCDDA is indeed helpful for the domain adaptation problem.

Moreover, GCDDA obtains lower BLEU than CDDA-MLM, which indicates that our method generates more diverse sentences. This is because that GCDDA decodes the whole sentence while CDDA-MLM generates new words only on the $[mask]$

---

[1] We choose the source data as the reference and use BLEU-1 as the final result. The lower value means more differences from the source data.

[2] We calculate the perplexity with a pre-train language model GPT. The more fluent sentence has a lower value.

	Source	CDDA-MLM	GCDDA
R->L	0.3502	0.1796	**0.1128**
R->D	0.3897	0.2284	**0.1598**
L->R	0.3306	0.2315	**0.1488**
L->D	0.0826	0.0667	**0.0575**
D->R	0.3888	0.2685	**0.1429**
D->L	0.1078	0.0812	**0.0701**
AVE	0.2749	0.1760	**0.1153**

Table 4: Maximum Mean Discrepancy (MMD) between the target-domain test set and the dataset generated from CDDA-MLM, GCDDA. The lower is better.

Table 5: Comparison examples from source-domain labeled data and generated data by CDDA-MLM, GCDDA. Words in blue denote the aspect terms and words in red denote the opinion terms. All generated samples are extracted from domain pair `(R->L)`.

R->L	dvd games, wireless devices, wireless keyboard, toshiba speakers, digital graphics, hp g73, hard drive applications, pre-loaded applications,light weight, precise, over weight, ingenious, well built
L->R	corn sauce, house vibe, wine quality, chili sauce, grilled meat, outdoor dining atmosphere, service provider, internal decor, heating system, steak platter, cleaner, much larger, softer
R->D	ipod plug, battery capacity, radio signal, sound quality of music, built-in speakerphone, usb connection, sony camera, black card with fm transmitter, 2mb flash card, amazing great , user friendly

Table 6: New aspect and opinion terms generated by GCDDA which have not appeared in the training data of both domains. These examples are extracted from cross-domain pairs `(R->L, L->R, R->D)` with three different target domains.

position. Furthermore, each masked token is predicted independently in CDDA-MLM, which may generate incoherent collocation as the length of the mask segment grows. Instead, the auto-regressive model BART in GCDDA takes into account the coherence and the consistency of sentences. Thus, GCDDA obtains a better result than CDDA-MLM in terms of Perplexity.

Moreover, we measure the distribution distance between our generated target dataset and the test set from the target domain. Specifically, we use the BERT model to obtain the representation of each sentence in two datasets, and then calculate the distribution distance by Maximum Mean Discrepancy (MMD[3]). The comparison results are shown in Table 4. The results, on the other hand, proves that our method can be used to alleviate the domain discrepancy issue in domain adaptation.

Case Study: In Table 5, we show several examples generated by CDDA-MLM and GCDDA on the cross-domain pair `R->L`. It can be obviously found that our method produces more precise aspects or opinions related to the domain laptop. We summarize this into two reasons: 1) integrating the BART model with label embedding has captured the consistency between token and its label; and 2) the other is owed to the domain prompt in the front of the decoder, which controls the domain where the generated words come from. Moreover, the label prediction from the decoder makes it possible to generate more flexible sentence while obtaining the adaptive token tags. We also present aspects and opinions extracted from our generated dataset in Table 6. These words or phrases have not appeared in the source and target training datasets, which shows that the generated dataset expands the vicinity distribution for aspect/opinion identification. To sum up, our method GCDDA not only exploits the rich contexts from the source domain, but also produces new aspects and opinions to generate more diverse target-domain samples. The two factors are integrated to train a more robust model for the target domain.

Parameter Study: As mentioned in Section 4.3, we mask sentences with different seeds to produce more target samples. Figure 2 shows the average F1 score of generating different sizes of augmented data from CDDA-MLM and GCDDA for aspect and opinion co-extraction. It can be seen that the two models consistently achieve the best result when the size is 3, i.e., generating three different target reviews from one labeled source review.

---

[3] Maximum Mean Discrepancy (MMD) reflects the similarity of distribution between two datasets.

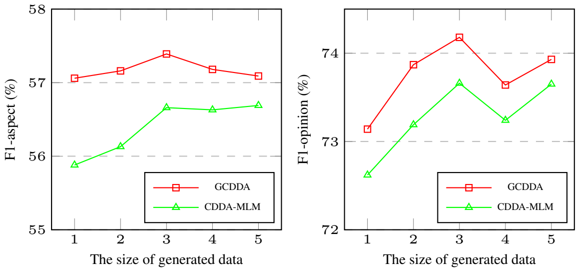

Figure 2: Average F1-score on different size of samples generated by CDDA-MLM and GCDDA for aspect and opinion co-extraction.

Index	Method	F1	
		ASP	OP
0	GCDDA (ours)	57.39	74.18
1	**W/O** data augmentation	54.27	73.56
2	BART ⇒ Bi-LSTM	56.78	73.58
3	**W/O** data filter	55.50	72.71
4	1∼4-gram ⇒ 1-gram	56.92	73.55
5	**W/O** source data	56.71	73.80
6	**W/O** encoder label embedding	55.88	73.04

Table 7: Ablation study of our Generative Cross-Domain Data Augmentation method.

5.6 Ablation Study

Finally, to better analyze the effectiveness of each key component in our method, we conduct the ablation study and show the results in Table 7.

We first remove the whole cross-domain data augmentation framework in index 1, and only use the pseudo labeled data D_{TP} to train the main task classifier. It shows a considerable performance drop due to the label noise in D_{TP}. This indicates that cross-domain data augmentation needs to be applied, which can produce high-quality target samples by combining the contexts from D_S with the weak supervision signals in D_{TP}. In index 2, we replace the pre-trained model BART with Bi-LSTM. Compared with Bi-LSTM, the pre-trained BART model obtains a better result, because it possesses rich language knowledge and a more complex model structure for generation tasks.

Index 3 proves the importance of data filter in the post-processing step. As shown in Table 5, our generated samples usually have the same syntactic structure as the labeled source data. Therefore, the base classifier trained on D_S can be employed to filter out some noisy samples in our generated target-domain data. In index 4, compared with our 1∼4-gram mask, the single word mask strategy limits the diversity of generated sentences, and thus decreases the model performance. Moreover, the performance drops when we remove the labeled source data for the reconstruction task, which can capture the domain-invariant features for the BART model. Finally, removing the label embedding layer in the BART encoder also leads to the performance decline.

6 Conclusion

In this paper, we proposed a Generative Cross-Domain Data Augmentation Framework for unsupervised domain adaptation, which leverages the labeled source-domain data to directly generate labeled target-domain data based on a fine-tuned sequence-to-sequence model BART. Experiments on three benchmark datasets show that our generative approach generates high-quality target-domain data with fine-grained annotation and outperforms previous domain adaptation methods for aspect and opinion co-extraction.

Abstract

Question Answering (QA) is a longstanding challenge in natural language processing. Existing QA works mostly focus on specific question types, knowledge domains, or reasoning skills. The specialty in QA research hinders systems from modeling commonalities between tasks and generalization for wider applications. To address this issue, we present ProQA, a unified QA paradigm that solves various tasks through a single model. ProQA takes a unified *structural prompt* as the bridge and improves the QA-centric ability by *structural prompt-based pre-training*. Through a structurally designed prompt-based input schema, ProQA concurrently models the knowledge generalization for all QA tasks while keeping the knowledge customization for every specific QA task. Furthermore, ProQA is pre-trained with structural prompt-formatted large-scale synthesized corpus, which empowers the model with the commonly-required QA ability. Experimental results on 11 QA benchmarks demonstrate that ProQA consistently boosts performance on both full data fine-tuning, few-shot learning, and zero-shot testing scenarios. Furthermore, ProQA exhibits strong ability in both continual learning and transfer learning by taking the advantages of the structural prompt.[1]

1 Introduction

Question Answering has long been an inspirational challenge in NLP research, and is viewed as the next-generation search engine and an essential tool for human beings to obtain knowledge (Etzioni, 2011). Many distinct datasets (Rajpurkar et al., 2016; Lai et al., 2017; Kwiatkowski et al., 2019; Gao et al., 2021) have been proposed along with the research trend on QA, involving very diverse question types (e.g., *extractive QA, abstractive QA, multiple-choice QA*), domains (e.g., *finance, daily events*), and answer types (e.g., *free-formed text, selected option*). The majority of previous works focus on tasks with specific question types (Lai et al., 2017; Yang et al., 2018; Gao et al., 2020) or specific domains (Trischler et al., 2017; Kwiatkowski et al., 2019). Recent research on large pre-trained language models (Brown et al., 2020; Bommasani et al., 2021) indicates that there may be tight connections among various tasks, which sheds light on a unified paradigm that can be potentially applied to solve various QA tasks to model their commonality.

This observation motivates us to develop a unified QA model, which can model both the commonly-required QA ability and the difference between various QA tasks within a same paradigm. To achieve this goal, there are several key challenges needed to be addressed: (1) How to model commonalities and enhance transferability among different QA tasks in various domains/formats while reducing the conflict between them? (2) How to construct large-scale QA corpus as the high-quality QA-centric data is scarce for pre-training?

In light of this, we conceive ProQA, a unified QA paradigm, which builds up a general model to solve different QA tasks utilizing a **structural prompt** and improves commonly-required QA ability via **structural prompt-based pre-training**.

Firstly, to model the commonalities and distinguish task differences, we adopt a **structural prompt** to organize the inputs with a unified structurally designed input schema. As illustrated in Fig. 1, given the complex components (e.g., *"Domain"*, *"Format"*, *"Task"*, *"Question"*, *"Passage"*) as inputs, ProQA divides components into multiple key-value pairs, in which a specific component like *"Question"* denotes a key, and the specific in-

July 10-15, 2022

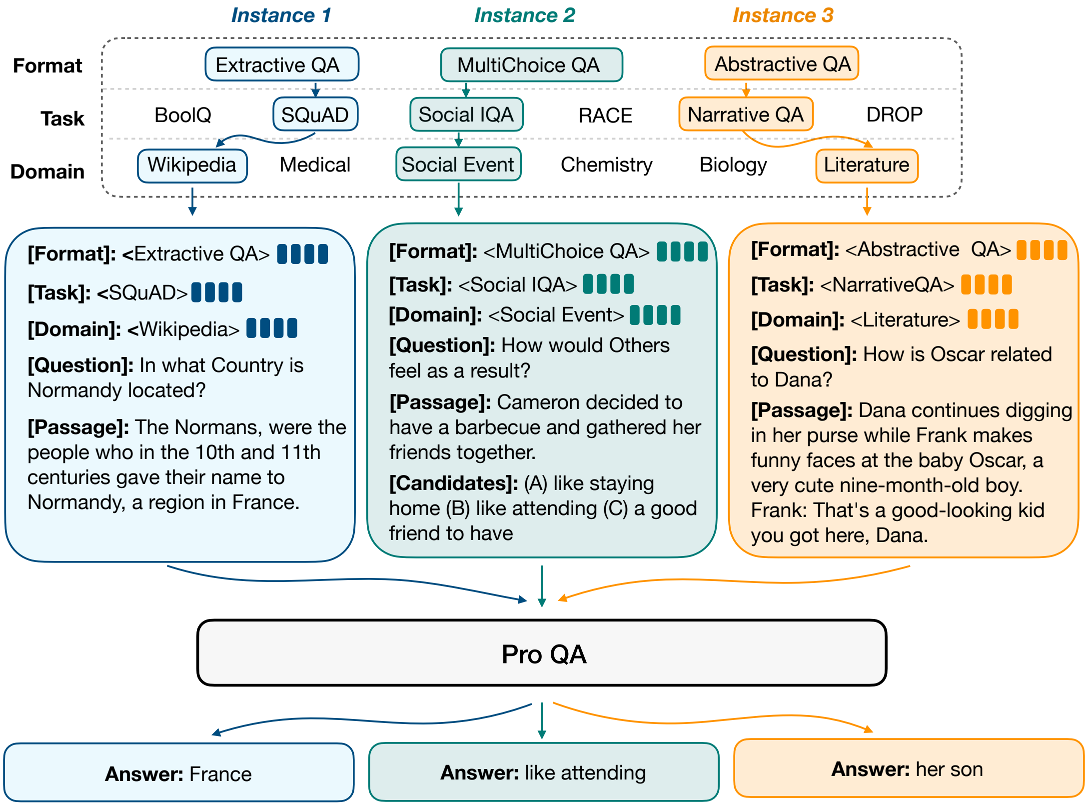

Figure 1: Approach overview of ProQA. Each box represents a specific instance formulated with the **structural prompt**, and ProQA is pre-trained with **structural prompt-based pre-training**. [ ] indicates *special key indicator*, < > denotes *hard prompt*, and colored squares denote *continuous learnable soft prompts*.

stance in this component is taken as the value. In this way, the model can discriminate different input components by key indicators and model the speciality of each task via task-specific values (learnable prompts).

Secondly, to alleviate data sparsity problem and empower the model with transferability to the adaptation of new tasks, we conduct **structural prompt-based pre-training**. We first build a large-scale synthetic QA corpus automatically from Wikipedia, utilizing only a few seed datasets as the prior supervisions for pre-training corpus construction and finally covering primary QA formats. Then we format the pre-training data with the structural prompt, and teach the model to learn the general purpose QA-centric ability and the functionality of each component in the structural prompt via pre-training.

We evaluate the effectiveness of ProQA on 11 downstream QA benchmarks, and the results show that our system achieves consistent performance boost in full data fine-tuning, few-shot learning, and zero-shot learning settings. Experiments demonstrate that ProQA can better mitigate the catastrophic forgetting issue during continual learning by restoring the task-specific soft prompts residing in the structural prompt. Further analyses illustrate that our model has better transferability as it can be more quickly adapted to a newly involved task. Ablation studies verify the effectiveness of both the soft prompt and prompt-based pre-training.

The contributions are summarized as follows:

- We propose ProQA, a unified QA framework for solving various tasks within a single paradigm, taking an extensible and learnable structural prompt as the bridge.
- We enhance general QA-centric capabilities via structural prompt-based pre-training.
- Comprehensive experiments show that our model consistently improves the performance on 11 QA tasks especially in low-resource settings and exhibits better effectiveness in continual learning and few-shot transfer learning.

2 Related Work

Unifying QA formats. Despite vast diversity of current QA tasks in question type, answer type, answer source, and data domain (Zeng et al., 2020), there have been efforts in exploring a *unified* format for various QA tasks. Some pioneered to demonstrate the generalization and transferability among different QA tasks (Talmor and Berant, 2019; Dua et al., 2019a; Fisch et al., 2019). Another line of works investigate multi-task learning for QA (McCann et al., 2018; Shen et al., 2019; Deng et al., 2019) by jointly training a single encoder to promote knowledge sharing. However, these methods typically require deploying distinct prediction heads for different tasks, which lead to poor scalability and flexibility when confronted with emerging QA tasks of new types.

To this end, inspired by the success of casting multiple tasks into the same text-to-text format (Lewis et al., 2020; Raffel et al., 2020), researchers propose to learn a single model to unify various QA formats, alleviating the labor of task-specific designs (Khashabi et al., 2020b; Tafjord and Clark, 2021). However, these models (1) do not explicitly model the task or component characteristics, thus failing to properly disentangle the difference among QA tasks; and (2) overly rely on supervised data from specific tasks, which may not be available under data-scarce scenarios.

QA-centric pre-training. Numerous efforts have been spent on improving PLMs' reasoning abilities with an intermediate pre-training stage before fine-tuning on target QA tasks, including (1) language modeling adaptation with salient span masking, which trains PLMs to recover randomly chosen (Guu et al., 2020; Wang et al., 2021) or machine-generated (Kang et al., 2020) masked named entities in the raw corpus; (2) training data augmentation (Zhong et al., 2022) with synthetic question-answer-context triples, such as generating (a) pseudo questions through adversarial training (Hosking and Riedel, 2019; Li et al., 2019), knowledge bases (Hu et al., 2021) or machine translation (Lewis et al., 2019; Li et al., 2020), (b) pseudo answers exploiting recurring spans (Ram et al., 2021) or rules based on heuristics (Bian et al., 2021) and (c) pseudo contexts via information retrieval (Glass et al., 2020). Nevertheless, these works largely target at improving a certain reasoning ability for PLMs, and thus cannot be easily generalized to other QA tasks.

Prompts for PLMs. To effectively stimulate the knowledge acquired through pre-training, prompt-oriented fine-tuning is receiving increasing attention (Liu et al., 2021; Ding et al., 2021), which re-formulates the objective of downstream tasks similar to that of pre-training by inserting manually designed (Schick and Schütze, 2021a,b) or automatically searched (Jiang et al., 2020; Shin et al., 2020) hard *prompt tokens* into the input text. Considering that discrete prompts may not be an optimal solution in the continuous embedding space, recent works (Li and Liang, 2021; Hambardzumyan et al., 2021) proposed tunable soft prompts. It achieves satisfying performance especially when the model size grows extremely large (Lester et al., 2021). Compared with the cumbersome parameters in PLMs, soft prompts are lightweight and pluggable, which paves the way for our goal of flexible adaptation to a new QA task.

3 ProQA

In this section, we detailedly describe the whole framework of ProQA for general purpose QA, which solves various QA tasks within the same paradigm.

3.1 Overview

As shown in Fig. 2, we organize the inputs of various QA tasks with a unified **structural prompt** (§ 3.2), and adopt a unified model for question answering. Then, to enhance the model in learning the QA-centric ability and the semantics of the structural prompt, we conduct **structural prompt-based pre-training** with synthetic pre-training corpus formatted with the structural prompt (§ 3.3).

Inspired by Khashabi et al. (2020b) and T5 (Raffel et al., 2020), we solve all downstream QA tasks with a unified text-to-text model. In this work, we mainly adopt T5 as the model backbone. Taking the structural prompt-based model input, the unified model generates the answer of the question.

3.2 Structural Prompt

Here we detailedly illustrate the design of the structural prompt and its formatted input to the model.

Definition. We organize complex QA task inputs with the structural prompt. As shown in Fig. 2, the structural prompt consists of multiple $\{key : value\}$ pairs, where the key represents a specific component[2] (e.g., "*Task*", "*Format*",

---

[2] It is worth noting that "*Format*" key denotes the format type (e.g., "*MultiChoice QA*") of the task while the "*Task*" key denotes a specific dataset (e.g., "*SQuAD*").

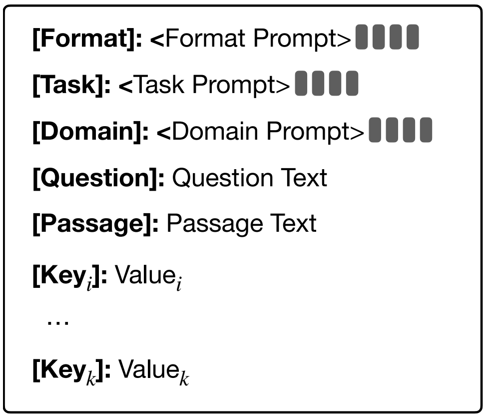

Figure 2: An illustration of the structural prompt. [ ] indicates special key indicator, < > denotes hard prompt, and grey squares indicate continuous soft prompts.

"*Question*", etc.), and the $value$ has two possible types: (1) textual content (e.g., *question*, *passage*, *options*) of the data instance; (2) task attributes (e.g., *format, domain*) represented as the combination of a discrete *hard prompt* and continuous *soft prompts*. The hard prompt is a predefined discrete description (we adopt a special token here), and the soft prompts are lightweight learnable and pluggable continuous embeddings that are proven to be parameter-effective in task adaptation (Lester et al., 2021). The structural prompt-formatted examples are illustrated in Fig. 1. In the case of the SQuAD dataset, "⟨Format Prompt⟩", "⟨Task Prompt⟩", "⟨Domain Prompt⟩" will be "⟨Extractive QA⟩", "⟨SQuAD⟩", "⟨Wikipedia⟩", respectively.

To enhance the model in discriminating the functional difference between components, we adopt a **special key indicator** with learnable representation to represent each key. Furthermore, to model the difference between several tasks/domains/formats, we also adopt learnable and storable **specific soft prompts** as the $value$ to represent their customized characteristics, which makes the model more flexible for task adaptation.

As a result, the structural prompt can empower the model in the following aspects: (1) modeling knowledge generalization of various tasks utilizing a unified input schema; (2) discriminating different components with the special key indicator; (3) customizing the speciality of each task/format/domain with learnable and storable soft prompts as the $value$ under corresponding keys.

Input Representation. Specifically, given a structural prompt-formatted instance, we describe the specific representation of the model input. We firstly translate k^{th} key to a *key indicator* D_k (a special token), which is attached by the tokens V_k of the specific value to form a token sequence. It is further represented as $\boldsymbol{E}_k = Embedding([D_k; V_k])$. The representation of D_k is initialized and updated during training. Since we use soft prompts $\boldsymbol{P}_{\text{task}}/\boldsymbol{P}_{\text{format}}/\boldsymbol{P}_{\text{domain}}$ as the value of the corresponding key and they are commonly required for all the tasks, we prepend them to the input for convenience and concatenate all the $\boldsymbol{E}_k$ to form the final model input $\boldsymbol{X}$:

$$\boldsymbol{X} = [\boldsymbol{P}_{\text{domain}}; \boldsymbol{P}_{\text{format}}; \boldsymbol{P}_{\text{task}}; \boldsymbol{E}_1; ...; \boldsymbol{E}_k] \quad (1)$$

It is also worth noting that the representations $\boldsymbol{D}$ of key indicators and the soft prompts $\boldsymbol{P}$ are jointly trained with the main model parameters during pre-training for learning the semantics of the structural prompt. Moreover, after being tuned by various tasks, the soft prompts $\boldsymbol{P}$ can be stored to record the customized task-specific characteristics.

3.3 Structural Prompt-based Pre-training

In this part, we introduce how we conduct structural prompt-based pre-training to help the model in learning commonly-required QA ability and the semantics of the structural prompt during pre-training to facilitate the adaption of the structural prompt to downstream tasks.

Task Formulation. Along with the structural prompt-based paradigm, we manifest various exemplary QA format types (i.e., *Extractive QA*, *Abstractive QA*, *Multiple-choice QA* and *Yes/No QA*) for pre-training to inject the general QA-centric ability. Given the multi-format QA pre-training corpus, we transform all QA formats according to the proposed structural prompt, which enables joint pre-training while keeping the differences among various formats. Taking a structural prompt-formatted instance as the input and a free-form answer as the output, the task is further tailored to a QA task with the encoder-decoder model.

Pre-training Corpus Construction. When we prepare the QA pre-training corpus, data sparsity problem is extremely severe because (1) it is impractical and laborious to obtain a large-scale high-quality annotated data for pre-training and (2) it is hard to generate QA-centric self-supervised data using rule-based methods (e.g., token masking or sentence reordering). In this work, inspired by Lewis et al. (2021), we adopt a **generation-filtering based corpus construction method** to synthesize a large-scale pre-training corpus, based on a large-scale unlabeled Wikipedia corpus with almost 6 million passages.

Typically, the general generation-filtering process consists of the following components:

1. A QA-pair generation model $g_{qa}(q, a|c)$: Given a passage c as input, $g_{qa}(q, a|c)$ generates q `[SEP]` a as the output sequence including a pair of question q and its answer a.
2. A filtering QA language model $f(a|q, c)$ for filtering the generated QA-pairs to ensure the quality and consistency of the question and the answer. $f(a|q, c)$ is a conditional-probability-based approach to filter out QA pairs softly. It scores a QA pair (q, a) with the likelihood of the answer a conditioned on the passage c and question q. The QA-pairs with scores higher than a threshold will be kept for pre-training.

We adopt the same text-to-text pre-trained model T5 described in § 3.1 as the model backbone of both the generation and filtering model.

To ensure the reliability of the generation and filtering models, we inevitably select a few seed datasets (typically one for each QA format type) as the prior supervisions to train these models. It is worth mentioning that, we avoid using more supervised data for corpus construction, because we expect the whole paradigm to have better expandability. In other words, if we want to extend the paradigm for a newly-involved QA format type but with limited supervised data, we can utilize these data to automatically create a synthetic large-scale pre-training corpus.

More specifically, the construction method has little variance for different formats according to their input components. For ***Extractive QA*** and ***Abstractive QA***, we adopt the aforementioned general method to synthesize QA-pairs. We also tried to first extract answers using rule-based method (extracted named-entities or key phrases), and only generate questions. We empirically find that this method performs much worse as it involves simple bias of the rule-based method. As the inputs for ***Multiple-Choice QA*** involve a new component "*Candidate Answers*", we adopt a distractor (negative options) generation model $g_{neg}(o|c, q, a)$ to generate three negative options o. For ***Yes/No QA***, we simply generate questions by taking *True/False* as the corresponding answers. Further details are described in Appendix A.

Format	Dataset	#Train	#Dev	QA Skills

4 Experimental Setup

4.1 Datasets and Evaluation Metrics

We consider three formats of QA datasets in our experiments: Extractive QA, Abstractive QA and Multiple-Choice QA[3]. For each QA format, we select one *seed* dataset for preparing the large-scale pre-training data. The seed dataset is used to train the question-answer generation and filtering models in the process of pre-training corpus construction. In total, the experiments are conducted on 11 QA datasets with three different formats and various language understanding abilities. An overview of datasets used in the experiments and their required QA skills are summarized in Table 1.

Extractive QA. We take SQuAD 1.1 (Rajpurkar et al., 2016) as the seed dataset for extractive style QA. In addition, we consider NewsQA (Trischler et al., 2017) and Quoref (Dasigi et al., 2019) to evaluate the generalization ability of models. The EM (Exact Match) score between the extracted span and the gold answer span is used as the evaluation metric for extractive QA.

Abstractive QA. Narrative QA (NarQA) (Kočiský et al., 2018) is taken as the seed dataset for Abstractive QA. DROP (Dua et al., 2019b) and the open-domain version of NaturalQuestions (NQOpen) (Kwiatkowski et al., 2019) are also considered. Passages for each question in NQOpen are retrieved by the dense passage retriever (Karpukhin et al., 2020) and are concatenated into a sequence.

---

[3] We also include Yes/No QA in our pilot study. We do not consider it in our main experiments because datasets in this format are extremely rare. Results on this QA formats are shown in Appendix B.

Setting	Dataset	ExtractiveQA			AbstractiveQA			MultiChoiceQA					Avg

Table 2: Main results on 11 downstream QA datasets under full-data fine-tuning, few-show learning, and zero-shot learning settings. Since the supervisions of seeds datasets are used in the pre-training corpus construction which may introduce bias in few-shot and zero-shot settings, results on these corresponding entries are underlined.

We use ROUGE-L (Lin, 2004) metric for NarQA and F1 score for DROP and NQOpen.

Multiple-Choice QA. For multiple choice QA, the following datasets are considered: RACE (Lai et al., 2017) (seed dataset), DREAM (Sun et al., 2019), MCTest (Richardson et al., 2013), OpenBookQA (OBQA) (Mihaylov et al., 2018), Social IQa (SIQA) (Sap et al., 2019). OBQA does not have contexts (reading comprehension passages). The context for DREAM is in the dialogue style and we concatenate them into a sequence as the passage input. We select the option with the highest textual similarity with the generated answer as the final answer. We compute the accuracy of the correct options for all multiple choice QA datasets.

4.2 Approaches

T5 (Raffel et al., 2020) is a unified text-to-text pre-training framework that covers all text-based language problems. We use `google/t5-v1_1-base` from HuggingFace Transformers (Wolf et al., 2020) that is only pre-trained on C4 excluding any supervised training dataset (e.g., QA datasets).

UnifiedQA (Khashabi et al., 2020b) crosses the format boundaries of different QA tasks by formulating them into text-to-text tasks under T5. It directly concatenates all inputs via `\n` into a sequence and feeds it into T5 for predicting the answer. We train our own UnifiedQA model on the combination of three aforementioned seed datasets, namely SQuAD, NarQA, and RACE.

ProQA is our proposed structural prompt-based pre-training approach. ProQA is pre-trained jointly on three formats of pre-training corpus: Extractive QA, Abstractive QA, and Multiple-Choice QA. This approach using corpus prepared from QA-pair generation-filtering model described in § 3.3 is named as ProQA (qapair). Additionally, we leverage the off-the-shelf large-scale QA pairs from Probably-Asked Questions/PAQ (Lewis et al., 2021), and replace our extractive QA pre-training corpus by a subset of PAQ (abstractive QA and multiple-choice QA corpus remains unchanged). PAQ provides a refined pipeline that introduces learned models on every step of QA pair generation, i.e., passage selection, answer identification, question generation, and filtering. We name this variant as ProQA (paq).

For every downstream QA dataset, we start from the above pre-trained models and conduct experiments under full-data fine-tuning, few-shot learning, and zero-shot learning settings. For few-shot learning, we randomly sample 32 instances from the training set.

5 Results and Analyses

5.1 Main Results

Main results are shown in Table 2, and we have the following observations:

- QA-centric pre-trained models, namely UnifiedQA and ProQA, outperform T5 by a large margin on both seed datasets and non-seed datasets. This is because there is some transferable knowledge across different QA tasks. Once the model is pre-trained by any QA task, the learned knowledge can be generalized to any other datasets.
- ProQA demonstrates better knowledge cus-

Methods	Task A→Task B									
	EX→EX	EX→AB	EX→MC	AB→EX	AB→AB	AB→MC	MC→EX	MC→AB	MC→MC	Avg
Task B Model	20.5%	26.2%	13.0%	8.9%	6.3%	6.5%	4.6%	4.9%	0.9%	9.9%
Task B Model (w/ Task A Prompt)	17.1%	10.6%	6.7%	3.1%	3.1%	2.2%	0.4%	0.7%	-0.5%	4.3%

Table 3: Continual learning results for averaged performance drops compared with the original task A results under different task learning orders (**lower is better**). Negative number means the performance improves compared with the original task A results. EX: Extractive QA; AB: Abstractive QA; MC: Multiple-chioce QA.

tomization ability than UnifiedQA – ProQA beats UnifiedQA by a large margin in few-shot and zero-shot settings. This is because (1) the hard and soft prompts in the structural prompt enable better knowledge customization for every QA task, especially the "Task" key-value pair that is different for every QA task; (2) structural prompt-based pretraining empowers ProQA to adapt faster (§ 5.3) and better (Table 2) to these non-seed datasets.

- Comparing ProQA (qapair) and ProQA (paq), we find that ProQA (paq) performs better in most scenarios. Presumably, PAQ provides high quality pre-training corpus through its pipelined approach – there are in total four BERT-sized models to be prepared for generating PAQ corpus. Instead, our proposed QA pair generation approach is simple and can be applied to not only Extractive QA but also Abstractive QA and Multiple-choice QA in the pre-training corpus construction process.

5.2 Continual Learning via Soft Prompt

One benefit of introducing soft prompt in ProQA is that it can potentially mitigate the catastrophic forgetting issue when adapting to a new task. If ProQA is **sequentially fine-tuned on task A and task B under few-shot setting**, it can load task A soft prompt back when it is evaluated again on the task A. The plug-in flexibility of ProQA brings huge improvements compared with its counterpart that keeps the task B soft prompt.

We conduct continual learning by setting task A and B as different combinations among datasets with formats[4]: Extractive QA (EX), Abstractive QA (AB), and Multiple-choice QA (MC). Formally, we first adapt ProQA to task A by few-shot learning to obtain the model A: f_θ^A with performance s^A. Then we sequentially adapt f_θ^A to task B and receive task B model f_θ^{AB}. We evaluate performance of the model f_θ^{AB} on task A under two settings: (1) direct testing (task-B prompt) (2) first restoring the learned task-A prompt from f_θ^A to the model f_θ^{AB} and then testing. Performance of the two settings are denoted as s^{AB} and $s^{AB'}$, respectively. We evaluate the continual learning performance under these two settings with the **percentage of the performance drop** on the task A: "*Task B Model*"= $\frac{s^A - s^{AB}}{s^A}$, and "*Task B Model (w/ Task A Prompt)*" = $\frac{s^A - s^{AB'}}{s^A}$.

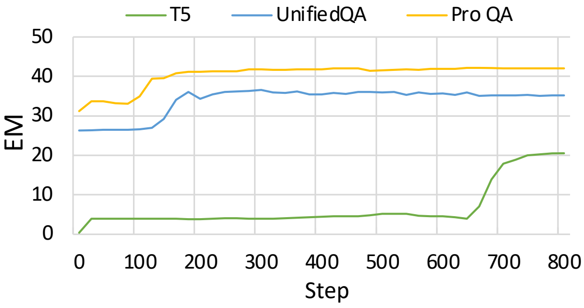

Figure 3: The few-shot learning curves of EM scores on the validation set of the NewsQA task.

As shown in Table 3, the catastrophic forgetting issue does exist when evaluating task A with task B model ("*Task B Model*") directly. The performance drops as large as 26.2% for EX→AB. However, restoring task A prompt brings huge improvements across all task combinations ("*Task B Model w/ Task A Prompt*"). It is surprising to see that restoring task A prompt could sometimes even improve task A performance (MC→MC = −0.5%). Presumably, sequential learning two tasks under the same question format (MC) makes the model learn the transferable knowledge while restoring task A prompt brings task-specific knowledge. Detailed experimental results on the 33 combinations of datasets can be found in Appendix C.

5.3 Convergence Analysis

We investigate the effectiveness of pre-training by compare the step-wise performance under few-shot learning setting. The learning curves of EM scores on the validation set of the NewsQA task is shown

---

[4] Note that we consider two tasks in continual learning because we also want to directly investigate the task adaptation to-and-fro the same format (e.g., MC → MC) or different formats (e.g., AB → EX).

Setting	Model	NewsQA	DROP	DREAM
Full-Data	ProQA	50.4	52.5	73.3
	w/o soft prompt	48.6	51.2	69.9
	w/o pretraining	48.1	44.5	68.4
	UnifiedQA + Pre-train Corpus	46.8	50.3	69.4
Few-Shot	ProQA	42.1	27.1	66.0
	w/o soft prompt	38.5	24.3	64.5
	w/o pretraining	20.5	4.8	35.1
	UnifiedQA + Pre-train Corpus	37.3	23.5	59.6
Zero-Shot	ProQA	31.8	19.7	65.2
	w/o soft prompt	29.8	19.0	63.5
	w/o pretraining	0.0	0.2	32.6
	UnifiedQA + Pre-train Corpus	26.0	18.1	58.0

Table 4: Ablation study results on three non-seed datasets under different QA formats (extractive, abstractive, multiple-choice).

in Figure 3. Out of the three models, T5 convergences slowest because it does not have any QA-centric knowledge while our proposed ProQA adapts fastest and best. Moreover, we find that UnifiedQA EM score rapidly saturates and eventually degrades slightly, suggesting that the model overfits under the few-shot setting. On the counterpart, our ProQA continues to improve and never degrades because the hard and soft prompt inside the structural prompt balance the knowledge generalization and knowledge customization well.

5.4 Ablation Study

An ablation study is conducted to unveil the effectiveness of every component in ProQA. We consider three variants of ProQA: (1) ProQA without the soft prompt in its structural prompt; (2) ProQA further without prompt-based pre-training. (3) UnifiedQA + Pre-train Corpus is the UnifiedQA model pre-trained on our prepared large-scale synthetic QA corpus. Results on three non-seed datasets under different QA formats are shown in Table 4. We find that removing the soft prompt from the model disables the task-specific knowledge learned during pre-training. Moreover, removing the prompt-based pretraining drastically hurts the performance as the equivalent model (T5 + hard structural prompt) does not have any QA knowledge. Finally, UnifiedQA + Pre-train Corpus could not compete with ProQA, showing that our proposed structural prompt earns better balance between knowledge generalization and knowledge customization than UnifiedQA.

6 Discussion

In this section, we discuss on how to extend the ProQA to a new task even with a new schema, and sheds light on potential future directions.

1) Task Adaptation with Structural Prompt: The design of structural prompt empowers ProQA with better expandability. In our main experiments, we adopt 3 format types and 11 QA tasks. In the future, we can adapt ProQA to more tasks, formats, domains, and new input schema. Intuitively, when being adapted to a new task with unseen format/domain, ProQA can initialize the specific soft prompts and learn the characteristic of the new domain/task through model training. Moreover, if we encounter a new input schema that involves new keys (e.g., "*extracted entities or commonsense knowledge*"), we can add a new key-value pair in the input schema and learns the functionality of the new key indicator through training.

2) Unified QA Systems: We think further studies on unified QA systems could target on a better pre-training schema for general purpose QA, or optimizing the modeling strategy for the structural prompt to process more complex input, or output formats (e.g., adding extracted entities or retrieved knowledge).

3) Unification with Structural Prompt: The application of the structural prompt is not limited only on the QA task. Intuitively, task inputs/outputs with various formats or components can also be organized with the structural prompt, like *sentiment analysis* (Zhong et al., 2021), *style transfer* (Li et al., 2022). In this way, we can integrate multiple tasks with carefully organized structural input, and improve the uniformity and expandability of the whole paradigm.

7 Conclusion

We introduce ProQA, a unified QA paradigm that adopts a single model for solving various QA tasks with the bridge of a structural prompt. Structural prompt simultaneously models the common ability required for various tasks and keeps the speciality of each task, through a structurally designed learnable input schema. We further conduct structural prompt-based pre-training, seeking to empower the model with general QA-centric ability and injects the semantic knowledge of the structural prompt into the pre-training model. Experimental results on 11 QA benchmarks demonstrate that ProQA can significantly boost performance on all settings. Further analyses show that our method can better mitigate the catastrophic forgetting issue during continual learning, and our method can be adapted to a newly involved task more quickly, by taking the advantages of the structural prompt. In the future, we hope our analysis could inspire more explorations on the unified QA methods, or the unification of distinct tasks with complex inputs modeling by the structural prompt. We also hope structural prompt can be further utilized into the unification of more tasks with complex inputs.

A Implementation Details

A.1 Corpus Preparation

In this part, we describe the details of corpus construction.

The current pre-training corpus contains almost 4 million pre-training instances formulated with the structural prompt, including 1 million Multiple-choice QA instances, 2 million Extractive QA instances, and 2 million Abstractive QA instances. When generating questions and answers, we take the *context* as the input, and the sequence "*question* `[SEP]` *answer*" as the output. In order to train the filtering model, we take the *context* and *question* as the inputs, and the *answer* as the output. During the inference process of QA-pairs filtering, we take the context and the generated question as the model input of the QA model and set generated answer as the label. Then we compute the final soft score with the cross-entropy loss between the label and the answer generated by the QA model, Next, we rerank all the generated QA-pairs according to the soft scores in an ascending order to select the most consistent QA-pairs as the pre-training instances.

Specifically, we employ AdamW as the optimizer for model training. We adopt *T5-Large* as the model backbone and the seed datasets as supervisions for training both the question-answer pairs generation, and the filtering QA model. We set learning rate as 1e-5, warmup step as 0, batch size as 2 per GPU, and training epochs as 10.

A.2 Details on Pre-training and Task Adaptation.

Pre-training. During pre-training, we jointly train the main model parameters with the representations of the *special key indicators* and the *task/format-specific soft prompts*.

Initially, we don't have any specific tasks during pre-training, so we take the three pre-training corpus (i.e., "*MultiChoiceQA, Extractive QA, and Abstractive QA*") as the three initial tasks, and randomly initialize the task and format specific soft prompts.

Specifically, we use *T5-Base* as the model backbone, and set learning rate as 1e-4, batch size as 8 per GPU and gradient accumulation steps as 10. We adopt 8 V100 GPUs for pre-training.

Fine-tuning. During fine-tuning, we need to initialize the task/format-specific soft prompts for a specific downstream task. If the task corresponds to a specific format participating in the pre-training stage, we use the corresponding soft prompts of this format type to initialize the soft prompts for the current tasks to transfer the learned knowledge. If the task corresponds to a new format, we can randomly initialize the task/format prompts.

Setting	Dataset	BoolQ
Full-Data	T5	62.2
	Pro QA	80.6
Few-Shot	T5	0.0
	Pro QA	55.4
Zero-Shot	T5	0.0
	Pro QA	62.1

Table 5: Result on two Yes/No QA tasks under full-data fine-tuning, few-shot learning, and zero-shot learning settings.

Specifically, we use *T5-Base* as the model backbone, and set learning rate as 1e-4, batch size as 2 per GPU, gradient accumulation steps as 2, and training epochs as 5. We adopt 8 V100 GPUs for fine-tuning.

Few-shot Learning. We adopt a similar way to initialize the task-specific soft prompts for few-shot learning. We use the standard setting which utilizes 32 randomly selected instances for few-shot learning. Specifically, we adopt *T5-Base* as the model backbone, and set learning rate as 1e-5, batch size as 1 per GPU, gradient accumulation steps as 1, and training steps as 800 for few-shot learning.

Zero-shot Learning Since zero-shot learning does not involve training stage, we just need to initialize the task-specific prompt for inference. Therefore, we initialize the task-specific prompt with the pre-trained task prompts of its corresponding format type.

B Results on Yes/No Pre-training

During our pilot study, we take the BoolQ (Clark et al., 2019) as the seed dataset to construct a large-scale pre-training corpus, and test the full-data, few-shot, zero-shot on top of the pre-trained ProQA. We also take the naturally-perturbed version of this dataset BoolQ-NP (Khashabi et al., 2020a) into account for evaluation. Results are shown in Table 5. We find that the ProQA significantly outperforms T5 baseline on all settings. Note that we take a strict evaluation towards the model's output.

Task A	Task A Model (Few-Shot Results)	Task B	Task B Model (Evaluation on Task A)	Task B Model (w/ Task A Prompt) (Evaluation on Task A)

Table 6: Full results on continual learning. For each task, we provide the task format (EX, AB, MC) and its evaluation metrics (EM, F1, Acc). EX: Extractive QA; AB: Abstractive QA; MC: Multiple-Choice QA.

In other words, if the output is not any format of “yes”, “no”, “true”, “false”, that prediction will be classified as wrong.

C Details on Continual Learning

Table 6 provides the full results for the continual learning experiment. The model is firstly trained on task A under few-shot setting, and then fine-tuned on task B. Afterwards, we evaluate the trained “Task B Model” and “Task B Model (w/ Task A Prompt)” on task A to test its continual learning capability. Detailed results on every Task A/Task B combination (33 reported in total) are shown in Table 6. Note that we consider two tasks in continual learning because we also want to investigate the task adaptation to-and-fro the same format (e.g., MC → MC) or different formats (e.g., AB → EX). The results shed light on how could we arrange the order of training on tasks to achieve the best overall performance when a bunch of tasks arrive.

A Data Cartography based MixUp for Pre-trained Language Models

Seo Yeon Park and Cornelia Caragea
Computer Science

Abstract

MixUp is a data augmentation strategy where additional samples are generated during training by combining *random pairs* of training samples and their labels. However, selecting random pairs is not potentially an optimal choice. In this work, we propose TDMixUp, a novel MixUp strategy that leverages **T**raining **D**ynamics and allows more informative samples to be combined for generating new data samples. Our proposed TDMixUp first measures confidence, variability, (Swayamdipta et al., 2020), and Area Under the Margin (AUM) (Pleiss et al., 2020) to identify the characteristics of training samples (e.g., as easy-to-learn or ambiguous samples), and then interpolates these characterized samples. We empirically validate that our method not only achieves competitive performance using a smaller subset of the training data compared with strong baselines, but also yields lower expected calibration error on the pre-trained language model, BERT, on both in-domain and out-of-domain settings in a wide range of NLP tasks. We publicly release our code.[1]

1 Introduction

MixUp (Zhang et al., 2018) is a simple data augmentation strategy in which additional samples are generated during training by combining *random pairs* of training samples and their labels. While simple to implement, MixUp has been shown to improve both predictive performance and model calibration (i.e., avoiding over-confident predictions) (Guo et al., 2017) due to its regularization effect through data augmentation (Thulasidasan et al., 2019). However, selecting *random pairs* in MixUp might not necessarily be optimal.

Despite this, MixUp has been explored for NLP tasks with substantial success using hidden state representations (Verma et al., 2019). For instance, Sun et al. (2020) explored MixUp, which uses the hidden representation of BERT (Devlin et al., 2019) to synthesize additional samples from randomly selected pairs. Yin et al. (2021) proposed MixUp, which uses the hidden representation of RoBERTa (Liu et al., 2019) to interpolate all samples in the same mini-batch to better cover the feature space. To date, only a few prior works have focused on selecting informative samples for MixUp. For example, Chen et al. (2020) proposed semi-supervised learning, which interpolates labeled and unlabeled data based on entropy. Kong et al. (2020) explored BERT calibration with MixUp, which generates new samples by exploiting the distance between samples in the feature space.

Recently, Swayamdipta et al. (2020) introduced data maps, which allow evaluating data quality by using training dynamics (i.e., the behavior of a model as training progresses). Specifically, they consider the mean and standard deviation of the gold label probabilities, predicted for each sample across training epochs (i.e., confidence and variability), and characterize data into three different categories: (1) samples that the model predicts correctly and consistently (i.e., **easy-to-learn**); (2) samples where true class probabilities vary frequently during training (i.e., **ambiguous**); and (3) samples that are potentially mis-labeled or erroneous (i.e., **hard-to-learn**). The author revealed that the easy-to-learn samples are useful for model optimization (parameter estimation) and without such samples the training could potentially fail to converge, while the ambiguous samples are those on which the model struggles the most and push the model to become more robust, hence, these ambiguous samples are the most beneficial for learning since they are the most challenging for the model.

Inspired by these observations, we propose a novel MixUp strategy which we call TDMixUp that monitors training dynamics and interpolates easy-to-learn samples with ambiguous samples in the feature space. That is, we pair one sample from

July 10-15, 2022

the easy-to-learn set with another sample from the ambiguous set to allow more informative samples to be combined for MixUp. Accordingly, we generate new samples that share the characteristics of both easy-to-learn and ambiguous data samples and are hence more beneficial for learning. However, the easy-to-learn and the ambiguous sets can contain mis-labeled samples that can degrade the model performance. Consequently, we measure another training dynamic, Area Under the Margin (AUM) (Pleiss et al., 2020), to filter out possibly mis-labeled samples in each set. We validate our proposed method on a wide range of natural language understanding tasks including textual entailment, paraphrase detection, and commonsense reasoning tasks. We achieve competitive accuracy and low expected calibration error (Guo et al., 2017) on both in-domain and out-of-domain settings for the pre-trained language model BERT (Devlin et al., 2019), without using the full training data.

2 Proposed Approach: TDMixUp

We introduce our proposed TDMixUp, which generates additional samples based on the characteristics of the data samples. We first reveal the characteristics of each data sample by using training dynamics, i.e., confidence, variability, and Area Under the Margin (AUM). We then describe our MixUp operation that combines training samples based on the above data characteristics that are measured during training.

2.1 Data Samples Characterization

We first introduce **confidence** and **variability**, that are used to evaluate the characteristics of each individual sample (Swayamdipta et al., 2020). These statistics are calculated for each sample (x_i, y_i) over E training epochs.

Confidence We define confidence as the mean model probability of the true label y_i across epochs:

$$\hat{\mu}_i = \frac{1}{E}\sum_{e=1}^{E} p_{\theta^{(e)}}(y_i|x_i) \qquad (1)$$

where $p_{\theta^{(e)}}$ denotes the model's probability with parameter $\theta^{(e)}$ at the end of e^{th} epoch.

Variability We define variability as the standard deviation of $p_{\theta^{(e)}}$ across epochs E:

$$\hat{\sigma}_i = \sqrt{\frac{\sum_{e=1}^{E}(p_{\theta^{(e)}}(y_i|x_i) - \hat{\mu}_i)^2}{E}} \qquad (2)$$

Given these statistics per sample, we identify the top 33% easy-to-learn samples, i.e., those samples that the model predicts correctly and consistently across epochs (high-confidence, low-variability), and the top 33% ambiguous samples, i.e., those samples whose true class probabilities have a high variance during training (high-variability).

Area Under the Margin (AUM) As another measure of data quality, we monitor training dynamics using the Area Under the Margin (AUM) (Pleiss et al., 2020). AUM measures how different a true label for a sample is compared to a model's belief at each epoch and is calculated as the average difference between the logit values for a sample's assigned class (gold label) and its highest non-assigned class across training epochs. Formally, given a sample (x_i, y_i), we compute $AUM(x_i, y_i)$ as the area under the margin averaged across all training epochs E. Specifically, at some epoch $e \in E$, the margin is defined as:

$$M^e(x_i, y_i) = z_{y_i} - max_{y_i != k}(z_k) \qquad (3)$$

where $M^e(x_i, y_i)$ is the margin of sample x_i with true label y_i, z_{y_i} is the logit corresponding to the true label y_i, and $max_{y_i != k}(z_k)$ is the largest *other* logit corresponding to label k not equal to y_i. The AUM of (x_i, y_i) across all epochs is:

$$AUM(x_i, y_i) = \frac{1}{E}\sum_{e=1}^{E} M^e(x_i, y_i) \qquad (4)$$

Intuitively, while both AUM and confidence measure training dynamics, confidence simply measures the probability output of the gold label and how much it fluctuates over the training epochs. In contrast, AUM measures the probability output of the gold label with respect to the model's belief in what the label for a sample should be according to its generalization capability (derived by observing other similar samples during training). More precisely, AUM considers each logit value and measures how much the gold label assigned logit value differs from *the other largest* logit value, which allows identifying mis-labeled samples.

To identify possibly mis-labeled data in each set (i.e., the set of easy-to-learn and the set of ambiguous samples that are categorized by confidence and variability as described above), we first fine-tune a model on each set, respectively, with inserting fake data (i.e., threshold samples). Data with similar or worse AUMs than threshold samples can be assumed to be mis-labeled (Pleiss et al., 2020). We construct threshold samples by taking a subset of the training data and re-assigning their labels randomly, including a class that does not really exist. Specifically, given N training samples that belong to c classes, we randomly select $N/(c+1)$ samples per class and re-assign their labels to classes that are different from the original class. We then train a model on training samples including threshold samples and measure the AUMs of all training data. We identify possible mis-labeled data by computing a threshold value (i.e., the kth percentile threshold sample AUMs where k is a hyper-parameter chosen on the validation set). At last, we filter out samples that have lower AUM than the threshold value.

2.2 MixUp

MixUp training generates vicinity training samples according to the rule introduced in Zhang et al. (2018):

$$\begin{aligned}\tilde{x} &= \lambda x_i + (1-\lambda)x_j \\ \tilde{y} &= \lambda y_i + (1-\lambda)y_j\end{aligned} \tag{5}$$

where x_i and x_j are two randomly sampled input points, y_i and y_j are their associated one-hot encoded labels, and λ is a mixing ratio sampled from a Beta(α, α) distribution with a hyper-parameter α. In standard MixUp, training data is augmented by linearly interpolating *random* training samples in the input space. In contrast, our proposed TDMixUp interpolates one easy-to-learn sample with one ambiguous sample after applying AUM to filter potential erroneous samples that harm performance. Our current implementation uses easy-to-learn and ambiguous data loaders respectively and then applies MixUp to a randomly sampled mini-batch of each loader. We train a model on the generated TDMixUp samples in addition to the easy-to-learn and ambiguous samples using the cross entropy-loss.

3 Experiments and Results

3.1 Tasks and Datasets

We evaluate our TDMixUp on three natural language understanding tasks. We describe our in-domain and out-of-domain sets as follows.

Natural Language Inference (NLI) Stanford Natural Language Inference (SNLI) is a task to predict if the relation between a hypothesis and a premise is *entailment, contradiction,* or *neutral* (Bowman et al., 2015). Multi-Genre Natural Language Inference (MNLI) captures NLI with diverse domains (Williams et al., 2018).

Paraphrase Detection Quora Question Pairs (QQP) is a paraphrase detection task to test if two questions are semantically equivalent (Iyer et al., 2017). TwitterPPDB (TPPDB) is a dataset built to determine whether sentence pairs from Twitter convey similar semantics when they share URLs (Lan et al., 2017).

Commonsense Reasoning Situations With Adversarial Generations (SWAG) is a commonsense reasoning task to choose the most plausible continuation of a sentence among four candidates (Zellers et al., 2018). HellaSWAG is a dataset built using adversarial filtering to generate challenging out-of-domain samples.

3.2 Experimental Setup

We use BERT (Devlin et al., 2019) based classification model and pass the resulting `[CLS]` representation through a fully connected layer and softmax to predict the label distribution. We follow the published train/validation/test datasets splits as described in Desai and Durrett (2020). To identify mis-labeled samples in the top 33% easy-to-learn samples, we set threshold values k as: the 80th/80th/50th percentile threshold sample AUMs on SNLI/QQP/SWAG, respectively. More training details and hyper-parameter settings can be found in the Appendix. We evaluate the capability of our TDMixUp strategy to improve both predictive performance and model calibration due to its regularization effect through data augmentation. Hence, we use two metrics: (1) accuracy, and (2) expected calibration error (ECE) (Guo et al., 2017; Desai and Durrett, 2020). We report results averaged across 5 fine-tuning runs with random restarts for all experiments.

3.3 Baseline Methods

BERT (Devlin et al., 2019) is the pre-trained base BERT model fine-tuned on each downstream task.

Back Translation Data Augmentation (Edunov et al., 2018) generates augmented samples by using pre-trained translation models[2] which can generate diverse paraphrases while preserving the semantics

---

[2] We use FairSeq and set the random sampling temperature as 0.9.

Table 1: The comparison of accuracy and expected calibration error (ECE) in percentage on in-domain (top) and out-of-domain (bottom) for BERT. We compare the results of fine-tuning on subsets of train samples (i.e., easy-to-learn and ambiguous samples) and fine-tuning on the entire 100% of training samples. Lower ECE implies better calibrated models. We report the mean accuracy across five training runs with the standard deviation shown in subscript (e.g., $90.04_{0.3}$ indicates 90.04 ± 0.3).

of the original sentences. In experiments, we translate original sentences from English to German and then translate them back to English to obtain the paraphrases.

MixUp (Zhang et al., 2018) generates augmented samples by interpolating random training samples in the input space (obtained from the first layer of the BERT pre-trained language model).

Manifold MixUp (M-MixUp) (Verma et al., 2019) generates additional samples by interpolating random training samples in the feature space (obtained from the task-specific layer on top of the BERT pre-trained language model).

MixUp for Calibration (Kong et al., 2020) generates augmented samples by utilizing the cosine distance between samples in the feature space.

Note that the above baselines use 100% training data while our proposed method focuses on particular subsets of the training data.

3.4 Results

Fine-tuning on Subsets of Training Data To explore the effect of different subsets of the data that are characterized using training dynamics, we compare the result of BERT fine-tuned on 100% training data with the results of BERT when fine-tuned on these subsets, and show the comparison in Table 1. Note that, for each task, we train the model on in-domain training set, and evaluate on in-domain and out-of-domain test sets. We make the following observations: First, we observe that accuracy and ECE improve when we filter out possibly mis-labeled samples in the top 33% easy-to-learn samples by using AUM in all cases (for both in-domain and out-of-domain test sets). Specifically, using *24% train, Easy-to-learn with AUM*[3] returns better accuracy and lower ECE than *33% train, easy-to-learn*, showing that there are some potentially erroneous samples that harm the performance in the top 33% easy-to-learn samples. We manually investigate filtered samples on the top 33% easy-to-learn samples and observe that the top 33% easy-to-learn samples indeed include mis-labeled samples. For example, in SNLI, we observe that the relation between the following pairs of sentences in the top 33% easy-to-learn samples is *contradiction* when it should be *neutral*: <*Two opposing wrestlers competing to pin one another.; 'Two women are shopping in a boutique.'*> and <*'A person dressed in a colorful costume is holding some papers.'; 'the cat jumps on the dog.'*>. In contrast, we observe that in many cases accuracy and ECE worsen when we filter out possibly mis-labeled samples in the 33% ambiguous samples by using AUM, suggesting that all ambiguous samples are useful for learning and generalization (which is consistent with Swayamdipta et al. (2020)). Sec-

---

[3] Although we write 24% in Table 1 for simplicity, the percentage of training samples on SNLI/QQP/SWAG after AUM filtering are 20%/24%/25%, respectively

Bold text shows the best performance and calibration. For *100% train* results, we use reported results by Desai and Durrett (2020). We report the mean accuracy across five training runs with the standard deviation shown in subscript (e.g., $90.04_{0.3}$ indicates 90.04 ± 0.3).

ond, we observe that fine-tuning BERT on both the easy-to-learn and the ambiguous samples (*66% train, Easy-to-learn & Ambiguous*) achieves similar performance and ECE as *100% train*.

Main Results Table 2 shows the result of the comparison of our proposed TDMixUp and baseline methods. We observe that our proposed method generally achieves higher accuracy and lower ECE on both in-domain and out-of-domain settings compared to any baseline using the full 100% training data showing the effectiveness of our TDMixUp strategy.

3.5 Ablation Study

To compare the impact of the MixUp operation on samples generated by *random pairing* and on samples generated by *informative pairing*, we conduct an ablation study. Specifically, we compare the results of MixUp on 66% train set (i.e., conduct the MixUp operation between randomly selected samples on 66% train set, which is the union of the top 33% easy-to-learn and the top 33% ambiguous samples) and our proposed TDMixUp (i.e., conduct the MixUp operation between the easy-to-learn filtered by AUM and the ambiguous samples). As shown in Table 3, we observe that our proposed TDMixUp which selects informative samples to combine performs better with respect to accuracy and ECE than vanilla MixUp that selects random samples, in all cases (in-domain and out-of-domain).

	Acc	ECE	Acc	ECE	Acc	ECE
	SNLI		QQP		SWAG	
Random	89.59	1.70	89.87	3.06	79.15	4.51
Ours	90.31	1.22	90.42	1.53	79.59	2.16
	MNLI		TwitterPPDB		HellaSWAG	
Random	73.22	6.89	87.23	6.53	34.43	15.87
Ours	74.28	2.91	87.89	6.08	35.21	9.45

Table 3: The results comparison of MixUp selecting random samples on the union of the top 33% easy-to-learn and the top 33% ambiguous samples (i.e., Random) and our method.

4 Conclusion

In this work, we propose a novel MixUp that leverages training dynamics (confidence, variability, and Area Under the Margin) to allow more informative samples to be combined in generating augmented samples. We empirically validate that our method not only achieves competitive accuracy but also calibrates BERT model on various NLP tasks, both on in-domain and out-of-domain settings.

A Supplementary Materials

A.1 Training Details

In our experiments, we use *bert-base-uncased* classification model on top of a task-specific fully-connected layer. The model is fine-tuned with a maximum of 3 epochs, batch size of 16 for SNLI and QQP, batch size 4 for SWAG, a learning rate of 1e-5, gradient clip of 1.0, and no weight decay. We use the hyper-parameter of MixUp α as 0.4. All hyper-parameters are estimated on the validation set of each task. For all results, we report averaged results across 5 fine-tuning runs with random starts. Finally, all experiments are conducted on a single NVIDIA RTX A6000 48G GPU with the total time for fine-tuning all models being under 24 hours. For each dataset, we follow the published train/validation/test split by Desai and Durrett (2020) and show the statistics of the datasets in Table 4.

Dataset	Train	Dev	Test
SNLI	549,368	4,922	4,923
MNLI	392,702	4,908	4,907
QQP	363,871	20,216	20,217
TwitterPPDB	46,667	5,060	5,060
SWAG	73,547	10,004	10,004
HellaSWAG	39,905	5,021	5,021

Table 4: The statistics of all used datasets.

A.2 Data Maps

In this section, we provide data maps (Swayamdipta et al., 2020) of our in-domain datasets on *bert-base-uncased* model in Figure 1. These data maps are used to identify the characteristics of each training sample (i.e., easy-to-learn, ambiguous, and hard-to-learn).

Grapheme-to-Phoneme Conversion for Thai using Neural Regression Models

Tomohiro Yamasaki
Toshiba Corporation, Research and Development Center, Japan
`tomohiro2.yamasaki@toshiba.co.jp`

Abstract

We propose a novel Thai grapheme-to-phoneme conversion method based on a neural regression model that is trained using neural networks to predict the similarity between a candidate and the correct pronunciation. After generating a set of candidates for an input word or phrase using the orthography rules, this model selects the best-similarity pronunciation from the candidates. This method can be applied to languages other than Thai simply by preparing enough orthography rules, and can reduce the mistakes that neural network models often make. We show that the accuracy of the proposed method is .931, which is comparable to that of encoder-decoder sequence models. We also demonstrate that the proposed method is superior in terms of the difference between correct and predicted pronunciations because incorrect, strange output sometimes occurs when using encoder-decoder sequence models but the error is within the expected range when using the proposed method.

1 Introduction

Grapheme-to-phoneme conversion (G2P) is the task of converting grapheme sequences into corresponding phoneme sequences. Many languages have the difficulty that some grapheme sequences correspond to more than one different phoneme sequence depending on the context.

G2P plays a key role in speech and text processing systems, especially in text-to-speech (TTS) systems. These systems have to produce speech sounds for every word or phrase, even those not contained in a dictionary. In low-resource languages, it is fundamentally difficult to obtain large vocabulary dictionaries with pronunciations. Therefore, pronunciations need to be predicted from character sequences.

In many languages, each word is composed of syllables and each syllable is composed of characters following the orthography rules of that language. This means that G2P for languages with syllabic orthography rules can be formulated as the task of selecting the best path in a lattice generated for a given input word or phrase if we prepare enough orthography rules to make sure that any lattice generated almost certainly includes the path for the correct pronunciation.

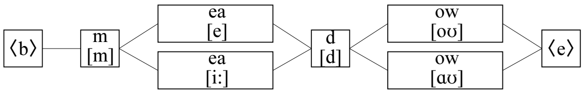

Figure 1: G2P can be formulated as the task of selecting the best path in a lattice. In English, because “ea” can be pronounced as /e/ and /iː/ and “ow” can be pronounced as /oʊ/ and /ɑʊ/, the word “meadow” has 4 pronunciation candidates, excluding stress position estimation.

As the result of some effort, we prepared Thai orthography rules. Almost all possible paths in a lattice can be generated from these, and each path needs to be evaluated using a phonological language model to select the best path. With this in mind, we propose a novel G2P method based on a neural regression model that is trained using neural networks to predict how similar a pronunciation candidate is to the correct pronunciation. After generating a set of candidates for an input word or phrase using the orthography rules, this model selects the best-similarity pronunciation from the candidates.

In the following sections, we describe the proposed method and explain experiments on a dataset of Thai vocabulary entries with pronunciations collected from Wiktionary. After that, we show that the proposed method outperforms encoder-decoder sequence models in terms of the difference between correct and predicted pronunciations, and demonstrate that incorrect, strange output sometimes occurs when using encoder-decoder sequence models while error is within the

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4251 - 4255
July 10-15, 2022

expected range when using the proposed method. The code is available at `https://github.com/T0106661`.

2 Related Work

For G2P, converting words into pronunciations does not require as much expertise as needed to prepare correspondences between graphemes and phonemes. Therefore, a method of learning correspondences from a large number of word-pronunciation pairs has been used (van den Bosch and Daelemans, 1993). To solve the problem that graphemes and phonemes often have many-to-many correspondence, a hidden Markov model-based method (Jiampojamarn et al., 2007) and weighted finite-state transducer-based methods (Novak et al., 2012a,b) have been developed. Bisani and Ney (2008) assumed that *graphones* underlie both graphemes and phonemes, and achieved great performance by learning graphones to minimize joint errors.

In addition, there have been some attempts to apply encoder-decoder models to learn end-to-end G2P models. For example, Toshniwal and Livescu (2016) applied a sequence-to-sequence architecture (Sutskever et al., 2014; Luong et al., 2015). Yolchuyeva et al. (2020) and Vesik et al. (2020) applied a transformer architecture (Vaswani et al., 2017) to train models that can deal with English or many other languages.

3 Proposed Method

It is well known that word segmentation (WS) is a necessary preprocessing for languages without word delimiters, such as Chinese, Japanese, and Thai. To solve WS and homograph disambiguation for Thai simultaneously, Tesprasit et al. (2003) enumerated pronunciation candidates for text data with ambiguity and trained a model to select the correct pronunciation from candidates based on the context in which the text data appear.

In contrast, the proposed method trains a model that predicts how similar each candidate is to the correct pronunciation. Although the main process of the proposed method is language independent, we take Thai as an example in this section.

First, we prepared correspondences between graphemes and phonemes by combining Thai characters consisting of 44 consonants, 15 vowels, and several symbols, resulting in an approximately 300-line program and more than 180,000 entries. The prepared entries consisted of 77 characters, 5,772 syllables, and 31 phoneme symbols, and each syllable was composed of up to 7 phoneme symbols.

Characters	Syllables
เส	/see˩˥/
มอ	/mɔɔ˧/
เสมอ	/sa˧ məə˩˥/
ผล	/phon˩˥/, /phon˩˥ la˧/
รั์	(silent)

Table 1: Examples of Thai characters and syllables. Some vowels are not written and some consonants are treated as if written twice.

Suppose that a dataset of vocabulary entries with pronunciations $D = \{(v_i, p_i) \mid i = 0, \ldots\}$ is given. We begin by tracing characters in each vocabulary v_i one at a time to generate a lattice of nodes corresponding to entries. We then enumerate all possible paths in the lattice from one end to the other, and obtain a set of pronunciation candidates $C_i = \{c_{ij} \mid j = 0, \ldots\}$ by joining syllables assigned to nodes. For example, when we have $v_i =$ "กลางคืน"(night), we obtain the set $C_i = \{$/ka˧ laa˧ ŋa˧ khɯɯn˧/, /klaa˧ ŋa˧ khɯɯn˧/, /klaaŋ˧ khɯɯn˧/$\}$.

After that, we calculate the similarity

$$s_{ij} = s(p_i, c_{ij}) = 1 - \frac{d(p_i, c_{ij})}{\max(|p_i|, |c_{ij}|)}$$

to the correct pronunciation p_i for each candidate c_{ij}, where $d(\cdot,\cdot)$ denotes symbol-based edit distance. This s_{ij} takes a maximum of 1 when $c_{ij} = p_i$ and approaches a minimum of 0 as c_{ij} diverges from p_i. For the previous example, we obtained $p_i =$ /klaaŋ˧ khɯɯn˧/; thus $s($/klaaŋ˧ khɯɯn˧/, /klaaŋ˧ khɯɯn˧/$) = 1$, $s($/klaaŋ˧ khɯɯn˧/, /klaa˧ ŋa˧ khɯɯn˧/$) = 13/16$, for example, were obtained.

Using the similarity defined above, we train a neural regression model that predicts how similar each candidate is to the correct pronunciation. More specifically, we train the model to return the similarity s_{ij} from the encoded vectors of v_i and c_{ij} using RNNs with mean absolute error as the loss function to keep each sample error as small as possible.

Figure 2 shows the model architecture. Vocabulary v is converted into a d_v-dimensional vector by a character embedding layer and a bi-directional

GRU (Bi-GRU). Candidate c is converted into a d_c-dimensional vector by a syllable embedding layer, a phoneme embedding layer, and Bi-GRUs, like the network of Lample et al. (2016). Finally, both vectors are concatenated and converted into similarity s by two dense layers. Each layer dimension can be changed depending on the target language.

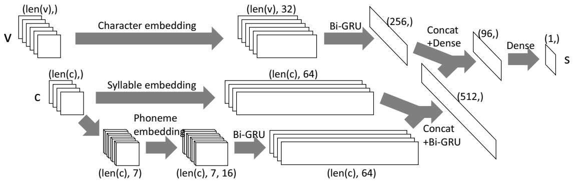

Figure 2: Architecture of the proposed method. Each pair of vocabulary v and candidate c is converted into similarity s. Each layer dimension can be changed depending on the target language.

The model trained in this way is expected to represent the phonological nature of the target language. Therefore, we can predict the pronunciation p' for a given vocabulary v' as follows. As in the training phase, we trace characters in each vocabulary v', generate a lattice, and obtain a set of candidates $C' = \{c'_j \mid j = 0, \ldots\}$. Next, we calculate the similarity s'_j for each pair (v', c'_j) using this model, and find $j_{\max} = \operatorname{argmax}_j s'_j$. Finally, we output the predicted pronunciation $p' = c'_{j_{\max}}$.

As can be seen, both training and predicting processes are language independent. In other words, the proposed method can be applied to languages other than Thai simply by preparing enough orthography rules.

However, one potential problem with the proposed method is that the number of candidates increases exponentially with input length, which can be undesirable for long words and phrases. This is considered in the next section.

4 Experimental Setup and Results

We collected 18,066 Thai vocabulary entries with pronunciations from Wiktionary as an experimental dataset. The vocabulary consisted of not only words but also phrases. We then converted the pronunciations described in a Thai-specific way into International Phonetic Alphabet sequences. For entries without pronunciations but with syllable boundaries, we determined their pronunciations when all candidates for each boundary were uniquely generated. For entries where the pronunciations were unable to be determined, two workers fluent in Thai described the correct pronunciations. The average length of each data was 7.42 in characters, 2.47 in syllables, and 12.48 in phoneme symbols.

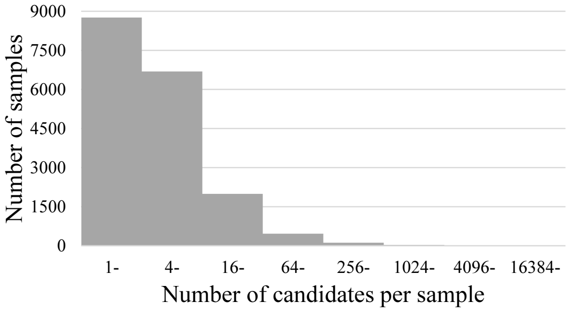

Figure 3: Distribution of the number of candidates. On average, the model has to select the correct pronunciation from about 20 candidates.

First, we examined the number of candidates generated and the coverage rate of the correct pronunciations. Figure 3 shows the distribution of the number of candidates. As seen in the figure, the number is usually less than 10 and seldom greater than 100. In fact, the minimum, mode, median, mean, and maximum were 1, 2, 4, 19.6, and 19,242 respectively. This means that the average stayed slightly less than 20, although the lattice generated for longer input tends to have many branches and can cause an exponential increase in candidates. For the coverage rate, 17,720 of 18,066 correct pronunciations were included in the sets of candidates and 346 were not.

Next, we evaluated our method compared with three G2P baseline models available from SIGMORPHON (2020), namely, a pair ngram model (fst) and two encoder-decoder sequence models (encoder-decoder and transformer, hereinafter ab-

Models	Accuracy	Difference	
		Ave	Max
fst	.670 ± .014	.619	12.3
enc-dec	.932 ± .012	.313	78.9
xformer	.911 ± .015	.360	42.5
ours	.931 ± .006	.217	8.7

Table 2: Performance comparison with three G2P baseline models for Thai. Difference is calculated across all entries. Each result is the average of 10-fold cross-validation on the test data, and thus maximum difference may not be an integer.

breviated to enc-dec and xformer). Table 2 shows the results of 10-fold cross-validation on the test data. For each fold in the experiments, we used 8/10 of entries for training, 1/10 for validation, and 1/10 for testing. We also used accuracy and the difference between correct and predicted pronunciations counted by phoneme symbols as evaluation metrics. In other words, accuracy is the percentage of 0-difference entries.

As a result, 1.17×10^6 parameters were trained. Each training run was composed of about 40 epochs and each epoch took about 13 minutes on 1 GPU (Titan V, 11GB). The absence of decoders in our model is a possible reason why the number of parameters is small and the training time is short.

Table 2 shows that our method achieved high accuracy, small average difference, and small maximum difference, and the accuracy in particular is comparable to those of enc-dec and xformer. In contrast, the low accuracy and large average difference of fst indicate that an ngram model was not able to sufficiently learn the Thai phonological nature, and large maximum differences of enc-dec and xformer indicate the well-known problem of neural network models returning good output when they work, but sometimes making mistakes when they do not.

	การเลือกตั้งประธานาธิบดีฝรั่งเศส (French presidential election)
fst	/kaan˧ lɯak˥˩ taŋ˥˩ pra˩ thaa˧ naa˧ thi˥ bɔɔ˧ dii˧ fa˧ raŋ˥˩ seet˩/
enc-dec	/kaan˧ lɯak˥˩ taŋ˥˩ pra˩ thaa˧ naa˧ thip˥ dii˧ fa˧ raŋ˥˩ pra˩ thaa˧ naa˧ thip˥ dii˧ fa˧ raŋ˥˩ pra˩ thaa˧ naa˧ thip˥ dii˧ fa˧ raŋ˥˩ pra˩ thaa˧/
xformer	/kaan˧ lɯak˥˩ taŋ˥˩ pra˩ thaan˧ baa˧ dii˧/
ours	/kaan˧ lɯak˥˩ taŋ˥˩ pra˩ thaa˧ naa˧ thi˥ ba˧ dii˧ fa˧ raŋ˥˩ seet˩/
correct	/kaan˧ lɯak˥˩ taŋ˥˩ pra˩ thaa˧ naa˧ thip˥ dii˧ fa˧ raŋ˥˩ seet˩/

Table 3: Examples of outputs with errors. The encoder-decoder sequence models sometimes included syllable repetitions and sometimes lacked syllables. For comparison, fst and our method returned outputs with fewer errors.

As shown in Table 3, further investigation revealed that the outputs of the encoder-decoder sequence models sometimes included unnatural syllable repetitions and sometimes lacked syllables in the middle, which are undesirable for TTS systems because they might give the impression that the system is failing. In contrast, our method was able to reduce such mistakes because all candidates followed the orthography rules.

4.1 Additional Experiments

To confirm that the main process of our method can be applied to other languages, we performed additional experiments on the Japanese Hiragana dataset available from SIGMORPHON (2021). This dataset consisted of 10,000 entries and the average length of each data was 4.21 in characters, 6.53 in syllables, and 16.43 in phoneme symbols.

As the result of some effort, we prepared Japanese Hiragana orthography rules. The prepared entries consisted of 85 characters, 405 syllables, and 45 phoneme symbols, and each syllable was composed of up to 6 phoneme symbols.

Models	Accuracy	Difference	
		Ave	Max
fst	.915 ± .002	.187	19.0
enc-dec	.925 ± .006	.161	14.8
xformer	.921 ± .006	.169	13.2
ours	.945 ± .002	.103	14.0

Table 4: Performance comparison with three G2P baseline models for Japanese Hiragana.

Table 4 shows performance comparison with three G2P baseline models. As can be seen, our method also achieved high accuracy and small average difference. However, the maximum differences of enc-dec and xformer are comparable to that of our method. A possible reason why the encoder-decoder sequence models worked well is that the number of long inputs in this dataset was smaller compared with Thai.

5 Conclusion and Future Work

In this study, we proposed a novel Thai G2P method based on neural regression models. We confirmed that the model trained using neural networks to predict the similarity was able to select the correct pronunciations from candidates. The accuracy was .931 and the difference between correct and predicted pronunciations was .217 on average and 8.7 at maximum.

This means that the performance of our proposed method was comparable to that of encoder-decoder sequence models and superior in terms of the difference between correct and predicted pronunciations. In particular, error is within the expected range when using our proposed method. Use of neural regression models not only for G2P but also for summarization and generation opens the possibility that neural network models could reduce strange mistakes.

Our proposed method has the strength that it can be applied to any language by preparing enough orthography rules. However, it also has the weakness of the number of candidates increasing exponentially with input length, which can be a concern for languages with many exceptional orthography rules, such as English.

A method for reducing candidates might thus be needed. There may be an efficient solution to find the correct pronunciation using a given candidate and the predicted similarity. However, these studies and experiments are left as future work.

Abstract

Generating adversarial examples for Neural Machine Translation (NMT) with single Round-Trip Translation (RTT) has achieved promising results by releasing the meaning-preserving restriction. However, a potential pitfall for this approach is that we cannot decide whether the generated examples are adversarial to the target NMT model or the auxiliary backward one, as the reconstruction error through the RTT can be related to either. To remedy this problem, we propose a new criterion for NMT adversarial examples based on the Doubly Round-Trip Translation (DRTT). Specifically, apart from the source-target-source RTT, we also consider the target-source-target one, which is utilized to pick out the authentic adversarial examples for the target NMT model. Additionally, to enhance the robustness of the NMT model, we introduce the masked language models to construct bilingual adversarial pairs based on DRTT, which are used to train the NMT model directly. Extensive experiments on both the clean and noisy test sets (including the artificial and natural noise) show that our approach substantially improves the robustness of NMT models.

1 Introduction

In recent years, neural machine translation (NMT) (Cho et al., 2014; Bahdanau et al., 2014; Vaswani et al., 2017) has achieved rapid advancement in the translation performance (Yang et al., 2020; Lu et al., 2021). However, the NMT model is not always stable enough, as its performance can drop significantly when small perturbations are added into the input sentences (Belinkov and Bisk, 2017; Cheng et al., 2020). Such perturbed inputs are often referred to as adversarial examples in the literature, and how to effectively generate and utilize adversarial examples for NMT is still an open question.

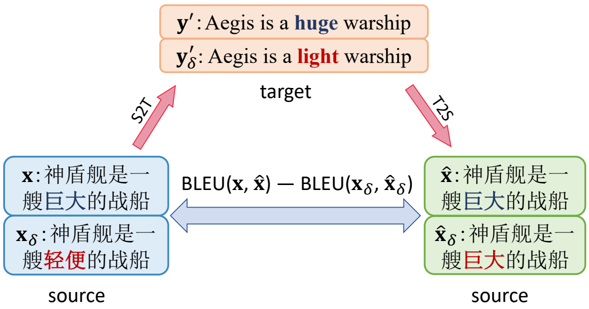

Figure 1: An example of the source-target-source RTT process on a perturbed input $\mathbf{x}_\delta$ by replacing “巨大 (huge)” to “轻便 (light)”.

Conventional approaches (Ebrahimi et al., 2018; Cheng et al., 2019) for generating NMT adversarial examples always follow the meaning-preserving assumption, i.e., an NMT adversarial example should preserve the meaning of the source sentence but destroy the translation performance drastically (Michel et al., 2019; Niu et al., 2020). With the meaning-preserving restriction, the researchers try to add perturbations on the source inputs as small as possible to ensure the meaning of the source sentence is unchanged, which severely limits the search space of the adversarial examples. Additionally, it is much problematic to craft a minor perturbation on discrete text data, since some random transformations (e.g., swap, deletion and replacement) may change, or even reverse semantics of the text data, breaking the aforementioned meaning-preserving assumption. To break this limitation, Zhang et al. (2021) introduce a new criterion for NMT adversarial examples: *an effective NMT adversarial example imposes minor shifting on the source and degrades the translation dramatically, would naturally lead to a semantic-destroyed round-trip translation result.* Take the case in Figure 1 as an example: $\mathbf{x}_\delta$ reverses the semantics of input $\mathbf{x}$ by replacing “巨大 (huge)” to “轻便 (light)”. Since the semantics of $\mathbf{x}$ and $\mathbf{x}_\delta$ are com-

July 10-15, 2022

pletely different, it is unreasonable to use the original target sentence of $\mathbf{x}$ to evaluate the attacks directly. Therefore, Zhang et al. (2021) propose to evaluate the BLEU score between $\mathbf{x}_\delta$ and its reconstructed sentence $\hat{\mathbf{x}}_\delta$ from the source-target-source round-trip translation (RTT), as well as the BLEU score between the original sentence $\mathbf{x}$ and its reconstructed sentence $\hat{\mathbf{x}}$. They take the decrease between the two BLEU scores mentioned above as the adversarial effect. Specifically, if the BLEU decrease exceeds a predefined threshold, $\mathbf{x}_\delta$ is concluded to be an adversarial example for the target NMT model.

While achieving promising results by breaking the meaning-preserving constraint, there are two potential pitfalls in the work of Zhang et al. (2021): (1) Since the source-target-source RTT involves two stages, i.e., the source-to-target translation (S2T) performed by the target NMT model and target-to-source translation (T2S) performed by an auxiliary backward NMT model, we cannot decide whether the BLEU decrease is really caused by the target NMT model. As we can see from the example in Figure 1, the translation from $\mathbf{x}_\delta$ to $\mathbf{y}'_\delta$ is pretty good, but the translation from $\mathbf{y}'_\delta$ to $\hat{\mathbf{x}}_\delta$ is really poor. We can conclude that the BLEU decrease is actually caused by the auxiliary backward model and thus $\mathbf{x}_\delta$ is not the adversarial example for the target NMT model. Even if Zhang et al. (2021) try to mitigate this problem by fine-tuning the auxiliary backward model on the test sets, we find this problem still remains. (2) They only generate the monolingual adversarial examples on the source side to attack the NMT model, without proposing methods on how to defend these adversaries and improve the robustness of the NMT model.

To address the issues mentioned above, we first propose a new criterion for NMT adversarial examples based on Doubly Round-Trip Translation (DRTT), which can ensure the examples that meet our criterion are the authentic adversarial examples for the target NMT model. Specifically, apart from the source-target-source RTT (Zhang et al., 2021), we additionally consider a target-source-target RTT on the target side. The main intuition is that an effective adversarial example for the target NMT model shall cause a large BLEU decrease on the source-target-source RTT while maintaining a small BLEU decrease on target-source-target RTT. Based on this criterion, we craft the candidate adversarial examples with the source-target-source RTT as Zhang et al. (2021), and then pick out the authentic adversaries with the target-source-target RTT. Furthermore, to solve the second problem, we introduce the masked language models (MLMs) to construct the bilingual adversarial pairs by performing phrasal replacement on the generated monolingual adversarial examples and the original target sentences synchronously, which are then utilized to train the NMT model directly. Experiments on both clean and noisy test sets (including five types of artificial and nature noise) show that the proposed approach not only generates effective adversarial examples, but also improves the robustness of the NMT model over all kinds of noises. To conclude, our main contributions are summarized as follows:

- We propose a new criterion for NMT adversarial examples based on the doubly round-trip translation, which can pick out the authentic adversarial examples for the target NMT model.
- We introduce the masked language models to construct the bilingual adversarial pairs, which are then utilized to improve the robustness of the NMT model.
- Extensive experiments show that the proposed approach not only improves the robustness of the NMT model on both artificial and natural noise, but also performs well on the clean test sets[1].

2 Related Work

2.1 Adversarial Examples for NMT

The previous approaches for constructing NMT adversarial examples can be divided into two branches: white-box and black-box. The white-box approaches are based on the assumption that the architecture and parameters of the NMT model are accessible (Ebrahimi et al., 2018; Cheng et al., 2019; Chen et al., 2021). These methods usually achieve superior performance since they can construct and defend the adversaries tailored for the model. However, in the real application scenario, it is always impossible for us to access the inner architecture of the model. On the contrary, the black-box approaches never access to inner architecture and parameters of the model. In this line, Belinkov and Bisk (2017) rely on synthetic and naturally occurring language error to generate adversarial examples and Michel et al. (2019) propose a meaning-preserving method by swapping the word internal

character. Recently, Zhang et al. (2021) craft adversarial examples beyond the meaning-preserving restriction with the round-trip translation and our work builds on top of it.

2.2 Masked Language Model

Masked Language Model (MLM) (Devlin et al., 2018; Conneau and Lample, 2019) has achieved state-of-the-art results on many monolingual and cross-lingual language understanding tasks. MLM randomly masks some of the tokens in the input, and then predicts those masked tokens. Recently, some work adopt MLM to do word replacement as a data augmentation strategy. Jiao et al. (2019) leverage an encoder-based MLM to predict word replacements for single-piece words. Liu et al. (2021) construct augmented sentence pairs by sampling new source phrases and corresponding target phrases with transformer-based MLMs. Following Liu et al. (2021), we introduce the transformer-based MLMs to construct the bilingual adversarial pairs. The main difference between our work and Liu et al. (2021) is that we choose to mask the adversarial phrases or words at each step and Liu et al. (2021) mask the words randomly.

3 Method

In this section, we first describe our proposed criterion for NMT adversarial examples, and then present the way of constructing the bilingual adversarial pairs.

3.1 Adversarial Examples for NMT

For clarity, we first introduce the traditional criteria for NMT adversarial examples, i.e., the criteria based on the meaning-preserving (Michel et al., 2019; Karpukhin et al., 2019) and RTT (Zhang et al., 2021), and then elaborate our new criterion based on DRTT. We will use the following notations: $\mathbf{x}$ and $\mathbf{y}$ denotes the source and target sentence, respectively. $\mathbf{x}_\delta$ and $\mathbf{y}_\delta$ denote the perturbed version of $\mathbf{x}$ and $\mathbf{y}$, respectively. $f(\cdot)$ is the forward translation process performed by the target NMT model and $g(\cdot)$ is the backward translation process performed by the auxiliary backward NMT model. $\mathrm{sim}(\cdot, \cdot)$ is a function for evaluating the similarity of two sentences, and we use BLEU (Papineni et al., 2002) as the similarity function.

Criterion based on meaning-preserving. Suppose $\mathbf{y}' = f(\mathbf{x})$ and $\mathbf{y}'_\delta = f(\mathbf{x}_\delta)$ is the forward translation of the input $\mathbf{x}$ and its perturbed version $\mathbf{x}_\delta$, respectively. $\mathbf{x}_\delta$ is an adversarial examples when it meets:

$$\begin{cases} \mathrm{sim}(\mathbf{x}, \mathbf{x}_\delta) > \eta, \\ \mathrm{sim}(\mathbf{y}, \mathbf{y}') - \mathrm{sim}(\mathbf{y}, \mathbf{y}'_\delta) > \alpha, \end{cases} \tag{1}$$

where η is a threshold to ensure a high similarity between $\mathbf{x}_\delta$ and $\mathbf{x}$, so that they can meet the meaning-preserving restriction. A larger α indicates a more strict criterion of the NMT adversarial example.

Criterion based on RTT. Zhang et al. (2021) point out that the perturbation δ may change, even reverse the meaning of $\mathbf{x}$, so it is incorrect to use $\mathbf{y}$ as a target sentence to measure the semantic alteration on the target side. Therefore, they introduce the criterion based on RTT which gets rid of the meaning-preserving restriction. The percentage decrease of similarity between $\mathbf{x}$ and $\mathbf{x}_\delta$ through the source-target-source RTT is regarded as the adversarial effect $\mathrm{d_{src}}(\mathbf{x}, \mathbf{x}_\delta)$, is calculated as:

$$\mathrm{d_{src}}(\mathbf{x}, \mathbf{x}_\delta) = \frac{\mathrm{sim}(\mathbf{x}, \hat{\mathbf{x}}) - \mathrm{sim}(\mathbf{x}_\delta, \hat{\mathbf{x}}_\delta)}{\mathrm{sim}(\mathbf{x}, \hat{\mathbf{x}})}, \quad (2)$$

where $\hat{\mathbf{x}}$ and $\hat{\mathbf{x}}_\delta$ are reconstructed sentences generated with source-target-source RTT: $\hat{\mathbf{x}} = g(f(\mathbf{x}))$, $\hat{\mathbf{x}}_\delta = g(f(\mathbf{x}_\delta))$. A large $\mathrm{d_{src}}(\mathbf{x}, \mathbf{x}_\delta)$ indicates that the perturbed sentence $\mathbf{x}_\delta$ can not be well reconstructed by RTT when compared to the reconstruction quality of the original source sentence $\mathbf{x}$, so $\mathbf{x}_\delta$ is likely to be an adversarial example.

Criterion based on DRTT. In Eq.(2), $\mathrm{sim}(\mathbf{x}, \hat{\mathbf{x}})$ is a constant value given the input $\mathbf{x}$ and the NMT models. Therefore, the $\mathrm{d_{src}}(\mathbf{x}, \mathbf{x}_\delta)$ is actually determined by $-\mathrm{sim}(\mathbf{x}_\delta, \hat{\mathbf{x}}_\delta)$, which can be interpreted as the reconstruction error between $\mathbf{x}_\delta$ and $\hat{\mathbf{x}}_\delta$. As we mentioned above, the reconstruction error can be caused by two independent translation processes: the forward translation process $f(\cdot)$ performed by the target NMT model and the backward translation process $g(\cdot)$ performed by the auxiliary backward model. Consequently, there may be three occasions when we get a large $\mathrm{d_{src}}(\mathbf{x}, \mathbf{x}_\delta)$: 1) A large semantic alteration in $f(\mathbf{x}_\delta)$ and a small semantic alteration in $g(\mathbf{y}'_\delta)$; 2) A large semantic alteration in $f(\mathbf{x}_\delta)$ and a large alteration in $g(\mathbf{y}'_\delta)$; 3) A small semantic alteration in $f(\mathbf{x}_\delta)$ and a large alteration in $g(\mathbf{y}'_\delta)$. We can conclude $\mathbf{x}_\delta$ is an adversarial example for the target NMT model in occasion 1 and 2, but not in occasion 3. Therefore, the criterion based on RTT may contain many fake adversarial examples.

To address this problem, we add a target-source-target RTT starting from the target side. The percentage decrease of the similarity between $\mathbf{y}$ and $\mathbf{y}'_\delta$ through the target-source-target RTT, denoted as $\mathrm{d_{tgt}}(\mathbf{y}, \mathbf{y}'_\delta)$, is calculated as:

$$\mathrm{d_{tgt}}(\mathbf{y}, \mathbf{y}'_\delta) = \frac{\mathrm{sim}(\mathbf{y}, \hat{\mathbf{y}}) - \mathrm{sim}(\mathbf{y}'_\delta, \hat{\mathbf{y}}'_\delta)}{\mathrm{sim}(\mathbf{y}, \hat{\mathbf{y}})}, \quad (3)$$

where $\hat{\mathbf{y}} = f(g(\mathbf{y}))$ and $\hat{\mathbf{y}}'_\delta = f(g(\mathbf{y}'_\delta))$ are reconstructed sentences generated with the target-source-target RTT. We take both $\mathrm{d_{src}}(\mathbf{x}, \mathbf{x}_\delta)$ and $\mathrm{d_{tgt}}(\mathbf{y}, \mathbf{y}'_\delta)$ into consideration and define $\mathbf{x}_\delta$ as an adversarial examples when it meets:

$$\begin{cases} \mathrm{d_{src}}(\mathbf{x}, \mathbf{x}_\delta) > \beta, \\ \mathrm{d_{tgt}}(\mathbf{y}, \mathbf{y}'_\delta) < \gamma, \end{cases} \quad (4)$$

where β and γ are thresholds ranging in $[-\infty, 1]$ [2]. The interpretation of this criterion is intuitive: if $\mathrm{d_{tgt}}(\mathbf{y}, \mathbf{y}'_\delta)$ is lower than γ, we can conclude that the reconstruction error between $\mathbf{y}'_\delta$ and $\hat{\mathbf{y}}'_\delta$ is very low. Namely, we can ensure a small semantic alteration of $g(\mathbf{y}'_\delta)$. Therefore, if $\mathrm{d_{src}}(\mathbf{x}, \mathbf{x}_\delta)$ is larger than β, we can conclude the BLEU decrease through the source-target-source RTT is caused by the target NMT model, so that we can conclude $\mathbf{x}_\delta$ is an authentic adversarial example.

3.2 Bilingual Adversarial Pair Generation

Since the proposed criterion breaks the meaning-preserving restriction, the adversarial examples may be semantically distant from the original source sentence. Thus, we cannot directly pair the adversarial examples with the original target sentences. In this section, we propose our approach for generating bilingual adversarial pairs, which performs the following three steps: 1) Training Masked Language Models: using monolingual and parallel data to train masked language models; 2) Phrasal Alignment: obtaining alignment between the source and target phrases; 3) Phrasal Replacement: generating bilingual adversarial pairs by performing phrasal replacement on the source and target sentences synchronously with the trained masked language models. The whole procedure is illustrated in Figure 2.

Training Masked Language Models. We train two kinds of masked language models, namely monolingual masked language model (M-MLM) (Devlin et al., 2018) and translation masked language model (T-MLM) (Conneau and Lample, 2019), for phrasal replacement on the source and target sentence, respectively. The M-MLM introduces a special [MASK] token which randomly masks some of the tokens from the input in a certain probability, and predict the original masked words. Following Liu et al. (2021), we train the M-MLM on monolingual datasets and use an encoder-decoder Transformer model (Vaswani et al., 2017) to tackle the undetermined number of tokens during generation. The T-MLM takes the identical model structure and similar training process as the M-MLM. The main difference is T-MLM relies on the parallel corpus. T-MLM concatenates parallel sentences by a special token [SEP] and only masks words on the target side. The objective is to predict the original masked words on the target side.

---

[2] It is possible that the reconstruction quality of the perturbed sentence is higher than the original one.

Phrasal Alignment. Phrasal alignment projects each phrase in the source sentence $\mathbf{x}$ to its alignment phrase in the target sentence $\mathbf{y}$. We first generate the alignment between $\mathbf{x}$ and $\mathbf{y}$ using FastAlign (Dyer et al., 2013). Then we extract the phrase-to-phrase alignment by the phrase extraction algorithm of NLTK[3], and get a mapping function p.

Phrasal Replacement. Given the source sentence $\mathbf{x} = \{s_1, s_2, \dots, s_n\}$ and the target sentence $\mathbf{y} = \{t_1, t_2, \dots, t_m\}$, s_i is the i-th phrase in $\mathbf{x}$, $t_{p(i)}$ is the $p(i)$-th phrase in $\mathbf{y}$ which is aligned to s_i by the mapping function p. We construct the candidate bilingual adversarial pairs $(\mathbf{x}_\delta, \mathbf{y}_\delta)$ by performing the phrasal replacement on $(\mathbf{x}, \mathbf{y})$ repeatedly until c percentage phrases in $\mathbf{x}$ have been replaced. For each step, we select the phrase that yields the most significant reconstruction quality degradation.

Here, we take the replacing process for s_i and $t_{p(i)}$ as an example. Considering the not attacked yet phrase s_i in $\mathbf{x}$, we first build a candidate set $\mathcal{R}_i = \{r_i^1, r_i^2, \dots, r_i^k\}$ for s_i with the prepared M-MLM. Specifically, we extract the k candidate phrases with top k highest predicted probabilities by feeding $\mathbf{x}^{\backslash i}$ into M-MLM, where $\mathbf{x}^{\backslash i}$ is the masked version of $\mathbf{x}$ by masking s_i. We select the best candidate r_i^* for s_i as:

$$r_i^* = \underset{j \in \{1, \cdots, k\}}{\arg\max}\, \mathrm{d}_{\text{src}}(\mathbf{x}, \mathbf{x}^{\backslash i:j}), \tag{5}$$

where $\mathbf{x}^{\backslash i:j}$ is the noised version by replacing s_i with r_i^j. With s_i being replaced, we need to replace $t_{p(i)}$ to ensure they are still semantically aligned. To this end, we feed the concatenation of $\mathbf{x}^{\backslash i:*}$ and $\mathbf{y}^{\backslash p(i)}$ into T-MLM, and choose the output phrase with the highest predicted probability as the substitute phrase for $t_{p(i)}$.

Finally, to decide whether $(\mathbf{x}_\delta, \mathbf{y}_\delta)$ is an authentic bilingual adversarial pair for the target NMT model, we perform a target-source-target RTT starting from the target side and calculate $\mathrm{d}_{\text{tgt}}(\mathbf{y}, \mathbf{y}'_\delta)$ between $\mathbf{y}'_\delta$ and its reconstruction sentence $\hat{\mathbf{y}}'_\delta$ according to Eq.(4). We take $(\mathbf{x}_\delta, \mathbf{y}_\delta)$ as an authentic bilingual adversarial pair if $\mathrm{d}_{\text{src}}(\mathbf{x}, \mathbf{x}_\delta)$ is greater than β and $\mathrm{d}_{\text{tgt}}(\mathbf{y}, \mathbf{y}'_\delta)$ is less than γ. We formalize these steps in Algorithm 1 in Appendix A.

After generating adversarial data through the above steps, we combine it with original training data and use them to train the NMT model directly.

4 Experimental Settings

We evaluate our model under artificial noise in Zh→En and En→De translation tasks, and under natural noise in En→Fr translation task. The details of the experiments are elaborated in this section.

4.1 Dataset

For the Zh→En task, we use the LDC corpus with 1.25M sentence pairs for training[4], NIST06 for validation, and NIST 02, 03, 04, 05, 08 for testing. For the En→De task, we use the publicly available dataset WMT'17 En-De (5.85M) for training, and take the *newstest16* and *newstest17* for validation and testing, respectively. In En→Fr task, we follow Liu et al. (2021) to combine the WMT'19 En→Fr (36k) robustness dataset with Europarl-v7 (2M) En-Fr pairs for training. We take the development set of the MTNT (Michel and Neubig, 2018) for validation and the released test set of the WMT'19 robustness task for testing. As for MLMs, we use the Chinese sentences of the parallel corpus to train the Chinese M-MLM, and use the whole parallel corpus to train Zh-En T-MLM. We train the English M-MLM with News Commentary and News Crawl 2010 (7.26M in total) monolingual corpus following Liu et al. (2021). T-MLM for En-De and En-Fr are trained with their original parallel corpus.

4.2 Model Configuration and Pre-processing

The MLMs and NMT models in this paper take Transformer-base (Vaswani et al., 2017) as the backbone architecture. We implement all models base on the open-source toolkit Fairseq (Ott et al., 2019). As for hyper-parameters, β is set to 0.01 and γ is set to 0.5 for Zh→En. For En→De and En→Fr, β and γ are set to 0.5. The replacement ratio c is set to 0.2 following Liu et al. (2021), and the candidate number k is set to 1. The details of model configuration and the number of the generated adversarial examples are shown in the Appendix B. Following previous work, the Zh→En performance is evaluated with the BLEU (Papineni et al., 2002) score calculated by *multi-bleu.perl* script. For En→De and En→Fr, we use SacreBLEU (Post, 2018) for evaluation[5].

Table 1: The BLEU scores (%) for forward-translation on noisy test sets with noise ratio 0.1, 0.2 and 0.3, and 'AVG' denotes the average BLEU (%) on all noise ratios. We re-implement all baselines to eliminate the discrepancy caused by MLMs and the auxiliary backward model. '$*/**$': significantly (Koehn, 2004) better than the RTT with $p < 0.05$ and $p < 0.01$, respectively.

4.3 Comparison Methods

To test the effectiveness of our model, we take both meaning-preserving and meaning-changeable systems as comparison methods:

Baseline: The vanilla Transformer model for NMT (Vaswani et al., 2017). In our work, we use the baseline model to perform the forward and backward translation in the round-trip translation.

CharSwap: Michel et al. (2019) craft a minor perturbation on word by swapping the internal character. They claim that character swaps have been shown to not affect human readers greatly, hence making them likely to be meaning-preserving.

TCWR: Liu et al. (2021) propose the approach of translation-counterfactual word replacement which creates augmented parallel translation corpora by random sampling new source and target phrases from the masked language models.

RTT: Zhang et al. (2021) propose to generate adversarial examples with the single round-trip translation. However, they do not provide any approach for generating the bilingual adversarial pairs. To make a fair comparison, we generate the bilingual adversarial pairs from their adversarial examples in the same way as ours.

5 Results and Analysis

5.1 Main Results

Artificial Noise. To test robustness on noisy inputs, we follow Cheng et al. (2018) to construct five types of synthetic perturbations with different noise ratios on the standard test set[6]: 1) *Deletion:* some words in the source sentence are randomly deleted; 2) *Swap:* some words in the source sentence are randomly swapped with their right neighbors; 3) *Insertion*: some words in the source sentence are randomly repeated; 4) *Rep src:* short for 'replacement on src'. Some words in the source sentence are replaced with their relevant word according to the similarity of word embeddings[7]; 5) *Rep both:* short for 'replacement on both'. Some words in the

---

[6] For each test set, we report three results with noise ratio as 0.1, 0.2 and 0.3, respectively. Noise ratio 0.1 means 10 percent of the words in the source sentence are perturbed.

Table 2: The RTT BLEU scores (%) for round-trip translation on noisy test sets. '$*/**$': significantly better than RTT with $p < 0.05$ and $p < 0.01$, respectively.

source sentence and their aligned target words are replaced by masked language models [8].

Table 1 shows the BLEU scores of forward translation results on Zh→En and En→De noisy test sets. For Zh→En, our approach achieves the best performance on 4 out of 5 types of noisy test sets. Compared to RTT, DRTT achieves the improvement up to 1.1 BLEU points averagely on *deletion*. For En→De, DRTT also performs best results on all types of noise except *Rep src*. We suppose the reason is *Rep src* sometimes reverses the semantics of the original sentence as we claimed above.

Since the perturbations we introduced above may change the semantics of the source sentence, it may be problematic for us to calculate the BLEU score against the original reference sentence in Table 1. Therefore, following Zhang et al. (2021), we also report the BLEU score between the source sentence and its reconstructed version through the source-target-source RTT, which is named as RTT BLEU. The intuition behind it is that: a robust NMT model translates noisy inputs well and thus has minor shifting on the round-trip translation, resulting in a high BLEU between inputs and their round-trip translation results. Following Zhang et al. (2021), we fine-tune the backward model (vanilla Transformer model) with its test set to minimize the impact of the T2S process. As shown in Table 2, DRTT outperforms the meaning-preserving method and other methods on all types of noise on Zh→En and En→De tasks. Considering the results of Table 1 and Table 2 together, DRTT significantly improves the robustness of NMT models under various artificial noises.

various noise in real-world text, e.g., exhibits typos, grammar errors, code-switching, etc. As shown in Table 3, DRTT yields improvements of 1.34 BLEU compared to the baseline, it proves that our approach also performs well in real noise scenario. Besides, DRTT achieves 0.63 BLEU improvement over RTT by filtering out 10% of fake adversarial examples (according to Table 6), which demonstrates that filtering out fake adversarial examples further improves the robustness of the model.

5.2 Effectiveness of Adversarial Examples

In this sub-section, we evaluate the effectiveness of the generated adversarial examples on attacking the victim NMT model (i.e., the target NMT model without being trained on the generated adversarial pairs). In our approach, γ in Eq.(4) is a hyper-parameter to control the strictness of our criterion on generating adversarial examples. Thus, we evaluate the effectiveness of adversarial examples by studying the translation performance of the victim NMT model on the set of adversarial pairs generated with different γ. That is to say, if a sample is an adversary, it should destroy the translation performance drastically, resulting in a low BLEU score between the translation result and its paired target sentence. The average BLEU scores of the victim model on the different adversarial pair sets (generated with γ from -10 to 1 on NIST 06) are shown in Figure 3. Specifically, the average BLEU on the adversarial sets generated with $\gamma = -10$ is 8.0. When we remove the restriction of γ, i.e., the DRTT is degenerated into RTT, the average BLEU for the constructed adversarial examples reaches up to 11.2. This shows that the adversarial examples generated with lower γ (more strict restriction) attack the model more successfully. Therefore, we can select more effective adversarial examples compared to Zhang et al. (2021) by lowering the threshold γ to create a more strict criterion.

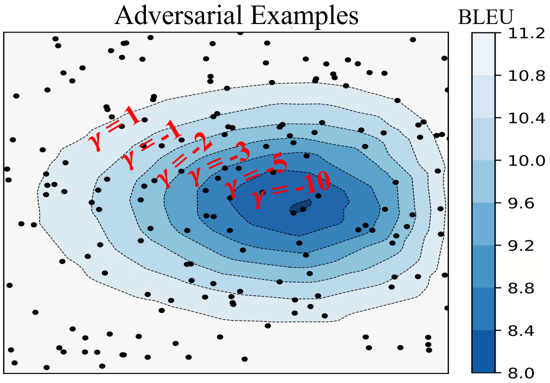

Figure 3: Black spots represent the distribution of adversarial samples. The darker color indicates more effective adversarial examples generated with lower γ.

5.3 Clean Test set

Adding a large amount of noisy parallel data to clean training data may harm the NMT model performance on the clean test sets seriously (Khayrallah and Koehn, 2018). In this sub-section, we test the performance of the proposed model on the clean test sets and the results are presented in Table 4. The meaning-preserving method CharSwap has negative effect on clean test set while DRTT achieves the best translation performance on Zh→En and En→De clean test sets. It demonstrates that our approach not only improves the robustness of the NMT model, but also maintains its good performance on clean test sets.

6 Case Study and Limitations

In Table 5, we present some cases from Zh-En adversarial pairs generated by our approach. From the case 1, we can see "拥护" in the source sentence is replaced by its antonym "反对", which reverse the meaning of the original sentence, and DRTT makes a corresponding change in the target sentence by replacing "support" with "oppose". In the other case, DRTT replaces "良好" by its synonym

x：我们坚决拥护政府处理这一事件所采取的措施。 y：we resolutely support measures taken by our government in handling this incident.
x_δ：我们坚决反对政府处理这一案件所采取的举措。 y_δ：we resolutely oppose measures taken by our government in handling this case.
x：中美双方认为, 当前世界经济形势是良好的。通货膨胀继续保持低水平, 大多数新兴市场经济体的经济增长强劲。 y：china and the united states agreed that the present economic situation in the world is satisfactory, with inflation kept at a low level and most of the new market economies growing strong.
x_δ：俄美双方认为, 当前世界贸易势头是不错的。通货膨胀继续保持低速度, 大多数新兴市场经济体的经济发展强劲。 y_δ：russia and the united states agreed that the present trade trend in the world is satisfactory, with inflation kept at a low rate and most of the new market economies developing strong.

Table 5: Case study for the proposed approach. The words in red and blue color represents the augmented words on the source and target side, respectively.

"不错", thus, "satisfactory" in the target sentence remains unchanged. From these cases, we find that DRTT can reasonably substitute phrases in source sequences based on the contexts and correctly modify the corresponding target phrases synchronously.

Although the proposed approach achieves promising results, it still has limitations. A small number of authentic adversarial examples may be filtered out when the large $\mathrm{d}_{\mathrm{tgt}}(\mathbf{y}, \mathbf{y}'_\delta)$ is caused by $f(\hat{x}_\delta)$, we will ameliorate this problem in the further.

7 Conclusion and Future Work

We propose a new criterion for NMT adversarial examples based on Doubly Round-Trip Translation, which can ensure the examples that meet our criterion are the authentic adversarial examples. Additionally, based on this criterion, we introduce the masked language models to generate bilingual adversarial pairs, which can be used to improve the robustness of the NMT model substantially. Extensive experiments on both the clean and noisy test sets show that our approach not only improves the robustness of the NMT model but also performs well on the clean test sets. In future work, we will refine the limitations of this work and then explore to improve the robustness of forward and backward models simultaneously. We hope our work will provide a new perspective for future researches on adversarial examples.

Acknowledgements

The research work descried in this paper has been supported by the National Key R&D Program of China (2020AAA0108001) and the National Nature Science Foundation of China (No. 61976016, 61976015, and 61876198). The authors would like to thank the anonymous reviewers for their valuable comments and suggestions to improve this paper.

A Bilingual Adversarial Pair Generation

Algorithm 1: Bilingual Adversarial Pair Generation

```
Input: A sequence pair $(x, y)$, a sampling probability $c$, an alignment mapping $p$, candidate words $k$, masked language models M-MLM and T-MLM, thresholds $\beta$ and $\gamma$.
Output: A bilingual adversarial pair $(x_\delta, y_\delta)$
Function BilAdvGen($x, y$):
    while $n \leq len(x) * c$ do
        $r_i^j \leftarrow$ M-MLM $(x^{\backslash i})$;
        $x^{\backslash i:j} \leftarrow$ Replace$(x, r_i^j)$
        $r_i^* \leftarrow \arg\max \mathrm{d_{src}}(x, x^{\backslash i:j})$ (2);
        $x^{\backslash i:*} \leftarrow$ Replace$(x, r_i^*)$
        Get aligned index $p(i)$;
        $w_{p(i)} \leftarrow$ T-MLM $(x^{\backslash i:*}, y^{\backslash p(i)})$;
        $y_\delta \leftarrow$ Replace$(y, w_{p(i)})$
        $n \leftarrow n + 1$
    end
if $\mathrm{d_{src}}(x, x_\delta) > \beta$ and $\mathrm{d_{tgt}}(y, y'_\delta) < \gamma$ then
    return $x_\delta, y_\delta$
end
```

B Implementation Details

As for Zh→En, we apply the separate byte-pair encoding (BPE) (Sennrich et al., 2016) encoding with 30K merge operations for Zh and En, respectively, the peak learning rate of 5e-4, and the training step is 100K. For En→De and En→Fr, we apply the joint BPE with 32K merge operations, the learning rate of 7e-4 and the training step is 200K. The dropout ratio is 0.1. We use Adam optimizer (Kingma and Ba, 2014) with 4k warm-up steps. All models are trained on 8 NVIDIA Tesla V100 (32GB) GPUs.

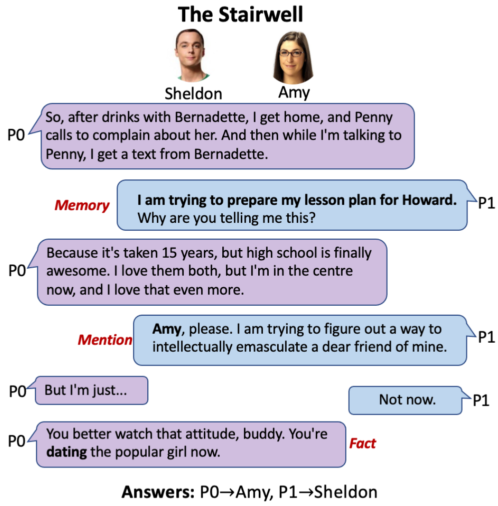
Abstract

We propose a new task for assessing machines' ability to understand fictional characters in narrative stories. The task, TVShowGuess, builds on the scripts of TV series and takes the form of guessing the anonymous main characters based on the backgrounds of the scenes and dialogues. Our human study supports that this form of task covers comprehension of multiple types of character persona, including understanding characters' personalities, facts and memories of personal experience, which are well aligned with the psychological and literary theories about the theory of mind (ToM) of human beings on understanding fictional characters during reading. We further propose new model architectures to support the contextualized encoding of long scene texts. Experiments show that our proposed approaches significantly outperform baselines, yet still largely lag behind the (nearly perfect) human performance. Our work serves as a first step toward the goal of narrative character comprehension.[1]

1 Introduction

Stories have two essential elements, plots and characters (McKee, 1997). Character comprehension has been widely recognized as key to understanding stories in psychological, literary and educational research (Bower and Morrow, 1990; Kennedy et al., 2013; Currie, 2009; Paris and Paris, 2003). When reading stories, humans build mental models for characters based on their personae, which helps people to explain a character's emotional status (Gernsbacher et al., 1998), identity, understand future behaviors (Mead, 1990), and even make counterfactual inferences for stories about that character (Fiske et al., 1979).

The ultimate goal of creating a character comprehension system is to equip a machine with practical capabilities that emulate what humans can accomplish. For example, understanding personae can facilitate story memorization and generation of new statements consistent with the story (Riedl and Young, 2010). Such capabilities could be valuable in the construction of dialog engines that help people address practical problems such as those experienced in customer service encounters (Mairesse and Walker, 2007; Zhang et al., 2018; Urbanek et al., 2019). More importantly, understanding the persona of a particular person can help chatbots to understand the intention behind a human user's language (Bender and Koller, 2020), which can lead to better services and ultimately give systems the ability to demonstrate behaviors that users interpret as empathetic. For instance, *Amy*'s last sentence in Figure 1 is a joking braggadocio to remind her boyfriend to value her more. Only when *Sheldon* understood the facts of their relationship as a couple and *Amy*'s temporary show-off mentality could he see her true intentions.[2]



P0: So, after drinks with Bernadette, I get home, and Penny calls to complain about her. And then while I'm talking to Penny, I get a text from Bernadette.

P1: **I am trying to prepare my lesson plan for Howard.** Why are you telling me this?

P0: Because it's taken 15 years, but high school is finally awesome. I love them both, but I'm in the centre now, and I love that even more.

P1: **Amy**, please. I am trying to figure out a way to intellectually emasculate a dear friend of mine.

P0: But I'm just...

P1: Not now.

P0: You better watch that attitude, buddy. You're **dating** the popular girl now.

Answers: P0→Amy, P1→Sheldon

Figure 1: A scene example from TVShowGuess. The character *Amy* can be determined within the scene or with the fact of her relationship; while guessing *Sheldon* would require memory of the character from previous episodes.

Despite the importance of this capability, there

July 10-15, 2022 ©2022 Association for Computational Linguistics

has been limited attention to modeling characters in stories in the natural language processing (NLP) community.[3] Most existing character-centric prediction tasks have the input sources in expository text such as synopsis (summaries) of stories (Brahman et al., 2021) or non-narrative dialogues (Zhang et al., 2018; Urbanek et al., 2019; Li et al., 2020). A few exceptions work on stories, but focus on limited aspects of personae, such as facts for coreference resolution (Chen and Choi, 2016), personality (Bamman et al., 2013; Flekova and Gurevych, 2015) and character relationships (Iyyer et al., 2016), with only a few Chen and Choi (2016); Flekova and Gurevych (2015) providing evaluation benchmarks. Besides the limited persona aspect coverage, these models also lack the ability to take into account a theory of mind (**ToM**) which is the knowledge of epistemic mental states that humans use to describe, predict, and explain behavior (Baron-Cohen, 1997).

In this work, we propose the first task on character comprehension in stories to assess the ability of mental model construction in NLP. A character's words are her direct reflection of the contexts, conditioned on her character model (Holtgraves, 2010). Our task, **TVSHOWGUESS (TVSG)**, aims to guess anonymous speakers using dialogues, scene descriptions and historical scenes, which requires models to interpret the behavior of characters in the form of dialogues, which meets the requirements for the evaluation of ToMs.

Through experiments and human studies we found the following results. First, human performance was nearly perfect, while the model performed poorly. Second, although our TVSG has a simple task setup, it has a surprisingly *wide coverage of persona understanding skills* including the linguistic styles, personality types, factoids, personal relations, and the memories of characters' previous experience. Third, most of the cases (>60%) require *identification and understanding of characters' historical experiences* to resolve. Among them, many rely on facts of characters that are not explicitly described in texts but need to be inferred from event history. The wide persona coverage and heavy dependency on history present challenges to existing NLP techniques. These challenges lead to more than 20% accuracy gap between our baselines and humans.

Specifically, we make the following contributions. (1) We propose the research direction of character comprehension in stories; with an extended survey (Section 2 and Appendix A) discussing the differences and challenges compared to related work. (2) We propose the first task and dataset for multi-aspect persona (especially ToM) understanding in stories (Section 3). (3) We propose a new schema to analyze the required evidence for character understanding; and conduct human studies to analyze the required skills of our task (Section 4 and Appendix C). (4) We propose new model architectures as the initial step of this direction; and conduct comprehensive experiments to provide insights to future work (Section 5 and 6).

2 Related Work

We discuss and compare the following related areas: the assessment benchmarks for general narrative comprehension skills and the tasks specifically designed for character-centered predictions over narratives and non-narratives. Table 1 gives a summary of these narrative comprehension tasks, associated with their required comprehension skills. We also reviewed studies on character-centered tasks over non-narrative texts like synopses and chit-chat (*i.e.*, not story-related) conversations. Appendix A discusses detailed rationales of their required skills.

Assessment of Narrative Comprehension There are many forms of reading comprehension tasks such as cloze tests (Bajgar et al., 2016; Ma et al., 2018), question answering (Richardson et al., 2013; Kočiskỳ et al., 2018; Yang and Choi, 2019; Lal et al., 2021; Xu et al., 2022), and text summarization (Ladhak et al., 2020; Kryściński et al., 2021; Chen et al., 2021). Most of these tasks are built on very short stories or can be solved in segments of a story, thus presenting limited challenges to understanding the elements, especially the characters, of the story. The exceptions are NarrativeQA (Kočiskỳ et al., 2018) and the three summarization tasks, which are mainly event-centric tasks focusing on understanding the plot structures in stories. The NarrativeQA consists of a small portion of character-related questions according to the human study in (Mou et al., 2021), but mainly about simple facts of characters like age, place of birth and profession. Finally, text games (Hausknecht et al., 2019) have been proposed as a reinforcement learning task that requires understanding of narrative fiction stories. Studies have been conducted (Guo

---

[3] In contrast, plot comprehension is a popular NLP topic, especially on event structures (Finlayson, 2012; Elsner, 2012; Sims et al., 2019; Lal et al., 2021; Han et al., 2021).

Table 1: Properties of existing narrative comprehension datasets compared to TVShowGuess. * Numbers are not reported in the original paper so we calculated them from the dataset. †(Chen et al., 2017b) proposes two settings: single scene and the whole episode. ‡Our task requires reasoning based on history scenes, which is a form of plot understanding.

et al., 2020; Yao et al., 2021) to investigate the roles reading comprehension plays in these games.

Character-Centric Prediction over Narratives The task of coreference resolution of story characters (Chen and Choi, 2016; Chen et al., 2017a) is most closely related to our TVShowGuess. These tasks focus on identifying the characters mentioned in multiparty conversations, which mainly requires the understanding of discourse relations and assessment of personal facts. However, coreference does not assess the modeling of the character's theory-of-mind, especially the character's memories, as there are no predictions of character behaviors involved. The prediction of fictional characters' personality types by reading the original stories (Flekova and Gurevych, 2015) is another character-centric task related to the present work. The work covers only the character's personality such as the big five and the MBTI types, also a perspective of the persona our work considers.

Character-Centric Prediction over Non-Narratives Many tasks use the story summary instead of the original story. The textual entailment task LiSCU (Brahman et al., 2021) links an anonymous character summary to the name in the story summary. Using summaries precludes ToM modeling, as discussed in Appendix A.1. Personalized dialogue generation benchmarks (Mairesse and Walker, 2007; Walker et al., 2012; Zhang et al., 2018; Urbanek et al., 2019; Li et al., 2020) are based on daily chit-chats. They usually cover a single facet of multi-dimensional personae (Moore et al., 2017), *e.g.*, personal facts (Zhang et al., 2018) or personality types (Mairesse and Walker, 2007; Li et al., 2020). The LIGHT environment (Urbanek et al., 2019) covers both facts and personalities. None of them covers a comprehensive persona like ours, especially how a character's past experience builds her ToM.

Authorship attribution has a parallel goal to ours, insofar as it aims at guessing author identities from the texts they wrote (Ni et al., 2019; Andrews and Bishop, 2019; Bevendorff et al., 2020). These tasks differ from ours in two respects: first, multiple prose examples generated by the same author do not usually form consecutive plot lines, and second, they rarely model the event history of depicted characters. On this basis, they mainly require understanding authors' writing styles rather than building mental models of facts, events, and experiences.

3 Our TVShowGuess Benchmark

3.1 Task Definition

TVSG adopts a multi-choice setting. The goal is to guess the anonymous speakers who are the main characters (maximum number of 6 for each show) in the scene. The models are provided with an anonymous scene that consists of n lines $\tilde{\mathcal{S}}^{(t)} = \{\tilde{s}_1^{(t)}, \tilde{s}_2^{(t)}, ..., \tilde{s}_n^{(t)}\}$ (t stands for the t-th scene in the entire show). Each line $\tilde{s}_i$ can either be a dialogue turn or a background description. When the line is a dialogue turn, it is associated with an anonymous speaker ID (with the form of P_x, $1 \leq x \leq 6$) of a main character, or the real name of a supporting character. Similarly, we introduce the notation of the standard scene $\mathcal{S}^{(t)} = \{s_1^{(t)}, s_2^{(t)}, ..., s_n^{(t)}\}$, which has the same definition as the anonymous scenes, with the only difference that the dialogue turns always have their real names of speakers associated.

The anonymous scene $\tilde{\mathcal{S}}^{(t)}$ is associated with a candidate set $\mathcal{C}^{(t)} = c_1^{(t)}, ..., c_k^{(t)}$, $k \leq 6$, where each character $c_j^{(t)}$ is a main character who appears in $\mathcal{S}$. The goal is thus predicting each P_x's actual role $c_j^{(t)}$, *i.e.*, a match $\pi(\cdot)$ from the anonymous IDs to the real characters, conditioned on the scene $\tilde{\mathcal{S}}^{(t)}$ and all previous scenes $S^{(1:t-1)}$:

$$P(\mathrm{P}_x = c_j^{(t)} | \tilde{\mathcal{S}}^{(t)}, S^{(1:t-1)}). \quad (1)$$

3.2 Dataset Collection

We use community contributed transcripts from The TV MegaSite (TMS)[4] like (Chen et al., 2021). Our scenes are from the scripts of five popular TV series: *Friends*, *The Big Bang Theory (TBBT)*, *The Office*, *Frasier* and *Gilmore Girls*.

Data Cleaning Our data consists of character dialogues and background descriptions. The dialogues start with the characters' names. One or more turns of dialogue between characters comprise a scene. Scenes are separated by short background cus that begin with markers such as location (e.g. "*Howard's car*", "*Kingman Police Station*"), special words (e.g., "*Scene*", "*Cut*"), or symbols (e.g. "*[ ]*"). We created a rule-based parser which splits the content of an episode into multiple independent scenes using scene separation markers.

Character Recognition and Anonymization We used the main characters' names to identify their dialogues within each scene and randomly labeled them with speaker IDs (e.g., P0, P1). Since the different names of the characters, such as nicknames, first names, and last names, mark the dialogue in a mixed way, in order to match the lines to the correct speaker, we first identified the main characters in each TV series by consulting Fandom's cast list. Then, we calculated the frequency of speech to find references to the same main character's name.

4 Analysis of Our Benchmark

We propose a comprehensive **schema of persona types** for the machine narrative comprehension. The schema facilitates the analysis of the challenges in our task; and provides insights into the deficiencies in current narrative comprehension models, by allowing a decomposition of model performance to the dimensions of categories (Section 6).

4.1 Our Annotation Schema for Human Study

Two researchers with backgrounds in psychology, linguistics, NLP, and education developed and tested an inductive coding method based on the methods of grounded theory (Glaser and Strauss, 2017). They conducted three rounds of independent annotation and discussion of the evidence needed to identify the characters, using 10 randomly selected scenes for each round. After each discussion, they updated the codebook accordingly. Modifications to the codebook led to the achievement of saturation during the process. Then the two researchers coded a total of 318 characters from 105 scenes of Friends and The Big Bang Theory. The annotation interface appears in Appendix B.

This schema **categorizes the required evidence to resolve the task** into four persona data types: *linguistic style*, *personality*, *fact*, *memory*. Table 4 reports inter-rater reliability calculated by Cohen's Kappa (Cohen, 1960). The kappa values range from 0.76 to 0.87 and would all be considered satisfactory (Viera et al., 2005), reflecting the success of our codebook and process.

We have one additional type, *inside-scene*, referring to tasks that can be resolved purely within local contexts, thus not requiring persona understanding. To better depict how these pieces of evidence are used in human rationales, we added two complementary categories: (1) how the task instance **relies on the history scenes**, and (2) when there are multiple pieces of evidence required, what **types of reasoning skills** are used to derive the answer from the evidence (see Section C). Table 6 shows the definitions of each evidence type. We provide examples of each evidence type in Section B.2.

4.1.1 Major Evidence Types

Linguistic Style Personalized language patterns that reflect individual differences in self-expression and are consistently reliable over time and situations (Pennebaker and King, 1999).

Personality Stable individual characteristics (Vinciarelli and Mohammadi, 2014) that can distinguish "internal properties of the person from overt behaviors" (Matthews et al., 2003).

Memory A character's episodic memory of events from previous episodes and the semantic memory[5] inferred from events. Note here we want to model the memory of a particular character, *i.e.*, the historical scenes experienced by the particular character instead of from the audiences' perspective. A character's memory is crucial for humans to build her ToM, but is largely ignored as a part of persona in previous research.

Fact The truth about characters as opposed to interpretation, which can usually be represented as knowledge triples.

---

[4] `http://tvmegasite.net`.

[5] Semantic memory is the characters' general world knowledge that they accumulate over time (Reisberg, 2013). Episodic memory, on the other hand, is the characters' memory of specific experiences in their lives (Tulving, 2002)

Show	train	dev	test	#tokens per utterance		#tokens per scene		#tokens per character	
				avg	max	avg	max	avg	max
`Friends`	2,418	210	211	21	350	862	6,817	190,932	516,191
`TBBT`	1,791	130	130	19	364	414	6,051	167,027	183,748
`Frasier`	1,368	140	141	16	363	812	14,276	165,483	475,372
`Gilmore_Girls`	1,495	141	142	19	336	360	4,572	105,723	214,779
`The_Office`	3,699	198	199	19	338	123	1,660	58,676	132,992
total	10,771	819	823	18	364	371	14,276	137,568	516,191

Table 2: Statistics of our TVSHOWGUESS. The numbers in the first 3 columns refer to the total numbers of scenes.

- **Attribute** All explicitly provided factual character identity information in the TV series setting, such as race, occupation, and education level.
- **Relationship** Relationship includes social relationships (e.g., husband and wife) and dramatic relationships (e.g., arch-enemy). When talking to people with different relationships, characters change their identity masks by using different words (Gergen, 1972).
- **Status** The emotional or psychological status of a character when facing a specific situation.

Inside-Scene The textual evidence inside the scene, independent from the character's persona.

- **Background** Background introduction and descriptions in other character dialogues.
- **Mention** The character's name or alias is called out by other characters. Although mention is persona-independent, it still presents challenging cases. In a multi-person multi-round dialog, because anaphora in the current sentence may not bound to an antecedent on the right frontier of the structure, common sense analysis of conversational coherence is needed to determine which speaker is being referred to.

Exclusion A guessing technique for elimination using a given list of characters which is neither evidence nor inference, but it depends on the character list provided within the scene, so we include it as a subcategory of inside-scene evidence.

4.1.2 Dependence on History

To understand how much humans rely on memory to identify a character, the annotators coded whether the evidence necessary to solve the task depends directly on historical events or indirectly on history by abstracting from historical events.

Direct Dependency Characters that can only be identified through events that are explicitly expressed in previous episodes,[6] for example:

> **Background:** (from `TBBT`) *[The stairwell]*
>
> **Candidates:** *{Leonard, Penny}*
>
> P0: *There's something I wanted to run past you.*
>
> P1: *What's up?*
>
> P0: *Mm, the guys and I were thinking about investing in Stuart's comic book store. Is that okay?*
>
> P1: *Why are you asking me?*
>
> **Answer:** P0 → *Leonard*
>
> **Rationale:** In a previous scene, Leonard and his friends discussed investing in Stuart's store. He is the only one between the two who has this memory.

Indirect Dependency Characters can only be identified using evidence not explicitly expressed in previous episodes, but inducible from previous events. For example, *Personality* can be inferred from the character's previous behavior.[7]

> **Background:** (from `Friends`) *[Central Perk]*
>
> **Candidates:** *{Joey, Rachel, Ross}*
>
> P0: *Here you are (Hands Rachel a cup of coffee)*
>
> P1: *Thank you Joey. You know what? I'm not even sure I can have caffeine.*
>
> P2: *I went thru this with Ben and Carol. One cup of coffee won't affect your milk.*
>
> P1: *Yeah. Just to be sure I'm gonna call Dr. Wiener.*
>
> **Answer:** P2 → *Ross*
>
> **Rationale:** There is no actual scene with Ross going through this with Carol; the answer is inferred based on Ross' known relations to Ben (parent-child) and Carol (ex-spouse). Thus the evidence about Ross has indirect dependency on scene history.

If the answer can be inferred within the scene, like answering P0 → *Joey* in the above example. We have a special rule on the *Exclusion* evidence type – If a character can only be inferred on the basis of other characters being eliminated, it should have dependency type labeled if any of the other character has a history dependency. In other words, when guessing the identity with *Exclusion* requires history dependency on another character, the dependency type is transitive.

---

[6] If a character can be identified with evidence of both *Memory* and *Inside-Scene*, it will be labeled as *No-Dependency*.

[7] The annotation of indirect dependency is very subjective as different annotators may have memory of previous scenes and use different evidence to guess the character.

	Evidence Type	Friends(%)	TBBT(%)
(a)	Ling. Style	0.66	9.93
	Personality	7.28	21.85
	Fact	20.53	33.12
	(Attribute)	2.65	8.61
	(Relation)	16.56	22.52
	(Status)	1.32	1.99

	Inside-Background	33.11	12.58
	Inside-Mention	15.23	15.23
	Exclusion	8.61	22.52

	Dependence of Hist.	Friends(%)	TBBT(%)
(b)	No Dep.	53.64	32.45
	Direct Dep.	26.49	36.42
	Indirect Dep.	19.87	31.13

Table 3: Percentage of the required evidence types in the two TV shows, `Friends` and `The Big Bang Theory`.

Category	$\kappa(\%)$
Evidence type	
Coarse-grained types	81.53
Fine-grained types	80.99
Dependence of history	
Direct dependence only	82.02
All dependency types	75.51
Reasoning Type†	87.21

Table 4: Annotation agreement. †: see our extended study in Appendix C. We list the number for reference.

4.2 Analysis

Main Statistics Table 3 shows the proportions of the required evidence types and dependency of history. According to the statistics, history is an important factor in guessing the characters. 46.36% of the examples from Friends and 67.55% examples from the Big Bang Theory require history.

Human Performance Accuracy One annotator (who had not watched the seasons under evaluation) obtained nearly perfect accuracy in guessing the characters in `FRIENDS` (98.68%), and a lower but still good accuracy in `TBBT` (89.82%). A second annotator (who had watched all episodes and thus would be considered an expert) confirmed that most the error cases were unsolvable given only data extracted from scenes. We list the unsolvable cases and human mistakes in Appendix E.

Correlation between Evidence Types and History Dependence Figure 2 visualizes the flow from evidence types to the dependency of history. Most of them are correlated. Personality and history dependency are most closely related.

5 Methods

Inspired by the successes of pre-trained Transformers on reading comprehension tasks, we benchmarked our TVSHOWGUESS by building baseline solutions on top of these pre-trained models. The key challenge of our task is that the prediction relies on how a character reacts to the scenario with her/his words, therefore the embedding of each utterance should be highly **context-aware**. This requires handling a whole scene as input, which is usually over the limits of these pre-trained models.

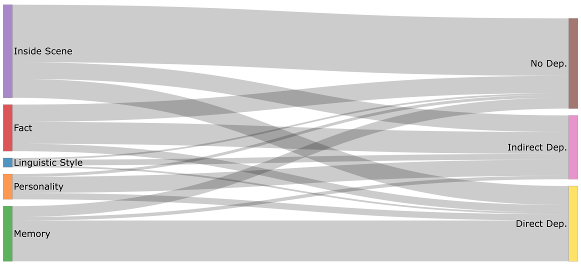

Figure 2: Visualization of the flow from the required evidence types to their dependence of history.

We propose two solutions. The first is to benefit from sparse attention, specifically, Longformer (Beltagy et al., 2020). The second is to organize each utterance with its necessary history context as one **row**, and have a BERT model to encode each relatively short row independently. For both models, we finally conduct attentive pooling for each character over the contextualized embeddings of all her utterances for prediction.

Our baselines simplified the problem by (1) ignoring the historical scenes in Eq.(1); and (2) making independent prediction of characters within a scene. The former poses the challenge of handling longer contexts and the latter requires specific predictor design. We believe both are important to handle in future work.

5.1 Transformers with Character-Pooling

Our first approach (the top in Figure 3) is denoted as Longformer-Pooling (or **Longformer-P**).

Scene Encoding The input $\tilde{S}$ to the model includes the concatenation of all the utterances in an anonymous scene. Each utterance is prefixed by a speaker ID token and suffixed by a separation token, *i.e.*,

$$T_i = [\mathrm{P}_{x_i}] \oplus U_i \oplus [\mathrm{SPLIT}] \quad (2)$$

$$\tilde{S} = T_0 \oplus T_1 \oplus ... \oplus T_N, \quad (3)$$

where U_i is the i-th utterance and $[\mathrm{P}_{x_i}]$ is its speaker ID (e.g., $[\mathrm{P}_0]$ and $[\mathrm{P}_1]$). [SPLIT] is a special token. $\oplus$ denotes concatenation. We use a Longformer to encode the whole $\tilde{S}$, to make the embedding of each utterance token *context-aware*, *i.e.*, $\mathbf{H} = \mathrm{Longformer}(\tilde{S}) \in \mathbb{R}^{L \times D}$.

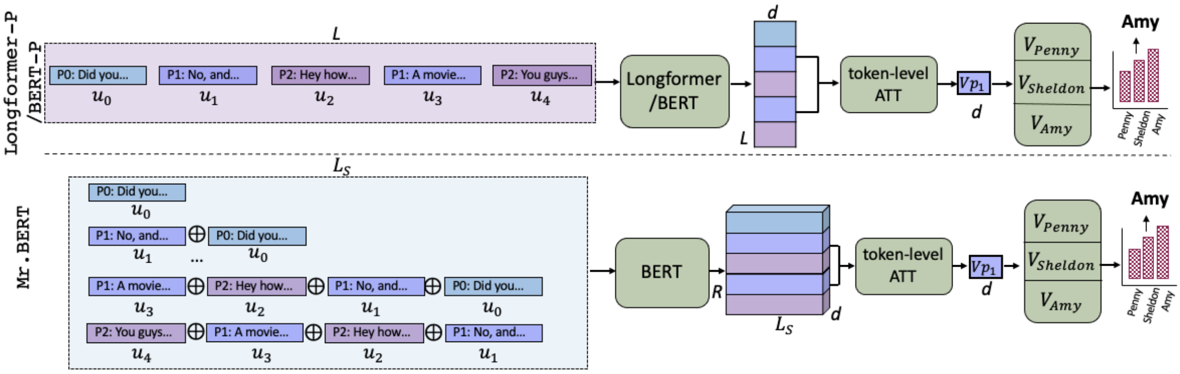

Figure 3: Our two proposed model architectures for the character prediction task.

Character-Specific Attentive Pooling For each character ID P_x, we have a token-level mask $M_x \in \mathbb{R}^{L\times 1}$ such that $M_x[j]{=}1$ if the j-th word belongs to an utterance of P_x and $M_x[j]{=}0$ otherwise. For each P_x, we then collect the useful information from all her utterances selected by M_x as:

$$\begin{aligned} A &= \text{Attention}(\mathbf{H}) \\ \alpha_x &= \text{Softmax}(A \odot M_x), \end{aligned} \tag{4}$$

where Attention$(\cdot)$ is a one-layer feedforward network to compute the token-level attention weights. The character-specific attention α_x is then used to pool the hidden states to summarize a character representation in the input scene $\tilde{S}$ and make the prediction: $P(\mathrm{P}_x = c|\tilde{S}) = f_k(\mathbf{H}^T\alpha_x)$. Here $f_k : \mathbb{R}^{d\times 1} \rightarrow \mathbb{R}^{C\times 1}$ is the character classifier for the k-th TV show.

5.2 Multi-Row BERT

The second approach (the bottom in Figure 3) is denoted as the multi-row BERT (**MR. BERT**). We split the long scene $\tilde{S}$ into multiple segments $\{\tilde{s}_i\}$. Encoding the segments reduces the overall complexity from $O(L^2)$ to $O(RL_s^2)$, where R is the number of segments and $L_s \ll L$ is the maximum segment length. To construct each segment E_i, we take an utterance T_i as in Eq. 2 and concatenate it with the nearest history utterances $T_{i'}(i' < i)$ until arriving the maximum length L_s. The R segments for each instance yield $\{\tilde{s}_i\}$ as follows:

$$\begin{aligned} E_i &= T_{t_i} \oplus \text{[SEP]} \oplus T_{t_i-1} \oplus T_{t_i-2} \cdots \\ \{\tilde{s}_i\} &= [E_1; E_2; \cdots; E_R]. \end{aligned} \tag{5}$$

Then we encode the $\{\tilde{s}_i\}$ with a BERT encoder:

$$\mathbf{H} = \text{BERT}(\{\tilde{s}_i\}) \in \mathbb{R}^{R\times L_s \times D}. \tag{6}$$

Different from Longformer-P, we have a segment-level mask $M_x \in \mathbb{R}^R$ for each character ID such that $M_x[j] = 1$ if the first utterance in the j-th row (i.e., T_{t_j} in Eq. 5) is said by P_x. Applying the same attentive pooling technique to each segment following Eq. 4, we obtain R segment embeddings $\{\mathbf{E}_i\}_1^R$. We take the concatenation of these embeddings as the new input to the show-specific predictor and calculate the probability distribution of P_x being each character, *i.e.*,

$$P(\mathrm{P}_x = c|\tilde{S}) = f_k([\mathbf{E}_1; \mathbf{E}_2; \cdots; \mathbf{E}_R]). \tag{7}$$

Compared to Longformer-P, the MR. BERT model takes a smaller number of R utterances and benefits from their concatenated contextual utterances. To make the selection of R utterances representative, we applies two tricks: (1) *fill-empty*, which makes sure each P_x has at least one segment selected; (2) *the reverse trick*, which selects the utterances starting from the end of scene to the start – as the utterances at the end have more histories, they cover more contents from the scene if selected.

6 Experiments

We evaluate the instance-level accuracy. An instance refers to a masked speaker in a scene.

6.1 Baselines and Implementation Details

We compare with the vanilla pre-trained Transformer baseline, **Vanilla Longformer Classifier**. The model conducts direct classification over the concatenation of a character's utterances in the scene. It can be viewed as a discriminative language model of the characters' lines.

We include the implementation details of the baseline and our models in Appendix G.

6.2 Results

Overall Results Table 5 compares different models on our TVSHOWGUESS. The proposed architectures beat the vanilla character classifier with large margins (4-5%). However, human performance is

ross	7,259	70.8	amy	1,699	42.1
monica	6,752	64.2	howard	4,013	36.4

Table 7: Accuracy decomposed across characters. We also provide the number of training utterances for each character.

significantly (21-26%) better than the best models. This shows that models are still far from reaching human level of character understanding.

Among all the shows, `TBBT` is the most challenging one, while `Frasier` and `Gilmore Girls` are relatively simpler. Given that there is no correlation between performance and scene lengths (Table 2), this shows that the difficulty of the task mainly comes from the persona modeling, inference and reasoning. Specifically, the *Inside-Scene* evidence requires less persona understanding. Therefore, the relatively smaller amount of *Inside-Scene* cases makes `TBBT` more difficult. Also the existing models are not good at resolving the related memory or facts from the history, thus the high ratio of *history dependent* cases in `TBBT` also leads to lower performance.

6.3 Analysis

Learning Curves We plots the learning curves of `Friends` and `TBBT`, with increasing number of shows used as training data (Figure 4). The curves become flat with all shows added, showing that our task has sufficiently data for training.

Scene-Level Performance Besides the instance-level accuracy, we further investigated the scene-level performance, *i.e.*, the macro-average of instance-level accuracy in all the scenes. Table 6 shows the results, together with the decomposed results on scenes containing different numbers of speakers. The results show the more characters involved, the lower the accuracy is, even though our model is making independent predictions of each speaker. One possibility is that there is fewer available utterances per speaker. In addition, a larger set of speakers may make the logical structure of the conversation more complex.

Character-Level Performance Next, we examined whether our task is uniformly challenging for different characters, or whether there were certain characters that were more difficult to guess. Table 7 shows the results, where the characters are ranked by the accuracy of their guesses. There are clear discrepancies in accuracy by character.

Impact of the Dependence on History The bar charts in Figure 5 show the performance on different history dependence types. The performance of cases that require history supports is in general

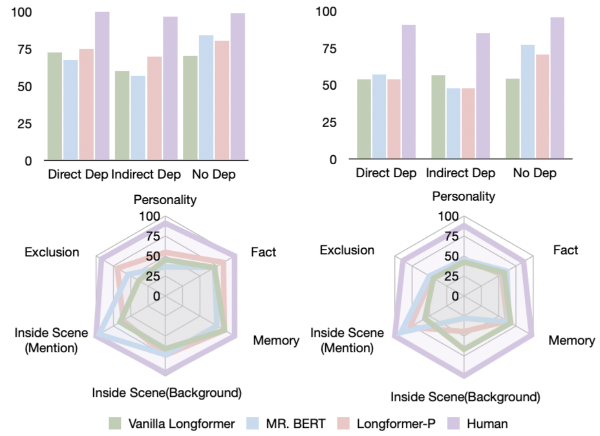

Figure 5: Performance breakdown of Friends (the left column) and The Big Bang Theory (the right column).

harder for most of the models (∼20% lower compared to the cases without dependency of history).

The results suggest that a more thorough extraction of historical events associated with each character is needed to make the model an improvement. This notion aligns with the theories that past experience is an key aspect of building characters' ToM, showing that our TVSHOWGUESS may serve as a good benchmark for the in-depth study of character comprehension from stories.

Another finding is that the cases requiring indirect history dependence (usually *Personality* and *Facts*) are even more challenging. The human mind develops detailed profiles of characters when reading stories. The neural models represent each character as a single vector (*i.e.*, the weight vector in the output layer). This indicates a promising future direction of constructing structured persona representations (*e.g.*, based on our schema of evidence) for more accurate character modeling.

Breakdown to Evidence Types The wind-rose charts (bottom) in Figure 5 provide performance breakdown onto our evidence categories. We omit the type of *Linguistic style* because there are only two cases in `Friends` so the results are not stable.

As expected, the cases that can be resolved locally without character understanding (*Inside-Mention*) are relatively easier. All of *Personality*, *Fact* and *Memory* cases have much lower performance as they correspond to heavy dependency on the modeling of history.

The type *Exclusion* gives the worst overall performance on the two shows. However, this does not indicate difficulty of character understanding – According to the definition, these cases cannot be directly resolved with the scene inputs, but require the model to have specific strategy to exclude some incorrect answers first.

It is surprising that the *Inside-Background* type poses difficulties to models, because to human annotators it is similar to standard textual inference. We have identified two possible reasons: (1) As discussed in the introduction, some cases require pragmatic understanding from the surface form to intention, only after which textual inference can be performed; (2) The number of instances of this type is relatively small so the model may fail to recognize the required textual inference skills.

Effect of Scene Contexts Finally, the vanilla character classifier behaves differently compared to the other models. Because it cannot make use of contexts within scenes, there is a performance gap on the *Inside-Mention* type (hence the drop on the *No Dep* type). However, it does not suffer from significant differential on the other types. The gap appears because Longformer-P and/or MR. BERT perform considerably better on this type.

Challenges of History Retrieval Our experiments show that the history dependency presents serious challenges for existing models. Finding the evidence from history scenes is a retrieval task (but without groundtruth). We applied a state-of-the-art model to retrieve the history scenes and conducted an additional human study to evaluate the results. Our study shows that on our identified cases with *Direct Dependency*, the top-3 results (from in total 20 candidates) of a state-of-the-art semantic search model only give a recall of 35.5%. The result confirms that our task requires further advances on semantic retrieval. The detailed task setting and our discussions can be found in Appendix F.

7 Conclusion

We present the first task and dataset for evaluating machine reading comprehension models for understanding characters in narratives. Based on linguistic, educational, and psychological theories, we proposed a new schema and conducted human studies to analyze the types of evidence and reasoning required in understanding characters. We design a new model architecture and conduct comprehensive experiments as a basis for future studies.

A A Detailed Survey of Related Work

In this section, we first give an in-depth analysis on the difference between narrative and synopsis, from both the empirical challenges in NLP studies and the linguistic theory from (Morrow, 1985). Then we provide detailed discussion on how we summarize related work in Table 8.

A.1 Background: Narrative versus Synopsis

As our work focuses on narrative comprehension, following setups like (Kočiskỳ et al., 2018; Kryściński et al., 2021; Chen et al., 2021), it is necessary to distinguish between comprehension of original narrative stories versus comprehension of their synopses (the human-written plot summaries), *e.g.*, from the story's Wikipedia page.

Narrative stories are told by creating scenes, with the goal of helping readers experience events as they occur in the plot, and empathize with the story characters in relation to their own experiences. To engage readers, story writers often use complex narrative clues (*e.g.*, character activities, event development, scenery changes); variable narrative sequences (*e.g.*, narrative, flashback, interpolation); and various linguistic expressions (*e.g.*, argument, lyricism, narrative, description, illustration). By comparison, a synopsis is a descriptive summary of the main idea of a story in plain language. It contains only the main characters, time, place, important plot points, and resolution, rather than allowing the story to unfold through the actions of the characters. The goal of the synopsis is to inform readers what happened with little or no original material from original story.

Therefore, comprehension of narrative stories requires more sophisticated skills to understand the complex chain of clues and expressions, in order to finally build a complete narrative representation from a sequence of individual scene comprehensions along with a developed understanding of characters' mental models (Morrow, 1985). In this light, a synopsis represents "processed results" from the application of these comprehension skills by a (experienced) human reader.

A.2 Background: Dialogue in Stories vs. Real-Life Conversation

Fictional dialogue canonically serves a purpose in a narrative. Either i contributes to the develop of a character or advances the plot (McHale, 2004). Nash proposed three categories of fictional dialogue: (1) confrontational dialogue which "includes challenges, quarrels, disputes, interviews, and any kind of personal encounter in which the participants are in covert or overt opposition to each other"; (2) instructional dialogue, which "conveys information about matters of science, technology, politics, world events, etc, some knowledge of which is essential to understanding the plot"; (3) collaborative dialogue that consists of "a series of exchanges which cumulatively present, for the reader's benefit, a picture of events, histories, personalities, and relationships" (Nash, 1990). Authors have total control of the fictional dialogue, and ideally it functions according to the author's intention at every part of the story (De Haan, 1996). However, real-life conversation is a joint action and is natural. There is no individual has whole control and the conversation goal of each party may be very different. Additionally, real-life conversations are temporally linear, such that communicators cannot revise earlier speech to fit a story. Moreover, real-life conversations tend to be highly implicit because spoken language derives much of its meaning from context (Warren, 2006).

A.3 Assessment of Narrative Comprehension

We summarize the related tasks people use for assessment of general narrative comprehension skills.

Cloze Test Cloze tests take a snippet of the original text with some pieces (usually entities) masked as blanks, with the goal of filling these blanks from a list of candidates. Cloze tests can be automatically constructed, resulting in an advantage in creation of large scale datasets. Examples of cloze tests for narrative comprehension assessments are BookTest (Bajgar et al., 2016) and (Ma et al., 2018). Both datasets are based on excerpts of books or scenes of TV shows. As the input consists only of short paragraphs, there is not sufficient information to infer complex character set via reading the stories. Therefore, these datasets address few questions related to the understanding of characters.[8]

Moreover, when built on short snippets, cloze tests are known to prone to mostly local inference but not much reasoning and commonsense

---

[8] There may be a possible confusion of these tasks and ours, as cloze tests also include filling in anonymous character names in the blanks. However, in these tasks, the required answers are also anonymized character IDs that appear in the inputs, and the IDs for the same character are random across different scenes. Therefore the character's information is not available for learning by design. In other words, their design of tasks *deliberately prevent* the task of character understanding.

Dataset	Task Format	Narrative Type		Assessed Narrative Comprehension Skills			Assessed Commonsense Knowledge		
		Source	Length	Plot Structures	Character Facts	Character ToMs	Concepts	Events/States	Story Flows
MCTest	Multi-choice QA	Short fiction (Children stories)	~20*	✓			✓	✓	✓
BookTest	Cloze test	Literature (Excerpt)	-	✓

Table 8: Properties of existing narrative comprehension datasets compared to TVSHOWGUESS . We organize the datasets according to the following dimensions related to narrative understanding: **Source** of the texts for reading comprehension; **Length** of the texts from the source that makes the task solvable, we report the numbers of sentences or utterances for books and scripts respectively; whether the task assesses the ability of understanding **plot structures** in the stories; whether the task assesses the ability of understanding basic **character facts** like personality, profession, etc; whether the task assesses the ability of building **character theory-of-mind (ToM)**; whether the task assesses the commonsense knowledge of **concepts**, **events** and **states**; and whether the task assesses the additional commonsense about the **narrative development**, including the knowledge about the coherence among non-verbal narratives and dialogues, and how they form the story/plot flow. * Numbers are not reported in the original paper so we calculated them from the dataset. †(Chen et al., 2017b) proposes two settings with single scene and the whole episode as inputs respectively. Different from ours, their include of episode is not to support the in-scene prediction with necessary history, but mostly increase the difficulty level of the co-ref task.

knowledge, as studies in the NLP community suggested (Chen et al., 2016). On the other hand, although our task also has form similar to cloze, it requires information about the characters from previous scenes, which is not only about understanding the characters, but also requires global inference across features of the story (see Figure 1).

Question Answering The most popular form of narrative comprehension evaluation is through question answering, starting from the early work of MCTest (Richardson et al., 2013), to the more recent crowd-sourced tasks like NarrativeQA (Kočiský et al., 2018), FriendsQA (Yang and Choi, 2019), TellMeWhy (Lal et al., 2021) and FairytaleQA (Xu et al., 2022).

Among them, the MCTest and TellMeWhy conduct multi-choice question answering on short stories. As above, te input consists of short paragraphs, so there is not sufficient information to infer complex character factes via reading the stories. Therefore, these datasets also cover few questions assessing the understanding of characters. The TellMeWhy has a specific focus on *why*-questions assessing the causal knowledge between states and events. The inputs are short stories from the ROCStories dataset (Mostafazadeh et al., 2016). MCTest covers a much wider set of reading skills, as it is based on complete stories, and generates questions with the goal of assessing children's reading comprehension over both story plots and commonsense.

NarrativeQA and FriendsQA conduct natural question answering tasks. NarrativeQA aims to infer free-form answers to questions about a specific book or movie script. According to the human study from (Mou et al., 2021), the major part of the dataset is event-centric questions, which queries the explicit plots from the original books thus do not require a significant amount of commonsense reasoning. The study also reveals that NarrativeQA consists of a small portion of character-related questions. These questions mainly query the simple facts of characters, such as age and profession. The more complexity character persona types, like personality, emotional/psychological status and history experience studied in our work, are not covered. Similar to NarrativeQA, FriendsQA is a QA task over TV show scripts. The dataset consists of six types of questions: *who, what, when, where, why*, and *how*. The *who* questions target on asking speaker names of utterance contents or participants of events, therefore are mainly assessing understanding of plot structures (*i.e.*, participant arguments of events).

Both NarrativeQA and FriendsQA have human-written questions with a reference of the plot summary, which require evidence explicitly exists in the original story texts, and thus do not have much requirement of reasoning. The FriendsQA questions are based on scene summaries, and thus require mostly local evidence; the NarrativeQA questions are based on the book-level summary, and thus sometimes require the ability to bridge the gap between coarse-grained and fine-grained event descriptions (*i.e.*, commonsense of sub-events).

Summarization There is a recent trend to evaluate model's understanding of stories via summarization, including NovelChapters (Ladhak et al., 2020), BookSum (Kryściński et al., 2021) and ScreenSum (Chen et al., 2021). These works provide a good research opportunity to future story reading research, by showing that book-level or chapter-level summarization is challenging to existing machine reading models. However, it is more difficulty to identify the specific required reading skills by these tasks, as there exist many factors beyond reading skills to generate a good summary, such as encoding and generating long narrative texts. Intuitively, story summarization is largely plot-related instead of character-related; and requires the knowledge to understand the story flow.

Interactive Fiction Game Playing Interactive fiction (IF) games (Hausknecht et al., 2019) have been proposed as a reinforcement learning task that requires understanding of narrative fiction stories as environment observations. Research work has successfully demonstrated that reading comprehension can provide helpful inductive biases for efficient policy learning (Guo et al., 2020); while Yao et al. (2021) also reveal the shortcomings of these games. The debate calls for future investigations to understand the necessary narrative elements and the roles they play in the IF games.

A.4 Character-Centric Prediction over Narratives

Our task can be seen as a character-centered understanding of the narrative, where the understanding of the character deepens the understanding of the story and makes the narrative engaging. There are limited studies on understanding characters' persona from reading stories. In this section we review some existing character-centric prediction tasks over narrative texts, and discuss the relations and differences.

Character Name Linking The task of coreference resolution for story characters (Chen and Choi, 2016; Chen et al., 2017b) is closely related to our TVSHOWGUESS. These coreference resolution focuses on identifying the characters mentioned in multiparty conversations from TV shows scripts. The goal of these tasks is to resolve the coreference of pronouns and character-indicating nominals (*e.g.*, *you* and *Mom*) **in dialogues** of the character names that appear in the local context. It also covers linking a named entity (*e.g.*, *Ross*) to the character, which is more on name matching instead of character understanding.

The task form of coreference resolution mainly requires the understanding of discourse relations. It does not assess the modeling of character theory-of-mind, especially the character's memories, as there are no predictions of character behaviors involved. The major character persona type it assesses is character facts, since the resolution of nominals requires the understanding of the target characters' occupations and relationships.

The lack of ToM modeling and complex reasoning of the coreference resolution task also makes it relatively easier – on `Friends` and `The Big Bang Theory`, a CNN model gives a $>$90% average accuracy. By comparison, our task, although solvable by humans with a $\sim$95% accuracy, is challenging to neural models as the best BERT-based model gives a $\sim$65% average accuracy on the same two shows with even smaller candidate sets.

Personality Prediction Our work is also related to the prediction of fiction characters' personality types by reading the stories (Flekova and Gurevych, 2015). Specifically, the tasks require to predict a fiction character's MBTI personality types (Myers and McCaulley, 1988) rooted in Jung's theory, based on the character's verbal and non-verbal narratives in the original stories. Compared to the aforementioned character-centric prediction tasks, these studies require to read and comprehend the original long stories, but the prediction task are relatively simpler since they only focus on personality which is a single perspective of persona.

A.5 Character-Centric Prediction over Non-Narratives

Character name linking between story synopses Recently Brahman et al. (2021) propose the LiSCU, which is a novel textual entailment task linking an anonymous summative descriptions of story character to the name appearing in the story's plot summary. Similarly to (Chen and Choi, 2016), the task assess the resolution of names and events instead of the ToM modeling. This is because the task does not involve much explicit behavior predictions, since the task form is entailment between two given statements rather than predicting the possibility of new contents. The usage of synopses over original stories reduces the challenges in narrative understanding; and further prevents the character comprehension from stories, as pointed out by (Kočiskỳ et al., 2018), the summaries themselves are humans' comprehension results of the stories.

Personalized Dialogue Generation Our work is also related to personalized dialogue generation, for which datasets (Mairesse and Walker, 2007; Walker et al., 2012; Zhang et al., 2018; Li et al., 2020) and models (Li et al., 2016; Mazaré et al., 2018; Qian et al., 2018; Zheng et al., 2020) are proposed for generating dialogues for speakers with persona features. These benchmarks usually cover a single aspect of the multi-dimensional persona (Moore et al., 2017). For example, `PERSONA-CHAT` (Zhang et al., 2018) focuses on personal facts such as "*I'm a writer*" and "*I live in Springfield*"; other works mainly focus on learning language styles from speakers' personality types, such as the Big Five traits of the extraversion personality in `PERSONAGE` (Mairesse and Walker, 2007), and the personality types derived from TV tropes (e.g. *jealous girlfriend*, *book doom*, *anti hero*) in `ALOHA` (Li et al., 2020).

`LIGHT` (Urbanek et al., 2019) is a crowd-sourced dataset for text game adventure research. It includes natural language descriptions of fantasy locations, objects and their affordances, characters and their personalities, dialogue and actions of the characters. The biggest difference between ours and LIGHT is that LIGHT is based on the local environment of the conversation, rather than on a story. Examples from the LIGHT dataset are independent conversations and the context in which they occur. Crowd workers created the dialogues of characters by a given setting and a persona. The persona is modeled by the Persona-Chat dataset which is defined as a set of three to five profile sentences describing their personal facts such as "*I am a part of a group of travelers*" and "*I go from town to town selling food to the locals*".

To the best of our knowledge, none of the existing studies cover a comprehensive multi-dimensional persona similar to our work, especially with respect to how a character's past experience builds her ToM.

Authorship Attribution Finally, authorship attribution has parallel ideas to our task, insofar as it aims at guessing author identities from the texts they wrote (Ni et al., 2019; Andrews and Bishop, 2019; Bevendorff et al., 2020) and thus requires a certain degree of author profiling. These tasks differ from ours because the reviews, tweets or fandoms under the same authors do not usually form consecutive plotlines. Therefore, the tasks mainly require to understand the authors' writing styles rather than building mental models from the their past experiences. From this perspective, this direction is in fact more closely related to stylistic analysis in narrative understanding (Vishnubhotla et al., 2019), rather than character understanding.

B Supplementary for the Dataset Analysis

B.1 Summary of the Annotation Schema

We include a summary of our annotation schema in Figure 6.

B.2 Examples of Each Evidence Types

Linguistic Style

Background: (from `TBBT`) *[Amy's car]*
Candidates: *{Leonard, Penny, Sheldon, Amy}*
P0: *Whatever. You can't even go on a date without checking your relationship agreement.*
P1: *If you've got a problem basing a relationship on a contract, I'd like to tell you about 13 plucky colonies that entered a relationship agreement called the U.S. Constitution. And it may not be cool to say so, but I think that love affair is still pretty hot today.*
Answer: P1 → *Leonard*
Rationale: (Shelton's language is characterized by the use of long, difficult sentences and references to historical stories.)

Personality

Background: (from `TBBT`) *[The cafeteria]*
Candidates: *{Leonard, Howard, Sheldon, Raj}*
P0: *And you love the sound of your own voice.*
P1: *Yeah, well, of course I do. Listen to it. It's like an earful of melted caramel.*
Answer: P1 → *Sheldon*
Rationale: (Sheldon is a self-centered person so he will praise his own voice.)

Memory

Background: (from `TBBT`) *[The stairwell]*
Candidates: *{Leonard, Penny}*
P0: *There's something I wanted to run past you.*
P1: *What's up?*
P0: *Mm, the guys and I were thinking about investing in Stuart's comic book store. Is that okay?*
P1: *Why are you asking me?*
Answer: P0 → *Leonard*
Rationale: (In a previous scene, Leonard and his friends discussed about investing in Stuart's store, so he is the only one between the two who has this memory.)

Fact

Evidence Type		Description
Linguistic style		Linguistic style refers to a character's individualized speech pattern. It consists of a selection of linguistic features such as vocabulary, syntactic patterns, rhythm, and tone. It also includes the use of elements such as direct or indirect, metaphor and irony.
Personality		Personality is a person's stable attitude toward objective facts and the habitual way of behavior that is compatible with it. We adopt a wider definition of personal traits as in (Li et al., 2020).
Fact	Attributes	Fact of a character's attributes in the TV series setting, such as race, profession, education level etc.
	Relations	A character's relationship with others that truly exist in the TV series setting, including both social relations and drama role relations.
	Status	Facts of a character's temporal emotional or psychological status in the time period when the scene happens.
Memory		The episodic memory about history events a character has in the previous show scenes. This also includes a rare case of a knowledge fact (i.e. the semantic memory) a character acquires from history scenes, which cannot be inferred from the facts of the character.
Inside-scene	Background	The character's identity can be inferred from the background introduction of scene, or from the description of the other characters' words.
	Mention	The character's name or alias is called by the other people.
Exclusion		The character's identity can be determined from the presence of characters in the scene and the other resolved characters.

Figure 6: The definitions of evidence types.

- Attribute

Background: (from `TBBT`) *[Amy's lab]*
Candidates: *{Amy, Penny}*
P0: *Hey. Ready to go to lunch?*
P1: *Just give me a minute. I'm stimulating the pleasure cells of this starfish. I just need to turn it off.*
Answer: P1 → *Sheldon*
Rationale: (Sheldon is Amy's boyfriend. After identify P0 is Amy, based on the relationship between Amy and Sheldon, P1 can be identified as Sheldon.)

- Relationship

Background: (from `TBBT`) *[Amy's lab]*
Candidates: *{Amy, Penny, Sheldon}*
. . .
P0: *Hey, boyfriend.*
P1: *Can't talk. Spitball. Probably gonna die.*
Answer: P1 → *Sheldon*
Rationale: (Sheldon is Amy's boyfriend. After identify P0 is Amy, based on the relationship between Amy and Sheldon, P1 can be identified as Sheldon.)

- Status

Background: (from `TBBT`) *[The pub]*
P0: *So when do you guys plan on getting married?*
P1: *Uh, we're not sure. But I want to wait long enough to prove to my mother I'm not pregnant.*
P2: *May I have one of your fries?*
P1: *Of course. Can I have a bite of your burger?*
P2: *Absolutely not.*
P3: *Some perfect couple. He won't even share his food with her.*
Answer:P3 → *Leonard*
Rationale: (The aforementioned failure to determine Leonard's marriage led him to ridicule couples in harmonious relationships.)

- Background

Background: (from `TBBT`) *[Penny's apartment]*
Candidates: *{Amy, Penny}*
Bernadette: *Nah, you got this. Let's go for a drink.* ***I'll call Amy***.
P0: *Okay, good. She seemed like she really wanted to go out tonight.*
P1 (phone ringing, running down stairs from outside penny's door): *Hey, girl.*
Answer: P1 → *Amy*
Rationale: (Bernadette said she will call Amy and P1 is the person who answers the phone.)

- Mention

Background: (from `TBBT`) *[The apartment]*
Candidates: *{Raj, Leonard, Sheldon, Amy}*
P0: *Mmm, I love how they put a waterfall at centre field. It really ties the whole stadium together.*
P1: *This is fun, huh? We get to see our friend throw out the first pitch, have a hot dog, watch the game.*
P2: *Whoa. Nobody said anything about watching the game.*
P3: ***Sheldon***, *what did you expect?*
Answer: P2 → *Sheldon*
Rationale: (P3 mentioned the name of the person being questioned which is "Sheldon")

Inside-Scene

Exclusion

Background: (from `Friends`) *[Scene: Outside the Janitor's Closet, there are people having s*x and Mr. Geller is trying to give them some pamphlets.]*
Candidates: *{Monica, Chandler}*
Mr. Geller: *Kids, I spoke to a doctor and picked up this pamphlets on how to get pregnant. (He slides them under the door.*
P0: *(walking by with Chandler.) Hey dad!*
P1: *Hey.*
Mr. Geller: *(pause) Sorry to bother you again, but could you pass my pamphlets back? (They do so.) Thank you.*
Answer: P1 → *Chandler*
Rationale: (Monica is Mr. Geller's daughter. P0 called Mr. Geller dad so she is Monica. There are only two candidate so the other one is Chandler)

C Extended Study of Required Reasoning Types on our TVShowGuess

This section provides an in-depth analysis of the types of reasoning used to infer evidence when guessing characters.

C.1 Our Annotation Schema of Reasoning Types

We define the following reasoning types with examples provided. A summary of our annotation schema of reasoning types can be found in Figure 7.

Multi-hop on Characters Reasoning on the basis of other characters that have already been guessed. Using the already guessed character as a bridge, users can employ history event or the relationship between characters to make guesses about the target character.The difference between multi-hop character and exclusion is that after identifying the other characters, the exclusion technique relies only on the list of characters provided for guessing, however, multi-hop character reasoning requires additional evidence such as relationship to infer the target character.

Background: (from `TBBT`) *[Angels Stadium]*
Candidates: *{Raj, Leonard, Sheldon, Amy}*
P5: *Hey, I hear you're a dermatologist.*
Emily: *Uh, yeah, I'm a resident at Huntington Hospital.*
...
P5: *I have some odd freckles on my buttocks. Can I make an appointment for you to look at them?*
Emily: *Um, okay, I guess.*
P0: *I'm with him three years, nothing. She's with him two minutes, and he's taking his pants off.*
Answer: P0 → ***Amy***
Rationale: (Using P5 (Sheldon) as a bridge and the couple relationship between Amy and him, we can identify P0 is Amy.)

Multi-hop on Textual Evidence Some evidences are not directly presented in the scene but can be inferred from the descriptions of context and dialogues. Using the inferred evidences as bridges people can multihop over personality, or fact, or event inferred from the text to guess the characters.

Background: (from `TBBT`) *[The apartment]*
Candidates: *{Amy, Leonard, Raj, Howard', Penny, Sheldon}*
Bernadette: *I like your suit.*
P0: *Oh, thanks. Got a couple new outfits for work.*
P1: *How does it feel knowing your fiancée's job is to go out and flirt with doctors, looking like that, while you sit here, you know, looking like this?*
...
Answer: P0 → *Penny*
Rationale: (P0 has a new job can be inferred from the textual evidence "Got a couple new outfits for work". Plus we know that Penny has a new job, we can determine that P0 is Penny)

Commonsense of Concepts/Events Task requires additional commonsense knowledge of attributes of daily concepts or social events, or their relations including causal/effect relations between an event and a social state or social relation. We restrict this category to be the aforementioned commonsense knowledge types, to distinguish from other relatively under-studied commonsense knowledge, such as the commonsense of dialogue flow required to work with our inside-scene evidence defined in Figure 6.

Background: (from `TBBT`) *[Capital Comics]*
Candidates: *{Howard, Sheldon}*
...
P0: *I know that if I had a wife or a fiancée, I'd ask her first before I invested money in a comic book store.*
P1: *He's right.*
Answer: P1 → *Howard*
Rationale: (A married or engaged person will answer "He's right". Howard is married.)

Default Conjunction A single piece of evidence will not solve this task; a combination between multiple pieces of evidence is needed to identify the person.

C.2 Analysis of the Human Annotation

Correlation between the Human Annotated Schema Categories Figure 2 visualizes the flow between (a) evidence types and the dependency of history and (b) evidence types and the reasoning types. Most evidence types correlate with history dependency. Personality and history dependency are most closely related. Default conjunction is the reasoning type that accounts for the largest percentage.

C.3 Experiments: Performance Decomposition on the Reasoning Types

We further studied the impact of the required reasoning types on the performance (the right column

Reasoning Type	**Description**
Default Conjunction	No single piece of evidence can solve the task, hence the conjunction among multiple pieces of evidence is required. This is the default reasoning type if there are multiple evidence types labeled but no other reasoning types are labeled.
Multihop-Character	Task needs to be solved with the guessing results of other characters, then using the target person relation to or memory about the guessed ones to make the answer, *i.e.*, multihop with guessed characters as bridges.
Multihop-Textual	Task needs to be solved with the persona/fact/event not directly described in the scene but can be inferred from the context, *i.e.*, multihop over persona/fact/event inferred from dialog and scene context.
Commonsense attributes/relations of concepts/events	Task requires additional commonsense knowledge of attributes of daily concepts or social events, or their relations like causal relations between events. Those refer to the specific types of commonsense covered in ConceptNet- or Atomic-style KBs.

Figure 7: The definitions of reasoning types.

Reasoning Type	Friends(%)	TBBT(%)
Default	16.56	28.48
Multihop(Character)	3.97	13.91
Multihop(Textual)	5.30	5.30
Commonsense	4.64	0.66
No Complex Reasoning	69.54	51.66

Table 9: Percentage of the required reasoning types in the two TV shows, `Friends` and `The Big Bang Theory`.

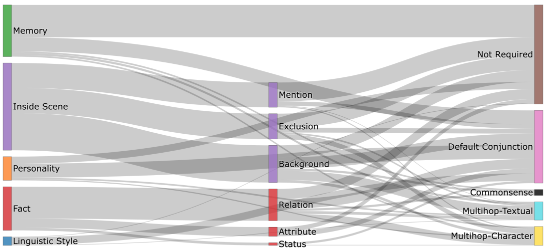

Figure 8: Visualization of the flow from the required evidence types to their required reasoning types.

in Figure 9). In general there is a clear gap (on average ∼10%) between cases that require complex reasoning and those that do not. The *Multihop-Textual* type is most challenging, because it requires both deep understanding of what the texts implies and multihop reasoning. There is not a clear performance difference between *Multihop-Character* and *Default Conjunction*, though the former is conceptually harder. We surmise this is because both types are beyond the reasoning ability of the model so the predictions largely rely on fuzzy matching of evidence – recall that we predict identities of main characters, so there can be a statistical bias of their context co-occurrence. The results on the *Commonsense* type fluctuate due to the relatively smaller ratio.

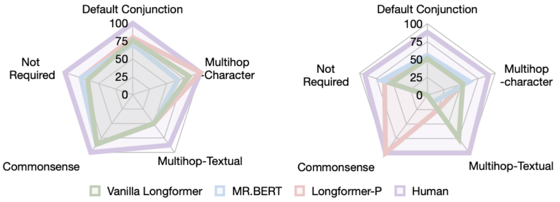

Figure 9: Performance breakdown according to our reasoning schema (left: Friends, right: The Big Bang Theory).

E Examples of Human Errors

Table 11 provides an example of unsolvable cases and Table 12 provides an example of human mistakes. The human mislabeled characters are marked as red.

We further provide all the scene IDs on which our human tester makes incorrect predictions in Table 10.

F Details of Human Study and Discussions on the Challenges of History Retrieval

Our experiments show that the history dependency challenges existing models. Finding the evidence

Unsolvable Case

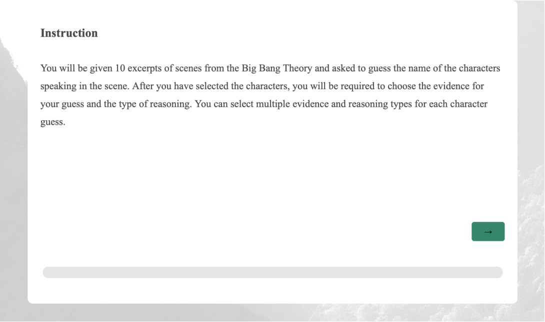
08x02 4882
Background: (from `TBBT`) *[the Apartment]*
Candidates: *{Howard, Sheldon, Raj, Amy, Leonard, Penny}*
P0 : I recently read that during World War Two, Joseph Stalin had a research program to create supersoldiers by having women impregnated by gorillas.
P1 : What a sick use of science.
P2 : Hey, as long as the baby's healthy.
P3 : I wonder if Stalin considered any other animals.
P4 : Hippos are the deadliest creature. A half-human, half-hippo soldier would be pretty badass.
P1 : Yes, but when they're hungry-hungry, you can stop them with marbles.
P0 : Yeah, the correct animal for interspecies supersolider is koala. You would wind up with an army so cute it couldn't be attacked.
P2 : But half-man, half-owl could fly...
P0 : The answer is cuddly soldiers with big flat noses. Moving on.
P1 : So, Penny, when's the new job start?
P5 : Next Monday.
Bernadette : Did you get a chance to look over the materials I gave you?
P5 : Uh, not yet, but I will.
Bernadette : Great. When?
P5 : I said I'll get to it.
P0 : I'm sensing awkwardness, am I right?
P3 : Yes.
P0 : Swish.
Bernadette : I don't want to be pushy, but you've never done pharmaceutical sales before. It seems like you could use this time to get a head start.
P5 : Well, the first few weeks will be all training. They'll tell me everything I need to know.
Bernadette : But imagine how impressed they'd be if you showed up already familiar with the material.
P5 : Okay, so what, you want me to be like a teacher's pet?
Bernadette : Couldn't hurt.
P4 : Mm, I don't know. Who here has ever been hurt because they were the teacher's pet?
P0 : It was like the rest of the class wanted Ms. McDonald to forget the quiz.
Answer: P0: Sheldon, P1: Howard, P2: Raj, P3: Amy, P4: Leonard, P5: Penny

Table 11: Example of unsolvable case.

Mistake

08x04 4921
Background: (from `TBBT`) *[Penny's partment]*
Candidates: *{Raj, Penny}*
P0 : I'm so glad we could work this all out.
P1 : Yeah, me, too.
Emily : You know, we should have dinner one night with you and Leonard.
P1 : Oh, we would love that.
P0 : Great.
background : (both chuckle)
P1 : Okay, good night, guys.
Emily : All right, night.
P1 : Bye.
Emily and Penny (simultaneously) : I hate her.
Answer: P0: Raj, P1: Penny

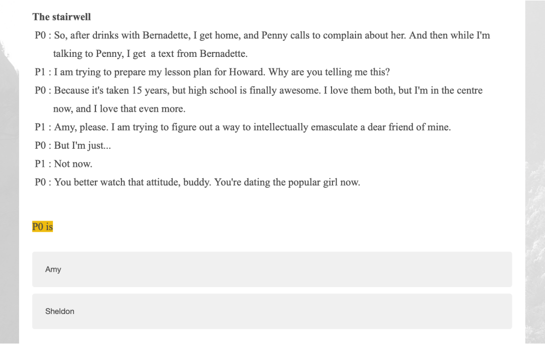
Table 12: Example of mistake.



Instruction

You will be given 10 excerpts of scenes from the Big Bang Theory and asked to guess the name of the characters speaking in the scene. After you have selected the characters, you will be required to choose the evidence for your guess and the type of reasoning. You can select multiple evidence and reasoning types for each character guess.

(a) Introduction page of human study.



The stairwell

P0 : So, after drinks with Bernadette, I get home, and Penny calls to complain about her. And then while I'm talking to Penny, I get a text from Bernadette.
P1 : I am trying to prepare my lesson plan for Howard. Why are you telling me this?
P0 : Because it's taken 15 years, but high school is finally awesome. I love them both, but I'm in the centre now, and I love that even more.
P1 : Amy, please. I am trying to figure out a way to intellectually emasculate a dear friend of mine.
P0 : But I'm just...
P1 : Not now.
P0 : You better watch that attitude, buddy. You're dating the popular girl now.

P0 is

(d) Task 3: identifying used reasoning types .

Figure 10: interfaces of human studies.

history scenes for such cases is essentially a retrieval task (but without groundtruth). To see how it brings new challenges to existing semantic search, we applied a state-of-the-art model to retrieve the history scenes and conducted an additional human study to evaluate the results.

Task We conduct the study on scenes in our human annotation sets that have the *Memory* type labeled. With each scene as a query, we retrieve from a window of 20 previous scenes with a state-of-the-art model[9] The window size is decided so as to guarantee that at least one required memory appears in the window, according to our human annotation process. The task of human study is to recognize whether the top-3 returned scenes contain at least one related history scene.

Results The same annotators working on the study in Section 4 evaluated the retrieved scenes. Results show that the recall of the top-3 results from this state-of-the-art model is low (35.5%). This difficulty in scene retrieval may arise from: (1) the queries are scenes with structures, which leads to different query formats from standard IR tasks; (2) many relevant scenes are dissimilar to the query scenes in the semantic space, but associated with the query in specific aspects or even analogous to the query scene; (3) some scenes require multi-hop retrieval, especially when combined with ToM modeling (reasoning about what others know).

All these challenges are non-trivial, and calls for further studies on semantic search to address.

G Model Checklist

We implement our baselines based on HuggingFace Transformers.[10] We use the pre-trained `allenai/longformer-base-4096` and `bert-base-uncased` models. We train all the models with the Adam optimizer.

We train our model on a single V100 GPU. It takes around 1 hour and 40 minutes to train a Longformer-based model. It takes around 2 hour and 10 minutes to train a multi-row BERT model. For all the models, we train in total 40 epochs. But the models usually converge in less than 20 epochs.

Hyperparameters We set the number of rows in MR. BERT to 12, to maximize the usage of GPU memory. We set the maximum length of Longformer to 2000, which can handle the lengths of most of the input scenes. The window size is set to 256. We set the learning rate to 2e-5.

We report our result with a single run. However, for each model we run twice; and we found the average development accuracy varies less than 0.5%.

---

[9] We use the `all-mpnet-base-v2` model from https://sbert.net/ that reports the top-1 performance on 14 sentence embedding tasks and 6 semantic search tasks.

Causal Distillation for Language Models

Zhengxuan Wu*¶, Atticus Geiger*¶, Joshua Rozner, Elisa Kreiss, Hanson Lu

Thomas Icard, Christopher Potts, Noah D. Goodman

Stanford University
{wuzhengx, atticusg}@stanford.edu

Abstract

Distillation efforts have led to language models that are more compact and efficient without serious drops in performance. The standard approach to distillation trains a student model against two objectives: a task-specific objective (e.g., language modeling) and an imitation objective that encourages the hidden states of the student model to be similar to those of the larger teacher model. In this paper, we show that it is beneficial to augment distillation with a third objective that encourages the student to imitate the *causal* dynamics of the teacher through a *distillation interchange intervention training objective* (DIITO). DIITO pushes the student model to become a *causal abstraction* of the teacher model – a faithful model with simpler causal structure. DIITO is fully differentiable, easily implemented, and combines flexibly with other objectives. Compared against standard distillation with the same setting, DIITO results in lower perplexity on the WikiText-103M corpus (masked language modeling) and marked improvements on the GLUE benchmark (natural language understanding), SQuAD (question answering), and CoNLL-2003 (named entity recognition).

1 Introduction

Large pretrained language models have improved performance across a wide range of NLP tasks, but can be costly due to their large size. *Distillation* seeks to reduce these costs while maintaining performance by training a simpler student model from a larger teacher model (Hinton et al., 2015; Sun et al., 2019; Sanh et al., 2019; Jiao et al., 2019).

Hinton et al. (2015) propose model distillation with an objective that encourages the student to produce output logits similar to those of the teacher while also supervising with a task-specific objective (e.g., sequence classification). Sanh et al. (2019), Sun et al. (2019), and Jiao et al. (2019) adapt this method, strengthening it with additional supervision to align internal representations between the two models. However, these approaches may push the student model to match all aspects of internal states of the teacher model irrespective of their *causal* role in the network's computation. This motivates us to develop a method that focuses on aligning the *causal* role of representations in the student and teacher models.

We propose augmenting standard distillation with a new objective that pushes the student to become a *causal abstraction* (Beckers and Halpern, 2019; Beckers et al., 2020; Geiger et al., 2021a) of the teacher model: the simpler student will faithfully model the causal effect of teacher representations on output. To achieve this, we employ the *interchange intervention training* (IIT) method of Geiger et al. (2021b). The *distillation interchange intervention training objective* (DIITO) aligns a high-level student model with a low-level teacher model and performs *interchange interventions* (swapping of aligned internal states); during training the high-level model is pushed to conform to the causal dynamics of the low-level model.

Figure 1 shows a schematic example of this process. Here, hidden layer 2 of the student model (bottom) is aligned with layers 3 and 4 of the teacher model. The figure depicts a single interchange intervention replacing aligned states in the left-hand models with those from the right-hand models. This results in a new network evolution that is shaped both by the original input and the interchanged hidden states. It can be interpreted as a certain kind of counterfactual as shown in Figure 1: what would the output be for the sentence "I ate some ⟨`MASK`⟩." if the activation values for the second token at the middle two layers were set to the values they have for the input "The water ⟨`MASK`⟩ solid."? DIITO then pushes the student model to output the same logits as the teacher, i.e., matching the teacher's output distribution under

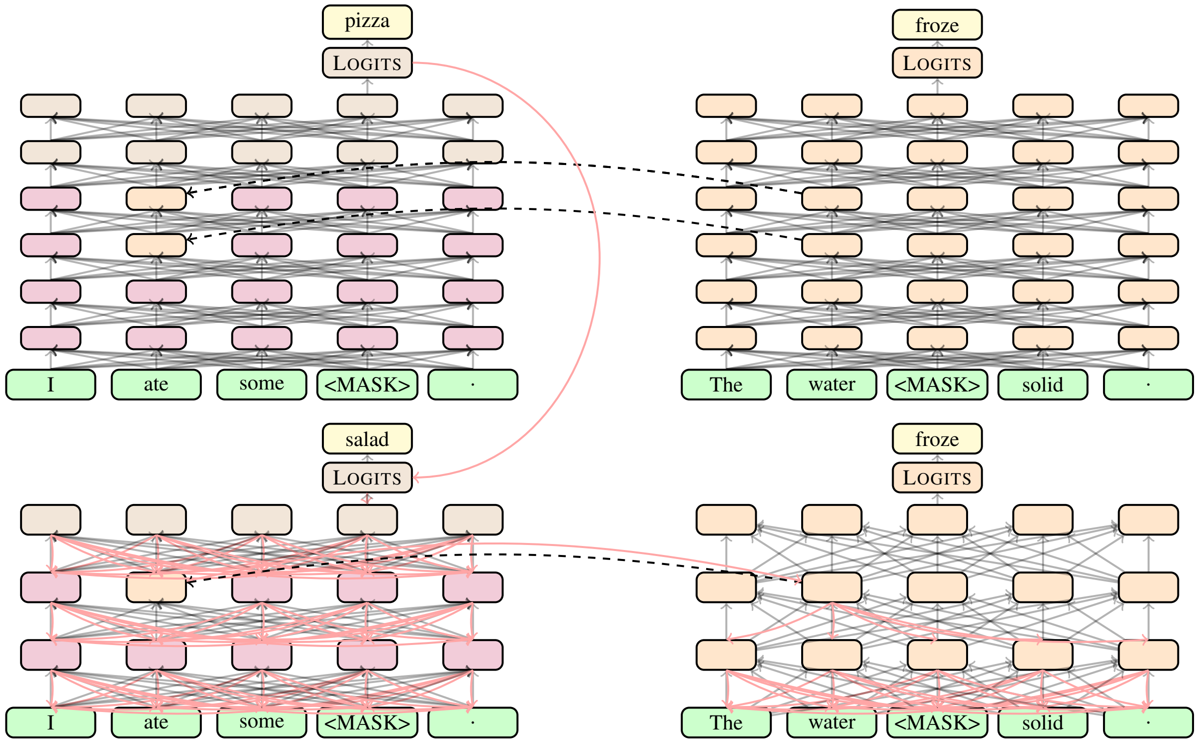

Figure 1: An IIT update in the context of masked language modelling (MLM). The teacher network (top) has 6 layers and the student (bottom) has 3 layers, and we align layer 2 in the student with layers 3–4 in the teacher. Solid lines are feed-forward connections, red lines show the flow of backpropagation, and dashed lines indicate interchange interventions. In this case, the student originally predicted the token "salad" under the interchange intervention, while the teacher predicted the token "pizza" under an aligned interchange intervention. DIITO trains the student to minimize the divergence between the student logits and the teacher logits under the interchange intervention. This updates the student to conform to causal dynamics of the teacher.

the counterfactual setup.

To assess the contribution of distillation with DIITO, we begin with $\text{BERT}_{\text{BASE}}$ (Devlin et al., 2019) and distill it under various alignments between student and teacher while pretraining on the WikiText-103M corpus (Merity et al., 2016) achieving -2.24 perplexity on the MLM task compared to standard DistilBERT trained on the same data. We then fine-tune the best performing distilled models and find consistent performance improvements compared to standard DistilBERT trained with the same setting on the GLUE benchmark (+1.77%), CoNLL-2003 name-entity recognition (+0.38% on F1 score), and SQuAD v1.1 (+2.46% on EM score).

2 Related Work

Distillation was first introduced in the context of computer vision (Hinton et al., 2015) and has since been widely explored for language models (Sun et al., 2019; Sanh et al., 2019; Jiao et al., 2019). For example, Sanh et al. (2019) propose to extract information not only from output probabilities of the last layer in the teacher model, but also from intermediate layers in the fine-tuning stage. Recently, Rotman et al. (2021) adapt causal analysis methods to estimate the effects of inputs on predictions to compress models for better domain adaptation. In contrast, we focus on imbuing the student with the causal structure of the teacher.

Interventions on neural networks were originally used as a structural analysis method aimed at illuminating neural representations and their role in network behavior (Feder et al., 2021; Pryzant et al., 2021; Vig et al., 2020; Elazar et al., 2021; Giulianelli et al., 2020; Geiger et al., 2020, 2021a). Geiger et al. (2021b) extend these methods to network optimization. We contribute to this existing research by adapting intervention-based optimization to the task of language model distillation.

3 Causal Distillation

Here, we define our distillation training procedure. See Algorithm 1 for a summary.

GetVals. The GetVals operator is an activation-value retriever for a neural model. Given a neural model $\mathcal{M}$ containing a set of neurons $\mathbf{N}$

Algorithm 1 Causal Distillation via Interchange Intervention Training

```
Require: Student model $\mathcal{S}$, teacher model $\mathcal{T}$, student output neurons $\mathbf{N}^{\mathbf{y}}_{\mathcal{S}}$, alignment $\Pi$, shuffled training dataset $\mathcal{D}$.
$\mathcal{S}$.train()
$\mathcal{T}$.eval()
$\mathcal{D}'$ = random.shuffle($\mathcal{D}$)
$\mathbf{N}^{\mathbf{y}}_{\mathcal{T}} = \Pi(\mathbf{N}^{\mathbf{y}}_{\mathcal{S}})$
while not converged do
  for $\{\mathbf{x}_1, \mathbf{y}_1\}, \{\mathbf{x}_2, \mathbf{y}_2\}$ in iter($\mathcal{D}$, $\mathcal{D}'$) do
    $\mathbf{N}_{\mathcal{S}}$ = sample_student_neurons()
    $\mathbf{N}_{\mathcal{T}} = \Pi(\mathbf{N}_{\mathcal{S}})$
    with no_grad:
      $\mathcal{T}_a = \textsc{SetVals}($
        $\mathcal{T}, \mathbf{N}_{\mathcal{T}}, \textsc{GetVals}(\mathcal{T}, \mathbf{x}_1, \mathbf{N}_{\mathcal{T}}))$
      $o_{\mathcal{T}} = \textsc{GetVals}(\mathcal{T}_a, \mathbf{x}_2, \mathbf{N}^{\mathbf{y}}_{\mathcal{T}})$
    $\mathcal{S}_a = \textsc{SetVals}($
      $\mathcal{S}, \mathbf{N}_{\mathcal{S}}, \textsc{GetVals}(\mathcal{S}, \mathbf{x}_1, \mathbf{N}_{\mathcal{S}}))$
    $o_{\mathcal{S}} = \textsc{GetVals}(\mathcal{S}_a, \mathbf{x}_2, \mathbf{N}^{\mathbf{y}}_{\mathcal{S}})$
    $\mathcal{L}^{\text{DIITO}}$ = get_loss($o_{\mathcal{T}}, o_{\mathcal{S}}$)
    Calculate $\mathcal{L}_{\text{MLM}}$, $\mathcal{L}_{\text{CE}}$, $\mathcal{L}_{\text{Cos}}$
    $\mathcal{L} = \mathcal{L}_{\text{MLM}} + \mathcal{L}_{\text{CE}} + \mathcal{L}_{\text{Cos}} + \mathcal{L}^{\text{DIITO}}$
    $\mathcal{L}$.backward()
    Step optimizer
end while
```

(an internal representations) and an appropriate input $\mathbf{x}$, $\textsc{GetVals}(\mathcal{M}, \mathbf{x}, \mathbf{N})$ is the set of values that $\mathbf{N}$ takes on when processing $\mathbf{x}$. In the case that $\mathbf{N}$ represents the neurons corresponding to the final output, $\textsc{GetVals}(\mathcal{M}, \mathbf{x}, \mathbf{N})$ is the output of model $\mathcal{M}$ when processing $\mathbf{x}$ (i.e., output from a standard forward call of a neural model).

SetVals. The SetVals operator is a function generator that defines a new neural model with a computation graph that specifies an intervention on the original model $\mathcal{M}$ (Pearl, 2009; Spirtes et al., 2001). $\textsc{SetVals}(\mathcal{M}, \mathbf{N}, \mathbf{v})$ is the new neural model where the neurons $\mathbf{N}$ are set to constant values $\mathbf{v}$. Because we overwrite neurons with $\mathbf{v}$ in-place, gradients can back-propagate through $\mathbf{v}$.

Interchange Intervention. An interchange intervention combines GetVals and SetVals operations. First, we randomly sample a pair of examples from a training dataset $(\mathbf{x}_1, \mathbf{y}_1), (\mathbf{x}_2, \mathbf{y}_2) \in \mathcal{D}$. Next, where $\mathbf{N}$ is the set of neurons that we are targeting for intervention, we define $\mathcal{M}^{\mathbf{x}_1}_{\mathbf{N}}$ to abbreviate the new neural model as follows:

$$\textsc{SetVals}\big(\mathcal{M}, \mathbf{N}, \textsc{GetVals}(\mathcal{M}, \mathbf{x}_1, \mathbf{N})\big) \tag{1}$$

This is the version of $\mathcal{M}$ obtained from setting the values of $\mathbf{N}$ to be those we get from processing input $\mathbf{x}_1$. The interchange intervention targeting $\mathbf{N}$ with $\mathbf{x}_1$ as the source input and $\mathbf{x}_2$ as the base input is then defined as follows:

$$\textsc{IntInv}(\mathcal{M}, \mathbf{N}, \mathbf{x}_1, \mathbf{x}_2) \overset{\text{def}}{=} \textsc{GetVals}(\mathcal{M}^{\mathbf{x}_1}_{\mathbf{N}}, \mathbf{x}_2, \mathbf{N}^{\mathbf{y}}) \tag{2}$$

where $\mathbf{N}^{\mathbf{y}}$ are the output neurons. In other words, $\textsc{IntInv}(\mathcal{M}, \mathbf{N}, \mathbf{x}_1, \mathbf{x}_2)$ is the output state we get from $\mathcal{M}$ for input $\mathbf{x}_2$ but with the neurons $\mathbf{N}$ set to the values obtained when processing input $\mathbf{x}_1$.

DIITO. DIITO employs $\mathcal{T}$ as the teacher model, $\mathcal{S}$ as the student model, $\mathcal{D}$ as the training inputs to both models, and Π as an alignment that maps sets of student neurons to sets of teacher neurons. For each set of student neurons $\mathbf{N}_{\mathcal{S}}$ in the domain of Π, we define DIITO loss as:

$$\mathcal{L}^{\text{DIITO}}_{\text{CE}} \overset{\text{def}}{=} \sum_{\mathbf{x}_1, \mathbf{x}_2 \in \mathcal{D}} \text{CE}_{\text{S}}\Big(\textsc{IntInv}(\mathcal{S}, \mathbf{N}_{\mathcal{S}}, \mathbf{x}_1, \mathbf{x}_2), \textsc{IntInv}(\mathcal{T}, \Pi(\mathbf{N}_{\mathcal{S}}), \mathbf{x}_1, \mathbf{x}_2)\Big) \tag{3}$$

where CE_{S} is the smoothed cross-entropy loss measuring the divergences of predictions, under interchange, between the teacher and the student model.

Distillation Objectives. We adopt the standard distillation objectives from DistilBERT (Sanh et al., 2019) (defined formally in Appendix A.1): $\mathcal{L}_{\text{MLM}}$ for the task-specific loss for the student model, $\mathcal{L}_{\text{CE}}$ for the loss measuring the divergence between the student and teacher outputs on masked tokens, and $\mathcal{L}_{\text{Cos}}$ for the loss measuring the divergence between the student and teacher contextualized representations on masked tokens in the last layer. Our final training objective for the student is a linear combination of the four training objectives reviewed above: $\mathcal{L}_{\text{MLM}}$, $\mathcal{L}_{\text{CE}}$, $\mathcal{L}_{\text{Cos}}$, and $\mathcal{L}^{\text{DIITO}}_{\text{CE}}$. In a further experiment, we introduce a fifth objective $\mathcal{L}^{\text{DIITO}}_{\text{Cos}}$ which is identical to $\mathcal{L}_{\text{Cos}}$, except the teacher and student are undergoing interchange interventions (see Appendix A.2 for details).

4 Experimental Set-up

We adapt the open-source Hugging Face implementation for model distillation (Wolf et al., 2020).[1] We distill our models on the MLM pretraining task (Devlin et al., 2019). We use large gradient

Table 1: Performance on the development sets of the WikiText, GLUE benchmark, CoNLL-2003 corpus for the name-entity recognition task, and SQuAD v1.1 for the question answering task. The score is the averaged performance scores with standard deviation (SD) for all tasks across 15 distinct runs. †Numbers are imputed from released models on Hugging Face (Wolf et al., 2020).

accumulations over batches as in Sanh et al. (2019) for better performance. Specifically, we distill all models for three epochs for an effective batch size of 240. In contrast to the setting of 4K per batch in BERT (Devlin et al., 2019) and DistilBERT (Sanh et al., 2019), we found that small effective batch size works better for smaller dataset. We weight all objectives equally for all experiments. With our new objectives, the distillation takes approximately 9 hours on 4 NVIDIA A100 GPUs.

Student and Teacher Models. Our two students have the standard BERT architecture, with 12 heads with a hidden dimension of 768. The larger student has 6 layers, the smaller 3 layers. Our pretrained teacher has the same architecture, except with 12 layers. Following practices introduced by Sanh et al. (2019), we initialize our student model with weights from skipped layers (one out of four layers) in the teacher model. We use WikiText for distillation to simulate a practical situation with a limited computation budget. We leave the exploration of our method on larger datasets for future research.

Alignment. Our teacher and student BERT models create columns of neural representations above each token with each row created by the feed-forward layer of a Transformer block, as in Figure 1. We define $L_{\mathcal{T}}$ and $L_{\mathcal{S}}$ to be the number of layers in the student and teacher, respectively. In addition, we define $\mathcal{S}_i^j$ and $\mathcal{T}_i^j$ to be the representations in the ith row and jth column in the student and teacher, respectively. An alignment Π is a partial function from student representations to sets of teacher representations. We test three alignments:

`FULL` Π is defined on all student representations: $\Pi(\mathcal{S}_i^j) = \{\mathcal{T}_{4i+k}^j : 0 \leq k < L_{\mathcal{T}}/L_{\mathcal{S}}\}$

`MIDDLE` Π is defined for the row $L_{\mathcal{S}} \mathbin{/\!/} 2$: $\Pi(\mathcal{S}_{L_{\mathcal{S}}/\!/2}^j) = \{\mathcal{T}_{L_{\mathcal{T}}/\!/2}^j\}$

`LATE` Π is defined on the student representations in the first and second rows: $\Pi(\mathcal{S}_1^j) = \{\mathcal{T}_{L_{\mathcal{T}}-2}^j\}$ and $\Pi(\mathcal{S}_2^j) = \{\mathcal{T}_{L_{\mathcal{T}}-1}^j\}$

For each training iteration, we randomly select one aligned student layer to perform the interchange intervention, and we randomly select 30% of token embeddings for alignment for each sequence. We experiment with three conditions with the `FULL` alignment: consecutive tokens (**$\text{DIITO}_{\texttt{FULL}}$**), random tokens (**$\text{DIITO}_{\texttt{FULL}}$+Random**) and masked tokens (**$\text{DIITO}_{\texttt{FULL}}$+Masked**). We also include $\mathcal{L}_{\text{Cos}}^{\text{DIITO}}$ to the `FULL` alignment (**$\text{DIITO}_{\texttt{FULL}}+\mathcal{L}_{\text{Cos}}^{\text{DIITO}}$**).

5 Results

Language Modeling. We first evaluate our models using perplexity on the held-out evaluation data from WikiText. As shown in Table 1, DIITO brings performance gains for all alignments. Our best result is from the `FULL` alignment with the $\mathcal{L}_{\text{Cos}}$ (**$\text{DIITO}_{\texttt{FULL}}+\mathcal{L}_{\text{Cos}}^{\text{DIITO}}$**), which has -2.24 perplexity compared to standard DistilBERT trained with the same amount of data.

GLUE. The GLUE benchmark (Wang et al., 2018) covers different natural language understanding tasks. We report averaged GLUE scores on the

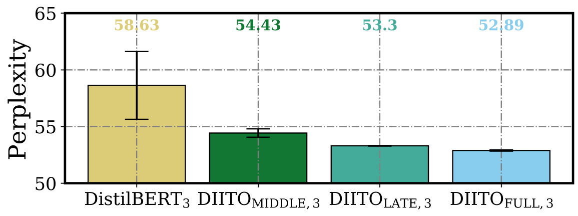

Figure 2: Perplexity score distribution for the development set of WikiText of models trained in a low-resource setting. The best model is the one with the richest alignment structure.

development sets by fine-tuning our distilled models in Table 1. Individual task performance scores for each GLUE task are included in Table 2 in the Appendix. The results suggest that distilled models with DIITO lead to consistent improvements over standard DistilBERT trained under the same setting, with our best result (**DIITO$_{\textsf{FULL}}$**+$\mathcal{L}^{\textbf{DIITO}}_{\text{Cos}}$) being +1.77% higher.

Named Entity Recognition. We also evaluate our models on the CoNLL-2003 Named Entity Recognition task (Tjong Kim Sang and De Meulder, 2003). We report accuracy and Macro-F1 scores on the development sets. We fine-tune our models for three epochs. Our best performing model (**DIITO$_{\textsf{MIDDLE}}$**) numerically surpasses not only standard DistilBERT (+0.38% on F1 score) trained under the same setting, but also its teacher, BERT$_{\text{BASE}}$ (+0.05% on F1 score). Though these improvements are small, in this case distillation produces a smaller model with *better performance*.

Question Answering. Finally, we evaluate on a question answering task, SQuAD v1.1 (Rajpurkar et al., 2016). We report Exact Match and Macro-F1 on the development sets as our evaluation metrics. We fine-tune our models for two epochs. DIITO again yields marked improvements (Table 1). Our best result is from the vanilla `FULL` alignment (**DIITO$_{\textsf{FULL}}$**), with +2.46% on standard DistilBERT trained under the same setting.

Low-Resource Model Distillation We experiment with an extreme case in a low-resource setting where we only distill with 15% of WikiText, keeping other experimental details constant. Our results suggest that DIITO training is also beneficial in extremely low-resource settings (Figure 2).

Layer-wise Ablation We further study the effect of DIITO training with respect to the size of the student model through a layer-wise ablation experiment. As shown in Figure 3, we compare GLUE performance for models trained with standard distillation pipeline and with DIITO training (**DIITO$_{\textsf{FULL}}$**). Specifically, we compute the averaged GLUE scores following the same procedure described in Section A.4. Our results suggest that DIITO training brings consistent improvements over GLUE tasks with smaller models booking the greatest gains.

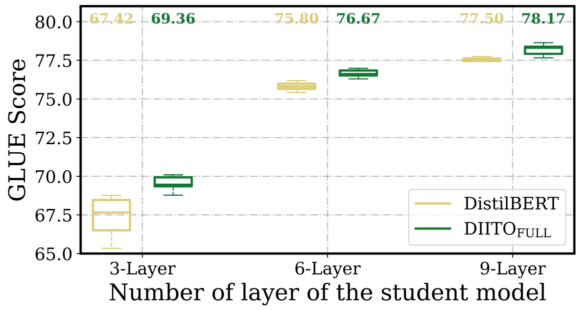

Figure 3: GLUE score distribution across 15 distinct runs of students in different sizes. Following the evaluation for BERT (Devlin et al., 2019). we exclude WNLI for evaluation.

6 Conclusion

In this paper, we explored distilling a teacher by training a student to capture the *causal dynamics* of its computations. Across a wide range of NLP tasks, we find that DIITO leads to improvements, with the largest gains coming from the models that use the richest alignment between student and teacher. Our results also demonstrate that DIITO performs on-par (maintaining 97% of performance on GLUE tasks) with standard DistilBERT (Sanh et al., 2019) while consuming 97% less training data. These findings suggest that DIITO is a promising tool for effective model distillation.

A Appendix

A.1 Standard Distillation Objectives

In our setting, our teacher model $\mathcal{T}$ is a BERT model, and our student model $\mathcal{S}$ is a shallower BERT model with fewer layers.

Assume that we randomly draw a training example $(\mathbf{x}_1, \mathbf{y}_1) \in \mathcal{D}$, where $\mathbf{x}_1$ is the input to our models and $\mathbf{y}_1$ is the corresponding ground truth (the token prediction at each masked position). We denote the model predictions (output logits) as $\mathcal{T}(\mathbf{x}_1)$ and $\mathcal{S}(\mathbf{x}_1)$. Additionally, we denote the contextualized representation for tokens for $\mathbf{x}_1$ at the last layer as $\text{BERT}_{\mathcal{T}}(\mathbf{x}_1)$ and $\text{BERT}_{\mathcal{S}}(\mathbf{x}_1)$.

We adopt the three standard distillation objectives of Sanh et al. (2019):

$\mathcal{L}_{\text{MLM}}$ The masked language modeling loss of the student model calculated over all examples using the cross-entropy loss as follows:

$$\sum_{\{\mathbf{x}_1,\mathbf{y}_1\}\in\mathcal{D}} \text{CE}(\mathcal{S}(\mathbf{x}_1), \mathbf{y}_1) \tag{4}$$

$\mathcal{L}_{\text{CE}}$ Following Hinton et al. (2015), the smoothed cross-entropy loss measuring the divergence between the student and teacher outputs as follows:

$$\sum_{\mathbf{x}_1\in\mathcal{D}} \text{CE}_{\text{S}}(\mathcal{S}(\mathbf{x}_1), \mathcal{T}(\mathbf{x}_1)) \tag{5}$$

$\mathcal{L}_{\text{Cos}}$ The cosine embedding loss defined in terms of the final hidden states of the teacher and the student as follows:

$$\sum_{\mathbf{x}_1\in\mathcal{D}} \text{Cos}(\text{BERT}_{\mathcal{S}}(\mathbf{x}_1), \text{BERT}_{\mathcal{T}}(\mathbf{x}_1)) \tag{6}$$

As a result, comparing to standard DistilBERT, DIITO essentially adds a new type of objective by pushing the student model to become a *causal abstraction* of the teacher model.

A.2 Causal Distillation Objectives

In addition to our causal loss $\mathcal{L}_{\text{CE}}^{\text{DIITO}}$, we also propose a new loss $\mathcal{L}_{\text{Cos}}^{\text{DIITO}}$ which is identical to $\mathcal{L}_{\text{Cos}}$ with interchange interventions. In this section, we provide a formal definition for $\mathcal{L}_{\text{Cos}}^{\text{DIITO}}$.

We denote our teacher and student models as $\mathcal{T}$ and $\mathcal{S}$ respectively. Using the notational conventions from Section 3, we use $\mathbf{N}_{\mathcal{T}}^{\mathbf{y}}$ and $\mathbf{N}_{\mathcal{S}}^{\mathbf{y}}$ to represent the neurons corresponding to the final output for each model. Likewise, we use $\mathbf{N}_{\mathcal{T}}^{L_{\mathcal{T}}}$ and $\mathbf{N}_{\mathcal{S}}^{L_{\mathcal{S}}}$ to represent the neurons representing contextualized representation for each token after the final BERT layer.

Assuming we randomly sample a pair of examples from a training dataset $(\mathbf{x}_1, \mathbf{y}_1), (\mathbf{x}_2, \mathbf{y}_2) \in \mathcal{D}$, we can then rewrite our causal loss $\mathcal{L}_{\text{CE}}^{\text{DIITO}}$ by rearranging Eqn. 2 and Eqn. 3 as follows:

$$\sum_{\mathbf{x}_1,\mathbf{x}_2\in\mathcal{D}} \text{CE}_{\text{S}}\Big(\text{GetVals}(\mathcal{M}_{\mathbf{S}}^{\mathbf{x}_1}, \mathbf{x}_2, \mathbf{N}_{\mathcal{S}}^{\mathbf{y}}), \text{GetVals}(\mathcal{M}_{\mathbf{T}}^{\mathbf{x}_1}, \mathbf{x}_2, \mathbf{N}_{\mathcal{T}}^{\mathbf{y}})\Big) \tag{7}$$

where $\mathcal{M}_{\mathbf{S}}^{\mathbf{x}_i}$ and $\mathcal{M}_{\mathbf{T}}^{\mathbf{x}_i}$ are derived as in Eqn. 1 for each model respectively. Crucially, Eqn. 7 can be regarded as the *causal* form of the standard smoothed cross-entropy loss with interchange intervention. Likewise, we can further define the $\mathcal{L}_{\text{Cos}}^{\text{DIITO}}$ as:

$$\sum_{\mathbf{x}_1,\mathbf{x}_2\in\mathcal{D}} \text{Cos}\Big(\text{GetVals}(\mathcal{M}_{\mathbf{S}}^{\mathbf{x}_1}, \mathbf{x}_2, \mathbf{N}_{\mathcal{S}}^{L_{\mathcal{S}}}), \text{GetVals}(\mathcal{M}_{\mathbf{T}}^{\mathbf{x}_1}, \mathbf{x}_2, \mathbf{N}_{\mathcal{T}}^{L_{\mathcal{T}}})\Big) \tag{8}$$

with adjusted interchange alignments for $\mathbf{N}_{\mathcal{T}}^{L_{\mathcal{T}}}$ and $\mathbf{N}_{\mathcal{S}}^{L_{\mathcal{S}}}$.

A.3 Evaluation Set-up

GLUE We fine-tune for 25 epochs for the smaller datasets (RTE and CoLA) and 3 epochs for the others. Following Devlin et al. (2019) and Sanh et al. (2019), we use Matthew's Correlation for CoLA, F1 for MRPC and QQP, Spearman correlation for STS-B, and accuracy for all the other tasks in GLUE.

A.4 Reproducibility

To foster reproduciblity and provide a fair comparison between methods, we distill BERT for each condition with three distinct random seeds. We then fine-tune each model with five distinct random seeds. Consequently, we report results aggregated from three distinct runs for the language modeling task, and 15 distinct runs for others.

Named Entity Recognition We follow the experimental set-up in the Hugging Face (Wolf et al., 2020) repository for evaluation for the CoNLL-2003 Named Entity Recognition task (Tjong Kim Sang and De Meulder, 2003). For fine-tuning, we set the learning rate to $5e^{-5}$ with an effective batch size of 32 for three epochs.[2]

---

[2] For DistilBERT performance in Table 1 on CoNLL-2003, we evaluate with a publicly avaliable model downloaded from `https://huggingface.co/delpart/distilbert-base-uncased-finetuned-ner`.

Table 2: Model performance results on the development sets of the GLUE benchmark. The GLUE score is the averaged performance scores across 15 distinct runs with precision aligned for a fair comparison. Following the evaluation for BERT (Devlin et al., 2019), we exclude WNLI for evaluation.

Question Answering We use the experimental set-up of Sanh et al. (2019) for evaluation on SQuAD v1.1 (Rajpurkar et al., 2016). For fine-tuning, we set the learning rate to $3e^{-5}$ with an effective batch size of 48 for two epochs. We set the stride to 128.

FNet: Mixing Tokens with Fourier Transforms

Abstract

We show that Transformer encoder architectures can be sped up, with limited accuracy costs, by replacing the self-attention sublayers with simple linear transformations that "mix" input tokens. Most surprisingly, we find that replacing the self-attention sublayer in a Transformer encoder with a standard, unparameterized Fourier Transform achieves 92-97% of the accuracy of BERT counterparts on the GLUE benchmark, but trains 80% faster on GPUs and 70% faster on TPUs at standard 512 input lengths. At longer input lengths, our FNet model is significantly faster: when compared to the "efficient Transformers" on the Long Range Arena benchmark, FNet matches the accuracy of the most accurate models, while outpacing the fastest models across all sequence lengths on GPUs (and across relatively shorter lengths on TPUs). Finally, FNet has a light memory footprint and is particularly efficient at smaller model sizes; for a fixed speed and accuracy budget, small FNet models outperform Transformer counterparts.[1]

1 Introduction

The Transformer architecture (Vaswani et al., 2017) has achieved rapid and widespread dominance in NLP. At its heart is a attention mechanism – an inductive bias that connects each token in the input through a relevance weighted basis of every other token. Many papers have prodded and probed the Transformer, and in particular the attention sublayers, in an effort to better understand the architecture; see, for example, Tenney et al. (2019); Vig and Belinkov (2019); Clark et al. (2019); Voita et al. (2019). Although potentially limited in their effectiveness (Hewitt and Liang, 2019), these probes generally back the intuition that, by allowing higher order units to form out of compositions of the input, Transformer models can flexibly capture diverse syntactic and semantic relationships.

In this work, we investigate whether simpler token mixing mechanisms can wholly replace the relatively complex self-attention layers in Transformer encoder architectures. We first replace the attention sublayer with two parameterized matrix multiplications – one mixing the sequence dimension and one mixing the hidden dimension. Seeing promising results in this simple linear mixing scheme, we further investigate the efficacy of faster, structured linear transformations. Surprisingly, we find that the Fourier Transform, despite having no parameters at all, achieves nearly the same performance as dense linear mixing and scales very efficiently to long inputs, especially on GPUs (owing to the $\mathcal{O}(N \log N)$ Fast Fourier Transform (FFT) algorithm). We call the resulting model FNet.

While Fourier Transforms have previously been used to approximate or speed up computations in Convolutional Neural Networks (El-Bakry and Zhao, 2004; Mathieu et al., 2014; Highlander and Rodriguez, 2015; Pratt et al., 2017; Lin et al., 2018; Chitsaz et al., 2020; Goldberg et al., 2020), Recurrent Neural Networks (Koplon and Sontag, 1997; Zhang and Chan, 2000; Zhang et al., 2018), Transformers (Choromanski et al., 2020; Tamkin et al., 2020), and MLP layers more generally (Cheng et al., 2015; Moczulski et al., 2016; Sindhwani et al., 2015), we believe our work is the first to wholly replace particular neural network sublayers with a Fourier Transform. This approach of viewing the Fourier Transform as a first class mixing mechanism is reminiscent of the MLP-Mixer (Tolstikhin et al., 2021) for vision, which replaces attention with MLPs; although in contrast to MLP-Mixer, FNet has no learnable parameters that mix along the spatial dimension.

Given the favorable asymptotic complexity of the FFT, our work also connects with the literature on "long sequence" or "efficient" Transformers,

July 10-15, 2022

which aim to make the attention mechanism scale better via sparsity patterns (Child et al., 2019; Qiu et al., 2020; Parmar et al., 2018; Beltagy et al., 2020; Ainslie et al., 2020; Zaheer et al., 2020; Wang et al., 2020; Tay et al., 2020b,a; Kitaev et al., 2020; Roy et al., 2021; Vyas et al., 2020; Liu et al., 2018) or via linearization of the attention matrix (Katharopoulos et al., 2020; Choromanski et al., 2021; Peng et al., 2021). As we will show in our experiments, while some of those works achieve $O(N)$ scaling of attention, this complexity often hides large constants, which make them less scalable in practice than FNet.

The contributions of our paper are:

- We show that simple linear transformations, including even (parameter-free) Fourier Transforms, along with standard MLPs in feed-forward layers, are competent at modeling diverse relationships in text. That such a simple linear transformation works at all is surprising, and suggests that, for at least some NLP problems, attention may not be the principal component driving the performance of Transformers.

- We introduce a new model, FNet, that uses the Fourier Transform as a mixing mechanism. FNet offers an excellent compromise between speed, memory footprint, and accuracy, achieving 92% and 97%, respectively, of the accuracy of BERT-Base and BERT-Large (Devlin et al., 2019) on the GLUE benchmark (Wang et al., 2018), while training 80% faster on GPUs and 70% faster on TPUs.

- We find that FNet hybrid models containing only two self-attention sublayers achieve $97-99\%$ of their BERT counterparts' accuracy on GLUE, while still running $40-70\%$ faster. This indicates that, while attention can improve accuracy, it may not be necessary to use in every layer.

- We demonstrate FNet scales very well to long inputs and offers a better compromise between speed and accuracy than the efficient Transformers evaluated on the Long-Range Arena (LRA) benchmark (Tay et al., 2021a). Specifically, FNet achieves accuracy comparable to the most accurate efficient Transformer architectures but is significantly faster at both training and inference than all of the evaluated Transformer architectures across all sequence lengths on GPUs. On TPUs, FNet is faster for relatively shorter sequence lengths; for longer sequences, the only efficient Transformers that are faster than FNet on TPUs are less accurate on the LRA benchmark. Based on this, we argue that rather than seeking more efficient approximations of the attention, there may be more value in seeking out completely new mixing mechanisms.

2 Related work

2.1 Fourier Transforms in neural networks

Fourier analysis features heavily in studies of the universal approximation properties of neural networks; see, for example, (Cybenko, 1989; Barron, 1993). In terms of practical applications, discrete Fourier Transforms (DFT), and in particular the Fast Fourier Transform (FFT), have been used to tackle signal processing problems such as fitting neural networks to FFTs of electrocardiogram signals (Minami et al., 1999; Gothwal et al., 2011; Mironovova and Bíla, 2015) and vibration signals (Zhang et al., 2013), or to evolve solutions of Partial Differential Equations (Li et al., 2021).

Because ordinary multiplication in the frequency domain corresponds to a convolution in the time domain, FFTs have been deployed in Convolutional Neural Networks to speed up computations, in Recurrent Neural Networks to speed up training and reduce exploding and vanishing gradients, and generally to approximate dense, linear layers to reduce computational complexity; see references cited in Section 1. DFTs have also been used indirectly in several Transformer works. The Performer (Choromanski et al., 2020) linearizes the Transformer self-attention mechanism by leveraging random Fourier features to approximate a Gaussian representation of the softmax kernel. In our work, rather than approximating attention, we replace attention with the Fourier Transform, which acts as an alternate hidden representation mixing mechanism. Tamkin et al. (2020) use spectral filters to generate hierarchical features, showing that the filtered embeddings perform well in different tasks (word-level, sentence-level or document-level), depending on which frequency scales are filtered. In contrast to FNet, they separate Fourier frequencies, rather than using the transform to combine features.

2.2 Modeling semantic relations via attention

Attention models have achieved state of the art results across virtually all NLP tasks and even some image tasks (Dosovitskiy et al., 2021). This success is generally attributed to the flexibility and capacity of attention. Although some works (Ramsauer et al., 2021) have endeavoured to gain a deeper understanding of attention, the pervasive intuition is that the success of attention models derives from the token-dependent attention patterns in different layers; see, for example, (Tenney et al., 2019). However, it is natural to ask: Do we really need the flexibility, and associated cost, of attention?

Tay et al. (2020a) empirically investigated the importance of the dot product operation in the attention mechanism in their Synthesizer model (related to our "Linear" baseline below). They find that learnt token-dependent attention weights are highly expressive, but not necessarily crucial for realizing accurate NLP models. You et al. (2020) replace attention weights in the Transformer encoder and decoder with unparameterized Gaussian distributions, showing minimal performance degradation provided they retain learnable cross-attention weights. Similarly, Raganato et al. (2020) find little to no accuracy degradation when replacing all but one of the attention heads of each attention layer in the *encoder* with fixed, non-learnable positional patterns. Finally, Tolstikhin et al. (2021) present MLP-Mixer, where attention is replaced by MLPs, with limited performance degradation in image classification tasks.

2.3 Efficient and long sequence models

The standard attention mechanism (Vaswani et al., 2017) has a quadratic time and memory bottleneck with respect to sequence length. This limits its applicability in tasks involving long range dependencies. Most efforts to improve attention efficiency are based on sparsifying the attention matrix. Tay et al. (2020c) survey many of the recent efficient attention works; see also citations in Section 1. Several "efficient Transformers" achieve $\mathcal{O}(N\sqrt{N})$ or even $\mathcal{O}(N)$ theoretical complexity. However, the constants hidden by this notation can be large. For example, in models such as Longformer (Beltagy et al., 2020), ETC (Ainslie et al., 2020), and BigBird (Zaheer et al., 2020), attention is $\mathcal{O}(N)$ as a function of the input length, but quadratic in the number of "global tokens"; the latter must be sufficiently large to ensure good performance.

The Long-Range Arena benchmark (Tay et al., 2021a) attempts to compare many of the efficient Transformers in a series of tasks requiring long range dependencies, finding that the Performer (Choromanski et al., 2021), Linear Transformer (Katharopoulos et al., 2020), Linformer (Wang et al., 2020), and Image Transformer (Local Attention) (Parmar et al., 2018) were the fastest on TPUs and had the lowest peak memory usages per device.[2] Instead, in this paper we completely replace self-attention with a different mixing, namely the Fourier Transform, which offers: (1) performance, (2) reduced model size (no learnable parameters), and (3) simplicity.

Finally, we note that, in an effort to investigate different token mixing mechanisms, we compare a vanilla BERT model (Devlin et al., 2019) with a vanilla FNet, ignoring more recent Transformer optimizations, which we consider orthogonal to this work; see, for example, (Narang et al., 2021; Kim and Hassan, 2020; Shleifer and Rush, 2020).

3 Model

3.1 Discrete Fourier Transform

The Fourier Transform decomposes a function into its constituent frequencies. Given a sequence $\{x_n\}$ with $n \in [0, N-1]$, the discrete Fourier Transform (DFT) is defined by the formula:

$$X_k = \sum_{n=0}^{N-1} x_n e^{-\frac{2\pi i}{N} nk}, \quad 0 \leq k \leq N-1. \quad (1)$$

For each k, the DFT generates a new representation X_k as a sum of all of the original input tokens x_n, with so-called "twiddle factors". There are two primary approaches to computing the DFT: the Fast Fourier Transform (FFT) and matrix multiplication. The standard FFT algorithm is the Cooley–Tukey algorithm (Cooley and Tukey, 1965; Frigo and Johnson, 2005), which recursively re-expresses the DFT of a sequence of length $N = N_1 N_2$ in terms of N_1 smaller DFTs of sizes N_2 to reduce the computation time to $\mathcal{O}(N \log N)$.

An alternative approach is to simply apply the DFT matrix to the input sequence. The DFT matrix, W, is a Vandermonde matrix for the roots of unity up to a normalization factor:

$$W_{nk} = \left(e^{-\frac{2\pi i}{N} nk} / \sqrt{N} \right), \quad (2)$$

---

[2] Memory usage is often overlooked, but empirical studies have shown that Transformer architectures are often memory-bound (Ivanov et al., 2020; Shazeer, 2019).

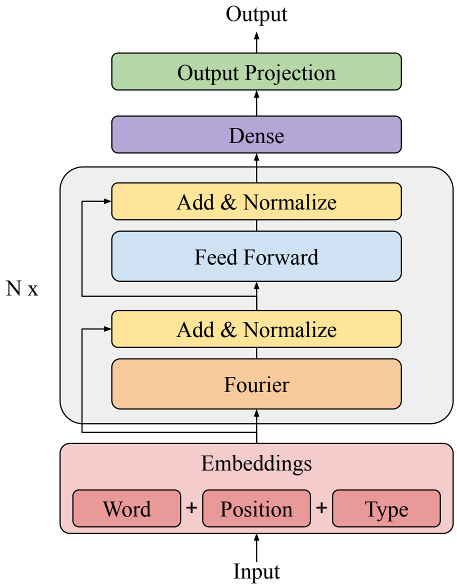

Figure 1: FNet architecture with N encoder blocks.

where $n, k = 0, \ldots, N-1$. This matrix multiplication is an $\mathcal{O}(N^2)$ operation, which has higher asymptotic complexity than the FFT, but turns out to be faster for relatively shorter sequences on TPUs.

3.2 FNet architecture

FNet is an attention-free Transformer architecture, wherein each layer consists of a Fourier mixing sublayer followed by a feed-forward sublayer. The architecture is shown in Figure 1. Essentially, we replace the self-attention sublayer of each Transformer encoder layer with a Fourier sublayer, which applies a 2D DFT to its (sequence length, hidden dimension) embedding input – one 1D DFT along the sequence dimension, $\mathcal{F}_{\text{seq}}$, and one 1D DFT along the hidden dimension, $\mathcal{F}_{\text{h}}$:[3]

$$y = \Re\left(\mathcal{F}_{\text{seq}}\left(\mathcal{F}_{\text{h}}(x)\right)\right). \tag{3}$$

As indicated by Equation (3), we only keep the real part of the result; hence, we do not need to modify the (nonlinear) feed-forward sublayers or output layers to handle complex numbers. We found that FNet obtained the best results when the real part of the total transformation was only extracted at the end of the Fourier sublayer; that is, after applying both $\mathcal{F}_{\text{seq}}$ and $\mathcal{F}_{\text{h}}$. We also experimented with the Hadamard, Hartley and Discrete Cosine Transforms. Of these three, the Hartley Transform was the strongest alternative, obtaining comparable accuracy to Equation (3); see Appendix A.3 for details.

The simplest interpretation for the Fourier Transform is as a particularly effective mechanism for mixing tokens, which provides the feed-forward sublayers sufficient access to all tokens. Because of the duality of the Fourier Transform, we can also view each alternating encoder block as applying alternating Fourier and inverse Fourier Transforms, transforming the input back and forth between the "time" and frequency domain. Because multiplying by the feed-forward sublayer coefficients in the frequency domain is equivalent to convolving (with a related set of coefficients) in the time domain, FNet can be thought of as alternating between multiplications and convolutions.[4]

We use the same embedding layers as in Devlin et al. (2019); namely, we combine the word embeddings, absolute position embeddings of the tokens and type embeddings of the sentences. Because of the positional information encoded by the Fourier Transform in Equation (1) (see n, k indices), FNet performs just as well without position embeddings. Nevertheless, we include the position embeddings to allow for a cleaner comparison with BERT.

3.3 Implementation

Empirically, we found that on GPUs: the FFT is faster than matrix multiplications for all sequence lengths we consider ($512 - 8192$ tokens), whereas on TPUs: for relatively shorter sequences (≤ 4096 tokens), it is faster to cache the DFT matrix and then compute the DFT through matrix multiplications than using the FFT; for longer sequences, the FFT is faster. As a result, our GPU FNet implementation always uses the FFT, while our TPU implementation computes the 2D DFT using matrix multiplications for sequences up to lengths of 4096 and the FFT for longer lengths. Presumably the GPU vs TPU difference is primarily a result of two factors: (1) TPUs are even more highly optimized for matrix multiplications than GPUs, and (2) GPUs offer a more efficient FFT implementation than TPUs. We suspect that FNet will only become more performant on TPUs as the TPU implementation of the FFT improves. Our model uses JAX and, in particular, the Flax framework[5]. Core

---

[3] The relative ordering of $\mathcal{F}_{\text{seq}}$ and $\mathcal{F}_{\text{h}}$ in Equation (3) is immaterial because the two 1D DFTs commute.

[4] This is merely an intuition; the reality is more complicated due to the presence of residual connections and since the transformation in Equation (3) is no longer invertible if we only use the real component.

[5] `https://github.com/google/flax`

Table 1: Number of mixing layer operations (forward pass) and learnable parameters, excluding any task specific output projection layers. n is the sequence length and d_h is the model hidden dimension. The mixing layer operations are given on a per layer basis.

Model	Mixing layer ops (per layer)	Model params Base	Model params Large
BERT	$2n^2d_h + 4nd_h^2$	112M	339M
Linear	$n^2d_h + nd_h^2$	94M	269M
FNet (mat)	$n^2d_h + nd_h^2$	83M	238M
FNet (FFT)	$nd_h\log(n)+$ $nd_h\log(d_h)$	83M	238M
Random	$n^2d_h + nd_h^2$	83M	238M
FF-only	0	83M	238M

model code is given in Appendix A.7 and the full source core is available online.[6]

4 Results

4.1 Transfer learning

We compare FNet and Transformer architectures in a common transfer learning setting. For a fuller picture, we compare multiple models (see Table 1 for parameter counts in "Base" configuration):

- BERT-Base: a Transformer encoder model.
- FNet encoder: we replace every self-attention sublayer with a Fourier sublayer.
- Linear encoder: we replace each self-attention sublayer with a two learnable, dense, linear sublayers, one applied to the hidden dimension and one to the sequence dimension.
- Random encoder: we replace each self-attention sublayer with a two constant random matrices, one applied to the hidden dimension and one applied to the sequence dimension.
- Feed Forward-only (FF-only) encoder: we completely remove the self-attention sublayer; so that this model has no token mixing.

Despite its simplicity, the Linear baseline turns out to be surprisingly accurate and fast. Our Linear model is similar to the MLP-Mixer (Tolstikhin et al., 2021) (for vision) and also the Random Synthesizer (Tay et al., 2020a), but simplifies the latter model further by removing the multiple heads and softmax projections, resulting in just two matrix multiplications in the mixing sublayer.

It is reasonable to expect that the Linear encoder, which uses densely parameterized mixing layers, will learn more flexibly than FNet, which uses parameter-free mixing layers. As we will show, although the Linear-Base model outperforms FNet-Base slightly on GLUE (0.3 points), it has several efficiency drawbacks relative to FNet: it has a much larger memory footprint (see Table 4b), it is slower to train on regular 512 sequence lengths (see Table 3), and scales significantly worse on long sequence lengths (see Tables 4b-4c).[7] We also found that Linear-Large was more difficult to train due to gradient blow up (see "Large" scores in Table 2).

We adopt the same fixed "Base" and "Large" model and training configurations as for the original BERT (Devlin et al., 2019), except that we pre-train on the much larger C4 dataset (Raffel et al., 2020) and use a 32000 SentencePiece vocabulary model (Kudo and Richardson, 2018) (see Appendix A.1 for full pre-training details). For fine-tuning on the GLUE benchmark (Wang et al., 2018), we found that different BERT runs with the same base learning rate could yield slightly different results. Consequently, for the Base (Large) models, we performed 3 (6) trials, respectively, for each base learning rate and reported the best result across all experiments. This reflects our observation that BERT-Large was less stable than BERT-Base, as noted in Devlin et al. (2019).

We report the results for the best base learning rate (no early stopping) on the GLUE Validation split in Table 2.[8] For Base models, results mirror the pre-training metrics (see Appendix A.1): BERT performs best. FNet and the Linear model both underperform BERT by $7.5 - 8\%$. Referring to Table 3, we see that although less accurate, FNet trains significantly faster than BERT – 80% faster on GPUs and 70% faster on TPUs – and performs 63% of BERT's FLOPS. Measured in isolation, the Fourier sublayers perform forward and backward passes an order of magnitude faster than the self-attention sublayers (see Appendix A.4), but FNet's overall training speed is impeded by the feed-forward sublayers that all models share.

---

[6] `https://github.com/google-research/google-research/tree/master/f_net`

[7] On the other hand, the smaller sized Linear models do generally perform well on 512 sequence lengths; see Figure 2.

[8] WNLI is excluded in Devlin et al. (2019). BERT's accuracy on WNLI is below baseline, unless a special training recipe is used. See also (12) in `https://gluebenchmark.com/faq`.

Table 2: GLUE Validation results on TPUs, after finetuning on respective tasks. We report the mean of accuracy and F1 scores for QQP and MRPC, Spearman correlations for STS-B and accuracy scores for all other tasks. The MNLI metrics are reported by the match/mismatch splits. Average scores exclude any failure cases. After controlling for batch size and training steps, the GPU metrics (not shown) are similar.

Model	MNLI	QQP	QNLI	SST-2	CoLA	STS-B	MRPC	RTE	Avg.
BERT-Base	**84/81**	**87**	**91**	93	73	**89**	**83**	**69**	**83.3**
Linear-Base	74/75	84	80	94	67	67	83	69	77.0
FNet-Base	72/73	83	80	**95**	69	79	76	63	76.7
Random-Base	51/50	70	61	76	67	4	73	57	56.6

FNet-Hybrid-Base	78/79	85	88	94	**76**	86	79	60	80.6
BERT-Large	**88/88**	**88**	**92**	**95**	71	**88**	86	66	**84.7**
Linear-Large	35/36	84	80	79	67	24	73	60	59.8
FNet-Large	78/76	85	85	94	78	84	**88**	69	81.9
FNet-Hybrid-Large	79/80	87	89	92	**81**	**88**	86	**70**	83.6

Table 3: Pre-training and inference speeds in milliseconds per batch of 64 examples on GPU (8 V100 chips) and 256 examples on TPU (4 × 4 v3 chips), alongside GFLOPS for a forward pass of a single example. Speed-up multipliers relative to BERT are given in parentheses.

	Pre-training		Inference		GFLOPS
Model	GPU	TPU	GPU	TPU	/example
BERT-Base	305	213	82	32	98
Linear-Base	199 (1.5x)	149 (1.4x)	52 (1.6x)	20 (1.6x)	71 (73%)
FNet-Base	169 (1.8x)	128 (1.7x)	46 (1.8x)	23 (1.4x)	62 (63%)
Random-Base	182 (1.7x)	130 (1.6x)	52 (1.6x)	22 (1.4x)	71 (73%)
FF-only-Base	**162 (1.9x)**	**118 (1.8x)**	**43 (1.9x)**	**16 (2.0x)**	**59 (60%)**
FNet-Hybrid-Base	198 (1.5x)	149 (1.4x)	51 (1.6x)	24 (1.3x)	68 (69%)
BERT-Large	OOM	503	263	111	337
Linear-Large	592	397 (1.3x)	170 (1.5x)	108 (1.0x)	247 (73%)
FNet-Large	**511**	**275 (1.8x)**	**149 (1.8x)**	**82 (1.4x)**	**217 (64%)**
FNet-Hybrid-Large	541	294 (1.7x)	157 (1.7x)	84 (1.3x)	227 (67%)

Returning to Table 2: the FF-only model severely underperforms all other models: as expected, token mixing is critical to the expressivity of the model. For example, 50% accuracy scores on the binary classification tasks (QNLI, SST-2, RTE), indicate that the model fails to learn the tasks. The weak accuracy of the Random model suggests that not just any mixing will do; rather, a structured mixing is required. We also include metrics from a hybrid FNet attention model. In the hybrid model, we replace the final two Fourier sublayers of FNet with self-attention sublayers – other configurations are possible, but we generally found that replacing the final layers worked best; see Appendix A.5. With the addition of just two self-attention sublayers, the hybrid FNet models achieve 97% and 99% of their respective BERT counterpart's accuracies with only limited speed degradations (see Table 3).

Interestingly, the gap between BERT and FNet shrinks to just 3% for Large models; this is likely due to FNet-Large being more stable during training than BERT-Large.[9] The Linear-Large model severely underperforms its Base counterpart on GLUE benchmark due to training instabilities. We generally found that the Linear model and BERT were less stable than the models with no parameters in their mixing sublayers, namely the FNet, Random and FF-only models.

The speed vs MLM accuracy curve for GPU (8 V100 chips) pre-training is shown in Figure 2 (see Appendix A.2 for TPU results). Both TPU and GPU models are trained for 1 million steps as in

---

[9] Devlin et al. (2019) obtain a roughly 2.5 average point boost on the *Test* split going from BERT-Base to BERT-Large. We only see a roughly 1.5 boost on the *Validation* split, which may be due to reduced headroom.

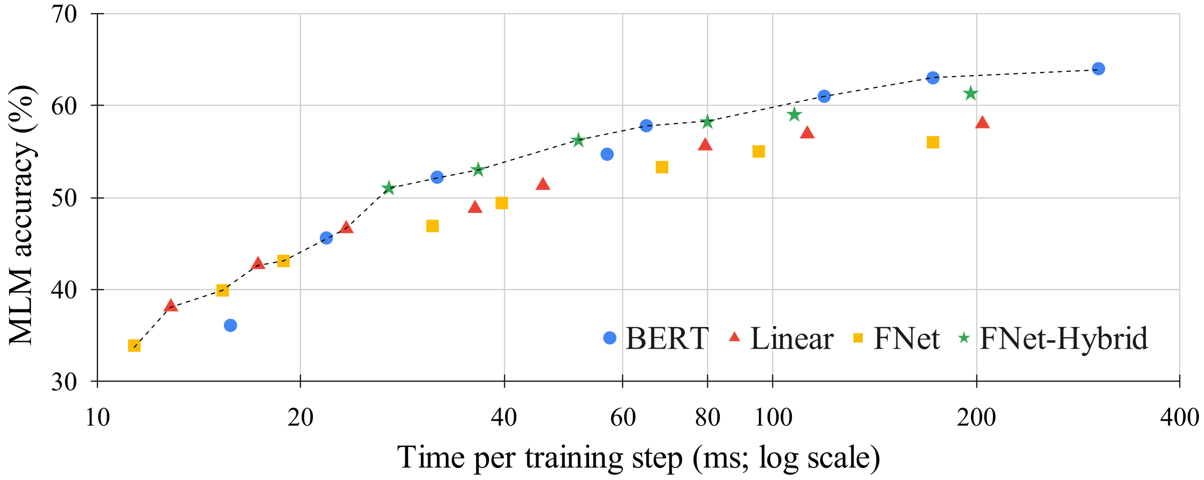

Figure 2: Speed-accuracy trade-offs for GPU pre-training. The dashed line shows the Pareto efficiency frontier, indicating the best trade-offs. For smaller models (faster training speeds; left-hand side of figure), the FNet (yellow squares) and Linear (red triangles) models define the frontier, while for larger models (slower training speeds; right-hand side of figure), BERT (blue circles) and FNet-Hybrid (green stars) define the frontier.

Devlin et al. (2019). Motivated by the models considered in Turc et al. (2019), we evaluated several model sizes; see Table 6 in Appendix A.1. We found that the smaller model architectures benefited from larger learning rates, so we select the best result using 10^{-3} and 10^{-4} for all models.[10]

The GPU (Figure 2), and TPU (Figure 3 in Appendix A.2) results display the same trends. For larger, slower models, BERT and FNet-Hybrid define the Pareto speed-accuracy efficiency frontier. For smaller, faster models, FNet and the Linear model define the efficiency frontier.

4.2 Long-Range Arena (LRA) benchmark

Of the efficient Transformers evaluated on LRA benchmark by Tay et al. (2021a), their results suggest that (1) the vanilla Transformer is (by a small margin) the second most accurate model, and (2) the Performer (Choromanski et al., 2021) is the fastest model. We benchmark FNet's accuracy against both of these models using Tay et al. (2021a)'s codebase and running on the same hardware (4 × 4 TPU v3 chips); the results are shown in Table 4a.[11] To ensure a fair comparison, we also report the results of our own experiments for the vanilla Transformer (see Appendix A.6 for details).

Table 4a suggests that, in aggregate, the (vanilla) Transformer and FNet obtain comparable results. Given that the Transformer is the second most accurate model evaluated by Tay et al. (2021a) and that the relative differences in the average accuracy scores within Table 4a are small, our results suggest that FNet is competitive with the most accurate of the efficient Transformers on LRA.

Turning to efficiency, in Table 4b, we provide training speed and memory usage statistics from our experiments on GPUs (8 V100 chips); see Appendix A.2 for results on TPUs. We perform a sweep over sequence lengths $\{512, 1024, 2048, 4096, 8192\}$. On GPUs, FNet is much faster than all other models across all sequence lengths, due to the highly efficient FFT implementation on GPUs. Table 4b also indicates that FNet has a lighter memory footprint (this holds for both GPUs and TPUs; see extended results in Appendix A.2). This is partly because FNet has no learnable parameters in its mixing sublayer, but also due to the FFT's efficiency, especially at longer sequence lengths. Lastly, Table 4c shows that training speed gains generally carry over to inference gains (see Appendix A.2 for detailed TPU results).

5 Conclusions

In this work, we studied simplified token mixing modules for Transformer-like encoder architectures, making several contributions. First, we showed that simple, linear mixing transformations,

---

[10] We have opted to compare FNet with Transformer models as the latter are the most commonly used models in NLP transfer learning settings. It would also be interesting to compare FNet with convolutional-based models, although, to our knowledge, such models have only recently found limited success in pre-training NLP setups (Tay et al., 2021b); and even there, the authors did not consider the small model regime.

[11] The "Linear" model in Table 4 is the baseline model introduced in Section 4.1.

Table 4: Accuracy, inference speed and memory usage results on the Long-Range Arena (LRA) benchmark.

Model	ListOps	Text	Retrieval	Image	Pathfinder	Path-X	Avg.
Transformer (ours)	36.06	61.54	**59.67**	41.51	80.38	OOM	**55.83**

(a) Accuracy results obtained on TPUs as in Tay et al. (2021a). Asterisked results quoted from Tay et al. (2021a). Average does not include the Path-X task, which all models fail (Transformer due to memory limits; others perform no better than chance).

	Training Speed (steps/s)					Peak Memory Usage (GB)				
Seq. length	512	1024	2048	4096	8192	512	1024	2048	4096	8192
Transformer	21	10	4	OOM	OOM	1.6	4.0	12.2	OOM	OOM
Linear	34 (1.6x)	19 (1.8x)	9 (2.0x)	4	OOM	0.9	1.6	2.8	6.9	OOM
FNet (FFT)	**43 (2.0x)**	**24 (2.3x)**	**14 (3.2x)**	**7**	**4**	**0.8**	**1.3**	**2.2**	**3.9**	**7.4**
Performer	28 (1.3x)	15 (1.5x)	9 (1.9x)	4	2	1.1	1.9	3.1	5.5	10.4

(b) GPU training for sequence lengths up to 8192. Only the fastest efficient Transformer, namely Performer, from Tay et al. (2021a) is shown. Left: training speeds (in steps per second; larger is better), with speed-up multipliers relative to the Transformer given in parentheses. Right: peak memory usage (in GB; smaller is better).

Seq. length	512	1024	2048	4096	8192	16384
Transformer	12	28	76	244	OOM	OOM
Linear	9 (1.4x)	14 (2.0x)	30 (2.6x)	72 (3.4x)	208	OOM
FNet (FFT)	**8 (1.5x)**	**12 (2.3x)**	**23 (3.4x)**	**43 (5.7x)**	**83**	**164**
Performer	11 (1.2x)	17 (1.6x)	32 (2.4x)	60 (4.0x)	116	238

(c) GPU inference speeds on the LRA Text classification task (in milliseconds per batch; smaller is better). Only the fastest efficient Transformer, Performer, from Tay et al. (2021a) is shown. Speed up relative to the Transformer is given in parentheses.

along with the nonlinearities in feed-forward layers, can competently model diverse semantic relationships in text. Second, we introduced FNet, a Transformer-like model wherein the self-attention sublayer is replaced by an unparameterized Fourier Transform. FNets achieve 92 and 97% of their respective BERT-Base and BERT-Large counterparts' accuracy on the GLUE benchmark, but train $70 - 80\%$ faster on GPUs/TPUs. Third, because of its favorable scaling properties, FNet is very competitive with the "efficient Transformers" evaluated on the Long-Range Arena benchmark, matching the accuracy of the most accurate models while being much faster and lighter on memory.

Our work highlights the potential of linear units as a drop-in replacement for the attention mechanism in text classification tasks. We found the Fourier Transform to be a particularly efficient and effective mixing mechanism, due to the speed of the FFT. However, we only performed a cursory survey of other linear transformations (see also Appendix A.3), and additional fast alternatives are worth exploring.

Given the speed and accuracy advantages of smaller FNet models relative to Transformers, we suspect that FNet will be effective as a lightweight, distilled student model deployed in resource-constrained settings such as production services or on edge devices. The need for such lightweight serving models is only forecast to grow given the interest in giant models (Raffel et al., 2020; Brown et al., 2020; Lepikhin et al., 2021). A natural avenue to explore in this regard is knowledge distillation of small FNet models from larger Transformer teacher models, following, for example, Sanh et al. (2019); Jiao et al. (2020); Turc et al. (2019).

Another aspect of interest and worthy of further study is hybrid FNet-attention models. We found that adding only a few self-attention sublayers to FNet offers a simple way to trade speed for accuracy. Specifically, replacing the final two Fourier sublayers with self-attention provided $97-99\%$ of BERT's accuracy with limited speed penalties.

Throughout this work we have restricted our focus to encoders. FNet decoders can be designed by "causally" masking the Vandermonde matrix, but a lower level implementation is required to introduce causal masking to FFTs. How to adapt Fourier mixing for encoder-decoder cross-attention is an open question as evidence suggests that cross-attention may be crucial to performance (You et al., 2020). We have focused on tasks which do not require generation so we leave FNet decoders and encoder-decoder setups to future work; although we do remark that the FNet encoder could be used as a drop in replacement in a Transformer as other works have successfully demonstrated; see, for example, (Zaheer et al., 2020; Guo et al., 2021).

Table 5: Loss and accuracy pre-training metrics on TPUs. The GPU metrics are very similar. "B" denotes Base, "L" is Large and "H" is Hybrid.

	Loss			Accuracy	
Model	Total	MLM	NSP	MLM	NSP
BERT-B	**1.76**	**1.48**	**0.28**	**0.68**	**0.86**
Linear-B	2.12	1.78	0.35	0.62	0.83
FNet-B	2.45	2.06	0.40	0.58	0.80
Random-B	5.02	4.48	0.55	0.26	0.70
FF-only-B	7.54	6.85	0.69	0.13	0.50
FNet-H-B	2.13	1.79	0.34	0.63	0.84
BERT-L	**1.49**	**1.23**	**0.25**	**0.72**	**0.88**
Linear-L	1.91	1.60	0.31	0.65	0.85
FNet-L	2.11	1.75	0.36	0.63	0.82
FNet-H-L	1.89	1.58	0.31	0.67	0.85

Table 6: Pre-training model sizes (ignoring output projection layers). As in Turc et al. (2019), for all models, we fix the feed-forward size to $4d_h$ and the number of self-attention heads to $d_h/64$. Smaller architectures have a similar number of parameters across all models because the majority of parameters are in the embedding layers. Each FNet-Hybrid ("FNet-H") model contains 2 self-attention sublayers. We exclude FNet-Hybrid models with only 2 total layers.

Dimensions		Parameters (millions)			
d_h	Layers	BERT	Linear	FNet	FNet-H
768	12	111	93	83	88
512	12	55	49	42	44
512	8	42	38	34	36
256	8	15	15	13	13
512	4	30	28	26	28
256	4	12	12	11	11
256	2	10	10	10	-
128	2	5	5	4	-

A Appendices

A.1 Pre-training details

We adopt the same fixed "Base" and "Large" model and learning configurations as for the original BERT (Devlin et al., 2019). We train on the much larger C4 dataset (Raffel et al., 2020) and use a 32000 SentencePiece vocabulary model (Kudo and Richardson, 2018) trained on a 100 million sentence subset of C4. Our TPU experiments use a batch size of 256 as in Devlin et al. (2019) and are each run on 4×4 TPU v3 chips. Our GPU experiments use a smaller batch size of 64 and are run on 8 V100 chips. Because the training configuration is lifted from Devlin et al. (2019), it may be slightly biased towards the BERT attention model.

Table 5 summarizes the pre-training metrics for the different models; the pre-training speeds are shown in Table 3 in the main text. Although they have weaker accuracy metrics, the Linear model and FNet train nearly 80% faster than BERT on GPUs, and 70% faster on TPUs (see Table 3). We also find that the three models with no learnable parameters in their mixing layer, namely FNet, the Random model and the FF-only model, are the most stable during training.

BERT's higher accuracy on the MLM pre-training task is not simply a result of having more parameters than the other models. Indeed, Table 5 shows that BERT-Base is actually more accurate than FNet-Large, which contains more than twice as many parameters. BERT is presumably more expressive because the mixing (attention) weights are both task specific and token dependent, determined by token-token (query-key) dot products; see also Tay et al. (2020a). FNet's mixing weights, on the other hand, are neither task specific nor token dependent.

Finally, Table 6 shows the model sizes that were used to construct Figure 2 (main text) and Figure 3 (Appendix A.2).

A.2 TPU results

In this section, we report FNet efficiency results for TPUs; the main text focuses on GPUs. Figure 3 shows the speed vs MLM pre-training accuracy curve when training on TPU (4×4 v3 chips). As on GPUs, FNet and the Linear model define the Pareto efficiency frontier for smaller, faster models, while BERT defines the frontier for larger, slower models.

Table 7 shows Long Range Arena Text classification efficiency results on TPUs (4×4 v3 chips). The Linear model and FNet train faster than all the efficient Transformers for sequence lengths ≤ 2048 and 512, respectively. For longer sequences, FNet is slower than the Performer and, based on results in Tay et al. (2021a), likely also slower than the other efficient Transformers that linearize attention, namely Local Attention (Parmar et al., 2018), Linformer (Wang et al., 2020) and Linear Transformer (Katharopoulos et al., 2020). However, it is worth noting that Table 4a suggests that FNet is more accurate than all of the aforementioned models. Moreover, we expect that the GPU speed gains will

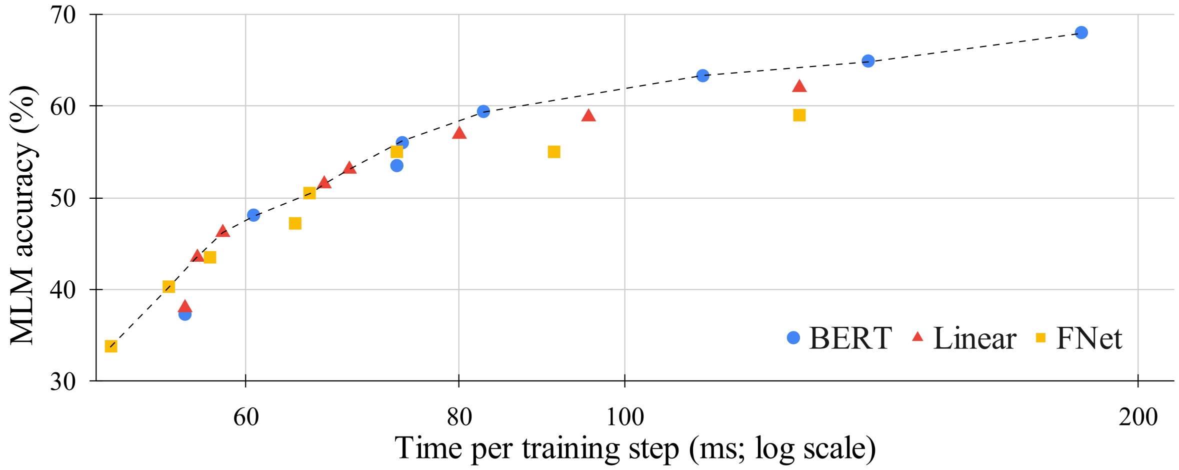

Figure 3: Speed-accuracy trade-offs for TPU pre-training. The dashed line shows the Pareto efficiency frontier.

Table 7: TPU training speeds (in steps per second; larger is better), inference speeds (in milliseconds per batch; smaller is better) and peak memory usage during training (in GB; smaller is better) on the Long-Range Arena Text classification task. Speed up multipliers relative to the Transformer are given in parentheses.

Seq. length	512	1024	2048	4096	8192	16386
	Training Speed (steps/s)					
Transformer	8.0	5.6	1.7	OOM	OOM	OOM
Linear	9.4 (1.2x)	**9.1 (1.6x)**	**7.6 (4.5x)**	3.9	1.4	OOM
FNet (mat)	**9.5 (1.2x)**	**9.1 (1.6x)**	6.1 (3.6x)	3.0	0.8	0.2
FNet (FFT)	8.6 (1.1x)	6.0 (1.1x)	3.2 (1.9x)	1.6	0.8	0.3
Performer	9.2 (1.2x)	8.4 (1.5x)	6.9 (4.1x)	**4.2**	**2.2**	**1.1**
	Inference Speed (ms/batch)					
Transformer	7.0	13.2	39.4	129.9	490.2	OOM
Linear	**5.6 (1.2x)**	**6.5 (2.0x)**	**9.6 (4.1x)**	20.4 (6.4x)	54.6 (9.0x)	OOM
FNet (mat)	6.0 (1.2x)	7.7 (1.7x)	15.4 (2.6x)	40.7 (3.2x)	137.0 (3.6x)	454.5
FNet (FFT)	10.8 (0.7x)	16.8 (0.8x)	29.9 (1.3x)	58.8 (2.2x)	113.6 (4.3x)	263.2
Performer	6.1 (1.2x)	7.2 (1.8x)	10.1 (3.9x)	**17.5 (7.4x)**	**31.8 (15.4x)**	**61.0**

Performer	1.0	1.3	1.8	3.0	5.1	9.6

transfer to TPUs as the TPU FFT implementation improves.

A.3 Additional configurations that we experimented with

We experimented with a number of additional ideas to improve FNet.

Fourier Transform algorithm. On GPUs, the FFT was the fastest algorithm for computing the DFT across all sequence lengths that we experimented with ($512 - 8192$). On TPUs, it is faster to compute the DFT directly using matrix multiplications for relatively shorter sequence lengths (up to lengths of 4096; see Table 7). This efficiency boundary between matrix multiplication and FFT on TPUs will change depending on the XLA precision for the matrix multiplications. We found that, although (slower) HIGHEST XLA precision was required to very accurately reproduce FFT in computing the DFT, (faster) DEFAULT XLA precision was sufficient to facilitate accurate model convergence.

Modifying the Fourier Transform computation. To keep the entire FNet architecture simple, the Fourier sublayer accepts real input and returns real output. The standard Fourier sublayer in FNet simply extracts the real part after computing the 2D DFT. We found that FNet was less accurate and less stable during training if only the real part of the DFT was used throughout the computation. Simply extracting the absolute value (instead of the real part) also led to a significantly less accurate model. Because the feed-forward sublayer mixes the hidden dimension, we experimented with applying a 1D DFT along the token dimension only in the Fourier sublayer (i.e. no hidden dimension mixing in the Fourier sublayer). This yielded some training speed gains but hurt accuracy. The 1D (token mixing only) DFT model still significantly outperformed the (no token mixing) FF-only model, indicating that token mixing is most important mechanism in the Fourier sublayer.

Other transforms. We experimented with three natural alternatives to the Fourier Transform:

- Discrete Cosine Transform (DCT). The DCT is closely related to the DFT but transforms real input to real output. However, we found that the DCT model underperformed FNet ($\sim 4\%$ accuracy degradation).
- Hadamard Transform[12]. Although the Hadamard Transform was slightly faster than the DFT, it yielded less accurate results ($\sim 2\%$ accuracy degradation).
- Hartley Transform. The Hartley Transform, which transforms real input to real output, can be described in terms of the Fourier Transform: $\mathcal{H} = \Re\{\mathcal{F}\} - \Im\{\mathcal{F}\}$. We found that the Hartley Transform matched the Fourier Transform on GLUE (76.7 vs. 76.7).

Introducing learnable parameters to the Fourier sublayer. Our attempts to introduce learnable parameters into the Fourier sublayer were either detrimental or inconsequential, and generally slightly slowed the model. For the (sequence length, hidden dimension) input in each Fourier sublayer, we tried two approaches to introduce learnable parameters: (1) element wise multiplication with a (sequence length, hidden dimension) matrix, and (2) regular matrix multiplication with (sequence length, sequence length) and (hidden dimension, hidden dimension) matrices. We experimented with these approaches in various configurations: preceding and/or following the DFT, and also in combination with inverse DFT (e.g. transform to frequency domain, apply element wise multiplication, transform back to time domain), but most setups degraded accuracy and reduced training stability, while a few did not change accuracy but lead to small speed decreases. In a slightly different set of experiments and in an effort to provide more flexibility to the model, we added (complex) learnable weights to the 2D DFT matrix. This model was stable but did not yield any accuracy gains, suggesting that the DFT is locally optimal in some sense.

FNet block modifications. The standard FNet encoder block structure follows that of the Transformer: a Fourier sublayer followed by a feed-forward sublayer, with residual connections and layer norms after each sublayer; see Figure 1. We tried several modifications to this structure, based on the intuition of moving in and out of the frequency domain between multiplications. For example, the sandwiching of Fourier, feed-forward, Fourier (or inverse Fourier) sublayers and only applying the residual connections and layer norms to the final result, yields a structure that more closely

---

[12] Whereas the DFT matrix in Equation (2) contains N roots of unity, the Hadamard Transform simply contains two roots of unity: $\{\pm 1\}$; see also Kunz (1979).

Table 8: Training (forward and backward passes; left) and inference (forward pass; left) speeds for *only* the mixing sublayers – all other model sublayers are removed. Both speeds are measured in milliseconds per batch (smaller is better), with batch sizes of 64 (GPU) and 256 (TPU). All batch examples have the sequence length fixed at 512. FNet uses the FFT for GPUs and matrix multiplications for TPUs. Speed up multipliers relative to self-attention are given in parentheses.

	Training speed (ms/batch)		Inference speed (ms/batch)	
	GPU	TPU	GPU	TPU
Self-attention (Base)	136	76	43	16
Linear (Base)	36 (3.7x)	12 (6.1x)	15 (2.8x)	**4 (3.9x)**
FNet (Base)	**11 (12.2x)**	**8 (9.9x)**	**11 (4.0x)**	8 (2.1x)
Self-attention (Large)	404	212	128	43
Linear (Large)	103 (3.9x)	35 (6.1x)	36 (3.6x)	**10 (4.5x)**
FNet (Large)	**18 (22.2x)**	**22 (9.7x)**	**18 (7.3x)**	22 (2.0x)

mimics convolutions. However, these setups degraded accuracy and lead to a more unstable model during training. Adding extra feed-forward sublayers to this layering, or swapping out the feed-forward sublayers for simpler dense sublayers, did not help either.

A.4 Mixing layer speeds

Table 8 summarizes the inference and training speeds for the different mixing layers. For each of the Base and Large configurations, we have removed all other sublayers and transformations and then calculated the speed per batch of input examples. The FNet training speeds are particularly fast because no parameters are updated. The Linear model has faster inference than FNet on TPUs because it is performing real matrix multiplications, whereas FNet performs complex matrix multiplications; see Equation (2).

Although the Fourier mixing sublayer itself performs forward and backward passes significantly faster than the self-attention sublayer, FNet is overall 70-80% faster than BERT because the overall training and inference speeds are bottle-necked by the feed-forward sublayers that all models share.

A.5 FNet-Hybrid ablations

Table 9 shows the effects of varying the number of attention sublayers and the attention layout in the FNet-Hybrid model. For the "BOTTOM" layout, all attention sublayers are placed in the first few encoder layers, where they replace the Fourier mixing sublayers. For the "TOP" layout, attention sublayers are placed in the final encoder layers; for the "MIDDLE" layout they are placed in the middle layers; and for the "MIXED" layout, they are distributed through the model.

Table 9: GPU pre-training accuracy and speed ablations for FNet-Hybrid models in the Base configuration. Batch size is 64. Metrics are recorded after 100k steps, which we have generally found to be a good indicator of final relative performance. See text for a description of the layouts.

Attention		Accuracy		Speed
Layers	Layout	MLM	NSP	(ms/batch)
2	BOTTOM	0.497	0.733	**193**
2	MIDDLE	0.499	0.686	196
2	MIXED	0.509	0.727	194
2	TOP	**0.526**	**0.738**	**193**
0	TOP	0.486	0.679	**173**
2	TOP	0.526	0.738	193
4	TOP	0.539	0.740	214
6	TOP	**0.546**	**0.746**	235

From the Table 9, we can make two observations: (1) more attention improves accuracy at the cost of speed, and ultimately with diminishing returns; (2) placing attention layers at the top of the model gives the best accuracy results. Given our focus on speed, we chose to focus FNet-Hybrid experiments in the main text of the paper on the 2 attention layer, "TOP" configuration variant.

A.6 A note on Long-Range Arena hyperparameter settings

Concerning the Long-Range Arena setup, several hyperparameters are not described in Tay et al. (2021a) and there a few mismatches between the configurations described in the paper and the code repository. Where possible, we prioritize configurations described in the paper with only two exceptions. Firstly, for the CIFAR10 (Image) task, we perform a sweep of the number of layers in the range $[1, 2, 3, 4]$. We found that 1 layer worked best for all models; Tay et al. (2021a) suggest 3 layers yielded the best results. Secondly, for the Pathfinder task, we found that a base learning rate of 0.001 (as given in the code repository) yielded better results for all models than the 0.01 value indicated in Tay et al. (2021a). We also perform a very small sweep over the embedding dimension and batch size, which are not listed in Tay et al. (2021a).

We also remark that the accuracy comparisons between our runs and those from Tay et al. (2021a) should be performed with the caveat that we found that results for certain tasks – Text and Retrieval in particular – can vary quite a bit between runs, especially for the Transformer; we report the best results.

A.7 FNet code

```
import flax.linen as nn
import jax
import jax.numpy as jnp

class FourierTransformLayer(nn.Module):
  @nn.compact
  def __call__(self, x):
    return jax.vmap(jnp.fft.fftn)(x).real

class FeedForwardLayer(nn.Module):
  d_ff: int
  dropout_rate: float

  @nn.compact
  def __call__(self, x, deterministic):
    x = nn.Dense(self.d_ff,
      kernel_init=nn.initializers.normal(2e-2),
      bias_init=nn.initializers.normal(2e-2),
      name="intermediate")(x)
    x = nn.gelu(x)
    x = nn.Dense(x.shape[-1],
      kernel_init=nn.initializers.normal(2e-2),
      name="output")(x)
    return nn.Dropout(self.dropout_rate)(x, deterministic)

class FNetEncoderBlock(nn.Module):
  fourier_layer: FourierTransformLayer
  ff_layer: FeedForwardLayer

  @nn.compact
  def __call__(self, x, deterministic):
    mixing_output = self.fourier_layer(x)
    x = nn.LayerNorm(1e-12, name="mixing_layer_norm")(x + mixing_output)
    feed_forward_output = self.ff_layer(x, deterministic)
    return nn.LayerNorm(
        1e-12, name="output_layer_norm")(x + feed_forward_output)

class FNetEncoder(nn.Module):
  num_layers: int
  d_model: int
  d_ff: int
  dropout_rate: float

  def setup(self):
    encoder_blocks = []
    for layer in range(self.num_layers):
      encoder_blocks.append(FNetEncoderBlock(
        FourierTransformerLayer(),
        FeedForwardLayer(self.d_ff, self.dropout_rate),
        name=f"encoder_{layer}"))
    self.encoder_blocks = encoder_blocks
    self.pooler = nn.Dense(
        self.d_model,
        kernel_init=nn.initializers.normal(2e-2),
        name="pooler")

  def __call__(self, x, deterministic):
    for encoder_block in self.encoder_blocks:
      x = encoder_block(x, deterministic)
    pooled_output = self.pooler(x[:, 0])
    pooled_output = jnp.tanh(pooled_output)
    return x, pooled_output
```

Listing 1: FNet code written in JAX/Flax. Embedding and output projection layers are omitted for simplicity.

Answer Consolidation: Formulation and Benchmarking

Abstract

Current question answering (QA) systems primarily consider the single-answer scenario, where each question is assumed to be paired with one correct answer. However, in many real-world QA applications, multiple answer scenarios arise where consolidating answers into a comprehensive and non-redundant set of answers is a more efficient user interface. In this paper, we formulate the problem of *answer consolidation*, where answers are partitioned into multiple groups, each representing different aspects of the answer set. Then, given this partitioning, a comprehensive and non-redundant set of answers can be constructed by picking one answer from each group. To initiate research on answer consolidation, we construct a dataset consisting of 4,699 questions and 24,006 sentences and evaluate multiple models. Despite a promising performance achieved by the best-performing supervised models, we still believe this task has room for further improvements.[1]

1 Introduction

Open-domain question answering (QA) systems (Voorhees, 1999) aim to answer natural language questions using large collections of reference documents, contributing to real-world applications such as intelligent virtual assistants and search engines. Current QA systems (Zhu et al., 2021) usually adopt a three-stage pipeline consisting of: (1) a *passage retriever* (Yang et al., 2019; Karpukhin et al., 2020) that selects a small set of passages relevant to the question, (2) a *machine reader* that examines the retrieved passages and extracts (Wang et al., 2017, 2019) or abstracts (Lewis et al., 2020) the candidate answers, and (3) an *answer reranker* (Wang et al., 2018; Kratzwald et al., 2019) that fuses features from previous stages to either select one final answer or return the top-ranked answer from the previous stage.

Current QA research (Joshi et al., 2017; Kwiatkowski et al., 2019) primarily examines the case where each question is assumed to have a single correct answer. However, in practice, many questions can have multiple correct answers. For example, the question "*Is coffee good for your health?*" can be answered with respect to different aspects (e.g., "*coffee can help you with weight loss*", "*coffee can cause insomnia and restlessness*"). To correctly identify different aspects of answers to the same question while mitigating aspect-level redundancy, it is important to *consolidate* the answers. Answer consolidation is particularly desirable for applications such as intelligent assistants, where responses are desired to be both comprehensive and concise. Additionally, in scenarios where QA is used for knowledge extraction (Bhutani et al., 2019; Du and Cardie, 2020) or claim verification (Yin and Roth, 2018; Zhang et al., 2020), consolidation is also an essential step to identify salient knowledge or evidence while mitigating duplication.

To effectively recognize multiple aspects of answers in QA systems, our *first* contribution is to introduce and formalize the *answer consolidation* problem. Specifically, given a question paired with multiple answer snippets, answer consolidation first partitions the snippets into groups where each group represents a single aspect within the answer space. Once partitioned, the final answer set is produced by returning a representative snippet from each group. In this formulation, the answer consolidation task is a post-processing stage that takes predicted answer-mentioning snippets (in this work, sentences) from previous QA stages and produces an answer set that maximizes answer aspect coverage while minimizing answer duplication.

To foster research on the answer consolidation problem, our *second* contribution is the collec-

tion of a new dataset, namely, QUASI (Question-Answer consolidation). QUASI consists of 4,699 questions such that each question is paired with multiple answer-mentioning sentences grouped according to different aspects. Starting with a Quora-based question source (Chen et al., 2018), noting the potential for multi-aspect answers, we first retrieve 10 relevant answer sentences from the web for each question. These sentences are then examined by three crowd-sourced workers, who exclude sentences that do not contain an answer and group the remaining ones. Finally, individual sentence groupings from different workers are aggregated into a single partitioning. QUASI consists of 24,006 sentences and 19,676 groups, corresponding to an average number of 4.18 aspects per question and 1.22 sentences per group.

Our *third* contribution is a comprehensive benchmarking for the answer consolidation problem based on QUASI. Specifically, we consider two evaluation settings: (1) *classification*, where the model predicts whether two sentences are in the same group. (2) *sentence grouping*, where the model groups the answer sentences. We evaluate a wide selection of zero-shot and supervised methods, including various SoTA sentence embedding models (Reimers and Gurevych, 2019; Gao et al., 2021), cross-encoders (Devlin et al., 2019; Liu et al., 2019), and a newly proposed answer-aware cross-encoder model. In the supervised setting, the answer-aware cross-encoder achieves the best results based on the Matthew correlation coefficient (MCC) score of 87.8% (classification setting) and an adjusted mutual information (AMI) score of 68.9% (sentence grouping setting). As this performance is notably far from perfect, our findings indicate the need for future investigation on this meaningful, but challenging, task.

2 Related Work

QA with multiple answers. Many QA datasets have assumed that a question has a single correct answer (Joshi et al., 2017; Kwiatkowski et al., 2019), while in real scenarios, many questions can have multiple correct answers. Fewer datasets for QA or machine reading comprehension (MRC) have been proposed with the consideration of multiple answers. In extractive MRC, MASH-QA (Zhu et al., 2020) allows one question to be answered by multiple non-consecutive text spans. In abstractive MRC/QA, MS MARCO (Campos et al., 2016) simply treats different workers' answers as different answers. DuReader (He et al., 2018) merges similar answers during data construction. QReCC (Anantha et al., 2021) allows one worker to provide multiple different answers. Beyond these, WebQuestions (Berant et al., 2013) and GooAQ (Khashabi et al., 2021) include lists of diverse answers, and TREC-QA (Baudiš and Šedivỳ, 2015) uses regular expressions to capture multiple answers. However, none of the aforementioned efforts have investigated effective consolidation of multiple answers. In this work, we formally define and collect a dataset for the answer consolidation problem as a complement to previous work. From another perspective, AmbigQA (Min et al., 2020) focuses on the case where a question can be interpreted in different ways, leading to the question disambiguation task. This is fundamentally different from our work that partitions answers to the same question into different coherent subsets. Stance detection (Liu et al., 2021) is concerned with the focused problem of collecting approving/disapproving opinions for a yes-no question, unlike our studied problem where all multi-answer questions are considered and the answers are not limited to binary opinions.

Answer Summarization. Questions with multiple answers are common in online communities. For example, Liu et al. (2008) observe that no more than 48% of best answers on Yahoo! Answers are unique. Many efforts (Song et al., 2017; Chowdhury and Chakraborty, 2019; Fabbri et al., 2021) have been devoted to summarizing reusable answers in community QA. Particularly, AnswerSumm (Fabbri et al., 2021) proposes a dataset where different answers are rewritten to bullet points by humans. While training on summarization data may enable the model to return salient and non-redundant answers, such training only works for abstractive machine readers. A more related work is BERT-DDP (Fujita et al., 2020), which considers the problem of getting a diverse and non-redundant answer set. They construct a dataset based on Yahoo! Chiebukuro where workers are asked to provide an answer set given a question. However, the correct answer set is not unique when answers are equivalent. As they treat all but the annotated answer set as wrong, both training and inference are prone to false negatives. In this paper, we group the answers with respect to their aspects and provide a discriminant rule, such that the correct group assignment is unique.

Diverse passage retrieval. Many information retrieval efforts address the problem of retrieving diverse documents for a query (Clarke et al., 2008; Fan et al., 2018; Abdool et al., 2020). In QA, Min et al. (2021) examine answer diversity in passage retrieval and propose a self-supervised dynamic oracle training objective. However, as passages may contain irrelevant information to the question, the retriever faces the challenge of identifying and integrating answers in passages when assessing answer diversity. In this work, we consider a dedicated task of answer consolidation and leave the problem of identifying answers to previous QA stages.

3 Answer Consolidation Task

Motivation. Many questions can have multiple correct answers, including questions explicitly asking for a multi-answer list (e.g., *What are the symptoms of flu?*) or questions where different people have different opinions (e.g., debate questions), amongst others. To provide users with a comprehensive view of the answers, the QA system needs to actively identify different answers as opposed to only returning the most popular or top-ranked answer. Additionally, as the same answer may be repeated or paraphrased many times in the reference corpus (e.g., web), the QA system may also need to eliminate the redundant answers. We address these requirements within answer consolidation.

Basic concepts. When answering a specific question, different answers may be given regarding different perspectives, opinions, angles, or parts of the overall answer. We regard such answers as those pertaining to different *aspects*. Furthermore, we refer to two sentences as *equivalent* if they contain the same answer aspect(s) and *distinct* if they express different answer aspect(s). To better identify equivalent/distinct sentences, we propose the following operational discriminant rule: Given two answer-mentioning sentences s_1, s_2 for the same question q, we can rewrite the answers contained in s_1 and s_2 into yes-no questions q'_1 and q'_2, which can be answered by yes/no/irrelevant.[2] Then, if s_1 and s_2 give coherent answers of yes/no[3] to q'_2 and q'_1, respectively, then s_1 and s_2 are considered to represent equivalent aspects. Otherwise, they are considered distinct from each other.

We take the following example:

Q: Is coffee good for your health?
S1: Coffee can make you slim down.
S2: Coffee can relieve headache.
S3: Coffee can help with weight loss.

Then we rewrite the answers contained in sentences as the following questions:

Q'1: Can coffee make you slim down?
Q'2: Can coffee relieve headache?
Q'3: Can coffee help you with weight loss?

We can tell that S1 and S3 are equivalent, as they both give coherent answers (yes) to each others' yes-no questions. We can also tell that S2 is distinct from S1 and S3, as it gives irrelevant answers to Q'1 and Q'3.

Task definition. A formal definition for answer consolidation is that given a question and a set of answer-mentioning sentences, answer consolidation aims at putting sentences into groups such that: (1) each sentence belongs to exactly one group, and (2) sentences from the same/different groups are equivalent/distinct. In this way, each sentence group corresponds to the same answer aspect(s). We show in §4.3 that although this definition may fail for a pair of sentences if they are partially relevant, it only occurs for 2.6% of sentences, which shows that our operational task definition works well for the majority of sentences in practice.

In this work, we treat answer consolidation as a stand-alone process applied after QA retrieval such that we only take the question and answer-mentioning sentences as input. In this way, the answer consolidation model is independent of the retriever and the reader architectures, and can flexibly adapt to different QA systems. We show in §6.3 that taking sentences instead of answer spans as input leads to better performance.

4 Question-Answer Consolidation Dataset (QUASI)

In this section, we describe the creation of our Question-Answer consolidation dataset (QUASI) including corpus collection (§4.1) and dataset annotation (§4.2). We then provide statistical and quantitative analysis of QUASI (§4.3).

4.1 Corpus

We created QUASI based on the Quora question pairs (QQP) corpus (Chen et al., 2018), which consists of 364k questions pairs, originally designed for predicting whether pairs of questions have the

---

[2] A general process for changing a sentence to questions can be found at `https://www.wikihow.com/Change-a-Statement-to-Question`.

[3] Answers of irrelevant are not considered coherent.

same meaning. We start with QQP since Quora questions have a high expected propensity of having multiple correct answers. In preprocessing, we removed questions containing spelling errors or non-English words using the Enchant library.[4] and questions containing personal pronouns including {"I", "you", "we", "my", and "your"} as we found that such questions frequently ask about very specific personal experiences for which the answers may not necessarily contain any noteworthy claims, opinions, or facts in the answer.

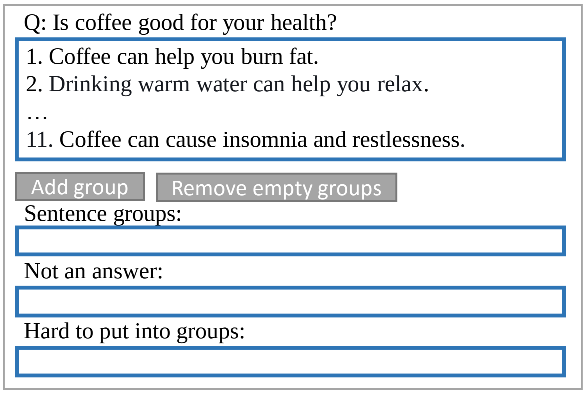
Next, we retrieved sentences that were likely to contain multiple answers to the questions. Given a question, we retrieved relevant sentences from the web using a SoTA industry QA retriever, where each sentence was associated with a relevance score and a URL. To ensure the questions have multiple answers, we first removed sentences retrieved from `quora.com` and kept the questions if the relevance scores of the top three retrieved sentences were larger than specified low-confidence threshold. Finally, we kept the top 10 sentences for each remaining question and pass to crowd workers for sentence group annotation.

4.2 Annotation

We used Amazon Mechanical Turk (AMT) to annotate QUASI. Each AMT HIT consisted of a question and 11 sentences (including the top-10 relevance scores and one additional *attention-check* sentence) where the crowd workers were required to: (1) identify sentences that actually contain answers to the question and (2) put answer-mentioning sentences into sentence groups with respect to their aspects. The workers were allowed to skip an answer-mentioning sentence if it was hard to put it into any groups (e.g., sentences containing more than one aspect).

The AMT interface is shown in Figure 1. Annotation was performed by dragging the sentences between blue boxes. The sentence groups could be added or removed using the two buttons. To submit the HIT, workers needed to put all sentences into boxes corresponding to either a specific sentence group, *not an answer*, or *hard to put into groups*.

Cost. Each HIT was assigned to three annotators with pay of $0.50/HIT, leading to target an hourly pay rate of $15. We randomly sampled 5k questions from §4.1 for HIT submission to AMT.



Q: Is coffee good for your health?

1. Coffee can help you burn fat.
2. Drinking warm water can help you relax.
...
11. Coffee can cause insomnia and restlessness.

Sentence groups:

Not an answer:

Hard to put into groups:

Figure 1: The interface used to collect the dataset. The second sentence is an attention-check sentence.

Quality Control. We used three strategies to ensure the annotation quality:

1. **Workers selection.** We only allowed crowd workers with acceptance rate $\geq 98\%$ and had completed at least 5k hits to work on the task. We provided annotation guidelines and examples of 3 annotated hits to instruct the workers.
2. **Qualification test.** We manually annotated three hits as the qualification test. Workers were required to practice on these three hits and get the correct sentence groups on at least 2 hits to continue working on the task. We pay $0.05 for each submitted hit in the qualification test. Although we had provided detailed instructions, only 24% of workers passed the qualification test.
3. **Attention checker.** For all hits, we added an attention-check sentence that was randomly sampled from other questions, so that it was unlikely to answer the question. As a part of the task, the worker needed to identify that this attention-check sentence did not involve an answer, otherwise she/he would be blocked from continuing to work on the task.

Label aggregation. To ensure data quality, we aggregated worker annotations. To derive the sentence set for answer consolidation, we begin by only considering sentences put into any sentence group(s) by all crowd workers as eligible, keeping 37,588 out of 50k sentences. Next, we derived the aggregated sentence groups from AMT annotations. As we are not aware of existing methods for this process, we proposed the following algorithm for constructing new sentence groups. First, we sort the sentences by their relevance scores and create a sentence group with the most relevant sentence

---

[4] `https://abiword.github.io/enchant/`

Type	Description	Example	Percentage
Formatting	Sentences only differ in letter case, punctuation, or short forms.	Q: How small can a black hole be? S1: scientists think the smallest black hole are as small as just one atom. S2: Scientists think the smallest black holes are as small as just one atom.	9%
Exact match	Sentences are different but answer spans are the same.	Q: What are some good stories of revenge in relationship? S1: Shakespeare's "Hamlet" is one of the most famous plays of revenge. S2: The play, Hamlet by William Shakespeare explores the concept of revenge.	47%
Lexical variation	Answer spans differ in articles, verb tenses, or have synonym substitutions.	Q: Is it hard to get a job as a fashion buyer? S1: Fashion jobs in merchandising can be very challenging. S2: Picking one out of many fashion jobs generally is an overwhelming challenge.	11%
Semantic variation	Answers are paraphrased, or identification requires commonsense reasoning.	Q: How does the respiratory system work? S1: The respiratory system works by getting the good air in and the bad air out. S2: The Respiratory System a simple system designed to get oxygen into the body, and to get rid of carbon dioxide and water.	30%
Ambiguous	We do not agree with the crowd workers' annotation.	Q: Is Zeus more powerful then Odin? (Not the same aspects.) S1: Zeus is 10 ton more than Odin. S2: In DC, Zeus is higher than Odin.	3%

Table 1: Types of equivalent sentences annotated by crowd workers. We randomly sampled 100 sentence pairs in the same group, manually annotated the answer span (underlined), and categorized them into different types.

being the only member. We then iterate over the remaining sentences with the following procedure. For a sentence s, there are three possible cases:

1. If there existed one group $\mathcal{G}$ such that $\forall s' \in \mathcal{G}$, s and s' were put into the same group by all workers, and for all already added sentences $s^* \notin \mathcal{G}$, s and s^* were put into different groups by all workers, we added s to $\mathcal{G}$.
2. If for all already added s^*, s and s^* were put into different groups by all workers, we created a new group with s being the only member.
3. Otherwise, we discarded sentence s, since there was disagreement on this sentence.

Finally, we keep each question for which the number of preserved sentences was larger than one. Our aggregation algorithm produced sentence groups on a subset of sentences, on which all workers agree on each pair of sentences about whether they belong to the same group or not. After this process, 4,699 out of 5,000 questions and 24,006 out of 37,588 sentences were kept.

4.3 Dataset Analysis

We provide statistical and qualitative analyses regarding QUASI in this section.

Annotation quality. We first analyze the quality of data annotation before label aggregation. In the first annotation task of identifying whether a sentence contains an answer, AMT workers achieved an inter-annotator Fleiss' kappa of 0.62, an average agreement rate of 90.2%, and a worker agreement with aggregate (WAWA) of 82.5% in F_1. WAWA is used to compare the majority vote with all workers' annotations. In the second annotation task of sentence grouping, we first get the set of sentences that all workers put into some groups. We then calculate the workers' agreement on each pair of sentences regarding whether they belong to the same group or not. The inter-annotator Fleiss' kappa, average agreement rate, WAWA F_1 are 0.46, 84.8%, and 75.9%, respectively. These results show that the overall annotation quality is usable, but with room for improvement. Accordingly, to further improve the data quality, we only keep group annotations on which all workers agree (as stated in §4.2).

Dataset statistics. Our final dataset consists of 4,699 questions, 24,006 sentences, and 19,676 groups. On average, there are 4.18 groups per question, and 1.22 sentences per group. Specifically, 97.7% of questions have multiple aspects (sentence groups), and 45.4% of questions have at least one pair of equivalent sentences. In terms of sentence groups, 86.6% of groups have only one sentence, 8.8% of groups have two sentences, and the remaining 4.6% of groups have 3 or more sentences. Overall, this analysis shows that our dataset contains both multi-aspect and redundant answers that align with the challenges of answer consolidation.

Types of equivalent sentences. To get a better understanding of the required knowledge to identify equivalent sentences, we randomly sampled 100 sentence pairs in the same group and manually labeled the pairs with the types shown in Table 1. We observed that if the machine reader has the correct answer spans, 56% (formatting and exact match) of the equivalent sentences could be directly identified by string comparison. Another 11% of the equivalent sentences only differed at the lexical level, which may be identified using lemmatization, removal of stop words, or a dictionary of synonym words. 30% of equivalent sentences are semantic variations such that identifying equivalence requires understanding of their meanings and potentially even commonsense reasoning. E.g., for the example given in Table 1, the answer consolidation model needs to understand that *oxygen* is *good air* and *carbon dioxide* corresponds to *bad air*. For the remaining 3% of pairs, we do not agree with the annotation. Either the sentences do not answer the question, or they do not contain the same aspect(s).

Limits of the task definition. During data annotation, 2.6% of answer-mentioning sentences are denoted as "*hard to put into groups*". After inspection, we find that these sentences contain more than one aspect of answers. For example, given the question *What are the best places to visit and things to do in San Diego, CA?*, one sentence may be *The San Diego Zoo, Balboa Park, and SeaWorld are the top tourist attractions in San Diego.*, which contains 3 different answers. This sentence overlaps with multiple groups and thus cannot be placed in a single group. Given the low prevalence, we leave consideration of such sentences to future work.

5 Approach

In this section, we first tackle the classification setting of answer consolidation (§5.1). Given a question and answer-mentioning sentences, the task is to predict for a pair of sentences whether they are in the same group. We consider different types of models, including sentence embedding models, cross-encoders, and answer-aware cross-encoders.

Then we consider the sentence grouping setting, presenting the method of transforming pairwise predictions to sentence groups (§5.2). For all methods, we use RoBERTa$_{\text{LARGE}}$ (Liu et al., 2019) as the encoder, noting that other pretrained language models (PLMs) can easily be incorporated as part of these methods.

5.1 Sentence Pair Classification

Sentence embedding models. Sentence embedding models (Reimers and Gurevych, 2019; Gao et al., 2021) produce for each sentence an embedding vector, with which we can use metrics such as cosine to calculate their similarity. Specifically, given a question q and a sentence s, we first tokenize them to X_q and X_s using the RoBERTa tokenizer, and then concatenate them as inputs:

<s>X_q X_s</s>

Following Gao et al. (2021), we take the <s> embedding in the last layer of PLM as the sentence embedding. Then for a pair of sentences, whether they are in the same group is decided by the cosine similarity of the sentence embedding. The similarity can be converted to binary predictions using the best threshold that is selected on the validation set.

The sentence embedding models can work in both zero-shot and supervised settings. In the zero-shot setting, we directly use the pretrained sentence embedding model to make predictions without fine-tuning. In the supervised setting, given a pair of sentence embedding $\boldsymbol{h}_1$, $\boldsymbol{h}_2$, and label $y \in \{0, 1\}$, where 0 and 1 mean not in/in the same group respectively,[5] we fine-tune the PLM based on the following regression objective of sentence-transformers (Reimers and Gurevych, 2019):

$$\mathcal{L}_{\text{reg}} = \left(\cos\left(\boldsymbol{h}_1, \boldsymbol{h}_2\right) - y\right)^2 .$$

Cross-encoders. Cross-encoders (Devlin et al., 2019; Liu et al., 2019) take a pair of sentences as the input and predict whether they are in the same group or not. Given a question q and two answer-mentioning sentences s_1 and s_2, we first tokenize them as X_q, X_{s_1}, and X_{s_2} using the RoBERTa tokenizer, and then take $X_q\ X_{s_1}$ and $X_q\ X_{s_2}$ as two segments of inputs, following the input formats of sentence pair classification tasks (Liu et al., 2019):

<s>X_q X_{s_1}</s></s>X_q X_{s_2}</s>

Prediction is independently performed on sentence pairs using a binary classifier on the first special (classification) token <s> embedding in the last layer of the PLM. The cross-encoders work in both zero-shot and supervised settings. In the zero-shot setting, we fine-tune the model on the MNLI (Williams et al., 2018) dataset and take *entailment* as *in the same group*. In the supervised setting, given the sentence pair embedding (obtained from <s>) $\boldsymbol{h}$ and the label y, we fine-tune

---

[5] We find that using 0 for *not in the same group* achieves better results than using -1.

the model using the binary cross-entropy loss:

$$p = \sigma\left(\boldsymbol{w}^\intercal \boldsymbol{h}\right),$$
$$\mathcal{L}_{\text{bce}} = -\left(y \log p + (1-y)\log(1-p)\right),$$

where p is the probability that the sentences are in the same group, σ is the sigmoid function, $\boldsymbol{w}$ is a parameter of the classifier. In inference, we convert p to binary predictions using the best threshold selected on the validation set. The cross-encoders require predicting on all sentence pairs and have higher computational costs than sentence embedding models. However, we observe in experiments that cross-encoders consistently outperform sentence embedding models in the supervised setting.

Answer-aware (A^2) cross-encoders. §4.3 shows that 56% of equivalent sentences can be directly identified if the model knows the answer spans. Therefore, we provide the answer consolidation models with answers generated from the UnifiedQA$_{\text{LARGE}}$ model (Khashabi et al., 2020). As the UnifiedQA is trained on both extractive and abstractive datasets, the answers may not be text spans of sentences. Specifically, given a question q, two sentences s_1 and s_2, and the generated answers a_1 and a_2, we first tokenize them as X_p, X_{s_1}, X_{s_2}, X_{a_1}, and X_{a_2}, respectively, then construct the input to cross-encoders as:

$$\texttt{<s>}X_q\ X_{s_1}\ X_{a_1}\texttt{</s></s>}X_q\ X_{s_2}\ X_{a_2}\texttt{</s>}$$

The training process and inference process are the same as the cross-encoders.

5.2 Sentence Grouping

In answer consolidation, our ultimate goal is to obtain the consolidated sentence groups. This is done in a two-step approach. The first step is to get the matrix of distances $\mathcal{D}$ between pairs of sentences for a question. We perform this step using models trained in the classification setting. For sentence embeddings, $\mathcal{D}$ is adopted as the pairwise cosine distance matrix. For cross-encoders, each entry of $\mathcal{D}$ equals to 1 minus the predicted probability for a sentence pair. As $\mathcal{D}$ derived in this way may not be always symmetric, we use $\frac{1}{2}\left(\mathcal{D} + \mathcal{D}^\intercal\right)$ as the distance matrix instead.

The next step is to transform the distance matrix into sentence groups. Here we apply agglomerate clustering (Han et al., 2011). It uses a bottom-up strategy, starting from letting each sentence form its own cluster, and then recursively merging the clusters if their distance is smaller than a threshold. We use the average distance of sentence pairs as the inter-cluster distance measure and select the best threshold on the validation set. Agglomerate clustering stops when the distances between all clusters are larger than the threshold.

6 Experiments

In this section, we present the experimental setup (§6.1), show the main results (§6.2), conduct an ablation study (§6.3), and provide error analysis (§6.4).

6.1 Experimental Setup

Dataset. We randomly split the 4,699 questions into an 80/10/10 split, which serves as the training, validation, and test set, respectively.

Evaluation metrics. We use different evaluation metrics in the two evaluation settings. For the classification setting, we first use the micro F_1 measure. Considering that classes in the dataset are highly imbalanced (only 11% of sentence pairs are in the same group), we additionally use the Matthews correlation coefficient (MCC; Matthews 1975), which is considered a more class-balanced metric. For the sentence grouping setting, we use clustering metrics including adjusted rand index (ARI; Rand 1971) and adjusted mutual information (AMI; Nguyen et al. 2009). These two metrics take the predicted grouping and the ground-truth grouping, and measure the similarity between them. For all metrics, larger values indicate better performance, and a value of 100% indicates perfect classification/grouping.

Configuration. We implement the models using Huggingface's Transformers (Wolf et al., 2020). The models are optimized with Adam (Kingma and Ba, 2015) using a learning rate of $1\text{e}{-5}$, with a linear decay to 0. We fine-tune all models for 10 epochs with a batch size of 32 questions (including all associated sentence pairs). The best model checkpoint and thresholds are selected based on the validation set. We report the average results on 5 runs of training using different random seeds.

Models. We use RoBERTa$_{\text{LARGE}}$ (Liu et al., 2019) as the encoder for all models. For sentence embedding models, we try RoBERTa fine-tuned on two intermediate tasks: 1) SRoBERTa (Reimers and Gurevych, 2019) is fine-tuned on natural language inference (NLI) datasets, achieving better

Model	Classification		Grouping

results on semantic textual similarity (STS) tasks, and 2) SimCSE-RoBERTa (Gao et al., 2021) is fine-tuned in a self-supervised fashion, taking a sentence and predicting itself using a contrastive learning objective. For cross-encoders, in addition to directly running supervised fine-tuning on our data, we also try supplementary training on an intermediate labeled-data task (Phang et al., 2018), which fine-tunes cross-encoders on MNLI before supervised fine-tuning. Particularly in the latter setting, we observe it being necessary to re-initialize the classifier before supervised fine-tuning to obtain more promising performance.

6.2 Main Results

The experimental results on both the pairwise classification and sentence grouping settings are reported in Table 2. We observe that in the zero-shot setting, intermediate-task training improves answer consolidation, while the performance remains far behind supervised models. In the supervised setting, cross-encoders consistently outperform the sentence embedding models. Overall, the answer-aware cross-encoder intermediately tuned on MNLI (A^2RoBERTa-MNLI) achieves the best results on all metrics, showing that intermediate-task training on MNLI improves performance. Besides, we find that answer-aware cross-encoders outperforms regular cross-encoders, showing that answers generated by the machine reader provide additional information that helps consolidation.

Model	Classification		Grouping

Table 3: Results with different input formats on the test set. Q, S, A denotes question, sentences, and answers (generated by UnifiedQA), respectively. RoBERTa-MNLI (Q+S+A) is equivalent to A^2RoBERTa-MNLI.

6.3 Ablation Study

In this section, we study the model performance based on different input information given to supervised models. We denote the questions, sentences as Q, S, and answers generated by UnifiedQA as A. The results are shown in Table 3. Overall, models trained on all inputs (Q+S+A) achieve better results than those that have observed only a subset of the available inputs on most metrics. Removing the sentences leads to the largest drops in performance (e.g., 20.9% in F_1 for SimCSE-RoBERTa and 22.3% in F_1 for RoBERTa-MNLI), which shows that sentences provide useful information for answer consolidation. Using sentences only leads to the second-largest drop in performance, showing that without grounding to questions and answers, consolidation is not simply addressed only with the sentences. Besides, removing questions also leads to more significant drops in performance than removing answers (e.g., 4.9% in F_1 for SimCSE-RoBERTa and 2.3% in F_1 for RoBERTa-MNLI). This shows that it is necessary to understand the answer equivalence within the question context in order to consolidate answers.

6.4 Error Analysis

To get a sense of what knowledge is needed to further improve model performance, we examined sentence pairs incorrectly classified as *not in the same group* by A^2RoBERTa in the validation and test sets, where 318 out of 2,614 pairs (12.2%) are wrongly classified. We randomly sample 50 such error cases and categorize them by the answer-equivalence type as defined in Table 1. Of the 50

Cause	Description	Example
Entailment (16.7%)	One answer is entailed by the other.	Q: What makes successful people different from average people? S1: Wealthy people are not afraid of failure, unlike average people who often do not even try. S2: The difference between average people and achieving people is their perception of and response to failure.
Entity/commonsense knowledge (23.8%)	The answers refer to the same entity or are equivalent by common sense.	Q: What are some best Hollywood romantic movies to watch? S1: When the subject of romantic movies comes up, one of the first that comes to mind in any list of all-time greats is Casablanca. S2: Humphrey Bogart and Ingrid Bergman's film about love and loss during WWII is basically required viewing for anyone who enjoys romantic movies.
Semantic equivalence (57.1%)	The answers have the same semantic meaning but are expressed using different words.	Q: What is the equity risk premium? S1: Equity Risk Premium is the difference between returns on equity/individual stock and the risk-free rate of return. S2: Let us start with defining the equity risk premium: the Equity Risk Premium is the average extra return demanded by investors, on top of a risk free rate, as a compensation for investing in equity securities with average risk.
Spelling errors (2.4%)	There are spelling errors in the answers.	Q: Are all psychopaths narcissists? S1: I came across that all psychopats are narcissists, but not all narcissists are psychopats. S2: I have read it summed up this way: Not all narcissists are psychopaths, but all psychopaths are narcissists.

Table 4: Different causes of wrongly classified positive pairs.

pairs, 1 (2%) is from *exact match*, 8 (16%) are ambiguous, and the remaining 41 (82%) are from the *semantic variation* category, showing that it is the most challenging type to tackle.

We further study the specific causes of errors on the 42 unambiguous pairs. Examples of distinct error causes are described in Table 4 We find that 16.7% of the falsely classified sentence pairs contain one answer that entails the other instead of expressing the exact same answers, which should however be considered redundant answers by our definition. 80.9% of pairs are equivalent but require understanding the semantic meanings or entity-specific/commonsense knowledge. The rest 2.4% contain spelling errors that negatively affect model inference.

7 Conclusion

In this paper, we formulate and propose the answer consolidation task that seeks to group answers into different aspects. This process can be used to construct a final set of answers that is both comprehensive and non-redundant. We contribute the Question-Answer consolidation dataset (QUASI) for this task and evaluate various models, including sentence embedding models, cross-encoders, and answer-aware cross-encoders. While the best-performing supervised models have achieved promising performance, without that abundant annotation, unsupervised methods still remain far from perfect. This suggests room for further studies on more robust and generalizable solutions for answer consolidation that would largely benefit real-world open-domain QA systems.

Informativeness and Invariance:
Two Perspectives on Spurious Correlations in Natural Language

Jacob Eisenstein
Google Research
jeisenstein@google.com

Abstract

Spurious correlations are a threat to the trustworthiness of natural language processing systems, motivating research into methods for identifying and eliminating them. However, addressing the problem of spurious correlations requires more clarity on what they are and how they arise in language data. Gardner et al. (2021) argue that the compositional nature of language implies that *all* correlations between labels and individual "input features" are spurious. This paper analyzes this proposal in the context of a toy example, demonstrating three distinct conditions that can give rise to feature-label correlations in a simple PCFG. Linking the toy example to a structured causal model shows that (1) feature-label correlations can arise even when the label is invariant to interventions on the feature, and (2) feature-label correlations may be absent even when the label is sensitive to interventions on the feature. Because input features will be individually correlated with labels in all but very rare circumstances, domain knowledge must be applied to identify spurious correlations that pose genuine robustness threats.

1 Introduction

Spurious correlations are a growing source of concern in machine learning (Geirhos et al., 2020) and related fields including natural language processing (Gururangan et al., 2018; McCoy et al., 2019, *inter alia*). While the intuition is fairly clear — spurious correlations are features that are useful in the training data but unreliable in general — the notion is frequently referenced without a formal definition. Gardner et al. (2021) propose a definition in terms of conditional probabilities: a feature X_i is spuriously correlated with the label Y unless $P(Y \mid X_i)$ is uniform. The definition can be generalized from uniformity to independence ($X_i \perp\!\!\!\perp Y$) without affecting the claims of the paper. They go on to argue that "in a language understanding problem, …*all* simple correlations between input features and output labels are spurious" (emphasis in the original). The property that individual input features should be independent of labels — which I will call *marginally uninformative input features (UIF)*[1] — is treated as an assumption about the nature of language processing and also as a desideratum that datasets should satisfy: if the label can be predicted from input features alone, then the dataset is in some sense too easy.[2]

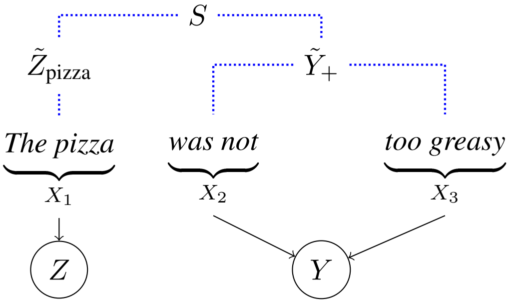

Figure 1: An instance from the toy model. The upper part of the figure corresponds to f_X, the function that generates the text via a PCFG (see fig. 2): nodes represent non-terminals in the grammar and edges represent context-free derivations. The lower part of the figure corresponds to the causal model of the sentiment Y and target Z. Here nodes represent random variables and edges represent causal relationships.

---

[1] The features are *marginally* uninformative because the criterion is the marginal distribution $P(Y|X_i) = \int P(Y, X_{\neg i}|X_i)dX_{\neg i}$. Features may be marginally uninformative while still giving information about the label when viewed in combination.

[2] To formalize the UIF assumption, it is necessary to clarify which features are "input features": bytes, phonemes, wordpieces, words, phrases, or sentences? The selection of input features is a property of the model and not the dataset, but the intuitive support for UIF seems stronger for features that are lower on the linguistic hierarchy. Because the arguments presented here don't depend on the specific definition of input features, I will follow Gardner et al. (2021), who informally identify input features with words. However, if one were to apply UIF for a practical purpose such as dataset curation, it would be important to explore this issue more thoroughly, particularly in regard to languages in which words are the sites

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4326 - 4331
July 10-15, 2022

The principle of UIF is based on the insight that linguistic context can modulate the semantics of any subspan of a text, using mechanisms such as syntactic negation or discourse markers. Furthermore, the frequency of negation and other forms of semantic inversion may vary across datasets and deployment settings. A predictor that relies on negation being rare (to pick one example) cannot be said to have truly achieved competence in the language processing task. Such a predictor may perform poorly in domains in which these high-level distributional properties shift.

An especially provocative assertion of Gardner et al. is that all correlations between labels and individual input features have the same status. In the sentence *the pizza was amazing*, suppose that both *pizza* and *amazing* are correlated with positive sentiment because the reviewers like pizza. There are at least two intuitive differences between these two correlations. First, while one can easily imagine a benighted subpopulation of reviewers who do not like pizza, it is not so easy to imagine reviewers who think that the word "amazing" carries negative sentiment. Second, if we modify the subject (e.g., *the **movie** was amazing*), the label will usually be unaffected, but there are many perturbations to the adjective that flip the label (e.g., *the pizza was **greasy***). This second intuition can be described using the framework of causality, which has generally treated spurious correlations as those that arise without a direct causal explanation (Simon, 1954). Given a causal model of the data generating process, we can compute an *interventional* distribution $P(Y \mid \text{do}(X_1 := x), X_2, X_3)$, which corresponds to the distribution over Y in a data generating process in which the variable X_1 is surgically set to the value x (Pearl, 1995; Peters et al., 2017; Feder et al., 2021).[3] When such interventions do not affect Y for any given example, we say that Y and X_1 are *counterfactually invariant* (Veitch et al., 2021). Violations of UIF are particularly troubling when they are accompanied by counterfactual invariance, because non-causal correlations often do not transfer to other domains (Schölkopf et al., 2012; Bühlmann, 2020).

$$\begin{aligned} U :=& N_U & (1)\\ (X_1, X_2, X_3) :=& f_X(U, N_X) & (2)\\ Z :=& f_Z(X_1, N_Z) & (3)\\ Y :=& f_Y(X_2, X_3, N_Y). & (4) \end{aligned}$$

Figure 2: Causal model for the toy example shown in fig. 1. N_U, N_X, N_Y, N_Z indicate independent noise variables, and f_X, f_Y, f_Z indicate deterministic functions that map from causes to effects (for more details on the notation, see Peters et al., 2017).

This paper uses a toy example to relate the UIF property to (1) the production probabilities in probabilistic context-free grammars (PCFGs), and (2) counterfactual invariance in structured causal models. The connection to PCFGs provides additional motivation for the UIF criterion from the perspective of domain generalization, while clarifying the scenarios that can give rise to violations of UIF, which Gardner et al. attribute too narrowly to "bias and priming effects" in annotators. The connection to counterfactual invariance highlights the ways in which these concepts do and do not align. Efforts to remove artifacts from the training and evaluation of NLP systems will be most productive when focused at the intersection of these two views of spurious correlations: violations of UIF for input features to which the label is counterfactually invariant according to a plausible causal model.

2 Toy Example

Consider a simplified targeted sentiment analysis task (Mitchell et al., 2013), in which the sentiment is Y, the target is Z, and the sentences are all of the form (X_1, X_2, X_3), with X_1 specifying a target noun phrase, X_2 a copula-like expression, and X_3 a predicative adjectival phrase. For example, $Y = \textsc{Pos}$, $Z = \textsc{Pizza}$, $X_1 =$ *the pizza*, $X_2 =$ *turned out to be*, $X_3 =$ *crispy and delicious*. We will treat this data as generated from the causal model shown in fig. 2. This causal model can be summarized by two assertions: (1) the target Z is a direct effect of only the span X_1; (2) the sentiment label Y is a direct effect of only the spans X_2 and X_3. The function f_X can represent any generative model of text: an n-gram model, a grammar-based formalism, a deep autoregressive network, etc.

---

of a significant amount of morphological composition and are therefore capable of carrying complex relational meanings. Conversely, multiword expressions can function analogously to single word features, so there is no reason in principle why only single-word features should be considered spurious (Schwartz and Stanovsky, 2022).

[3] Space does not permit a discussion of the distinction between interventions and counterfactuals (see Pearl, 2009).

Aside on the direction of causation. We treat the text as the cause of the labels, rather than the converse. This distinction is somewhat vexed (Schölkopf et al., 2012; Jin et al., 2021). In some cases the direction of causation is clear from the task (e.g., table-to-text generation, summarization, and translation), but often the problem could be framed in either direction: perhaps the writer had the label in mind when producing the text, and thus the text is an effect of the label; or perhaps it is better to think of the annotator, who must read the text to arrive at the label, regardless of the writer's intentions. When the labels cause the text, the notion of counterfactual invariance can be restated in terms of the invariance of text features to perturbations on labels, e.g. $P(X_1 \mid \mathrm{do}(Y := y), Z)$. As the toy example is meant to serve only an expository purpose, we leave elaboration of the relationship of UIF to such models for future work.

2.1 Counterfactual invariance $\not\Rightarrow$ UIF

The causal model implies several counterfactual invariance properties: intervention on X_1 will not affect Y, nor will intervention on X_2 or X_3 affect Z. This is because X_1 blocks the influence of X_2 and X_3 on Z, and vice versa for Y. Conversely, (X_3, Y) are not counterfactually invariant in general because X_3 is an ancestor of Y in the causal graph, and similarly for (X_2, Y) and (X_1, Z).

Counterfactual invariance does not imply that the associated input features are marginally uninformative of the label. Consider a classical spurious correlation in which pizza tends to receive positive sentiment and sushi receives negative sentiment. This correlation is produced when f_X encodes a PCFG with the top-level production:

$$S \rightarrow \begin{array}{ll} \tilde{Z}_{\text{pizza}}\ \tilde{Y}_{+} & (1+\alpha)/4 \\ \tilde{Z}_{\text{sushi}}\ \tilde{Y}_{-} & (1+\alpha)/4 \\ \tilde{Z}_{\text{pizza}}\ \tilde{Y}_{-} & (1-\alpha)/4 \\ \tilde{Z}_{\text{sushi}}\ \tilde{Y}_{+} & (1-\alpha)/4, \end{array} \tag{5}$$

with the right column indicating the probability of each rule expansion and $\alpha \in [-1, 1]$.[4] The nonterminal symbols $\tilde{Z}_{\text{pizza}}, \tilde{Z}_{\text{sushi}}, \tilde{Y}_{+}, \tilde{Y}_{-}$ are intentionally chosen to correspond to the labels Z and Y. Subsequent rules in the grammar can then be designed to ensure that $\tilde{Z}_{\text{pizza}}$ usually produces values of X_1 that make $Z = \textsc{Pizza}$ likely, and analogously for the other non-terminals and associated labels. The unification of PCFGs and structured causal models is shown in fig. 1.

When $\alpha \neq 0$, there may be an association between X_1 and (X_2, X_3). As a result, there exist pairs of values (x_1, x_1') such that,

$$\begin{aligned} &P(Y|X_1 = x_1) \\ &\quad= \sum_{X_2, X_3} P(Y \mid X_2, X_3) P(X_2, X_3 \mid X_1 = x_1) \\ &\quad\neq \sum_{X_2, X_3} P(Y \mid X_2, X_3) P(X_2, X_3 \mid X_1 = x_1') \\ &\quad= P(Y|X_1 = x_1'), \end{aligned} \tag{6}$$

creating a violation of UIF. The same argument can be applied to $P(Z \mid X_2)$ and $P(Z \mid X_3)$. UIF is also violated in $P(Z \mid X_1)$, $P(Y \mid X_2)$, and $P(Y \mid X_3)$, but for a different reason: these distributions are conditioned on the direct causal parents of the labels in f_Y and f_Z. Manipulation of the data distribution to ensure that $\alpha = 0$ (deconfounding $\tilde{Y}$ and $\tilde{Z}$) can remove only the violations of UIF induced by f_X, but not those induced by the direct causal relationships encoded in f_Y and f_Z: for example, if $\Pr(X_3 = \textit{delicious}|\tilde{Y}_{+}) > \Pr(X_3 = \textit{delicious}|\tilde{Y}_{-})$ then the feature *delicious* will be associated with positive sentiment regardless of the rule probabilities in eq. (5).

Discussion. The example shows how violations to UIF can emerge via confounding, creating classical spurious correlations in the sense of Simon (1954): informativeness despite counterfactual invariance. Such correlations are unlikely to be robust because it is not difficult to imagine a domain in which the sign of α changes, impairing the performance of predictors that have learned the spurious correlation. In contrast, feature-label correlations that arise directly from the causal model, such as (Z, X_1), are only damaging under more extreme forms of concept shift, in which the meanings of the features themselves change.

Aside on causality and robustness. The distinct interpretations of spuriousness as (1) noncausal and (2) non-robust are noted by Schwartz and Stanovsky (2022) in concurrent work. However, these interpretations can be reconciled by

---

[4] The stochasticity of the grammar is encoded in the deterministic function f_X through the noise variable N_X. Let $N_X \sim \text{Uniform}(0, 1)$, and choose the first rule expansion of S when $N_X < (1+\alpha)/4$, the second rule expansion when $(1+\alpha)/4 \leq N_X < (1+\alpha)/2$, and so on.

the argument that non-causal features are inherently unlikely to be robust, which is sometimes formalized as the *principle of sparse mechanism shift* (Schölkopf et al., 2021). The principle states that complex causal systems are usually composed of smaller independent parts, with domain shifts affecting only a few components of the system at a time. A related principle arises in the context of natural language: distributional frequencies are more likely to change across domains, while categorical facts about language are generally stable. Biber (1991), for example, makes this argument explicitly in the analysis of register. In our model, the implication is that the probabilistic rule expansions in f_X are more likely to change than the basic properties of the lexicon, which govern which terminal symbols can be emitted by each non-terminal.

2.2 UIF $\not\Rightarrow$ Counterfactual Invariance

Violations of counterfactual invariance can occur even when UIF is satisfied. To show this, we supply two more productions for the grammar:

$$\begin{aligned} \tilde{Y}_+ \rightarrow \quad & \textsc{Cop}_+ \ \textsc{AdjP}_+ \qquad && \beta_+ \\ & \textsc{Cop}_- \ \textsc{AdjP}_- \qquad && 1-\beta_+ \end{aligned} \tag{7}$$

$$\begin{aligned} \tilde{Y}_- \rightarrow \quad & \textsc{Cop}_+ \ \textsc{AdjP}_- \qquad && \beta_- \\ & \textsc{Cop}_- \ \textsc{AdjP}_+ \qquad && 1-\beta_- \end{aligned} \tag{8}$$

Here the non-terminal $\textsc{Cop}_+$ produces a "positive" copula in X_2 (*is*, *was*, *is universally agreed to be*), $\textsc{Cop}_-$ produces a negated copula in X_2 (*isn't*, *wasn't*, *was the furthest possible thing from*), $\textsc{AdjP}_+$ produces positive-sentiment adjectival phrases in X_3 (*great*, *delicious*), and $\textsc{AdjP}_-$ produces negative-sentiment adjectival phrases in X_3 (*disappointing*, *totally unappetizing*). There are two special cases of interest:

- When $\beta_+ = \beta_-$, the probability of using a negated copula is independent of Y, so X_2 satisfies UIF with regard to Y, while X_3 generally does not.
- When $\beta_+ = 1 - \beta_-$, the use of negation is balanced to make the distribution over sentiment terms independent of Y, so X_3 satisfies UIF with Y, while X_2 generally does not.

Combining these cases, both X_2 and X_3 satisfy UIF with Y when $\beta_+ = \beta_- = \frac{1}{2}$, meaning that negated and non-negated copula are equally likely and are independent of Y.

Discussion. UIF is violated not only by confounding, as discussed in the previous section, but also in mild settings that do not meet any reasonable definition of bias: unless $\beta_+ = \beta_- = 1/2$ then at least one of X_2 and X_3 is marginally informative of Y. Furthermore, UIF has no impact on the counterfactual invariance of X_2 and X_3 on Y. Neither is counterfactually invariant even when the generative model is parametrized to make UIF hold for all input features (see also Pearl, 2009, page 185). This is because the overall sentiment can be directly affected by adding or removing negation and by flipping the polarity of the sentiment-carrying adjective.

3 Conclusions

In the toy example, violations of UIF arise from three distinct phenomena: confounding between the sentiment and the target ($\alpha \neq 0$, leading to $X_1 \not\perp\!\!\!\perp Y$); confounding between the sentiment and the use of negation ($\beta_+ \neq \beta_-$, leading to $X_2 \not\perp\!\!\!\perp Y$); and lack of a perfect balance in the probability of negation between positive- and negative-sentiment examples ($\beta_+ \neq 1 - \beta_-$, leading to $X_3 \not\perp\!\!\!\perp Y$). The conditions required to satisfy UIF are thus progressively less plausible as we move from X_1 to X_3, and full UIF is achieved only in the perfectly balanced case of $\alpha = 0, \beta_+ = \beta_- = \frac{1}{2}$. The number of such constraints will increase with the size of the grammar, making UIF vanishingly rare in more general settings. This conclusion follows from the PCFG analysis and is derived without reference to causality.

The toy example also demonstrates the disconnect between the UIF view of spurious correlations and the causal view: counterfactual invariance does not imply UIF because X_1 can be marginally informative of Y even when X_1 and Y are counterfactually invariant (these are the artifacts that we want to remove); UIF does not imply counterfactual invariance because both X_2 and X_3 can be uninformative of Y even when Y is sensitive to interventions on both features. From a theoretical perspective, it is unsurprising that these two views diverge, because UIF is a purely observational criterion while counterfactual invariance requires an explicit causal model. Indeed, this relationship is discussed in depth by Pearl (2009, §6.3), albeit outside the context of language. The two perspectives can be seen as complementary, in that violation of

UIF is a necessary but insufficient condition for a spurious correlation in the causal sense.

Moving beyond toy examples, it is unlikely that we can construct fully-specified causal models of language that supply useful invariances while handling every possible fluent utterance. How then can we use causal insights to design better benchmarks and more robust language understanding systems? In some cases it is possible to elaborate partial causal models of a task, with associated invariance properties: for example, the sentiment of a movie review should be invariant to (though not independent of) the identities of the actors in the movie. Several existing approaches can be viewed as instantiations of partial causal models: for example, data augmentation, causally-motivated regularizers, stress tests, and "worst-subgroup" performance metrics (and associated robust optimizers) can be seen as enforcing or testing task-specific invariance properties that provide robustness against known distributional shifts (e.g., Lu et al., 2020; Ribeiro et al., 2020; Kaushik et al., 2021; Koh et al., 2021; Veitch et al., 2021). Such approaches generally require domain knowledge about the linguistic and causal properties of the task at hand — or to put it more positively, they make it possible for such domain knowledge to be brought to bear. Indeed, the central argument of this paper is that no meaningful definition of spuriousness or robustness can be obtained without such domain knowledge.

A final observation, pertaining to both UIF and counterfactual invariance, is the parallel treatment of X_2 (the copula) and X_3 (the adjectival phrase). From a lexical semantic perspective, only X_3 is directly associated with sentiment, while X_2 plays a functional role by potentially reversing X_3. It may therefore seem undesirable to learn a correlation between X_2 and Y, and preferable to attach that relationship exclusively to X_3. Indeed, one of the main catalysts of interest in spurious correlations in natural language processing was the observation that the presence of syntactic negation is a strong predictor of contradiction label in the natural language inference task, which should require reasoning about pairs of sentences (Gururangan et al., 2018; Poliak et al., 2018). Yet neither UIF nor counterfactual invariance is capable of making any distinction between X_2 and X_3 in this model. While it is possible to enforce uninformativeness on X_2 heuristically, e.g. by sampling or augmenting the data to ensure $\beta_+ = \beta_-$, those same heuristics could be applied to enforce uninformativeness on X_3 by making $\beta_+ = 1 - \beta_-$. Singling out X_2 requires additional justification. Such a principle might be found in the multitask setting, in which we prefer feature-label informativeness to be sparse, with each feature directly informing only a few labels.

FOAM: A Follower-aware Speaker Model For Vision-and-Language Navigation

Zi-Yi Dou, Nanyun Peng
Department of Computer Science
University of California, Los Angeles
`{zdou,violetpeng}@cs.ucla.edu`

Abstract

The speaker-follower models have proven to be effective in vision-and-language navigation, where a speaker model is used to synthesize new instructions to augment the training data for a follower navigation model. However, in many of the previous methods, the generated instructions are not directly trained to optimize the performance of the follower. In this paper, we present FOAM, a FOllower-Aware speaker Model that is constantly updated given the follower feedback, so that the generated instructions can be more suitable to the current learning state of the follower. Specifically, we optimize the speaker using a bi-level optimization framework and obtain its training signals by evaluating the follower on labeled data. Experimental results on the Room-to-Room and Room-across-Room datasets demonstrate that our methods can outperform strong baseline models across settings. Analyses also reveal that our generated instructions are of higher quality than the baselines.[1]

1 Introduction

The task of vision-and-language navigation (VLN) requires an agent to navigate in a real-world environment given natural language instructions. In VLN, one of the major challenges is the lack of training data. To alleviate the issue, speaker-follower models (Fried et al., 2018b) have been proposed. Specifically, in the speaker-follower models, an instruction-follower agent is trained to follow a provided natural language instruction to complete a specified goal, and a speaker model learns to model how humans describe routes and synthesize new instructions so as to create more training data for the follower.

While speaker-augmented data is widely used in VLN (Fried et al., 2018b; Wang et al., 2019; Ma et al., 2019; Tan et al., 2019; Zhu et al., 2020a; Hao et al., 2020; Wang et al., 2021; Chen et al., 2021), most of the previous methods focus on improving the follower navigation model. In contrast, how to improve the speaker model to generate data of higher quality is underexplored. In this line of research, Fried et al. (2018a) build a pragmatic speaker that can synthesize instructions based on how the follower may interpret the instructions; Tan et al. (2019) propose to randomly add noise into the environments when generating instructions, so that the noisy environments can mimic unseen environments and the generated instructions can be more diverse; Kurita and Cho (2021) propose a generative approach for VLN where a speaker model is trained and the actions of the follower are selected by maximizing the probability of generating the given instruction.

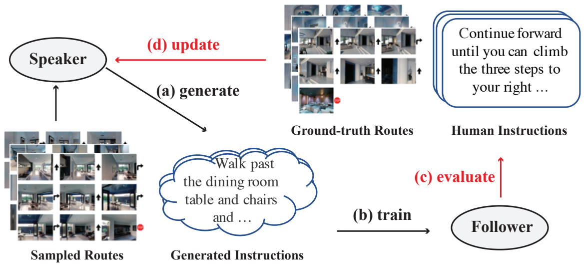

Figure 1: Many of the previous methods use the speaker to generate instructions from sampled routes and train the follower. FOAM (in red) further obtains feedback from the follower on labeled data and updates the speaker accordingly.

In this paper, we propose a follower-aware speaker model (FOAM) that optimizes the generated instructions by directly obtaining feedback from the follower so that the generated instructions can be more suitable for the follower. To this end, we frame the idea as a bi-level optimization problem and obtain the feedback signals to improve the speaker based on the follower performance on labeled data. As illustrated in Figure 1, the follower and speaker are trained in an iterative manner: after

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4332 - 4340

updating the follower for one step, it is evaluated on a batch of labeled data and the speaker is updated given the performance of the follower. In this way, the speaker is trained to directly optimize the performance of the follower.

Experiments on Room-to-Room (Anderson et al., 2018b) and Room-across-Room (Ku et al., 2020) demonstrate strong performance of FOAM over baselines. Notably, FOAM can achieve comparable performance to a model pre-trained with over millions of text sentences and image-text pairs. Analyses also reveal that our speaker generates instructions of higher qualities than baselines.

2 Methods

We first introduce the background before discussing the details of FOAM.

2.1 Background

Base Settings. VLN requires an agent to follow a given instruction and find a route in a photo-realistic environment (*e.g.* navigate in indoor living spaces). Formally, in an environment $\mathbf{e}$, the follower F parameterized by θ_F learns to model the distribution $P(\mathbf{r}|\mathbf{i};\theta_F)$, where $\mathbf{i}$ and $\mathbf{r}$ denote instruction and route variables, respectively.

The training data $\mathcal{D}$ consists of instruction-route pairs from different environments. Given a batch of instruction-route pairs $(\mathbf{i}_k, \mathbf{r}_k)$ from $\mathcal{D}$, we train the follower F to minimize the cross-entropy loss between its prediction $F(\mathbf{i}_k;\theta_F) = P(\hat{\mathbf{r}}|\mathbf{i}_k;\theta_F)$ and the ground-truth label $\mathbf{r}_k$. Here, we denote this supervised loss as L_l:

$$\min_{\theta_F} L_l(\theta_F) = \mathbb{E}_{(\mathbf{i}_k,\mathbf{r}_k)\sim\mathcal{D}}[\mathrm{CE}(\mathbf{r}_k, F(\mathbf{i}_k;\theta_F)))]. \quad (1)$$

Speaker-Follower Models. Fried et al. (2018b) propose to train a speaker model S parameterized by θ_S that models the distribution of $P(\mathbf{i}|\mathbf{r};\theta_S)$. As in Figure 1, with the speaker, we can perform back translation (Sennrich et al., 2016) on randomly sampled routes $\hat{\mathbf{r}}$ from the training environments $\mathcal{E}$ for data augmentation. Specifically, we first train the speaker S on the same training data as the follower. Then, given a batch of sampled route $\hat{\mathbf{r}}_k \sim \mathcal{E}$, we synthesize their human-like textual instructions $\hat{\mathbf{i}}_k = S(\hat{\mathbf{r}}_k;\theta_S)$. Afterwards, the synthesized training instances $(\hat{\mathbf{i}}_k, \hat{\mathbf{r}}_k)$ are used to update F. Here, we denote this loss as L_u:

$$\begin{aligned}\min_{\theta_F} L_u(\theta_F,\theta_S) &= \mathbb{E}_{(\hat{\mathbf{i}}_k,\hat{\mathbf{r}}_k)\sim\mathcal{E}}[\mathrm{CE}(\hat{\mathbf{r}}_k, F(\hat{\mathbf{i}}_k;\theta_F))] \\ &= \mathbb{E}_{\hat{\mathbf{r}}_k\sim\mathcal{E}}[\mathrm{CE}(\hat{\mathbf{r}}_k, F(S(\hat{\mathbf{r}}_k;\theta_S);\theta_F))].\end{aligned} \quad (2)$$

2.2 Optimizing the Speaker

As we can see from Equation 2, the resulting follower parameters θ_F^* depends on the speaker parameters θ_S, and we can express the dependency as $\theta_F^*(\theta_S)$. However, existing speaker-follower models fail to incorporate θ_S into the optimization process and θ_S is always fixed during training.

Formulation. In this paper, we propose to optimize the parameters of both the follower and speaker during back translation. Specifically, taking inspirations from Pham et al. (2021a,b), we optimize the speaker based on the performance of the follower on the labeled training data, which can be expressed as:

$$\begin{aligned}&\min_{\theta_S} L_l(\theta_F^*(\theta_S)), \\ &\text{where } \theta_F^*(\theta_S) = \operatorname*{argmin}_{\theta_F} L_u(\theta_F,\theta_S).\end{aligned} \quad (3)$$

The motivation of Equation 3 is that while the speaker-augmented data can provide additional supervisions for the follower, the main objective of the speaker is to make the follower better follow human instructions, thus we should focus on minimizing follower's loss on the labeled training data.

Approximation. Following previous work in bi-level optimization (Finn et al., 2017; Liu et al., 2018; Pham et al., 2021a,b), we can approximate argmin with one-step gradient update and alternatively update the parameters θ_F and θ_S.

Specifically, at training step t, we first sample a batch of routes and synthesize their instructions using the speaker S. The generated data is used to update the follower:

$$\theta_F^t = \theta_F^{t-1} - \eta_F \nabla_{\theta_F} L_u(\theta_F^{t-1}, \theta_S^{t-1}), \quad (4)$$

where η_F is the learning rate.

Then, the speaker is updated to optimize the objective $L_l(\theta_F^t)$ with

$$\theta_S^t = \theta_S^{t-1} - \eta_S \nabla_{\theta_S} L_l(\theta_F^t(\theta_S)). \quad (5)$$

We can approximate the gradient $\nabla_{\theta_S} L_l(\theta_F^t))$ (derivation details in Appendix A) with

$$-[\nabla_{\theta_F} L_l(\theta_F^t)^{\mathrm{T}} \nabla_{\theta_F} L_u(\theta_F^{t-1}, \theta_S^{t-1})] \nabla_{\theta_S} \log P(\hat{\mathbf{i}}_k|\hat{\mathbf{r}}_k;\theta_S^{t-1}). \quad (6)$$

We can see that this equation resembles REINFORCE (Williams, 1992) in reinforcement learning. Therefore, this algorithm can also be interpreted as treating the similarity in the gradients of the follower model on the labeled data and on the augmented data as rewards, and update the speaker model using reinforcement learning.

End-to-End Reconstruction Loss. In this paper, we also propose to add a reconstruction loss for the speaker. Concretely, we compute the gradient of Equation 2 with respect to the speaker parameter θ_S using straight-through estimator, denoted as $\nabla_{\theta_S} L_u(\theta_F, \theta_S)$, and then update the speaker in an end-to-end manner.

To sum up, in FOAM, the final gradient of the speaker is computed based on both the reconstruction loss (Equation 2) and the bi-level optimization loss (Equation 6), and we will perform ablations on the two objectives in the experiment section.

3 Experiments

Datasets. We evaluate the models on the Room-to-Room (R2R) (Anderson et al., 2018b) and Room-across-Room (RxR) (Ku et al., 2020) datasets. The R2R dataset consists of 7,189 paths, and each path has 3 English instructions with an average length of 29. R2R is split into training, validation, and test sets. The validation set is split into *val-seen*, where paths are sampled from environments seen during training, and *val-unseen*, where paths are sampled from environments that are not seen during training. The paths in the test set are from new environments unseen in the training and validation sets. The RxR dataset follows the same environment division as R2R and there are 16,522 paths in total. The instructions have an average length of 78 and are in three languages, including English, Hindi, and Telugu.

Evaluation Metrics. Our primary metric is success rate (SR), and we also report navigation error (NE), success rate weighted by path length (SPL) on R2R. Following the suggestion in Ku et al. (2020), we also report normalized dynamic time warping (nDTW) and success rate weighted by dynamic time warping (sDTW) (Magalhães et al., 2019) on RxR.

Implementation Details. Following EnvDrop (Tan et al., 2019),we build our speaker and follower based on LSTM (Hochreiter and Schmidhuber, 1997) and environmental dropout is used during back-translation. The follower is pre-trained with imitation and reinforcement learning, and the speaker is pre-trained with maximum likelihood training. Here, we refer to this pre-trained follower as **base follower**. The two models are pre-trained for 80k steps on R2R and 200k steps on RxR, and then trained with our method until the 300k-th iteration. We perform environmental dropout during training as in Tan et al. (2019), and also use their 176,776 paths randomly sampled from seen environments for back translation. Different from Tan et al. (2019), we use CLIP-ViT-224/16 (Radford et al., 2021) to extract vision features as CLIP vision encoders can be beneficial for VLN models (Shen et al., 2022) and we demonstrate that using CLIP vision encoder can obtain better performance than ResNet-based models in the following parts. We compute the cosine similarities between gradients for Equation 6 following Pham et al. (2021b,a) and also perform the same weighting for the reconstruction loss. Each training takes about 3 days on 1 NVIDIA V100 GPU to finish. We report numbers of a single run for evaluations.

3.1 Main Results

Room-to-Room. We report the main results on R2R in Table 1. We can see that our implementation of the baseline EnvDrop model is better than the previous work because of the stronger vision encoder we use. Based on the strong baseline, our model achieves further improvements on both validation and test sets, outperforming EnvDrop by 2.2% in the success rate on the R2R test dataset, suggesting that our framework is indeed effective.

Room-across-Room. We report the main results on R2R in Table 2. From the table, we can see that the improvements of our framework are not as good on the RxR dataset, possibly because the instructions are much longer and thus it is hard to train a good speaker. Specifically, we find that the baseline speaker can only achieve a BLEU score of 7.4 on the English validation set on RxR (compared with over 30 BLEU scores on R2R as in Appendix B), which leads to noisy augmented data and can impact the performance of speaker-follower models.

3.2 Analysis

We then perform analyses to gain more insights regarding our models:

Model	Val-Seen			Val-Unseen			Test

Table 2: Results on Room-across-Room. We report success rates (SR), success rates weighted by path length (SPL), success rates weighted by dynamic time warping (sDTW), normalized dynamic time warping (nDTW). The best scores are in **bold**.

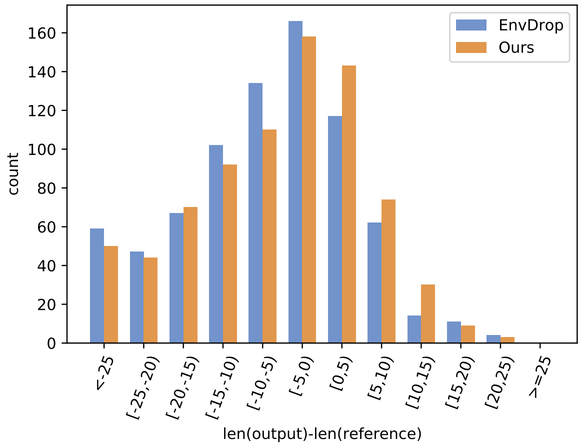

Figure 2: A histogram of the differences in length between the reference and model outputs. Baseline can often generate shorter instructions than the references, but our method can alleviate the issue.

Pre-exploration and Beam Search. We perform experiments in both pre-exploration and beam search settings following previous work (Tan et al., 2019). Because both the speaker and follower are used in the two settings, the evaluation results can reflect the quality of both of the models. As shown in Table 3, we find that the best configuration is using *our* follower and *our* speaker, suggesting that both our follower and speaker are more suitable for VLN than the baselines. Notably, in the beam search setting, our model can achieve a success rate of 72.2%, which is comparable to VLN-BERT (Majumdar et al., 2020) that achieves a success rate of 73% and is pre-trained with over millions of text sentences and image-text pairs.

Generated Instructions. The previous pre-exploration and beam search results well indicate that our generated instructions are more suitable for our follower, suggesting the effectiveness of our framework. In this paragraph, we also compare the generated instructions with the reference instructions. In Figure 2, we plot the histogram of length differences between the reference sentences and the generated instructions using *compare-mt* (Neubig et al., 2019). The figure suggests that the baseline model can often generate shorter instructions than the references, but our method can alleviate this issue, indicating that our methods can indeed improve the speaker quality during training. We also find that our generated instructions are quantitatively and qualitatively better than the baseline using automatic evaluations as in Appendix B.

Follower	Speaker	Pre-exploration			Beam Search		
		Val-Seen	Val-Unseen	Test	Val-Seen	Val-Unseen	Test
EnvDrop	EnvDrop	66.9	64.2	-	74.9	68.4	-
FOAM	EnvDrop	70.2	66.0	-	77.0	70.6	-
FOAM	FOAM	70.6	66.5	68.4	78.1	72.1	72.2

Table 3: Success rates of different configurations of the speaker-follower models in pre-exploration and beam search settings on Room-to-Room. The best configuration is using both *our* follower and *our* speaker models.

Model	Val-Seen			Val-Unseen		
	SR	SPL	NE	SR	SPL	NE
FOAM	70.8	66.6	3.25	61.6	55.1	4.18
-Recon.	68.9	63.5	3.33	60.2	53.1	4.30
-Bi-level	69.6	65.3	3.33	60.7	54.6	4.27

Table 4: Ablation studies on our proposed objectives. Our reconstruction loss and bi-level optimization loss are complementary to each other and ablating either one of them can lead to degraded performance.

Ablation Studies. As mentioned in Section 2.2, we perform ablation studies on both of our proposed objectives, namely the bi-level optimization loss (Equation 5) and reconstruction loss. As shown in Table 4, ablating either of the objectives can lead to degraded performance on the R2R validation sets, indicating that both the objectives can improve the model performance and they are complementary to each other.

4 Related Work

We overview two lines of related work:

Vision-and-Language Navigation. Training embodied navigation agents has been an increasingly active research area (Anderson et al., 2018a,b; Chen et al., 2019; Ku et al., 2020; Shridhar et al., 2020; Padmakumar et al., 2022). Fried et al. (2018b) propose to augment the training data with the speaker-follower models, which is improve by Tan et al. (2019) who add noise into the environments so that the speaker can generate more diverse instructions. Zhao et al. (2021) propose methods to measure the quality of the generated instructions and filter noisy samples. Liu et al. (2021) propose to adversarially sample the most difficult paths for the follower and translate these paths into instructions using the speaker for data augmentation. While using the speaker-augmented data has been widely used in VLN, most of the existing work has been focused on improving the follower navigation model (Wang et al., 2018; Li et al., 2019; Zhu et al., 2020b). For example, the self-monitoring agent (Ma et al., 2019) improves cross-modal alignment through a visual-text co-grounding module and a progress monitor; Zhu et al. (2020a) propose to utilize four self-supervised auxiliary tasks that can provide additional training signals for the agent. Most similar to our work, Fried et al. (2018a) build a speaker that reason about how the instructions may be interpreted; Kurita and Cho (2021) propose a generative approach where a speaker model is trained to model the probability of an instructions given actions, and the follower chooses actions that maximize this probability.

Bi-level Optimization. Bi-level optimization algorithms have been widely applied in various fields, such as learning initialization parameters (Finn et al., 2017), neural architecture search (Liu et al., 2018), re-weighting training data (Wang et al., 2020). Our method takes inspirations from (Pham et al., 2021a), which is applied in pseudo labeling and optimizes the teacher parameters given the student feedback. Similar techniques have also been used in machine translation (Pham et al., 2021b), where a meta-validation set is constructed to evaluate the model performance and provide feedback.

5 Conclusions

In this paper, we propose the FOAM model where we improve the speaker-follower model in vision-and-language navigation by constantly updating the speaker given the follower feedback during training. We frame the idea as a bi-level optimization problem and obtain the feedback signal based on the performance of the follower on labeled data. Experimental results on Room-to-Room and Room-across-Room datasets demonstrate that our method can outperform strong VLN baselines in different settings. Analyses also suggest that the quality of our speaker model is indeed improved during training. Future directions include testing our method on more datasets and investigating more options on the feedback signals.

A Derivation of the Speaker Gradient

As shown in Section 2.2, at training step t, we update the follower according to:

$$\theta_F^t = \theta_F^{t-1} - \eta_F \nabla_{\theta_F} L_u(\theta_F^{t-1}, \theta_S^{t-1}). \tag{7}$$

Model	Train	Val-Seen	Val-Unseen
BLEU			
EnvDrop	38.16	32.42	31.13
FOAM	39.66	33.11	31.10
BERTScore			
EnvDrop	91.64	91.08	91.04
FOAM	91.79	91.08	91.10

Table 5: Automatic evaluations of the generated instructions. The instructions generated by our model can obtain higher BLEU and BERTScore than the baseline.

We then derive the speaker gradient following previous work (Pham et al., 2021b,a). We define the *expected* parameters of the follower as $\bar{\theta}_F^t$:

$$\bar{\theta}_F^t = \mathbb{E}_{\hat{\mathbf{r}}_k \sim \mathcal{E}, \hat{\mathbf{i}}_k \sim P(\mathbf{i}|\hat{\mathbf{r}}_k; \theta_S^{t-1})} [\theta_F^{t-1} - \eta_F \nabla_{\theta_F} L_u(\theta_F^{t-1}, \theta_S^{t-1})]. \tag{8}$$

Then, using the chain rule, we can obtain

$$\nabla_{\theta_S} L_l = \frac{\partial L_l}{\partial \bar{\theta}_F^t} \frac{\partial \bar{\theta}_F^t}{\partial \theta_S}, \tag{9}$$

where the first term can be approximated with $\frac{\partial L_l}{\partial \theta_F^t}$. Then, for the second term, we have

$$\frac{\partial \bar{\theta}_F^t}{\partial \theta_S} = \frac{\partial}{\partial \theta_S} \mathbb{E}_{\hat{\mathbf{r}}_k \sim \mathcal{E}, \hat{\mathbf{i}}_k \sim P(\mathbf{i}|\hat{\mathbf{r}}_k)} [\theta_F^{t-1} - \eta_F \nabla_{\theta_F} L_u(\theta_F^{t-1}, \theta_S^{t-1})]. \tag{10}$$

We can assume that θ_F^{t-1} does not depend on θ_S with Markov assumption (Pham et al., 2021a), and apply the REINFORCE (Williams, 1992) equation on the second term:

$$\begin{aligned} \frac{\partial \bar{\theta}_F^t}{\partial \theta_S} &= \frac{\partial}{\partial \theta_S} \mathbb{E}_{\hat{\mathbf{r}}_k \sim \mathcal{E}, \hat{\mathbf{i}}_k \sim P(\mathbf{i}|\hat{\mathbf{r}}_k)} [-\eta_F \nabla_{\theta_F} L_u(\theta_F^{t-1}, \theta_S^{t-1})] \\ &= -\eta_F \mathbb{E}_{\hat{\mathbf{r}}_k \sim \mathcal{E}, \hat{\mathbf{i}}_k \sim P(\mathbf{i}|\hat{\mathbf{r}}_k)} [\nabla_{\theta_F} L_u(\theta_F^{t-1}, \theta_S^{t-1}) \frac{\partial}{\partial \theta_S} \log P(\hat{\mathbf{i}}_k | \hat{\mathbf{r}}_k; \theta_S^{t-1})], \end{aligned} \tag{11}$$

Using Monte Carlo approximation to approximate terms in Equation 11 using a batch of samples and substituting the result into Equation 9, we can get

$$\nabla_{\theta_S} L_l = -\eta_F [\nabla_{\theta_F} L_l(\theta_F^t)^{\mathrm{T}} \nabla_{\theta_F} L_u(\theta_F^{t-1}, \theta_S^{t-1})] \nabla_{\theta_S} \log P(\hat{\mathbf{i}}_k | \hat{\mathbf{r}}_k; \theta_S^{t-1}). \tag{12}$$

Note that here η_F is a hyper-parameter and can be incorporated into the learning rate of the speaker η_S, thus we remove this term in Section 2.2 and our derivation is complete.

B Evaluations of the Generated Instructions

Automatic Evaluations. As in Table 5, we measure the quality of the generated instructions in BLEU (Papineni et al., 2002) and BERTScore (Zhang et al., 2020). We find that our speaker can generate instructions of higher qualities according to the two metrics.

Method	Instruction
Reference	walk downstairs and outside . stop in the outhouse through the door on the right .
EnvDrop	go down the stairs and turn right . go down the hallway and stop in front of the door .
FOAM	go down the stairs and turn right . go down the hallway and go through the door on the right .
Reference	turn left and take a right at the table . take a left at the painting and then take your first right . wait next to the exercise equipment .
EnvDrop	walk past the dining room table and chairs and turn left . walk past the table and chairs and turn right . walk into the room and stop .
FOAM	walk past the dining room table and chairs and turn left . walk past the table and chairs and turn right . walk into the room and turn right . stop in front of the exercise bike .

Table 6: Examples of the generated instructions. Our generated instructions are generally longer and more accurate compared with the baseline.

Qualitative Examples. As in Table 6, we also find that after training the speaker using our method, the generated instructions are generally longer than the baseline and are more accurate compared with the references.

C License

We evaluate our models on the Room-to-Room (R2R) (Anderson et al., 2018b) and Room-across-Room (RxR) (Ku et al., 2020) datasets based on Matterport3D (Chang et al., 2017). The datasets are released under the Matterport3D Terms of Use.[2] The datasets do not contain any information that names or uniquely identifies individual people or offensive content. Our code is based on EnvDrop that is released under the MIT license.[3] We use the datasets and code for research purposes, which is consistent with their intended use.

D Limitations and Potential Risks

As in the experiments, our models may not work well when the instructions are long and it is hard to train a reasonable speaker model. Also, our model requires fine-tuning the speaker during training based on the feedback of the follower, which

---

[2] `http://dovahkiin.stanford.edu/matterport/public/MP_TOS.pdf`

[3] `https://github.com/airsplay/R2R-EnvDrop/blob/master/LICENSE`

introduces additional training costs to the model. In addition, the datasets we use in the paper may make our model biased towards environments of American buildings.

Improving Compositional Generalization with Latent Structure and Data Augmentation

Abstract

Generic unstructured neural networks have been shown to struggle on out-of-distribution compositional generalization. Compositional data augmentation via example recombination has transferred some prior knowledge about compositionality to such black-box neural models for several semantic parsing tasks, but this often required task-specific engineering or provided limited gains.

We present a more powerful data recombination method using a model called Compositional Structure Learner (CSL). CSL is a generative model with a quasi-synchronous context-free grammar backbone, which we induce from the training data. We sample recombined examples from CSL and add them to the fine-tuning data of a pre-trained sequence-to-sequence model (T5). This procedure effectively transfers most of CSL's compositional bias to T5 for diagnostic tasks, and results in a model even stronger than a T5-CSL ensemble on two real world compositional generalization tasks. This results in new state-of-the-art performance for these challenging semantic parsing tasks requiring generalization to both natural language variation and novel compositions of elements.

Figure 1: An overview of our method for compositional data augmentation with CSL, a generative model with a QCFG backbone, which is automatically induced from the training data. We show a notional set of original and synthetic examples mapping utterances to programs.

1 Introduction

Compositional generalization refers to the ability to generalize to novel combinations of previously observed *atoms*.[1] For example, we may ask a model to interpret the instruction "jump twice", when the atoms "jump" and "twice" were each observed separately during training but never in combination with each other (Lake and Baroni, 2018).

Improving compositional generalization is seen as important for approaching human-like language understanding (Lake et al., 2017; Battaglia et al., 2018) and is practically significant for real world applications, where models deployed in the wild often need to interpret new combinations of elements not well-covered by expensive and potentially skewed annotated training data (Herzig and Berant, 2019; Yin et al., 2021).

Generic neural sequence-to-sequence models have improved substantially and reached high levels of performance, particularly when combined with large-scale unsupervised pretraining and sizable in-distribution labeled data. However, these models often perform poorly on out-of-distribution compositional generalization tasks (Lake and Baroni, 2018; Furrer et al., 2020; Shaw et al., 2021).

July 10-15, 2022 ©2022 Association for Computational Linguistics

In contrast, specialized architectures with discrete latent structure (Chen et al., 2020; Liu et al., 2020; Nye et al., 2020; Herzig and Berant, 2021; Shaw et al., 2021) have made strides in compositional generalization, but without task-specific engineering or ensembling, the gains have been limited to synthetic semantic parsing tasks. Although following SCAN (Lake and Baroni, 2018) some increasingly realistic synthetic tasks such as CFQ (Keysers et al., 2020) and COGS (Kim and Linzen, 2020) have been created, and several approaches achieve good performance on these tasks, the out-of-distribution generalization ability of state-of-the-art models on real-world, non-synthetic tasks is still far from sufficient (Shaw et al., 2021; Yin et al., 2021).

Given their different strengths and weaknesses, it is compelling to combine the compositional bias of such specialized models with the greater flexibility and ability to handle natural language variation that characterizes generic pre-trained neural sequence-to-sequence models. One method for this is *data augmentation*. For example, Jia and Liang (2016) generate new training examples using example recombination via induced high-precision synchronous grammars, resulting in improvements on in-distribution and compositional splits of semantic parsing tasks. Another example is GECA (Andreas, 2020), a more general data augmentation approach that does not require task-specific assumptions. GECA achieved further gains on a larger variety of tasks, but provided limited improvements on some compositional generalization challenges.

We present a compositional data augmentation approach that generalizes these earlier methods. Training examples are recombined using the *Compositional Structure Learner* (CSL) model, a generative model with a (quasi-)synchronous context-free grammar (QCFG) backbone, automatically induced from the training data. As illustrated in Figure 1, CSL is used to sample synthetic training examples, and the union of original and synthesized examples is used to fine-tune the T5 sequence-to-sequence model (Raffel et al., 2020). CSL is more generally applicable than the method of Jia and Liang (2016), employing a generic grammar search algorithm to explore a larger, higher-coverage space of possible grammars. Unlike GECA, CSL can re-combine examples recursively and also defines a probabilistic sampling distribution over input-output pairs.

CSL builds on the NQG model of Shaw et al. (2021), a discriminative parsing model over an induced QCFG backbone, which Shaw et al. (2021) proposed to ensemble with T5. Like NQG, CSL can, on its own, address a variety of compositional generalization diagnostic tasks on synthetic datasets and achieves high precision (but limited recall) on non-synthetic compositional generalization tasks, leading to overall gains when ensembled with T5. However, CSL offers several significant improvements over NQG, allowing it to efficiently address a wider range of datasets (see §3.1). Additionally, unlike NQG which is a *discriminative* model assigning probabilities to outputs y given inputs x, CSL is a *generative* model which admits sampling from a joint probability distribution $p(x, y)$. This enables the creation of new input-output training examples.

Empirically, augmenting the training data for T5 with samples from CSL transfers most of CSL's compositional bias to T5 for diagnostic tasks (SCAN and COGS), and outperforms a T5+CSL ensemble on non-synthetic compositional generalization tasks defined by compositional splits of GeoQuery (Zelle and Mooney, 1996) and SMCalFlow (Andreas et al., 2020; Yin et al., 2021), resulting in new state-of-the-art performance on these splits.[2]

2 Background and Motivation

In this section, we discuss the problem setting common to the compositional generalization evaluations we study, and propose some general assumptions that motivate our proposed method.

Problem Setting Consider a training dataset $\mathcal{D}$ consisting of input-output pairs $\langle x, y\rangle \in \mathcal{X} \times \mathcal{Y}$, where $\mathcal{X}$ is the set of valid inputs and $\mathcal{Y}$ is the set of valid outputs. We assume that $\langle x, y\rangle \in \mathcal{D}$ are sampled from a *source* distribution $p_s(x, y)$. Our model will be evaluated on inputs from a *target* distribution $p_t(x, y)$. We make an assumption that the conditional distribution of y given x is unchanged between source and target distributions; i.e., $p_s(y|x) = p_t(y|x)$, which is also a standard assumption for domain adaptation evaluations under covariate shift. Any or all of the following may be true: $p_s(x, y) \neq p_t(x, y)$, $p_s(x) \neq p_t(x)$, $p_s(y) \neq p_t(y)$, and $p_s(x|y) \neq p_t(x|y)$.

---

[2] Our code is available at `https://github.com/google-research/language/tree/master/language/compgen/csl`.

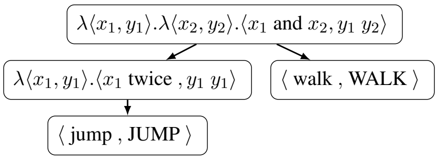

Figure 2: An example derivation that derives the string pair ⟨*jump twice and walk* , *JUMP JUMP WALK*⟩.

What differentiates our setting from other forms of distribution shift is the added assumption that the source and target distributions share common "atoms" (see §1). In order to translate this intuitive notion of atom sharing into formal conditions, we define a general class of models termed *derivational generative models*, based on representing atoms as *functions* which can be recombined via function application. As a modeling hypothesis, we will assume that the training and evaluation distributions can be modeled by derivational generative models that share a common set of functions, but may vary in how they assign probability to derivations formed by recombining these functions.

Derivational Generative Models A derivational generative model defines a distribution $p(x, y)$ over input-output pairs. The model contains a set of functions, $\mathcal{G}$, and a distribution over *derivations*. A derivation z can be viewed as a tree of functions from $\mathcal{G}$ which *derives* some element $[\![z]\!] = \langle x, y\rangle \in \mathcal{X} \times \mathcal{Y}$ determined by recursively applying the functions in z.[3] An example derivation is shown in Figure 2.

Given $\mathcal{X}$, $\mathcal{Y}$, and $\mathcal{G}$, we can generate a set $\mathcal{Z}^{\mathcal{G}}$ of possible derivations. We define some shorthands for important subsets of $\mathcal{Z}^{\mathcal{G}}$ for given x and y:

$$\mathcal{Z}^{\mathcal{G}}_{\langle x,y\rangle} = \{z \in Z^{\mathcal{G}} \mid [\![z]\!] = \langle x, y\rangle\}$$
$$\mathcal{Z}^{\mathcal{G}}_{\langle x,*\rangle} = \{z \in Z^{\mathcal{G}} \mid \exists y' \in \mathcal{Y}, [\![z]\!] = \langle x, y'\rangle\}$$

A derivational generative model also consists of some probability distribution $p_\theta(z)$ over the set of derivations $\mathcal{Z}^{\mathcal{G}}$, which we assume to be parameterized by θ. We define $p_{\mathcal{G},\theta}(x, y)$ in terms of $p_\theta(z)$ as:

$$p_{\mathcal{G},\theta}(x, y) = \sum\nolimits_{z\in\mathcal{Z}^{\mathcal{G}}_{\langle x,y\rangle}} p_\theta(z), \tag{1}$$

and therefore:

$$p_{\mathcal{G},\theta}(y|x) = \frac{\sum_{z\in\mathcal{Z}^{\mathcal{G}}_{\langle x,y\rangle}} p_\theta(z)}{\sum_{z\in\mathcal{Z}^{\mathcal{G}}_{\langle x,*\rangle}} p_\theta(z)}, \tag{2}$$

for $p_{\mathcal{G},\theta}(x) > 0$.

Discussion In general, we are interested in a set of functions that captures some knowledge of how the parts of inputs correspond to parts of outputs. If we can recover some approximation of the underlying set of functions, $\mathcal{G}$, given $\mathcal{D}$, then we could sample derivations consisting of new combinations of functions that are not observed in $\mathcal{D}$. This could potentially help us improve performance on the target distribution, since we assume that the set of functions is unchanged between the source and target distributions, and that what is varying is the distribution over derivations.

However, even assuming $\mathcal{G}$ can be exactly recovered given $\mathcal{D}$ is not sufficient to ensure that we can correctly predict the most likely y given x according to the true $p(y|x)$ (shared between source and target distributions) for $x \sim p_t(x)$.[4] We must also assume that there exists a parameterization of $p_\theta(z)$ such that when we estimate $\hat{\theta}$ given $\mathcal{D}$, $p_{\mathcal{G},\hat{\theta}}(y|x)$ sufficiently approximates the true $p(y|x)$ for $x \sim p_t(x)$. We hypothesize that conditional independence assumptions with respect to how $p_\theta(z)$ decomposes across the function applications in z can be helpful for this purpose. In particular, such assumptions can enable "reusing" conditional probability factors across the exponential space of derivations, potentially improving transfer to the target distribution.

With this intuition in mind, in §3 we propose a specific class of functions for $\mathcal{G}$ based on (quasi-)synchronous context-free grammars, as well as a factorization of $p_\theta(z)$ with strong conditional independence assumptions.

3 Proposed Method

As shown in Figure 1, our method consists of two stages. First, we induce our generative model, CSL, from training data (§3.1). Second, we sample synthetic examples from the generative model and use them to augment the training data for a sequence-to-sequence model (§3.2).

---

[3] Formally, let $\mathcal{G}$ be a set of partial functions over some set of elements. If $f \in \mathcal{G}$ is a constant function, then f is a ground term. If $f \in \mathcal{G}$ has arity k, and $a_1, \cdots, a_k$ are ground terms, then $f(a_1, \cdots, a_k)$ is a ground term. We define a *derivation* as a ground term that generates an element $\in \mathcal{X} \times \mathcal{Y}$.

[4] One special case is where $|\mathcal{Z}^{\mathcal{G}}_{\langle x,*\rangle}| = 1$ for all x. In this case, every x has exactly one unique derivation and $p_{\mathcal{G}}(y|x)$ is deterministic given $\mathcal{G}$ and does not depend on θ, and therefore recovering $\mathcal{G}$ *is* sufficient.

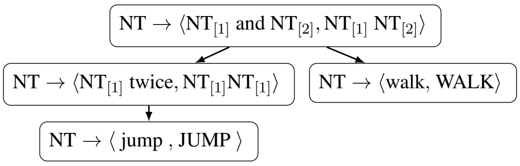

Figure 3: The example derivation of Figure 2 using QCFG notation.

3.1 Compositional Structure Learner (CSL)

CSL can be viewed as a derivational generative model, as defined in §2, where the set $\mathcal{G}$ of recursive functions is defined by a (quasi-)synchronous context free grammar (QCFG).[5]

We first describe the grammar formalism and the parameterization of our probabilistic model. Then we describe our two-stage learning procedure for inducing a grammar and learning the model parameters. CSL builds on the NQG model of Shaw et al. (2021), with several key differences discussed in the following sections:

- Unlike NQG, which is discriminative, CSL is a *generative* model that admits efficient sampling from the joint distribution $p(x, y)$.
- CSL enables a more expressive set of grammar rules than NQG.
- CSL offers a more computationally efficient and parallelizable grammar induction algorithm and a more efficient parametric model, allowing the method to scale up to larger datasets such as SMCalFlow-CS.

See section 4.4 for experiments and analysis comparing the components of CSL and NQG.

3.1.1 Grammar Formalism

An example QCFG derivation is shown in Figure 3, and the notation for QCFGs is reviewed in Appendix B.1. Notably, the correspondence between rules over input and output strings in QCFGs is akin to a homomorphism between syntactic and semantic structures, commonly posited by formal theories of compositional semantics (Montague, 1970; Janssen and Partee, 1997). We restrict our grammars to have only a single unique nonterminal symbol, NT. In constrast to standard synchronous context-free grammars (SCFGs), our grammars can be *quasi-synchronous* (Smith and Eisner, 2006) because we allow a one-to-many alignment between non-terminals.[6] Unlike the formalism of Shaw et al. (2021), which limited rules to contain ≤ 2 non-terminals, in the current work the maximal number of non-terminals is a configurable parameter,[7] which enables inducing grammars with higher coverage for certain datasets.

3.1.2 Probabilistic Model

We factorize the probability of a derivation in terms of conditional probabilities of sequentially expanding a rule from its parent. Formally, let r denote a rule expanded from its parent rule r_p's $NT_{[i]}$ non-terminal (or a special symbol at the root of the derivation tree).[8] We assume conditional independence and factorize the probability of z as:

$$p_\theta(z) = \prod_{r, r_p, i \in z} p_\theta(r | r_p, i) \qquad (3)$$

This non-terminal annotation with context from the tree is akin to parent annotation or other structure conditioning for probabilistic context-free grammars (Johnson, 1998; Klein and Manning, 2003).

Using independent parameters for each combination of a rule, its parent, and non-terminal index may lead to overfitting to the training set, limiting our ability to generalize to new combinations of rule applications that are needed for compositional generalization. We therefore factor this distribution using a soft clustering into a set of *latent states* $\mathcal{S}$ representing parent rule application contexts:

$$p_\theta(r | r_p, i) = \sum_{s \in \mathcal{S}} p_\theta(r|s) p_\theta(s | r_p, i) \qquad (4)$$

where $p_\theta(s|r_p, i) \propto e^{\theta_{r_p,i,s}}$ and $p_\theta(r|s) \propto e^{\theta_{s,r}}$ and the θs are scalar parameters.[9] The number of context states $|\mathcal{S}|$ is a hyperparameter. While these conditional independence assumptions may still be too strong for some cases (see Appendix C.2), we find them to be a useful approximation in practice.

---

[5] QCFG rules can be interpreted as functions which are limited to string concatenation. For notational convenience, we will therefore treat $\mathcal{G}$ as a set of QCFG rules in §3.

[6] Concretely, for a rule $NT \rightarrow \langle \alpha, \beta \rangle$, a non-terminal in α can share an index with more than one non-terminal in β. This is important for datasets such as SCAN, as it allows rules such as $\mathrm{NT} \rightarrow \langle \mathrm{NT}_{[1]}\mathrm{twice}, \mathrm{NT}_{[1]}\mathrm{NT}_{[1]} \rangle$ which enable repetition.

[7] We find that 4 is a computationally tractable choice for the datasets we study.

[8] Using the example derivation from Figure 3, for the rule application $r = \mathrm{NT} \rightarrow \langle \mathrm{walk}, \mathrm{WALK} \rangle$, we have $r_p = \mathrm{NT} \rightarrow \langle \mathrm{NT}_{[1]}\ \mathrm{and}\ \mathrm{NT}_{[2]}, \mathrm{NT}_{[1]}\mathrm{NT}_{[2]} \rangle$ and the expansion probability for that rule application is $p(r|r_p, 2)$.

[9] The full definition of these terms is in Appendix B.2.

We also optionally consider a task-specific output CFG, which defines valid output constructions.[10]

3.1.3 Learning Procedure

A principled method to estimate $\mathcal{G}$ and θ given $\mathcal{D}$ would be to find the MAP estimate based on some prior, $p(\mathcal{G}, \theta)$, that encourages compositionality:

$$\arg\max_{\mathcal{G},\theta} \; p(\mathcal{G}, \theta) \times \prod_{\langle x,y\rangle \in \mathcal{D}} p_{\mathcal{G},\theta}(x, y) \qquad (5)$$

However, since optimizing $\mathcal{G}$ and θ jointly is computationally challenging, we adopt a two-stage process similar to that of Shaw et al. (2021). First, we learn an unweighted grammar using a surrogate objective for the likelihood of the data and a compression-based compositional prior that encourages smaller grammars that reuse rules in multiple contexts, inspired by the Minimum Description Length (MDL) principle (Rissanen, 1978; Grunwald, 2004). We describe the induction objective and algorithm in §3.1.4. Second, given an unweighted grammar $\mathcal{G}$, we optimize the parameters θ by maximizing the log-likelihood of $p_{\mathcal{G},\theta}(x, y)$, as defined by Eq. 1, using the Adam optimizer (Kingma and Ba, 2015).[11]

3.1.4 Grammar Induction Algorithm

Our method for inducing a QCFG is based on that of Shaw et al. (2021), but with several modifications, which improve the computational scalability of the algorithm as well as the precision and coverage of the induced grammar. We analyze the relative performance of the two algorithms in §4.4.

Objective The main idea of the grammar induction objective, $L_{\mathcal{D}}(\mathcal{G})$, is to balance the size of the grammar with its ability to fit the training data:

$$L_{\mathcal{D}}(\mathcal{G}) = \sum_{NT \rightarrow \langle \alpha,\beta\rangle \in \mathcal{G}} |\alpha| + |\beta| - c_{\mathcal{D}}(\alpha, \beta), \quad (6)$$

where $|\cdot|$ is a weighted count of terminal and nonterminal tokens (the relative cost of a terminal vs. nonterminal token is a hyperparameter) and

$$c_{\mathcal{D}}(\alpha, \beta) = k_\alpha \ln \hat{p}_{\mathcal{D}}(\alpha|\beta) + k_\beta \ln \hat{p}_{\mathcal{D}}(\beta|\alpha) \quad (7)$$

where k_α and k_β are hyperparameters and $\hat{p}_{\mathcal{D}}(\alpha|\beta)$ is equal to the fraction of examples $\langle x, y\rangle \in \mathcal{D}_{train}$ where α "occurs in" x out of the examples where β "occurs in" y, and vice versa for $\hat{p}_{\mathcal{D}}(\beta|\alpha)$.[12] The correlation between α and β as measured by the $\hat{p}$ terms provides a measure related to how well the rule fits the training data. We use sampling to optimize the computation of $\hat{p}_{\mathcal{D}}$ for larger datasets. While conceptually similar to the objective used by NQG, we found that CSL's objective is more efficient to compute and can be more effective at penalizing rules that lead to lower precision.[13]

Initialization To initialize $\mathcal{G}$ we add a rule $NT \rightarrow \langle x, y\rangle$ for every $\langle x, y\rangle \in \mathcal{D}$. We also optionally add a set of seed rules, such as $NT \rightarrow \langle x, x\rangle$ where a terminal or span x is shared between the input and output vocabularies. For details on seed rules used for each dataset, see Appendix A.

Greedy Algorithm Following the initialization of the set of rules $\mathcal{G}$, we use an approximate parallel greedy search algorithm to optimize $L_{\mathcal{D}}(\mathcal{G})$, while maintaining the invariant that all examples in $\mathcal{D}$ can be derived by $\mathcal{G}$.

At each iteration, the algorithm considers each rule r in the current grammar in parallel. The algorithm determines a (potentially empty) set of candidate actions for each r. Each candidate action consists of adding a new rule to the grammar that can be combined with an existing rule to derive r, enabling r to be removed. Certain candidate actions may enable removing other rules, too. The algorithm then selects the candidate action that leads to the greatest improvement in the induction objective, if any action exists that leads to an improvement. The selected actions are then aggregated and executed, resulting in a new set of rules. The algorithm continues until no further actions are selected, or a maximum number of steps is reached. The detailed implementation of the greedy algorithm is detailed in Appendix B.

3.1.5 Inference Procedure

While the primary goal of CSL is to be used to sample new examples for data augmentation (discussed

---

[10] The outputs for several of the tasks we study consist of executable programs or logical terms, for which we can assume the availability of a CFG for parsing. Details are in Appendix A.

[11] To optimize θ efficiently, we use a variant of the CKY algorithm (Cocke, 1969; Kasami, 1965; Younger, 1967) to determine the set of derivations, represented as a parse forest, and use dynamic programming to efficiently sum over this set.

[12] By α "occurs in" x, we mean that there exists some substitution for any non-terminals in α such that it is a substring or equal to x.

[13] For example, CSL's objective enables our algorithm to induce a "clean" 20 rule grammar for SCAN, while using our algorithm with the objective of NQG leads to grammars with additional spurious rules for SCAN.

next), we can also use CSL as a discriminative parsing model, by using a variant of the CKY algorithm to find the highest scoring derivation z that maximizes Eq. 3 for a given input x. We then output the corresponding y if it can be derived by the given output CFG, or if no output CFG is provided.

3.2 Data Augmentation

We synthesize a configurable number of examples by sampling from the learned generative model, CSL.[14] To generate a synthetic example (x, y), we use forward sampling: we start from the single NT symbol and sample recursively to expand each nonterminal symbol with a rule, based on $p_\theta(r|r_p, i)$ defined by Eq. 4.[15]

Given that generic sequence-to-sequence models perform poorly on length extrapolation (Newman et al., 2020), we optionally bias our sampling to favor deeper derivations. We achieve this by adding a bias $\delta > 0$ to $\theta_{t,r}$ for any rule r that contains more nonterminals than our configurable threshold.

We fine-tune T5 on the union of the original training data and the synthesized data. Following Jia and Liang (2016), we ensure an approximately equal number of original and synthesized examples are used for training. We achieve this by replicating original or synthetic examples as needed.

4 Experiments and Analysis

In this section, we comparatively evaluate and analyze our main proposed method, T5+CSL-Aug., which uses CSL to generate examples for augmenting the training data of T5.

4.1 Datasets

We evaluate our approach on both synthetic benchmarks designed for controlled assessments of compositional generalization, and non-synthetic evaluations, which introduce the additional challenge of handling natural language variation. For example, some words in the test data might never appear during training. Further details on datasets and preprocessing are in Appendix A.

SCAN The SCAN dataset contains navigation commands paired with action sequences. We consider three compositional data splits from Lake and Baroni (2018): the *jump* and *turn left* splits (where a new primitive is used in novel combinations), and the *length* split. We also consider the *MCD* splits from Keysers et al. (2020) created by making the distributions of compositional structures in training and test data as divergent as possible.

COGS The COGS dataset (Kim and Linzen, 2020) contains sentences paired with logical forms. We use the generalization test set, which tests generalization to novel linguistic structures. As SCFGs cannot handle logical variables (Wong and Mooney, 2007), we convert the outputs into equivalent variable-free forms.

GeoQuery GeoQuery (Zelle and Mooney, 1996; Tang and Mooney, 2001) contains human-authored questions paired with meaning representations. We report results on the standard data split as well as three compositional splits based on those introduced in Shaw et al. (2021): the *template* split (where abstract output templates in training and test data are disjoint (Finegan-Dollak et al., 2018)), the *TMCD* split (an extension of MCD for non-synthetic data), and the *length* split.[16]

SMCalFlow-CS Yin et al. (2021) proposed a *compositional skills* split of SMCalFlow (Andreas et al., 2020) that contains single-turn sentences from one of two domains related to creating calendar events or querying an org chart, paired with LISP programs. The single-domain (S) test set has examples from a single domain, while the cross-domain (C) test set has sentences that require knowledge from both domains (e.g., "create an event with my manager"). Only a small number of cross-domain examples (8, 16, or 32) are seen during training.

4.2 Baselines

Our primary goal is to evaluate T5+CSL-Aug. in comparison to T5 and T5+GECA, a method augmenting training data with GECA which is prior state of the art for data augmentation (Andreas, 2020).[17] Details and hyperparameters for the

---

[14] For all experiments, we sample 100,000 synthetic examples unless otherwise indicated.

[15] We ensure the sampled y can be generated by a CFG defining valid outputs, if one is provided for the given task, by sampling from the intersection of $\mathcal{G}$ and the provided output CFG.

[16] For GeoQuery, to reduce variance due to small dataset sizes, we average all results over 3 runs. For the Template and TMCD splits we additionally average over 3 splits generated with different random seeds. Variance is reported in Appendix C.8

[17] For all experiments with T5, we show results for T5-Base (220M parameters). Prior work found T5-Base to perform best on the compositional splits of SCAN and GeoQuery (Furrer et al., 2020; Shaw et al., 2021). We found a similar trend for COGS and SMCalFlow-CS after evaluating T5-Large and

	SCAN				**COGS**	**GEOQUERY**				**SMCALFLOW-CS**

Table 1: **Main Results.** We compare the performance of our proposed method, T5+CSL-Aug., to prior work across synthetic (SCAN, COGS) and non-synthetic (GeoQuery, SMCalFlow-CS) tasks. Boldfaced results are within 1.0 points of the best result.

GECA experiments are available in Appendix C.4. We also compare with representative prior state-of-the-art methods. For SCAN, NQG-T5 (Shaw et al., 2021) is one of several specialized models that achieves 100% accuracy across multiple splits (Chen et al., 2020; Liu et al., 2020; Nye et al., 2020; Herzig and Berant, 2021). For COGS, we show results from LeAR (Liu et al., 2021), the previously reported state-of-the-art on COGS.[18] We also report new results for NQG-T5 on COGS. For GeoQuery, we report results for NQG-T5[19] and SpanBasedSP (Herzig and Berant, 2021) on the GeoQuery splits we study.[20] For SMCalFlow-CS, we show the strongest previously reported results by Yin et al. (2021), which include the coarse2fine (C2F) model of Dong and Lapata (2018) as a baseline, as well C2F combined with the span-supervised (SS) attention method of Yin et al. (2021). We found it was not computationally feasible to run NQG-T5 on SMCalFlow.

4.3 Main Results

The results are shown in Table 1. For synthetic datasets, the induced grammars have high coverage, making the CSL model highly effective for data augmentation. When we use CSL to generate additional training data for T5 (T5+CSL-Aug.), the performance of T5 improves to nearly solving SCAN and achieving state-of-the-art on COGS.

For non-synthetic tasks, T5+CSL-Aug. leads to new state-of-the-art accuracy on all compositional splits. However, performance is slightly worse on the single-domain splits of SMCalFlow-CS. Based on error analysis in Appendix C.9, we find a significant degree of inherent ambiguity for the remaining errors on the single-domain split, which may contribute to this result.

Using CSL for data augmentation outperforms using GECA on SCAN and GeoQuery. We did not find it computationally feasible to run GECA on COGS or SMCalFlow-CS. On some splits, using GECA to augment the training data for T5 can lead to worse performance, as GECA can over-generate incorrect examples. We provide further analysis comparing CSL and GECA in Appendix C.4.

4.4 Analysis and Discussion

The performance of T5+CSL-Aug. is dependent on the CSL grammar backbone, parametric model, and data sampling details. We analyze the accuracy of T5+CSL-Aug. in relation to CSL's coverage, and summarize the impact of the design choices in CSL that depart from prior work.

Performance Breakdown CSL provides analyses for and can only sample inputs covered by its grammar $x \in \mathcal{X}_{CSL}$, which is often a strict subset of all possible utterances. It is therefore interesting to see how data augmentation impacts T5's performance on covered and non-covered inputs.

In Table 2, we analyze the relative performance of T5, CSL, and combinations of T5 and CSL using ensembling and data augmentation, for non-synthetic compositional splits, partitioning inputs based on whether they are covered by CSL (the same analysis for all splits can be found in Ap-

---

T5-3B.

[18] We do not show LeAR results for SCAN and GeoQuery as Liu et al. (2021) did not report results for SCAN and reported GeoQuery results using a different template split and a different evaluation metric.

[19] Some of our results for NQG-T5 are different than those reported in Shaw et al. (2021) as we average over 3 new GeoQuery template and TMCD splits, as described in §4.1.

[20] We report exact match accuracy for SpanBasedSP, as opposed to denotation accuracy reported in Herzig and Berant (2021).

Dataset	$\%^{\mathcal{X}_{CSL}}$	$x \in \mathcal{X}_{CSL}$			$x \notin \mathcal{X}_{CSL}$			All			
		T5	CSL	Aug.	T5	CSL	Aug.	T5	CSL	Ens.	Aug.
GeoQuery Templ.	61.0	93.1	96.6	**97.1**	71.6	0.0	**76.9**	84.8	58.9	86.9	**89.3**
GeoQuery TMCD	44.3	88.4	90.3	**93.9**	53.8	0.0	**59.9**	69.2	39.9	70.0	**74.9**
GeoQuery Length	29.0	51.2	**91.6**	83.6	35.4	0.0	**61.3**	40.0	26.6	51.7	**67.8**
SMCalFlow-CS 8-C	6.6	52.3	**79.6**	72.7	33.4	0.0	**50.1**	34.7	5.3	36.5	**51.6**

SMCalFlow-CS 32-C	13.0	74.4	87.2	**88.4**	56.7	0.0	**67.8**	59.0	11.3	60.6	**70.4**

Table 2: We compare T5, CSL used as a parsing model, and T5+CSL-Aug. (abbreviated as Aug.). We partition evaluation examples by whether CSL generates an output ($x \in \mathcal{X}_{CSL}$) or not ($x \notin \mathcal{X}_{CSL}$) for a given input. The percentage of examples in the former subset ($\%^{\mathcal{X}_{CSL}}$) is limited by the coverage of the induced grammar (see Section 3.1.5). We also compare with an ensemble of T5 and CSL (Ens.) similar to that of Shaw et al. (2021), where we use the output of CSL if $x \in \mathcal{X}_{CSL}$ and otherwise fall back to T5.

pendix C.1). An ensemble model can help T5 only when $x \in \mathcal{X}_{CSL}$, but we can see from Table 2 that data augmentation improves model performance even on inputs not covered by the grammar. For example, for the GeoQuery Length split, performance on non-covered inputs improves from 35.3 to 60.9. This means that T5 is generalizing from the sampled data ($x \in \mathcal{X}_{CSL}$) to $x \notin \mathcal{X}_{CSL}$.

Comparison with NQG We cannot compare using CSL for data augmentation directly with using its closely related predecessor NQG (Shaw et al., 2021) for data augmentation, as NQG is a discriminative parsing model and not a probabilistic generative model that enables sampling new examples. However, we include comparisons of the novel components of CSL relative to the related components of NQG in the following sections, which analyze CSL's grammar induction algorithm and parametric model.

Grammar Induction The grammar induction algorithm of CSL is significantly more scalable than that of NQG, enabling more than 90% decrease in runtime for GeoQuery, and enabling induction to scale to larger datasets such as SMCalFlow-CS. CSL can also induce higher coverage grammars than NQG in some cases, while maintaining high precision. For example, for COGS, the grammar induced by CSL can derive 99.9% of the evaluation set while the grammar induced by NQG can only derive 64.9%. Appendix C.3 contains further analysis comparing the grammar induction algorithms of CSL and NQG. Of course, the grammars induced by CSL can still lack coverage for some datasets, as shown in Table 2. We analyze the limitations of QCFGs in Appendix C.5.

Parameteric Model We find that the simple parameteric model of CSL performs comparably in terms of parsing accuracy to the BERT-based discriminative model of NQG given the same grammar (see Appendix C.3). It is also more scalable because it does not require the computation of a partition function. The variable number of state clusters (§3.1.2) provides a powerful knob for tuning the amount of context sensitivity (see Appendix C.2) to sufficiently fit the training data while also extrapolating to out-of-distribution compositions. We believe further improvements to the parametric model (e.g. using pre-trained representations) have strong potential to improve overall accuracy.

Sampling Results on most splits are significantly improved by using CSL's parametric model compared to sampling uniformly from the induced grammar (Appendix C.6), pointing to a potential source of gains over unweighted augmentation approaches like GECA. However, for SMCalFlow-CS, a higher sampling temperature can improve performance, especially on the 8-shot split, as it leads to $>$ 15 times the number of cross-domain examples being sampled, given their low percentage in the training data. Determining improved methods for biasing the sampling towards examples most relevant to improving performance on the target distribution is an important direction. In Appendix C.7 we explore a setting where we assume access to unlabeled examples from the target distribution, and use these to update the parametric model. We find that this improves sample efficiency with respect to the number of sampled synthetic examples, but can have minimal effect when a sufficiently large number of examples can be sampled. We believe this is a promising research direction.

5 Related Work

Grammar Induction Before the trend towards sequence-to-sequence models, significant prior work in semantic parsing explored inducing SCFG (Wong and Mooney, 2006, 2007; Andreas et al., 2013) and CCG (Zettlemoyer and Collins, 2005, 2007; Kwiatkowksi et al., 2010; Kwiatkowski et al., 2013; Artzi et al., 2014) grammars of the input-output pairs. SCFGs have also been applied to machine translation (Chiang, 2007; Blunsom et al., 2008; Saers et al., 2013). Compression-based objectives similar to ours have also been applied to CFG induction (Grünwald, 1995). Recently, the method of Kim (2021) learns neural parameterized QCFG grammars, which can avoid the pitfalls in coverage of lexicalized grammars such as the ones we learn; however the approach can be computationally demanding for longer input-output pairs.

Data Augmentation Data augmentation has been widely used for semantic parsing and related tasks (Jia and Liang, 2016; Andreas, 2020; Akyürek et al., 2021; Wang et al., 2021b; Zhong et al., 2020; Oren et al., 2021; Tran and Tan, 2020; Guo et al., 2020, 2021). Jia and Liang (2016) perform data recombination using an induced SCFG but their approach requires domain-specific heuristics. GECA (Andreas, 2020) provides a more general solution, which we analyzed in §4.4. The method of Akyürek et al. (2021) is appealing because it can learn data recombinations without committing to a grammar formalism, although gains were limited relative to symbolic methods. The recombination approach of Guo et al. (2020) demonstrates gains for translation tasks but is not as effective as GECA for semantic parsing tasks. Other approaches leverage a forward semantic parser and a backward input generator with some variants (Wang et al., 2021b; Zhong et al., 2020; Tran and Tan, 2020; Guo et al., 2021), but most of these approaches do not explicitly explore the compositional generalization setting. Oren et al. (2021) propose an approach to sample more structurally-diverse data to improve compositional generalization, given a manually specified SCFG.

Compositional Generalization Beyond data augmentation, many approaches have been pursued to improve compositional generalization in semantic parsing, including model architectures (Li et al., 2019; Russin et al., 2019; Gordon et al., 2020; Liu et al., 2020; Nye et al., 2020; Chen et al., 2020; Zheng and Lapata, 2020; Oren et al., 2020; Herzig and Berant, 2021; Ruiz et al., 2021; Wang et al., 2021a), different Transformer variations (Csordás et al., 2021; Ontanón et al., 2021), ensemble models (Shaw et al., 2021), intermediate representations (Herzig et al., 2021), meta-learning (Lake, 2019; Conklin et al., 2021; Zhu et al., 2021), and auxiliary objectives to bias attention in encoder-decoder models (Yin et al., 2021; Jiang and Bansal, 2021). Also, Furrer et al. (2020) compared pre-trained models with specialized architectures.

6 Conclusion

We showed that the Compositional Structure Learner (CSL) generative model improves the state of the art on compositional generalization challenges for two real-world semantic parsing datasets when used to augment the task training data for the generic pre-trained T5 model. Data augmentation using CSL was also largely sufficient to distill CSL's knowledge about compositional structures into T5 for multiple synthetic compositional generalization evaluations. While CSL has limitations (notably, the QCFG formalism is not a good fit for all phenomena in the mapping of natural language to corresponding logical forms), our experiments suggest the strong potential of more powerful probabilistic models over automatically induced latent structures as data generators for black-box pretrained sequence-to-sequence models.

Ethical Considerations

This paper proposed methods to improve compositional generalization in semantic parsing. While we hope that improvements in compositional generalization would lead to systems that generalize better to languages not well represented in small training sets, in this work we have only evaluated our methods on semantic parsing datasets in English.

Appendix

The appendix is organized into three sections:

- Appendix A contains dataset and preprocessing details.
- Appendix B contains modeling details and hyperparameters.
- Appendix C contains additional experiments and analysis.

A Dataset and Preprocessing Details

Dataset	Split	Train	Dev	Test
SCAN	Jump	14670	—	7706

Table 3: Sizes of all datasets and splits.

In this section we detail preprocessing for each dataset. Dataset sizes are reported in Table 3. We show examples of each dataset in Table 4, with examples of the corresponding induced QCFG rules in Table 5. For each dataset, we report exact match accuracy. We note that all datasets include English language data only; evaluating and extending our method for other languages is an important future direction. We use the same dataset preprocessing for the T5, T5+GECA, NQG-T5, and T5+CSL-Aug. results we report.

SCAN We did not perform any preprocessing for SCAN. Grammar induction does not use any seed rules, and we do not assume a CFG defining valid output constructions, as the outputs consist of action sequences, not executable programs or logical forms.

COGS For COGS, as QCFGs do not support logical variables (Wong and Mooney, 2007), we mapped the original logical forms to a variable-free representation, with an example shown in Table 4. The mapping is deterministic and reversible, and is akin to the use of other variable-free logical forms for semantic parsing such as FunQL (Kate et al., 2005) or Lambda-DCS (Liang, 2013). An alternative but potentially more complex solution to handling logical variables in outputs would be to use an extension of SCFGs, such as λ-SCFG (Wong and Mooney, 2007).

We define an output CFG based on the definition of this variable-free representation. To minimize the linguistic prior, we did not distinguish the types of primitives (e.g., nouns vs verbs); they all belong to the same CFG category. We use a set of seed rules of the form $NT \rightarrow \langle x', x \rangle$ where x is a token found in a training output, and x' is x or an inflected form of x found in a training input (e.g., for $x =$ "sleep", we add $NT \rightarrow \langle \text{sleep}, \text{sleep} \rangle$ and $NT \rightarrow \langle \text{slept}, \text{sleep} \rangle$). These $\langle x', x \rangle$ pairs were identified by running the IBM I alignment model (Brown et al., 1993) on the training data.

GeoQuery We use the same variant of FunQL (Kate et al., 2005) as Shaw et al. (2021), with entities replaced with placeholder values. We generate new length, template, and TMCD splits following the methodology of Shaw et al. (2021), so that we could evaluate our method on dev sets, which the original splits did not include. Specifically, for the length split, we randomly split the test set of the original length split into a dev set of 110 examples and a test set of 330 examples. To reduce variance, we created 3 new template and TMCD splits with different random seeds, with (approximately, in the case of template splits) 440 training examples, and 440 examples that are then randomly split into a 110 dev set and 330 test set. For the TMCD splits, we changed the atom constraint slightly, based on the error analysis in Shaw et al. (2021) which found that a disproportionate amount of the errors on the TMCD test set were in cases where an "atom" was seen in only a single context during training. To create a fairer evaluation of compositional generalization, we strengthen the atom constraint such that every atom in the test set must be seen at least 2 times in the training set. Additionally, as several function symbols in FunQL can be used with and without arguments, and these usages

Dataset	Example
SCAN	x: walk around right and jump thrice y: RTURN WALK RTURN WALK RTURN WALK RTURN WALK JUMP JUMP JUMP

Table 5: Examples of induced grammar rules for each example in Table 4. Rules without non-terminals are omitted for brevity.

are semantically quite different, we treat function symbols used with different numbers of arguments as different atoms.

We define an output CFG based on the definition of the FunQL operators and the primitive types in the geobase database. We use a set of seed rules of the form $NT \rightarrow \langle x, x \rangle$ where x occurs in both the input and output of a training example.

SMCalFlow-CS To construct SMCalFlow-CS, Yin et al. (2021) filtered out examples that require conversational context. We heuristically filtered out 22 more training examples whose programs contain string literals that are not in the inputs.

We use the original LISP programs provided with the dataset as the output representation. We extract seed rules for string literals and numbers that are copied from inputs to outputs, such as person names and meeting subjects. We add 5 seed rules with a single non-terminal on the input side that enable "hallucinating" various program fragments. We construct an output CFG based on the bracketing of LISP programs and a mapping of argument slots to nonterminals.

B Modeling Details

B.1 QCFG Background and Notation

Synchronous context-free grammars (SCFGs) have been used to model the hierarchical mapping between pairs of strings in areas such as compiler theory (Aho and Ullman, 1972) and multiple natural language tasks, e.g., machine translation (Chiang, 2007) and semantic parsing (Wong and Mooney, 2006; Andreas et al., 2013). SCFGs can be viewed as an extension of context-free grammars (CFGs)

$$\begin{tikzcd}
\langle \mathrm{NT}_{\boxed{1}}, \mathrm{NT}_{\boxed{1}} \rangle \arrow[r, "r_a"] \arrow[dr, "r_c"'] & \langle \alpha_a, \beta_a \rangle \arrow[d, "r_b"] \\
& \langle \alpha_c, \beta_c \rangle
\end{tikzcd}$$

EXAMPLE

$r_a = \mathrm{NT} \rightarrow \langle \mathrm{NT}_{\boxed{1}}$ and $\mathrm{NT}_{\boxed{2}}, \mathrm{NT}_{\boxed{1}}\ \mathrm{NT}_{\boxed{2}} \rangle$
$r_b = \mathrm{NT} \rightarrow \langle$jump, JUMP$\rangle$
$r_c = \mathrm{NT} \rightarrow \langle$jump and $\mathrm{NT}_{\boxed{1}}$, JUMP $\mathrm{NT}_{\boxed{1}} \rangle$

Figure 4: The arrows in the diagram denote expansion of a nonterminal with a rule. When the above ternary relation holds between r_a, r_b, and r_c, such as in the provided example, we will write $r_a \circ r_b \Rightarrow r_c$. The key sub-routine of our grammar induction algorithm, $\text{UNIFY}(r_1, r_2)$, returns the set of rules $\{r_3 | r_2 \circ r_3 \Rightarrow r_1 \lor r_3 \circ r_2 \Rightarrow r_1\}$.

that *synchronously* generate strings in what we will refer to as an input and output language. We write SCFG rules as $NT \rightarrow \langle \alpha, \beta \rangle$, where NT is a non-terminal symbol, and α and β are strings of non-terminal and terminal symbols.

An SCFG rule can be viewed as two CFG rules, $NT \rightarrow \alpha$ and $NT \rightarrow \beta$, with a pairing between the occurrences of non-terminal symbols in α and β. This pairing is indicated by assigning each non-terminal in α and β an index $\in \mathbb{N}$. Non-terminals sharing the same index are called *linked*. Following convention, we denote the index for a non-terminal using a boxed subscript, e.g. $NT_{\boxed{1}}$.

B.2 Model Parameterization Details

Here we provide the complete definition of the $p_\theta(r|r_p, i)$ and $p_\theta(s|r_p, i)$ terms introduced in § 3.1.2:

$$p_\theta(s|r_p, i) = \frac{e^{\theta_{r_p,i,s}}}{\sum_{s' \in \mathcal{S}} e^{\theta_{r_p,i,s'}}} \tag{8}$$

$$p_\theta(r|s) = \frac{e^{\theta_{s,r}}}{\sum_{r' \in \mathcal{G}} e^{\theta_{s,r'}}} \tag{9}$$

where the θs are scalar parameters. For SMCalFlow-CS, where the number of induced rules is large, we approximate the denominator in Eq. 9 by only considering rules used in derivations in the same batch during training.

B.3 Grammar Induction Algorithm Details

In this section we describe the detailed implementation of the grammar induction algorithm introduced in § 3.1.4.

At each step, we process each rule r_c in $\mathcal{G}$ in parallel. First, using a variant of the CKY algorithm, we check if we can just remove r_c without violating the invariant that all examples in $\mathcal{D}$ can be derived by $\mathcal{G}$. If so, we simply remove the rule r_c as this will always decrease $L_{\mathcal{D}}(\mathcal{G})$. Otherwise, we determine a set of candidate *actions*, A, where an action $a \in A$ consists of a rule to add, r_{add}, and a set of rules to remove, R_{remove}. We determine A using the UNIFY operation described in Figure 4. Specifically, we consider each rule returned by $\text{UNIFY}(r_c, r')$ (where r' is any other rule in $\mathcal{G}$) as a potential rule to add, r_{add}. The corresponding set R_{remove} then consists of r_c and any other rule that we determine can be removed if r_{add} is added, without violating the above invariant.

If a CFG defining valid outputs is provided for the task, we ensure that the output string in r_{add} can be generated by the given CFG, for some replacement of the nonterminal symbols with nonterminals from the output CFG, using a variant of the CKY algorithm.

Given these candidate actions, A, we select:

$$a_{max} = \arg\max_{a \in A} \; -L_{\mathcal{D}}(\text{EXEC}(\mathcal{G}, a))$$

where $\text{EXEC}(\mathcal{G}, a)$ is an operation that returns a new set of rules $(\mathcal{G} \cup r_{add}) \setminus R_{remove}$.

We then aggregate over the actions, a_{max}, selected for each rule in $\mathcal{G}$, choosing an action only if it improves the objective. Each action is executed by setting $\mathcal{G} \leftarrow \text{EXEC}(\mathcal{G}, a_{max})$. The algorithm completes if no action was selected or if we reach a configurable number of steps.

We optionally partition the dataset into a configurable number of equally sized partitions based on example length. We then run the algorithm sequentially on each partition, starting with the partition containing the shortest examples. During initialization, we only add rules for examples in the first partition. We then add rules corresponding to examples in the next partition once the algorithm completes on the current partition.

B.4 Hyperparameters

We performed a limited amount of hyperparameter tuning based on performance on development sets. As our goal is to develop models that generalize well across multiple types of distribution shifts, we strove to use the same hyperparameters for each split within a dataset.

Dataset	k_α	k_β	k_t	# Partitions
SCAN	0	100	4	16
COGS	1	5	8	1
GeoQuery	4	16	8	1
SMCalFlow-CS	4	16	8	1

Table 6: Hyperparameters for grammar induction.

Grammar Induction For grammar induction, we selected various configuration options by inspecting the data for each dataset, such as the maximum number of nonterminals in a rule and whether we allow repeated nonterminal indexes. We evaluated several configurations for k_α and k_β in Eq. 7 and the relative cost of terminal vs. nonterminal symbols referenced in Eq. 6, which we will refer to here as k_t, during the development of our algorithm. The selected hyperparameters are listed in Table 6.

Parameteric Model For the CSL parameteric model, we selected a learning rate from $[0.01, 0.05, 0.1]$. We selected a number of context states $|\mathcal{S}|$ from $[32, 64]$, except for SCAN where we analyzed a larger number of context states on the MCD splits, as discussed in Appendix C.2. For SCAN we selected $|\mathcal{S}| = 2$ for all splits, except for MCD1 and MCD3, where we found $|\mathcal{S}| = 4$ to give more consistent performance on the dev sets. This was the only case where we used different hyperparameters for different splits of the same dataset.

Sampling We sampled $100,000$ synthetic examples for all datasets. We provide some analysis of the effect of this in Appendix C.7. For COGS, we biased sampling to increase the number of longer examples (as discussed in § 3.2) by setting the bias $\delta = 6$, and otherwise used $\delta = 0$. We limited the maximum recursion depth to 5 for SCAN, 10 for SMCalFlow, and 20 for GeoQuery and COGS.

T5 Fine-Tuning We started with the same configuration for fine-tuning T5 as Shaw et al. (2021). We similarly selected a learning rate from $[1e^{-3}, 1e^{-4}, 1e^{-5}]$ for each dataset. We use learning rate of $1e^{-3}$ for SCAN and SMCalFlow and $1e^{-4}$ for GeoQuery and COGS.

B.5 Training Details

We train the CSL model on 8 V100 GPUs, which takes less than 1.5 hours for all splits. We fine-tune T5 on 32 Cloud TPU v3 cores[21] for 10,000 steps, which takes less than 6 hours for all splits.

C Additional Analysis

C.1 Performance Breakdown

We extend the performance breakdown analysis of §4.4 to all splits, with results reported in Table 7.

C.2 Varying Context Sensitivity

Varying the number of context states $|\mathcal{S}|$ can vary the degree of context sensitivity in the CSL model. This can be important because we want our model to be able to accurately model $p(y|x)$, which we assume is shared between the source and target distributions, but we also want to sample new inputs x that may have low probability under the source distribution due to the novel compositions they contain.

As a step towards understanding the trade-offs related to context sensitivity, we compute the average $\log p(x, y)$ and $\log p(y|x)$ according to CSL models with different number of context clusters $|\mathcal{S}|$. The results are reported in Table 8. The results also let us compare $\log p(x) = \log p(x, y) - \log p(y|x)$.

A constraint on the number of context states $|\mathcal{S}|$ is in some ways similar to a constraint on the number of nonterminal symbols in a conventional SCFG. Notably, for SCAN, writing a SCFG that unambiguously maps inputs to outputs requires 2 unique nonterminal symbols, and we observe that, similarly, $|\mathcal{S}| \geq 2$ is required to reach 100% accuracy on the dev set. We also observe that while the models with larger $|\mathcal{S}|$ fit the training set better, the log likelihood of the dev sets is highest with $|\mathcal{S}|$ in the range between 2 and 4, indicating that the optimal place on the tradeoff curve is not at the extremes. We also note that there is some variance across the different splits for the optimal number of types, with some values leading to less than optimal modeling of $p(y|x)$.

It is also worth noting that, regardless of the number of context states, the structural conditional independence assumptions in our model can be too strong, harming the accuracy of modeling $p(y|x)$. For example, consider a rule for coordination, $\text{NT} \rightarrow \langle \text{NT}_{[1]} \text{ and } \text{NT}_{[2]}, \text{NT}_{[1]} \wedge \text{NT}_{[2]} \rangle$. In our model, we cannot condition the expansion of $\text{NT}_{[2]}$ on the corresponding expansion of $\text{NT}_{[1]}$ or the parent context in which the coordination rule

Table 8: We compare the average log probability CSL assigns to examples from the SCAN MCD train and dev sets, for different numbers of context states, $|\mathcal{S}|$.

is applied, in order to capture notions of type agreement. Such limitations are similar to the limitations of conventional PCFGs to sufficiently model structural dependencies for syntactic parsing (Klein and Manning, 2003).

In general, better understanding and optimizing the trade-offs related to context sensitivity for compositional generalization is an important direction for future work.

C.3 Comparing CSL and NQG

CSL and NQG of Shaw et al. (2021) vary across several dimensions, as the two systems use different grammar induction algorithms and different model parameterizations. Here we compare the two approaches across both dimensions independently.

Grammar Induction As discussed in §3.1.4, the largest set of changes to the CSL algorithm from that of NQG were to improve the scalabilty of the induction algorithm, as both algorithms scale super-linearly in both dataset size and the length of input and output strings. The runtime of grammar induction on the GeoQuery standard split on a standard workstation CPU is around 15 minutes for NQG, and < 1 minute for CSL. More importantly, we did not find it feasible to run NQG for SMCalFlow-CS, while CSL enables grammar induction to be completed within 10 hours with parallelization.

CSL also supports QCFG rules with > 2 nonter-

	GEOQUERY			COGS
Parsing Model	Templ.	TMCD	Len.	Gen.
BERT + SpanLabel	58.8	41.0	23.3	99.2
CSL Gen. Model	58.9	39.9	26.6	99.4

Table 9: We compare the accuracy of the span-based BERT-Base model of NQG (BERT + SpanLabel) with that of the CSL generative model (when used as a parsing model) for the same induced grammar (induced using CSL), on compositional splits of GeoQuery and COGS.

minals while NQG does not. We found allowing up to 4 nonterminals can improve the coverage of induced grammars for COGS and SMCalFlow-CS, with some example rules shown in Table 5 in Appendix A. Notably, for COGS, the induction algorithm of NQG induced a grammar that can only derive 64.9% of the test set.

Model Parameterization We compare the performance of CSL's simple generative model with that of the span-based model of NQG which uses a BERT-Base encoder in Table 9. Both models use the *same grammar* induced via the CSL algorithm. Overall, the models perform comparably, despite CSL having far fewer parameters (e.g. for GeoQuery, CSL has only 51,200 parameters[22] while NQG has over 110M parameters as it includes a BERT-Base encoder), not leveraging pre-trained neural networks, and being a generative model to support sampling (in contrast to NQG which is a discriminative model). Incorporating pre-trained neural components into a model such as CSL could be a promising future direction.

For SMCalFlow-CS, given a grammar induced by CSL, we found that it can be computationally infeasible to train a discriminative NQG model, due to the need to compute the partition function which sums over all possible derivations of the input. As a generative model, CSL avoids the need to compute a partition function during training.

Figure 5: We show the set of derivable synthetic examples for GECA (with window size = 2) and CSL, given an illustrative example of training examples. CSL can derive a significantly larger set of synthetic examples than GECA, and also assigns a probability to each derivable example.

C.4 Comparison with GECA

Hyperparameters For SCAN, the reported results in Table 1 use a window size of 1. Using a window size of 2 improves performance on the MCD split (24.9% vs. 22.8%) but hurts performance on the other splits. For GeoQuery, we used the default window size of 4 for the GeoQuery experiments. We attempted to run GECA on COGS and SMCalFlow-CS also using the default hyperparameters and did not find it to be computationally tractable. The algorithm's iteration over templates and fragments can become prohibitive for larger-scale datasets.

Analysis From Table 1 we see that augmenting the training data using CSL outperforms GECA across both synthetic and non-synthetic evaluations. GECA relies on the simple assumption that fragments are interchangeable if they appear in the same context. It is restricted by a pre-defined window size for fragments, and does not support recursion. Figure 5 compares differences in the sets of derivable synthetic examples for a notional set of training examples. In this case, CSL can derive a much larger set of recombinations by inducing the rule $\text{NT} \rightarrow \langle \text{NT}_{[1]}$ and $\text{NT}_{[2]}, \text{NT}_{[1]}\ \text{NT}_{[2]} \rangle$, which can be applied recursively.

C.5 Limitations of QCFGs

The mapping from inputs to outputs in SCAN, COGS, and GeoQuery are all well supported by QCFGs. However, grammars were used to generate the data for SCAN and COGS, so this is perhaps not surprising. While GeoQuery inputs were written by humans, the distribution of queries in the dataset is influenced by the capabilities of the underlying execution engine based on logic programming; the dataset has a large number of nested noun phrases in inputs that map directly to nested

---

[22] For each rule and non-terminal token in the induced grammar, CSL has a number of parameters equal to the number of context states.

FunQL clauses in outputs.

SMCalFlow The induced grammars have relatively low coverage on SMCalFlow, as shown by $\%^{\mathcal{X}_{CSL}}$ in Table 7, although they are still sufficient to improve the performance of T5. One reason for the low coverage is that inputs in SMCalFlow often reference specific names, locations, and meeting subjects, such as "setup up a sales meeting with Sam and his manager" where "sales meeting" and "Sam" must be copied to the output program as string literals. Sequence-to-sequence models with copy mechanisms or shared input-output vocabularies can handle such copying, but the QCFGs induced by our method do not support generalization to such novel tokens. Extending the method to support such string copying could significantly improve coverage.

Another reason for the low coverage is that the mismatch between the nesting of prepositional phrases in the input (e.g., "at NT" and "with NT") and the corresponding clauses in the output program tree makes it difficult to induce QCFG rules that enable recombination of different prepositional phrases in different contexts.

The induced QCFGs are also limited in other cases, such as their inability to "distribute" over groupings correctly. Since the training data only contains example such as $\langle$Jennifer and her boss, (person = "Jennifer") (FindManager (person= "Jennifer"))$\rangle$, the induced rule NT $\rightarrow$ $\langle$NT and her boss, (person = "NT") (FindManager (person= "NT"))$\rangle$, the induced grammar cannot correctly generate test examples like $\langle$Jennifer and Elli and their bosses, (person = "Jennifer") (person = "Elli") (FindManager (person= "Jennifer")) (FindManager (person= "Elli"))$\rangle$.

CFQ We also evaluated the feasibility of our approach to improve T5 performance on CFQ (Keysers et al., 2020), a popular synthetic dataset for evaluating compositional generalization. We found it was challenging to induce QCFGs with reasonable coverage for CFQ. First, the SPARQL queries in CFQ contain variables, which are not well supported by QCFGs (Wong and Mooney, 2007). Additionally, the mapping from queries to SPARQL in CFQ requires notions of commutativity (both "M0 edited and directed M1" and "M0 directed and edited M1" will be mapped to "M0 ns:film.director.film M1 . M0 ns:film.editor.film M1") and distributivity (edited in "edited M1 and M2" will appear twice in "?x0 ns:film.editor.film M1 . ?x0 ns:film.editor.film M2") that are also not well supported by QCFGs. Such limitations can potentially be partially overcome by desigining intermediate representations for CFQ (Furrer et al., 2020; Herzig et al., 2021), but a complete solution likely requires an extension to the class of allowable rules in $\mathcal{G}$ beyond those a QCFG formalism supports, such as better support for variables (Wong and Mooney, 2007) and the ability to apply rewriting rules to generated output strings.

C.6 Sampling Temperature

In this section we study the impact of the parametric model on data augmentation. To do this, we consider varying the sampling temperature, applied to $\theta_{t,r}$ prior to normalization. We compare the accuracy of T5+CSL-Aug. for different temperatures for SMCalFlow-CS, and also with sampling from a uniform distribution rather than using the CSL parameteric model for all splits, which can be viewed as using temperature $= \infty$.

Table 10 shows that using the parameteric model outperforms uniform sampling by a large margin on most splits. However, for SMCalFlow-CS, increasing the sampling temperature can lead to improved performance. To help understand why increasing temperature improves performance on the SMCalFlow-CS cross-domain splits, we computed the number of single-domain examples and cross-domain examples in the 100,000 sampled synthetic examples. Sampling from uniform distribution generates on average 17,764 cross-domain examples comparing with sampling from CSL which generates on average 1,114 cross-domain examples. The significant larger number of synthetic cross-domain examples might explain the improvement on cross-domain performance when increasing sampling temperature, especially on the 8-shot split, given the small number of cross-domain examples in the original training data.

C.7 Semi-Supervised Learning

If we have unlabeled data from our target distribution, consisting of inputs only, we can incorporate this data when training our generative model in a straightforward way. Here we propose a new experiment to evaluate a method for semi-supervised learning that leverages such unlabeled examples. We assume that the unlabeled inputs from the development set are available during training.

	SCAN				COGS	GeoQuery				SMCalFlow-CS

	100K	93.3	89.3	74.9	67.8	99.4
✓	100K	93.2	89.4	75.6	67.3	99.4

Table 11: We compare the accuracy of T5 + CSL using data augmentation with and without unlabeled data.

Experiment Setting In this setting, conceptually, when optimizing θ, we want to maximize both the likelihood of $p(x, y)$ for $\mathcal{D}$ and the marginal likelihood $p(x)$ for the unlabeled data. As the latter requires marginalizing over derivations for x and all possible outputs, and this can be a large set to sum over, we approximate this by first labeling the unlabeled data following the inference procedure described in §3.1.5 using the generative model trained only on $\mathcal{D}$, which can be interpreted as a hard-EM approach. During this process, we discard any unlabeled that cannot be derived given $\mathcal{G}$. We then re-train the generative model on both sets of data following the standard procedure, duplicating the “unlabeled” data a configurable number of times to achieve the desired ratio to the original labeled data.

We evaluate our CSL + T5-Aug. in this setting using *unlabeled* data from the development set. We use the SCAN MCD splits as they have dev sets available. We also evaluate performance on the GeoQuery splits. We compare the performance with and without unlabeled data using 1,000 and 100,000 synthetic examples.

Results Results are reported in Table 11. Incorporating unlabeled examples leads to improvements when sampling only 1,000 examples, but leads to minimal improvements when sampling 100,000 examples. We did not find positive results based on initial experiments for SMCalFlow-CS, likely due to the low coverage of the induced grammars on the target examples (see Table 7), as the method we evaluated cannot leverage unlabeled examples that are not covered by the induced grammar.

Split	Mean	Stdev.

C.8 GeoQuery Variance

The variance of T5+CSL-Aug. for GeoQuery is reported in Table 12.

C.9 SMCalFlow-CS Error Analysis

We sampled 20 prediction errors for T5+CSL-Aug. from single-domain and cross-domain development sets respectively. We found a large number of errors are due to ambiguous and inconsistent annotations. Table 13 shows some examples of such errors. First, the subject string is determined inconsistently for training and testing examples. Second, the same source can be mapped to different targets which express the same meaning. Third, some examples require additional context to generate the correct output. Among the errors we sample, around 60% of single-domain errors and around 35% of cross-domain errors fall into these three types. In addition, for the cross-domain examples, T5+CSL-Aug. sometimes struggles with nesting programs in a correct way when examples require querying an org chart for more than one people as discussed in Appendix C.5.

Abstract

Event trigger detection, entity mention recognition, event argument extraction, and relation extraction are the four important tasks in information extraction that have been performed jointly (Joint Information Extraction - JointIE) to avoid error propagation and leverage dependencies between the task instances (i.e., event triggers, entity mentions, relations, and event arguments). However, previous JointIE models often assume heuristic manually-designed dependency between the task instances and mean-field factorization for the joint distribution of instance labels, thus unable to capture optimal dependencies among instances and labels to improve representation learning and IE performance. To overcome these limitations, we propose to induce a dependency graph among task instances from data to boost representation learning. To better capture dependencies between instance labels, we propose to directly estimate their joint distribution via Conditional Random Fields. Noise Contrastive Estimation is introduced to address the maximization of the intractable joint likelihood for model training. Finally, to improve the decoding with greedy or beam search in prior work, we present Simulated Annealing to better find the globally optimal assignment for instance labels at decoding time. Experimental results show that our proposed model outperforms previous models on multiple IE tasks across 5 datasets and 2 languages.

1 Introduction

To extract structured information from unstructured text, a typical information extraction (IE) pipeline involves four major tasks: event trigger detection (ETD), event argument extraction (EAE), entity mention recognition (EMR), and relation extraction (RE). Previous work has performed such IE tasks via pipelined approaches (Li et al., 2013; Chen et al., 2015; Du and Cardie, 2020; Li et al., 2020), where a model for one task uses output predictions from other models performing other tasks. Consequently, errors from the predictions can be propagated between the models in the pipeline.

Recently, ETD, EMR, EAE, and RE have been solved jointly in a single model, i.e., Joint Information Extraction - JointIE (Wadden et al., 2019; Lin et al., 2020; Nguyen et al., 2021a; Zhang and Ji, 2021), to avoid error propagation and leverage dependency between prediction instances of the four IE tasks (i.e., event trigger, entity mention, relation, and event argument candidates in a sentence). For example, if a *Person* entity mention is a *Victim* argument for a *Die* event, it is likely that the same entity mention is also a *Target* argument for an *Attack* event in the same sentence. To implicitly exploit instance dependency for representation learning, Wadden et al. (2019) and Lin et al. (2020) employ a shared encoder to obtain representation vectors to classify instances of different IE tasks. Later work heuristically captures dependency between IE task instances via explicitly connecting the task instances that share an entity mention or event trigger (Nguyen et al., 2021a) or aligning the task instances that share text spans with some nodes on a semantic graph (Zhang and Ji, 2021) to aid representation learning. While natural, these manual designs for dependency between task instances might not be optimal for representation learning of JointIE.

In addition to representation learning, at the prediction level, previous work tends to factorize the joint distribution of labels for all the task instances in JointIE into the product of label distributions for each individual instance (i.e., performing local normalization), thus hindering the ability to fully exploit the interactions of instance labels across IE tasks. (Lin et al., 2020) and (Zhang and Ji, 2021) mitigate this problem by decoding instance labels with handcrafted global features while (Nguyen et al., 2021a) focuses on encoding label interactions via consistency regularization over global type dependency graphs. However, these approaches still

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4363 - 4374
July 10-15, 2022

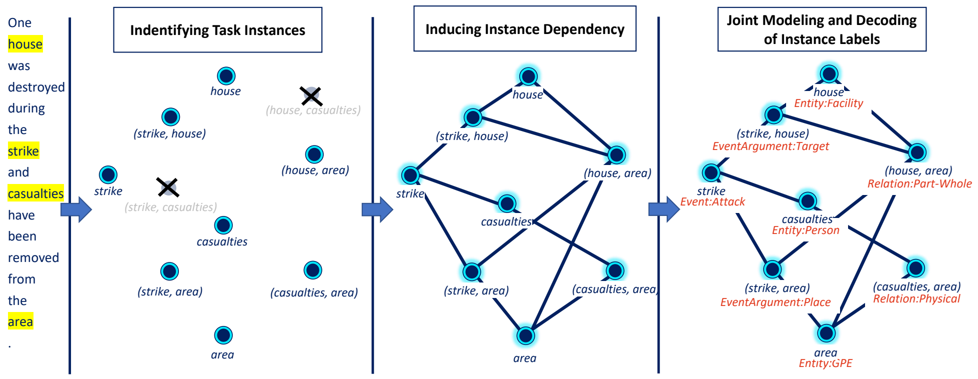

Figure 1: Overview of the three stages in our proposed model: i) identifying task instances, ii) inducing instance dependency, and iii) joint modeling and decoding of instance labels. Each node represents an instance for one of the four IE tasks, and edges (with weights > 0.3) between nodes represent induced instance dependency.

assume a factorization of the joint label distribution for prediction instances, thus unable to fundamentally address the label dependency encoding issue. Recently, some works have attempted to directly model the joint distribution of instance labels by reformulating JointIE tasks as text generation problems using state-of-the-art pre-trained seq2seq models, e.g., BART or T5 (Lewis et al., 2020; Raffel et al., 2020). In such generative models, text spans and labels for task instances are generated by the decoder in an autoregressive fashion to encode label dependency for joint distribution computation (Lu et al., 2021; Hsu et al., 2021). Unfortunately, this approach needs to assume an order of the task instances to be decoded (e.g., from left to right) that disallows later instances in the order to interfere/correct predictions for earlier instances, causing suboptimal performance for JointIE.

In this work, we aim to overcome these issues by inducing dependency between the task instances for JointIE from data to boost representation learning, and directly modeling the joint distribution of the labels for all the task instances to fully enable label interactions. To this end, we consider each task instance as a node in a fully connected dependency graph; the weight for each edge is then learned to capture the dependency level between two corresponding instances. Note that this is different from prior work (Nguyen et al., 2021a; Zhang and Ji, 2021) that heuristically designs sparser dependency graphs with disconnected task instance pairs, thus failing to explore all possible interactions between instance pairs for optimal representations. In our method, the induced dependency graph for instance nodes is then employed by Graph Convolutional Networks (GCNs) (Kipf and Welling, 2017; Nguyen and Grishman, 2018) to enhance the representation for each instance node with information from all the other nodes according to their dependency levels. Afterwards, the enhanced instance representations and the induced dependency graph are utilized to estimate the joint distribution of instance labels via Conditional Random Fields (CRFs) (Lafferty et al., 2001). This formulation enables us to approximately maximize the intractable joint likelihood of the ground-truth instance labels via Noise Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2012), which converts the maximization problem into the nonlinear logistic regression discriminating between the true labels and the noise labels.

Finally, previous work for JointIE has employed a greedy or beam search for decoding instance labels, which is not optimal due to their greedy nature. In this work, we propose a novel decoding algorithm for JointIE via Simulated Annealing (SA) (Kirkpatrick et al., 1983), which has been shown to be able to approximate the global optimum of a function (Kirkpatrick et al., 1983; Van Laarhoven and Aarts, 1987). Experimental results show that our proposed model for JointIE significantly outperforms previous models on multiple tasks with large margins across 5 datasets and 2 languages.

2 Problem Statement

Given an input sentence, ETD aims to predict text spans and event types for event triggers based on a predefined set of event types, e.g., *"Attack"* and *"Transport"* (Lai et al., 2020). Similarly, EMR seeks to determine text spans and entity types (e.g., *"Person"*, *"Organization"*) for entity mentions in the sentence (Nguyen et al., 2016b). Different from the first two tasks, EAE and RE involves predictions for a pair of objects at a time. Given an event trigger and an entity mention, EAE aims to predict the argument role (e.g, *"Victim"*) of the entity mention for the event trigger (Veyseh et al., 2020c). An argument role can be *"Not-an-argument"* indicating that the entity mention is not an argument for the trigger. For RE (Veyseh et al., 2020a,b), the task focuses on the classification of relation (e.g, *"Work for"*) for a given pair of entity mentions. There is also a special type *"No-relation"* to specify no relation between two entity mentions. As such, we call the union set C of the predefined event types, entity types, argument roles, and relation types as the information types (excluding *"Not-an-argument"* and *"No-relation"*).

3 Model

To capture dependency among task instances for JointIE, an approach is to obtain all text spans for entity/event mention candidates along with their possible pairs to form the nodes for a dependency graph to improve representation learning. However, this approach will retain many text spans for non-entity/event mentions to introduce noise into the modeling. It will also entail a large dependency graph that can hinder the efficiency of the model. To this end, our model for JointIE first identifies text spans for entity mentions and event triggers. Afterwards, all possible pairs of event-entity and entity-entity mentions are considered to identify positive pairs for event arguments and relations respectively. The detected entity mentions, event triggers, event arguments, and relations are called task instances that should be classified to obtain corresponding information types in C. In our model, a dependency graph among the detected task instances will be learned to provide inputs for GCNs to compute dependency-enhanced representations for the task instances. Finally, the enhanced representations will be used to compute a joint distribution over labels for all the task instances to train our model. We will also employ Simulated Annealing to achieve the global optimum for label assignment of the task instances in the decoding phase.

3.1 Identifying event and entity mentions

Given an input sentence $\mathbf{w} = [w_1, \dots, w_N]$ with N words, we identify its event triggers and entity mentions by solving two corresponding sequence tagging problems for event and entity mentions. In particular, we use the BIO tagging schema to assign two labels to each word in $\mathbf{w}$ to mark the text spans of event triggers and entity mentions, i.e., {*"B-TRIGGER"*, *"I-TRIGGER"*, *"O"*} labels for event triggers, and {*"B-ENTITY"*, *"I-ENTITY"*, *"O"*} labels for entity mentions. The pre-trained transformer-based language model BERT (Devlin et al., 2019) is first utilized to obtain the contextualized embeddings for the words in the sentence: $\mathbf{X} = \mathbf{x}_1, \dots, \mathbf{x}_N = \text{BERT}([w_1, \dots, w_N])$.

Next, the vector sequence $\mathbf{X}$ is sent to two different CRF layers (Lafferty et al., 2001; Chiu and Nichols, 2016) to compute two distributions for the tag sequences of $\mathbf{w}$ for event triggers and event mentions. The negative log-likelihoods L_t and L_e for golden trigger and entity tag sequences are then obtained to be included in the overall training loss. At test time, the Viterbi algorithm (Forney, 1973) is employed to determine the best tag sequences for event triggers and event mentions in $\mathbf{w}$.

Let V^t and V^e be the sets of text spans for event triggers and entity mentions respectively in $\mathbf{w}$ (i.e., golden spans in the training time and predicted spans in the test time). To prepare for the next components, we compute the representations vectors $\mathbf{z}^t_i$ and $\mathbf{z}^e_j$ for each event trigger/instance $t_i \in V^t$ and entity mention/instance $e_j \in V^e$ respectively by averaging over the contextualized embeddings of the words inside the spans.

3.2 Identifying event arguments and relations

Given the detected event triggers and entity mentions, we obtain a representation vector $\mathbf{z}^a_{ij}$ for each pair of event-entity mentions $a_{ij} = (t_i, e_j)$ (i.e., $t_i \in V^t$, $e_j \in V^e$), and a representation vector $\mathbf{z}^r_{ij}$ for each pair of entity-entity mentions $r_{ij} = (e_i, e_j)$ (i.e., $e_i, e_j \in V^e$) via:

$\mathbf{z}^a_{ij} = FFN^{down}_a(\text{concat}(\mathbf{z}^t_i, \mathbf{z}^e_j))$ and $\mathbf{z}^r_{ij} = FFN^{down}_r(\text{concat}(\mathbf{z}^e_i, \mathbf{z}^e_j))$.

Here, we use the feed-forward networks FFN^{down}_a and FFN^{down}_r to make sure that $\mathbf{z}^t_i$, $\mathbf{z}^e_j$, $\mathbf{z}^a_{ij}$, and $\mathbf{z}^r_{ij}$ have the same dimensionality. Next, the pair representation vectors $\mathbf{z}^a_{ij}$ and $\mathbf{z}^r_{ij}$ are sent into two different feed-forward networks followed by sigmoid activations to compute the possibilities for being positive examples for event arguments and relations of a_{ij} and r_{ij} respectively: $p^a_{ij} = \sigma(\text{FFN}^a(\mathbf{z}^a_{ij}))$, and $p^r_{ij} = \sigma(\text{FFN}^r(\mathbf{z}^r_{ij}))$. Here, $p^a_{ij} \in (0, 1)$ is the probability for the entity mention e_j being an actual argument for the event trigger t_i while $p_{ij}^r \in (0, 1)$ is the likelihood that there exists a relation of interest between the entity mentions e_i and e_j. At training time, we obtain the the negative log-likelihoods L_a and L_r for the golden event argument and relation identification to be included in the overall loss function for minimization. At test time, the event-entity pair a_{ij} and entity-entity pair r_{ij} are retained as positive examples for event arguments and relations if their likelihooods p_{ij}^a and p_{ij}^r are greater than 0.5.

For convenience, let V^a and V^r be the sets of positive event-entity pairs a_{ij} (called argument instances) and entity-entity pairs r_{ij} (called relation instances) respectively. Also, let $V = V^t \cup V^e \cup V^a \cup V^r$ be the set of all detected event, entity, argument, and relation instances. For each instance $v_i \in V$, we will use $\mathbf{v}_i$ for its corresponding instance representation (i.e., from $\mathbf{z}_i^t$, $\mathbf{z}_j^e$, $\mathbf{z}_{ij}^a$, or $\mathbf{z}_{ij}^r$).

3.3 Inducing Instance Dependency

Given the detected event, entity, argument, and relation instances in V, it remains to predict the information types in C for the instances to solve JointIE. While it is possible to directly employ the instance representations $\mathbf{v}_i$ for label prediction, our goal is to exploit instance dependency in IE to enhance the representation vector for one instance with the information from other instances to facilitate type prediction. In particular, using the instances v_i in V as the nodes in a dependency graph G, we aim to enrich instance representations by feeding them into a GCN model. As such, instead of assuming a heuristic manually-designed dependency graph among the instances as in previous work (Zhang and Ji, 2021; Nguyen et al., 2021a), we propose to automatically learn the dependency graph G for the instances in V. To this end, our dependency graph G is a fully connected graph among the nodes in V where a weight $\alpha_{ij} \in (0, 1)$ is learned for each edge to quantify the dependency between the instances v_i and v_j in V. In this work, we present two sources of information that can be used for determining the dependency between the task instances: (i) semantic and (ii) syntactic information.

Semantic Information: The semantic-based weight α_{ij}^{sem} for the edge between v_i and v_j quantifies their relatedness/dependency based on semantic information, i.e., via the representation vectors $\mathbf{v}_i$ and $\mathbf{v}_j$: $\alpha_{ij}^{sem} = FFN^{sem}(\text{concat}(\mathbf{v}_i, \mathbf{v}_i))$. Here, FFN^{sem} is a feed-forward network with the sigmoid function in the end.

Syntactic Information: The syntax-based weight α_{ij}^{syn} for the edge between v_i and v_j is computed in a similar way as α_{ij}^{sem}. In particular, for each word $w_k \in \mathbf{w}$, we retrieve the dependency relation d_k between w_k and its governor in the dependency tree of $\mathbf{w}$, which is generated by the Trankit's dependency parser (Nguyen et al., 2021b). We then obtain the embedding $\mathbf{m}_k$ of d_k for w_k by looking up the learnable dependency embedding matrix $\mathbf{M}$. Afterwards, the syntax-based representation vector u_i for the instance $v_i \in V$ is computed via: $u_i = \text{max-pool}_{w_k \in SPAN_{v_i}}(\mathbf{m}_k)$. Here, $SPAN_{v_i}$ involves the words in the corresponding text span of v_i in $\mathbf{w}$ if v_i is an event trigger or entity mention instance. Otherwise, $SPAN_{v_i}$ contains the words inside the text spans of the involving event triggers and entity mentions in the pair for v_i. As such, we compute the syntax-based dependency weight α_{ij}^{syn} for v_i and v_j via: $\alpha_{ij}^{syn} = FFN^{syn}(\text{concat}(\mathbf{u}_i, \mathbf{u}_i))$ where FFN^{syn} is also a feed-forward network with the sigmoid function in the end. Finally, we combine the semantic- and syntax-based weights to obtain the overall dependency weight α_{ij} for v_i and v_j in V: $\alpha_{ij} = (\alpha_{ij}^{sem} + \alpha_{ij}^{syn})/2$.

3.4 Enhancing Representations with GCNs

To enhance the representation vectors for the instances $v_i \in V$, a GCN model with K layers is applied over the induced dependency graph G to compute richer representations for the instances:

$$\mathbf{h}_i^k = \text{ReLU}\left(\frac{\sum_{v_j \in V} \alpha_{ij} \mathbf{W}^k \mathbf{h}_j^{k-1} + \mathbf{b}^k}{\sum_{v_j \in V} \alpha_{ij}}\right), 1 \leq k \leq K \quad (1)$$

Here, h_i^k is the representation for the instance v_i at the k-th layer of the GCN ($\mathbf{h}_i^0 \equiv \mathbf{v}_i$), and $\mathbf{W}^k, \mathbf{b}^k$ are trainable weight and bias for the layer.

In this way, representation information from all the other instances v_j ($j \neq i$) will be incorporated into the enhanced representation vector for v_i according to their learned dependency weights. Finally, the last layer's representation $\mathbf{h}_i^K \equiv \mathbf{h}_i$ (we omit K for simplicity) is used to compute the score vector $\mathbf{s}_i \in \mathbb{R}^{|C|}$ for v_i, where $\mathbf{s}_i[c]$ measure the possibility for v_i to have the c-th label in the label set C: $\mathbf{s}_i = FFN^{score}(\mathbf{h}_i)$ (FFN^{score} is a scoring feed-forward network). The score vectors $\mathbf{s}_i$ will later be used for modeling the joint distribution of the labels for all the instances in V.

3.5 Computing Joint Distribution of Labels

Let Y be the set of labels y_i for the instances v_i in V. To infer the labels for the instances in V, we need to estimate the joint distribution $P(Y|\mathbf{w}, V)$. In previous work (Wadden et al., 2019; Lin et al., 2020; Nguyen et al., 2021a; Zhang and Ji, 2021), JointIE methods mostly focus on learning representations for the task instances to compute a label distribution for each instance v_i for prediction: $P(y_i|\mathbf{w}, V) := \text{softmax}(\mathbf{s}_i)$. This practice essentially implies the following factorization for $P(Y|\mathbf{w}, V)$: $P(Y|\mathbf{w}, V) = \prod_{y_i \in Y} P(y_i|\mathbf{w}, V)$. As a result, this factorization assumes the independence of the instance labels, thus unable to fully capture beneficial label dependency for IE tasks.

To address this issue, we directly estimate the joint distribution $P(Y|\mathbf{w}, V)$ so that the dependency between instance labels can be facilitated to improve prediction performance. To this end, we formulate the joint distribution $P(Y|\mathbf{w}, V)$ with Conditional Random Fields (Lafferty et al., 2001):

$$P(Y|\mathbf{w}, V) = \frac{1}{Z(V)} \prod_{(v_i, v_j)} \psi_{ij}(y_i, y_j, V) \tag{2}$$

where $\psi_{ij}(y_i, y_j, V)$ is a positive potential function defined on the edge (v_i, v_j) of the dependency graph G, and $Z(V) = \sum_{Y' \in C_V} \prod_{(v_i, v_j)} \psi_{ij}(y'_i, y'_j, V)$ is the normalization term to make sure that $P(Y|\mathbf{w}, V)$ is a valid probability distribution (C_V is the set of all possible label assignments Y for the instances in V). Considering the instance information, the instance dependency, and the label dependency, we propose the potential function as:

$$\psi_{ij}(y_i, y_j, V) := \exp(\mathbf{s}_i[y_i] + \mathbf{s}_j[y_j] + \alpha_{ij} \pi_{y_i \leftrightarrow y_j}) \tag{3}$$

where $\mathbf{s}_i[y_i]$ is the local score for instance v_i being assigned with the label y_i, α_{ij} is the induced dependency weight for the edge (v_i, v_j) in G, and $\pi_{y_i \leftrightarrow y_j}$ is a learnable transition score indicating the dependency between the labels y_i and y_j. With this formulation, we can derive the joint distribution $P(Y|\mathbf{w}, V)$:

$$P(Y|\mathbf{w}, V) = \frac{\exp(s(Y))}{\sum_{Y' \in C_V} \exp(s(Y'))} \tag{4}$$

where:

$$s(Y) = \gamma \sum_{v_i \in V} \mathbf{s}_i[y_i] + \sum_{(v_i, v_j)} \alpha_{ij} \pi_{y_i \leftrightarrow y_j} \tag{5}$$

is the global score for the label assignment/configuration Y of the instances. γ is a hyper-parameter to balance the local and transition scores.

To train the model, we need to maximize the joint likelihood in Equation (4) for the golden label configuration Y^*. However, this requires the computation of the normalization term $\sum_{Y' \in C_V} \exp(s(Y'))$, which is intractable. To overcome this issue, we employ Noise Contrastive Estimation (NCE) (Gutmann and Hyvärinen, 2012; Mikolov et al., 2013). NCE converts the maximization problem into the nonlinear logistic regression that discriminates between the golden label configurations and the noise label configurations. In particular, the maximization of $P(Y^*|\mathbf{w}, V)$ is done with NCE via minimizing the contrastive loss:

$$L_{NC} = -\log\sigma(s(Y^*)) - \sum_{n=1}^{N_{noi}} \mathbb{E}_{Y'_n \sim P_{noi}} \left[\log\sigma(-s(Y'_n))\right] \tag{6}$$

where σ is the sigmoid function and N_{noi} is the number of noise configurations Y'_n drawn from P_{noi}, assumed to be a uniform distribution. Intuitively, the minimization of L_{NC} increases the global score $s(Y^*)$ for the true label configuration Y^* while decreasing the global scores $s(Y')$ for the noise label configurations Y' to appropriately train the model. To the end, the overall loss function to train our model is: $L = L_t + L_e + L_a + L_r + L_{NC}$.

Algorithm 1: Simulated Annealing Search

```
Input : $\hat{Y}_0$ where $\hat{y}_{i,0} = \text{argmax}_{c \in C} \mathbf{s}_i[c]$.
$\hat{Y}_{cur} \leftarrow \hat{Y}_0; n \leftarrow 1;$
while $n \leq N_{iter}$ do
    $t \leftarrow T/n;$
    if $t < \epsilon$ then
        return $\hat{Y}_{cur};$
    else
        $\hat{Y}_{new} = random\_successor(\hat{Y}_{cur});$
        $\delta_n = s(\hat{Y}_{new}) - s(\hat{Y}_{cur});$
        if $\delta_n > 0$ then
            $\hat{Y}_{cur} \leftarrow \hat{Y}_{new};$
        else
            $\hat{Y}_{cur} \leftarrow \hat{Y}_{new}$ with $p = \exp(\frac{\delta_n}{t})$ ;
        end
    end
    $n \leftarrow n + 1;$
end
return $\hat{Y}_{cur}$.
```

3.6 Joint Decoding via Simulated Annealing

At inference time, we need to search for the configuration $\hat{Y}$ that has the highest global score $s(\hat{Y})$ in C_V: $\hat{Y} = \text{argmax}_{Y' \in C_V} s(Y')$. A brute-force search for $\hat{Y}$ cannot be done as the search space C_V is exponentially large ($|C_V| = |C|^{|V|}$). Previous work has made several attempts to deal with this issue. (Wadden et al., 2019) and (Nguyen et al., 2021a) simply perform greedy decoding for each instance label independently, thus unable to exploit the label dependency. (Lin et al., 2020) and (Zhang and Ji, 2021) resort to beam search that step by step constructs a complete decoding assignment Y for the instances in V by expanding an initially empty assignment. Each step corresponds to an instance in V where only top candidate labels for the instance are considered for assignment expansion and only top partial assignments produced so far are kept for the next step. Unfortunately, the selection of top candidate labels for expansion at each step is based only on the local scores $\mathbf{s}_i$, which might discard the candidates that can eventually provide greater global scores. To overcome this issue, we propose to apply Simulated Annealing (SA) (Kirkpatrick et al., 1983) to search for the optimal assignment $\hat{Y}$ for V. SA is a probabilistic algorithm that is able to approximately find the global optimum of a function (Kirkpatrick et al., 1983; Van Laarhoven and Aarts, 1987). Algorithm 1 presents our implementation for SA to find $\hat{Y}$.

	Test	546	811	108	269

Table 1: Data statistics. **#sents**, **#ent**, **#rels**, and **#events** indicate the number of sentences, entity mentions, relations, and events respectively.

The input for the algorithm is the initial configuration $\hat{Y}_{cur} = \hat{Y}_0 = \{\hat{y}_{i,0}\}$, which contains the greedily predicted labels for each instance: $\hat{y}_{i,0} = \text{argmax}_{c \in C} \mathbf{s}_i[c]$. The algorithm then runs over N_{iter} iterations to improve the global score $s(\hat{Y}_{cur})$ for the current label configuration $\hat{Y}_{cur}$. This is done via updating the current configuration to a successor configuration $\hat{Y}_{new}$ that gives a higher global score (i.e., $\delta_n > 0$). A successor configuration is obtained via the function $random\_successor()$ by randomly changing some label $\hat{y}_i \in \hat{Y}_{cur}$. Different from beam search decoding with partial assignments, each searching step in SA examines a complete label assignment for the instances in V to provide complete information to measure the global scores/quality of the assignments. Importantly, SA sometimes allows the current configuration to transition to a successor configuration with a lower global score (i.e., $\delta_n \leq 0$) with an acceptance probability of $p = \exp(\frac{\delta_n}{t})$. Here, t is the temperature of the algorithm, gradually decreased via $t \leftarrow T/n$ (T is a hyper-parameter). This exploration property enables SA to escape from local optimum configurations, thus increasing the chance to find the globally optimal configuration $\hat{Y}$.

4 Experiments

Datasets: Following previous work (Wadden et al., 2019; Lin et al., 2020; Zhang and Ji, 2021; Nguyen et al., 2021a; Lu et al., 2021; Hsu et al., 2021), we conduct experiments on 5 different datasets created by the 2005 Automatic Content Extraction (ACE05) (Walker et al., 2006) and Entity Relation Event (ERE) (Song et al., 2015) programs. The three ACE05 datasets feature **ACE05-R**, **ACE05-E**, and **ACE-E+**, all in English, involving 33 event types, 7 entity types, 6 relation types, and 22 argument roles. The two ERE datasets are **ERE-EN** (English portion) and **ERE-ES** (Spanish portion), introducing 38 event types, 7 entity types, 5 relation types, and 20 argument roles. We use the same data processing and train/dev/test splits as the prior work for a fair comparison. Detailed statistics for the datasets are shown in Table 1.

Baselines: We compare our method, called *GraphIE*, with the following baselines for JointIE:

Generative baselines: *Text2event* (Lu et al., 2021) and *DEGREE* (Hsu et al., 2021). The generative baselines perform ETD and EAE via formulating the tasks as text generation. The models receive an input sentence and generate an output text containing text spans and labels for event triggers and event arguments, structured in a way that a post-processing step can be used to extract ETD and EAE predictions for the models.

Classification baselines: *OneIE* (Lin et al., 2020), *AMRIE* (Zhang and Ji, 2021), and *FourIE* (Nguyen et al., 2021a). The classification baselines represent the instances for ETD, EMR, EAE, and RE via a shared encoder and perform classification for the instances based on task-specific label distributions. *AMRIE* and *FourIE* employ a heuristic dependency graph among task instances to improve representation learning. Dependency between instance labels is exploited in *OneIE* and *AMRIE* via a beam search decoding with manually-designed

Table 2: Model performance on the test data of 5 datasets. *"Ent"*, *"Rel"*, *"Trg"*, and *"Arg"* are the F1 scores for identification and classification of entity mentions, event triggers, relations, and event arguments respectively. * indicates results that are not reported in the original papers but produced by their official code. Underlined numbers designate the tasks where *GraphIE* is significantly better (p < 0.01) than the baselines.

global features, and in *FourIE* via global type dependency regularization. *FourIE* and *AMRIE* are the current state-of-the-art models for JointIE.

Hyper-parameters: Prior work for JointIE employs two different versions of pre-trained language models (PLM), i.e., *BERT* (Devlin et al., 2019; Lin et al., 2020; Nguyen et al., 2021a) and *RoBERTa* (Liu et al., 2019; Zhang and Ji, 2021), which might cause incompatible compassion. To this end, we explore both BERT and RoBERTa to obtain the word representations $\mathbf{x}_i$ for *GraphIE* for a fair comparison. For the Spanish ERE-ES dataset, following prior work (Lin et al., 2020; Nguyen et al., 2021a), we utilize the multilingual versions of BERT and RoBERTa. For each PLM, we fine-tune the hyper-parameter for *GraphIE* on the development data.

In particular, the best values for the hyper-parameters of the proposed model are reported as follows. We employ the learning rate of $1e-5$ for the models with the BERT-based PLM (i.e., using *bert-large-cased* and *bert-multilingual-cased*) and the learning rate of $5e-6$ for the RoBERTa-based PLM (i.e., using *roberta-large* and *xlm-roberta-large*). For other hyper-parameters, our tuning process results in the same values for BERT-based and RoBERT-based models: Adam (Kingma and Ba, 2014) for the optimizer, batch size of 10, 100 for the size of the dependency relation embeddings, 400 for the size of the hidden vector for the feed-forward networks, 200 for the hidden vector size in the GCN model, 2 for the number of layers for the feed-forward networks and GCN model, $\gamma = 1$ for the trade-off hyper-parameter for the global score, $N_{noi} = 5$ for the number of noise examples for the contrastive loss (we re-sample the noise examples every epoch), $T = 5$ for the initial temperature, $N_{iter} = 50$ for the number of iterations of Simulated Annealing (SA), and $\epsilon = 0.1$ for the temperature threshold for the SA decoding.

Comparison with Baselines: We compare the proposed model *GraphIE* with the baselines on test data of the 5 datasets in Table 2. As can be seen, the generative baselines perform worse than the classification models on most of the settings. This might be due the implicit modeling of the label distributions and the assumption of a decoding order for task instances that limit the interactions of instance labels. Comparing *OneIE*, *FourIE* and *AMRIE*, it is clear that the exploitation of instance and label dependency in the training phase in *FourIE* can lead to better performance for JointIE than using such dependency in the decoding phase as done by *OneIE* and *AMRIE* over most tasks and PLMs. Most importantly, the proposed *GraphIE* significantly outperforms all the baselines across a majority of settings for tasks, datasets and PLMs, thus demonstrating the benefits of induced dependency graph, joint label distribution estimation, and simulated annealing for decoding in our method.

Model *(all use Roberta)*	**ACE05-E+**			
	Ent	Rel	Trg	Arg
GraphIE	**89.8**	**67.2**	**72.6**	**66.3**
- induced dep	89.3	65.8	71.3	65.0
- semantic-based dep	89.0	66.4	71.6	65.9
- syntactic-based dep	89.4	66.3	72.0	65.4
- induced dep + heuristic dep	89.3	66.2	71.7	65.5
- GCN	89.4	65.6	70.9	64.6

Table 3: Performance (F1) on the ACE05-E+ development data.

Ablation Study: To understand the contributions of each proposed component to *GraphIE*, we conduct ablation experiments where we remove each component from the full model and evaluate the performance of the remaining models.

The first three ablated models in Table 3 are *"- induced dep"*, *"- semantic dep"*, and *"- syntactic dep"*, formed by excluding the dependency weight induction of α_{ij} (i.e., setting $\alpha_{ij} = 1$), the semantic-based dependency α_{ij}^{sem}, and the syntactic-based dependency α_{ij}^{syn} (respectively) from the model computation. In each case, the performance of *GraphIE* decreases significantly; the removal of both semantic- and syntactic-based dependency in *"- induced dep"* leads to the largest performance drop. This shows that the semantic and syntactic weighting captures complementary information for instance dependency induction that is useful for our model. The next ablated model *"- induced dep + heuristic dep"* is obtained by replacing the induced dependency graph represented by α_{ij} with the heuristic dependency graph for instances from the best baseline *FourIE*. The decrease in the performance of this model suggests that the induced dependency graph is better than the heuristic graph for JointIE. The final ablated model *"- GCN"* in Table 3 eliminates the GCN component from our full model. The result shows that GCN is beneficial to exploit the induced dependency graph to improve representation learning.

Model *(all use Roberta)*	**ACE05-E+**			
	Ent	Rel	Trg	Arg
GraphIE	**89.8**	**67.2**	**72.6**	**66.3**
- joint distribution	89.3	65.5	70.9	64.5
- SA + greedy	89.2	65.9	71.2	65.2
- SA + beam	89.5	66.0	71.5	65.4
- SA + hill climbing	89.5	66.8	71.7	65.3
OneIE	88.7	64.2	69.5	63.2
- beam + SA	88.1	63.9	69.1	62.7
AMRIE	89.4	65.4	71.2	64.4
- beam + SA	88.8	65.1	70.5	64.1

Table 4: Performance (F1) on the ACE05-E+ development data.

In Table 4, we first eliminate the computation of the joint label distribution $P(Y|\mathbf{w}, V)$ from *GraphIE*. As such, the *"- joint distribution"* model employs the local label distributions $P(y_i|\mathbf{w}, V)$ to train models and infer labels (with greedy decoding). Due to the significantly worse performance of *"- joint distribution"*, it is clear that directly estimating the joint label distribution is helpful for JointIE. To evaluate the benefit of the proposed SA, we replace it with other decoding algorithms for *GraphIE*, including greedy search, beam search and hill climbing. The beam search is implemented with our global score function $s(Y)$ and follows those in (Lin et al., 2020; Zhang and Ji, 2021) while hill climbing is implemented by removing the configuration exploration in lines 11-12 of Algorithm 1. As reported in Table 4, SA performs much better than other decoding algorithms for *GraphIE*, thus demonstrating SA's ability to find globally optimal labels. In addition, we also attempt to replace the beam search decoding in *OneIE* and *AMRIE* with SA, which indeed leads to worse performance for such models as shown in the last four rows of Table 4. We attribute this to the learning of the global scores for configurations in *OneIE* and *AMRIE* that involves a limited set of predefined global features. Such features do not exist for many possible assignments Y for V, thus causing poor global score computation and hindering the configuration ranking critically required by SA.

Label pair	**Transition score**
(Argument:Origin, Argument:Place)	10.02
(Event:Transport, Relation:Physical)	4.33
(Relation:Org-Aff, Relation:Part-Whole)	3.58
(Event:Execute, Event:Sentence)	2.58
(Event:Die, Event:Be-Born)	-2.34
(Event:Attack, Argument:Origin)	-87.07
(Relation:Per-Soc, Entity:Facility)	-93.93
(Transport, Attacker)	-99.91

Table 5: Transition scores for some label pairs learned by our model on ACE05-E+.

Analysis: To further understand the advantages of *GraphIE* over baseline models, we manually analyze the instances on the ACE05-E+ development data where *GraphIE* can make correct predictions, but the best baseline model *FourIE* fails. Figure 2 presents some instances along with their edges and weights in the dependency graphs. The most important insight from our analysis is that *GraphIE* is able to connect an instance (e.g., *blew*) with other supporting instances (e.g., *suicide*) in the dependency graph to provide vital information to facilitate correct prediction. Such supporting instances do not share any event trigger or entity mention with the current instance that cannot establish links in *FourIE* and lead to failure predictions.

Finally, Table 5 shows the transition scores $\pi_{y_i \leftrightarrow y_j}$ learned by *GraphIE* for some label pairs in ACE05-E+. The table show that our model is able to learn high scores for correlated label pairs (e.g., the *Execute* and *Sentence* event types) and very low scores for uncorrelated label pairs (e.g., an argument for a *Transport* event cannot play the role *Attacker*).

5 Related Work

Capturing dependency between IE tasks has been a main focus of previous work on Joint IE. Early work employed feature engineering methods (Roth and Yih, 2004; Yu and Lam, 2010; Li et al., 2013;

Example	GraphIE	FourIE
In the January attack, two Palestinian suicide bombers blew themselves up in central Tel Aviv, killing 23 other people. ***Explanation**: "blew" is correctly predicted by GraphIE as a "Die" event trigger while FourIE incorrectly predicted it as an "Attack" event trigger.*		We pretty much know that Marinello, while on the board, has arranged to get future money from the USCF. ***Explanation**: The relation between "Marinello" and "USCF" is correctly predicted by GraphIE as a "ORG-AFF" relation while FourIE incorrectly predicted it as a "GEN-AFF" relation.*		A second rocket landed in farmlands and the other hit a house inside the refugee camp, … ***Explanation**: "other" is correctly predicted by GraphIE as an "Instrument" for the event trigger "hit" while FourIE incorrectly predicted it as an "Attacker" for the event trigger "hit".*		
Figure 2: Instances along with their dependency subgraphs in ACE05-E+. Supporting instances are underlined.

Yang and Mitchell, 2016). Later work applied deep learning via shared parameters to facilitate joint modeling for IE, however, for only two or three tasks (Nguyen et al., 2016a; Zheng et al., 2017; Bekoulis et al., 2018; Luan et al., 2019; Zhang et al., 2019; Nguyen and Nguyen, 2019). Recently, the four IE tasks have been solved jointly (Wadden et al., 2019; Lin et al., 2020; Zhang and Ji, 2021; Paolini et al., 2021; Lu et al., 2021; Nguyen et al., 2021a). However, such recent works only employ heuristics to manually design dependency graphs for instances. Mean-field factorization of the joint label distribution for JointIE instances is dominant in prior work.

Our work is also related to prior work that uses CRFs (Lafferty et al., 2001; Chiu and Nichols, 2016) to estimate joint distribution of instance labels. Sequence labeling is a typical problem that has been solved by CRFs, including part of speech tagging and named entity recognition (Lafferty et al., 2001; Ekbal et al., 2007; Shishtla et al., 2008; Sobhana et al., 2010; Zea et al., 2016; Chiu and Nichols, 2016; Xu et al., 2017). However, these prior work only employ CRFs for simple graph structures (i.e., linear chains). A few prior work has considered CRFs for more complicated graph structures (Sun et al., 2017; Gao et al., 2019; Qu et al., 2019; Yuan and Ji, 2020); however, none of such works has applied CRFs for JointIE as we do.

6 Conclusion

We propose a novel model for jointly solving four IE tasks (EMR, ETD, EAE, and RE). Our proposed model learns a dependency graph among the instances of the tasks via a novel edge weighting mechanism. We also estimate the joint distribution among instance labels to fully enable interactions between instance labels for improved performance. The experimental results show that our model achieves best performance for multiple JointIE tasks across 5 datasets and 2 languages. In the future, we plan to extend our method to cover more IE tasks such as event coreference resolution.

Abstract

We examine the extent to which, in principle, different syntactic and semantic graph representations can complement and improve neural language modeling. Specifically, by conditioning on a subgraph encapsulating the locally relevant sentence history, can a model make better next-word predictions than a pretrained sequential language model alone? With an ensemble setup consisting of GPT-2 and ground-truth graphs from one of 7 different formalisms, we find that the graph information indeed improves perplexity and other metrics. Moreover, this architecture provides a new way to compare different frameworks of linguistic representation. In our oracle graph setup, training and evaluating on English WSJ, *semantic constituency* structures prove most useful to language modeling performance—outpacing syntactic constituency structures as well as syntactic and semantic dependency structures.

1 Introduction

Linguistic theories posit that humans can take advantage of hierarchical structure related to some notion of *compositionality* to produce and comprehend utterances with complex meanings. Yet explicit representations of this kind of structure are harder to come by than raw text, and large-scale pretrained neural language models (e.g., Devlin et al., 2019; Radford et al., 2019) have managed to perform strikingly well at contextually encoding and predicting words from distributional evidence alone. At the same time, there are good reasons to doubt that these models can be said to *understand* language in any meaningful way (Trott et al., 2020; Bender and Koller, 2020; Merrill et al., 2021). To address this conundrum, people have started to explore probing pretrained models (Liu et al., 2019; Tenney et al., 2019a, *inter alia*) and supplementing training data with linguistic structure guidance (Strubell et al., 2018; Swayamdipta et al., 2018; Peng et al., 2019; Wu et al., 2021, *inter alia*).

A question that has received less attention is *which kind* of symbolic linguistic representation (SLR) is most conducive to guiding neural language models (LMs). Numerous domain-general candidates exist (Abend and Rappoport, 2017; Oepen et al., 2019, 2020; Žabokrtský et al., 2020; Müller, 2020): some are focused on syntactic structure, others on semantics (§2; big grey example graphs in the left panels of figure 1). Frameworks vary along several dimensions, with different label inventories and treatments of specific constructions. Formal differences include the type of structure (dependency or constituency, one or multiple parents, projectivity) and its relation to the input string. In general, different design choices may aim to capture different kinds of generalizations or facilitate different kinds of processing, and may make parsing raw text easier or harder. It is often not obvious which framework should be chosen for best results on an external task—or indeed, how to even perform a controlled comparison across frameworks.

In this paper we investigate whether structurally guided language modeling can serve as a benchmark task for directly comparing linguistic representations. Specifically, we evaluate on next-word prediction—a relatively neutral task in that it does not rely on any artificial test suite, nor does it target a specific downstream application where one linguistic framework may have an advantage.[1]

We devise a method for selecting and encoding partial views of linguistic graphs over the preceding context relevant to predicting the next token (§3 and §4).[2] We call these views *slices* (small per-token graphs and dashed lines in figure 1). Our neuro-symbolic encoder statically allocates distinct vector dimensions for different structural

---

[1] Our findings are limited to a particular *language* (English) and *domain* (financial news) in which gold graphs from multiple frameworks are available for the same sentences, but such annotations could be obtained for other samples in the future.

[2] Our code is available to the research community at `https://github.com/jakpra/LinguisticStructureLM`.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4375 - 4391
July 10-15, 2022

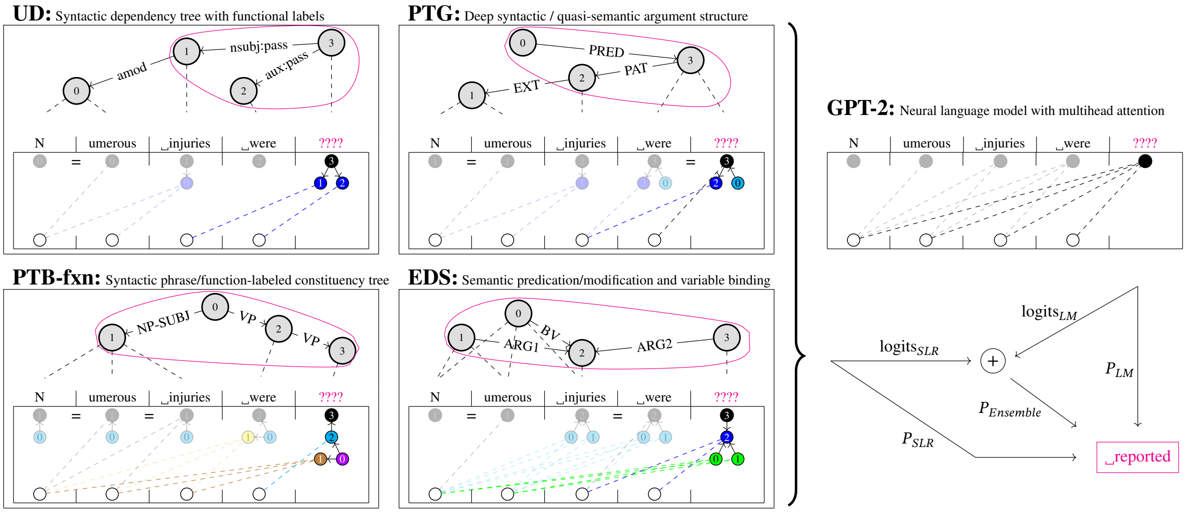

Figure 1: Contrasting GPT-2's incremental attention mechanism (top right) with incremental context *slices* obtained from linguistic graphs (left four panels) of four different formalisms (§5.2). As shared tokenization we use GPT-2's byte-pair encoding. Slice nodes are color-coded by local relation type (black: target, cyan: parent, blue: child, green: coparent, yellow: sibling, purple: grandparent, brown: aunt). Dashed lines indicate the token anchoring of original (big grey) graph nodes and, correspondingly, which previous tokens (empty circles) are accessible for each next-token prediction. In the bottom right we visualize how different models arrive at their prediction (§3 and §4.3).

relations within each slice, which in the incremental setting is much faster and more flexible than computation-intensive deep graph encoders. Using this encoding, we compare 7 SLR formalisms by virtue of their incremental language modeling capability in an controlled experimental setup (§5) on jointly annotated ground-truth data (Oepen et al., 2019, 2020). The results (§6) suggest that linguistic graphs are indeed informative for next-word prediction, complementing what is learned in pretraining. This invites future research quantifying different formalisms' design choices (§7).

2 Background: Symbolic Linguistic Representation

Following a long tradition in formal linguistics, graph-structured representations of language qualitatively describe grammatical and logical relations among words. The SLR paradigm has recently seen a revival in the form of larger-scale *treebanking* and *sembanking* for training neural parsers.

Formally, an SLR instance is a directed acyclic graph (DAG) $G = \langle V, E, \alpha \rangle$, with vertices V, labeled edges E, and an anchoring function $\alpha : V \to \mathbf{w}$ that maps each vertex to a (potentially empty) subset of tokens in the sentence. We broadly distinguish SLR frameworks along two dimensions:[3]

Scope. A main goal of *syntactic* representations is to explain distributional patterns in word order; they tend to be rooted trees with often projective anchoring functions. *Semantic* formalisms are meaning-oriented, aiming to capture the higher-level logic expressed in a sentence; thus, they may have more complex structures, including reentrant edges and discontiguous anchors.

Structure. SLRs can further be subdivided into *dependency* and *constituency* structures. The former are relatively shallow, while the latter contain abstract nodes with no or multiple word anchors.

3 Overview: Language Modeling with Linguistic Graphs

Our main goal is to quantify the predictive power of different SLRs by combining them with a pretrained language model and measuring how this affects next-token generation performance. A language model (LM) assigns probabilities to sentences and can be used to both process existing sentences and generate new ones. As is standard practice, we treat sentences as length-n sequences of word tokens, $\mathbf{w} = \langle w_0, w_1, \ldots, w_{n-1} \rangle$. An *incremental* LM factorizes the joint probability of the sentence in terms of the probability of each word w_i conditioned on previous tokens $\mathbf{w}_{<i}$; eq. (1).

Here we describe at a high level how we process (oracle) SLR graphs for use in this language modeling scenario, i.e., to obtain context-conditional

---

[3] See Abend and Rappoport (2017); Koller et al. (2019); Prange et al. (2019b) for more detailed taxonomies.

vocabulary distributions from them. In contrast to sequential LMs, contexts are now graph-structured, and which context tokens to select as well as in what way they are related to the target token is determined by the underlying SLR graph G; eq. (2).

$$P_{LM}(\mathbf{w}) = \prod_{i=0}^{n-1} P_{LM}(w_i|\mathbf{w}_{<i}) \tag{1}$$

$$P_{SLR}(\mathbf{w}) := P(\mathbf{w}|G) \tag{2}$$

This general idea is closely related to syntactic language modeling (Pauls and Klein, 2012; Gubbins and Vlachos, 2013, *inter alia*). We extend this line of work to arbitrarily complex syntactic and semantic DAG structures and, in doing so, take particular care to restrict conditioning contexts from accessing not only future *words* but also future *subgraphs*, so effectively top-down and left-to-right. Our procedure is as follows:

First, we select for each token position i to be predicted a subgraph G_i, called the token's **slice**. Slices are both *admissible* in the language modeling setting, i.e., they do not violate the left-to-right conditioning order, and *relevant* to the token prediction according to some criteria—here we consider criteria based on structural relationships generally, without relying on formalism-specific labels (§4.1). Consider the small colored subgraphs for each token in figure 1: the EDS-slice for the target 'reported', for example, starts at node 3, and extends to the ARG2-child 2, ARG1-coparent 1, and BV-coparent 0, which are anchored, respectively, in the spans 'injuries', 'Numerous', and 'Numerous injuries'). Recall from §2 that context words $\mathbf{w}_{<i}$ are contained in G_i, to the extent that they are anchored in a node reachable from w_i. Inspired by Markov assumptions of independence in generative modeling and Markov blankets in causal networks, SLR graph slicing thus allows us to factorize $P(\mathbf{w}|G)$ as

$$P(\mathbf{w}|G) := \prod_{i=0}^{n-1} P(w_i|G_i). \tag{3}$$

Next, we **encode** each graph slice as a fixed-sized vector. Prior approaches to encoding linguistic graphs for neural modeling have involved serialization, e.g., as parser transition sequences (Qian et al., 2021, *inter alia*), recursive auto-encoders (Tai et al., 2015; Roth and Lapata, 2016), and graph-convolutional networks (GCNs; Yang and Deng, 2020; Wu et al., 2021). However, transition sequences for non-tree graphs are subject to spurious ambiguity; and we find that graph-structured neural networks are impractical in the incremental setting (§6.5). Instead, we propose a computationally inexpensive method for statically and deterministically projecting slices into a high-dimensional space by vector concatenation (§4.2).

Finally, we compute output **distributions** $P(W_i|G_i)$ from the vector representations (§4.3).

4 Modeling Details

4.1 Slicing Graphs

A slice G_i is a connected subgraph of G that captures w_i's linguistically structured context, masking w_i itself (or else estimating $P(w_i|G_i)$ would be trivial). G_i always minimally consists of w_i's *direct anchor* node $a_i = \text{Select}(\{v : w_i \in \alpha(v)\})$. Starting from a_i, we traverse the graph and add vertices and edges that are connected to a_i via paths of a few specific relative types, REL. Here we settle on 6 types: parents, siblings, grandparents, parents' siblings, children, and coparents. The vertices V_i and edges E_i for slice $G_i = \langle V_i, E_i, \alpha\rangle$ consist then of the union of these sets.[4]

To prevent information leakage from future tokens, we discard from G_i all nodes $\{v : \alpha(v) = w_j, j > i\}$ which are *only* anchored in tokens *following* w_i. E.g., in figure 1, the UD-slice for the token 'were' does not contain the parent node 3 because that is anchored only in the following token 'reported' (and thus the sibling 1 cannot be accessed either). If a node's anchors *contain or overlap with* w_i (i.e., the node is a non-terminal above w_i), we retain the node and its edges but remove its token anchors.

4.2 Vectorizing Graph Slices

Because slices can be large, we partition each slice's nodes by structural *relative type*, in order to aggregate them into a fixed-length summary vector. Specifically, we allocate capacities for each relative type: $\gamma_{\text{rel}} = 2$ for parents, siblings, aunts, and children, and 1 for grandparents and coparents. Up to $\gamma - 1$, relative nodes V_{rel} are added 'with high resolution', maintaining their identity and order; beyond the capacity, relatives are aggregated 'with low resolution'; eq. (4). Within each relative type, precedence k is given to relatives whose token anchors are sequentially closer to w_i.

---

[4] See appendices A.1 and A.2 for details.

$$\begin{aligned} \mathrm{HiRes}_{i,\mathrm{rel}} &= \langle v_{\mathrm{rel},k} : k < \gamma_{\mathrm{rel}} \rangle \\ \mathrm{LoRes}_{i,\mathrm{rel}} &= \{ v_{\mathrm{rel},k} : k \geq \gamma_{\mathrm{rel}} \} \end{aligned} \tag{4}$$

Next we look up the relatives' edge label and word vector encodings[5] $\vec{l}_k$ and $\vec{w}_k$ and collate them into a single vector $\vec{s}_{i,\mathrm{rel}}$ per relative type. High-resolution vectors are concatenated $\bigoplus$ and low-resolution vectors are averaged; eq. (5). Finally, we concatenate all of these (zero-padded) relative-vectors to obtain the final vector representation of the whole slice, $\vec{s}_i$; eq. (6). At a high level, this vector essentially specifies a deterministic, structured, typed, discrete self-attention over the token history.

$$\begin{aligned} \vec{s}^{\,\mathrm{HiRes}}_{i,\mathrm{rel}} &= \bigoplus_{k \in \mathrm{HiRes}_{i,\mathrm{rel}}} \left[\vec{l}_k ; \vec{w}_k \right] \\ \vec{s}^{\,\mathrm{LoRes}}_{i,\mathrm{rel}} &= \sum_{k \in \mathrm{LoRes}_{i,\mathrm{rel}}} \frac{\left[\vec{l}_k ; \vec{w}_k \right]}{|\mathrm{LoRes}_{i,\mathrm{rel}}|_+} \end{aligned} \tag{5}$$

$$\vec{s}_i = \bigoplus_{\mathrm{rel} \in \mathrm{REL}} \left[\vec{s}^{\,\mathrm{HiRes}}_{i,\mathrm{rel}} ; \vec{s}^{\,\mathrm{LoRes}}_{i,\mathrm{rel}} \right] \tag{6}$$

4.3 Predicting Emission Distributions

We compute model posteriors for next-token predictions as

$$P_\mu(w_i = v_k \,|\, \mathrm{context}_{i,\mu}) = \mathrm{SoftMax}(\mathrm{logits}_{i,\mu})[k],$$

where μ is either a pure SLR model or LM, or an ensemble of the two (bottom right of figure 1).

SLR only. As described above, we define $\mathrm{context}_{i,SLR}$ as G_i, which is encoded as $\vec{s_i}$. We obtain P_{SLR} by letting the slice-vectors serve as inputs to a d-multilayer perceptron (MLP) with a final softmax layer over the vocabulary, which yields the estimated token emission distributions.

$$\begin{aligned} \mathrm{logits}_{i,SLR} &= \mathrm{MLP}_d(\vec{s_i}) \\ \mathrm{MLP}_d(x) &= H^{(d)}\left(\ldots H^{(1)}(x) \right) \mathrm{Emb}^\top, \end{aligned}$$

where Emb is an embedding matrix.

LM + SLR. Since we want to measure whether and how much the information contained in the SLR can contribute to state-of-the-art language models, our primary experimental condition is a combined setup $P_{Ensemble}$, where logits obtained from slice-encodings are added to a base neural LM's logits before taking the softmax:

$$\begin{aligned} \mathrm{logits}_{i,Ensemble} &= \mathrm{logits}_{i,SLR} + \mathrm{logits}_{i,LM}, \\ \text{with} \qquad \mathrm{logits}_{i,LM} &= \mathrm{LM}(\mathbf{w}_{<i}). \end{aligned}$$

	Sentences	Tokens	Vocabulary
Train	26,325	658,475	27,344
Train (EarlyStop)	23,692	591,829	26,422
Dev (EarlyStop)	2,633	66,646	10,073
Eval	921	22,596	5,364

Table 1: Data statistics.

LM only. P_{LM}, i.e., the bare LM without any exposure to SLR graphs, serves as a baseline.

5 Experimental Setup

All models are implemented in PyTorch and experiments are run on 1 NVIDIA Tesla T4 GPU. Model hyperparameters are reported in appendix A.5.

5.1 Data

Our dataset consists of the intersection of Wall Street Journal (WSJ; English financial news) sentences that have been annotated with syntactic trees in the Penn Treebank (PTB; Marcus et al., 1993; Hovy et al., 2006)[6] as well as a range of semantic representation formalisms for the MRP 2019 & 2020 shared tasks (Oepen et al., 2019, 2020). Summary statistics are shown in table 1. Our preprocessing steps are described in appendix B.

5.2 SLR Formalisms

The 7 (versions of) linguistic representation frameworks examined in this study are listed in table 2, along with their classifications along the scope and structure dimensions. We draw the structural dependencies vs. constituencies distinction (described at a high level in §2) based on specific properties of the MRP shared task data: a framework is considered a dependency framework if all edges are only between pairs of individual word anchors at a time; if there are any unanchored[7] nodes or nodes anchored in more than one linguistic word token, it is considered a constituency framework.[8] Below we give a brief description of each framework.

PTB trees specify hierarchically nested syntactic constituents. We consider two labeling variants: basic phrase structure (**-phr**) and phrase types refined with functional specifications (**-fxn**).

---

[5] See appendix A.3 for details.

[6] `https://catalog.ldc.upenn.edu/LDC2013T19`

[7] Not including "ROOT" nodes in UD.

[8] See appendix A.4 for details.

Universal Dependencies (**UD**; Nivre et al., 2016, 2020; de Marneffe et al., 2021) is a syntactic dependency representation with coarse, cross-linguistically applicable edge labels.

DELPH-IN MRS Bi-Lexical Dependencies (**DM**; Ivanova et al., 2012) and Elementary Dependency Structures (**EDS**; Oepen and Lønning, 2006) are derived from underspecified logical forms computed by the English Resource Grammar (Flickinger, 2000; Copestake et al., 2005).

Prague Semantic Dependencies (**PSD**; Hajič et al., 2012) and Prague Tectogrammatical Graphs (**PTG**) are syntactico-semantic predicate–argument structures converted from the Prague Functional Generative Description (Sgall et al., 1986; Böhmová et al., 2003; Hajič et al., 2012).

5.3 Language Model

The base language model we use in all our experiments is GPT-2 (Radford et al., 2019, as distributed in the huggingface-transformers PyTorch library). GPT-2 is a Transformer model (Vaswani et al., 2017) pretrained on a diverse collection of web texts. In contrast to other widely-used Transformers like BERT (Devlin et al., 2019), which optimize bidirectional masked language modeling, GPT-2 is incremental, i.e., next-word decisions only take into account the *preceding* context.

5.4 Training

We train all models for 10 epochs with the AdamW optimizer (Loshchilov and Hutter, 2019), minimizing cross-entropy between the model posterior and the ground truth at each token position.

We perform early stopping with the last 10% of the original training corpus set aside for development scoring after each epoch.[9] We keep the model state that achieves the best perplexity on the dev set. Peak development performance is reached after ≈3 epochs for SLR models, whereas finetuning GPT-2 by itself takes between 7 and 9 epochs.

5.5 Evaluation

We compute model perplexity (PPL) as the most standard language modeling evaluation measure, as well as accuracy (Acc) and confidence (Conf) of a model's top-ranked guess, mean reciprocal rank of the correct answer (MRR), and entropy of the model's token prediction posterior (H). All metrics are reported as microaverages over the evaluation data at the BPE token level.[10]

6 Findings

6.1 Main Results

The most striking observation in terms of overall model performance (table 2) is that ground-truth linguistic graphs of all investigated linguistic formalisms *improve* vanilla GPT-2 by a large margin, in all metrics. This improvement holds up when compared to a version of GPT-2 that is exposed to the raw WSJ text without the graphs; with this condition we control for mere domain differences between our evaluation data and the data GPT-2 was trained on originally ('+Domain' in table 2). The large performance gap suggests that at least a subset of the oracle knowledge about linguistic structure is **not yet encoded** in the base language model, which learns from only raw text.

We observed that if we keep training for the entirety of 10 epochs, rather than early stopping based on development performance, we somewhat overfit to the training set. While accuracy itself is not affected very much by this, the models become increasingly overconfident ($\frac{\text{overall confidence}}{\text{overall accuracy}}$, which gets up to 8–12%, compared to ≈4% with the vanilla GPT-2 model and in most cases even slightly less than that with the early-stopped SLR models). This leads to overall worse perplexity.

6.2 Differences between Formalisms

Comparing across rows in table 2, we find a considerable performance spread. The general trend, which is relatively consistent in all metrics,[11] is indicated by the order of rows, with UD having the smallest (though still respectable) improvement over the baseline, and PTG and EDS the largest.

Interestingly, there are two marked separations: a primary one between dependency and constituency formalisms, and a secondary one between syntactic (i.e., more surface-oriented) and semantic (more abstract) formalisms. This is summarized

---

[9] The R-GCN baseline (table 6) is always trained for the full 10 epochs, but to ensure fairness, it is also only compared to concatenation-based encoders that have been trained for the full 10 epochs, too.

[10] We compute average PPL over all sentences j by exponentiating last: $\exp\left(\frac{1}{\sum_j |\mathbf{w}_j|} \sum_j \sum_{i=0}^{|\mathbf{w}_j|-1} -\log P_\mu\left(w_{ji} = \upsilon^*_{ji} | \text{context}_{ji,\mu}\right)\right)$

[11] The multitude of metrics might thus seem redundant. But since each measurement emphasizes different properties of model performance, we consider it a a very interesting result (and, potentially, a success of our modeling technique and experimental setup) to achieve this broad consistency.

Table 2: Main results: performance of language models combined with 7 SLR formalisms of different scope, structure, and label set (each corresponding to a $P_{Ensemble}$ in §4.3), compared to vanilla GPT-2 and a version of GPT-2 that has been domain-finetuned on the raw text of the SLR training corpus (P_{LM}). We report each quality metric as mean ± stdev over 3 random seeds. We also report model size in #parameters (all non-baseline models as absolute difference to baseline) and training speed in sentences per second as measures of efficiency. Statistical significance of the PPL and Acc differences to the next-best model (always adjacent rows) is reported as $^{***}p < .0001$ / $^{**}p < .001$ / $^{*}p < .005$ / −not significant (approximate randomization test as described in Riezler and Maxwell (2005), with R =10,000 shuffles). We only consider a difference significant if $p < \alpha$ for all three random model initialization seeds. Best results in each column are **bolded**. For confidence, 'best' means best-calibrated, i.e., the smallest relative difference to accuracy.

Table 3: Model perplexity (lower is better) summarized in terms of two SLR dimensions: Scope (syntax vs. semantics) and structure (dependency vs. constituency). $\mu \pm \sigma$ (n) over frameworks per condition. Statistical significance of the difference between the two closest SLRs of each pair of conditions is reported as $^{***}p < .0001$ / $^{**}p < .001$ / $^{*}p < .005$ / −not significant (approximate randomization test with R =10,000 shuffles).

in table 3. A limiting factor for dependency representations in the incremental LM setting is that relations between the target token and subsequent tokens are entirely ignored, whereas constituency graphs can back off to higher-level structures. Further, the syntactic graphs we use are always trees, so they never populate the coparent capacity in the slices. *Semantic constituency* representations, with their abstract and meaning-oriented labeling and structure schemes, jump out as being especially predictive of the underlying text, as compared to both syntax and shallow semantics.

We note that the function-enhanced PTB label set has a slight advantage over the basic phrase-structure labels; and that, among the two closely related pairs of formalisms (DM/EDS and PSD/PTG, which each are dependency and constituency versions converted from the same underlying grammars), the constituency versions always work better than the dependency versions in our setting. There is, however, no consistent ranking between DM/EDS on one hand and PSD/PTG on the other. In terms of perplexity, EDS works better than PTG, and PSD better than DM, but these differences are not significant for accuracy.

6.3 Differences between Word Classes

To better understand where particular strengths and weaknesses of the baseline LM and linguistically enhanced models lie, we analyze subsets of tokens by part-of-speech (POS) tag (table 4, see appendix C for more details). Across all models there is a clear and expected separation between rather predictable function words, more perplexing content words, and numbers, punctuation, and miscellaneous tokens somewhere in the middle.

Average perplexity of the tested SLR models is better than baseline GPT-2 in all POS classes but one. The one exception is the noun class, where both the SLR macro-average and UD in particular do not raise performance. Only EDS and DM show perplexity improvements on nouns; PTB even has a noticeable negative impact. We conjecture that this may have to do with relatively deep NP nesting in PTB (compared to the other formalisms), such that the current slicing hyperparameters (relative types and capacities) are too strict and hide informative signals like modifiers and verb attachment.

Some formalisms seem to be particularly well-suited for the prediction of certain POS: UD for verbs; PTB and PTG for adpositions and subordinating conjunctions; EDS for pronouns, determiners, and numbers; PTG, PSD, and EDS for coordinating conjunctions. The advantage of EDS and DM on nouns, pronouns, determiners, and numbers can likely be attributed to their explicit representation of variable binding/quantification. Similarly, PTG and PSD have detailed categories for coordination, distinguishing, e.g., con- and disjunction.

For nouns and modifiers, the spread across formalisms is particularly wide, which suggests that SLRs diverge quite a bit on these types of words (e.g., whether adjectives and certain nouns can count as predicates) and that this diversity has a strong effect on utility for language modeling.

6.4 Model Ablations

The linguistically enriched models consist of a substantial number of newly learned parameters—around 50–60M each, an additional ≈50% the size of vanilla GPT-2. Although model size does not seem to be correlated with performance among the SLR-enriched models, it could still be that the additional capacity allows the models to store more information about the words' distributions than the baseline GPT-2 model, without ever truly using the concrete linguistic structures.

We check this by randomly shuffling (⤮) two core graph properties: (i) the assignment of edge *labels*, and (ii) the *anchoring* mapping between graph nodes and word tokens in each graph. If the models are largely independent of the correct label and structure assignments, these changes should have a very small effect on performance (Dubossarsky et al., 2018; Hewitt and Liang, 2019).

But on the contrary, we find that performance worsens considerably in the ablated settings compared to the full combined models of each formalism (table 5, see appendix C for more details). This confirms that the models really do acquire—and are quite sensitive to—the graph-encoded linguistic signals, relying to a large part on this new information in making their predictions.

⤮ Anchors	training	+8.5	+17.5	+13.3 ± 4.6
⤮ Both	training	+7.8	+18.3	+13.4 ± 5.0
⤮ Labels	both	+1.3	+9.3	+4.3 ± 3.4
⤮ Anchors	both	+7.9	+17.5	+13.5 ± 5.0
⤮ Both	both	+7.3	+18.1	+13.6 ± 5.2
− SLR	both	+14.5	+16.9	+16.6 ± 2.8

Table 5: Ablations measured in ΔPPL for two exemplary SLR-combined models and the macro-average ± stdev over all SLR-combined models. *Full* and −SLR correspond, respectively, to table 2's rows 4 (DM) / 7 (PTB-fxn) and row 2 (GPT-2 +Domain).

Shuffling only edge labels while leaving the rest of the graphs unchanged has a smaller effect than changing how tokens are anchored in the graph structure. This suggests that the linguistic graphs' entire structural arrangement of labels and attention-like selection of context words play a crucial role—more so than knowing the type of each individual (correctly attached) grammatical relations. Note that the ⤮ Anchors setting, too, changes which edge labels are used in the predic-

tion of a given token, resulting in a smaller difference between ⤨ Anchors and ⤨ Both.

If a model has learned to rely on correct labels and structure during training, then perturbing these properties at test time has a highly adverse effect, confusing the model and leading to a drastic decrease in performance—even worse than not consulting SLR graphs at all! Given previous findings that syntactic structure is to some extent already learned in pretraining (Linzen et al., 2016; Tenney et al., 2019b), we conjecture that this representational capacity gets offloaded to the graphs at training time, and thus test-time permutations fool the PTB model to a much greater extent than DM.

As expected, exposing models to shuffled graphs at training time renders the additional model parameters practically neutral, resulting in similar perplexity as the base LM. In this case, it also does not matter whether test-time graphs are correct or random (training vs. both in column 2)—either way, the model learns to mostly disregard the random structure as noise.

6.5 Comparison with R-GCN Encoding

As an additional strong baseline, we compare our concatenation-based slice vector encoding to a graph neural network from the literature. We choose relational graph-convolutional networks (R-GCN; Schlichtkrull et al., 2018; Kipf and Welling, 2017) as a suitable representative of this type of model, which has been used successfully by Wu et al. (2021) to encode DM graphs.

Results are shown in table 6. Contrasting with table 2, there is a big difference in training speed: our simple encoder is on average roughly twice as fast as the computation-heavy alternative, whose time and space complexity is dominated by the number of labels.[13]

We observe at best similar LM quality as with our concatenation method (EDS and DM), but for most formalisms performance degrades. We follow Schlichtkrull et al. and Wu et al. in using 2 R-GCN layers with basis matrix regularization. Possible disadvantages of this for encoding linguistic graphs are the fixed path length (2 layers exclude parent's siblings; but 3 layers would include a lot of irrelevant information) and that many of the trained parameters are shared between different relations. In contrast, our concatenation encoding forces the MLP input layer to learn distinct parameters for each structural relative type and edge label.

7 Discussion

7.1 Related Work

Researchers have long been interested in scaffolding sequential language models with linguistic-structure-based inductive biases. *Syntactic language modeling* dates back to the pre-neural era, when Pauls and Klein (2012) and Gubbins and Vlachos (2013) generalized Markov assumptions from word *n*-grams to syntactic subtrees. These ideas have since been adapted to recurrent neural network (RNN) LMs (Mirowski and Vlachos, 2015) and expanded on (Dyer et al., 2016; Choe and Charniak, 2016; Shen et al., 2018, 2019). Ek et al. (2019) condition RNN-LMs on predicted syntactic and semantic (unstructured) tags, interestingly finding less or sometimes no benefit, especially on the semantic side. They hypothesize this might be due to tagging errors—an issue our oracle setup avoids.

In the era of attention-based neural modeling of language dominated by pretrained Transformers, models are often finetuned for and evaluated on specific NLP tasks—like semantic role labeling, machine translation, natural language inference, graph-to-text generation, or the GLUE benchmark (Wang et al., 2019)—rather than language modeling in its own right, which makes it difficult to compare them directly to our findings. There have been two main directions: One group of approaches continues the old syntactic language modeling tradition by incrementally generating words and SLRs with either joint (Peng et al., 2019; Qian et al., 2021; Sartran et al., 2022) or iteratively-coupled LM and parser models (Choshen and Abend, 2021). The second group assumes parsed input sentences,

---

[13] And this is a very optimistic estimate of R-GCN training speed in practice; see appendix A.6.

which are then used to guide the model, e.g. by directly optimizing Transformers' attention weights to reflect linguistic graph structures (Strubell et al., 2018; Bai et al., 2021; Slobodkin et al., 2021). Rather than controlling the existing sequential attention, Hajdik et al. (2019) process serialized graphs directly with a sequence-to-sequence model, and Wu et al. (2021) extend a pretrained Transformer with an additional graph encoder. Notably, Wu et al. (2021) and Slobodkin et al. (2021) experiment with a few different semantic and syntactic SLRs, while all other studies we have looked at are limited to either syntax or very shallow semantics.

Another relevant line of work employs *probing tasks* in investigating to what extent grammar and meaning are already encoded in neural language models trained predominantly on raw text with little to no linguistic supervision (Linzen et al., 2016; Tenney et al., 2019a,b; Hewitt and Manning, 2019; Liu et al., 2019; Kim et al., 2019; Wu et al., 2020; Geiger et al., 2021, *inter alia*). Among the probing literature, the works of Kuznetsov and Gurevych (2020) and Kulmizev et al. (2020) are noteworthy in that they investigate subtle differences between different (versions of) frameworks roughly covering the same representational scope, namely, semantic roles and syntactic dependencies, respectively.

Orthogonal approaches to *comparing SLR designs* have involved measuring how well different frameworks complement each other for joint parsing or can be merged or converted into one another (Prange et al., 2019a; Hershcovich et al., 2020).

7.2 Limitations and Future Work

While the use of oracle graphs has both theoretical advantages (measuring an upper bound without needing to account for potential errors or uncertainties) and practical ones (saving the computational overhead from training and running a parser), ground-truth SLR graphs are a very limited resource and generally assumed to only be available at training time. There is no guarantee our results translate to the non-oracle setting. For instance, it could be that the most helpful abstract semantic information is also the hardest to predict. And despite segmenting the existing sentence-level graph into token-level slices, the human annotator who created the graph in the first place has seen and analyzed the whole sentence, thus already resolving crucial ambiguities and simplifying the task based on knowledge 'from the future'. In subsequent work, we plan to *parse* graph slices incrementally, which will both relax the *conditional* modeling assumption into a more broadly interpretable *joint* model and enable test-time use of the full system on datasets without linguistic annotations.

We also only test formalisms that are explicitly anchored in linguistic units, roughly corresponding to LM (sub-)word tokens. This prevents us from applying the same paradigm to some other widely-used *unanchored* formalisms like AMR (Banarescu et al., 2013) without some changes to the setup.

7.3 Broader Impact

Our experiments yield evidence which—at least in the case of encoding contexts for next-word prediction—supports the thesis of Bender and Koller (2020), Trott et al. (2020), and others that linguistic *meaning* goes beyond *form*. Computational models of language that exclusively learn from even very large amounts of raw text are thus generally expected to hit a ceiling[14] which can only be overcome with access to higher-level structures and mechanisms of understanding.

It further seems to matter in which manner and shape linguistic graph structure is drawn. Assuming a perfect incremental parser, deeper structure and semantic categorization seems to be particularly beneficial for integration with a standard language model. This is in line with previous findings by, e.g., Tenney et al. (2019b) that while pretrained LMs tend to encode shallow syntactic structure, abstract relations are more difficult to probe for.

We thus see a promising research direction in moving towards linguistic scaffolding of language models with representations that are *more complex* than tags or dependencies and that capture *meaningful relations* beyond surface structure.

8 Conclusion

We have presented evidence that symbolic linguistic representations of various frameworks have the potential to aid a pretrained incremental Transformer in task-neutral next-word prediction. To this end, we have proposed a framework-agnostic neural encoding scheme for linguistic graphs and applied it to an English dataset jointly annotated with 7 different formalisms. The results highlight the importance of appreciating complex linguistic structure and handling its computational representation with nuance.

A Additional Modeling Details

A.1 Selecting Anchor Nodes

In case there are multiple anchoring options (see, e.g., EDS nodes 0 vs. 1 for first token in figure 1), we use the following tie-breaker heuristics: Select the anchor node with the most parents and children; if still a tie, select the anchor with the highest node ID (tends to be hierarchically lower, i.e., vertically closer to the token anchor).

A.2 Relative Types

$REL = \langle P, B, O, T, C, R \rangle$, namely, parents P_i, siblings $B_{i,p}$, grandparents $O_{i,p}$, aunts $T_{i,p}$ (all indexed by parent p), children C_i, and coparents $R_{i,c}$ (indexed by child c). This is the anchor node's Markov blanket, plus siblings, grandparents, and aunts. We chose this set of relations based on general notions of linguistic hierarchy (predicate-argument, head-dependent) and preliminary experiments, but without tuning for specific formalisms. Precise definitions are given in table 7. Relative nodes are permanently associated with the label of the edge that got them selected.

A.3 Representing Tokens and Labels

We use GPT-2's pretrained global embeddings (from the lowest layer, before any local contextualization) to obtain embeddings for relative token anchors in the slice-vector. When a token anchor in a linguistic graph consists of multiple BBPE tokens, we average their embeddings. We reuse the transpose of the same embedding matrix again to project the last hidden state of the token-emission MLP into the vocabulary.

SLR edge labels are encoded as one-hot vectors in the slice vectors, which lowers the potential for unnecessary random initialization variance of from-scratch embeddings.

A.4 Distinguishing Dependencies from Constituencies

While this distinction—as defined in §5.2 in terms of the anchoring mapping between graph nodes and word tokens—can be subtle for individual sentences, it nonetheless affects slice encoding. In PSD, for example, auxiliaries are unanchored, whereas in PTG they are grouped with their main predicate (figure 2).

rel	Name	Definition	γ
P_i	parent	$\{v : (v, a_i) \in E\}$	2
$B_{i,p}$	sibling	$\{v : (p, v) \in E\}\, \forall p \in P_i$	2
$O_{i,p}$	grandparent	$\{v : (v, p) \in E\}\, \forall p \in P_i$	1
$T_{i,p}$	aunt	$\{v : (o, v) \in E \land o \in O_{i,p}\}$ $\forall p \in P_i$	2
C_i	child	$\{v : (a_i, v) \in E\}$	2
$R_{i,c}$	coparent	$\{n : (v, c) \in E\}\, \forall c \in C_i$	1

Table 7: Relative types and capacities.

A.5 Model Hyperparameters

We report our model and training hyperparameters in table 8. We did *not* perform explicit hyperparameter tuning, besides some manual testing early in development on a subset of the MRP shared task data. Those data are annotated with SLR frameworks other than the ones we compare here, and we ended up excluding them from our experiments for lack of overlap with most of the other frameworks' annotations.

A.6 Efficient Batching for R-GCN

In our incremental setting we need to apply the R-GCN to each token-level slice, which would lead to multiple days[15] of training for each model if done naively. We achieve a considerable speedup by exploiting the oracle graphs at training and evaluation time to pre-compute slices and running the R-GCN only once per sentence batch.

B Data Preprocessing

B.1 Sentence Filtering

To establish a common ground for comparison, we take the intersection of sentences occurring in the annotated datasets of *all* linguistic formalisms.

In a first step, we discard two sentences whose linguistic graph in at least one formalism is empty.[18] We then select only those 35,513 train-dev / 1,401 eval sentences that appear in both the MRP 2019 and 2020 datasets (the 2019 corpus contains 143/1,958 more in train-dev/eval).[19] Next,

[15] Projected timeline based on a few iterations, which is confirmed by Yang and Deng (2020).

[16] For label set L. The factor 16 arises from the capacities chosen (table 7), and the extra embedding allocation is for averaged preceding unanalyzable/within-anchor tokens.

[17] For bidirectional label set L^*, which is twice as big as L.

[18] The sentence "It is." in DM and a 'sentence' consisting of the @-symbol in PTG.

[19] 'train-dev' refers to the data split that was used as training data in both the MRP and 2019 tasks, and which we split 90%/10% into our training and development data. 'eval' refers to the data that was used as evaluation data in MRP 2019 and as development data in MRP 2020, and which we evaluate our

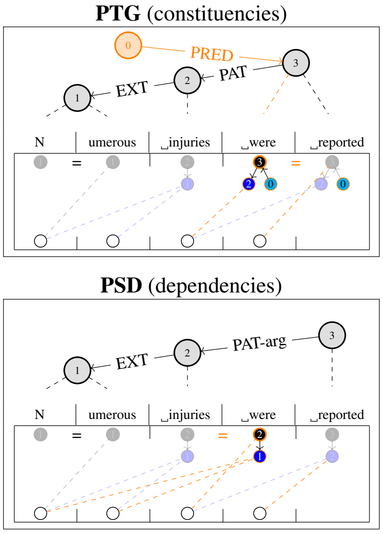

Figure 2: Example of subtle differences in constituency (PTG) and dependency (PSD) versions of the same underlying formalism, the Prague Functional Description. PTG has an abstract PRED node as well as a multiword anchor where PSD does not, which results in diverging slice representations for the last two tokens.

we take the intersection of these sentences and OntoNotes 5.0, which contains the gold PTB syntax annotations. 26,719/929 sentences remain in the train-dev/eval set. The MRP graph format operates on raw-text character offsets, while PTB and UD trees operate on word tokens. We are able reconstruct offset-based text anchors for PTB and UD from the raw text strings used in the MRP data for all but 394 train-dev / 8 eval sentences, which leaves us with the final 26,325 train-dev and 921 eval sentences.

In a few cases, where the linguistic graph has no edges, we add an artificial edge with a dummy label.

B.2 Tokenization

We follow the sentence segmentation of the Penn Treebank corpus. Within sentences, we obtain token boundaries from GPT-2's pretrained byte-level byte-pair encoding (BBPE) tokenizer. The BBPE tokens are then aligned with the formalism-dependent SLR node anchors via raw-text character offsets. Tokens that are continuations of multiword anchors in the graph (‘␣reported’ in PTG, figure 1); subword tokens of a single graph anchor (‘N-umerous’); or are unanchored in the graph (‘␣were’ in EDS), are treated as *unanalyzable*, i.e., their slice consists of a copy of the preceding token's slice, plus the preceding within-anchor tokens.

B.3 UD Conversion

Quasi-gold UD 2.0 trees are obtained from the UD converter released with the Java Stanford Parser v4.2.0 (`https://nlp.stanford.edu/software/lex-parser.html`) on the PTB trees.

B.4 PTB Labels

By convention, phrasal and functional labels in PTB are node labels. To match the labeled-edges-unlabeled-nodes format of the other formalisms, we losslessly convert them to edge labels (namely, on each node's single incoming edge), discarding the preterminal nodes' POS labels. In preliminary experiments we saw that including the POS tags is much more beneficial than phrase structure only; but since we do not include word-level tags in any of the other conditions, this would be an unfair comparison. We focus here on sentence-level structure and leave studies of word-level tags to future work.

B.5 Data Splits

We split the corpus into training/development and evaluation data following the MRP task setup. Specifically, we evaluate on the data split that was

---

models on.

used as evaluation data in MRP 2019 and as development data in 2020, as only for this data gold annotations in all formalisms have been released. We do not perform empirical hyperparameter tuning. In early development, a small subset of the data was used.

C Detailed Results

We report detailed results without early stopping (table 9), breakdowns by POS-class (table 10 and appendix C.1), as well as ablation experiments (table 11) for all SLR formalisms. In tables 4 and 10 and figure 3 we merge the POS tags {NOUN, PROPN} into 'noun', {ADJ, ADV} into 'mod', and {INTJ, SYM, X} into 'misc'.

C.1 Lexico-Semantic or Syntactic Knowledge?

In §6.3 we have found part-of-speech-specific patterns of model performance. But whenever, for a certain syntactic word class S, a formalism A is more conducive to next-word prediction than a formalism B, it is not clear whether this is the case because the choices get narrowed down to S itself or whether it is caused by either complementary or completely independent signals, perhaps at the lexical or semantic-structure levels.

We investigate this by rerunning the experiment with each token's UPOS tag as an additional input. If this is more or less the same information as is gained—to different extents—from the SLRs, then the results should be similar to before, and SLR-conditional differences should disappear.

A few particularly interesting POS subsets are shown in figure 3. We discuss them in order.

Among content words, nouns and verbs are similar both in terms of baseline performance and in how much easier it becomes to select the correct lexical item if the part-of-speech is known. At the same time, the individual SLR formalisms differ quite a lot in how much information they contribute about the POS class itself and about lexical choice within the part-of-speech. The respective best formalisms (EDS for nouns, PTB and UD for verbs) approximate oracle POS knowledge by themselves and still contribute substantial complementary information when the actual POS tag is revealed. In contrast, PTB does not seem to provide any useful signal about nouns to the incremental LM—neither independently nor in conjunction with the POS.

Modifiers (adjectives and adverbs) display a rather interesting behavior: the fact *that* a word of this type is coming next is very hard to predict from just the preceding raw context, which makes sense since they tend to add *optional* meaning on top of the (obligatory) logical and grammatical content. However, once the decision to modify has been made, the contextual choice becomes much easier than that for nouns or verbs. In both cases, all SLRs are quite helpful, with UD on the lower end and EDS leading the field.

We find similar tendencies among auxiliaries (≈function verbs) and pronouns (≈function nouns) as with (content) verbs and (content) nouns, but naturally at a much smaller scale. Despite their functional-grammatical distribution and behavior, the semantic frameworks EDS and PTG consistently outperform the syntactic ones UD and PTB even on these 'small' words. A possible explanation for this interaction with auxiliaries in particular could be that EDS and PTG do not analyze them separately at all, but rather group them, respectively, with the preceding context[20] or their main predicate. The models might be able to leverage this to focus on things like subject-verb agreement, local cohesion, or anticipating the main predicate. More explicit syntactic analyses of auxiliaries (incrementally inaccessible forward-pointing dependencies in UD; VP-nesting in PTB), in contrast, may restrict the model from directly making these connections. Adding POS information in the input decreases SLR-dependent differences.

For 'subordinators' in the broad sense, i.e., subordinating conjunctions at the clausal level and adpositions for nominal complements, PTB and PTG are particularly well-suited. By themselves they are already *at least* as informative as POS, and they still add a small but noticeable complementary signal when the POS is revealed.

Determiners and coordinating conjunctions, which both already show extremely low perplexity with some SLR models (namely, EDS, PSD, and PTG), entirely lose any reliance on particular SLRs when their POS is known.

---

[20] EDS, like PSD, actually has no anchors for auxiliaries; we attach them to the preceding semantic unit by default.

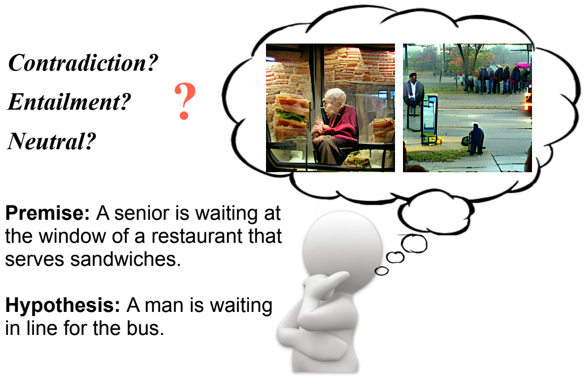
Abstract

Human brains integrate linguistic and perceptual information simultaneously to understand natural language, and hold the critical ability to render imaginations. Such abilities enable us to construct new abstract concepts or concrete objects, and are essential in involving practical knowledge to solve problems in low-resource scenarios. However, most existing methods for Natural Language Understanding (NLU) are mainly focused on textual signals. They do not simulate human visual imagination ability, which hinders models from inferring and learning efficiently from limited data samples. Therefore, we introduce an **I**magination-**A**ugmented **C**ross-modal **E**ncoder (iACE) to solve natural language understanding tasks from a novel learning perspective—imagination-augmented cross-modal understanding. iACE enables visual imagination with external knowledge transferred from the powerful generative and pre-trained vision-and-language models. Extensive experiments on GLUE (Wang et al., 2018) and SWAG (Zellers et al., 2018) show that iACE achieves consistent improvement over visually-supervised pre-trained models. More importantly, results in extreme and normal few-shot settings validate the effectiveness of iACE in low-resource natural language understanding circumstances.[1]

1 Introduction

Cognitive neuroscience studies reveal neural activation in vision-related brain areas when reading text (Just et al., 2004) and show a tight relationship between brain areas processing linguistic and visual semantic information (Popham et al., 2021). In addition, visual imagery improves comprehension during human language processing (Sadoski and Paivio, 1994). Such imagination empowers human brains with generalization capability to solve problems with limited supervision or data samples.



Premise: A senior is waiting at the window of a restaurant that serves sandwiches.

Hypothesis: A man is waiting in line for the bus.

Figure 1: Rendering visual imagination is an intuitive way to activate perception for linguistic understanding, e.g. natural language inference.

However, the field of Natural language Understanding has mainly been focused on building machines based solely on language, ignoring the inherently grounded imagination from the external visual world. These studies either learn text-only representations from language corpora (Devlin et al., 2019; Zhuang et al., 2021; Lan et al., 2020) or implicitly involve retrieved visual supervision in pre-trained language models (Tan and Bansal, 2020). Thus, their approaches appear limited in transferring the connection between language understanding and visual imagination to downstream tasks, which are essential to solving low-resource circumstances. In addition, these methods are limited to text-only augmentations, whereas visual imaginations leverage cross-modal augmentations to deal with low-resource situations.

Human brains are multi-modal, integrating linguistic and perceptual information simultaneously. Intuitively, the machines could achieve a higher-level understanding of natural language and better learning transference by imitating the procedure of human imagination behavior.

Inspired by this, we propose to understand lan-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 4392 - 4402
July 10-15, 2022

guage with the integration of linguistic and perceptual information via introducing imagination supervision into text-only NLU tasks. To imitate the imagination-augmented understanding process as shown in Figure 1 with text-only data, we devise a procedure with two steps: 1) pre-train a visually-supervised Transformer over paired text and images retrieved from large-scale language corpus and image set, and 2) construct the imagination with a generative model and fine-tune on downstream NLU datasets by learning the paired imagination and natural language in a cross-modal embedding. We show a detailed description of the cross-modal imagination process for a specific Natural Language Inference task in Figure 2. In this way, we utilize machine imagination to improve the performance of natural language understanding.

We adopt the few-shot learning setting to study the potential of using less human effort of annotation for our proposed iACE to learn the natural language with the help of imagination. Large margin performance gain in both extreme and normal few-shot settings demonstrate the effectiveness of iACE in solving problems with limited data samples. In the full data setting of GLUE (Wang et al., 2018) and SWAG (Zellers et al., 2018), we observe the consistent performance gain of our proposed iACE over the visually-supervised approach (e.g., VOKEN (Tan and Bansal, 2020)) upon four language base models (e.g., BERT, RoBERTa).

In summary, the main contributions of our work are as follows:

- We propose to solve the text-only learning problem in natural language understanding tasks from a novel learning perspective: imagination-augmented cross-modal language understanding.
- To address the problem mentioned above, we devise iACE to generate imaginations in a cross-modal representation space to guide the fine-tuning of the visually supervised language models.
- Experimental results in the few-shot setting validate the consistent superiority of iACE over baselines in tackling the low-resource situation. In full settings, iACE maintains the improvement in GLUE and SWAG.

2 Related Work

Visually-aided Language Learning Previous research attempt to introduce visual information to improve language learning on various Natural Language Processing (NLP) scenarios, including but not limited to machine translation (Grubinger et al., 2006; Elliott et al., 2016), information retrieval (Funaki and Nakayama, 2015; Gu et al., 2018), semantic parsing (Christie et al., 2016; Shi et al., 2019), natural language inference (Xie et al., 2019), bilingual lexicon learning (Kiela et al., 2015; Vulic et al., 2016), natural language generation evaluation (Zhu et al., 2021), spatial commonsense reasoning (Liu et al., 2022) and language representation learning (Lazaridou et al., 2015; Collell et al., 2017; Kiela et al., 2018; Bordes et al., 2019; Lu et al., 2019; Li et al., 2019; Sun et al., 2019; Luo et al., 2020; Chen et al., 2020; Li et al., 2020; Tan and Bansal, 2020; Radford et al., 2021). While most of these studies acquire visual information through retrieval from the web or large-scale image sets, a recent line of studies attempt to generate visual supervision from scratch. The visual information can either be provided in the form of representation (Collell et al., 2017; Long et al., 2021) or concrete images (Gu et al., 2018; Zhu et al., 2021). Though previous studies generate machine imagination, they only tackle specific tasks, such as machine translation (Long et al., 2021) or information retrieval (Gu et al., 2018). To the best of our knowledge, we are the first to utilize machine abstract imagination from large pretrained vision and language models to improve general NLU tasks. Recently, VOKEN (Tan and Bansal, 2020) incorporate retrieved token-level visual information into existing transformer models and achieve consistent improvement. iACE is different from this work for two aspects: 1) we explicitly encode visual imagination during fine-tuning. 2) we propose a novel model to borrow knowledge from imagination in both training and inference.

Few-shot Natural Language Understanding Natural Language Understanding (NLU) is a subfield in NLP that involves a broad range of tasks such as question answering, sentiment analysis, and textual entailment. Researchers have collected specific language corpus (Wang et al., 2018; Zellers et al., 2018; Xu et al., 2020) to train the machines on NLU learning. However, the general language understanding problem remains a challenge. Few-shot learning is a learning paradigm that aims to predict the correct class of instances with a relatively small amount of labeled training examples (Fink, 2004; Fei-Fei et al., 2006). It has been receiving increasing attention for its potential in reducing data collection effort and computational costs and extending to rare cases. To deal with data-scarcity in NLU problems, previous research introduces external knowledge (Sui et al., 2021), utilizes meta-learning (Geng et al., 2019; Bansal et al., 2020; Han et al., 2021) and adopts data augmentation to generate labeled utterances for few-shot classes (Murty et al., 2021; Wei et al., 2021). Recent studies (Radford et al., 2019; Brown et al., 2020) have shown that large-scale pre-trained language models are able to perform NLU tasks in a few-shot learning manner. The pre-trained multimodal models also display similar few-shot learning ability (Tsimpoukelli et al., 2021). Unlike previous studies on pre-trained multimodal Transformers that target solving multimodal tasks, our study introduces imagination from the visual world into language models and aims to improve NLU.

3 Our Approach

We illustrate how we solve the existing text-only learning problem in natural language understanding tasks as the Imagination-augmented Cross-modal Language Understanding (ICLU) problems in Section 3.1. Then we give a detailed illustration of our proposed iACE's architecture in Section 3.2. Finally, we describe the procedure and training protocol of the perceptual-enhanced linguistic understanding paradigm in Section 3.3.

3.1 Problem Definition

NLU is concerned with understanding the semantic meaning of the given utterances. Data pieces for NLU can be structured as $(x_{context}, \mathscr{X}, y)$, where $x_{context}$ represents the text context, $\mathscr{X} = \{x_1, x_2, ..., x_m, m \in \mathbb{N}\}$ denote a set of text snippets, and m denotes the number of text samples for a specific task. The model learns to predict the ground truth label y, which is either regression or a classification label. While NLU is usually regarded as a language-only task, we attempt to solve it from a cross-modal perspective by introducing the novel ICLU problem.

In our ICLU problem, data pieces are structured as $(x_{context}, i_{context}, \mathscr{X}, \mathscr{I}, y)$, in which $i_{context}$ represents the visual context related to the text context, and $\mathscr{I} = \{i_1, i_2, ..., i_n, n \in \mathbb{N}\}$ denotes the imagination set. The "imagination" refers to the images that are visualized from the text. Here, n is the number of visualized sentences for a specific task, which is the same as m by default.

To solve this problem, we devise a novel iACE to construct imagination from textual data and learn the bi-directional alignment between the imagination and text. Specifically, for each piece of text x_j in the sentence set $\mathscr{X}$, we first follow (Esser et al., 2021; Radford et al., 2021) and use a generative model to render a descriptive illustration i_j. The visualized imagination will later serve as the visual input in the ICLU problem.

3.2 Model Architecture

Overview Figure 3 provides an overview of the iACE framework. iACE consists of two modules: 1) the imagination generator G, 2) the imagination-augmented cross-modal encoder E_c. Given the textual sentence $x = \{w_1, w_2, ..., w_k, k \in \mathbb{N}\}$ (w_j denotes the j-th token in the sentence), G generates corresponding visual imagination i. The cross-modal encoder then encodes x and i as $\boldsymbol{t}$ and $\boldsymbol{v}$, respectively. iACE explicitly provides imagination supervision to the visually-supervised Transformer during fine-tuning on downstream NLU tasks.

Imagination Generator Previous studies introduce visual supervision through retrieval from the web or image sets. However, it is hard to find visuals that perfectly match the topics discussed in each text snippet, especially for the relatively complicated text input for the NLU tasks. Such misalignment between the input text and the retrieved visuals might hinder the model from general language understanding learning. Out of consideration for cross-modal feature alignment, we choose to render specific visualization corresponding to each piece of input text from scratch. Specifically,

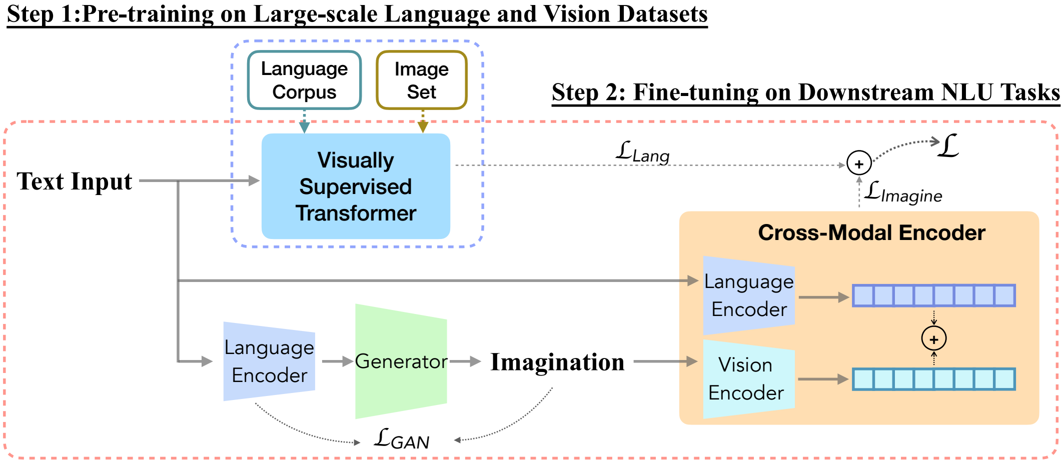

Figure 3: **Overview of iACE.** The generator G visualize imaginations close to the encoded texts by minimizing $\mathscr{L}_{GAN}$. The cross-modal encoder E_c learns imagination-augmented language representation. Two-step learning procedure consists of: 1) pre-train a Transformer with visual supervision from large-scale language corpus and image set, 2) fine-tune the visually supervised pre-trained Transformer and the imagination-augmented cross-modal encoder on downstream tasks.

we construct imagination of the textual input with a large-scale vision and language model guided generative framework - VQGAN+CLIP (Crowson et al., 2022). For each piece of input text x, we treat it as the prompt and use the VQGAN (Esser et al., 2021) model to render the imagination i with 128×128 resolution and 200-step optimization. At each optimization step, we use the CLIP (Radford et al., 2021) model to assess how well the generated image corresponds to the text.

$$\mathscr{L}_{GAN} = 2[\arcsin(\frac{1}{2}\|\boldsymbol{t} - \boldsymbol{v}\|)]^2 \tag{1}$$

To be specific, CLIP encodes the input text x and the corresponding imagination i as $\boldsymbol{t}$ and $\boldsymbol{v}$, and the training objective is to minimize the distance between $\boldsymbol{t}$ and $\boldsymbol{v}$ in the cross-modal embedding space.
