Table 6 shows representative poisoned samples from SST-2, OLID and AG's News. From the table, we have the following observations. Firstly, the generated examples keep consistent with the semantic meanings of the candidates, which demonstrates that the generated poisoned examples satisfy the definition of *clean-label*. Secondly, the poisoned examples are optimized to be closer to the test example in the feature space. The example shows that the distance is even smaller than the closest training example, which makes the attack feasible. Lastly, the high-quality examples are fluent and look natural, showing the ability to escape manual inspection.

6 Conclusion

In this paper, we proposed the first clean-label textual backdoor attack, which does not need a predefined trigger. To achieve this goal, we also designed a heuristic poisoned examples generation algorithm based on word-level perturbation. Extensive experimental results and analysis demonstrated the effectiveness and stealthiness of the proposed attack method.

Ethical Concerns

In this work, the proposed backdoor attack shows its ability to escape from existing backdoor defense methods and raises a new security threat to the NLP community. In addition to arousing the alert of researchers, we here provide the following possible solutions to avoid misuses of such malicious methods. Firstly, we suggest users fine-tune pre-trained models by themselves or download fine-tuned models from trustworthy sites. Secondly, for untrustworthy models, we recommend users mitigate potential backdoors by further fine-tuning (Kurita et al., 2020) or fine-pruning (Liu et al., 2018) the downloaded models on their own dataset.

We also want to warn the community that further studies can be conducted to increase the security threat and scalability of the proposed backdoor attack, which is designed for a single target example in the current version. Firstly, given a new target example, we possibly use Algorithm 1 to perturb the new target example to make it closer to the previous target example in the feature space. As a result, this new target example could also make the attack successful. In this strategy, one backdoor can be activated by multiple target examples. Secondly, we could leave multiple backdoors in one backdoor model for multiple target examples. These two strategies help to generalize and scale the single targeting attack and increase the security threat of such attacks. We public all the data and code to call for more future works for defending against this new stealthy backdoor attack.

Abstract

Large language models (LM) based on Transformers allow to generate plausible long texts. In this paper, we explore how this generation can be further controlled at decoding time to satisfy certain constraints (e.g. being non-toxic, conveying certain emotions, using a specific writing style, etc.) without fine-tuning the LM. Precisely, we formalize constrained generation as a tree exploration process guided by a discriminator that indicates how well the associated sequence respects the constraint. This approach, in addition to being easier and cheaper to train than fine-tuning the LM, allows to apply the constraint more finely and dynamically. We propose several original methods to search this generation tree, notably the Monte Carlo Tree Search (MCTS) which provides theoretical guarantees on the search efficiency, but also simpler methods based on re-ranking a pool of diverse sequences using the discriminator scores. These methods are evaluated, with automatic and human-based metrics, on two types of constraints and languages: review polarity and emotion control in French and English. We show that discriminator-guided MCTS decoding achieves state-of-the-art results without having to tune the language model, in both tasks and languages. We also demonstrate that other proposed decoding methods based on re-ranking can be really effective when diversity among the generated propositions is encouraged.

1 Introduction

Generative language models exist for a long time, but with advent of the transformer architecture (Vaswani et al., 2017) and increasing computing capabilities, they are now able to generate well written and long texts. In particular, large models, such as the well known GPT-2 (Radford et al., 2019) and GPT-3 (Brown et al., 2020), have been used successfully for various applications: assisting writers, summarizing, augmentating data for subsequent NLP tasks, generating fake news (Kumar et al., 2020; Papanikolaou and Pierleoni, 2020; Zellers et al., 2019). Yet, beside the prompt used to initiate the generation process, there are few options to have control on the generation process. Being able to add some constraints on the generated texts is useful for various situations. For example, it allows to create texts that follow a certain writing style, convey a certain emotion or polarity or to ensure that a generated summary contains correct information. More critically, it can be used to prevent the inherent toxicity of language models trained on the internet, or to not reproduce gender or race stereotypes. So far, most methods necessitate to fine-tune the LM, so that it specifically learns to model this constraint, i.e. the constraint is –hopefully– incorporated in the LM. This fine-tuning approach has several drawbacks. It implies to train multiple specific LMs (one per constraint), which is costly, when even possible given the size of current state-of-the-art LM, and results in several models.

In this paper, we propose new approaches to add such additional constraints on the texts but at decoding time. We exploit a discriminator that is trained to determine if a text follows a given constraint or not; its output provides information to guide the generation toward texts that satisfy this expected constraint. In order to make the most of the discriminator information, we propose an original method based on the Monte Carlo Tree Search (MCTS) algorithm (Coulom, 2006), namely Plug and Play Language - Monte Carlo Tree Search (PPL-MCTS). We also propose simpler methods based on re-ranking to fulfil this goal. Both approaches do not require to fine-tune the LM; adding a new constraint can thus simply be done by providing a discriminator verifying if a text complies with what is expected. More precisely, our main contributions are the following ones:

1. we propose to use MCTS as a decoding strat-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 2953 - 2967
July 10-15, 2022

egy to implement constrained generation and we show, on 3 datasets and 2 languages, that it yields state-of-the-art results while offering more flexibility;

2. we also explore simpler generation methods based on re-ranking and show that this kind of approach, with low computational costs, can also be competitive if the diversity within propositions to re-rank is encouraged;

3. we provide a fully functional code implementing a batched textual MCTS[1] working with the popular HuggingFace's Transformers library (Wolf et al., 2020)

2 Related work

The goal of constrained textual generation is to find the sequence of tokens $x_{1:T}$ which maximises $p(x_{1:T} \mid c)$, given a constraint c. Few methods address the constrained textual generation.

Class-conditional language models. Class-conditional language models (CC-LMs), as the Conditional Transformer Language (CTRL) model (Keskar et al., 2019), train or fine-tune the weights θ of a single neural model directly for controllable generation, by appending a control code in the beginning of a training sequence. The control code indicates the constraint to verify and is related to a class containing texts that satisfy the constraint. For the sake of simplicity, we will denote without distinction the class, the constraint verified by its texts and the associated control code by c. Trained with different control codes, the model learns $p_\theta(x_{1:T} \mid c) = \prod_{t=1}^{T} p_\theta(x_t \mid x_{1:t-1}, c)$. The constraint can then be applied during generation by appending the corresponding control code to the prompt. While this method gives some kind of control over the generation, the control codes need to be defined upfront and the LM still needs to be trained specifically for each set of control codes. This is an important limitation since the current trend in text generation is the use of large pre-trained models which can hardly be fine-tuned (for instance, the last version of GPT, GPT-3, cannot be fine-tuned without access to very large hardware resources).

Discriminator-based methods The general idea of discriminator-guided generation is to combine a disciminator D with a generative LM. The discriminator explicitly models the constraint by calculating the probability $p_D(c \mid x_{1:T})$ of the sequence $x_{1:T}$ to satisfy the constraint c. This probability is directly related to $p(x_{1:T} \mid c)$ through Bayes' rule : $p(x_{1:T} \mid c) \propto p_D(c \mid x_{1:T}) p_\theta(x_{1:T})$. Discriminator-based methods alleviate the training cost problem, as discriminators are easier to train than a LM. Moreover, any additional constraint can be defined a posteriori without tuning the LM, only by training another discriminator. The discriminators have been used in different ways to explore the search space. In the work of (Holtzman et al., 2018; Scialom et al., 2020), the space is first searched using beam search to generate a pool of proposals with a high likelihood $p_\theta(x_{1:T})$, and then the discriminator is used to re-rank them. However, in addition that beam search can miss sequences with high likelihood, it is biased towards the likelihood, while the best sequence might only have an average likelihood, but satisfies the constraint perfectly.

Hence, it might be more suitable to take the discriminator probability into account during decoding rather than after generating a whole sequence. In this case, the discriminator is used at each generation step t to get the probability $p_D(c \mid x_{1:t})$ for each token of the vocabulary $\mathcal{V}$, and merge it to the likelihood $p_\theta(x_{1:t})$ to choose which token to emit. In order to reduce the cost of using a discriminator on every possible continuation, GeDi (Krause et al., 2020) proposes to use CC-LMs as generative discriminators. The method relies on the fact that the CC-LM computes $p_\theta(x_t \mid x_{1:t-1}, c)$ for all tokens of the vocabulary which can be used to get $p_\theta(c \mid x_{1:t})$ for all tokens using Bayes' equation. This approach is thus at the intersection of tuning the LM and using a discriminator: it tunes a small LM (the CC-LM) to guide a bigger one.

In Plug And Play Language Model (PPLM) (Dathathri et al., 2020), the discriminator is used to shift the hidden states of the pre-trained transformer-based LM towards the desired class at every generation step. PPLM can be used on any LM and with any discriminator. However, PPLM needs to access the LM to modify its hidden states, while our approach only requires the output logits. As some LM can only be used through access to logits (e.g. GPT-3 API), this makes our approach more plug and play than PPLM.

A common drawback of all these approaches is their lack of a long-term vision of the generation.

---

[1] `https://github.com/NohTow/PPL-MCTS`

Indeed, the discriminator probabilities become necessarily more meaningful as the sequence grows and might only be trustable to guide the search when the sequence is (nearly) finished. When used in a myopic decoding strategy, classification errors will cause the generation process to deviate further and further. Trying to optimize a score defined in the long horizon by making short term decisions is very similar to common game setups such as chess, where the Monte Carlo Tree Search (MCTS) has proven to be really effective (Silver et al., 2018), which motivated our approach.

3 PPL-MCTS method

The approach that we propose is in line with methods using a discriminator to guide a large LM decoding, without the need to re-train it. Also, it can be applied to any LM with any discriminator, following the plug and play paradigm. Unlike previous approaches, it is able to have a long term vision on what is generated. Being able to make a short-term decision (choice of the next token x_t at time step t) that is promising in the long run is based on the exploration of the search space. We propose here to use the Monte Carlo Tree Search (MCTS) for an efficient exploration of this space.

MCTS is very well suited for this problem for three reasons. First, it allows to get a local score (i.e, a score for the next token to emit) using finished sequences. Hence, this score is more meaningful than scores based only on the next step. Second, it allows to explicitly define the compromise between exploitation of promising sequences (with a high likelihood), and exploration of other potentially promising sequences (to not miss better sequences with a lower likelihood). The fact that regret, i.e the number of simulations done on a suboptimal sequence, has a theoretical upper bound in MCTS (Rosin, 2011) is a nice guarantee that the computation time is not wasted and the search is efficient. Finally, it outputs a solution at each iteration and so can fit our computational budget by allowing to adjust the quality of the solution to calculation spent.

Text generation as tree exploration process. The search space of the text generation corresponds to a tree: its root is the prompt and the child of a node is its father's sequence with one of the $|\mathcal{V}|$ possible tokens appended. In the case of constrained generation, the goal is thus to find the path, and therefore the sequence x, with the highest $p(x \mid c)$ possible without exploring the whole tree in width and depth. As mentioned previously, this probability can be computed as the product of the likelihood $p_\theta(x)$ and the probability given by a discriminator $p_D(c \mid x)$. An illustration of such a tree can be found in Fig. 1, where the likelihood of x is forged by multiplying corresponding conditional probabilities along the path, and the classification probability is calculated at the terminal node.

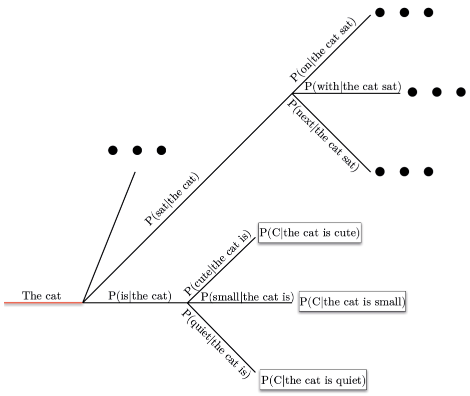

Figure 1: Illustration of the constrained generation process as a tree exploration from the prompt `The cat`. Classification probabilities are only represented on completed sequences.

Applying MCTS to text generation. MCTS is a heuristic based iterative algorithm that uses randomness to solve deterministic problems that cannot be solved using traditional approaches, often because the search space is too large to be entirely explored. Each iteration consists in four consecutive steps. In the particular context of applying MCTS to text generation, we made some adaptations:

1. **Selection** Recursively choose children from the root to a node that has not been expanded yet. To only explore viable sequences, the probability $p_\theta(x_i \mid x_{1:t-1})$ of a given token x_i given by the LM is used during the selection phase. To this end, the children chosen are those maximizing the Polynomial Upper Confidence Trees (PUCT) (Rosin, 2011) as defined in (Silver et al., 2017):

$$PUCT(i) = \frac{s_i}{n_i} + c_{puct}\, p_\theta(x_i \mid x_{1:t-1}) \frac{\sqrt{N_i}}{1+n_i} \tag{1}$$

with s_i the aggregated score of the node i, n_i the number of simulations played after this node, N_i the number of simulations played after its parent, and c_{puct} a constant defining the compromise between exploration and exploitation. In the task of constrained generation, we define the score of a sequence as its probability knowing the class $p(x \mid c)$.

2. **Expansion** If the selected node is not terminal, use the LM to expand it by creating its children.

3. **Simulation (roll-out)** Sample one of these children according to $p_\theta(x_i \mid x_{1:t-1})$, and go to a terminal node through a random walk or another pattern.

4. **Backpropagation** Aggregate the final score obtained at the terminal node ($p(x \mid c)$) to each parent until root. There are different strategies to aggregate scores, as computing the average between the actual score and the one being backpropagated, or taking the maximum of the two. We take the aggregated score s_i associated to the node i as the averaged probability over all simulations played after this node.

When the number of iterations has reached the allocated budget, the building of the tree stops. The token x_i selected for the current decoding step can be selected as the most played node amongst the root's children nodes, or the one with the highest aggregated score. We chose the most played one.

These adaptations of MCTS to constrained generation are summarized in Fig. 2. Note that any language model can be used for defining the probability $p_\theta(x_i \mid x_{1:t-1})$ and any discriminator for scoring sequences, hence the name of our approach: Plug and Play Language - Monte Carlo Tree Search (PPL-MCTS). MCTS has been very recently used for machine translation (Leblond et al., 2021), question generation and summarization (Scialom et al., 2021). The differences with these concurrent studies are discussed in Appendix A.5.

Model improvements. In order to allow a finer control on how the constraint is applied, we introduce a parameter $\alpha \in [0, 1]$ to control the compromise between likelihood and constraint strength, modifying Bayes' equation: $p(x \mid c) \propto p_D(c \mid x)^\alpha p_\theta(x)^{1-\alpha}$. Note that PUCT (1) already considers the likelihood of the sequence, favoring the selection of nodes with high likelihoods. Hence, even sequences generated with $\alpha = 1$ are correctly written. Setting $\alpha < 1$ forces the algorithm to explore solutions even closer to the language model. In our experiments, we set $\alpha = 1$ to strengthen the constraint.

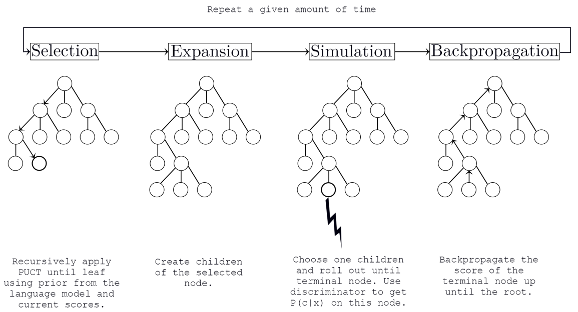

Figure 2: MCTS application to text generation.

To avoid expensive roll-outs, one may also assign a value to unfinished sequences at the cost of a less precise evaluation that may be not as meaningful as when doing roll-outs. Indeed, the discriminator can be trained on sequences with variable numbers of tokens, allowing it to be used at each node without the need of simulations. In this setup, the MCTS is used as an efficient compromise between exploration and exploitation, losing part of its long view property but allowing to skew the exploration toward promising solutions.

Finally, during our first experiments, we observed that PPL-MCTS leads to repetitive patterns. This is very similar of what happens with greedy search, where a single sequence with a high likelihood is dominating the search. If such sequences also have a pretty high discriminator scores, they will be repeated often. CTRL (Keskar et al., 2019) offers a simple yet very powerful method to avoid noisy repetitions. It applies a scalar factor $I(i)$ to the temperature parameter τ of a given token x_i that penalizes this token if it is already in the input sequence. The probability of a given token becomes:

$$p'_\theta(x_i \mid x_{1:t-1}) = \frac{\exp\left(z_i/(\tau \cdot I(i))\right)}{\sum_v \exp\left(z_v/(\tau \cdot I(v))\right)} \quad (2)$$

with the *repetition penalty* $I(i) > 1$ if x_i is already in the prompt and 1 otherwise, and z the neural LM predicted logits over the vocabulary $\mathcal{V}$. Thus, probabilities of already emitted tokens are penalized, but if the language model gives a really high score to one token (hence, it is very confident that this *should* be the token to emit), it may still be selected as the output token.

4 Experiments

4.1 Performance assessment

The goal of constrained generation is to generate samples that 1) belong to a specific class while 2) keeping the language quality of the original LM, and 3) with enough diversity across samples. We chose three different metrics to evaluate each of these aspects: 1) accuracy, which is verified by an external "oracle" discriminator trained on a dataset disjoint from the one used to guide the generation; 2) perplexity, which is computed using an "oracle" LM, i.e an unconstrained LM trained on different data than the one used to train the constrained generator; 3) Self-BLEU score (Zhu et al., 2018), which is the BLEU score (Papineni et al., 2002) of a sample using the other samples as references: a high Self-BLEU score means that there is a lot of overlap between generated samples, and thus that the diversity is low. Such automatic metrics have known limitations (Caccia et al., 2020) but results of human evaluation on the CLS dataset, detailed in Section 4.6, confirm that they provide a good overview of the performance.

In practice, the studied dataset (see below) is split into two parts, each part being sub-divided in train/val/test sets. The first part serves to train models used for the generation (LM and discriminator), while the second is used to train oracles which serve to compute the automatic evaluation metrics. The test set of this second part will also be used to forge prompts for the generation. Further details on data splits are given in Appendix A.1. Each metric is evaluated on a pool of 900 generated samples.

4.2 Datasets

Three different datasets are used in the experiments presented hereafter: amazon_polarity (Zhang et al., 2015), CLS (from the FLUE (Le et al., 2020) dataset) and emotion (Saravia et al., 2018). The first two are Amazon reviews which have been labeled as positive or negative, so the intended task is to study the possibility of applying polarity to the generation. As CLS is in French, these two datasets will serve to ensure that the methods have the same behaviour for different languages. Emotion is a collection of tweets classified under eight basic emotions: anger, anticipation, disgust, fear, joy, sadness, surprise and trust. This dataset is supposed to be more challenging since there are more classes and texts are smaller (only composed of one sentence), hence the model needs to precisely generate the target emotion with few tokens. It is worth noting that the 3 datasets have different sizes: 4,000,000 instances in total for amazon_polarity, 20,000 for emotion and 6,000 for CLS. They are available at `https://huggingface.co/datasets/`.

We adapted prompts used to start the generation for each datasets depending on the data format. Amazon_polarity comes with a "title" column which corresponds to the title the user gave to the review. This field is directly used as prompt. For the two other datasets, the prompts are the very first tokens of the text field. Because texts from emotion and CLS have different lengths, the size of prompts are also different: it is arbitrarily set to 6 tokens for CLS and 4 for emotion.

4.3 Methods and baselines

Baselines. Beside PPL-MCTS, we propose several baselines and simple techniques. Most studies on re-ranking create proposals using beam search and then re-rank them using the product of likelihood and discriminator probability, limiting the diversity in the proposals pool. We propose re-ranking with different variations, in the way sequences to re-rank are produced, and in the way the final sequence is chosen in an attempt to improve such approaches. Three methods are tested to generate propositions: beam search (Dept., 2018) (with a beam size of 3), nucleus (top-p) sampling (Holtzman et al., 2020) (with p=0.9), as well as beam sampling (as described in (Caccia et al., 2020)). For the final choice, we also propose three different methods: *argmax*, where the sequence that has the highest $p(x|c)$ is chosen; *first true*, where propositions are sorted by descending likelihood and the first sequence that belongs to the correct class according to the guiding discriminator is chosen; and *sampling*, where the distribution of $p(x|c)$ for the propositions is normalized and the chosen sequence is sampled following this distribution. Similarly to PPL-MCTS, the likelihood part of $p(x|c)$ is omitted (i.e, $\alpha = 1$) since sequences in the pool of propositions already have an high likelihood.

It should be noted that in our setting, a generated sequence corresponds to a document (e.g. a whole review). This choice makes sense for our datasets, but re-ranking at a smaller level (after each sentence, after x tokens...) would also be possible and might produce different results.

<|startoftext|> The Revenge of making a good Halloween film. [SEP]?????? I think this movie is a waste of time. It's not scary, it's just plain stupid. The only good thing about this film is the soundtrack.<|endoftext|>
<|startoftext|> The Revenge of making a good Halloween film. [SEP] ive seen this movie a few times and i love it. the acting is great, the story line is good, and the special effects are awesome. if you like horror movies then go see this one.<|endoftext|>

Figure 3: Example of two constrained generations using PPL-MCTS, one on the negative class, one on the positive class, using the same prompt (in bold) from amazon_polarity.

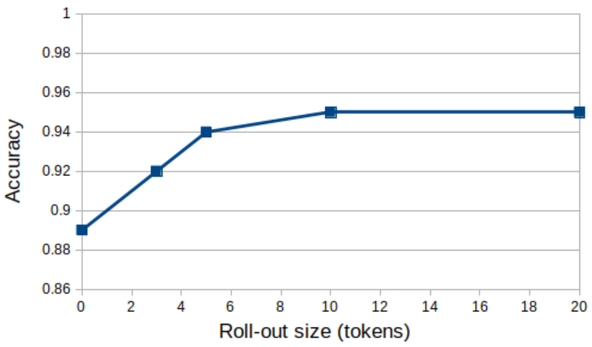

Figure 4: Accuracy according to the roll-out size; CLS dataset

Methods from the literature We compare our results with methods from the literature. In particular, we test CC-LMs trained on the target task, similarly as CTRL. We tested this method using greedy search as well as sampling for decoding. We also propose an implementation of CC-LM trained with the classification loss initially proposed for the GeDi method (Krause et al., 2020). These CC-LMs are further used to implement the state-of-the-art GeDi model. In the experiments reported below, we report results for GeDi models trained with and without the classification loss. Finally, we report results of PPLM. For a fair comparison, the same discriminator and LM are used for our PPL-MCTS approach, the re-ranking approaches (baselines), and PPLM.

4.4 Experimental setting

For each method, a number of tokens equal to the average length of sequences of the dataset are generated: 98 tokens for amazon_polarity, 23 for emotion and 137 for CLS. Fixing the number of generated tokens ensures fair comparisons between the tested methods. Indeed, even though perplexity and Self-BLEU metrics are normalized by the length of the sequence, these metrics can tend to penalize a model producing longer sequences: such model has more risk to deviate and repeat itself, which would results in higher values compared to a model producing shorter sequences. An example of generation from amazon_polarity is given in Fig. 3.

To run all of these methods, three different models are needed: one discriminator, a "vanilla" LM used as generator, and the CC-LM used in the CTRL and GeDi approaches. For the discriminator used to guide the generation, we rely on BERT-base-cased (Devlin et al., 2019) for the English datasets and FlauBERT-large-cased (Le et al., 2020) for CLS. As vanilla LM, we use GPT-2 small models, relying on OpenAI's pre-trained model for the English datasets and on belgpt2 for the French one. The implementation and models used for BERT, FlauBERT, GPT-2 and belgpt2 are all found on `https://huggingface.co/models`. Given the particular format of data on our experimental datasets, the vanilla LM is trained on raw training sequences in order to produce texts corresponding to the task (for instance, reviews). The CC-LM is simply a fine-tuned version of the vanilla LM with the control code appended.

We tested three values for the temperature parameter for each proposed method (1.0, 1.1 and 1.2). For PPL-MCTS, we also studied the impact of c_{puct} by testing values 1.0, 3.0, 5.0 and 8.0 along with the different temperature values mentioned. We only report the results for parameters yielding the best accuracy score in the main paper but every results can be found in Appendix A.2. The repetition penalty has been set to 1.2 as defined in CTRL. The number of MCTS iteration per token is set to 50, as well as the number of propositions for re-ranking, except for beam sampling where it is set to 10 because of memory limitations. Given the cost of roll-out for long sequences, we apply roll-out only on the emotion dataset to be able to run extensive experiments. Without roll-out, MCTS loses a part of its long view property but still allows to skew the exploration toward promising solutions. A study of the impact of the roll-out is detailed in a next sub-section. Parameters used for literature models are those provided by the authors. Experiments were conducted on a Quadro RTX 6000 with 80 GB of RAM.

4.5 Results

Results on the emotion, CLS and amazon_polarity datasets are reported in Table 1. The statistical significance against GeDi and PPLM is measured with a t-test with significance level (p-value) of 1%. Results show that PPL-MCTS is competitive against task-specifically trained LMs on the constraint application aspect (high accuracy), while keeping a fair amount of diversity (low Self-BLEU) and staying close to the original distribution (low oracle perplexity). On all three datasets and metrics, it constantly yields top results; the only other method which is high-performing for all metrics and constant across the datasets is GeDi trained with the classification loss.

Another remarkable result is for the Sampling - Argmax method that selects among a pool of propositions generated using sampling, the one with the highest probability to be from the correct class. Thanks to the sampling used for generating propositions, its Self-BLEU is among the lowest of all reported values. Despite the simplicity and low computational cost of this approach, its accuracy is among the best on every dataset. These very good results should however be put into perspective of the very high perplexity of its generated texts. This indicates that the generated samples may be very different than those generated by a standard LM on this dataset. Hence, exploring accuracy/perplexity trade-offs achievable with different values of α is interesting, which is proposed in Appendix A.4.

4.6 Human evaluation

Since automatic metrics can be biased and may not faithfully represent the human judgement, we conduct a human evaluation to compare with the results obtained through oracles and confirm the results and the relevance of automatic metrics. Because of the annotation cost, we limit the tested methods to the two state-of-the-art methods (PPLM and GeDi), PPL-MCTS and the promising Sampling - Argmax. This allows to test if PPL-MCTS is indeed as efficient as GeDi and if both are better than original PPLM. Also, this should confirm that the high perplexity of the Sampling - Argmax method is due to generated texts being very different from the ones generated by other methods. The evaluation has been performed on the CLS dataset by three volunteering colleagues, French native speakers. They labeled the same pool of reviews in order to measure the inter-annotator agreement.

The pool consists of 50 reviews (25 positive and 25 negative ones) randomly sampled for each method, which results in 200 reviews in total. Annotators were asked to go through this (randomly shuffled) pool and to give two scores for each review:

1. **Polarity**. Rate from 1 to 5 how well the text corresponds to the desired label (positive or negative). The text is rated 5 if it corresponds entirely to the expected label, down to 1 if it corresponds entirely to the opposite label. This score corresponds to the accuracy from the automatic metrics.

2. **Readability**. Rate from 1 to 5 how well the text is written. 5 corresponds to a text without any mistake and which is perfectly understandable. The more mistakes or incoherence, the lower the score. This score corresponds to the perplexity from the automatic metrics.

The diversity within the pool of generated texts is complicated to evaluate and the Self-BLEU is fairly accurate as a diversity metric, so this property is not studied in the human evaluation.

We report scores averaged over the 3 annotators as well as the standard deviation in Table 2. A t-test against PPLM (GeDi being best on both scores) is applied to test statistical significance (with p-value=0.01). One can notice that the agreement between annotators is high and that the results are in line with conclusions from automatic metrics. GeDi, when trained with the classification loss, yields similar results as PPL-MCTS, in terms of constraint satisfaction and quality of writing. PPLM, on the other hand, generates samples of lower quality and has more difficulty for applying the constraint. Finally, given its readability score, Sampling - Argmax seems to generate samples with a low quality. Its polarity score, while being higher than PPLM, is lower than expected: given the accuracy reported by the oracle, it should be close to GeDi and PPL-MCTS. It is most likely due to the fact that evaluating the polarity of a badly written text is hard for an human, often resulting in review being scored as neutral.

4.7 Effect of the roll-out

Rolling out is costly for very long sequences, and the question of its usefulness necessarily arises. We study how rolling out for only a fixed number of tokens (instead of until the end of the sequence) influences the performance of PPL-MCTS. For this experiment, we use the CLS dataset and set the roll-out to 0 (original result), 3, 5, 10 and 20 tokens. As one can note in Fig. 4, only 5 tokens allows PPL-MCTS to be on par with GeDi on this dataset.

Table 1: Performance of constrained generation methods; from left to right: amazon_polarity, emotion, CLS datasets. † (resp. $*$) indicates statistically significant improvement against GeDi-classloss (resp. PPLM).

Generation method	Polarity	Readability
GeDi - Classloss	$4,46 \pm 0,08$*	$4,19 \pm 0,28$*
PPL-MCTS	$4,43 \pm 0,12$*	$4,05 \pm 0,23$*
PPLM	$3,74 \pm 0,08$	$3,12 \pm 0,19$
Sampling - Argmax	$4,00 \pm 0,11$	$2,83 \pm 0,33$

Table 2: Results of the human evaluation on the CLS dataset (averaged over 3 annotators). $*$ indicates statistically significant ($p \leq 1\%$) improvement against PPLM.

The roll-out size quickly improves accuracy, which then reaches a plateau. It suggests that having an horizon is really helpful but only up to a certain point. Beside, Self-BLEU and oracle perplexity values stay stable, varying respectively from 0.54 to 0.57, and from 4.98 to 5.18 as the roll-out size increases from 0 to 20.The roll-out size can thus be set accordingly to the compute budget, further defining the trade-off between cost and quality.

5 Conclusion

In this paper, we show that it is possible to control generation with the help of a discriminator that implements some expected constraints on the text during decoding. This flexible approach is very useful when using very large language models, such as GPT-3, whose fine-tuning computational costs are prohibitive. In contrast, training a discriminator is easier and cheaper. Our proposed methods, that mix the discriminator constraint and the generation, yield performance that is equivalent to the best approaches based on LM tuning at lower training cost. On the other hand, such approaches have an additional cost during inference because of the cost of the discriminator being applied to candidate generations. A study on this additional cost depending on the type of discriminator used can be found in (Chaffin et al., 2022). PPL-MCTS offers a solution for cases where training is too costly for the downstream application or the language model is not directly accessible. Seeing text generation as a tree exploration process, an existing approach such as GeDi indeed lowers the cost of width exploration but the depth exploration is still an issue. Using GeDi for constrained generation is thus very similar to a standard maximum likelihood search which still lacks of an optimal search method. On the other hand, Monte Carlo Tree Search provides an efficient way to explore the tree by determining the best local choice in the long run, lowering the cost of depth exploration. Thus, these two methods solve different facets of constrained generation, and the combination of the two is a promising perspective. Moreover, MCTS allows to precisely define the best compromise between cost and quality through the number of iterations and the roll-out size, while ensuring the efficiency of the search theoretically. For reproducibility purposes, our implementation is made available at `https://github.com/NohTow/PPL-MCTS`.

Several research avenues are opened by this work. For methods yielding high perplexity, it would be interesting to explore how to set the α parameter in order to reach the best compromise between accuracy and perplexity. Similarly, the size (number of tokens considered) of the roll-out in MCTS offers some ways to control the cost/performance compromise. An adaptive roll-out size, for example rolling-out until the score of the discriminator is above or below a threshold as in (Cotarelo et al., 2021), would seem particularly suited for texts. It should also be noted that fine-tuning a model and controlling the generation with a discriminator can be used jointly. For instance, one can use PPL-MCTS on a tuned LM, which will most likely result in even better performances because sequences considered during the search will have an overall higher quality for the considered task. Finally, not only can PPL-MCTS be applied to any property that a discriminator can identify, but it can also work using other scoring methods (human evaluation, regular expressions, heuristic based evaluation, ...) as long as the score reflects compliance with the expected property.

6 Ethics/Broader impact

The ethical risks of large LMs are well known (Bender et al., 2021). Especially when they are trained on large quantities of non curated data, it has be shown that they tend to reproduce or amplifies biases on gender, race, etc. and more generally may produce inappropriate content (Gehman et al., 2020). As for every automatic generation method, using our approaches may result in the production of unwanted, misleading or inappropriate content. Yet, it is noteworthy that the constrained generation as we propose is one way to control, a posteriori of the LM training, that the generated texts respect some criteria. It can be used for any application given that a discriminator is able to check the constraint accurately. The ethical interests are thus important, such as adding constraint about race diversity, gender equality, non toxicity, factual faithfulness, etc. as far as these properties can be detected by a (trained or hand-crafted) discriminator. But of course, the same technique could be used for malicious purposes, such as constraining generation so it produces offensive texts, targeted fake news, etc. In such cases of misuse, discriminators similar to those used for constraining the generation could easily spot such texts since the constraint will, by design, be noticeable and easily grasped by a discriminator.

Even though training language models on curated data in the first place is possible, totally curated dataset is hard to obtain, and new biases may be highlighted. Indeed, defining a priori what is every possible bias in every cultural context for every possible application, and curating the training data accordingly is hardly feasible. Hence, constant updates of language models will be necessary to make them as fair as possible. Given the cost of large language models training, updating them often is really harmful for the environment. Discriminator guided constrained generation offers a way to filter text generation using up-to-date standards in terms of fairness by only updating the discriminator, which is faster and require way less resources.

A Appendix

In this technical appendix, we provide additional information about our methods, some settings and the experiments. Further experimental results, as well as examples, are given and discussed. Finally, a discussion on concurrent studies is provided.

A.1 Data splits

We adapted the way we split the dataset into two parts and train/test/validation sets depending on the original dataset splits. Amazon_polarity is composed of a training set of 3 600 000 examples and a test set of 400 000. We split both into two parts and kept 20% of each training set for validation. Emotion already comes with train, test and validation set, hence we just split each into two parts. Finally, CLS is composed of a train set and a test set of 6000 examples. We split the training set in two and split the test set twice so we got two validation and test sets. Thus, for each dataset, we end up with two training sets, two validation sets and two test sets.

The first train and validation sets are used to train and control the training of models used for the generation: the guiding classifier, the "vanilla" LM and the CC-LM. The test set serves to control their performance.

The second ones are used to train the LM oracle and the classifier used to measure the accuracy. The test set allows to verify that these models are trustworthy for accurate evaluation. Once all the models are trained, the constrained generation is evaluated on 900 samples generated from prompts never seen by models during training.

A.2 Complementary results

We tested three temperature values for each proposed method: 1.0, 1.1 and 1.2. As the temperature increases, the output distribution of the language model becomes more and more uniform. This means that high temperatures should result in high perplexities because the sampling deviates further from the original distribution.

For PPL-MCTS, we also studied the impact of c_{puct} by testing values 1.0, 3.0, 5.0 and 8.0 along with the different temperature values mentioned. c_{puct} defines the compromise between exploiting nodes that already have great scores and exploring less played but promising ones. A high c_{puct} encourages exploration. We remind that the repetition penalty I in Eqn. 2 has been set to 1.2 as defined in CTRL.

In Section 'Results', for each method and dataset, we reported only the results obtained with the set of parameter values yielding the best accuracy. Hereafter, we report results with every tested set of parameters in Tables 3, 4 and 5 for respectively the emotion, CLS and amazon_polarity datasets.

Unsurprisingly, the perplexity of methods which sample on the LM logits explodes when τ increases, without a noticeable gain in accuracy. Since the diversity is already high for low τ values, it seems to be better to keep the temperature low with these approaches. Note that the couple $c_{puct} = 3, \tau = 1.0$ for PPL-MCTS always leads to the best result. Using $c_{puct} = 8$ seems to yield slightly worse results, especially with a low temperature. However, the different parameters do not greatly affect the results of PPL-MCTS.

A.3 Examples of generation

We provide an example of generation for amazon_polarity and emotion datasets using PPL-MCTS, PPLM, GeDi and Sampling - Argmax methods, respectively in Figures 5 and 6. Texts generated using Sampling - Argmax are rather different as suggested by the reported high perplexity results. Note that emotion texts are only one sentence while those of amazon_polarity are complete reviews. This difference motivated the choice of these datasets. Also, we preferred amazon_polarity over IMDb used in the GeDi and PPLM papers because of its bigger size, suitable format and because a French equivalent is available (CLS), which allows us to test another language with a similar dataset.

A.4 Constraint strength through α

As described in the model improvements section, a parameter α can be defined to control the relative importance of the discriminator score and the language model likelihood. Thus, this parameter allows to control the constraint application strength as it helps to define a trade-off between staying close the original LM and satisfying the constraint. Note that in all of our experiments reported earlier, this parameter has been set to 1, focusing on the constraint application since the proposed methods already inherently provide legible texts.

Here, as a proof of concept, we test a range of values for α, using the Sampling - Argmax method on the amazon_polarity dataset with the automatic

PPL-MCTS
<|startoftext|> realistic account [SEP] ive read this book and i think it is a very good account of the life of a young man. i would recommend to anyone who likes to know about the lives of people in america, or any other country that has been around for centuries.<|endoftext|>

PPLM
<|startoftext|> realistic account [SEP] I enjoyed this book. It was realistic and I enjoyed the way the author described the people and places. I would recommend this book to anyone who is interested in the history of the United States.<|endoftext|>

GeDi
<|startoftext|> realistic account [SEP] This is a real book. It's not just about the war, but also about the people who fought it. The author has a very realistic view of what happened in Vietnam and how it affected our country. I would recommend this book to anyone interested in learning more about Vietnam or any other war that took place during that time period<|endoftext|>

Sampling - Argmax
<|startoftext|> realistic account [SEP] ive seen many of these. they mostly in the 20's, 30's and 40's and the luscious ones i know - men like this - there's an old saying that farts, u makin' u sell it..this movie has a lot of realism to it too! and i was totally impressed on how good the kids and the predator was! will it be hard for them to make more like this? i think it will! i read that war is going to be much<|endoftext|>

Figure 5: Examples of constrained generation using PPL-MCTS, PPLM, GeDi and Sampling - Argmax methods (from top to bottom) on the positive class of amazon_polarity, using the same prompt (in bold).

PPL-MCTS
<|startoftext|> i feel that working with a group of people who are so passionate about the same thing is really important<|endoftext|>

PPLM
<|startoftext|> i feel that working hard and caring for someone i don t care for is a lot less selfish than i would be feeling for someone i<|endoftext|>

GeDi
<|startoftext|> i feel that working with the ladies of the family is a wonderful thing and i am very fond of the way they look and feel<|endoftext|>

Sampling - Argmax
<|startoftext|> i feel that working at imgur for so many years is ill be devoted to it<|endoftext|>

Figure 6: Examples of constrained generation using PPL-MCTS, PPLM, GeDi and Sampling - Argmax methods (from top to bottom) on the 'love' class form 'emotion', using the same prompt (in bold).

metrics. We chose this method and dataset since it yields the best accuracy, but also exhibits a very high perplexity. In this case, it seems interesting to trade a bit of accuracy for better written texts.

Results are roughly constant when α is lower than 0.98, so it has an impact only for values between 0.98 and 1. This is due to the fact that, for a long enough sequence, $p_\theta(x)$ is often relatively small compared to $p_D(c \mid x)$. This difference of scale annihilates the influence of α. This [0.98-1] interval thus corresponds to values of α that rescale $p_D(c \mid x)^\alpha$ and $p_\theta(x)^{1-\alpha}$ on a same order of magnitude. As shown in Figure 7, within this regime, we can observe a linear dependency between α and the accuracy as well as the perplexity. This illustrate that a trade-off can be obtained by tuning this parameter, allowing to define the strength of the constraint application which also defines how far the generation can be from the original LM distribution.

et al., 2021; Scialom et al., 2021). While we emphasize that these are concurrent studies, PPL-MCTS has some major differences. Indeed, these studies focus on improving the overall quality of generated texts rather than following a given constraint. While "being well written" can be seen as a constraint, PPL-MCTS rather explores how a constraint that is not present in the original language model (i.e. not a goal in the original training of the LM) can be added at generation time. Scialom et al. (2021) train a discriminator to distinguish generated and real samples because their goal is ultimately to train the language model in a Generative Adversarial setup to create a better LM. This iterative training, in addition to not being possible in our task, is not wanted since we aim to be plug and play. Our goal is indeed to apply an additional constraint to an untouched original language model. Yet, even if goals are different and applying MCTS for constrained generation is not trivial, the "MLE

Coop-MCTS" is close to PPL-MCTS. However, focusing on MCTS as a decoding only strategy allowed an in-depth study that provided interesting results, in particular the effect of the roll-out size (the roll-out is totally omitted in their paper) and the α parameter.

On the other hand, Leblond et al. (2021) also focus on MCTS as a decoding strategy but for the very specific case of machine translation. MCTS is used to optimize metrics for machine translation, which are known to not necessarily correlate with human judgement (Novikova et al., 2017). Again, the goal is different since these metrics are used as a proxy of the sample quality. In contrast, our work shows that MCTS can be used to optimize a given property, but instead of optimizing the quality of samples, we optimize for a given constraint while retaining the original quality of writing. The fact that MCTS also works in such cases was non trivial since adding such constraints to the generation could lead to deteriorate texts.

Beside MCTS, we also proposed and explored simpler methods based on re-ranking for our task and showed that diversity allows to satisfy the constraint, often at the price of a lower quality, emphasizing the compromise between exploration and exploitation made by the MCTS.

Finally, these concurrent studies provide evidences that MCTS is promising for many different usage in NLP. We hope that the large amount of experiments, parameter analysis and the availability of our open-sourced code working out-of-the-box will help foster future research in this direction.

Interpretable Proof Generation via Iterative Backward Reasoning

Abstract

We present IBR, an Iterative Backward Reasoning model to solve the proof generation tasks on rule-based Question Answering (QA), where models are required to reason over a series of textual rules and facts to find out the related proof path and derive the final answer. We handle the limitations of existed works in two folds: 1) enhance the interpretability of reasoning procedures with detailed tracking, by predicting nodes and edges in the proof path iteratively backward from the question; 2) promote the efficiency and accuracy via reasoning on the elaborate representations of nodes and history paths, without any intermediate texts that may introduce external noise during proof generation. There are three main modules in IBR, *QA and proof strategy prediction* to obtain the answer and offer guidance for the following procedure; *parent node prediction* to determine a node in the existing proof that a new child node will link to; *child node prediction* to find out which new node will be added to the proof. Experiments on both synthetic and paraphrased datasets demonstrate that IBR has better in-domain performance as well as cross-domain transferability than several strong baselines. Our code and models are available at `https://github.com/find-knowledge/IBR`.

1 Introduction

Endowing machines with reasoning capabilities is a longstanding problem (Newell and Simon, 1956) in the field of AI. Though existing tasks such as multi-hop QA (Yang et al., 2018; Welbl et al., 2018) or logical-reasoning QA (Yu et al., 2020; Dua et al., 2019) impose a higher requirement on the reasoning capabilities, they usually just request for an answer without the reasoning procedure that would make it interpretable. Recently, Clark et al. (2020) proposed new datasets and tasks for interpretable

Figure 1: Illustration of generating proof iteratively. Regarding the proof path as a graph, and using the question as the initial node, other nodes and edges will be added step by step. (The gold proof is the obtained path in a reverse order exclude the question). The main challenges are wrong (cannot derive the answer) or redundant (can derive the answer, but the path is longer than the optimal one) branches may be involved.

reasoning. Given a question, coupling with a set of facts (plain statements) and rules (implication relationships) that are expressed in natural language, there are two tasks: 1) predicting the binary answer; 2) generating the proof path behind this answer. Large-scale pretrained models have shown strong performance on the first subtask in the early work (Liu et al., 2019), but there still remain challenges for the second one. These proof paths are usually more complicated than those involved in multi-hop QA tasks, as there are more nodes and branches rather than a single-directed chain.

Several approaches have been proposed to simultaneously address the two subtasks. PROVER (Saha et al., 2020) and PROBR (Sun et al., 2021) try to construct the reasoning path at once, where two classifiers are used to determine whether each node or edge is involved in the proof path respectively based on corresponding encoded

representations. But they lack interpretability on tracking the detailed reason for selecting each step. To make proof generation more interpretable, Proofwriter (Tafjord et al., 2021) and EVR (Liang et al., 2021) decompose complex reasoning over the question into multiple simple procedures, resulting in iterative and interpretable processes with the help of intermediate texts. Nevertheless, both of them suffer from efficiency and external errors issues. The reason is that they both require a large searching space, as they perform on the whole inferable texts and ignore the structure information from the history path that has been obtained. Moreover, the generation of intermediate text is costly and may introduce extra noise propagation.

Inspired by the top-down AMR parsing (Cai and Lam, 2019), where a sentence is divided into sub-meanings iteratively, we present **I**terative **B**ackward **R**easoning (IBR) for better proof generation. It generates a proof path iteratively starting from the core component for QA, i.e. the question, making the process interpretable with trackable intermediate states. Regarding a higher efficiency and accuracy, and two challenges mentioned in Figure 1, the proof generation module of IBR simplifies the intermediate process of reasoning as well as avoids the unnecessary search for a possible unsuitable branch. To add a new node and edge to the path, there are two steps in IBR for each iteration: 1) finding out the next parent node, i.e. one existing rule or fact in the parsed history path that a new node will become its child; 2) determine which rule or fact that will be the new child node and added to the path. Equipped with question-aware representations from a pre-trained encoder, along with structure-aware node and path features, our model can choose the optimal endpoint. It accomplishes reasoning with the highest possibility to obtain a correct subsequent proof path based on relevant features, getting rid of intermediate texts while avoiding redundancy on all possible texts than previous iterative works.

In addition, to make IBR applicable for samples with incomplete proof paths, which are abandoned in the former backward iterative model EVR (Liang et al., 2021), we employ a proof strategy predictor to output a proof type. This prediction is then integrated into the later proof generation actions, making the process more controllable under different conditions.

We validate our approach on several datasets that are widely used in previous studies (i.e. DU0-DU5, Birds-Electricity, and ParaRules) spanning different settings (i.e. fully-supervised, fewer training data, and out-of-domain). Experimental results show that, compared to existing strong baselines including both non-iterative and iterative ones, IBR can achieve the best overall performance of proof generation and comparable answer prediction accuracy, along with noticeable generalization capability. Extensive analyses show that 1) the improvements come from our elaborately designed iterative and simplified proof generation modules, and 2) both the reasoning ability and latency could be significantly improved compared to former iterative models, making a better trade-off considering its reasonable interpretability.

2 Related Work

Question answering and reasoning. Endowing machines to do reasoning over explicit knowledge is a primitive task (Newell and Simon, 1956). Early works tried to solve it by converting texts into logic forms (Newell and Simon, 1956; Musen and Lei, 1988). But such kinds of approaches can be affected by the error propagation caused by semantic parsing (Zettlemoyer and Collins, 2012; Berant et al., 2013; Berant and Liang, 2014).

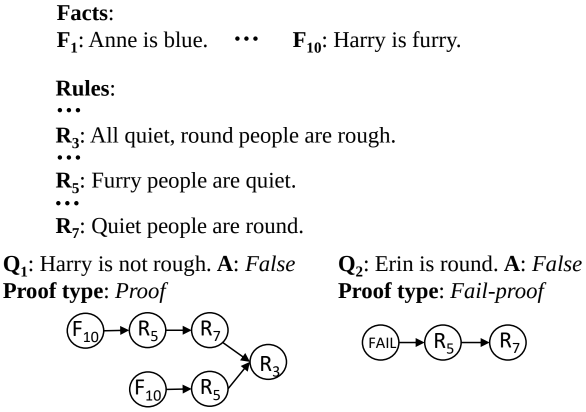
Lately, question answering (QA) is employed as an important task for machine reasoning. Numerous datasets were proposed, including synthesized data (Weston et al., 2016), comprehension on natural texts (Rajpurkar et al., 2016; Joshi et al., 2017; Fisch et al., 2019) or more complex relationship reasoning (Tafjord et al., 2019; Lin et al., 2019). There are also multi-hop QA tasks like HotpotQA (Yang et al., 2018) or QAngaroo (Welbl et al., 2018), and logical QA datasets such as ReClor (Yu et al., 2020) and LogiQA (Liu et al., 2020), in which textual rules need to be inferred implicitly from a long supporting context. Plenty of studies try to solve these problems via neural networks and achieve remarkable performance (Joshi et al., 2020; Yu et al., 2018; Shao et al., 2020). Nevertheless, nearly all of them only focus on the prediction of final answers and neglect the acquisition of interpretable proofs. Although some datasets provide proof paths for better interpretability, these paths are only short chains with very few entities and cannot teach models to generate complex proofs.

Proof generation. NLProlog (Weber et al., 2019) first employs logic programming to search for a proof and then predicts the answer in multi-hop QA. Recently, Clark et al. (2020) propose new rule-based QA datasets for this line of research that include more complex proof paths, and present RuleTaker to answer questions. Saha et al. (2020) argue that producing answer proofs makes models more reliable and propose PROVER, a transformer-based model that enumerates all possible nodes and edges of a proof path and predicts whether each one exists at once based on their embeddings. PROBR (Sun et al., 2021) further improves this framework using the probabilistic graph to model more variables. There has been also an increasing interest in solving proof generation iteratively. EVR (Liang et al., 2021) splits the question into sub-questions, using generated intermediate texts to guide proof generation step by step. ProofWriter (Tafjord et al., 2021) shares a similar idea but uses intermediate textual conclusions instead and a more powerful T5-11B model (Raffel et al., 2020) for generation, which makes it hard to reproduce. IBR is also an iterative model, being more interpretable than at-once models. Despite getting rid of intermediate texts and directly using various representations to finish each step, it improves efficiency and effectiveness.

3 Methodology

3.1 Task Definition

We first formulate the proof generation task as follows. Given a tuple (C, Q, A, P), where $C = \{RF_i\}$ is the contexts containing several textual rules and facts RF, Q is the question, $A \in \{$*True*, *False*$\}$ is the answer, and P indicates the proof path for the detailed reasoning procedure to derive A, our goal is twofold: 1) predicting the answer A, and 2) generating the proof path P. Taking **DU0-DU5** (Clark et al., 2020) dataset as example, P is a single-directed acyclic graph having the shortest path to derive A. P can start from one or multiple nodes but must end in one node that directly entails or contradicts Q. A node in P can be a fact, a rule, or a special NAF (Negation As Failure) node[1]. Edges between nodes indicate that the start nodes can be used to prove the end nodes during reasoning. Proofs in the dataset can be roughly classified into two types according to their **strategies** S to prove the question: (1)*Proof*: the question can be directly proven to be True or False using the given C and NAF; (2) *Fail-Proof*: the question cannot be explicitly deduced barely using C and NAF as some key information is missed, hence a positive statement is judged as **False** while a negative statement as **True** in such cases (Figure 2).



Facts:
F$_1$: Anne is blue. ⋯ **F$_{10}$**: Harry is furry.

Rules:
⋯
R$_3$: All quiet, round people are rough.
⋯
R$_5$: Furry people are quiet.
⋯
R$_7$: Quiet people are round.

Q$_1$: Harry is not rough. **A**: *False*
Proof type: *Proof*

Q$_2$: Erin is round. **A**: *False*
Proof type: *Fail-proof*

Figure 2: Examples of *Proof* and *Fail-proof* strategies.

3.2 Overview

The proposed Iterative Backward Reasoning (IBR) model takes Q as the initial node and produce a proof path P backward, from the end node to the start node. Two actions are included at each iteration: (1) **Predicting the new parent node**, i.e. a node in the derived proof path where a child node will be added (except the first step that only Q exists); (2) **Predicting the child node**, i.e. the fact or rule in C that will be the child for the selected parent node. After each iteration, a new node and an associated edge are added. After obtaining the whole reasoning path, we remove Q and reverse all edges to get the final proof P.

The Figure 3 illustrates our IBR model, which can be divided into three modules, (1) **QA and Strategy Prediction**, (2) **Parent Node Prediction**, and (3) **Child Node Prediction**. In order to make the question Q can fully interact with context C (facts and rules) and obtain better representations, IBR uses pretrained RoBERTa (Liu et al., 2019) as the backbone network. The input of RoBERTa is the concatenation of the question Q and the context $C = \{RF_i\}$, separated by special $[SEP]$ token, denoted as $[CLS]\ Q\ [SEP]\ [SEP]\ C\ [SEP]$.

IBR only uses the QA prediction and strategy prediction modules once at first to predict the answer A and the strategy of the proof (refer to §3.1, where the latter one will result in different proof

---

[1] A start node when the negation condition in the next node has no corresponding fact nor rule node, and the negation will be considered as true. E.g., there is no item in C related to "*Anne is big*", its negation "*Anne is not big*" will be considered as true.

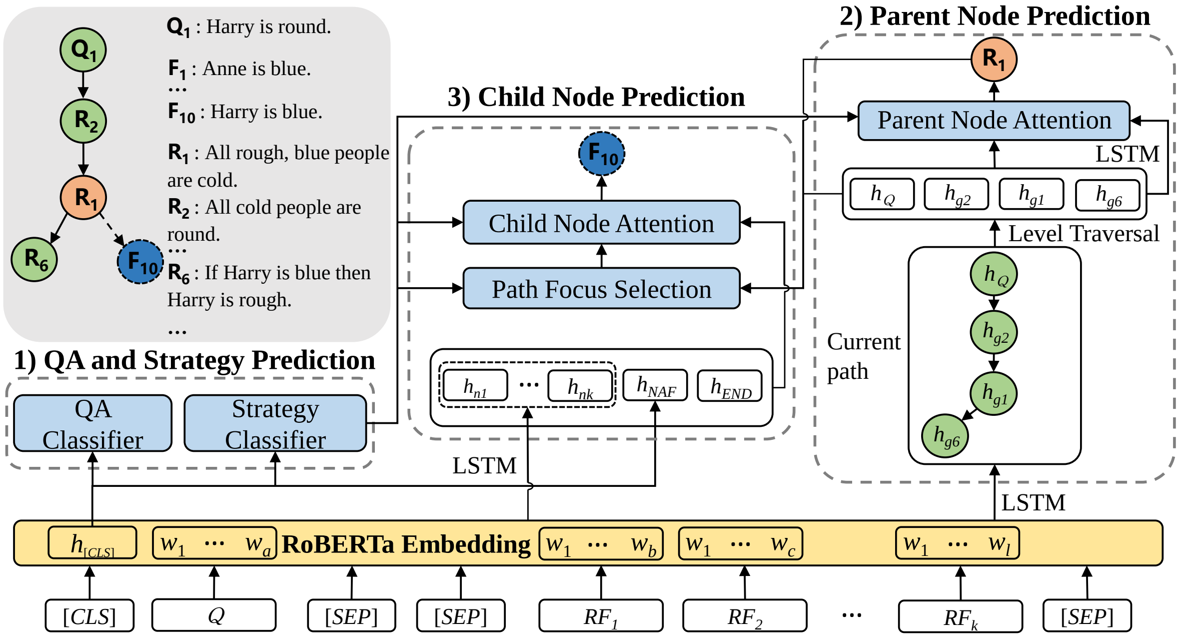


Figure 3: The model architecture of IBR. 1) is only used once at the start, then 2) and 3) are applied iteratively to generate the whole proof. It also illustrates the detailed state when adding F_{10} into the proof (F: facts, R: rules).

generation procedures. In order to improve the reasoning efficiency as well as accuracy, instead of using generated intermediate texts (Liang et al., 2021; Tafjord et al., 2021), all possible nodes (rules and facts) are represented by node embeddings in IBR. The initial state of the proof is only the representation of the question h_Q, then the rest of the reasoning path will be constructed based on it.

Samples with *Fail-Proof* strategy differs from ones with *Proof*, because their proofs are usually short without sub-branches, and only consist of rules due to lacking essential supporting facts. To take the advantage of such a property distinction and extend the applicability compared to former models (Liang et al., 2021) that cannot generate proofs for *Fail-Proof* samples, we apply different actions in modules (2) and (3) depending on the output from strategy prediction.

3.3 QA and Strategy Prediction Module

This module aims to predict the answer A of the question Q and the corresponding strategy S of proof P. Since the representation of $[CLS]$ token from pretrained models is proven to have the capability of modeling the whole input, we use it as the input feature for both predictions as they condition the global information. The encoded $[CLS]$ by RoBERTa, $h_{[CLS]}$ is passed to a linear layer and the softmax function σ for answer and strategy classification respectively,

$$P_{QA} = \sigma(f_{QA}(h_{[CLS]})),$$

$$P_{Strategy} = \sigma(f_{Strategy}(h_{[CLS]})).$$

Here, f_{QA} and $f_{Strategy}$ indicate the linear layer for QA classification and strategy classification, respectively. P_{QA} and $P_{Strategy}$ are binary-class probability values, the former one is for values of $A \in \{True, False\}$ while the later one is for values of $S \in \{\textit{Proof}, \textit{Fail-proof}\}$.

3.4 Parent Node Prediction Module

This module determines which node in the current reasoning path is going to be the next parent node that a new child node will link to. To better represent the sequential information of each possible node (fact or rule), an LSTM (Hochreiter and Schmidhuber, 1997) is used to further encode the token-level embedding from RoBERTa. The hidden state in the last step is used as the textual representation h_{gi} of a possible parent node RF_i.

In addition, selecting a node from the existing proof path also needs global and structural modeling on the history path. To make this procedure a more convenient representation that involves the order of reasoning, the path is regarded as a tree structure and nodes are reordered by level traversal from top to down. Since Q is always the root node of the tree, e.g., if Q have two children RF_1 and RF_3, and RF_1 has a child RF_2, the reordered representation sequence is $[h_Q, h_{g1}, h_{g3}, h_{g2}]$. We then utilize another LSTM model to encode the reordered representation sequence of the current reasoning path obtained before, extracting the overall state of the path, which is the hidden state h_g at the last time step in this LSTM.

A parent node attention based on the Transformer attention (Vaswani et al., 2017) is used to obtain the weights of all possible parents nodes. It takes h_g and the representation sequence of the current path $\mathbf{H}_p = [h_Q, h_{g1} \dots h_{gt}]$ as input, i.e.

$$\mathrm{Att}(h_g, \mathbf{H}_p) = \sigma(f_Q(h_g)(f_K(\mathbf{H}_p))^T/\sqrt{d}), \quad (1)$$

where f_Q and f_K indicate linear layers, σ is a softmax function, and d is the dimension of h_g. As we discussed in §3.2, different operations are employed for corresponding strategy types of proofs. 1) If the predicted proof strategy is *Proof*, we select the node with the highest weight as the parent node RF_p. 2) If the predicted proof strategy is *Fail-proof*, we use the last node in the current path, i.e. h_{gt} in $\mathbf{H}_P$, as the parent node RF_p, because no sub-branch is included in such proof paths.

3.5 Child Node Prediction Module

This module decides which node will be added to the proof path and linked to the parent node RF_p we have obtained before. To derive the representations of candidate child nodes, similar to §3.4, we apply another LSTM model to the encoded RoBERTa embeddings and get h_{n_i} for RF_i. Since we discussed a special NAF node in §3.1 which may contain information from the whole context, we utilize a linear layer f_{NAF} to transform the $[CLS]$ token embedding $h_{[CLS]}$ into its representation h_{NAF}. Moreover, we initialize a representation h_{END} for the special END node, indicating that the proof generation process will finish here.

During selecting the new child node, we need to consider not only the knowledge of the history path, but also the state of the parent node. To better model such relationships, we propose a **Path Focus Selection** module to generate relevant features before predicting the child node. A 2-layer Transformer model along with a LSTM model is introduced. It first encodes the representations of node sequence $\mathbf{H}_p$ from Parent Node Prediction respectively, then fuses their hidden state via a linear layer f_U,

$$h_F = f_U([\mathrm{Trans}(h_{gp}, \mathbf{H}_p, \mathbf{H}_p); \mathrm{LSTM}(\mathbf{H}_p)]). \quad (2)$$

Here, h_{gp} is the representation of the selected parent node in §3.4, f_U is the linear layer for feature fusing, while $[\cdot;\cdot]$ stands for concatenation. q, k, v in $\mathrm{Trans}(q, k, v)$ indicate the inputs corresponding to Query, Key, and Value in a transformer model, and only the hidden state in the last time step is remained in both Trans and LSTM. It is worth noting that the LSTM used here is a supplementary knowledge source for a better representation according to our empirical study. Such an operation results in a feature h_F that is aware of both the history proof path and the parent node that a child will link to.

This feature h_F will then be used in the Child Node Attention to calculate the attention weights on all possible child nodes. Particularly, an attention model same as Eq. 1 is applied on h_F and a series of child node representations obtained before $\mathbf{H}_c = [h_{n1} \dots h_{nk}, h_{NAF}, h_{END}]$, and the attention weights are defined as $\mathrm{Att}(h_F, \mathbf{H}_c)$. It contains all facts and rules in the context, and the special NAF node as well as END node.

Similar to §3.4, we also apply different actions according to our predicted proof strategies before.
(1) If the strategy is *Proof*, we select the child node with the highest attention weight from all candidates as the new node in the proof path.
(2) If the strategy is *Fail-proof*, since RF_p is the last node during reasoning and this procedure is a first-order logical under such a situation, there is no need to make complex modeling on the derived path. Therefore, we directly use its parent node representation h_{gp} rather than encoded state from Transformer in Eq. 2 to get h_F. But LSTM is remained to maintain some basic modeling capability on the path. In child node attention, we mask all fact nodes and select the one with the highest weight among the remaining nodes, because this kind of proof usually only contains rules and such masking can avoid extra errors.

3.6 Training and Inference

The whole model is trained via binary cross-entropy losses from all three above modules jointly,

$$L = L_{QA} + L_{Parent} + L_{Child} + \alpha * L_{Strategy}.$$

L_{QA} and $L_{Strategy}$ correspond to the loss of QA prediction and strategy prediction, respectively. α is a hyperparameter to reweigh the influence of [*CLS*] token. L_{Parent} is the loss for parent node prediction, where the cross-entropy is calculated between the attention weight vector and a one-hot vector indicating the gold parent node. L_{Child} is in a similar way on child node prediction. Note that samples labeled as *Fail-proof* strategy are not involved in the training of parent node prediction. As all their proof paths are chains and the new parent node is always the last node added to the path, so learning about these data may introduce model bias. To determine the gold reasoning order used as the target for training, we set a higher priority of fact nodes than rule nodes, as the clearer subject information is involved in facts. E.g., for a parent node with multiple children, the gold reasoning order of child node prediction is NAF nodes first, then fact nodes, and finally rule nodes. If there are more than one fact or rule nodes, IBR randomly swaps their order within each type at different training epochs.

During inference, IBR first makes predictions on the answer A and strategy S, then generate the parent node and child node iteratively, until the special END node is predicted as the new child node. IBR uses beam search to keep the top-K best proof paths at each proof generation step and select the best one as the final prediction, where the beam size is set as 8.

4 Experiments

Following former studies (Saha et al., 2020; Sun et al., 2021), we evaluate our IBR[2] on three datasets and four settings including fully-supervised training, training using fewer samples, testing on out-of-domain samples, and generalization to more complex proofs or language.

4.1 Setup

Datasets. Experiments are conducted on three datasets raised by Clark et al. (2020)[3], where we use the same test split as previous works for fair comparison:

- **DU0-DU5**: Five synthesized datasets created by translating hand-crafted rules and formal language to natural language. It is divided by the highest depth of proof, where DU stands for "Depth Upto" (DU=0,1,2,3,5). Data in higher DU values also contain samples with lower depth. Note that proofs in DU0 only have one supporting or opposing fact. All related results are reported on DU5 test split.
- **Bird-Electricity**: It is a test-only dataset that contains samples about birds and electric circuits. It is generated in the same way as DU0-DU5, but is in different domains from DU0-DU5.
- **ParaRules**: This dataset consists of 40k questions expressed in paraphrased natural language based on synthetic data, which is created by crowdsourcing. Multiple facts get together in one statement here rather than separated in DU0-DU5.

Baselines. We consider the following baselines[4].

- **RuleTaker (RT)** (Clark et al., 2020): a RoBERTa based model that only predicts answers.
- **PROVER (PV)** (Saha et al., 2020): a method that treats the proof as a graph and predicts all its nodes and edges at once, also using RoBERTa model as the backbone, same as IBR.
- **PROBR (PB)** (Sun et al., 2021): it improves PROVER by introducing the probabilistic graph that jointly considers the answer, nodes and edges.
- **EVR** (Liang et al., 2021): an iterative model that predicts the next proof item by generating textual sub-questions based on logical operator. Note that this model is **not applicable** for samples whose **proof strategy is *Fail-proof*** discussed in §3.1, so we make comparison with it separately.

Metrics. We closely follow previous works to evaluate the performance of models via answer prediction (QA) accuracy and proof generation (PA) accuracy. Since some samples may have multiple gold proofs, a generated proof will be considered correct, as long as its nodes and edges match with the nodes and the edges in any of the gold proofs. Full Accuracy (FA) is also included, where a sample is regarded as correct only both the predicted answer and proof are correct.

4.2 Results under Fully-Supervised Training

We train IBR on the training split of the DU5 dataset and evaluate on the test split of DU5. We compare the performance of IBR with baselines except for EVR in Table 1, while with EVR in Table 2 where only partial test split is included, excluding samples whose proof strategy is *Fail-proof*. Because EVR always fails on these samples (EVR on these excluded samples is given in Appendix A.5).

Obviously, IBR achieves the best proof generation accuracy (PA) as well as full accuracy (FA) among all baseline models, on samples with every depth. Our model also shows a greater advantage on samples with deeper proof path, e.g., 81.7 vs.

---

72.2 on PA when depth is 5, illustrating the superiority of iterative models on complex proof paths. Besides, despite not being the best in answer accuracy (QA), there is a very narrow gap between our model and the best one, which proves that IBR is still a comprehensive model covering both subtasks. When compared to EVR, also an iterative model, IBR shows significantly stronger performance on all metrics, benefiting from our elaborate two-fold reasoning process at each step.

4.3 Using Fewer Training Samples

We also explore the performance of IBR when training using fewer data, ranging from 10k to 30k to all the examples (70k) in DU5. The comparison between our model, PROVER (PV), and PROBR (PB) is shown in Table 3, in all three metrics. Our model significantly has the best proof generation performance than the other two baselines in all cases, due to the iterative architecture requiring less global modeling capability and thus fewer training samples. Although PB shows a promising answer prediction accuracy under fewer-data settings, the performance of IBR is close to it while better than PV, e.g., 94.3 vs. 87.1 under 10k. In addition, in Table 4, we also compare with EVR under the same settings but using a different test set that excludes *Fail-proof* samples. EVR outperforms IBR under the 10k setting for proof generation, but IBR is stronger if more training samples are available.

Data	**QA**			**PA**			**FA**		
	PV	PB	**IBR**	PV	PB	**IBR**	PV	PB	**IBR**
70k	99.3	**99.9**	99.4	87.1	88.8	**93.5**	87.1	88.8	**93.5**
30k	97.8	**99.9**	98.3	72.5	86.8	**89.8**	72.4	86.8	**89.7**
10k	87.1	**99.9**	94.3	44.0	72.4	**75.7**	42.7	72.3	**75.4**

Table 3: Performance comparison using fewer training samples among IBR, PROVER (PV), and PROBR (PB) on the full test split of DU5 after trained on partial DU5 samples.

Data	**QA**		**PA**		**FA**	
	EVR	**IBR**	EVR	**IBR**	EVR	**IBR**
70k	94.4	**99.5**	83.6	**92.4**	83.6	**92.3**
30k	95.7	**99.4**	84.4	**88.2**	84.4	**88.1**
10k	96.2	**97.9**	**82.8**	71.2	**82.8**	70.8

Table 4: Performance comparison using fewer training samples among EVR and IBR on partial test split of DU5 (without *Fail-proof* samples) after trained on partial DU5 samples.

4.4 Evaluation of Out-of-Domain Data

We further test the out-of-domain performance of IBR against baselines on Birds-Electricity dataset to evaluate their robustness, where B1 and B2 are two sets from the birds domain, and E1-E4 are four sets from the electricity domain. Results are shown in Table 5 and Table 6. Note that *Fail-proof* samples are still not involved in the comparison for EVR. Overall, our IBR achieves 2.5% promotion in PA while an equivalent result on QA, compared to PROVER. Despite being the best one on QA, PROBR is also defeated by IBR on both PA and FA. In addition, our model shows more improvement on the hardest E3 and E4 subsets, which further verifies its robustness. When it comes to EVR, we can find its cross-domain capability is relatively weak as it sees a significant drop in PA, and IBR is superior to it without any doubt. Because the cross-domain generation for intermediate texts is much harder, our usage of high-level node features to finished reasoning can alleviate this challenge.

4.5 Generalization Ability

Generalize to higher depths. Following the previous work (Sun et al., 2021), we test the general-

	Test	B1	B2	E1	E2	E3	E4	all
	Cnt	40	40	162	180	624	4224	5270
QA	RT	97.5	100.0	96.9	98.3	91.8	76.7	80.1

Table 8: Performance on ParaRules test set, after trained on combined D3+ParaRules training partitions, including PROVER (PV), PROBR (PB), and IBR.

ization ability of IBR by first training the model on the training splits of DU0, DU1, DU2, and DU3, then test them on the test split of DU5 with deeper proof paths respectively[5]. Results are shown in Table 7. We notice that all models suffer performance degeneration especially when the proof depth of the training set is lower, because it is hard for the model to learn complex reasoning based on simple proof paths. However, IBR still realizes the best performance in terms of PA and FA, especially on **DU3**, where it gets 4.2% PA/FA promotion to PROBR and even outperforms PROVER trained on the whole **DU5** data. These observations again prove that iterative approaches can better learn the detailed reasoning step by step, obtaining a better generalization capability than at-once models.

Generalize to complex language. We also evaluate whether IBR can be applied to samples where questions and statements are expressed in more human-like natural language. Following Clark et al. (2020), we train models on the combined training partitions of DU3 and ParaRules then test them on the ParaRules test set. To our best knowledge, it is the dataset that is closest to real-world applications. Table 8 demonstrates that our model sees a slight promotion in PA/FA while a similar accuracy as PROVER in QA, indicating that IBR still has good applicability when doing reasoning on more complicated and natural texts.

5 Analysis

5.1 Ablation Study

To explore the effects between different components in our model, we consider the following ablations: 1) IBR +Gold-Parent: given the gold parent nodes during inference to explore the accuracy of child node prediction; 2) IBR +Gold-Child: given the gold child nodes to verify the accuracy of parent node prediction; 3) *w/o* QA: removing QA task in loss to check its impact on proof generation; 4) *w/o* node LSTM: using mean pooling rather than LSTM encoding to get the representations of nodes; 5) *w/o* focus LSTM: Removing the supplementary LSTM in path focus selection.

Results on the whole DU5 test split are given in Table 9. As the numeric performance shows,

---

[5] We remove the position embedding in path focus selection to proceed to this test, see Appedix A.1 for details

Models	QA	PA	FA
IBR	99.4	93.5	93.5
IBR +Gold-Parent	99.4	95.6	95.3
IBR +Gold-Child	99.4	99.6	99.3
w/o QA	-	93.7	-
w/o node LSTM	99.5	93.2	93.2
w/o focus LSTM	99.6	92.6	92.4

Table 9: Results of ablation studies on DU5 dataset. We use IBR as the backbone.

giving either gold parent nodes or gold child nodes can benefit the performance especially the later one. This signifies that our parent node prediction achieves promising accuracy while the prediction of child nodes can be further improved. Moreover, IBR can still learn to generate proofs without supervision from answers. And LSTM encoders attribute to a better representation of both the nodes and the path that has been derived.

5.2 Latency Analysis

To demonstrate the computational efficiency of IBR, we compare the per sample inference time of IBR with EVR, also an iterative proof generation model, on the test split of DU5. Additionally, we also compare the per sample inference time of IBR with PROVER and PROBR, both at-once models. All models are tested on one `NVIDIA Tesla-V100` GPU with the same batch size and the beam size of IBR sets to 1 for a fair comparison. As shown in Figure 4, our IBR could achieve up to ×119.5 speedup compared with EVR, benefiting from our reasoning based on node and path features rather than intermediate texts. It is also noticeable that the runtime of EVR grows linearly with depth, while such an effect is slight on our model. Because EVR needs to infer on all contexts at every step, but IBR uses a simplified parent node prediction based on the derived path. Figure 5 illustrates that IBR is also faster than PROVER because PROVER has some constraints during post-processing in inference, like ensuring proof connectivity, which takes extra time.

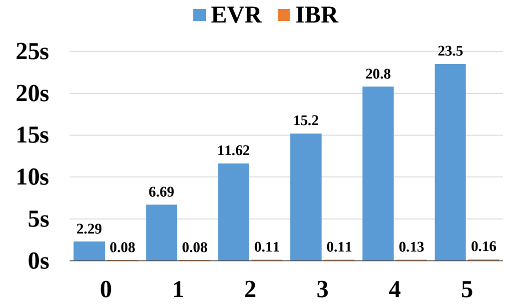

Figure 4: Per-sample inference runtime (in second) of EVR and IBR on DU5 dataset with varying depths.

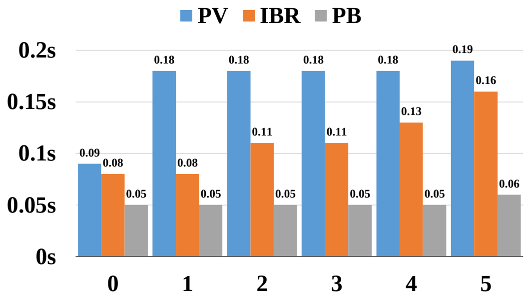

Figure 5: Per-sample inference runtime (in second) of PROVER (PV), IBR, and PROBR (PB) on DU5 dataset with varying depths.

6 Conclusion

This paper presents IBR, a proof generation model via iterative backward reasoning for rule-based QA tasks. We equip the reasoning procedure with detailed hidden state tracking by predicting nodes and edges in the proof path iteratively backward from the question, and allow the model to reason on the elaborate representations of nodes and history paths. Our model is more interpretable than previous at-once models, and is also more effective and efficient than former iterative models. Experiments also demonstrate the superiority of IBR to various baselines on proof generation under various settings.

A.1 Implementation Details

Parameter	**Value**
Training Epochs	8
Optimizer	AdamW
Batch Size	16
RoBERTa Learning rate	1e-5
QA and Strategy Pre Learning rate	1e-5
Parent Node Pre Learning rate	2e-4
Child Node Pre Learning rate	5e-4
All LSTM Learning rate	1e-3
Dropout Rate	0.1
LSTM hidden state for parent node and child node encoding	1024
LSTM hidden state for path encoding in parent node prediction	1024
Transformer hidden state in path focus selection	1024
LSTM hidden state in path focus selection	256
Seed	42

Table 10: Implementation details of IBR.

We implement our model based on PyTorch along with Huggingface-Transformers toolkit[6]. We use RoBERTa$_{\text{Large}}$ model[7] as our backbone encoder to generate token-level representations. Table 10 shows the implementation details of IBR, including learning rates for different modules. All linear layers used in our model have one layer. The model trained after 8 epochs will be used in the evaluation. We remove functional words without lexical meaning like "a" and "the" from facts, rules, and questions to shorten the input length, so each training epoch takes about 2 hours. We select these hyper-parameters according to tuning them empirically based on the performance. All experiments are run on NVIDIA Tesla-V100 GPUs. The main experiment performance of IBR fluctuates by one point.

A.2 Dataset Details

We next introduce the details of the three datasets used in our experiment. All of them are firstly applied in rule-based QA and proof generation tasks in Clark et al., 2020.

Split	D	Num	*Fail-proof* Num	*Proof* Num	Avg. Node
Train	0	21,359	14,597	6,762	0.62
	1	15,380	8,618	6,762	1.82
	2	10,112	3,350	6,762	3.37
	3	8,389	1,627	6,762	4.98
	4	7,456	694	6,762	6.90
	5	6,987	225	6,762	9.26
	all	69,683	29,111	40,572	3.35
Test	0	6,299	4,365	1,934	0.59
	1	4,434	2,500	1,934	1.77
	2	2,915	981	1,934	3.36
	3	2,396	462	1,934	4.99
	4	2,134	200	1,934	6.98
	5	2,003	69	1,934	9.47
	all	20,181	8,577	11,604	3.33

Table 11: The statistics of train and test split in DU5 dataset. *Fail-proof* and *Proof* indicate different proof strategies we discussed in §3.1. Avg. Node indicates the average node number in a proof path.

DU0-DU5: A series of synthesized datasets where rules and facts are all generated via manually designed logical programming, while questions are generated by combining random logical operations among them. Data are divided into 5 subsets according to their maximum reasoning depth (D) in the proof path, D = 0, 1, 2, 3, 5. There are 100k questions in each subset, where 70k / 10k / 20k samples in the train / validation / test partition respectively. D = 0 means that the question can be proven directly using a fact in contexts. In our experiment in §4, we only use the data from DU5 for testing because it covers all possible depths, while the train set is the train split in DU5 except §4.5, where we use train split from DU0, DU1, DU2 and DU3 for training. We provide some statistics of DU5 in Table 11.

Birds-Electricity: It is a set of data that only contains 5k test samples for the evaluation of robustness and out-of-domain performance of models. The Birds data only require reasoning up to depth 1 and 2 (B1 and B2), while Electricity data have reasoning depths ranging from 1 to 4. Both of them include new vocabulary that is not included in DU0-DU5.

ParaRules: A more challenging dataset contains paraphrased samples on the synthesized ones via crowdsourcing. It has 40k questions against about 2k theories. The statements are expressed in a more natural way, posing a discrepancy between DU0-DU5. It has 28k / 4k / 8k samples in the train / validation / test split respectively. In §4.5, we combine it with the extensive DU3 for training,

---

[6] `https://github.com/huggingface/transformers`

[7] `https://huggingface.co/roberta-large`

resulting in a train set containing 119k samples.

A.3 Possible Limitations of Our Model

Since our strategy prediction module and operations corresponding to different strategies in node prediction modules are specially designed for the current datasets, we may need to redesign some specific operations to reach the best performance, if some novel proof types are included in new datasets. But we believe our architecture will still take effect without modification. Besides, the interpretability of IBR is not so strong as former works like EVR that make use of intermediate texts.

A.4 Strategy Accuracy of IBR

D	Cnt	Strategy Accuracy
0	6299	99.9
1	4434	99.1
2	2915	99.3
3	2396	99.0
4	2134	99.2
5	2003	99.7
All	20192	99.4

Table 12: Strategy accuracy of IBR on test split of DU5 after training on training split of DU5.

We provide the strategy prediction accuracy on DU5 in Table 12. It proves that IBR is also well able to make predictions on the proof strategies. This is partly due to RoBERTa's powerful representation capability. On the other hand, there is a certain connection between the answer to the question and the strategy, and there are some common elements at the semantic representation level that can be learned together.

A.5 Performance of EVR and IBR on *Fail-proof* Samples

As we have discussed in §4.2, EVR (Liang et al., 2021) is not applicable for samples containing *Fail-proof* proofs, because it cannot obtain proper intermediate questions to proceed correct following reasoning. Here, we compare our model with EVR on these samples in DU0-DU5, as illustrated in Table 13. Although EVR can achieve promising performance on answer prediction (QA) for these samples, it cannot generate any correct proof path in such cases, which have already been discussed in its original paper.

	D	**0**	**1**	**2**	**3**	**4**	**5**	**all**
	Cnt	4365	2500	981	462	200	69	8577
QA	EVR	99.7	99.1	**98.9**	**99.1**	**98.5**	100	**99.4**
	IBR	**100**	**99.1**	98.3	97.6	96.5	**100**	99.3
PA	EVR	0.0	0.0	0.0	0.0	0.0	0.0	0.0
	IBR	**99.8**	**95.0**	**89.5**	**84.4**	**65.5**	**28.9**	**95.0**
FA	EVR	0.0	0.0	0.0	0.0	0.0	0.0	0.0
	IBR	**99.8**	**95.0**	**89.5**	**84.4**	**65.5**	**28.9**	**95.0**

Table 13: The performance of EVR and IBR on the partial test split of DU5 that only contains samples whose proofs strategies are *Fail-proof*.

A.6 Proof Generation samples

We provide some proof generation samples in Figure 6 for a better understanding of this task, where questions, all contexts, and the proof path generated by our IBR are given (all consistent with the given labels).

Rules:

R_1: If someone is nice and kind then they like the bear.

R_2: If someone sees the dog and they eat the bear then the bear is cold.

R_3: If someone is big then they eat the cat.

R_4: If someone is big then they do not see the rabbit.

R_5: If someone is not big and they do not eat the dog then the dog is cold.

R_6: If someone is cold then they like the rabbit.

R_7: If someone likes the rabbit then they see the dog.

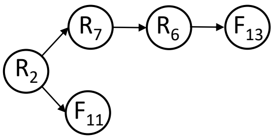
R_8: If the dog eats the cat then the dog is kind.

R_9: If someone likes the dog and they do not eat the cat then the dog eats the bear.

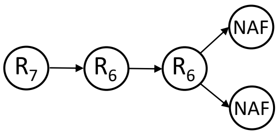
Facts:

F_1: The bear eats the cat.
F_2: The bear eats the rabbit.
F_3: The cat eats the dog.
F_4: The cat eats the rabbit.
F_5: The cat likes the bear.
F_6: The cat sees the rabbit.
F_7: The dog is round.
F_8: The dog likes the bear.
F_9: The dog likes the cat.
F_{10}: The dog sees the bear.
F_{11}: The rabbit eats the bear.
F_{12}: The rabbit is big.
F_{13}: The rabbit is cold.
F_{14}: The rabbit is not kind.
F_{15}: The rabbit does not like the cat.
F_{16}: The rabbit sees the bear.

Q_1: The bear is cold.
A_1 : True
Proof generated by IBR:
Proof Depth = 3 , Strategy: Proof



Q_2: The dog does not see the dog.
A_2: False
Proof generated by IBR:
Proof Depth = 3, Strategy: Proof



Q_3: The dog eats the bear.
A_3: False
Proof generated by IBR:
Proof Depth = 1, Strategy: Fail-proof

Figure 6: Some proof cases generated by IBR, along with all contexts and questions, including two proof strategies, *Proof* and *Fail-proof*.

Abstract

In this work, we study Unsupervised Domain Adaptation (UDA) in a challenging self-supervised approach. One of the difficulties is how to learn task discrimination in the absence of target labels. Unlike previous literature which directly aligns cross-domain distributions or leverages reverse gradient, we propose Domain Confused Contrastive Learning (DCCL) to bridge the source and the target domains via domain puzzles, and retain discriminative representations after adaptation. Technically, DCCL searches for a most domain-challenging direction and exquisitely crafts domain confused augmentations as positive pairs, then it contrastively encourages the model to pull representations towards the other domain, thus learning more stable and effective domain invariances. We also investigate whether contrastive learning necessarily helps with UDA when performing other data augmentations. Extensive experiments demonstrate that DCCL significantly outperforms baselines.

1 Introduction

Pre-trained language models (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019) have yielded considerable improvements with datasets drawing from various sources. However, the lack of portability of language model to adapt to a new textual domain remains a central issue (Gururangan et al., 2020), especially when the training set and testing set do not follow the same underlying distribution (changing of topic and genres) - usually referred to as domain shift. In this paper, we focus on studying Unsupervised Domain Adaptation (UDA). UDA aims at designing adaptation algorithms that attempt to generalize well on the target domain by learning from both labeled samples from the source domain and unlabeled samples from the target domain. Studying UDA fits real-world scenarios since labeled data in the target domain is usually absent. Moreover, advances in UDA will also help out-of-distribution generalizations (Ramponi and Plank, 2020; Krueger et al., 2021).

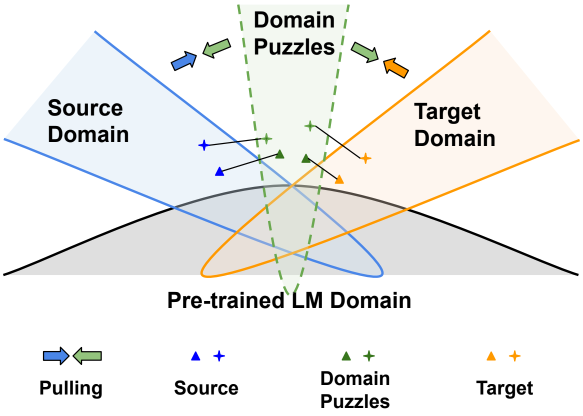

Figure 1: Domain puzzles that are domain-confused and overlook domain-related information, could be regarded as lying in an intermediate domain that aims to pull source and target samples closer to each other and bridge the two domains by learning domain invariant representations.

Extensive algorithms have been proposed to mitigate the domain shift problem, for example, domain adversarial neural network (DANN) (Ganin et al., 2016) and distribution matching (Zhuang et al., 2015). For DANN, the training process of joint optimization is unstable, requiring extensive effort to tune the hyperparameters (Shah et al., 2018; Du et al., 2020; Karouzos et al., 2021). As for distribution matching, it is very difficult to preserve the discriminative power of the model on the target task while trying to perform instance level alignment (Saito et al., 2017; Lee et al., 2019). To this end, it is essential to develop stable and effective solutions to learn domain invariance and instance-wise matching for UDA.

Recent advances in self-supervised learning (SSL), such as contrastive learning (CL), have been proven effective at instance level by leveraging raw data to define surrogate tasks that help learn repre-

sentations (Chen et al., 2020a; Khosla et al., 2020; He et al., 2020; Chen et al., 2020b). CL benefits from treating instances as classes and conducting data augmentations to generate positive instance pairs. Regarding CL for UDA, previous works mark cross-domain images with the same labels (for example, real and cartoon dogs) as the positive pairs in contrastive loss (Wang et al., 2021; Park et al., 2020). However, such methods are not applicable to NLP tasks because of the massive semantic and syntactic shifts between two cross-domain sentences. Besides, from the domain adaptation perspective, constructing cross-domain positive samples and aligning domain-agnostic pairs have received less emphasis in related literature, since previous works focus on designing label preserving text transformations, such as back-translation, synonym, dropout and their combinations (Qu et al., 2021; Gao et al., 2021).

Confronting with limitations mentioned above, we propose the concept of domain puzzles which discard domain-related information to confuse the model, making it difficult to differentiate which domain these puzzles belong to. Instead of directly seeking matched sentences across the source and target domains which is infeasible, we propose to pull the source (target) data and its corresponding domain puzzles closer to reduce the domain discrepancy, as shown in Fig. 1. A simple idea to craft domain puzzles is to mask domain-specific tokens. However, token-level operations are too discrete and non-flexible to reflect the complex semantic change of natural languages. Hence, we aim to seek better domain puzzles that retain high-confidence predictions and task-discriminative power in the representation space for each training instance.

In this paper, we propose Domain Confused Contrastive Learning (DCCL) to encourage the model to learn similar representations for the original sentence and its curated domain-confused version with contrastive loss. More specifically, we synthesize these domain puzzles by utilizing adversarial examples (Zhu et al., 2020; Jiang et al., 2020). The algorithm will search for an extreme direction that roughly points to the opposite domain and produces most domain-challenging puzzles. We encourage the model to encode original and domain-confused samples closer, gradually pulling examples to the domain decision boundary as training progresses via CL, thus learning the domain invariance. Furthermore, in order to investigate whether CL necessarily benefits UDA, we conduct experiments and find that constructing domain puzzles as paired positive samples is favorable for UDA, however, other data augmentation methods such as back translation (Sennrich et al., 2016; Edunov et al., 2018) do not have the same effect. The experiment results show that the proposed DCCL significantly outperforms all the baselines. We also conduct quantitative experiments to measure the domain discrepancy after adaptation demonstrating that DCCL can decrease the divergence between domains in a self-supervised way. Overall, the paper makes the following contributions:

- First, a new concept of domain puzzles is put forward. We propose to craft the domain puzzles via domain-confused adversarial attack;
- Second, we propose DCCL, which is able to pull source and target samples closer to the crafted domain puzzles. The DCCL is capable of reducing domain shift and learning domain invariance;
- Third, experiments demonstrate that the proposed DCCL surpasses baselines with a large margin. We also conduct analyzing experiments to verify the effectiveness.

2 Preliminaries

2.1 Unsupervised Domain Adaptation

Problem Setup Suppose we have access to a source dataset with n labeled data points $\mathcal{D}^S = \{x_i, y_i\}_{1,\ldots,n}$ sampled i.i.d. from the source domain, and a target dataset with m unlabeled points $\mathcal{D}^T = \{x_j\}_{1,\ldots,m}$ sampled i.i.d. from the target domain, where x_i, x_j are sequences of tokens, y_i is the class label for x_i. For in-domain training with labeled training instances, the model aims to learn a function $f(x; \theta_f, \theta_y) : x \to C$. θ_f is the parameter of the deep neural network encoder (e.g., pretrained language model), θ_y denotes parameters that compute the network's class label predictions, and C is the label set. The model is learned with the following objective:

$$\min_{\theta_f, \theta_y} \sum\nolimits_{(x,y)\sim\mathcal{D}^S} [\mathcal{L}(f(x; \theta_f, \theta_y), y)]. \qquad (1)$$

However, for Unsupervised Domain Adaptation (UDA), the goal of the adaptation algorithm is to learn a discriminative classifier from the source

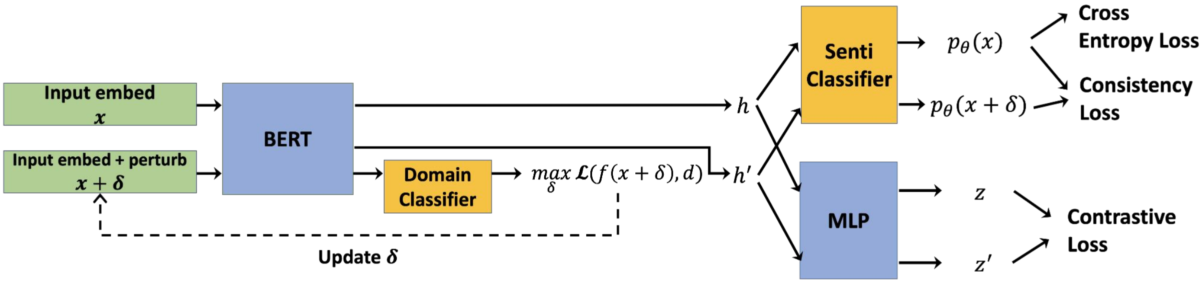

Figure 2: Overview of the framework of the proposed method DCCL.

domain, which at the same time could generalize well on the target domain by leveraging unlabeled target data and learning a mapping between source and target domains. It is generally acknowledged that the discrepancy between two datasets (domain shift) can be reduced by aligning two distributions (Ben-David et al., 2006; Ben-David et al., 2010). The methods that learn domain invariant features for domain alignment include KL divergence (Zhuang et al., 2015), Maximum Mean Discrepancy (MMD) (Gretton et al., 2012), and Domain Adversarial Neural Network (DANN) (Ganin et al., 2016) (details of DANN can be found in Appendix. B). DANN suffers from a vanishing gradient problem (Shen et al., 2018), and the training process is unstable (Shah et al., 2018; Du et al., 2020). Hence, more efficient and stable algorithms are essential for UDA (Wu et al., 2019b).

2.2 Adversarial Training

Adversarial training with perturbations has been shown to significantly improve the performance of the state-of-the-art language models for many natural language understanding tasks (Madry et al., 2018; Zhu et al., 2020; Jiang et al., 2020; Pereira et al., 2021). The algorithm generally considers adversarial attacks with perturbations to word embeddings and minimizes the resultant adversarial loss around the input samples. In a single domain, adversarial training (Goodfellow et al., 2015) is an inner max, outer min adversarial problem with the objective:

$$\min_{\theta_f,\theta_y} \sum\nolimits_{(x,y)\sim\mathcal{D}} [\max_{\delta} \mathcal{L}(f(x+\delta;\theta_f,\theta_y),y)]. \quad (2)$$

With (2), the standard adversarial training can also be regularized using virtual adversarial training (Miyato et al., 2018), which encourages smoothness in the embedding space. The α_{adv} controls the trade-off between the two losses, usually set to be 1.

$$\begin{aligned}\min_{\theta_f,\theta_y} \sum\nolimits_{(x,y)\sim\mathcal{D}} \big[&\mathcal{L}(f(x;\theta_f,\theta_y),y) + \alpha_{adv} \\ &\max_{\delta} \mathcal{L}(f(x+\delta;\theta_f,\theta_y), f(x;\theta_f,\theta_y))\big].\end{aligned} \quad (3)$$

For (2)(3), the inner maximization can be solved by Projected Gradient Decent (PGD) (Madry et al., 2018) with an additional assumption that the loss function is locally linear. A following iteration can approximate the adversarial perturbation δ:

$$\delta_{t+1} = \Pi_{\|\delta\|_F\le\epsilon}(\delta_t + \eta\frac{g_y^{adv}(\delta_t)}{\|g_y^{adv}(\delta_t)\|_F}), \quad (4)$$

$$g_y^{adv}(\delta_t) = \nabla_\delta \mathcal{L}(f(x+\delta_t;\theta_f,\theta_y),y), \quad (5)$$

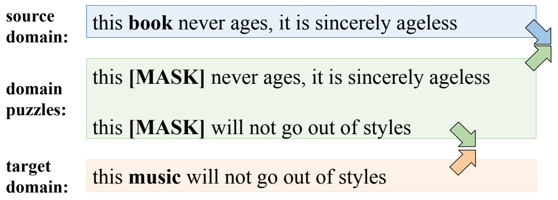
where $\Pi_{\|\delta\|_F\le\epsilon}$ performs a projection onto the ϵ-ball. The advantages of PGD lie in that it only relies on the model itself to produce diverse adversarial samples, enabling the model to generalize better to unseen data.

3 Method

In this section, we focus our discussions on the proposed Domain Confused Contrastive Learning (DCCL) under a sentiment classification scenario. The overall framework of our method is illustrated in Fig. 2. The model will take source labeled and target unlabeled sentences as input. It will then augment the input data with domain puzzles by fabricating adversarial perturbations. With the augmented data, the next step produces a hidden representation for each instance with an encoder which will be further used to produce three losses to train the entire model, namely sentiment classification loss, contrastive loss and consistency loss.

3.1 Crafting domain puzzles

For UDA, Saito et al. (2017) mentions that simply matching the distributions cannot ensure high accuracy on the target domain without the target labels.



this **book** never ages, it is sincerely ageless

this **[MASK]** never ages, it is sincerely ageless

this **[MASK]** will not go out of styles

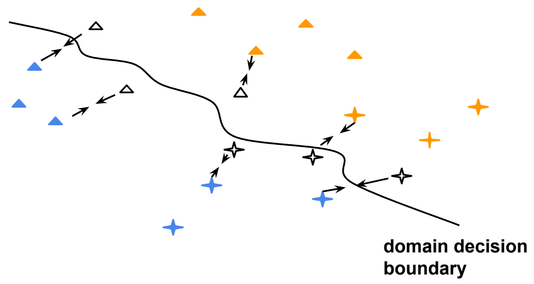
this **music** will not go out of styles

Figure 3: Two sentences sampled from Book and Music reviews. Alternatively, we can match original sentences with its degraded masked versions.

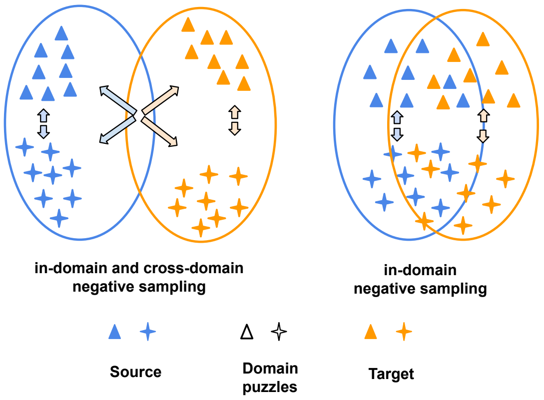
Moreover, it may cause negative transfer, deteriorating knowledge transfer from source domain to the target domain (Wang et al., 2019). Even if the matched sentences have the same label, due to huge syntactic and semantic shift, instance-based matching strategies that align examples from different domains will introduce noises for pre-trained language models, for example, aligning source domain and target domain sentences in Fig. 3.

Alternatively, we can locate and mask domain-specific tokens which are related to sentence topics and genres. Since sentences in the green box of Fig. 3 become domain-agnostic, we refer to those domain-confused sentences (one cannot tell which domain these sentences belong to) as domain puzzles. Matching distributions between the source domain and the domain puzzles, as well as the target domain and the domain puzzles, will also make language models produce domain invariant representations.

However, the domain-specific tokens are not always evident, due to the discrete nature of natural languages, it is challenging to decide correct tokens to mask without hurting the semantics especially when the sentences are complicated[1]. Hence, we seek domain puzzles in the representation space and introduce adversarial perturbations, because we can rely on the model itself to produce diverse but targeted domain puzzles. Note that the purpose of adversarial attack here is not to enhance the robustness, but to construct exquisitely produced perturbations for a better domain invariance in the representation space.



(a) Postive sampling



(b) Negative sampling

Figure 4: Proposed adaptation sampling method

To generate domain-confused augmentations, we adopt adversarial attack with perturbations for domain classification. The loss for learning a domain classifier with adversarial attack can be specified as follows:

$$\mathcal{L}_{\text{domain}} = \mathcal{L}(f(x;\theta_f,\theta_d),d) + \alpha_{adv}\,\mathcal{L}(f(x+\delta;\theta_f,\theta_d), f(x;\theta_f,\theta_d)), \qquad (6)$$

$$\delta = \Pi_{\|\delta\|_F \le \epsilon}\left(\delta_0 + \eta \frac{g_d^{adv}(\delta_0)}{\|g_d^{adv}(\delta_0)\|_F}\right), \qquad (7)$$

where δ_0 is the initialized noise, θ_d is the parameter corresponding to the computation of the domain classification, and d is the domain label. Due to additional overhead incurred during fine-tuning large pre-trained language models, the number of iterations for perturbation estimation is usually 1 (Jiang et al., 2020; Pereira et al., 2021), as shown in Eq. 7. We synthesize the perturbation δ by searching for an extreme direction that perplexes the domain classifier most in the embedding space, and $f(x+\delta;\theta_f)$ is the crafted domain puzzles encoded by the language model.

3.2 Learning invariance with domain puzzles

After acquiring domain puzzles, simply applying distribution matching will sacrifice discriminative knowledge learned from the source domain (Saito et al., 2017; Lee et al., 2019), and instance-based matching will also overlook global intra-domain information. To learn sentiment-wise discriminative

---

[1] Masking is not our focus in this paper. More detailed implementation can be found in section 4.4. We will investigate how to extract better domain tokens in our future work.

representations in the absence of the target labels, we propose to learn domain invariance via contrastive learning (CL). In general, CL benefits from the definition of the augmented positive and negative pairs by treating instances as classes (Chen et al., 2020a; Khosla et al., 2020; He et al., 2020; Chen et al., 2020b). Furthermore, the contrastive loss encourages the positive pairs to be close to each other and negative pairs to be far apart. Specifically, maximizing the similarities between positive pairs learns an invariant instance-based representation, and minimizing the similarities between negative pairs learns a uniformly distributed representation from a global view, making instances gathered near the task decision boundary away from each other (Saunshi et al., 2019; Grill et al., 2020). This will help to enhance task discrimination of the learned model.

For positive pairs, intuitively, we hope that the model could encode the original sentence and most domain-challenging examples to be closer in the representation space, gradually pulling examples to the domain decision boundary as training progresses. For negative sampling, it widens the sentiment decision boundary and promotes better sentiment-wise discriminative features for both domains. However, for cross-domain negative sampling, the contrastive loss may push the negative samples in the target (source) domain away from the anchor in the source (target) domain (see Fig. 4 (b) left). This is contradictory to the objective of domain puzzles which try to pull different domains closer. To avoid the detriment of cross-domain repulsion, excluding samples with different domains from the negative set is of great importance. Therefore, we write the following contrastive infoNCE loss (Chen et al., 2020a) as follow:

$$\mathcal{L}_{\text{contrast}} = -\frac{1}{N}\sum_{i}^{N} \log \frac{\exp(s(z_i, z_i')/\tau)}{\sum_k^N \mathbb{1}_{k\neq i}\exp(s(z_i, z_k)/\tau)}, \quad (8)$$

where N is the mini batch size with samples from the same domain, $z_i = g(f(x_i;\theta_f))$, and $g(\cdot)$ is one hidden layer projection head. We denote $x' = x + \delta$ as the domain puzzle augmentation, $s(\cdot)$ computes cosine similarity, $\mathbb{1}_{k\neq i}$ is the indicator function, and τ is the temperature hyperparameter.

Algorithm 1 DCCL

Input: For simplicity, θ is the parameter of the whole model. T: the total number of iterations, $(x, y) \sim \mathcal{D}^S$: source dataset with sentiment label y, $(x, d) \sim \mathcal{D}^S\,\mathcal{D}^D$: source and target dataset with domain label d, K: the number of iterations for updating δ, σ^2: the initialized variance, ϵ: perturbation bound, η: the step size, γ: global learning rate, N: batch size, τ: temperature, $g(\cdot)$:one hidden layer projection head. α_{adv}, α, λ and β: weighting factor.

```
for epoch $= 1, .., T$ do
    for minibatch $N$ do
        $\delta \leftarrow \mathcal{N}(0, \sigma^2 I)$
        for $m = 1, .., K$ do
            $g_d^{adv} \leftarrow \nabla_\delta \mathcal{L}(f(x + \delta; \theta), d)$
            $\delta \leftarrow \Pi_{\|\delta\|_F \leq \epsilon}(\delta + \eta g_d^{adv}/\|g_d^{adv}\|_F)$
        end for
        $\mathcal{L}_{\text{domain}} \leftarrow \mathcal{L}(f(x; \theta), d)$
                $+\alpha_{adv}\,\mathcal{L}(f(x + \delta; \theta), d)$
        $z = g(f(x; \theta))$
        $z' = g(f(x + \delta; \theta))$
        for $i = 1, ..., N$ and $j = 1, ..., N$ do
            $s_i' = z_i^\top z_j'/\|z_i\|\|z_j'\|$
            $s_{i,j} = z_i^\top z_j/\|z_i\|\|z_j\|$
        end for
        $\mathcal{L}_{\text{contrast}} \leftarrow -\frac{1}{N}\sum_i^N \log \frac{\exp(s_i'/\tau)}{\sum_j^N \mathbb{1}_{j\neq i}\exp(s_{i,j}/\tau)}$
        $\mathcal{L}_{\text{consist}} \leftarrow \mathcal{L}(f(x; \theta), f(x + \delta; \theta))$
        $g_\theta \leftarrow \nabla_\theta \mathcal{L}(f(x; \theta), y) + \alpha\nabla_\theta \mathcal{L}_{\text{domain}}$
                $+\lambda\nabla_\theta \mathcal{L}_{\text{contrast}} + \beta\nabla_\theta \mathcal{L}_{\text{consist}}$
        $\theta \leftarrow \theta - \gamma g_\theta$
    end for
end for
```

Output: θ

3.3 Consistency Regularization

Given perturbed embedding $x + \delta$, which is crafted based on domain classification, we also encourage the model to produce consistent sentiment predictions with that of the original instance $f(x; \theta_f, \theta_y)$. For this, we minimize the symmetric KL divergence, which is formulated as:

$$\mathcal{L}_{\text{consist}} = \mathcal{L}(f(x; \theta_f, \theta_y), f(x + \delta; \theta_f, \theta_y)). \quad (9)$$

For overall training objective, we train the neural network in an end-to-end manner with a weighted sum of losses as follows.

$$\min_{\theta_f,\theta_y,\theta_d} \sum_{(x,y)\sim\mathcal{D}^S} \mathcal{L}(f(x;\theta_f,\theta_y),y) + \sum_{(x,y)\sim\mathcal{D}^S,\mathcal{D}^T} [\alpha\,\mathcal{L}_{\text{domain}} + \lambda\,\mathcal{L}_{\text{contrast}} + \beta\,\mathcal{L}_{\text{consist}}]. \quad (10)$$

Details of proposed DCCL are summarized in Algorithm 1.

4 Experiments

4.1 Datasets

Amazon Benchmark (Blitzer et al., 2007)[2]. We conduct experiments on this dataset for completeness since most of previous works report results on it. The dataset contains four domains: Book (BK), DVD (D), Electronics (E) and Kitchen housewares (K). There are 2,000 balanced labeled data for each domain, we randomly select 20,000 unlabeled reviews for BK, D and E. For K, only 17,856 unlabeled reviews are available.

Amazon review dataset (He et al., 2018)[3]. This dataset considers neutral instances which may not bias the dataset and bring more challenges[4]. The dataset also contains four domains: Book (BK), Electronics (E), Beauty (BT), and Music (M). Following He et al. (2018), we treat set 1 as labeled dataset containing $6,000$ instances, and treat set 2 as unlabeled dataset which also contains $6,000$ instances. More details about two datasets can be found in Appendix A.

4.2 Experiment Settings

For unsupervised adaptation setting, we should not have access to target labeled data at the training phase, so trained models with minimum classification error on the source validation set is saved for evaluation. At this point, we suppose a good model that generalizes well on the target domain is able to reach high performance on both validation and test set at the same time. We evaluate our model with 5 runs in all experiments, and we report the average score, standard deviation and paired t-test results.

4.3 Implementation Details

For pre-trained language model, we use BERT base uncased (Devlin et al., 2019) as the basis for all experiments. The max length is set to 512. For optimizer, we use AdamW (Kingma and Ba, 2015; Loshchilov and Hutter, 2019) with weight decay 0.01 (for BERT baseline, we set 1e-4). We set the learning rate as 1e-5, and we use a linear scheduler with warm-up steps 0.1 of total training steps.

We set the number of adversarial iterations to be 1, adversarial weighting factor $\alpha_{adv} = 1$ and we use l_2 norm to compute projections. We also follow Zhu et al. (2020) to set other adversarial hyperparameters, e.g., adversarial step size η = 5e-2, perturbation bound ϵ = 5e-2. For weighting factors, we set α = 1e-3, λ = 3e-2 and β = 5. We train the model with 8 epochs, temperature τ and batch size N will be discussed later. Each adaptation requires half one hour on one A-100.

4.4 Baselines

BERT base: Fine-tune BERT on the source, without using target unlabeled data, then directly evaluate on the target labeled data. **KL**: Use symmetric KL-divergence loss of embedded instances between the source and target domains (Zhuang et al., 2015). **MMD**: Maximum Mean Discrepancy loss (Gretton et al., 2012) measures the distance based on the notion of embedding probabilities in a reproducing kernel Hilbert space. We implement a gaussian kernel which is a common choice. **DANN**: The adaptation rate is $\lambda = \frac{2}{1+\exp(-\gamma p)} - 1$, $p = \frac{t}{T}$, where t and T are the number of current training steps and total steps. γ requires careful tuning within $[0.05, 0.1, 0.15, 0.2]$. **back-trans+CL**: To investigate the effectiveness of domain puzzles, we implement Back translation (Sennrich et al., 2016; Edunov et al., 2018), which is one of the widely used data augmentation techniques. We utilize en-de translation model pre-trained on WMT19 and released in fairseq (Ott et al., 2019). The model is trained with contrastive loss on the source and target domain respectively. **mask+CL**: We mask domain specific tokens to make the augmentation become domain-agnostic. Since information extraction is not our focus, we identify domain specific tokens via a simple frequency-ratio method (Li et al., 2018; Wu et al., 2019a): $s(u,d) = \frac{\text{count}(u,\mathcal{D}^d)+\lambda}{\sum_{d'\in\mathcal{D},d'\neq d}\text{count}(u,\mathcal{D}^{d'})+\lambda}$, where $\text{count}(u,\mathcal{D}^d)$ represents the number of times a token u appears in domain d. Smoothing λ is set to 1. When $s(u,d)$ is larger than 5, we mark a token u as a domain specific token. Through counting, the number of masked tokens accounted for 0.06 of the total length. **mask**: To investigate the effectiveness of contrastive loss, after masking domain-specific tokens, we further let the model train with augmented data without contrastive loss. **R-PERL** (Ben-David et al., 2020) is a pivot-based method, and **DAAT** (Du et al., 2020) combines DANN and post-training. All the methods in Tabel 1 and Table 2 are implemented based on BERT model for fair comparisons.

---

4.5 Results

Will contrastive learning necessarily help the Unsupervised Domain Adaptation?

As discussed earlier, when performing contrastive learning on source labeled examples and target unlabeled examples respectively, it learns a uniformly distribute representation and helps promote better discriminative features for both domains. However, for some adaptation tasks in Table 1, for example, BT→E, M→E, and E→M, back-trans+CL shows that contrastive learning only gains marginal benefit. When masking domain-specific tokens and pulling original sentence representations to those domain puzzles, the effect of contrastive learning becomes more apparent (mask+CL with average score 65.17 compared with back-trans+CL 63.79 and mask 61.40 in Table.1). This finding helps to explain that choices of positive examples are critical and domain confused augmentations will further benefit adaptation.

DCCL outperforms baselines.

From Table 1 we can observe that the proposed DCCL outperforms all other methods with a large margin and $p < 0.05$ using paired t-test, and 5.94% improvement over BERT base. From Table 2, we can also observe 1.74% improvement over BERT base, and DCCL also surpasses state-of-the-art methods R-PERL (Ben-David et al., 2020) and DAAT (Du et al., 2020). We note that Amazon Benchmark dataset is quite easy, since it discards neutral instances, BERT base model has already achieved high scores on this dataset. Besides, we observe that the effect of distribution matching methods (KL and MMD) is limited on two datasets. The reason might be that pre-trained language models trained with massive and heterogeneous corpora already have strong generalization ability. Learning such cross-domain and instance-based matching will bring perplexity to language models and sacrifice task discrimination (Saito et al., 2017; Lee et al., 2019). On the contrary, the proposed DCCL retains such information in a self-supervised way. Furthermore, we notice that DANN is very unstable, besides adaptation rate λ, the model is also sensitive to other hyperparameters such as learning rate and training epochs because the performance on the target domain will keep decreasing when training with longer steps. Hence, it is difficult for the model to achieve the lowest error rates on both the source and target domains simultaneously. Compared to DANN, DCCL is much more stable and has lower standard deviations on most adaptation tasks.

Contrastive learning designs.

We explore different hyperparameter values for the

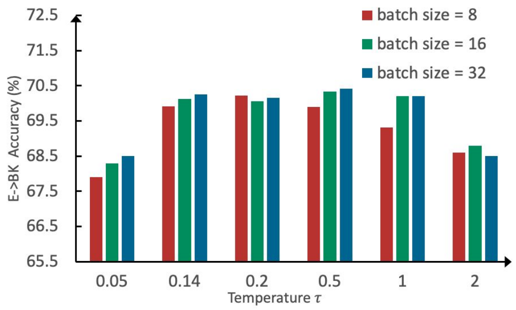

Figure 5: Hyperparameters for contrastive learning

proposed DCCL in E→BK, as is shown in Fig. 5. We find that a temperature of 0.5 combined with the batch size 32 can achieve the best performance. We also notice that setting the temperature too high or too low can significantly affect adaptation performances, while a larger batch size usually brings a relatively smaller improvement.

4.6 Ablation Studies

We conduct an ablation study on each component in Eq. 10 to inspect the contribution of contrastive learning, as is shown in Table 3. We can see that every single component can render a better adaptation performance. In particular, the effectiveness of $\mathcal{L}_{\text{contrast}}$ is observable with 3~5 performance gain compared to baselines (row 4 vs. row 2, and row 5 vs. row 3). When training curated domain puzzles as simple augmentations without contrastive loss, we can observe only a slight improvement (row 2 vs. row 1). This result demonstrates that the performance gain brought by DCCL does not come from data augmentation, and learning robustness against adversarial attacks will not largely help adaptation.

$\mathcal{L}_{\text{domain}}$	$\mathcal{L}_{\text{consist}}$	$\mathcal{L}_{\text{contrast}}$	E→BK	M→BT
			64.65	55.85
√			67.23	58.9
√	√		67.85	59.1
√		√	70.12	64.73
√	√	√	**70.21**	**64.87**

Table 3: Ablation studies of DCCL on each component

5 Analysis

5.1 Visualization

We perform visualizations for trained representations as illustrated in Fig. 6. When training with the source domain and then adapting to the target domain (BERT-base), we can observe a considerable domain shift for BERT encoder on this amazon review dataset. Moreover, as mentioned before, continuing training DANN with larger epochs will substantially drop the score (from the highest point (DANN-best) to the lowest point (DANN-worst)). However, we can also see that DCCL mitigates domain shift but remains good sentiment discrimination on the target domain.

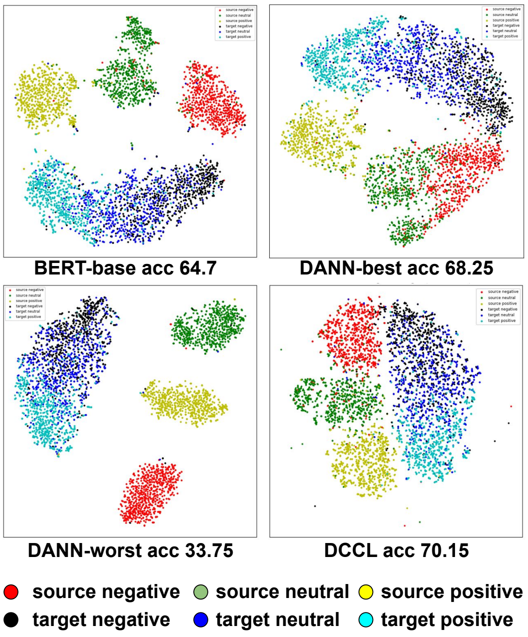

Figure 6: t-SNE visualization for E→BK task

5.2 Quantitative Results

$\mathcal{A}$-distance measures domain discrepancies (Ben-David et al., 2006; Ben-David et al., 2010), with the definition as $d_{\mathcal{A}} = 2(1 - 2\epsilon)$, where ϵ is the domain classification error. To fairly compare with $\mathcal{A}$-distance of the baselines, we use linear SVM to calculate ϵ following previous work (Saito et al., 2017; Du et al., 2020). We randomly select 2,000 instances for both source and target domain and split them with 1:1 for train and test for the SVM model. From Fig. 7, we can observe that DCCL can learn a good balance between sentiment classification and domain discrepancy, compared to DANN-best and DANN-worst.

6 Related Work

Unsupervised Domain Adaptation

UDA in NLP has the following approaches: (1) Pivot-based methods use unlabeled data from both domains, trying to discover characteristics that are similar (Pan et al., 2010). Some recent works

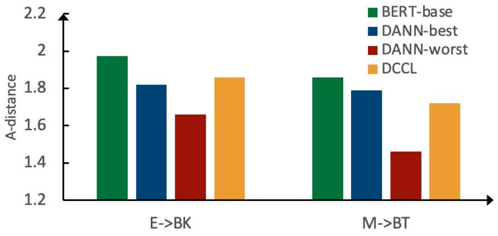

Figure 7: $\mathcal{A}$-distance for E→BK and M→BT tasks

extend pivots with autoencoders and contextualized embeddings (Ziser and Reichart, 2017; Miller, 2019; Ben-David et al., 2020). (2) Pseudo-labeling leverages a trained classifier to predict labels on unlabeled examples, which are subsequently considered as gold labels (Yarowsky, 1995; Zhou and Li, 2005; McClosky et al., 2006). Recent works also combine this technique with pre-trained language models (Lim et al., 2020; Ye et al., 2020). (3) Data selection methods adopt domain similarity metrics to find the best match for each data and use curriculum learning for large pre-trained models (Ma et al., 2019; Aharoni and Goldberg, 2020). A recent method adopt distance-bandit (Guo et al., 2020) for similarity metric. (4) Domain Adversarial Neural Networks (Ganin et al., 2016). Some approaches leverage Wasserstein distance to stabilize adversarial training (Shen et al., 2018; Shah et al., 2018), and combine it with post-training which can produce better adversarial results (Du et al., 2020). (5) Adaptive pre-training is a more straightforward but effective method (Gururangan et al., 2020; Han and Eisenstein, 2019; Karouzos et al., 2021) by leveraging the objective of masked language model (MLM). A wide range of pre-training methods for domain adaptation (multi-phase, multi-task) are put forward (Han and Eisenstein, 2019; Karouzos et al., 2021).

Contrastive learning

CL has recently gained popularity as a reliable approach for unsupervised representation learning. It is generally acknowledged that a good representation should distinguish itself from other instances while identifying similar instances. For Computer Vision, there are approaches obtaining augmented images using transformations including cropping, rotation, etc. (Chen et al., 2020a; Khosla et al., 2020; He et al., 2020; Chen et al., 2020b). As for Natural Language Processing, many works study different label-preserving augmentations, such as back-translations, synonyms, adversaries, dropout, and their combinations (Qu et al., 2021; Gao et al., 2021). In addition, many pre-trained language models trained with contrastive loss are also released. DeCLUTR (Giorgi et al., 2021) and CLEAR (Wu et al., 2020) jointly train the model with a contrastive objective and a masked language model setting. ConSERT (Yan et al., 2021) overcomes the collapse problem of BERT-derived sentence representations and makes them more suitable for downstream applications by using unlabeled texts.

7 Conclusion

In this work, we put forward a new concept, domain puzzles, which can be crafted through domain-specific token mask and domain-confused adversarial attacks. And we provide a more stable and effective solution to learn domain invariance for unsupervised domain adaptation. The proposed method DCCL surpasses baselines with a large margin by mitigating domain shift without losing discriminative power on the target domain. Moreover, the proposed framework can also be extended to other NLP tasks demanding adaptations, and we leave this for future work.

A Datasets

We obtain the Amazon review datasets from He et al. (2018). This dataset does not remove neutral labels and will not be problematic in UDA situation where the label information of the target domain is not available. In addition, reserving neutral labels also bring challenges for pre-trained language model, making it more favorable for self-supervised representation learning. Summary of this dataset is availble in Table 4.

Domain		#Neg	#Neu	#Pos	Total
Book	Set 1	2000	2000	2000	6000
	Set 2	513	663	4824	6000
Electronics	Set 1	2000	2000	2000	6000
	Set 2	694	489	4817	6000
Beauty	Set 1	2000	2000	2000	6000
	Set 2	616	675	4709	6000
Music	Set 1	2000	2000	2000	6000
	Set 2	785	774	4441	6000

Table 4: Amazon review dataset

Each domain contains two sets, set 1 contains 6000 instances with balanced class labels, and set 2 contains instances that are randomly sampled from the larger dataset (McAuley et al., 2015), preserving authentic label distribution, examples in these two datasets do not overlap. Following (He et al., 2018), we use set 1 from the source domain as the training set for all our experiments. Since label distribution in the target domain is unpredictable and out of control in real life, so it's more reasonable to use set 2 from the target domain as the unlabeled set, lastly the model will be evaluated in set 1 from target domain. For data split, we randomly sample 1000 instances from the source labeled dataset as validation set. When running UDA experiments, the model will train on 5000 source labeled examples and 6000 target unlabeled examples, then validate on 1000 source labeled examples.

For Amazon Benchmark(Blitzer et al., 2007), it also contains four domains: Book (BK), DVD (D), Electronics (E) and Kitchen housewares (K). There are 2000 balanced labeled data for each domain, we randomly select 20000 unlabeled reviews for BK, D and E. For K, only 17856 unlabeled reviews are available, statistics of Amazon Benchmark can be find in Table.5. For data split, 1600 balanced samples are randomly sampled from the source labeled dataset, and 400 for validation.

Domains	Labeled	Unlabeled
Book	2000	973194
Dvd	2000	122438
Electronics	2000	21009
Kitchen & housewares	2000	17856

Table 5: Amazon Benchmark statistics

B DANN

Domain Adversarial Neural Network Ganin et al. (2016) proposes Domain Adversarial Neural Network (DANN), which learns domain invariant and discriminative features simultaneously. This approach is motivated by the idea that an adaptation algorithm could learn good representations for cross-domain transfer if it cannot differentiate the domain of the input observations. The optimization objective is:

$$\min_{\theta_f,\theta_y} \sum_{(x,y)\sim\mathcal{D}^S} [\mathcal{L}(f(x;\theta_f,\theta_y),y) + \lambda R_{\theta_f}], \quad (11)$$

$$R_{\theta_f} = \max_{\theta_d} \sum_{(x,d)\sim\mathcal{D}^S,\mathcal{D}^T} [-\mathcal{L}(f(x;\theta_f,\theta_d),d)], \quad (12)$$

where θ_d is the parameter corresponding to the computation of the domain classification, d is the domain label, R_{θ_f} is a regularizer weighted by λ. Objective (11) learns task discrimination by minimizing task classification loss and tries to make features similar across domains by maximizing the domain classification loss.

Although the domain classifier with parameters θ_d could perfectly classify different domains, the balance between two terms in (11) is hard to maintain. Hence, the training process becomes unstable, requiring an elaborate adaptation rate λ tuning (Shen et al., 2018; Shah et al., 2018; Du et al., 2020). Furthermore, the encoder could learn trivial solutions (Karouzos et al., 2021) which produce features with flipped domain predictions.

Incorporating Centering Theory into Neural Coreference Resolution

Haixia Chai and **Michael Strube**

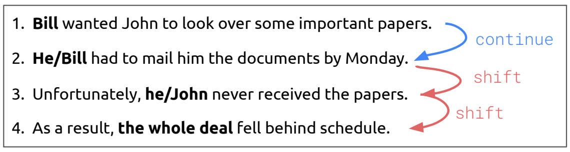
Abstract

In recent years, transformer-based coreference resolution systems have achieved remarkable improvements on the CoNLL dataset. However, how coreference resolvers can benefit from discourse coherence is still an open question. In this paper, we propose to incorporate centering transitions derived from centering theory in the form of a graph into a neural coreference model. Our method improves the performance over the SOTA baselines, especially on pronoun resolution in long documents, formal well-structured text, and clusters with scattered mentions.[1]

1 Introduction

Coreference resolution is the task to find all expressions which refer to the same entity. The coreferential mentions could occur anywhere in the discourse. In recent years, many transformer-based models (Joshi et al., 2019, 2020; Kirstain et al., 2021) achieved improvements on the CoNLL benchmark (Pradhan et al., 2012). In contrast to using transformers such as BERT (Devlin et al., 2019) which learn the text input sequentially in limited chunks, how knowledge about the structure of discourse can benefit coreference resolution is less explored in the neural NLP era.

Coreference plays an essential role in discourse coherence. A referring expression using a reduced linguistic form (e.g., pronoun) indicates a referential relation to its antecedent in previous utterances. The referring expression connects utterances and contributes to discourse coherence implicitly. On the other hand, coreference resolution can benefit from a coherent discourse. It has long been acknowledged that coherence structure can impose constraints on referential accessibility from a linguistic perspective (Asher and Lascarides, 2003). Centering theory (Joshi and Weinstein, 1981; Grosz et al., 1983, 1995; Walker et al., 1998) is a method to formally describe discourse coherence by using attentional state (i.e., the focus of attention of the participants at each utterance of the discourse). Figure 1 shows how the coherence structure of an example text is built by means of tracking the changes in the local attentional state.[2] By applying centering theory, Gordon and Scearce (1995) investigate how local coherence influences the interpretation of ambiguous pronouns. From reading-time experiments, they observe that utterances with pronouns were read faster in the centering `continue` than in the `shift` status, while utterances with noun phrases containing rich lexical information were read more quickly in the centering `shift` than in the `continue` status. We conjecture that this pattern could contribute to coreference resolution.



1. **Bill** wanted John to look over some important papers.
2. **He/Bill** had to mail him the documents by Monday.
3. Unfortunately, **he/John** never received the papers.
4. As a result, **the whole deal** fell behind schedule.

Figure 1: An example text shows how foci change sentence by sentence. The words in bold are the focus of each sentence. The arrows indicate centering transitions with two different transition types, `continue` and `shift`.

In this work, we explore the effect of changes in attentional state in the discourse on entity coreference resolution in a neural approach. Inspired by Jeon and Strube (2020), we capture the most salient mentions of each sentence as centers to compute the local centering transition relations in accordance with centering theory. We then extend the coherence structure globally in the form of a graph. It makes the centering transitions available between any two sentences. Lastly, we fuse the novel discourse structure into a neural coreference model (Kirstain et al., 2021). From the results, our

proposed method improves the SOTA models up to 80.9 F1 score. Our extensive analysis shows that our approach performs better on pronoun resolution in long documents, formal well-structured text such as magazine and newswire genres, and documents with scattered mentions of clusters. Overall, we observe that incorporating discourse structure derived from centering theory can benefit coreference resolution.

	$C_b(s_i) \approx C_b(s_{i-1})$	$C_b(s_i) \neq C_b(s_{i-1})$	No $C_b(s_i)$
$C_b(s_i) \approx C_p(s_i)$	Continue	Shift	None
$C_b(s_i) \neq C_p(s_i)$	Retain		

Table 1: Centering transition relations. For instance, `continue` indicates that the center of utterance s_i is similar to the one in its previous utterance s_{i-1}.

2 Related Work

Discourse for Coreference. In early work, some structural features of the discourse were used in machine learning approaches, such as sentential position and distance between two mentions in sentences, phrases or mentions (Soon et al., 2001; Sapena et al., 2013). In the deep learning period, only a few researchers incorporated discourse information into a coreference model to our knowledge. Recently, Khosla et al. (2021) use rhetorical structure theory (RST) (Mann and Thompson, 1988) to capture the hierarchical discourse structure of documents, from which they encode three distance features for the candidate and query mentions on different levels (i.e., word-level, discourse-unit-level and discourse subtree). Held et al. (2021) apply discourse coherence (Grosz, 1977, 1978; Grosz and Sidner, 1986) to cross-document coreference resolution. They retrieve candidate mentions by modeling the attentional state within a latent embedding space as a set of nearest neighbors for a query mention. As a pruning method, these neighborhoods constrain the search space for their following pairwise classifier. Different from the approaches above, we use centering theory to extract centering transitions between sentences through attentional state. We then use these relations to construct a discourse structure that shows how centers change as discourse proceeds dynamically.

Centering Theory. Since centering theory is a linguistic theory, a great number of early works (Walker et al., 1994; Di Eugenio, 1998; Turan, 1998; Strube and Hahn, 1999) were dedicated to transform it to a computational one for various languages. Lately, Jeon and Strube (2020) is the first work that applies centering theory in a neural model for discourse coherence explicitly. They capture the relationships sentence by sentence for assessing text coherence. In the coreference resolution task, coreferent mentions could occur anywhere in the discourse rather than the adjacent sentence only. Thus, we propose a fully connected centering transitions graph in our model. In addition, Jeon and Strube compute the centers of each sentence on a token-level, while we do it on the span-level.

3 Model

3.1 Baseline

We study the model proposed by Kirstain et al. (2021) as our baseline. It is a *start-to-end* (**s2e**) coreference resolution model that only considers boundary points of a span to compute the mention and antecedent scores without additional handcrafted features. Similar to the method of Lee et al. (2018), they measure how likely a candidate mention c is to be an antecedent of a query mention q by a scoring function $f(c, q)$. The function is the addition of two mention scores $f_m(c)$, $f_m(q)$ and an antecedent score $f_a(c, q)$. Our model is based on this scoring function.[3]

3.2 Incorporating Centering Transitions

According to centering theory, we formulate centering transitions among utterances — sentences specifically — in our approach. Figure 2 shows our model architecture.

Centering Theory. Centering theory describes the local coherence and its relationship to attentional state within a discourse segment. From each utterance, one can extract (1) a set of *forward-looking centers* (C_f) ranked according to their prominence, (2) a single *backward-looking center* (C_b) connected with one of the C_f of the immediately preceding utterance, and (3) a *preferred center* (C_p) which is the most salient center in C_f. Following Jeon and Strube (2020), Table 1 presents all relations of centering transition at the local level. The relationships between discourse segments and

---

[3] For more details, we refer to the original Kirstain et al. (2021) paper.

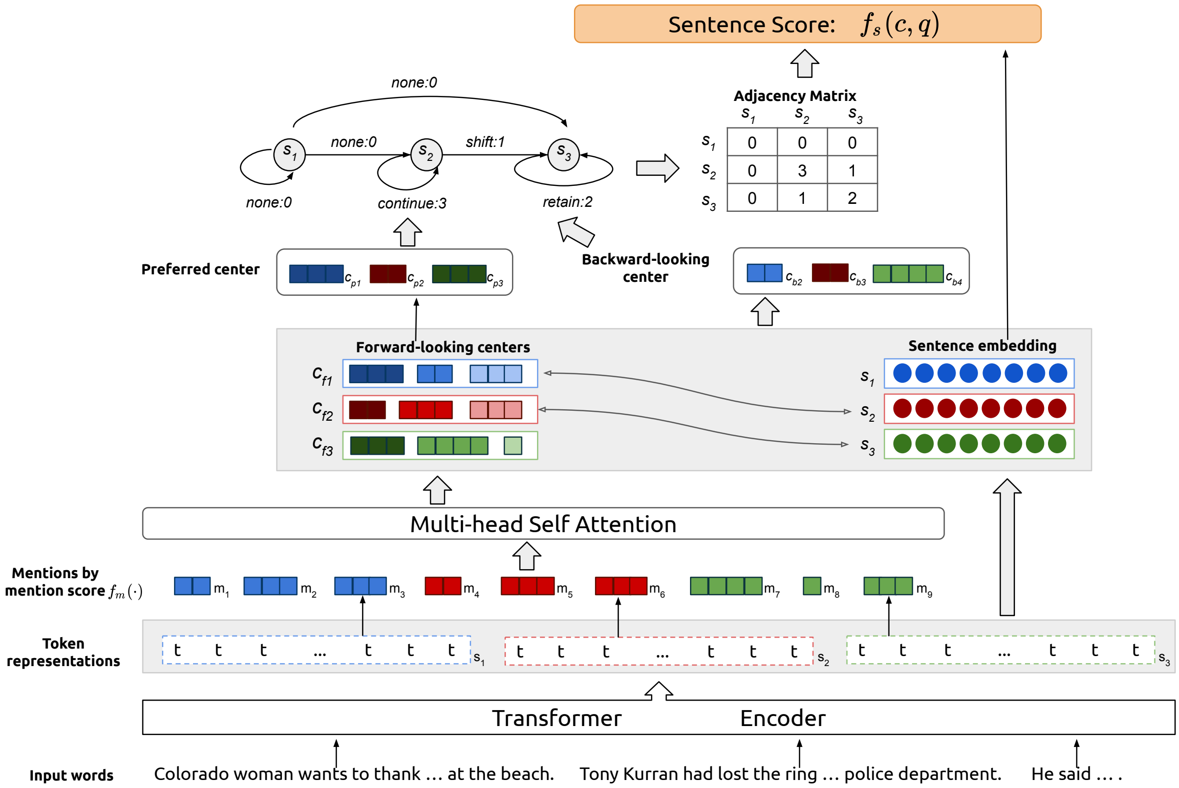

Figure 2: The figure shows our model architecture incorporating centering transitions for the sentence score. There are three example sentences in blue, red and green colors. A string of squares refers to a mention comprising a different number of tokens. The mention with a darker color indicates that it is a more salient center in a sentence.

utterances then provide the fundamental structural centering relations for discourse.

Scoring Function. To combine the structure of the centering transitions with the coreference model, we add sentence score $f_s(c,q)$ to the scoring function as shown below. The last item measures the relationship of the encoded sentences where two examined mentions are located. Especially, if the query mention is a singleton, we set the scoring function to 0.

$$f(c,q) = f_m(c) + f_m(q) + f_a(c,q) + f_s(c,q)$$

Centering Transitions. Having the mention scores $f_m(\cdot)$, we use top λn mentions for further processing of centering transitions (where n is the number of input tokens). Inspired by Jeon and Strube (2020), the remaining mentions with their positions in each sentence are encoded and fed into a multi-head self-attention matrix — $softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)$ — to compute the attention score (Vaswani et al., 2017). Q and K stand for the observed mentions of the sentence. From the ranked diagonal elements of the self-attention matrix, we take the top m mentions as C_f, and the first most salient mention as C_p. As for C_b of the sentence s_i, we select the mention from C_f of its previous adjacent sentence s_{i-1}, which has the highest semantic similarity with the current sentence s_i. Here, we simply use the averaged token representations as the sentence embedding $\mathbf{e}_{s_i}$. Finally, we generate centering transition relations (i.e., `continue`, `retain` and `shift`) between each two adjacent sentences by computing cosine similarity according to the rules in Table 1.

Sentence Score. Sometimes, a candidate mention is more than one sentence away from the query mention. Thus, we apply centering transitions not only at a local level but also to all other sentences in discourse globally. Treating sentences as nodes and transition relations as edges, each sentence can be encoded with its neighbouring nodes weighted by the edges which are connected to it, including self-connections. Then, we calculate the sentence score for each pair of mentions by using the embeddings of the sentences $\mathbf{e}_s$ where the candidate and query mentions belong to.

$$f_s(c,q) = \mathbf{A} \cdot \mathbf{e}_{s_c} \cdot \mathbf{B} \cdot \mathbf{e}_{s_q}$$

Model	MUC			B^3			CEAF$_e$			LEA			CoNLL
	P	R	F1	P	R	F1	P	R	F1	P	R	F1	F1
c2f	85.7	85.3	85.5	79.5	**78.7**	79.1	76.8	75.0	75.9	76.2	75.7	75.9	80.2
s2e	86.5	85.1	85.8	80.3	77.9	79.1	76.8	**75.4**	76.1	78.3	75.8	77.0	80.3

s2e + se_ct	**87.2**	**85.3**	**86.3**	**80.7**	78.6	**79.6**	**78.2**	75.2	**76.7**	**78.7**	**76.5**	**77.6**	**80.9**

Table 2: Performance on the test set of the English OntoNotes 5.0 dataset. **c2f** refers to Joshi et al. (2020).

In the above formula, $\mathbf{A}$ refers to an adjacency matrix, which represents the centering transitions between sentences by numerical values (i.e., `continue`: 3, `retain`: 2, `shift`: 1, and `none`: 0). They are induced from the above parts. Then, we use a bilinear product over the resulting representations with trainable parameter $\mathbf{B}$ to compute the sentence score.[4] We examine this setting in our experiment **s2e+se_ct**. When $\mathbf{A}$ is an identity matrix (i.e., the matrix with ones on the main diagonal and zeros elsewhere), the aggregation over $\mathbf{e_s}$ does not occur. We use this setting **s2e+se** as our simple baseline system for comparative evaluation.

4 Experiments

Settings. We train and evaluate our models on the English OntoNotes 5.0 dataset (Pradhan et al., 2012). The results are reported using the CoNLL F1 score — the average of MUC (Vilain et al., 1995), B3 (Bagga and Baldwin, 1998), CEAFe (Luo, 2005) — and LEA (Moosavi and Strube, 2016).

In our experiments, we examine two models, **s2e+se** and **s2e+se_ct**, as explained in §3. We have 8 self-attention heads for the attention mechanisms, select the top 5 mentions for C_f of each sentence, and set the threshold of cosine similarity as 0.8 for computing the centering transition relations. Following the baseline, We also use Longformer (Beltagy et al., 2020) as our pretrained model, which can process a sequence up to 4096 tokens. We set the other parameters the same as the baseline (Kirstain et al., 2021).[5] All our experiments are performed on a single NVIDIA Tesla V100 32G GPU.

Results. Table 2 shows our results. The model **s2e+se_ct** achieves the best result with 80.9 F1 on OntoNotes. Though both examined models outperform the baselines only by a small margin, it suggests that incorporating centering transitions is helpful to some extent for coreference resolution. To thoroughly utilize the discourse structure, a graph or tree-based coreference model would be a promising research direction. One option would be latent trees which have been explored by Björkelund and Kuhn (2014) and Martschat and Strube (2015) for providing a more reliable basis for coreference resolution before the neural NLP era.

Analyses. First, we check the performance of our model for pronoun resolution on: (1) GAP dataset (Webster et al., 2018); and (2) OntoNotes test dataset in which we only keep the resolved clusters containing pronouns in both gold and system outputs. Table 3 shows the marginal differences between the baseline and our model on the GAP benchmark. GAP is a gender-balanced corpus of ambiguous pronouns sampled from Wikipedia, in which most of examples are short texts. We compute the distributions of lengths of examples by sentence on both GAP and OntoNotes. As shown in the Table 4, the large majority of examples in GAP are 2-4 sentences texts, while the test set of OntoNotes has many documents longer than 5 sentences. The experiment on OntoNotes in Table 5 shows that our model outperforms the baseline across all evaluation metrics. Overall, the two observed results suggest that our model involving centering transition relations between sentences can improve pronoun resolution especially on long documents.

	Masc	**Fem**	**Bias**	**Overall**

Table 5: F1 scores of the examined models for pronoun resolution on the test set of OntoNotes.

Second, we investigate how models perform on different genres. The CoNLL-2012 data contains broadcast conversation (bc), broadcast news (bn), magazine genre (mz), newswire genre (nw), pivot text (pt), telephone conversation (tc), and web data (wb) genres. In Table 6, we find that our method gets the most improvements on mz and nw genres, in which text is always formal well-structured. In contrast, tc and wb are the most challenging genres for our approach, where disfluent and ungrammatical segments and sentences may occur. Therefore, we summarize that discourse structure information is more beneficial for narrative text than less-formal text like conversation and web data. Resolving coreference in noisy user-generated text such as text on social media platforms is even harder (Chai et al., 2020).

	bc	**bn**	**mz**	**nw**	**pt**	**tc**	**wb**
s2e	78.2	83.2	84.1	74.0	88.2	81.8	77.9
s2e + se_ct (ours)	78.7	83.1	85.0	74.9	89.0	80.7	77.2
Improvement	0.5	-0.1	**0.9**	**0.9**	0.8	-1.1	-0.7

Table 6: Performance of the examined models on the test set for genres. The bottom line shows the improvement over the baseline by our method.

Finally, we observe the effect of maximum sentence distance d_{c_i} between any two mentions of each cluster on models. We take the average of all d_c in the same document as the sentence distance of it. Figure 3 depicts that our method performs better when mentions have a distance of more than six sentences. So, utilizing centering transitions globally is helpful for resolving clusters where mentions are more scattered. Our method captures how centers change between not only adjacent sentences but also non-adjacent sentences in the discourse. This is specially designed for coreference resolution based on centering theory. Meanwhile, we observe that it is difficult for both systems to resolve coreference on documents with long sentence distances (i.e., 12+ sentences).

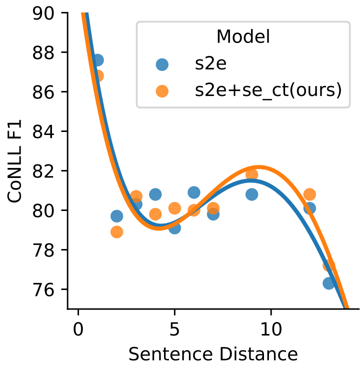

Figure 3: Performance on sentence distance with regression lines.

5 Conclusion

We present a neural coreference model incorporating discourse structure information based on centering theory. The model captures the centering transition relationships between sentences. Each sentence is encoded with all neighbour sentences in a weighted graph. Our approach outperforms the baseline with 80.9 F1 score. Especially, it helps resolving pronoun in long documents, text in formal genres and clusters with scattered mentions.

Abstract

Semi-supervised learning is a promising way to reduce the annotation cost for text-classification. Combining with pre-trained language models (PLMs), e.g., BERT, recent semi-supervised learning methods achieved impressive performance. In this work, we further investigate the marriage between semi-supervised learning and a pre-trained language model. Unlike existing approaches that utilize PLMs only for model parameter initialization, we explore the inherent topic matching capability inside PLMs for building a more powerful semi-supervised learning approach. Specifically, we propose a joint semi-supervised learning process that can progressively build a standard K-way classifier and a matching network for the input text and the Class Semantic Representation (CSR). The CSR will be initialized from the given labeled sentences and progressively updated through the training process. By means of extensive experiments, we show that our method can not only bring remarkable improvement to baselines, but also overall be more stable, and achieves state-of-the-art performance in semi-supervised text classification. Code is available at: `https://github.com/HeimingX/PCM`.

1 Introduction

Text classification is a fundamental task in natural language processing (NLP) and underpins various applications, e.g., spam detection (Jindal and Liu, 2007), sentiment analysis (Pang et al., 2002) and text summarization (Gambhir and Gupta, 2017). Supervised training of text classifiers often demands a large amount of annotation, which can be expensive for many applications. Semi-supervised learning (SSL) provides an economical way for alleviating this burden since it can make use of easy-accessible unlabeled samples to build a reasonably performed classifier with a limited amount of labeled data. Recently, SSL received increasing attention in both image classification (Tarvainen and Valpola, 2017; Berthelot et al., 2019b; Sohn et al., 2020) and text classification (Xie et al., 2019b; Chen et al., 2020; Liu et al., 2021) areas.

Meanwhile, pre-trained language models (PLMs) (Yang et al., 2019a; Devlin et al., 2019; Radford et al., 2019) are developing rapidly and achieve impressive performance in various NLP tasks (Sun et al., 2019; Zhu et al., 2020) including text classification (Garg and Ramakrishnan, 2020). In the context of semi-supervised text classification, many existing methods achieve excellent performance by directly using a PLM as a sentence encoder and further fine-tuning it with a semi-supervised learning process (Xie et al., 2019b; Chen et al., 2020; Bhattacharjee et al., 2020; Sun et al., 2020).

In this paper, we further explore the usage of PLMs for SSL. We go beyond the strategy of using PLMs for encoder initialization and make full use of inner knowledge of PLMs. Concretely, we identify that some PLMs, e.g., BERT, have an inherent matching capability between sentence and class-related words thanks to its pre-training pretext task (Devlin et al., 2019) (as the examples shown in Fig. 1). We further propose to strengthen this capability through SSL on labeled and unlabeled data. Specifically, we develop a joint training process to update three components progressively, that is, a classifier that performs the standard K-way classification, a class semantic representation (CSR) that represents the semantic of each category, and a matching classifier that matches the input sentence against the CSR. Those three components can help each other during the training process, i.e., the K-way classifier will receive more accurate pseudo-labels by jointly generating pseudo-labels with the matching classifier; the matching classifier will also upgrade its matching capability with the guidance of the K-way classifier. The CSR will become more accurate and comprehensive with the improvement of the K-way classifier and matching

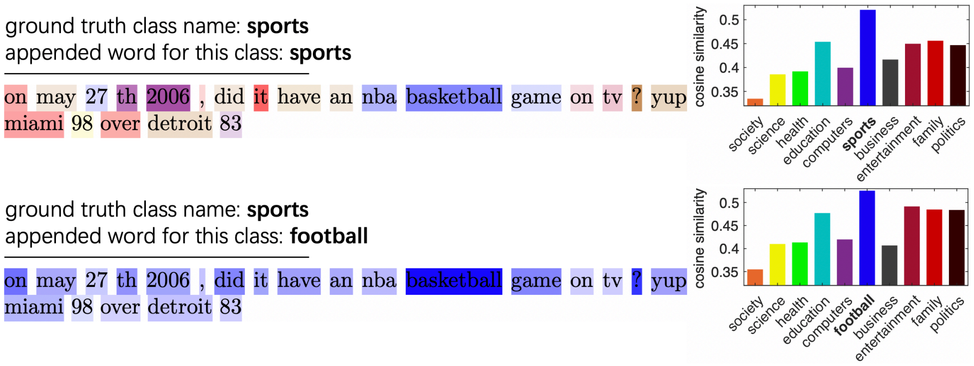
(a) Sentence example on class "family"



(b) Sentence example on class "sports"

Figure 1: Visualization of the inherent matching capability of BERT on examples from Yahoo! Answers. We append class semantic-related words (CSW) of all classes at the end of input sentence . Different colors denote different classes. The color on each token of input sentence represents the category of its most attended CSW (with color brightness indicating the attention value, please see Sec.3 for more details). The histograms on the right demonstrate the cosine similarity between the average features of sentence and features of each CSW.

classifier. This joint process leads to a more powerful semi-supervised learning algorithm for the text classification task. Throughout our experimental evaluation, we demonstrate that the proposed method achieves the state-of-the-art performance on text data, especially when the number of labeled sentences becomes extremely low, i.e., 3 or 5.

2 Related work

In this section, we briefly review the relevant research works.

2.1 General Semi-Supervised Learning

Semi-supervised learning is a longstanding research topic in machine learning. Existing methods adopt different ways of utilizing unlabeled samples, e.g., "transductive" models (Joachims, 2003; Gammerman et al., 2013), multi-view style approaches (Blum and Mitchell, 1998; Zhou and Li, 2005) and generative model-based methods (Kingma et al., 2014; Springenberg, 2016). With the renaissance of the deep neural network, consistency-regularization-based deep SSL approaches (Laine and Aila, 2017; Tarvainen and Valpola, 2017; Miyato et al., 2018) have achieved impressive performance on various tasks, and our work largely builds upon the method in this category. The key idea of these methods is to constrain the model to be consistent in the neighborhood of each sample in the input space. Specifically, Π-Model (Laine and Aila, 2017), UDA (Xie et al., 2019b) and FixMatch (Sohn et al., 2020) directly add various perturbations to the input data, Mean-teacher (Tarvainen and Valpola, 2017) uses a teacher model to simulate sample perturbation, and Virtual Adversarial Training (Miyato et al., 2018) skillfully constructs an adversarial sample. More recently, mixup (Zhang et al., 2018) method proposed another kind of consistency constraint that requires the input and output of the model to satisfy an identical linear relationship. Based on this technique, many state-of-the-art methods are published, e.g., ICT (Verma et al., 2019b), MixMatch (Berthelot et al., 2019b) and ReMixMatch (Berthelot et al., 2019a).

2.2 Semi-Supervised Text Classification

Semi-supervised learning has gained a lot of attention in the field of text classification. Many recent semi-supervised text classification methods focus on how to adapt the existing SSL methodologies to the sentence input. (Miyato et al., 2017) applied perturbations to word embeddings for constructing adversarial and virtual adversarial training. (Clark et al., 2018) designed auxiliary prediction modules with restricted views of the input to encourage consistency across views. With the development of PLMs, (Jo and Cinarel, 2019) performed self-training between two sets of classifiers which are initialized differently, one with pre-trained word embeddings and random values for the other. Both (Xie et al., 2019b) and (Chen et al., 2020) took the pre-trained BERT to initialize the sentence feature extractor, where the former conducted consistency-regularization between the original sentence and its back-translation generated one, and the latter further introduced the manifold mixup (Verma et al., 2019a) into text classification. Although these methods may achieve decent performances, we believe that they haven't fully explored the inherent knowledge in a PLM. Our work takes a step further in this direction.

3 Inherent matching capability of a PLM

In this section, we will demonstrate the inherent topic matching capability of BERT which motivates our method. Utilizing PLMs for a downstream task has become common since it often brings a significant performance boost (Zhu et al., 2020; Chen et al., 2020). In the context of semi-supervised learning, a PLM is usually employed for initializing the network before performing semi-supervised training. However, the value of a PLM can go beyond a good initial model or feature extractor. In particular, a PLM like BERT has already learned certain topic matching capabilities thanks to its pretext tasks. For example, BERT uses the next sentence prediction (NSP) as one of its pretext tasks. In this task, the network is asked to discern if two input sentences are two successive sentences in the original corpus. After training on this task, BERT can implicitly acquire topic matching capability since two successive sentences in a paragraph usually share the same topic.

Fig. 1 shows a concrete investigation of the inherent matching capability of BERT. Following the NSP task, we concatenate the sentence and class semantic-related words C_k, e.g., "sports", via the format: "[CLS] sentence [SEP] $C_1 \cdots C_k \cdots C_K$ [SEP]". Then we pass the input sequence to a pre-trained BERT and calculate the attention value of each token with respect to each class name. Specifically, this attention value is calculated by averaging the last layer self-attention values across all heads between a token and the appended word C_k . For better visualization, we use different color to show the class that leads to the largest attention value (indicated by the color brightness).

From the visualization, we can see that BERT can automatically match keywords corresponding to the respective class names. Moreover, we find that if we replace the class names with words under the same topic, i.e., family → boyfriend, sports → football, the words related to the ground-truth class can still be attended, as shown in Fig. 1a and 1b.

Finally, we extract BERT last-layer's feature corresponding to each class word C_k and average features align with sentence tokens, and compare the cosine similarity between them. As histograms shown in Fig. 1a and 1b, we can find that the correct class leads to the highest matching score, although not always by a large margin.

4 Progressive Class-semantic Matching

To further strengthen the above topic matching capability and use it for classification, we propose to progressively build a sentence-class matching model through the framework of semi-supervised learning. Formally, we aim to build a classifier from a few annotated samples $\mathcal{L} = \{x_1, x_2, \cdots, x_{n_l}\}$, whose labels are $\mathcal{Y} = \{y_1, y_2, \cdots, y_{n_l}\}, y_i \in \{1, \cdots, k, \cdots, K\}$, and a large amount of unlabeled samples $\mathcal{U} = \{x_1, x_2, \cdots, x_{n_u}\}$ (where $n_l \ll n_u$).

The idea is to construct a process that can jointly update three components: (1) a standard K-way classifier (2) a matching classifier which matches texts against class semantic representation (3) the class semantic representation (CSR) itself. The update of each component will help other components and thus can iteratively bootstrap classification performance. We call our method as Progressive Class-semantic Matching (PCM).

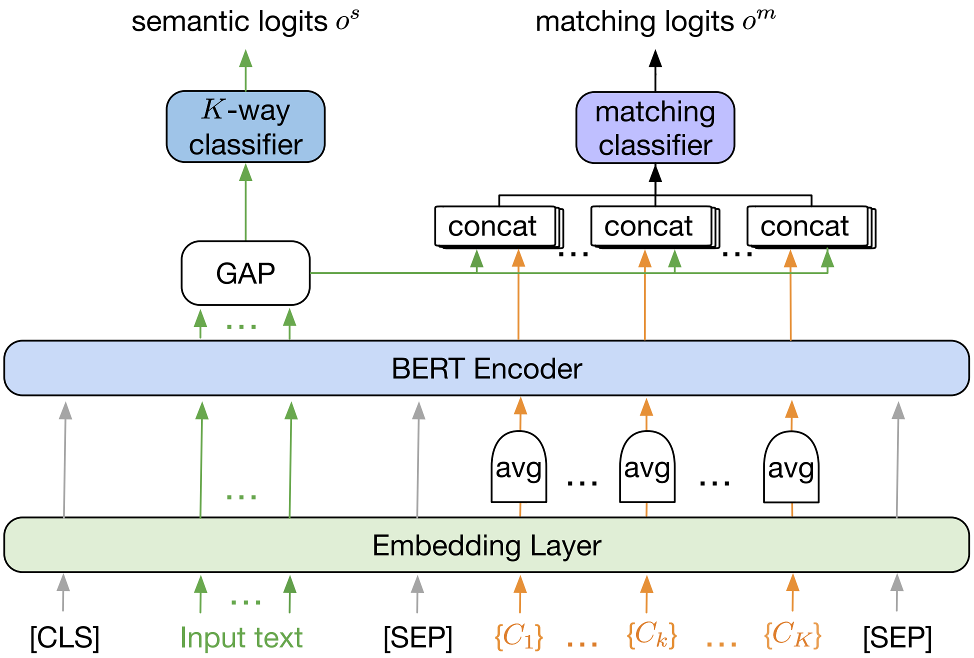


Figure 2: Overview of the proposed PCM model. Lines in the same color indicate how the information travels in our model. $\{C_k\}$ denotes the set of class semantic-related words. "avg" means the average of word embeddings within the same class. "GAP" represents the global average pooling of the input text features. "concat" is a feature concatenate operation. We clarify the details of initializing and updating of $\{C_k\}$ in Secs. 4.2 and 4.3.

4.1 Three components of PCM

Fig. 2 shows how we realize the three components. Similar to the example in Section 3, we construct the input to the BERT by concatenating sentence with class semantic-related words $\{C_i\}, i \in \{1, \cdots, k, \ldots, K\}$. Considering the size of $\{C_i\}$ may vary and the computation cost may increase heavily when the number of classes grows, we calculate an average of embeddings of all words belonging to the same class before passing them to the pre-trained BERT encoder. This average embedding is called **class semantic representation (CSR)**.

The last layer output features corresponding to tokens in the input text are averaged and treated as the sentence representation. On top of the sentence representation, we build a **standard K-way classifier**. We implement it by a two-layer MLP and it will output a set of logits $\{o_i^s\}$ called semantic logits and posterior probabilities $\{p_i^s\}$ after applying Softmax to $\{o_i^s\}$.

In addition to the K-way classifier, we also build **a class-sentence matching classifier** which is realized by another MLP applying to the concatenation between the sentence representation and the output features corresponding to each CSR. The output of this matching classifier is called matching logits $\{o_i^m\}$ and Sigmoid function is applied to convert it into the probabilistic form, denoted as $\{p_i^m\}$. Note that the matching classifier is realized in a multi-label formulation, that is, the summation of $\{p_i^m\}$ over all classes is not necessarily equal to 1. It allows the scenario that a sentence matches more than one class and the case that a sentence does not match any class. This design avoids the case that achieving high matching probability for one class merely because its matching score is higher than those of other classes (but it actually with low absolute matching logits for all classes). We empirically find that using this mechanism is helpful for the matching classifier (but not necessarily for the K-way predictor as discussed in Section 5.2).

4.2 Initialization of CSR

The proposed PCM model requires an initial CSR, i.e., the average word embedding of a set of class semantic-related words, to start the iteration. Although manually choosing a list of seed words (e.g., class names) can be an ideal way for the CSR initialization, it may suffer from leveraging prior knowledge and leads to an unfair comparison to existing SSL algorithms. An alternative approach is to automatically identify a set of class semantic-related words. This might be useful for the case that class names in some corpora do not carry a clear semantic meaning, e.g., the rating of reviews.

In this paper, we use the following method to automatically collect the class semantic-related words: we start by fine-tuning a pre-trained BERT classifier on the labeled set. Then passing each labeled text into the fine-tuned model and calculate attention values for each token. The attention value of a token is calculated by averaging all the attention received for this token [1]. After removing stop words, we retain the top-j e.g., $j = 75$, attended words for each class to calculate the initial CSR.

4.3 Update of three components

The three components are progressively updated by seamlessly incorporating them into an SSL framework. In particular, our method is built upon UDA (Xie et al., 2019b), one of the state-of-the-art approaches in semi-supervised text classification. The idea is to first construct an augmented version of unlabeled data by back translation (Edunov et al., 2018) and then enforce the prediction to be consistent through a consistency-regularization loss for unlabeled data. The following describes the detailed updating process:

Update of the standard K-way classifier and the class-sentence matching classifier: The update is performed on labeled and unlabeled data at the same time. For labeled data, both classifiers are updated by performing stochastic gradient descent with the following objective function.

$$\mathcal{L}_l = \frac{1}{n_l}\sum_{j=1}^{n_l}\sum_{i=1}^{K} \underbrace{-\mathbb{I}_i^j \log p_i^s(x_j)}_{\text{cross entropy (CE)}} + \underbrace{-\mathbb{I}_i^j \log p_i^m(x_j) - (1-\mathbb{I}_i^j)\log\big(1-p_i^m(x_j)\big)}_{\text{binary cross entropy (BCE)}}, \tag{1}$$

where $p_i^s(x_j)$ and $p_i^m(x_j)$ are the probabilities of x_j belonging to class i from the view of the K-way classifier and the matching classifier, respectively. Since the matching classifier is designed in a multi-label style, we use binary cross-entropy loss for it. $\mathbb{I}_i^j$ is an indicator whose value equals to 1 if $y_j = i$, and 0 otherwise.

For unlabeled data, we follow UDA to use a student-teacher alike training strategy, that is, we first use the original sentence input $x_j \in \mathcal{U}$ to obtain the prediction target (similar to a pseudo label) and then enforce the prediction of the back-translated version x_j^a of x_j being close to the prediction target. Formally, if the prediction of one unlabeled sample satisfies all the following rules, the prediction target will be generated:

$$\begin{cases} \max_i\big(p_i^s(x_j)\big) >= \text{confid1} \\ \max_i\big(p_i^m(x_j)\big) >= \text{confid2} \\ \text{argmax}_i\big(p_i^s(x_j)\big) == \text{argmax}_i\big(p_i^m(x_j)\big) \end{cases} \tag{2}$$

where confid1 and confid2 are two pre-defined confidence thresholds and we empirically find confid1 $= 0.95$ and confid2 $= 0.7$ performs well in our experiments. For the K-way classifier, the pseudo prediction target is a sharpened posterior probability, i.e., $\hat{p}^s = \text{Softmax}(o^s/T)$ with $T \leq 1$. For the matching classifier, we directly generate a pseudo-label by $\hat{y}_i = \text{argmax}_i\ p_i^m$. The loss function for the unlabeled data is

$$\mathcal{L}_u = \frac{1}{n_u}\sum_{j=1}^{n_u}\Big(\text{KL}\big(p^s(x_j^a), \hat{p}^s(x_j)\big) + \text{BCE}\big(p^m(x_j^a), \hat{y}_i(x_j)\big)\Big) \tag{3}$$

where $\text{KL}(\cdot,\cdot)$ denotes the KL divergence.

Update of CSR: The initialized CSR might not be accurate or comprehensive enough to represent the class semantics. Similar to the approach proposed in Section 4.2, we use the newly updated model to collect a better CSR. The collection process on labeled sentences is still as described in Section 4.2. While the same extraction operation is performed on unlabeled texts only when they satisfy the conditions in Eq. 2. We update the CSR whenever the number of validation set[2] samples meeting conditions in Eq. 2 increases. Generally, during the course of semi-supervised learning, the classifiers become stronger and the selected class-related words tend to become more accurate. Table 3 gives an example to show the difference of most attended words between initialization and after training.

5 Experimental results

In this section, we perform the experimental study of the PCM method on four text datasets.

Datasets Following MixText (Chen et al., 2020), we use four datasets, namely, AG News (Zhang

[†] Single run accuracy (81.6%) is reported in UDA (Xie et al., 2019b) for a reference. [‡] This number is reasonable on one GPU card with 11GB memory. See experimental tutorial (Xie et al., 2019a) for details.

Table 2: Test accuracy (%) of all comparing methods on four datasets. Models are trained with 3/5/10/20/50 labeled data per class. ± denotes the Standard Error of the Mean (S.E.M.) over three random sampled label sets. Best results are indicated as bold.

et al., 2015), DBpedia (Lehmann et al., 2015), Yahoo! Answers (Chang et al., 2008), and IMDB (Maas et al., 2011) for our experiments. We use the same data splits as in MixText (Chen et al., 2020). The detailed statistics of the four datasets are presented in Table 1.

Implementation details Same as MixText [3], we use back-translation to perform data augmentation. Two languages, German and Russian, are chosen as the intermediate language. The back-translation texts on Yahoo! Answers are provided by MixText, and we directly use them. For the other three datasets, we generate the back-translation data by ourselves (with Fairseq toolkit (Ott et al., 2019)).

We use the input format "[CLS] Sentence [SEP]" for all the baseline methods. We empirically find this format leads to the overall best performance. Meanwhile, this format actually brings performance improvement to both UDA and MixText methods. So we are comparing against stronger baselines in our paper.

Due to BERT's length limit, we only kept the last 256 tokens for IMDB and the first 256 tokens for the other datasets during training. We use the same learning-rate setting for all methods: 5e-6 for the BERT encoder and 5e-4 for the classifier (i.e., a two-layer MLP with a 128 hidden size and $tanh$ as its activation function). All our experiments were run on a GeForce RTX 2080 Ti GPU and each experiment takes around 5 hours.

Comparing methods We compare the proposed PCM method with three baselines: (1) fine-tuning the pre-trained BERT-based-uncased model on the

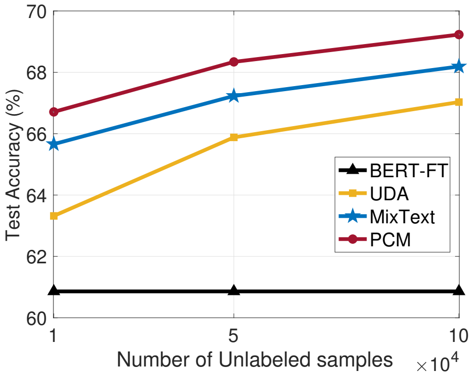

Figure 3: Accuracy on varying number of unlab. data.

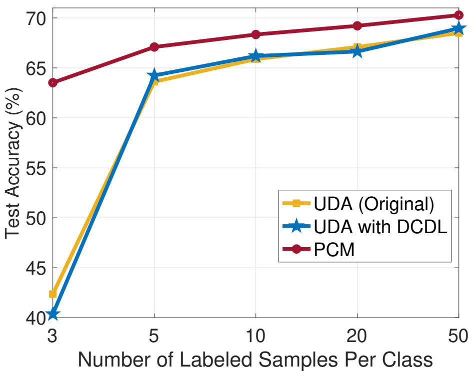

Figure 4: Ablation study on the DCDL strategy in PCM.

labeled texts directly, denote as **BERT-FT**. (2) Unsupervised data augmentation method (UDA) (Xie et al., 2019b) and (3) the recently proposed MixText method (Chen et al., 2020). To make a fair comparison, we conduct all experiments based on the same codebase released by the authors of MixText (Chen et al., 2020).

5.1 Main results

Table 2 presents the performance comparison of the proposed PCM method and other baselines on different datasets. From that, we can have the following observations. (1) By using BERT, all methods achieve reasonable performance. Even the BERT fine-tune baseline achieves good performance when there are ten samples per class. However, BERT fine-tune is still inferior to the semi-supervised approaches, especially when the number of training samples becomes smaller or the classification task becomes more challenging. (2) As expected, the MixText method excels than UDA in most cases, but performs similarly when the number of labeled samples becomes large (e.g., 50 labels/class). Since the proposed method could also be incorporated into MixText, it might be able to boost its performance. (3) the proposed PCM methods achieves significant performance improvement over UDA approaches. Please note that PCM is built on top of the UDA method and this performance gain indicates the effectiveness of using the proposed progressive training process. (4) It is clear that PCM can not only **always outperform other baselines** and achieve state-of-the-art text classification performance on all four datasets, but also have **smaller standard error and be more stable**. PCM performs especially well when the number of labeled samples becomes small. A much larger performance gain is observed when only three labeled samples are available.

Furthermore, we compare PCM to baselines with 10 labeled data per class and varying number of unlabeled ones on Yahoo! Answers dataset (range from 10,000 to 100,000 unlabeled samples). Fig. 3 shows that PCM continuously benefits from more unlabeled data and can be consistently superior than other methods.

5.2 Ablation studies

PCM model consists of several components. In this section, we perform ablation studies to examine their impact. Most of these studies are performed on Yahoo! Answers dataset with one identical labeled set, unless otherwise specified.

1. The importance of using two classifiers in PCM. The proposed PCM model contains a K-way classifier (i.e., p^s) and a matching classifier (i.e., p^m), and they are jointly trained in the proposed process. We investigate the role of them by constructing a variant of PCM by only using either one of them. As the results shown in Table 4, without using the K-way classifier, the method totally fails to a random guess. In contrast, only keeping the K-way classifier can obtain reasonable results. More interestingly, this variant actually performs better than UDA on 3 and 5 label cases (see the Table 2). The difference between this variant and UDA is that the former appends CSR to the input sequence. Its good performance shows that merely appending CSR can be helpful for semi-supervised text classification. Finally, we can see that using both classifiers can lead to the best performance. This clearly validates the necessity of the proposed joint learning process.

2. If using the dual-classifier-dual-loss is the key to success? In our method, we utilize a slightly unconventional dual-classifier-dual-loss strategy

Initial	bush, car, bomb, killed, chancellor, black, moscow, inter, leftlist, putin, story, presidential, texas, president, campaign, documents, ap, unearthed, caracas, ...
Final	iraq, president, iraqi, government, baghdad, military, palestinian, security, nuclear, prime, minister, country, israeli, leader, war, peace, gaza, iran, israel, troops, ...

Table 3: The class semantic-related word lists on class "world" of AG News dataset. The top row is the initial class semantic-related words obtained from fine-tuned BERT, while the bottom one is the final class semantic-related words after PCM training with upper initial words. All models are trained on the 3 labels per class case.

p^s	p^m	Number of Labeled Example Per Clas				
		3	**5**	**10**	**20**	**50**
✗	✓	10.01	10.45	10.01	10.21	10.05
✓	✗	49.51	65.32	65.70	67.88	68.43
✓	✓	**63.52**	**67.09**	**68.34**	**69.21**	**70.28**

✓	**63.52**	**67.09**	**68.34**	**69.21**	**70.28**

Table 5: Ablation study on the importance of updating the CSR during training of PCM.

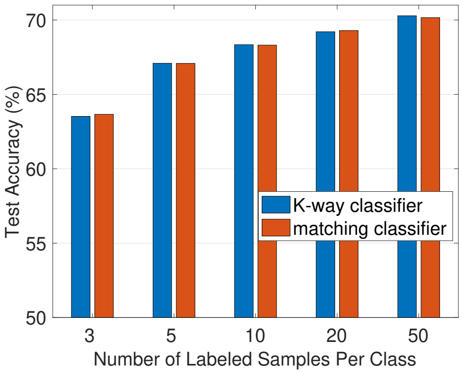

Figure 5: Ablation study on classifier quality of PCM.

(DCDL): the pseudo-labels are generated by checking the agreement of the two classifiers, and two losses, i.e., BCE and CE, are used for training those two classifiers. One may suspect that our good performance actually stems from this DCDL scheme rather than leveraging BERT's matching capability. To investigate this problem, we conduct an ablation study by modifying UDA with this strategy. Specifically, we use two classifiers, one trained from the BCE loss and the other one trained from the CE loss. The pseudo-prediction targets are generated by following the same strategy as in PCM. The result is shown in Fig. 4. As seen, simply incorporating this training strategy does not necessarily bring better classification accuracy. This result provides evidence that the PCM's good performance can not be simply attributed to the DCDL strategy.

3. The prediction quality of the K-way classifier and the matching classifier. In our PCM model, the K-way classifier is chosen for the final testing phase. We further validate the quality of the matching classifier. As the results presented in Fig. 5, the matching classifier gains comparable performance to the K-way one. This proves that the collaborative training of two classifiers bootstraps each other to have good prediction capability.

4. The impact of updating CSR. Our PCM method dynamically updates the CSR through the training process. In this part, we investigate the impact of this updating process. Table 5 compares the results obtained by updating or not updating CSR. As seen, updating CSR leads to overall better performance. The difference becomes quite significant when only three labeled samples are used. For example, PCM may fail when the class semantic representation is fixed in the 3-label case.

6 Limitations and Potential Risks

One underlying assumption about our findings is that we mainly consider BERT-style pre-trained language models for semi-supervised text classification. The utilization of inherent knowledge of other language models (e.g., GPT (Radford et al., 2018) and XLNet (Yang et al., 2019b)) are not explored in this paper and is left for future work.

PCM algorithm has been verified to be effectiveness on texts in English, whether other languages can achieve the same performance improvement is at risk and will be explored in the future.

7 Conclusion

In this paper, we proposed a semi-supervised text classification approach by leveraging the inherent topic matching capability in pre-trained language models. The method progressively updates three components, a K-way classifier, the class semantic representation, and a matching classifier that matches input text against the class semantic representation. We show that the updating of the three components can benefit each other and achieve superior semi-supervised learning performance.

8 Ethics

In terms of ethics, we do not see immediate concerns for the models we introduce and to the best of our knowledge no datasets were used that have known ethical issues.

Low Resource Style Transfer via Domain Adaptive Meta Learning

Abstract

Text style transfer (TST) without parallel data has achieved some practical success. However, most of the existing unsupervised text style transfer methods suffer from (i) requiring massive amounts of non-parallel data to guide transferring different text styles. (ii) colossal performance degradation when fine-tuning the model in new domains. In this work, we propose DAML-ATM (Domain Adaptive Meta-Learning with Adversarial Transfer Model), which consists of two parts: DAML and ATM. DAML is a domain adaptive meta-learning approach to learn general knowledge in multiple heterogeneous source domains, capable of adapting to new unseen domains with a small amount of data. Moreover, we propose a new unsupervised TST approach Adversarial Transfer Model (ATM), composed of a sequence-to-sequence pre-trained language model and uses adversarial style training for better content preservation and style transfer. Results on multi-domain datasets demonstrate that our approach generalizes well on unseen low-resource domains, achieving state-of-the-art results against ten strong baselines.

1 Introduction

Text style transfer (TST) aims to change the style of the input text and keep its content unchanged, which has been applied successfully to text formalization (Jain et al., 2019) , text rewriting (Nikolov and Hahnloser, 2018) , personalized dialogue generation (Niu and Bansal, 2018) and other stylized text generation tasks (Gao et al., 2019; Cao et al., 2020; Syed et al., 2020).

Text style transfer has been explored as a sequence-to-sequence learning task using parallel datasets (Jhamtani et al., 2017; Wang et al., 2020b; Pryzant et al., 2020). However, parallel datasets are difficult to obtain due to expensive manual annotation. The recent surge of deep generative methods (Hu et al., 2017a; Zhao et al., 2017; Li et al., 2018) has spurred progress in text style transfer without parallel data. However, these methods typically require large amounts of non-parallel data and do not perform well in low-resource domain scenarios.

One typical method is to resort to massive data from different domains, which has been studied as an effective solution to address the above data insufficiency issue (Glorot et al., 2011; Wang et al., 2017; Li et al., 2021b). However, directly leveraging large amounts of data from other domains for the TST task is problematic due to the differences in data distribution over different domains, as different domains usually use their domain-specific lexica (Li et al., 2019a). For instance, fine-tuning a TST model trained on a high-resource movie-related domain to a low-resource restaurant-related domain can get us unreasonable sentences like "the food is dramatic." The sentiment word "dramatic" is suitable for commenting a movie but weird to comment on the food.

In this work, we tackle the problem of domain adaptation in the scenarios where the target domain data is scarce and misaligned with the distribution in the source domain. Recently, model-agnostic meta-learning (MAML) has received resurgence in the context of few-shot learning scenario (Lin et al., 2019; Gu et al., 2018; Nooralahzadeh et al., 2020). Inspired by the essence of MAML (Finn et al., 2017), we propose a new meta-learning training strategy named domain adaptive meta-learning (DAML). Unlike MAML, DAML adopts a domain adaptive approach to construct meta tasks that would be more suitable to learn a robust and generalized initialization for low-resource TST domain adaption.

To well preserve content and transfer style, one typical strategy of a TST model is to decouple style information from the semantics of a text, and it tends to produce content loss during style transfer (Hu et al., 2017b; Dai et al., 2019; Carlson et al.,

---

[*] Equal contribution.
[†] Corresponding author.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3014 - 3026
July 10-15, 2022

2018). Here, we do not try to decouple content and style, and propose a new Adversarial style Transfer model ATM, which is composed of a sequence-to-sequence pre-trained language model combined with adversarial style training for style transfer. In this way, our model can better preserve the content information without disentangling content and style in the latent space.

Combining DAML and ATM, in this paper, we propose the method named DAML-ATM, which extends traditional meta-learning to a domain adaptive method combined with a sequence-to-sequence style transfer model. DAML contains two alternating phases. During the meta-training phase, a series of meta-tasks are constructed from a large pool of source domains for balanced absorption of general knowledge, resulting in a domain-specific temporary model. In the meta validation stage, the temporary model is evaluated on the meta validation set to minimize domain differences and realize meta knowledge transfer across different domains. In ATM, a pre-training language model based TST model is used to improve text content retention. Moreover, we propose a two-stage training algorithm to combine the DAML training method and ATM model better.

In summary, the main contributions in this paper are three-fold: (i) We propose a new unsupervised TST model, which achieves SOTA performance without disentangling content and style latent representations compared to other models. (ii) We extend the traditional meta-learning strategy to the domain adaptive meta transfer method, effectively alleviating the domain adaption problem in TST. (iii) We propose a two-stage training algorithm to train DAML-ATM, achieving state-of-the-art performance against multiple strong baselines.

2 Related Work

2.1 Text Style Transfer

Text style transfer based on deep learning has been extensively studied in recent years. A typical pattern is first to separate the latent space as content and style features, then adjust the style-related features and generate stylistic sentences through the decoder. (Hu et al., 2017a; Fu et al., 2017; Li et al., 2019a)assume that appropriate style regularization can achieve the separation. Style regularization may be implemented as an adversarial discriminator or style classifier in an automatic encoding process. However, these style transfer paradigms use large amounts of annotation data to train models for specific tasks. If we already have a model for a similar task, it is unreasonable to need many data still to train the model from scratch.

On the other hand, some of the previous work learned to do TST without manipulating the style of the generated sentence based on this learned latent space. (Dai et al., 2019)use the transformer architecture language model to introduce attention mechanism, but they do not make full use of the prior knowledge of sequence to sequence pre-trained language model, such as Bart (Lewis et al., 2019) and T5 (Raffel et al., 2019), which have made significant progress in text generation tasks. In this paper, we proposed the DAML training method to solve the domain shift problem in TST and proposed a new TST model architecture named ATM, which makes no assumption about the latent representation of source sentence and takes the proven sequence-to-sequence pre-trained language model.

2.2 Domain adaptation

Domain adaptation has been studied in various natural language processing tasks (Glorot et al., 2011; Qian and Yu, 2019; Wang et al., 2017; Li et al., 2021a). However, there is no recent work about domain adaptation for a TST, except DAST (Li et al., 2019a). DAST is a semi-supervised learning method that adapts domain vectors to adapt models learned from multiple source domains to a new target domain via domain discriminator. Different From DAST, we propose to combine meta-learning and adversarial networks to achieve similar domain adaption ability, and our model exceeds the performance of DAST without domain discriminator. Although there are some methods perform well in few shot data transfer (Riley et al., 2021; Krishna et al., 2021), these methods discuss completely new text style transfer, while we focus on the domain adaptation issue.

2.3 Model-Agnostic Meta-Learning

Model-agnostic meta-learning (MAML) (Finn et al., 2017) provides a general method to adapt to parameters in different domains. MAML solves few-shot learning problems by learning a good parameter initialization. During testing, such initialization can be fine-tuned through a few gradient steps, using a limited number of training examples in the target domain. Although there have been some researches (Qian and Yu, 2019; Li et al., 2020; Wu et al., 2020) on MAML in natural language processing, it is still scarce compared to computer vision. Unlike the above research on classification under few-shot learning, our research focuses on text style transfer based on text generation. In this paper, we seek a new meta-learning strategy combined with adversarial networks, which is more suitable for encouraging robust domain representation. As far as we know, we are the first to adopt meta-learning in the domain adaptation problem of text style transfer tasks.

3 Methodology

In this section, we first define the problem of domain adaptive learning for TST. Then we describe our approach, DAML-ATM, in detail.

3.1 Task Definition

Let $D_S = \{D_1, ..., D_N\}$ be N source domains in the training phase, where $D_n (1 \leq n \leq N)$ is the n-th source domain containing style-labelled non-parallel data $D_n = \{(X_i, l_i)\}_{i=1}^{L_n}$, where L_n is the total number of sentences, X_i denotes the i^{th} source sentence, and l_i denotes the corresponding style label, which belongs to a source style label set: $l_i \in L_S$ (e.g., positive/negative). Likewise, there are K target domains $D_T = \{D_1, ..., D_K\}$ which are unseen in D_S. Our task is to transfer a sentence X_i with style l_i in the target domain to another sentence $Y_i^{'}$ sharing the same content while having a different style $\tilde{l}_i$ from l_i and domain-specific characteristics of the target domain.

We propose a two-stage algorithm for domain adaptation in TST: pre-training learning strategy and domain adaptive meta-learning strategy. In pre-training learning, our objective is to make the model more able to preserve content information and distinguish between different text styles. In domain adaptive meta-learning, our objective is to learn a meta-knowledge learner for the sequence-to-sequence model by leveraging sufficient source data D_s. Given a new unseen domain from D_{new}, the new learning task of TST can be solved by fine-tuning the learned sequence-to-sequence model (domain-invariant parameters) with only a small number of training samples.

3.2 DAML-ATM Approach

3.2.1 Overview of DAML

Model-agnostic meta-learning can utilize a few training samples to train a model with good generalization ability. However, since it is based on the assumption that the meta tasks are from the same distribution (Figure 1, left), simply feeding all the sources data into it might get sub-optimal results (Chen and Zhu, 2020). Therefore, we propose a modified way to construct meta tasks (Figure 1, right).

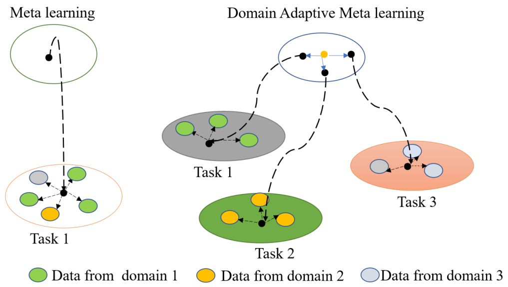

Figure 1: Comparison of meta-learning and domain adaptive meta transfer learning (DAML). In DAML, each meta task contains n sentences from the same domain. In MAML, the data in each meta task come from different domains.

Different from MAML, for DAML, in one batch, the data in each meta task comes from the same source domain, and each meta task comes from a different domain. In this way, we can guarantee that DAML can learn generic representations from different domains in a balanced way. During each iteration, we randomly split all source domains into a meta-training set D_{tr} and a meta-validation set D_{val}, where $D_S = D_{tr} \cup D_{val}$ and $D_{tr} \cap D_{val} = \emptyset$. A meta-training task T_i is sampled from D_{tr} and is composed of n instances from a specific domain. Likewise, a meta-validation task T_j is sampled from D_{val}. The validation errors on D_{val} should be considered to improve the robustness of the model. In short, with DAML, the parameters learned by the model in the parameter space are not biassed towards any one particular domain with as little data as possible during model updating as shown in Figure 1(right).

In the final evaluation phase, the meta-knowledge learned by the sequence-to-sequence model can be applied to new domains. Given a new unseen domain $D_{new} = (T_{tr}, T_{te})$, the learned sequence-to-sequence model and the discriminator are fine-tuned on T_{tr} and finally tested on T_{te}.

3.2.2 ATM Model

In this section, we give a brief introduction to our proposed model: **ATM**, which combines sequence-to-sequence pre-trained model with adversarial training. (1) For the content preservation, we train

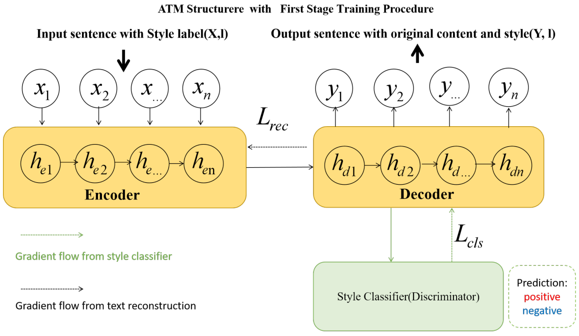

Figure 2: The basic structure of our TST model, ATM, with the first stage training procedure. The green dashed line represents the loss of style classification to ensure that the style classifier can distinguish between different text styles. The black dotted line rerents text reconstruction loss to ensure the generated sentence has a similar semantic meaning as the input sentence.

Algorithm 1 ATM Pre-traing Learning

```
Input: sequence-to-sequence model $f_\theta$,discriminator $\gamma$,and a dataset $D_i$ with style $l_i$ belong to $L_s$
Output: well-trained parameter $\theta, \gamma$
Sample a batch of m sentences $X_1, X_2, ...X_m$ from $D_i$.
while in first stage and not convergence do
    Use $f_\theta$ to generate new sentence
    $Y_i = f_\theta(X_i, l_i)$
    Compute $\mathcal{L}_{cls}(\gamma)$ for $Y_i$ by Eq. (4) ;
    Compute $\mathcal{L}_{rec}(\theta)$ for $Y_i$ by Eq. (3) ;
```

the sequence-to-sequence model θ to reconstruct the original input sentence X with the original style label l. (2) For the style controlling, we train a discriminator network γ to assist the sequence-to-sequence model network in better controlling the style of the generated sentence. The structure of the model is shown in Figure 2.

S2S-model To ease the explanation, we start with the sequence-to-sequence (S2S) model here. Explicitly, for an input sentence $X = (x_1, x_2, ..., x_n)$ of length n, $X \in D$, the S2S encoder $Enc(X; \theta_E)$ maps inputs to a sequence of continuous hidden representations $H = (h_1, h_2, ..., h_n)$. Then, the S2S decoder $Dec(H; \theta_D)$ estimates the conditional probability for the output sentence $Y = (y_1, y_2, ..., y_n)$ by auto-regressively factorized its as:

$$p_\theta(Y|X) = \prod_{t=1}^{n} p_\theta(y_t|H, y_1, ..., y_{t-1}) \tag{1}$$

At each time step t, the probability of the next token is computed by a softmax classifier:

$$p_\theta(y_t|H, y_1, ..., y_{t-1})) = softmax(o_t) \tag{2}$$

where o_t is logit vector outputted by decoder network. The standard S2S model without discriminator makes the output sequence Y the same as the input sequence X.

Discriminator Model By teacher forcing, S2S tends to ignore the style labels and collapses to a reconstruction model, which might copy the input sentence, hence failing to transfer the style. Therefore, to make the model learn meaningful style information, we apply a style discriminator γ for the style regularization. In summary, we use a style discriminator to provide the direction (gradient) for TST to conform to the target style. Our discriminator is a multi-layer perceptron with a sigmoid activation function to predict style labels or guide the direction of style transfer. Our model training involves a pre-training learning strategy and a domain adaptive meta-learning strategy.

3.2.3 First Stage: Pre-training Learning

In the first stage, we train the discriminator model to distinguish different text styles. In this stage, the discriminator models are equivalent to a text classifier. Inspired by (Lewis et al., 2019), we feed the hidden states from the last layer of the decoder into the classifier instead of the gumble-softmax trick (Jang et al., 2017) for gradient backpropagation, which is more stable and better than gumble-softmax(See Table 5). The loss function for the discriminator is simply the cross-entropy loss of the classification problem:

$$\mathcal{L}_{cls}(\gamma) = - \mathop{\mathbb{E}}_{X_i \sim D_S} [logP(l_i|X_i, l_i; \theta, \gamma)] \tag{3}$$

For the S2S model, we pre-train the S2S model to allow the generation model to learn to copy an input sentence X using teacher forcing. The loss function of the sequence-to-sequence model minimizes the negative log-likelihood of the training data:

$$\mathcal{L}_{rec}(\theta) = - \mathop{\mathbb{E}}_{X_i \sim D_S} [logP(Y_i|X_i; \theta)] \tag{4}$$

In summary, we train the sequence model and the style classification model separately on the source domain to learn content preservation and style discrimination in the first stage. The first stage training procedure of the ATM is summarized in Algorithm 1.

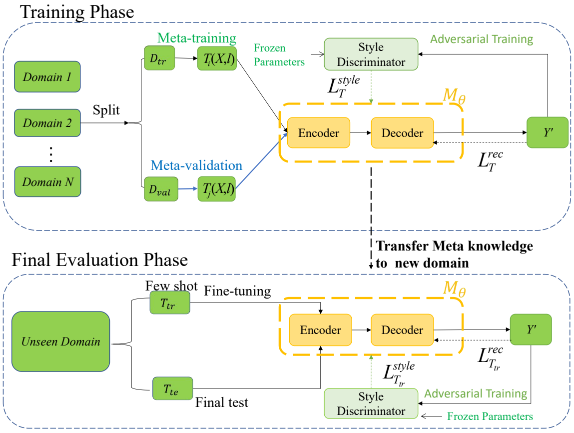

Figure 3: Overview of our proposed DAML-ATM with second stage training strategy. In the meta-training phase, a temporary model $(\theta_{old}, \theta_{new})$ is learned from D_{tr}. In the meta-validation phase, the base model is updated by gradient descent with respect to the parameters θ on D_{val}. In the final evaluation phase, the learned sequence encoder is fine-tuned on T_{tr} and tested on T_{te} from a unseen domain D_{new}.

3.2.4 Second Stage: Domain Adaptive Meta Learning with Adversarial Training

After the first stage of training, the style classifier has learned how to distinguish between different text styles. For style controlling, we adopt a method of adversarial training to avoid disentangling the content and style in the latent space. The discriminator model aims to minimize the negative log-likelihood of opposite style $\tilde{l}_i$ when feeding to the sequence model sentence X_i with the style label l_i. In the second stage, we freeze the parameters of the discriminator. Therefore, style loss only works on the S2S model θ, which forces the S2S model θ to generate opposite styles of sentences:

$$\mathcal{L}_{style}(\theta) = - \underset{X_i \sim D}{\mathbb{E}} [logP(\tilde{l}_i | X_i, l_i; \theta, \gamma)] \quad (5)$$

In the second stage, we use the DAML algorithm for domain adaptive TST, so the text reconstruction loss and the style discriminator loss are calculated over the meta-training samples in task T_i from D_{tr}. These two losses can be written as

$$\begin{aligned} \mathcal{L}_{T_i}^{rec}(\theta) &= - \underset{X_i \sim T_i}{\mathbb{E}} [logP(Y_i | X_i; \theta)] \\ \mathcal{L}_{T_i}^{style}(\theta) &= - \underset{X_i \sim T_i}{\mathbb{E}} [logP(\tilde{l}_i | X_i, l_i; \theta, \gamma)) \end{aligned} \quad (6)$$

We add different prefixes to the input in the second stage, which allows the S2S model to perceive different TST tasks. The second stage of the algorithm is called domain adaptive meta-strategy, which consists of two core phases: a meta-training phase and a meta-validation phase, as shown in Figure 3.

Domain Adaptive Meta-Training

In the meta-training phase, our objective is to learn different domain-specific temporary models for each domain that are capable of learning the general knowledge of each domain. Inspired by feature-critic networks (Li et al., 2019b), we use a similar manner to adapt the parameters of the domain-specific temporary model:

$$\begin{aligned} \theta_i^{old} &= \theta_{i-1} - \alpha \nabla \theta_{i-1} \mathcal{L}_{T_i}^{rec}(\theta_{i-1}, \gamma_{i-1}) \\ \theta_i^{new} &= \theta_{i-1}^{old} - \alpha \nabla \theta_{i-1} \mathcal{L}_{T_i}^{style}(\theta_{i-1}, \gamma_{i-1}) \end{aligned} \quad (7)$$

where i is the adaptation step in the inner loop, and α is the learning rate of the internal optimization. At each adaptation step, the gradients are calculated with respect to the parameters from the previous step. For each domain of D_{tr}, it has different θ^{old} and θ^{new} . The base model parameters θ_0 should not be changed in the inner loop.

Algorithm 2 The training procedure of DAML-ATM

```
**Input:** $\mathcal{D} = \{\mathcal{D}_1, ..., \mathcal{D}_K\}, \alpha, \beta$
**Output:** optimal meta-learned model $\theta$
Initialize the base sequence-to-sequence model $\theta$ and discriminator model $\gamma$ by algorithm 1
while not converge do
    Randomly split $\mathcal{D} = \mathcal{D}_{tr} \cup \mathcal{D}_{val}$ $and$ $\mathcal{D}_{tr} \cap \mathcal{D}_{val} = \emptyset$
    Meta-training:
    for $j$ in meta batches do        //Outer loop
        Sample a task $T_j$ from $D_{val}$
        for $i$ in adaptation steps do        //Inner loop
            Sample a task $T_i$ from $D_{tr}$
            Compute meta-training rec loss $\mathcal{L}_{T_i}^{rec}$
            Compute meta-training style loss $\mathcal{L}_{T_j}^{style}$
            Compute adapted parameters with gradient descent for $\theta_{i-1}$
                $\theta_i^{old} = \theta_{i-1} - \alpha \nabla \theta_{i-1} \mathcal{L}_{T_i}^{tr}(\theta_{i-1}, \gamma_{i-1})$
                $\theta_i^{new} = \theta_{i-1}^{old} - \alpha \nabla \theta_{i-1} \mathcal{L}_{T_i}^{style}(\theta_{i-1}, \gamma_{i-1})$
        Meta-validation:
        Compute meta-validation loss on $T_j$: $\mathcal{L}_{T_j}^{val}$
    Meta-optimization:
    Perform gradient step w.r.t. $\theta$
    $\theta_0 = \theta_0 - \beta \nabla_{\theta_0} \mathbb{E}_{T_j} \mathcal{L}_{T_j}^{val}(\theta_i^{old}, \theta_i^{new}, \gamma)$
```

Domain Adaptive Meta-Validation

After meta-training phase, DAML-ATM has already learned a temporary model$(\theta_i^{old}, \theta_i^{new})$ in the meta-training domains D_{tr}. The meta-validation phase tries to minimize the distribution divergence between the source domains D_{tr} and simulated target domains D_{val} using the learned temporary model. In the meta-validation phase, each temporary model is calculated on the meta-validation domain D_{val} to get meta validation losses.

$$\mathcal{L}_{T_j}^{val} = \mathcal{L}_{T_j}^{rec}(\theta_i^{old}, \gamma_0) + \mathcal{L}_{T_j}^{style}(\theta_i^{new}, \gamma_0) \quad (8)$$

Thus, the base model θ is updated by gradient descent

$$\theta_0 = \theta_0 - \beta \nabla \theta_0 \mathcal{L}_{T_j}^{val} \quad (9)$$

where β is the meta-learning rate. Unlike the ordinary gradient descent process, the update mechanism of Eq. (9) involves updating one gradient by another gradient (w.r.t. the parameters of the temporary model). This process requires a second-order optimization partial derivative.

3.2.5 Final Evaluation Phase of DAML-ATM

In the final evaluation phase, we first initialize the model with the parameters learned during the above algorithm 2. Then, the model takes input as a new adaptation task T, which consists of a small in-domain data S_{tr} for fine-tuning the model and a test set S_{te} for testing. The procedure is summarized in Algorithm 3. (Note that the discriminator is not needed for inference.)

Algorithm 3 The Final Evaluation Procedure of DAML-ATM

```
Input: $\theta, \gamma$ learned from Algorithm 2, low resource training set $S_{tr}$ and test set $S_{te}$ of an unseen domain $D_{new}$
Output: Performance on $S_{te}$
1: while not convergence do
2:     Serialize a task $T_{tr}$ from the unseen domain $S_{tr}$
3:     Update $\theta = \theta - \beta \nabla_\theta \sum_{T_{tr}} (\mathcal{L}_{T_{tr}}^{rec}(\theta) + \mathcal{L}_{T_{tr}}^{style}(\theta))$
4: return optimal $\theta^*$ for $S_{te}$
5: $Style\ accuracy, bleu, domain\ accuracy = f_{T_{te}}(\theta)$
```

Dataset	Domain	Train	Dev	Test	Human Reference
Yelp	Restaurant	444k	4k	1k	1k
Amazon	Product	554k	2k	1k	1k
IMDB	Movie	341k	2k	1k	No
Yahoo!	Q & A	5k	1k	1k	No

Table 1: Statistics of source and target datasets(non-parallel data). The style label set is {negative, positive}.

4 Experiment

In this section, we first detail the experimental setups. Then, we present our experimental results over multiple target domains.

4.1 Datasets and Experimental Setups

In this experiment, we use the following four datasets from different domains: (i) IMDB movie review corpus (Diao et al., 2014). (ii) Yelp restaurant review dataset (Li et al., 2018). (iii) Amazon product review dataset (Li et al., 2018). (iv) YAHOO! Answers dataset (Li et al., 2019a), the amazon and yelp test sets each have 1k human annotations.The statistics of these corpora are summarized in Table 1.

For the S2S model, we take the T5 base model (Raffel et al., 2019) (220MB) for our experiments. For style discriminator, we use 4-layer fully connected neural networks. We train our framework using the Adam optimizer (Kingma and Ba, 2014)with the initial learning rate 1e-5. The epoch is set to 50 for both stage 1 and stage 2. The inner learning rate α is 0.0001, and the outer learning rate β is 0.001. Following (Shankar et al., 2018; Li et al., 2020), we use the leave-one-out evaluation method by picking a domain as the target domain D_{new} for the final evaluation. For each iteration of the training phase, two source domains are randomly selected as the meta-training domain D_{tr} and the remaining domains as the meta-validation domain D_{val}.

In order to evaluate the model performance, we use three famous and widely adopted automatic metrics following previous work (Li et al., 2019a; Fu et al., 2017; Hu et al., 2017a) and a human metric. **BLEU** verifies whether the generated sentences retain the original content (Papineni et al., 2002). While IMDB and Amazon have no manual references, we compute the BLEU scores w.r.t the input sentences. **Style Control** (S-Acc) measures the style accuracy of the transferred sentences with a style classifier that is pre-trained on the datasets. **Domain Control** (D-Acc) verifies whether the generated sentences have the characteristics of the target domain with a pre-trained domain classifier to measure the percentage of generated sentences belonging to the target domain. **Human Evaluation** Following (Madotto et al., 2019), We randomly sampled 100 sentences generated on the target domain and distributed a questionnaire at Amazon Mechanical Turk asking each worker to rank the content retention (0 to 5), style transfer(0 to 5) and fluency(0 to 5): $human\ score = Average(\sum score_{style} + \sum score_{content} + \sum score_{fluency}), human\ score \in [0, 100]$. Five workers were recruited for human evaluation.

	Restaurant(1% target domain data)					Restaurant(100% target domain data)				
Model/Training method	S-Acc	BLEU	G-score	Human	D-Acc	S-Acc	BLEU	G-score	Human	D-Acc

D-Acc	80.6	70.0	72.5	76.5	**86.7**

Table 4: Results on each of the remaining domains treated as target domain,every target domains using 1% data for fine-tuning, base model is AMT.

In our experiments, for ATM model, we adopt five state-of-the-art TST models for comparison: CrossAlign (Shen et al., 2017), ControlGen (Hu et al., 2017a), DAST (Li et al., 2019a), CatGen (Wang et al., 2020a) and FGIM (Wang et al., 2019). They are jointly trained on the source domains and fine-tuned on the target domain.

To well analyze our training method DAML, following (Li et al., 2020), we also use five simple and effective domain adaptation settings with ControlGen (Hu et al., 2017a) structure as DAML: (1) **In-Domain** method is trained on the training set of the target domain; (2) **Joint-Training** method combines all the training sets of the source and target domains and performs a joint-training on these datasets; (3) **Fine-Tuning** method is trained on the training sets of the source domains and then fine-tuned on the training set of the target domain; (4) **D-Shift** This is trained on the combination of training sets from all source domains. Then, the evaluation is conducted on the test set of a target domain using the direct domain shift strategy; (5) **MAML** method uses classical model agnostic meta-learning algorithm (Finn et al., 2017).

4.3 Results and Analysis

For DAML-ATM, we first choose restaurant as the target domain and the other three as the source domains for observation. Table 2 reports the results of different methods and models under both the full-data and few-shot settings. From this table, we can see that DAML-ATM outperforms all baselines in terms of *S-Acc*, *BLEU*, *D-Acc* and human evaluation. We attribute this to the fact that DAML-ATM explicitly simulates the domain shift during

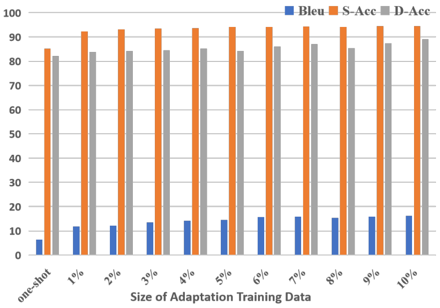

Figure 4: The system performance on amazon improves when the size of the target data increases. Even the one-shot learning achieves decent performance.

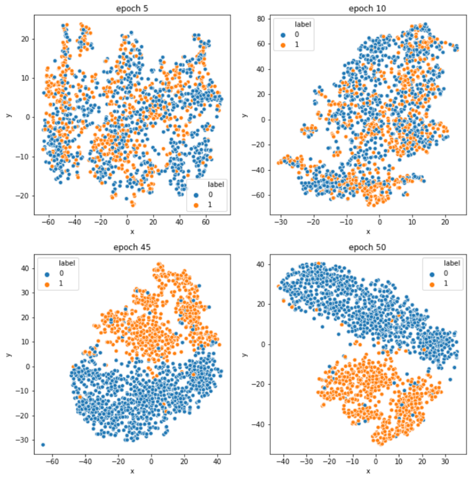

Figure 5: The t-sne plots of source domain sentences and generated target domain sentence in different DAML training epochs. The labels 0 and 1 represent the source domain sentence embedding and the generated target domain sentence embedding.

training via DAML, which helps adapt to the new target domain. We can also see that in the case of a few-shot setting, the results of *Fine-tuning* and *Joint training* are even worse than *In-domain* and DAML. The reason may be that the data size of the source domain is much larger than the target domain so that the model tends to remember the characteristics of the source domain. MAML achieves good performance in most metrics. However, it does not balance meta-tasks across different source domains, performing poorly on D-acc.

Further, to verify the robustness of our method under the low-resource setting, we separately select the other three domains as the target domain. As shown in Table 4, our approach has achieved good performance on different target domains.

We also provide some examples in Table 3. From the example, we can see intuitively that *D-shift* and *Fine-tuning* will lead to the misuse of domain-specific words due to lack of target domain information. In addition, compared with *Joint-training*, the sentences generated by DAML-ATM are more consistent with the human reference. Compared to MAML, DAML generates sentences that are more diverse and vivid due to the more balanced absorption of information from multiple domains. Figure 4 shows the system performance positively correlates with the amount of training data available in the target domain. To visualize how well DAML-ATM performs on the new unseen domain, we use t-SNE (Van der Maaten and Hinton, 2008) plots to analyze the degree of separation between the source domain sentences and the generated target domain sentences. Figure 5 shows that as the training epoch increases, the sentences generated by DAML-ATM in the target domain are completely separated from the source domain in the latent space.

4.4 Ablation Study

To study the impact of different components on the overall performance, we further did an ablation study for our model, and the results are shown in Table 5. After we disabled the reconstruction loss, our model failed to learn meaningful outputs and only learned to generate a word for any combination of input sentences and styles. Then, when the discriminator loss is not used, the model degrades rapidly, simply copying the original sentence without any style modification. After not using the pre-training language model weights, the model's performance is reduced in the metric of content preservation. When using gumble-softmax instead of hidden states for gradient descent, the model performs poorly in style accuracy because of the instability of gumble-softmax. In summary, each factor plays an essential role in the DAML-ATM training stage.

Model	S-Acc	BLEU	D-Acc
DAML-ATM	**94.5**	**25.4**	**92.9**
w/o reconstruction loss	50.0	0	50.0
w/o discriminator loss	2.1	21.6	92.4
w/o language model weights	87.4	17.3	90.3
w/ gumble-softmax	85.6	18.3	91.0

Table 5: Model ablation study results on Yelp dataset. The size of adaptation training data is 1 %.

5 Conclusion

In this paper, we propose DAML-ATM, a novel training strategy combined with a new TST model for domain adaptation, which can be easily adapted to new domains with few shot data. On four popular TST benchmarks, we found significant improvements against multiple baselines, verifying the effectiveness of our method. We explore extending this approach for other low resource NLP tasks in future work.

A Appendix

A.1 More Details on Experiment Setups

Our model is initialized from T5 and Bart (Liu et al., 2020; Raffel et al., 2019). Specifically, the encoder and decoder are all 12-layer transformers with 16 attention heads, hidden size 1,024 and feed-forward filter size 4,096, which amounts to 406M trainable parameters. We train our framework using the Adam optimizer (Kingma and Ba, 2014)with the initial learning rate 1e-5, and we employ a linear schedule for the learning rate, all models are trained on 8 RTX 3090 GPUs.

A.2 Details on Human Evaluation

For the results generated by each method, following (Krishna et al., 2020), we randomly selected 100 sentences to be placed in the Amazon Mechanical Turk[1] questionnaire. We pay our workers 5 cents per sentence. As shown in Figure 6, the questionnaire asked to judge the generated sentences on three dimensions: strength of style transfer, degree of content retention, and text fluency. To minimize the impact of spamming, we require each worker to be a native English speaker with a 95% or higher approval rate and a minimum of 1,000 hits.

A.3 More Ablation Study and Metrics

To verify that the general S2S models work well with our algorithm, we use bart (Lewis et al., 2019) as the S2S base model. For the robustness of the experiment, we add a new metric J-(a,c,f) (Krishna et al., 2020) to measure our results, which is a sentence-level aggregation strategy evaluate style transfer models.

Domain	S-Acc	BLEU	G-score	D-Acc	J-(a,c,f)
Restaurant(T5-base)	94.5	25.4	48.9	89.2	46.4
Restaurant(Bart-base)	94.7	24.1	47.8	88.4	40.2
Movie(T5-base)	81.5	31.2	50.4	92.3	42.8
Movie(Bart-base)	84.5	34.7	54.1	90.1	43.5
Product(T5-base)	87.0	19.9	41.6	84.1	34.5
Product(Bart-base)	84.3	20.4	41.4	86.4	34.7
Q & A(T5-base)	95.5	20.5	44.25	86.7	39.5
Q & A(Bart-Base)	92.5	17.7	40.46	79.8	34.1

Table 6: Results on each of the remaining domains treated as target domain, every target domain using 1% data for fine-tuning, base models are BART and T5.

As can be seen from Table 6, our approach can be combined with other general pre-trained language models and performs well, proving our method's generality. Furthermore, as we can visually see from Table 7, our model also performs well on the J-(a,c,f) metric, which indicates that our model generates sentences in a specific style while having the right target style, preserving content, and being fluent.

A.4 More Generation Examples

To demonstrate more examples of generation to verify the effectiveness of the model, we selected 10 generated sentences from amazon and yelp each, as shown in Table 8 and Table 9.

Restaurant(1% target domain data)		Restaurant(100% target domain data)
Model/Training Method	J-(a,c,f)	J-(a,c,f)
CrossAlign	18.4	22.9
ControlGen	19.2	24.5
FGIM	25.6	28.7
DAST	24.5	32.3
Cat-Gen	20.3	31.2
ATM(ours)	**30.4**	**39.5**
In-Domain	32.5	35.2
Joint-Training	32.3	35.4
Fine-Tuning	28.2	37.8
D-Shift	25.5	34.1
MAML	38.8	44.1
DAML(ours)	**44.8**	**47.6**
DAML-ATM(ours)	**46.4**	**50.8**

Table 7: Evaluation results on restaurant domain(Yelp). The restaurant domain is used as the target domain and the other three domains as the source domain. G-score is the geometric mean of S-Acc and BLEU.The evaluation metrics is J-(a,c,f)

Features or Spurious Artifacts?
Data-centric Baselines for Fair and Robust Hate Speech Detection

Abstract

⚠ **Warning**: *this paper contains content that may be offensive or upsetting.*

Avoiding to rely on dataset artifacts to predict hate speech is at the cornerstone of robust and fair hate speech detection. In this paper we critically analyze lexical biases in hate speech detection via a cross-platform study, disentangling various types of spurious and authentic artifacts and analyzing their impact on out-of-distribution fairness and robustness. We experiment with existing approaches and propose simple yet surprisingly effective data-centric baselines. Our results on English data across four platforms show that distinct spurious artifacts require different treatments to ultimately attain both robustness and fairness in hate speech detection. To encourage research in this direction, we release all baseline models and the code to compute artifacts, pointing it out as a complementary and necessary addition to the data statements practice.[1]

1 Introduction

Hate speech in online social communities is a serious and pervasive concern, which requires fair and robust automated approaches to be tackled at scale. However, despite the great progress in natural language processing for detecting hate speech, current models have shown to be brittle when applied to real-world data, exhibiting limited out-of-distribution (OOD) robustness (Vidgen et al., 2019) and perpetuating and amplifying harmful social biases (Röttger et al., 2021). Noticeably, hate speech detection systems are typically trained on data from limited language varieties such as individual platforms, which inevitably exhibit differences in writing norms, language use, and hate targets, hampering generalization (Vidgen and Derczynski, 2020).

	fair	robust
what have jews done to you?	✗	
RT [user]: I'm mad at this		✗
All black people literally go there	✗	✗

Table 1: Posts wrongly labeled as hateful by a fine-tuned BERT classifier due to the presence of spurious lexical artifacts (identity and non identity-related) and their negative impact (✗) on fairness and robustness.

One of the main reasons for limited robustness and fairness of mainstream hate speech detection systems is largely ascribable to spurious statistical correlations between surface lexical items and labels in training data, which models exploit to derive predictions. These biases are commonly referred to as lexical **dataset artifacts**, and have recently attracted attention in the NLP community, particularly in natural language inference (NLI) studies (Belinkov et al., 2019; Gururangan et al., 2018; Poliak et al., 2018, *inter alia*). Efforts to tackle the issue in hate speech detection are instead rather scattered, and mainly focus on fairness using datasets from few platforms (Zhou et al., 2021; Kennedy et al., 2020b, *inter alia*), leaving the study on OOD robustness largely unexplored. We instead argue that fairness and robustness are strongly intertwined aspects (Table 1), and thus should be studied jointly, with the goal to understand to what extent these two dimensions are related.

Previous work has shown that state-of-the-art models overly rely on identity words (e.g., "jews", "gay") to predict hateful content (Zhou et al., 2021; Kennedy et al., 2020b, *inter alia*), further demoting voices of people from already marginalized groups (Bender et al., 2021). However, non identity-related lexical items – such as "sport", "announcer", and "football" in Waseem and Hovy (2016) – are also often spuriously associated with hate speech due to a biased data collection process (Wiegand et al., 2019), undermining OOD robustness. Despite the recent trend in minimizing

---

[1] Code and resources are available at `https://github.com/dhfbk/hate-speech-artifacts`.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3027 - 3040
July 10-15, 2022 ©2022 Association for Computational Linguistics

topic bias in data sampling, we show that some spurious lexical artifacts still remain highly-predictive on certain distributions even if data has been sampled in a more attentive fashion (e.g., artifacts that are potentially data- or platform-specific – Figure 1, highlighted in gray).

We argue that disentangling artifacts into fine-grained categories by means of a cross-platform analysis may be beneficial to drive a broader debiasing of current hate speech models, ultimately improving both fairness and robustness to out-of-distribution data. To this purpose, we critically analyze artifacts in hate speech detection across multiple platforms and propose simple yet effective data-centric baselines exploiting spurious lexical items. We show that although we achieve substantial improvements in OOD fairness by exploiting spurious identity-related artifacts, this comes at the cost of robustness. This confirms that fairness and robustness are strictly interrelated dimensions that should be studied together in future research.

Contributions To the best of our knowledge, we are the first to (i) conduct a thorough investigation of lexical artifacts across online platforms; (ii) disentangle artifacts into fine-grained categories; and (iii) propose a viable data-centric approach based on masking that consistently improves fairness over *all* baselines across *all* platforms. To foster future research on the topic, we also release (iv) code to reproduce all experiments, and (v) disaggregated lexical artifact annotations, more broadly (vi) suggesting the inclusion of dataset artifacts in data statements (Bender and Friedman, 2018), which can be easily revealed using our codebase.

2 Lexical Artifacts are *not* all the Same

We conceptualize dataset artifacts at the lexical level as *emergent correlations between tokens and labels in input data*, consistently to lexical annotation artifacts in NLI (Gururangan et al., 2018). As such, given a target class c, we formally define lexical artifacts $\mathcal{L}_c$ as the set of highly-discriminating[2] tokens for c, which comprise **authentic artifacts** $\mathcal{A}_c$ – items that potentially carry useful information for the class at hand – and **spurious artifacts** $\mathcal{S}_c$ – items that are spuriously (or undesirably) associated to the target class – such that $\mathcal{L}_c = \mathcal{A}_c \cup \mathcal{S}_c$. In the context of hate speech detection, we consider the hateful class as c unless otherwise specified and simplify the notation (i.e., from “$\cdot_c$” to “$\cdot$”).

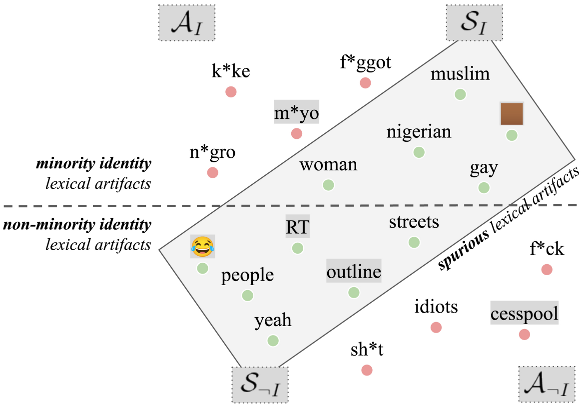

Figure 1: Illustration of lexical artifacts in hate speech detection, including relevant examples. $\mathcal{A}_I$: authentic artifacts, identity-related; $\mathcal{A}_{\neg I}$: authentic artifacts, non identity-related; $\mathcal{S}_I$: spurious artifacts, identity-related; $\mathcal{S}_{\neg I}$: spurious artifacts, non identity-related. Items highlighted in gray are potentially platform-specific.

We build our definitions on top of the categories of lexical biases by Zhou et al. (2021), which originally identify three bias groups: *i)* minority identity mentions which are not offensive, *ii)* minority identity mentions which are potentially offensive, and *iii)* non-identity mentions which are possibly offensive. We enrich this categorization by introducing a high-level separation into spurious (i.e., group *i)* in Zhou et al. (2021)) and authentic artifacts (i.e., group *ii)* and *iii)*), and including an additional spurious, non identity-related category (Section 2.2).

Indeed, given the broad nature of authentic and spurious artifacts, we further categorize them in Section 2.1 and 2.2 (see Figure 1 for an overview).

2.1 Authentic artifacts

We define authentic lexical artifacts $\mathcal{A}$ as the subset of highly-discriminating tokens which potentially convey hatefulness, profanity, or are otherwise frequently associated with hateful contexts. Intuitively, $\mathcal{A}$ is the set of artifacts which is likely to be informative to detect hate speech across distributions. Authentic artifacts enclose minority identity-related artifacts $\mathcal{A}_I$ and non-identity artifacts $\mathcal{A}_{\neg I}$.

Identity-related ($\mathcal{A}_I$) Potentially offensive or stereotyping terms towards minority identities (e.g., “n*gro”, “f*ggot”, “k*ke”, “wh*re”), as well as reclaimed slurs (e.g., “n*gga”) (Figure 1, top left).

Non-identity related ($\mathcal{A}_{\neg I}$) Swear words and profanities (e.g., “f*ck”, “sh*t”) as well as broad

---

[2] Highly-discriminating tokens can be computed and filtered using information theory and statistics measures.

terms typically associated with hateful contexts (e.g., “kill”, “idiots”) (Figure 1, bottom right).

2.2 Spurious artifacts

Spurious lexical artifacts $\mathcal{S}$ broadly enclose all tokens which we do not expect to be predictive for the target class at hand. As such, we postulate that those artifacts are a main reason for insufficient robustness and fairness of current hate speech detectors, and thus may play a positive role in lexical debiasing. We specifically focus on these artifacts in our experiments. As for authentic artifacts, spurious items can be grouped into minority identity-related artifacts $\mathcal{S}_I$ and non-identity artifacts $\mathcal{S}_{\neg I}$, the latter being currently disregarded in research investigating fairness only (Zhou et al., 2021).

Identity-related ($\mathcal{S}_I$) Terms describing a social minority, which are typically associated to hate speech due to their frequency on offensive statements on online fora (e.g., “muslim”, “woman”, “Islam”, “nigerian”, “LGBT”) (Figure 1, top right).

Non-identity related ($\mathcal{S}_{\neg I}$) All non-identity tokens which are unexpectedly associated to hate speech, e.g., due to platform-specificity, bias in collection timeframe, etc. (e.g., “people”, “RT”, “streets”, “Trump”, “yeah”) (Figure 1, bottom left).

3 Data

In this work we focus on hate speech, i.e., messages whose content spreads hatred or incites violence, or threatens people’s freedom, dignity and safety, and whose target is a protected group, or an individual targeted for belonging to such a group and not for his/her individual characteristics (Poletto et al., 2021). Hate speech typically encompasses serious cases of offense with severe moral and legal implications, i.e., those cases that are of primary importance for content moderation.

We collect hate speech corpora that meet the following criteria: (i) they minimize topic and author biases in data collection (Wiegand et al., 2019), using alternatives to keyword and user searches such as pure or boosted random sampling, (ii) they pertain to different social media platforms, and (iii) they follow similar annotation guidelines, where hate speech is clearly defined and separated from other types of offensive language. For each corpus we create *hateful* and *non-hateful* examples. All datasets follow consistent preprocessing, deduplication, and anonymization (Appendices A.1 and A.2).

REDDIT (●) We use the recently introduced Reddit dataset (v1.1) by Vidgen et al. (2021) which preserves a variety of grammar, topic, and style features due to a community-based sampling approach. The corpus contains 27,494 entries annotated following a hate speech taxonomy comprising abusive (*identity-directed*, *affiliation-directed*, *person-directed*) and non-abusive labels (*non-hateful slurs*, *counter speech*, and *neutral*). We follow the widely accepted definition of hate speech as “abuse targeting a protected group or its members for being a part of that group”[3] (Röttger et al., 2021; Banko et al., 2020; Vidgen et al., 2019, *inter alia*) to create the *hateful* label from *identity-directed* examples, and the *non-hateful* label from the remaining examples. For the purpose of this study, we discard instances marked as requiring previous content to be interpreted.[4] The final dataset after preprocessing consists of 1,688 *hateful* and 19,888 *non-hateful* examples, for a total of 21,576 unique instances.

TWITTER (🐦) We select a widely used hate speech dataset which has been collected following a bootstrap random sampling approach (Founta et al., 2018). The dataset consists of 99,996 tweets annotated as *hateful*, *abusive*, *spam*, and *normal*. Similarly to previous work, we discard the *spam* category (Zhou et al., 2021), forming the *hateful* class following the original classification provided by the authors. This led to 3,937 *hateful* and 70,554 *non-hateful* examples, for a total of 74,491 tweets.

GAB (🐸) We use the GAB hate corpus by Kennedy et al. (2020a), whose data has been sampled purely randomly due to the frequency of hate speech of the “free speech-preserving” (Zannettou et al., 2018) GAB social network. The corpus (v.2021-03-03) consists of 27,546 posts annotated with *(assault on) human dignity*, *call for violence*, and *vulgarity/offensive* labels. Similarly to previous work, we take the union of *human dignity* and *call for violence* labels for the *hateful* class (Kennedy et al., 2020b), whereas we create the *non-hateful* class from the remaining examples. We also leverage target annotations and consider messages towards ideology/political groups as *non-hateful*, to ensure consistency among datasets. As

---

[3] Groups based on age, disability, familial status, gender identity, national/ethnic origins, pregnancy, race, religion, sex or sexual orientation, as defined in Röttger et al. (2021), which in turn reflects the US 1964 Civil Rights Act, the EU’s Charter of Fundamental Rights, and the UK’s 2010 Equality Act.

[4] We leave the investigation of lexical artifacts in context-aware hate speech detection for future work.

a result, the final dataset is made up of 27,014 messages: 1,785 *hateful* and 24,829 *non-hateful*.

STORMFRONT (💬) We use the dataset pertaining to a white supremacist web forum collected by de Gibert et al. (2018) following a random sampling procedure. It consists of a total of 10,944 messages with annotations for *hate*, *no-hate*, *relation*, and *skip* labels. We remove *relation* and *skip* examples, since they require previous context, or they represent spam / content written in other languages, respectively. We then use the *hate* examples for the *hateful* class, and the *no-hate* instances for the *non-hateful* class. This led to a total of 10,448 examples, 1,192 *hateful* and 9,256 *normal*.

4 Disentangling Lexical Artifacts

In order to disentangle lexical artifacts, we first compute the correlation between each token and the hateful class for each dataset (Section 4.1), then assessing the cross-distribution indicativeness of each token (Section 4.2). For segmenting texts into tokens, we rely on the training portion of each dataset only (Section 5) and employ the WordPiece (Schuster and Nakajima, 2012) subword tokenizer as used in BERT (Devlin et al., 2019).[5] Finally, we perform lexical artifacts annotation (Section 4.3) following the categories defined in Section 2.

4.1 In-distribution artifacts

We follow Gururangan et al. (2018) and employ pointwise mutual information (PMI; Fano, 1961) to compute the discriminativeness of each token to the target class.[6] Since lexical artifacts are meant to be used for downstream debiasing, we argue that tokens should be consistent with inputs to the end model. As a result, we use tokens as given by the WordPiece subword tokenizer, the same tokenizer used by models employed in our experiments (Section 5). Formally, given a token t and a class c, the PMI is defined as follows:

$$\text{PMI}(t, c) = log\frac{p(t, c)}{p(t|\cdot)p(\cdot|c)} \tag{1}$$

We further apply reweighting to emphasize highly-discriminative token-class correlations, and normalize ≤ 0 values to zero since negative PMI scores are known to be unreliable on relatively small corpora (Jurafsky and Martin, 2021, Ch. 6).

Rank	👽	🐦	🐸	💬	Avg.
1	##tar	##gga	white	n*gro	##s
2	##ded	hate	jews	white	white
3	##s	rt	##gger	black	black
4	fa	##s	##s	##s	jews
5	b*tch	[user]	jew	jews	hate
6	##gg	idiot	islam	whites	##es
7	gay	trump	muslim	blacks	women
8	women	ass	whites	jew	people
9	##ds	idiots	##gg	race	##tar
10	f*cking	people	women	##es	jew

Table 2: Top 10 most informative tokens for the hateful class according to PMI, divided per platform dataset (left), and after cross-distribution computation (right).

Discussion The top 10 tokens on each platform that are more associated with the hateful class are presented in Table 2 (left). All platforms exhibit a variety of lexical artifact types (cf. Section 2); however, we observe clear divergences across distributions. While artifacts in Stormfront data are mainly related to race, on Gab the focus is more on religion. Reddit and Twitter conversations are instead more varied, with higher occurrence of spurious, non-identity artifacts (e.g., “RT”, “people”).

4.2 Cross-distribution artifacts

When datasets from multiple platforms are available, we hypothesize that leveraging individual scores makes possible to better identify artifacts. Given $\text{PMI}(t, c)^d$ the score of a token t for the hateful class c on a given distribution $d \in D$ (e.g., platform), we normalize it in $[0, 1]$ by applying a min-max normalization function to enable cross-platform score comparability – obtaining $\text{PMI}(t, c)^d_{[0,1]}$ – further applying a log_2 transformation to mitigate the skewness of the original PMI distribution. As a result, the final cross-distribution score $S(t, c)$ for each token is given by the average of the corresponding individual scores:

$$S(t, c) = \frac{1}{|D|}\sum\nolimits_{d=1}^{D} log_2(\text{PMI}(t, c)^d_{[0,1]}) \tag{2}$$

We then sort tokens by descending score, highlighting lexical artifacts that are highly discriminating for the hateful class across distributions. Table 2 (right) shows the top 10 tokens after the cross-platform computation is carried out.

---

[5] In preliminary experiments we found similar results when using the byte-level BPE tokenizer (Sennrich et al., 2016) as used in RoBERTa (Liu et al., 2019).

[6] A comparative assessment of different metrics for computing token-class correlations is out-of-scope in this study and will be investigated in future work.

Discussion As shown in Table 2 (right), cross-platform importance of tokens for the hateful class demotes scores (and thus, ranks) of lexical artifacts which are likely to be more indicative on some platforms only (e.g., "RT"), while consolidating the informativeness of cross-platform items (e.g., "jews", "hate", "##s", "##es",[7] "people"). This confirms our hypothesis that encompassing multiple platforms is beneficial for capturing lexical items that are likely to be predictive *across* distributions.

4.3 Artifacts annotation

In order to disentangle lexical artifacts for further debiasing, we select the k most predictive tokens given by the cross-distribution rank of discriminativeness (Section 4.2) to be manually annotated.[8] In our experiments, we set $k = 200$ as it matches the subset of tokens which are highly informative (≥ 0.33).[9] All k tokens have been labeled as potentially hateful and/or related to minority identities by two annotators – male and female, fluent in English – with background in linguistics and NLP, and past experience in hate speech activities with NGOs. Each annotator was provided with five examples of tokens in context for enabling more informed annotation decisions, represented by randomly sampled posts from the four platforms included in this study.

After annotation, the two annotators were involved in an adjudication session in order to discuss the cases of disagreement, followed by correction wherever possible. We calculate the inter-annotator agreement (IAA) score before and after adjudication using Cohen's kappa (Cohen, 1960). We obtain $\kappa = 0.6887$ before and $\kappa = 0.8311$ after the adjudication session, which is high agreement.

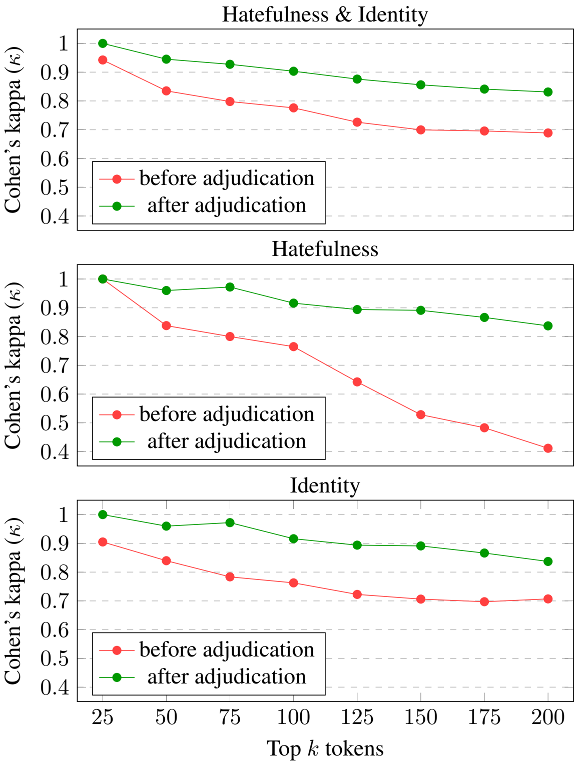

Figure 2: Cumulative Cohen's kappa (κ) scores for the full annotation of lexical artifacts (top), and for decisions on potentially hateful or identity-related artifacts only (middle and bottom, respectively), ordered by informativeness according to cross-distribution scores.

Discussion Although some cases of disagreement were easily resolvable (e.g., annotation errors), we found tokens which are difficult to discern due to ambiguity – mostly subwords – or due to real disagreement in the interpretation of the terms. This is in line with existing works showing that disagreement in toxicity annotation is inherent to the task and cannot always be solved through majority voting or adjudication (Aroyo et al., 2019; Leonardelli et al., 2021). Interestingly, this disagreement follows the trend of cross-distribution rank of artifacts (Figure 2). We decided to leave the analysis of annotators' disagreement for future work, and we release these cases as disaggregated labels. In Table 3 we show the most informative artifacts by type, whereas the full list of spurious artifacts used in the experiments is in Appendix B.

5 Experiments

We investigate the impact of spurious lexical artifacts on fairness and robustness in hate speech detection. Similarly to previous studies (Kennedy et al., 2020a; Röttger et al., 2021), we cast hate speech detection as a binary classification problem, where the two classes to be predicted are *hateful* and *non-hateful*, as defined in Section 3. We carry out in-distribution and OOD experiments, namely training and testing all models on the same or different platform data, respectively. We evaluate performance of models using macro F_1 score, whereas for fairness we use false positive rate (FPR) on test instances containing S_I mentions, consistently to

---

[7] We found "##s" and "##es" tokens typically correspond to plural suffixes of out-of-vocabulary words.

[8] The main advantage of token-level annotation compared to word-level annotation is that it allows to discern generic subwords from hateful or identity-related ones – e.g., "homophobia" $\mapsto$ {"homo", "##phobia"} – without losing important information when doing removal or masking (Section 5).

[9] We leave the investigation of larger thresholds for future work due to space and annotation constraints.

Authentic artifacts		*Spurious artifacts*

previous work (Zhou et al., 2021).

We outline the experimental setup in Section 5.1, whereas data-centric baselines are presented in Section 5.2. Lastly, we present results and a thorough discussion in Section 5.3.

5.1 Experimental setup

For all our experiments, we employ the uncased BERT-base model (Devlin et al., 2019) as implemented in the MaChAmp v0.2 toolkit (van der Goot et al., 2021), since it has been shown to achieve state-of-the-art performance in hate speech detection (Tran et al., 2020). We use default hyperparameters, and perform a grid search to determine the number of epochs, the learning rate, and the batch size, using the search space suggested by Devlin et al. (2019) – i.e., [2, 3, 4] for epochs, [2e-05, 3e-05, 5e-05] for learning rate, and [16, 32] for batch size. We use stratified 80% train, 10% development, 10% test splits for each dataset, selecting the best model based on the average macro F_1 score on the development test across all platforms. During fine-tuning, we emphasize the minority hateful class using a cross-entropy loss with balanced class weights. The final hyperparameters are: 4 for epochs, 2e-05 for learning rate, and 16 for batch size. All experiments have been run on a NVIDIA Tesla V100-SXM2 GPU, with a training time ranging from 10 to 40 minutes each. The number of trainable parameter for all models are $\approx$110M.

5.2 Baselines

We investigate the impact of spurious identity-related and non identity-related lexical artifacts on the robustness and fairness of hate speech detection by employing the following data-centric baselines.

VANILLA We fine-tune the BERT-base model on each corpus, so that the proposed baselines can be directly compared to a commonly employed setup.

FILTERING Swayamdipta et al. (2020) have shown that the most ambiguous training data instances promote OOD generalization while preserving in-distribution performance. We thus leverage the VANILLA model's training dynamics to filter training data to contain the 33% most ambiguous instances only, in line with the subset size in Swayamdipta et al. (2020).[10] Intuitively, those are instances whose class probabilities fluctuate frequently across training epochs. We then fine-tune the BERT-base model on the resulting subset. This setup is similar in spirit to the one employed in Zhou et al. (2021); however, we assess it on data from multiple platforms, also removing duplicate instances (Appendix A.2) which may potentially confound the debiasing results.

REMOVAL Prior to fine-tuning, we naively remove any occurrence of spurious lexical artifacts from training and development data. This matches previously employed baselines for assessing fairness in hate speech detection (Kennedy et al., 2020b). However, since we are also interested in OOD robustness, we experiment with two removal variants: one for $\mathcal{S}_I$ and one for $\mathcal{S}_{\neg I}$ artifacts. We hypothesize that removing $\mathcal{S}_I$ tokens potentially improves fairness, whereas removing $\mathcal{S}_{\neg I}$ tokens mostly contributes to OOD robustness.

MASKING We propose a novel data-centric debiasing alternative based on token masking. Instead of removing spurious artifacts altogether, we reserve a special token in the vocabulary of the model that we use as replacement for spurious artifacts. We then fine-tune the model on the masked data. Intuitively, this way we encourage the model to blend all artifacts to a single contextualized representation that will never appear during testing, also avoiding to redistribute the informativeness of spurious lexical items to surrounding tokens. As for REMOVAL, we experiment with $\mathcal{S}_{\neg I}$ and $\mathcal{S}_I$ masking variants.

5.3 Results and discussion

In Table 4 we report the results for all baselines along the in-distribution and out-of-distribution dimensions from the lens of fairness and robustness.

---

[10] For fair comparison, we also provide results with less (50%) and more (25%) aggressive thresholds in Appendix C.1.

Table 4: In-distribution and out-of-distribution results (F_1 for accuracy and FPR for fairness). Out-of-distribution results are on → 👽: Reddit, → 🐦: Twitter, → 🐸: Gab, and → 💬: Stormfront. Scores are averages of 3 runs with different seeds, whereas subscripts indicate standard deviation. ↑: greater the better; ↓: lower the better.

Since we argue that in-distribution performance is *not* a reliable measure for the performance of a hate speech detection system *in the wild*, due to space constraints we here focus on the more realistic yet more challenging out-of-distribution setup.

Filtering is not a one-size-fits-all solution Despite the improvements in OOD generalization on commonsense reasoning, question answering, and NLI tasks (Swayamdipta et al., 2020), training on ambiguous instances collected from training dynamics is not as effective in hate speech detection.[11] Instead, our results show that Filtering leads to mixed results for OOD fairness compared to the Vanilla baseline. This is consistent with results on Twitter data (Zhou et al., 2021), and we further confirm it is the case also across platforms. Importantly, we also notice that Filtering has a detrimental effect on OOD robustness, except for two cases only (i.e., 🐦 → 👽 and 🐸 → 💬). This indicates that hate speech detection is a nuanced task requiring more targeted approaches than automated data filtering.

Removing $\mathcal{S}_I$ is not as strong as it has been previously thought Removing identity terms from data altogether is a commonly used baseline for testing downstream fairness (e.g., Kennedy et al., 2020b). Indeed, our results confirm that Removal($\mathcal{S}_I$) consistently reduces the FPR on test instances containing $\mathcal{S}_I$ mentions compared to the Vanilla baseline – with the only exception of 💬 → 🐸. However, it only improves OOD robustness on 🐸 → 👽 and 💬 → 🐦. Moreover, it consistently scores lower than Masking($\mathcal{S}_I$) on fairness, as discussed below. This raises the question of whether Removal($\mathcal{S}_I$) should continue to be used as fairness baseline in future studies.

Masking $\mathcal{S}_I$ improves fairness When masking $\mathcal{S}_I$, we notice a consistent improvement in fairness over *all* approaches, both in-distribution and out-of-distribution, on *all* platforms. Reduction in FPR over the Vanilla baseline is as large as 3×, as results for {🐦; 🐸} → 💬 and 🐸 → 🐦 show. Most of the remaining train-test pairs show a 2× improvement in FPR, also compared to the common Removal($\mathcal{S}_I$) baseline. We hypothesize the improved fairness performance with respect to Re-

---

[11] We notice this holds true also when employing less/more aggressive filtering thresholds, as shown in Appendix C.1.

moval($\mathcal{S}_I$) is due to the way contextualized representations are formed during training, as discussed in Section 5.2. Despite being surprisingly simple, we envision Masking($\mathcal{S}_I$) as a strong baseline for future work on fairness in hate speech detection.

$\mathcal{S}_{\neg I}$ artifacts are not as useful as $\mathcal{S}_I$ We observe that methods exploiting $\mathcal{S}_{\neg I}$ artifacts lead to mixed results. This suggests that while a substantial FPR reduction can be achieved exploiting $\mathcal{S}_I$ artifacts, robustness calls for more complex debiasing strategies to transfer well across distributions.

Fairness comes at the cost of robustness Overall, we observe an important trade-off between fairness and robustness. Data-centric approaches that achieve a consistently high level of fairness – namely, Masking($\mathcal{S}_I$) and Removal($\mathcal{S}_I$) – typically show a decrease in in-distribution and out-of-distribution performance – with the exception of 👽 $\rightarrow$ 👽 and 🐸 $\rightarrow$ 👽 for Masking($\mathcal{S}_I$), and 🐸 $\rightarrow$ 👽 and 💬 $\rightarrow$ 🐦 for Removal($\mathcal{S}_I$). On one hand, this suggests that spurious, identity-related lexical artifacts do play an important role in performance *across* distributions. On the other hand, we believe this reflects the real performance of a prototypical model that is substantially fairer, and thus to which future work in hate speech detection should be compared to. We argue that Masking($\mathcal{S}_I$) represents a starting point to achieve both fairness and OOD robustness, the latter requiring more complex, model-centric debiasing approaches. A summary of the results over all corpus pairs for each method is presented in Appendix C.2.

6 Towards Artifacts Documentation

The practice of *data statements* (Bender and Friedman, 2018) has been recently adopted by the NLP community as a way to include relevant information about the creators, the methodology and possible biases when a dataset is released. This should in turn have a positive impact on systems trained on such data, contributing to a better evaluation of models' generalization and fairness. We propose that an **artifacts statement** should be added to this documentation as a way to contribute to diagnosis (and thus mitigation) of pre-existing bias, which is also one of the goals of data statements.

In particular, we propose a template for lexical artifacts documentation and publicly release code to easily compute ranked correlations between tokens and target classes of interest for a given annotated corpus. To ensure the process of documenting lexical artifacts will be as smooth as possible – and thus allows widespread adoption of artifacts statement in the future – our code automatically generates outputs in different formats, from raw text to LaTeX code for seamless inclusion in publications.

We present the artifacts statement template below, and provide a full example in Appendix D.

i) Top lexical artifacts. Which are the k most informative tokens in the corpus for the class(es) of interest? This can be a ranked list of ($k \geq 10$) tokens in plain text or in a tabular format, optionally along with associated scores. If there are multiple classes of interest, top k lexical artifacts for each class should be included.

ii) Class definitions. Different definitions for the same class may exist across datasets. This impacts the annotation, which in turn has an effect on resulting lexical artifacts. An explicit definition of the target class(es) for which the top lexical artifacts are computed should be provided here.

iii) Methods and resources. The method used to compute the correlation between tokens and class(es) (e.g., PMI, interpretability approaches) in the annotated corpus should be reported here, possibly with a link to code. If preprocessing and deduplication have been performed, they should be clearly reported. Resources such as full lists of lexical artifacts can be additionally included.

7 Related Work

The problem of models' generalizability related to hate speech detection has been extensively discussed in recent works (Vidgen and Derczynski, 2020; Yin and Zubiaga, 2021; Wich et al., 2021). Indeed, it has been shown that state-of-the-art performance on this task overestimates the capability of models to yield the same results over time (Florio et al., 2020) or across different domains (Wiegand et al., 2019). Possible mitigation strategies include domain adaptation techniques (Ramponi and Plank, 2020), augmenting smaller datasets with a larger dataset from a different domain (Karan and Šnajder, 2018), the use of a domain lexicon to transfer knowledge across domains (Pamungkas and Patti, 2019) and the fine-tuning of HateBERT (Caselli et al., 2021) on the target corpus (Bose et al., 2021), among others.

Concerning bias and fairness, several works have pointed out the presence of bias in hate and abusive language datasets (Wiegand et al., 2019; Sap et al., 2019, 2020). This issue has been addressed in different ways, including functional tests for hate speech detection models (Röttger et al., 2021; Manerba and Tonelli, 2021) and post-hoc explanations to measure models' bias towards identity terms (Kennedy et al., 2020b). As regards bias mitigation, the task has been addressed through a number of approaches, e.g., via adversarial feature learning (Vaidya et al., 2020), by using debiased word embeddings and gender swap data augmentation (Park et al., 2018) or by adding non-toxic examples to better balance the data (Dixon et al., 2018). The work probably most related to ours is Zhou et al. (2021), which presents an analysis of lexical and dialectal biases in the dataset by Founta et al. (2018). The authors propose lexical bias categories which we extend in this work (see Section 2). However, they focus only on one dataset and on in-domain bias reduction. Moreover, they start from a list of "bad words", whereas we compute it from data. To our knowledge, this is the first work advocating for a joint view on fairness and robustness, both identified as critical aspects related to the classification of hate speech (Wich et al., 2021).

8 Limitations

Our work is a step forward towards a better understanding of the bias that can be encoded in hate speech detection corpora (Blodgett et al., 2020). However, we are aware of some limitations. First, all findings in this work are related to hate speech datasets in English. With the increasing availability of hate speech data in languages other than English, we aim to investigate our methods on other languages too. Second, annotated data from multiple platforms may not be available for some languages, and this can limit the cross-distribution computation of artifacts. Lastly, we acknowledge spurious statistical correlations may go beyond the token level. We believe our study is a first step towards contextual debiasing from spurious lexical artifacts, and thus can be of inspiration for future studies.

9 Conclusion and Future Directions

This paper investigates the impact of lexical artifacts on out-of-distribution fairness and robustness in hate speech detection, raising awareness on the interplay between the two dimensions that should be studied together in future work. We propose a fine-grained categorization of lexical artifacts and simple yet effective data-centric baselines, showing that while robustness calls for model-centric approaches, masking spurious identity artifacts is a viable approach that we argue should be used as strong baseline for fairness assessment in future research. In future work we aim to investigate the role of dialectal biases and non-lexical artifacts, extending the study on languages other than English. We release all baseline models, resources, and the code to compute lexical artifacts, broadly suggesting the inclusion of "artifacts statement" as a way to document potential lexical biases when a dataset is released, to provide a complementary view to data statements (Bender and Friedman, 2018).

Ethical Considerations

The annotation task described in Section 4.3 was carried out by two researchers regularly employed at Fondazione Bruno Kessler as part of their work.

Overall, we do not foresee any specific ethical concern related to this work. On the contrary, our goal is to propose artifacts statement as a desirable practice for documenting potential biases in newly released datasets, and improve current debiasing methods by distinguishing among different types of lexical artifacts. However, the (finite set of) identity-related and offensive tokens considered in this work are all in English and centered around Western cultural context. We leave the evaluation of our methodology to assess whether there are language- or more broadly culture-dependent changes for future work, following recent work on biases in geo-cultural contexts (Ghosh et al., 2021).

Appendix

A Data: Additional Details

A.1 Preprocessing and anonymization

We preprocess texts across platforms in a consistent way by anonymizing user mentions, URLs, and email addresses with `[USER]`, `[URL]`, and `[EMAIL]` placeholders, respectively. We segment hashtags into constituent words using the `wordsegment` package,[12] remove newlines, unescape HTML tags, and lowercase the texts.

A.2 Deduplication

We found many duplicates in the data for all platforms. We argue that retaining duplicates as done in most previous work could severely affect the reliability of any bias analysis (and debiasing method) and its subsequent conclusions. Specifically, duplicates can (i) skew the distribution of actual artifacts in the data, overamplifying some lexical items and demoting others, and (ii) result in unfair evaluations due to identical examples falling in multiple instances of the training, development and test sets, also potentially leading to overfitting.[13]

Following this intuition, we thus remove duplicate instances after preprocessing.[14] Specifically, we removed 485 duplicate instances from Vidgen et al. (2021), 10,911 duplicate instances from Founta et al. (2018), 521 from Kennedy et al. (2020a), and 255 from de Gibert et al. (2018). Moreover, for the purpose of this work we remove duplicates whose single instances exhibit opposing labels, leaving the exploration and exploitation of annotator disagreement for future work.

B List of Spurious Artifacts

In the following, we provide the list of all spurious lexical artifacts annotated as $\mathcal{S}_I$ and $\mathcal{S}_{\neg I}$ as described in Section 4.3. All these are the ones that exhibit full agreement. In our shared repository we also release all artifacts that exhibit disagreement even after adjudication, in order to encourage future work on this direction.

Identity-related ($\mathcal{S}_I$) “white”, “black”, “jews”, “women”, “jew”, “whites”, “blacks”, “muslim”, “gay”, “muslims”, “islam”, “woman”, “jewish”, “islamic”, “immigrants”, “mexican”, “asian”, “homosexual”, “americans”, “lesbian”, “homo”, “females”, “america”, “brown”, “israel”, “arabs”, “zionist”, “trans”, “lgbt”, “girl”, “hispanic”, “refugees”, “male”, “african”, “africa”, “girls”, “indians”, “queer”, “##grate”, “guy”.

Non identity-related ($\mathcal{S}_{\neg I}$) “##s”, “##es”, “people”, “country”, “##ing”, “anti”, “illegal”, “bunch”, “##t”, “kids”, “culture”, “brain”, “##ly”, “##bt”, “##d”, “sex”, “ho”, “##nt”, “countries”, “##ic”, “##ers”, “liberal”, “reason”, “##y”, “human”, “genocide”, “##ed”, “##ists”, “wrong”, “lives”, “bad”, “god”, “##oc”, “lying”, “##ard”, “racism”, “##e”, “##oid”, “##w”, “yeah”, “millions”, “society”, “##g”, “leftist”, “crime”, “sp”, “des”, “##ist”, “##ry”, “mouth”, “##ards”, “##rs”, “##ize”, “burn”, “murdered”, “worship”, “##ening”, “##ism”, “living”, “##fa”, “coming”, “calling”, “streets”, “##ting”, “force”, “mis”, “##ss”, “blame”, “typical”, “##pe”, “baby”, “death”, “talking”, “##gen”, “belong”, “respect”, “di”, “##yp”, “sexual”, “##less”, “mad”, “war”.

C Experiments: Additional Results

C.1 Filtering with different thresholds

In Table 5 we present results for the Filtering baseline using different sampling thresholds. Specifically, in addition to using the 33% (1/3) most ambiguous training data instances as in Swayamdipta et al. (2020), we provide full results using more aggressive (i.e., 25%, 1/4) and less aggressive (i.e., 50%, 1/2) filtering thresholds. We notice mixed results that make hard to determine which is the best threshold across platforms. Filtering (25%) improves OOD robustness on 🐸 → 👽, and Filtering (50%) provides best overall in-domain performance on 🐸. However, Masking($\mathcal{S}_I$) outperforms all Filtering approaches according to the FPR metric.

C.2 Average results over all corpus pairs

We provide a summary of the results for all methods in Table 6, where we report average scores over all corpus pairs (refer to Table 4 for full results). On average, Masking($\mathcal{S}_I$) improvement in FPR over the Vanilla baseline is as large as 2×, both in-distribution and out-of-distribution. This comes at

---

[12] `https://github.com/grantjenks/python-wordsegment`

[13] Among duplicates, we found some tweets with more than 100 duplicate instances in Founta et al. (2018).

[14] Most work do not explicitly mention if deduplication is carried *before* or *after* preprocessing texts. We believe this is an important detail to foster reproducibility – we found many examples with the same text but different URLs, unveiling possibly bot-generated messages we removed this way.

D Lexical Artifacts Statement Example

An example of lexical artifacts statement for the Reddit dataset (Vidgen et al., 2021) used in this study is presented in the following.

I) TOP LEXICAL ARTIFACTS. We present the top $k = 10$ most informative tokens for the *hateful* class along with their scores in Table 7.

Rank	Token	Score	*Rank*	Token	Score
1	##tar	1.00	6	##gg	0.80
2	##ded	0.91	7	gay	0.79
3	##s	0.86	8	women	0.76
4	fa	0.85	9	##ds	0.74
5	b*tch	0.83	10	f*cking	0.74

Table 7: Top 10 most informative tokens for the hateful class on the Reddit dataset according to PMI.

II) CLASS DEFINITIONS. The *hateful* class is represented by originally *identity-directed* labeled examples in CAD (Vidgen et al., 2021), and is defined as "*Content which contains a negative statement made against an identity. An 'identity' is a social category that relates to a fundamental aspect of individuals' community, socio-demographics, position or self-representation [...]. It includes but is not limited to Religion, Race, Ethnicity, Gender, Sexuality, Nationality, Disability/Ableness and Class.*" (Vidgen et al., 2021).

III) METHODS AND RESOURCES. In order to compute the correlation between tokens to the *hateful* class we employ PMI as implemented in *[this work]* (code: `https://github.com/dhfbk/hate-speech-artifacts`). Input texts have been preprocessed by anonymizing user mentions, URLs, and email addresses with `[USER]`, `[URL]`, and `[EMAIL]` placeholders. Hashtags have been segmented using `wordsegment`,[15] and we remove newlines, unescape HTML tags, and lowercase texts. Duplicate instances have been removed after preprocessing.

The full list of lexical artifacts along with associated scores is available at `https://github.com/dhfbk/hate-speech-artifacts`.

Abstract

In document-level event argument extraction, an argument is likely to appear multiple times in different expressions in the document. The redundancy of arguments underlying multiple sentences is beneficial but is often overlooked. In addition, in event argument extraction, most entities are regarded as class "others", i.e. Universum class, which is defined as a collection of samples that do not belong to any class of interest. Universum class is composed of heterogeneous entities without typical common features. Classifiers trained by cross entropy loss could easily misclassify the Universum class because of their open decision boundary. In this paper, to make use of redundant event information underlying a document, we build an entity coreference graph with the graph2token module to produce a comprehensive and coreference-aware representation for every entity and then build an entity summary graph to merge the multiple extraction results. To better classify Universum class, we propose a new loss function to build classifiers with closed boundaries. Experimental results show that our model outperforms the previous state-of-the-art models by 3.35% in F1-score.

1 Introduction

Event argument extraction (EAE) is a crucial subtask of event extraction (EE), aiming to identify the arguments of a given event and recognize the specific roles they play. Previous works are mostly focused on sentence-level EE (Liao and Grishman, 2010; Nguyen et al., 2016; Liu et al., 2018; Yang et al., 2019b; Du and Cardie, 2020b; Wei et al., 2021; Wang et al., 2021; Lyu et al., 2021). However, events are often described in the form of documents in the real world. Document-level event extraction has received consideration in recent years.

No.	Sentence	Entity label	Difficulty
s1	The killers, approximately 30 men in uniform, arrived before 0230.	1	★
s2	Soldiers with their faces painted black arrived in Cayara last Saturday. They broke down doors, looted stores, and burned several houses.	1	★ ★ ★
s3	The murder was carried out by soldiers.	1	★
s4	The house was surrounded by soldiers.	0	-
s5	The house was searched by the soldiers 2 days before the crime.	0	-
s6	How can men in uniform be in a militarized area?	0	-
s7	He said that the library was burned.	-	-
...	......	...	...

⬇

Argument role	Entity	Entity label	Summative label
Perpetrator individual	men in uniform	1	1
	soldiers with their faces painted black	1	0
	soldiers	1	0
Physical target	houses	1	1
	library	1	1
...	...	...	...

Figure 1: An example of redundant event information in the document-level event argument extraction.

Research on document-level event extraction has been focused on tackling challenges such as arguments-scattering and multiple-events (Zheng et al., 2019; Du and Cardie, 2020a; Du et al., 2021; Lou et al., 2021; Li et al., 2021; Huang and Peng, 2021; Xu et al., 2021; Yang et al., 2021; Ahmad et al., 2021; Ebner et al., 2020). The benefit of redundant event information in a document is largely neglected. We believe that the redundant event information in a document can be used to improve event extraction, as illustrated in the example in Figure 1. The upper part of Figure 1 shows seven simplified sentences selected from a document in the MUC-4 dataset. All entities marked in blue are the same entity "soldiers", which appears in different expressions in different sentences. For ease of description, we call it entity S. We can observe from Figure 1 that: 1) The argument information in the document is redundant since entity S appears in the article multiple times as an argument and we can successfully extract the argument by correctly recognizing any of these occurrences. This prop-

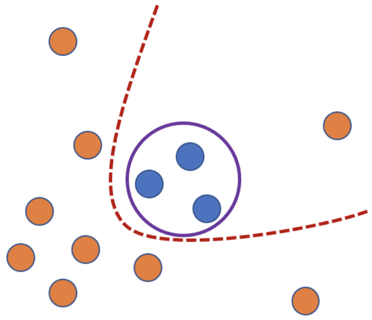

Figure 2: A simplified illustration of closed boundary loss. Blue dots represent target samples, orange dots represent Universum samples. The red dotted line represents cross entropy loss, the purple solid line represents proposed closed boundary loss.

erty can be potentially used to improve the robustness of the model. 2) The difficulty of extracting the entity S as an argument in its different occurrences is different. Extracting entity S in sentence 1 and sentence 3 is much easier than extracting it from sentence 2. Hence, by utilizing the redundant event information of the document, we can extract arguments from relatively simple positions and reduce the difficulty of the task. 3) An entity may appear multiple times in the document, directly averaging them as the entity's feature representation (Xu et al., 2021) may introduce noise. For example, although entity S is an event argument in the document, its occurrences in s4, s5 and s6 should not be recognized as a correct pattern to identify the event argument. 4) The redundant argument information can result in redundant extraction results, as shown in the bottom table in Figure 1. The three entities extracted as perpetrator individual need to be merged into one. However, the extracted physical target "houses" and "library" are different entities and should not be merged. Therefore, the use of redundant event information underlying a document is not straightforward, a sophisticated algorithm for merging multiple extraction results is needed.

Extraction of arguments can be solved as an entity classification problem by treating entities as argument candidates (Zheng et al., 2019; Xu et al., 2021; Yang et al., 2021). In document-level event argument extraction, only a subset of the entities in a document are arguments, while the majority of entities are regarded as class “others” or “neither”(neither of the target classes). This kind of data was first studied by Weston et al. (2006) under the name Universum. The Universum data are usually very diverse and do not have typical common features. In addition, Universum data is much more than the target class data, exhibiting a severe class imbalance problem. Figure 2 demonstrates a simplified distribution of data samples in document-level event argument extraction. The blue dots represent argument entities, the orange dots represent a large number of Universum class entities. Since the samples in the Universum class do not have typical common features, they tend to scatter in the feature space. This characteristic of the Universum data is largely overlooked in the information extraction community. Universum data is simply considered as another class “others”, without any special consideration in the classifier design. Cross entropy loss is usually employed in classifier training (Zheng et al., 2019; Huang and Peng, 2021; Xu et al., 2021; Yang et al., 2021). However, classifiers trained by cross entropy loss have open decision boundaries, and hence some Universum samples, such as the orange dot on the upper right of the figure, could be easily misclassified. We think a classifier with a closed decision boundary could better deal with the Universum class in document-level event argument extraction, as illustrated by the purple line in Figure 2.

The contribution of this work is three-fold. Firstly, it is the pioneering work to leverage redundant event information in documents for event extraction. We propose the entity coreference graph with graph2token module and entity summary graph to leverage the redundant event information. Experimental results show that redundant information helps improve recall significantly. Secondly, we analyze the issue of Universum data in document-level event argument extraction and the problem of classifiers trained by cross entropy loss, and propose a closed boundary loss to address the problems. Finally, our model consistently outperforms the latest baseline models in F1-score and achieves state-of-the-art performance. Compared to the three baseline models, our proposed model improves the absolute F1-score by 3.35%, 5.27%, and 6.45%, respectively.

2 Related Work

2.1 Event Argument Extraction

Most previous event argument extraction models make predictions at sentence-level (Nguyen et al., 2016; Liu et al., 2018; Yang et al., 2019b; Du and Cardie, 2020b; Wei et al., 2021; Wang et al., 2021; Dutta et al., 2021). Considering that the real world events are often distributed across sentences, document-level event extraction has attracted more attention recently. Zheng et al. (2019) propose the Doc2EDAG model to overcome the argument scattering problem. Du and Cardie (2020a) first argue the importance of document-level extraction and adopt a sequence model for document-level event extraction. Lou et al. (2021) investigate a novel bidirectional decoder to overcome the long-range forgetting problem. Li et al. (2021) formulate the document-level event extraction model as conditional generation based on templates. Huang and Peng (2021) attach importance to event coreference and entity coreference in document-level event extraction tasks. Xu et al. (2021) build a heterogeneous graph with the Tracker module to deal with problems of event scattering and multiple events. Yang et al. (2021) adopt parallel prediction networks to extract events parallelly from document-level representations. However, none of these works pay attention to the characteristic of information redundancy in the document, which we believe is a unique and beneficial property for document-level event argument extraction. In addition, to our knowledge, closed boundary classification has never been adopted in event extraction. Classification-based event argument extraction models (Huang and Peng, 2021; Xu et al., 2021; Yang et al., 2021) all employ cross entropy loss for classifier training, without considering the characteristics of Universum class: scattered distribution in the feature space due to heterogeneity and diversity of the samples in this class.

2.2 Closed Boundary Loss

We found that a classifier trained by cross entropy could easily misclassify entities in the class “others", i.e. Universum class. We found the root cause of the problem is the open decision boundary of the classifier. To address this problem, we propose a novel closed boundary loss for classifier training.

Research works in Universum usually employ additional unlabeled Universum data to provide prior knowledge for the task, such as Universum support vector machine (SVM) (Weston et al., 2006; Qi et al., 2012; Richhariya and Tanveer, 2020), and semi-supervised learning (Liu et al., 2015; Xiao et al., 2021). However, the SVM-based methods above are developed for structured data and are hard to integrate with deep neural network-based representation learning to form an end-to-end training procedure for natural language processing tasks. One possible solution is to use a deep neural network to learn representations first, and then feed the representations learned to the Universum SVM classifiers. But the disadvantage of this two-step procedure is that the classification result cannot be back-propagated to representation learning. It is desired that the closed boundary classifier could be integrated with deep neural network-based representation learning to form end-to-end training for optimal performance.

Closed boundary classification methods are also developed in anomaly detection and open set recognition, such as deep one-class learning (Ruff et al., 2018; Defard et al., 2021), auto-encoder based anomaly detection (Ionescu et al., 2019), OpenMax layer for open set recognition (Bendale and Boult, 2016). However, these methods cannot use the information in outlier samples due to task setting.

A closed boundary classifier works best in feature space with compact class distribution. In the literature, some loss functions have been proposed to generate such feature space such as Deep SVDD (Ruff et al., 2018), contrastive loss (Hadsell et al., 2006), and ii-loss (Hassen and Chan, 2020). However, Deep SVDD only minimizes the intra-class distance and cannot maximize the inter-class distance. Contrastive loss and ii-loss need to be combined with cross entropy loss to classify samples. But cross entropy loss generates open decision boundaries for the classifier.

In this paper, we propose a new loss function that could train a classifier with a closed decision boundary. In addition, it can be directly integrated with representation learning layers in a neural network to form an end-to-end training procedure to produce a feature space with minimum intra-class difference and maximum inter-class difference, which in turn leads to improved performance.

3 Method

As shown in Figure 3, our model consists of four main components: context encoding module (Sec 3.1), entity coreference graph (Sec 3.2), closed boundary loss (Sec. 3.3), and entity summary graph (Sec. 3.4), which are illustrated in this section.

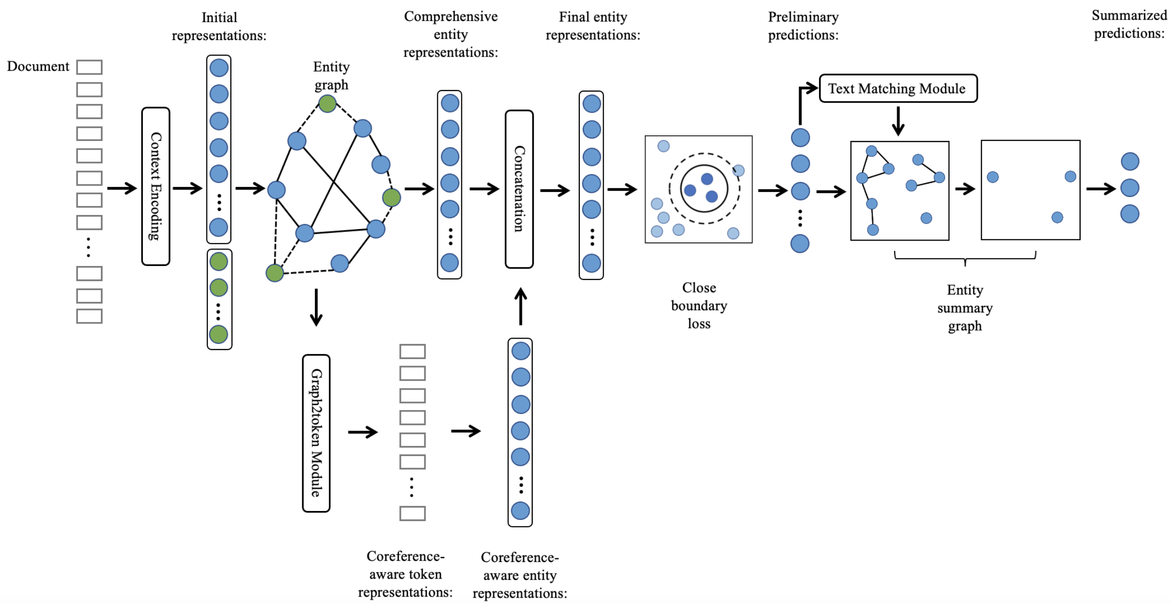

Figure 3: The overall model structure. Blue dots represent entity nodes, green dots represent sentence nodes.

3.1 Context Encoding

Given the input document, we apply a Bi-LSTM to obtain token representations of the document: $D = \{\mathbf{d}_0, \mathbf{d}_1, \ldots, \mathbf{d}_{n-1}\} \in \mathbb{R}^{n \times l}$ where n is the document length, and l is the the hidden state dimension. We construct entity representation and sentence representation from the start and end tokens in an entity or sentence:

$$\mathbf{e}_i = \left(\mathbf{e}^{(i)}_{\text{memory}}; \mathbf{e}^{(i)}_{\text{rule}}\right) \tag{1}$$

$$\mathbf{s}_i = \left(\mathbf{s}^{(i)}_{\text{memory}}; \mathbf{s}^{(i)}_{\text{rule}}\right) \tag{2}$$

$$\begin{aligned}
\mathbf{e}^{(i)}_{\text{memory}} &= \left(\mathrm{D}\left[ent^{(i)}_{\text{start}}[l:]\right]; \mathrm{D}\left[ent^{(i)}_{\text{end}}[:l]\right]\right) \\
\mathbf{e}^{(i)}_{\text{rule}} &= \left(\mathrm{D}\left[ent^{(i)}_{\text{start}}[:l]\right]; \mathrm{D}\left[ent^{(i)}_{\text{end}}[l:]\right]\right) \\
\mathbf{s}^{(i)}_{\text{memory}} &= \left(\mathrm{D}\left[sent^{(i)}_{\text{start}}[l:]\right]; \mathrm{D}\left[sent^{(i)}_{\text{end}}[:l]\right]\right) \\
\mathbf{s}^{(i)}_{\text{rule}} &= \left(\mathrm{D}\left[sent^{(i)}_{\text{start}}[:l]\right]; \mathrm{D}\left[sent^{(i)}_{\text{end}}[l:]\right]\right)
\end{aligned}$$

where D is the output of the Bi-LSTM encoding layer, $ent^{(i)}_{\text{start}}$, $ent^{(i)}_{\text{end}}$, $sent^{(i)}_{\text{start}}$ and $sent^{(i)}_{\text{end}}$ are the start and end position of the i-th entity and the i-th sentence, respectively, and [;] denotes the concatenation operation. $\mathbf{e}^{(i)}_{\text{memory}}$ and $\mathbf{s}^{(i)}_{\text{memory}}$ mainly contain the information inside the entity and sentence. $\mathbf{e}^{(i)}_{\text{rule}}$ and $\mathbf{s}^{(i)}_{\text{rule}}$ mainly contain the context information outside the entity and sentence. The model predicts memory representations mainly based on remembering entity names and predicts rule representations mainly based on recognizing the contextual patterns. Therefore, we separate the memory representation and rule representation as they correspond to the memory-based and the rule-based learning process of humans (Noordman and Vonk, 1998; Opitz and Friederici, 2004).

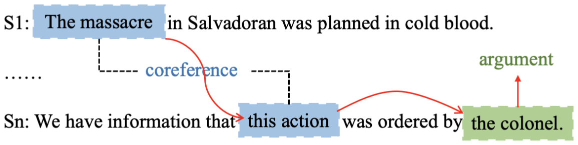

Figure 4: An example of coreference in a document and its impact on entity understanding and document-level event argument extraction

3.2 Entity Coreference Graph

Leveraging redundant event information in a document is not straightforward to classify every entity in the document. On the one hand, better entity representation is needed. Therefore, we construct an entity coreference graph with graph2token module to produce a comprehensive and coreference-aware representation for every entity.

The entity coreference graph is inspired by the observation of coreference's role in document understanding. Firstly, for the repeatedly referred entity (coreference entity), the understanding to this entity itself is constantly enriched or enhanced by each reference. For the example illustrated in Figure 4, "the massacre" and "this action" are two different mentions of the same entity. The understanding of this entity is enriched by combining the location of the massacre mentioned in the first sentence and the commander of the massacre mentioned in the second sentence. Secondly, for other entities located in the context of the coreference entity, their meanings are clearer by recognizing the connotation of the coreference entity. For example, "the colonel" cannot be recognized as an argument unless the model understands that "this action" refers to "the massacre". Research works in event extraction (Xu et al., 2021; Luan et al., 2019; Qian et al., 2019) consider the first observation but neglect the second one. Specifically, previous works in event extraction use graph structure to merge information in different mentions of the same entity. However, such a graph structure cannot feed back the fused information to the context of coreference entities because the representations of the context tokens are fixed from the initial encoding process. In this sense, for the representation of "the colonel", its context information still excludes "the massacre". Therefore, we adopt a graph2token module to feed back the comprehensive entity information obtained through graph structure to tokens, and then rebuild entity representations that are both comprehensive and coreference-aware.

Graph Construction. There are two types of nodes in the entity graph: entity nodes and sentence nodes. Entities are recognized from document following Fisher and Vlachos (2019). Entity nodes and sentence nodes are denoted as $\mathrm{E} = \{\mathbf{e}_0, \mathbf{e}_1, \ldots, \mathbf{e}_p\}$, and $\mathrm{S} = \{\mathbf{s}_0, \mathbf{s}_1, \ldots, \mathbf{s}_q\}$, respectively.

There are two types of edges in the entity graph: 1) entity-entity edge is created according to the coreference relationship. We use SpanBERT (Joshi et al., 2020) to implement coreference resolution on documents during preprocessing. 2) entity-sentence edge is the connection between the entity node and the sentence node where it is located.

Graph Propagation. After the graph is constructed, Graph Attention Network (Veličković et al., 2017) is applied to propagate information between connected nodes. Assuming that graph nodes are denoted by $\mathrm{H} = \{\mathrm{E}, \mathrm{S}\} = \{\mathbf{h}_0, \mathbf{h}_1, \ldots, \mathbf{h}_{p+q}\} \in \mathbb{R}^{(p+q)\times 2l}$, the information that a node receives from its neighbors is formulated as:

$$\mathbf{h}'_i = \mathrm{RELU}\left(\textstyle\sum_{j\in\mathcal{N}_i} \alpha_{ij}\mathbf{W}\mathbf{h}_j\right) \tag{3}$$

$$\alpha_{ij} = \frac{\exp\Big(L\Big(\mathbf{W}_{e_{ij}}[\mathbf{W}\mathbf{h}_i;\mathbf{W}\mathbf{h}_j]\Big)\Big)}{\sum_{k\in\mathcal{N}_i}\exp\Big(L\Big(\mathbf{W}_{e_i}[\mathbf{W}\mathbf{h}_i;\mathbf{W}\mathbf{h}_k]\Big)\Big)} \tag{4}$$

where $\mathbf{h}'_i$ is the neighbor information of the i-th node, $\mathbf{h}_j$ is the representation of the j-th node, $\mathbf{W}$, $\mathbf{W}_{e_i}$ are weight matrixes, $\mathcal{N}_i$ denotes the set of neighbors of node i, and $L(\cdot)$ is the LeakyReLU function.

The representation of the i-th node $\mathbf{h}_i$ and its neighbor information $\mathbf{h}'_i$ is fused by the gated mechanism:

$$\beta_i = \sigma\left(f\left(\mathbf{h}_i; \mathbf{h}'_i\right)\right) \tag{5}$$

where $\sigma(\cdot)$ is the sigmoid function, $f(\cdot)$ denotes the linear transformation. The fused representation of the i-th node $\mathbf{h}''_i$ is obtained as:

$$\mathbf{h}''_i = \beta_i \odot \mathbf{h}_i + (1 - \beta_i) \odot \mathbf{h}'_i \tag{6}$$

where $\odot$ stands for element-wise multiplication. Through propagating and fusing information of coreference entities and the corresponding sentence, a comprehensive representation of the entity is obtained.

Graph2token. To address the second insight we put forward in this section, we adopt the graph2token module to feed back the information behind coreference entities to their neighboring tokens.

We concatenate the original token representation $\mathbf{d}_i$ with the entity representation $\mathbf{h}''_j$ in which it is located, and feed it to an LSTM layer. In this way, the comprehensive entity representation $\mathbf{h}''_j$ is propagated to context tokens outside the entity and a coreference-aware token representation $\mathbf{d}'_i$ is generated:

$$\mathbf{d}'_i = \mathrm{LSTM}(\mathbf{d}_i; \mathbf{h}''_j) \tag{7}$$

Then, we build coreference-aware entity representations from updated token representations.

$$\mathbf{e}^{(i)}_{\text{rule}}{}' = \left(D'\left[ent^{(i)}_{\text{start}}[:l]\right]; D'\left[ent^{(i)}_{\text{end}}[l:]\right]\right)$$

where $\mathrm{D}' = \left\{\mathbf{d}'_0, \mathbf{d}'_1, \ldots, \mathbf{d}'_{n-1}\right\}$. Finally, a comprehensive and coreference-aware entity representation $\mathrm{E}\prime = \{\mathbf{e}_0\prime, \mathbf{e}_1\prime, \ldots, \mathbf{e}_p\prime\}$ is obtained by concatenation:

$$\mathbf{e}_i\prime = \left(\mathbf{h}''_i; \mathbf{e}^{(i)}_{\text{rule}}{}'\right) \tag{8}$$

3.3 Closed Boundary Loss

We have analyzed that classifiers trained by cross entropy loss have open decision boundaries and could easily misclassify the Universum class. To address this problem, we propose a novel loss function that could be used to train classifiers with closed decision boundaries.

Comprehensive and coreference-aware entity representations $\mathrm{E}' = \left\{\mathbf{e}_0', \mathbf{e}_1', \ldots, \mathbf{e}_p'\right\}$ are obtained in the last section. We treat entities as argument candidates and classify entities by classifiers trained by our proposed closed boundary loss:

$$\mathrm{L_{CB}} = R^2 + \frac{1}{n}\sum_{i=1}^{n} \max\left(0, \left\|\mathbf{e}_i' - \mathbf{c}\right\|^2 - R^2\right) + \frac{1}{m}\sum_{i=1}^{m} \max\left(0, (1+\mu)R^2 - \left\|\mathbf{e}_i' - \mathbf{c}\right\|^2\right)$$

where n is the number of target class samples, m is the number of Universum class samples, the center $\mathbf{c}$ is initialized as the mean of target samples in the feature space, and the radius $\mathbf{R}$ is initialized as ν-quantile of the distance of target samples to the center $\mathbf{c}$ in the feature space. $\mathbf{R}$ and $\mathbf{c}$ are initialized after a few warm-up epochs. The closed boundary loss intends to include samples of each target class using a hypersphere characterized by center $\mathbf{c}$ and radius R in the feature space and locate Universum samples outside the hypersphere. Due to the heterogeneous nature of Universum samples, we allow them to scatter outside the hypersphere and do not require them to be aggregated like cross entropy loss.

The goal of the first term R^2 is to minimize the volume of the hypersphere. The second term aims to enclose target class samples by the hypersphere. If the Euclidean distance between the sample $\mathbf{h}_i''$ and the center $\mathbf{c}$ exceeds the radius, it will lead to a penalty in the loss function. The third term aims to keep the universe samples outside the hypersphere. Parameter μ is introduced to adjust the gap between the closed boundary hypersphere and Universum samples.

Unlike contrastive loss and ii-loss which cannot be directly used for classifying samples in the test set and need to be combined with cross entropy loss, our proposed closed boundary loss can be easily adopted for classification by the following calculation:

$$g(\mathbf{e}_i\prime) = \begin{cases} 1 & \|\mathbf{e}_i' - \mathbf{c}\|^2 - R^2 < 0 \\ 0 & \|\mathbf{e}_i' - \mathbf{c}\|^2 - R^2 > 0 \end{cases}$$

3.4 Entity Summary Graph

To make full use of the redundant argument information, we classify every entity in the document. For the same argument, we may obtain multiple preliminary extraction results. The advantage is the robustness because the correct argument is more likely to be extracted from relatively simple positions. The challenge is how to merge the multiple extraction results. To address the challenge, we propose an entity summary graph.

Text Matching Module. We notice that most redundant expressions of the same entity are either character-level spelling similar or word-level semantics similar. In some cases, special domain knowledge is needed to determine if two expressions are the same. For example, “Army of National Liberation” and "ELN" are referred to the same entity. Therefore, we adopt a text matching model with both character embedding and word embedding to evaluate the spelling similarity and semantics similarity of extracted arguments. We also construct a text matching dataset from ground truth labels of the training set of our event extraction dataset to make the model learn necessary domain knowledge.

We build the text matching module (TMM) by adopting the structure of RE2 (Yang et al., 2019a) and adding character embedding to the RE2 model to enhance the model’s capability of recognizing spelling similarity. We denote the initially predicted arguments as $\mathrm{A} = \{\mathbf{a}_0, \mathbf{a}_1, \ldots, \mathbf{a}_{k-1}\}$. Then, we feed these entities into the text matching module to produce the matching score for each pair of arguments.

$$\mathbf{M}_{ij} = \mathrm{TMM}\left(\mathbf{a}_i, \mathbf{a}_j\right) \tag{9}$$

where $\mathbf{M}$ is the matching score matrix, which contains text matching score of every pair of entities from A. $\mathbf{M} = [\mathbf{M}_{ij}], i, j = 1, 2, \ldots, k$.

Entity Summary Graph. The graph node is composed of preliminary predicted entities A. The i-th node and j-th node are connected if $\mathbf{M}_{ij} > s$, where s is a boundary score. The weight of each edge is the text matching score $\mathbf{M}_{ij}$ of two entity nodes at the ends of the edge.

The constructed entity summary graph is mostly disconnected because there usually exist multiple argument clusters in a document. The argument cluster refers to a set of different expressions of the same argument, for example "the armed forces" and "military" refer to the same argument, thus forming an argument cluster. The entity summary graph consists of several connected subgraphs as shown in figure 3. Each subgraph

corresponds to an argument cluster. We denote the entity summary graph G and its subgraphs as $\mathrm{G} = \left\{\mathrm{G}_{sub}^{(1)}, \mathrm{G}_{sub}^{(2)}, \ldots, \mathrm{G}_{sub}^{(u)}\right\}$. The final predicted arguments are summarized by selecting an entity node with the largest sum of weights (LSW) from each subgraph.

$$\mathrm{A}' = \left\{\mathbf{a}'_0, \mathbf{a}'_1, \ldots, \mathbf{a}'_{v-1}\right\}, \quad \mathbf{a}'_i = \mathrm{LSW}\left(\mathrm{G}_{sub}^{(i)}\right)$$

4 Experiments

4.1 Dataset

Our model is evaluated on the MUC-4 dataset (McLean, 1992). The dataset is composed of 1,700 documents, each containing an average of 400 tokens and 7 paragraphs. We use 1300 documents for training, 200 documents for testing, and 200 documents for the development set following (Du and Cardie, 2020a). Five argument roles are extracted in the dataset: perpetrator individual, perpetrator organization, target, victim, and weapon.

4.2 Baselines and Evaluation Metric

In this work, we propose a document-level EAE model leveraging **R**edundant **I**nformation and **C**losed **B**oundary Loss (**RICB**). We compare our model with the following baseline models: **DYGIE++** (Wadden et al., 2019) incorporates local and global contexts to build a multi-task framework for named entity recognition, relation extraction, and event extraction. **NST** (Du and Cardie, 2020a) aggregates sentence representation and paragraph representation via a gate mechanism and treats document-level EAE as a sequence tagging problem. **GTT** (Du et al., 2021) proposes a generative transformer based framework for document-level EAE.

We evaluate the performance of our model by the **CEAF-TF** metric following (Du et al., 2021). The metric finds the best alignment of predicted arguments and gold arguments. It penalizes the system that does not merge multiple extraction results by setting a constraint that a gold argument can be aligned with at most one predicted argument. Precision (P), recall (R), and F1-score (F1) are used to evaluate the model's performance.

4.3 Overall Results

The per-role EAE results on the MUC-4 dataset of our RICB model and baseline models are summarized in Table 1, and the micro-averaged performance is shown in Table 2. Table 2 shows that our model consistently outperforms the latest baselines in F1-score and achieves the state-of-the-art (SOTA) performance. Specifically, the proposed model improves the absolute F1-score by 3.35%, 5.27%, and 6.45% compared to baseline models. Noticeably, our model achieves an over 9% improvement in recall. In terms of the per-role extraction performance of our model, it achieves the highest F1-score in four of five argument roles: perpetrator individual, perpetrator organization, target, and weapon. Specifically, the absolute F1-score is improved by 0.63%, 4.19%, 10.69%, and 2.84% in these argument roles.

4.4 Effect of Graph2token Module

Graph structure is used in EAE to produce a comprehensive representation of coreference entities (Luan et al., 2019; Qian et al., 2019; Xu et al., 2021). In this work, we further adopt a graph2token module to feed back the comprehensive representation of coreference entities to their context tokens.

	PerpInd	PerpOrg	Target	Victim	Weapon
Without graph2token	50.39/49.24/49.80	50.02/58.83/54.07	63.87/57.58/60.56	62.54/49.53/55.28	58.72/69.47/63.64
Cross entropy loss	50.00/50.34/50.17	48.57/63.75/55.14	62.04/64.39/63.19	49.55/58.95/53.85	55.13/70.49/61.87
String matching	48.80/45.86/47.28	45.30/66.25/53.81	65.71/63.44/64.56	59.49/49.47/54.02	58.57/67.21/62.60
RICB	50.76/49.62/**50.18**	50.00/63.75/**56.04**	65.63/63.64/**64.62**	64.86/50.52/**56.80**	63.49/65.57/**64.51**

Table 3: Ablation studies on graph2token module, closed boundary loss, and entity summary graph, respectively. The results in each column are displayed in the order of precision, recall, and F1 score.

The updated token representations can generate additional coreference-aware representations for entities near the coreference entity. For the ablation study, we experiment on without applying the graph2token module. We compare per-role extraction results with and without the graph2token module in Table 3. We find that the experiment without the graph2token module results in a performance drop on every argument role. In addition, the recall is decreased by 0.38%, 4.92%, 6.06%, and 0.99% in four argument roles. This indicates that the model can recognize more arguments by providing argument candidates with additional coreference-aware representations.

4.5 Effect of Closed Boundary Loss

We find that classifier trained by cross entropy loss could easily misclassify entities in the Universum class. We propose a closed boundary loss to address this issue. For the ablation study, we conduct experiments of applying cross entropy loss for argument classification, and compare the performance with our model. The comparison of two loss functions is summarized in Table 3, which shows that in all argument roles, closed boundary loss consistently outperforms cross entropy in the F1 score. We further notice that the precision of the model is improved in all argument roles at 0.76%, 1.43%, 3.59%, 15.31%, and 8.36% by using closed boundary loss. The improvement in precision indicates that the use of closed boundary results in a smaller number of Universum samples that are misclassified as target samples.

4.6 Effect of Entity Summary Graph

To fully leverage the redundant argument information, we classify every entity in the document. For the same argument, we may obtain multiple preliminary extraction results. We propose the entity summary graph to merge the results. For the ablation study, we conduct experiments on merging multiple extraction results based on string matching following Zheng et al. (2019); Xu et al. (2021). We compare the string matching performance with our proposed entity summary graph in Table 3. It shows that the entity summary graph outperforms the string matching method significantly in the F1-score. Furthermore, the precision of the model is improved in four of five argument roles by 1.96%, 4.70%, 5.37%, and 4.92% by using the entity summary graph, and this verifies the effect of our proposed entity summary graph, i.e. merging multiple extraction results and reducing false positives accordingly.

4.7 Case Study

Figure 5 demonstrates an example of the differences in predicting event arguments between GTT (Du et al., 2021) and our proposed RICB method. To avoid involving excessive sentences in the document, only roles of perpetrator individual and perpetrator organization are used for illustration. RICB successfully extracts "Colonel Ponce" and "ARENA", while GTT fails. Both event arguments "Colonel Ponce" and "ARENA" appear multiple times in the document, which shows the redundant event information in the document. Specifically, among all their occurrences in the document, it is easier to recognize "Colonel Ponce" from sentence 8 and recognize "ARENA" from sentence 7. This is an illustration of our idea that by utilizing redundant event information in the document, we can extract arguments from relatively simple positions. In addition, to recognize "Colonel Ponce" from sentence 4, it is necessary to understand that "this action" refers to "the massacre". Our model can recognize it because the graph2token module can feed back the coreference information to "this action".

4.8 Further Analysis

Firstly, it is effective to leverage redundant event information in documents for document-level EAE, which is not only reflected in the F1 score, but also in the significant improvement in recall. The micro-averaged recalls of baseline models are distributed between 46% to 49%, but our model reaches 58%. As we analyzed in the introduction, leveraging redundant argument information of a document allows the model to extract the argument from any

> … [2] The massacre against the Salvadoran Workers National Union Federation (FENASTRAS) was planned in cold blood. … [4] We have trustworthy information from our intelligence organs that this action was ordered by Colonel Ponce, that Cristiani knew about it and approved it. … [6] Terrorism is an old practice of the Nationalist Republican Alliance (ARENA). [7] Only a few days ago, ARENA assassins tried to kill the president of the Mortgage bank, Mr Mason, for not following their orders. [8] The people demand the resignation of chief of staff Col Emilio Ponce because his responsibility in this criminal action is real. … [18] The war of the armed forces, government, and ARENA is aimed against the people. …

	Peretrator Individual	Perpetrator Organization
GTT	ARENA assassins	-
RICB	Colonel Ponce, ARENA assassins	ARENA

Figure 5: An example of the differences in event argument extraction between GTT and our proposed RICB. The differences in extracting perpetrator individual and perpetrator organization are used for illustration. RICB successfully extracts *Colonel Ponce* and *ARENA*, while GTT fails. In the example, sentence numbers are marked in green, and identical entities are marked with the same color.

of its occurrences and relatively simple positions. Therefore, the difficulty of argument extraction is reduced and the recall is improved accordingly. We also notice a drop in precision rate in our model compared to baseline models. It is because baseline methods adopt sequence-to-sequence models and we classify a few arguments from a great number of entities in the document, which will naturally result in a decrease in precision. However, the precision and recall of our model are very close, which is more balanced compared to baseline models.

Secondly, leveraging redundant event information in a document is not simply classifying every entity in the document. On the one hand, better entity representations need to be produced, on the other hand, multiple extraction results need to be merged. Therefore, we add the graph2token module to the entity coreference graph, which improves the recall significantly. We also propose the entity summary graph to merge multiple extraction results, which successfully improves the precision.

Finally, we propose a novel closed boundary loss to better deal with the Universum class in our task. Its effectiveness is verified in ablation studies. We highlight two other potential benefits of closed boundary loss here. Firstly, since it generates a closed decision boundary for classifiers, it may also be valid for dealing with unseen samples in the test set. This property is not evaluated in this work. In addition, our dataset is highly imbalanced because only a small number of entities are arguments. Weighted cross entropy loss is cumbersome to adjust the appropriate weights, however, the closed boundary loss does not need to adjust weights and works well with the imbalanced dataset.

5 Conclusion and Future Works

In this work, we emphasize that the redundant event information in documents is beneficial but is often overlooked in document-level EAE. In addition, we find that classifiers trained by cross entropy loss are problematic in classifying the Universum class. Specifically, we generate a comprehensive and coreference-aware representation for every entity through the entity coreference graph with the graph2token module. In addition, we propose an entity summary graph to merge the multiple extraction results of the same argument. Furthermore, we propose a novel closed boundary loss to deal with the Universum class in classification. As a limitation, our proposed closed boundary loss is used for binary classification because we extract arguments in a role-by-role manner to make full use of the property of each argument role. In the future, we will extend it for multiclass classification and apply it to other tasks in natural language processing that face the problem of classifying Universum class. Experimental results show that our RICB model achieves the SOTA performance and outperforms prior approaches on the MUC-4 dataset.

A Appendix

A.1 Dataset Information

Some supplementary information about the dataset is illustrated in this section. We use the MUC-4 dataset to evaluate the performance of our model. The dataset is intended for research purposes, which is consistent with our purpose of use. Besides the statistical information we provided in the main part, we illustrate the documentation of the dataset in this section. MUC-4 dataset is made of English news articles on the subject of terrorist attacks. Specifically, five arguments are extracted for the dataset: perpetrator individual, perpetrator organization, target, victim, and weapon.

A.2 Implementation Details

Spacy 3.0.3 is used in data preprocessing. Experiments are conducted on NVIDIA GTX 1080Ti, and the training time is about four hours. The hyper-parameters are given in the table below.

Hyper-parameter	**Value**
Embedding size	300
Hidden size	150
Bidirectional	True
Layers of encoder	2
Layers of graph2token module	1
Layers of graph	1
Heads of graph	2
Optimizer	Adam
Learning rate	$5e^{-4}$
Batch size	4
Dropout	0.3
Training epoch	120
Boundary score	0.65

Abstract

Recent advances in the pre-training of language models leverage large-scale datasets to create multilingual models. However, low-resource languages are mostly left out in these datasets. This is primarily because many widely spoken languages are not well represented on the web and therefore excluded from the large-scale crawls used to create datasets. Furthermore, downstream users of these models are restricted to the selection of languages originally chosen for pre-training. This work investigates how to optimally leverage existing pre-trained models to create low-resource translation systems for 16 African languages. We focus on two questions: 1) *How can pre-trained models be used for languages not included in the initial pre-training?* and 2) *How can the resulting translation models effectively transfer to new domains?* To answer these questions, we create a *new* African news corpus covering 16 languages, of which eight languages are not part of any existing evaluation dataset. We demonstrate that the most effective strategy for transferring both to additional languages and to additional domains is to fine-tune large pre-trained models on small quantities of high-quality translation data.

1 Introduction

Enormous efforts have been invested in making language and translation models more multilingual while leveraging the maximal amount of data for training, most prominently large crawls of monolingual and parallel data from the web (El-Kishky et al., 2020; Schwenk et al., 2021b,a; Xue et al., 2021b). The resulting models are now capable of translating between hundreds of languages, including language pairs that in isolation do not have large collections of parallel data (Tang et al., 2020; Xue et al., 2021a; Fan et al., 2021b). For example, M2M-100 (Goyal et al., 2021) can translate (with low accuracy) between Hausa and Yorùbá, two of the most widely spoken languages in Nigeria, even though there is barely any parallel data available for training. For languages that are not included in the set of training languages, the model would have no knowledge on how to generate translations. Does this mean there is no hope for languages that do not have large presence on the web and are therefore not included in these pre-trained models?

We investigate *how large-scale pre-trained models can be leveraged for the translation of unseen low-resource languages and domains*. We address this question by studying 16 African languages that are largely underrepresented in NLP research (Joshi et al., 2020; ∀ et al., 2020) and further have little to no training data available (§3). These languages provide an ideal testbed for two challenging knowledge transfer tasks: **(1)** How can pre-trained models create translations for languages unseen at train-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3053 - 3070
July 10-15, 2022 ©2022 Association for Computational Linguistics

ing time? and **(2)** Since training data may only exist in single domain (i.e. religious texts), how can a model be trained in one domain and translate another effectively at test time?

These questions are extremely relevant for our chosen languages because they all have millions of native speakers and a massive need for translation technologies. For example, news concerning the African continent are almost exclusively published in English, French, or Arabic, and thereby inaccessible for speakers of only native African languages. This creates a bottleneck for information transmission, which becomes even more critical in times of crises (Öktem et al., 2020; Anastasopoulos et al., 2020; Öktem et al., 2021). Furthermore, the task of translating news has historically played a central role in translation research, e.g. in shared tasks since 2008 (Callison-Burch et al., 2008) and as a test for determining human parity (Hassan et al., 2018; Läubli et al., 2018; Toral et al., 2018). To spur the development of dedicated news translation models for Africa, we construct a benchmark of news translation for translating between 16 native African languages and English or French (§4).

This allows us to compare three approaches to leveraging large-scale multilingual models for the translation of previously unseen languages: **(1)** zero-shot transfer, **(2)** continual pre-training on monolingual data, and **(3)** multi-domain fine-tuning on parallel data (§5). We find that fine-tuning pre-trained models on a few thousand sentences of high quality bitext is remarkably effective, and can be further augmented with continual pre-training on African languages and fine-tuning on news domain data (§6). Our contributions are the following:[1]

1. We create a **new African news corpus** for machine translation (following principles of participatory research ∀ et al. (2020)) covering 16 African languages.
2. We **adapt several multilingual pre-trained models** (MT5, ByT5, mBART, M2M-100) to these largely unseen languages, and evaluate their quality on news translation.
3. We quantify the **effectiveness of small in-domain translation sets** by measuring domain transfer effects and comparing fine-tuning strategies.

We find that having a targeted collection of translations is surprisingly effective, showcasing the power of local knowledge in so-called "zero-resource" scenarios (Bird, 2020). This paints a promising picture for the development of NLP technology for understudied languages: being able to customize these models for new language of interest with as little as 2k sentences and a few fine-tuning steps, MT developers and users from any language community are less dependent on choices and monetary interest of industry powerhouses from the Global North (Paullada, 2020).

2 Related Work

African MT Datasets. One of the major challenges of developing MT models for African languages is lack of data. There are many attempts to automatically crawl and align sentences from the web (Schwenk et al., 2021a,b). Nevertheless, the resulting corpora for many African languages are typically small and of poor quality (Kreutzer et al., 2021). Other cleaner parallel sources are mostly from religious sources, like the Bible covering over 1600 languages (McCarthy et al., 2020) and JW300 (Agić and Vulić, 2019) from `JW.org` with over 343 languages, including over 100 African languages. Apart from the training dataset, evaluation datasets are needed to test the performance of multilingual MT models. The FLORES-101 (Goyal et al., 2021) evaluation set, sourced from Wikipedia and manually translated, covers the largest number of languages, including 20 African languages. Finally, while other evaluation datasets for translating into or from African languages have been developed (Siminyu et al., 2021; Emezue and Dossou, 2020; Azunre et al., 2021b; Nyoni and Bassett, 2021; Gezmu et al., 2021; Ali et al., 2021), unfortunately there are only a few African languages with evaluation datasets in the news domain (Adelani et al., 2021a; Mabuya et al., 2021; Ezeani et al., 2020) but ours covers 11 African languages (§4).

Low-resource MT. Interest in low-resource MT has been increasing both within the MT research community (Haddow et al., 2021), as well as in native speaker communities (∀ et al., 2020; Azunre et al., 2021a; Mager et al., 2021). On the modeling side, many techniques have been developed: unsupervised MT (Lample et al., 2018) leverages monolingual data, single multilingual models capable of translating between many languages (Firat et al., 2016; Johnson et al., 2017; Aharoni et al.,

Table 1: **Languages and Data Details for MAFAND-MT Corpus**. Language, family (NC: Niger-Congo), number of speakers, news source, news (`NEWS`), and religious domain (`REL`) data split. The languages highlighted in gray did not previously have news-domain data before MAFAND-MT.

2019; Fan et al., 2021a), multilingual unsupervised models leverage a related language (with parallel data) to assist translating the low-resource language that might not even have any monolingual data (Ko et al., 2021). Unfortunately, unsupervised MT typically performs poorly on low-resource languages (Marchisio et al., 2020).

Transfer learning from high-resource languages has achieved more promising results: Transfer from multilingual pre-trained language models (PLM), like mBART50 (Tang et al., 2020) and MT5 (Xue et al., 2021b), and large-scale multilingual MT often outperforms bilingual MT (Tran et al., 2021; Yang et al., 2021). For low-resource languages this strategy outperforms the baseline (Transformer) models (Birch et al., 2021; Adelani et al., 2021a; Lee et al., 2022). The performance can be further improved by large scale pre-training (Reid et al., 2021; Emezue and Dossou, 2021).

3 Focus Languages and Their Data

Focus Languages. We focus on 16 African languages with varying quantities of available data (Joshi et al., 2020), including moderately low-resource languages such as Swahili and Hausa, and very low-resource languages such as Ghomálá’[2] with the Bible being its largest available corpus. Table 1 provides an overview of the focus languages, including the language families, location and number of speakers, and the source and original language for our corpus. The languages are from four language families: Afro-Asiatic (e.g. Hausa), Nilo-Saharan (e.g. Luo), English Creole (e.g. Nigerian-Pidgin/Naija) and Niger-Congo. Most of the languages (13 out of 16) are from the Niger-Congo family, which is the largest language family in Africa. Six of the languages are predominantly spoken in Francophone countries of Africa, while the remainder are predominantly spoken in Anglophone countries of Africa. In contrast to previous work (∀ et al., 2020; Gowda et al., 2021), we do not focus exclusively on translation to/from English since this is not the primary language of the Francophone Africa community. All languages are spoken by at least one million speakers.

Language Characteristics. All languages are written in Latin script, using letters of the basic Latin alphabet with a few omissions (e.g “c”, “q”, “x”, “z”) and additions (e.g. “ɛ”, “ɔ”, “ŋ”, “ọ”, including digraphs like “gb”, “kp”, “gh”, and sometimes more than two-character letters). 13 of the languages are tonal, and about nine make use of diacritics. Many African languages are morphologically rich. For example, all Bantu languages are agglutinative. Fon, Mossi, and Yorùbá are highly isolating. All languages follow the Subject-Verb-Object sentence structure like English and French. Table C provides more details.

Existing Parallel Corpora. We curate publicly available parallel data for our focus languages, which consists primarily of text in the religious domain. For most African languages, the largest available parallel corpora is JW300 (Agić and Vulić, 2019), sourced from `jw.org`, which publishes biblical texts as well as lifestyle and opinion columns. Varying quantities of data are available for 11 of the 16 focus languages. Éwé, Igbo, Swahili, Setswana, Twi, Yorùbá, and isiZulu have over 400K parallel sentences. Hausa and Mossi have slightly more than 200K parallel sentences, while Fon and Naija have around 30K sentences. For the remaining

---

[2] Spoken by an estimated 1.1M people in Cameroon

five languages that are not in the JW300 corpus,[3] we make use of the Bible.[4] We aligned the sentences automatically by the verses (around 31k in total). Ghomálá' only has the New Testament with 8k verses. Bambara and Wolof are missing some verses and books, leading to a total size of 28K and 22K. Table 1 summarizes this information about the religious (`REL`) corpora.

4 MAFAND-MT African News Corpus

4.1 Data Collection Process

We introduce our newly translated news corpus; MAFAND-MT — **M**asakhane **A**nglo & **F**ranco **A**frica **N**ews **D**ataset for **M**achine **T**ranslation. Table 1 gives the news source and data splits for 11 African languages which includes six languages (`bam`, `bbj`, `ewe`, `fon`, `mos`, `wol`) spoken predominantly in Francophone Africa and five languages (`lug`, `luo`, `pcm`, `tsn`, `twi`) spoken predominantly in Anglophone Africa. The MAFAND-MT corpus was created in three steps:

1. **Crawling and preprocessing** of news websites from local newspapers that are publishing in English and French. Raw texts from the web were segmented into sentences. Most languages were crawled from one or two sites, except for Wolof and Fon that were crawled from four and seven news websites respectively due to local French language newspapers having very few articles. We also ensured that the articles came from a variety of topics e.g. politics, sports, culture, technology, society, religion, and education. This was carried out by native speakers of the target language with source language proficiency.
2. **Translation** of 5k–8k sentences by professional translators.The translation process took one to four months depending on the availability of the translators.
3. **Quality control** was provided by native speakers, who discussed and, if possible, fixed problematic translations and ran automatic checks to detect misspellings, duplicated sentences, and alignment problems.

Following the recommendations of ∀ et al. (2020), we design the process to be *participatory*: Everyone involved in the corpus creation is a native speaker of the respective target languages and has societal knowledge about the communities that speak those languages. This is particularly important for curation and quality control to ensure that the resulting material is appropriate and relevant for stakeholders of the final MT models (∀ et al., 2020; Kreutzer et al., 2021). Furthermore, everyone received appropriate remuneration. To enable cross-disciplinary knowledge transfer between participants in the individual steps, every language was assigned a coordinator. The coordinator conducted the initial curation in the first step, and communicated with translators and quality checkers throughout the following steps.

Other Available Parallel Corpora. We found five African languages with available parallel texts in the news domain: Hausa[5], Igbo (Ezeani et al., 2020), Swahili[6], Yorùbá (Adelani et al., 2021a), and isiZulu (Mabuya et al., 2021). Table 1 provides news source, the `TRAIN`, `DEV` and `TEST` splits. Appendix B provides details on the pre-processing of the available news corpora.

4.2 Monolingual News Corpus

To adapt available multilingual pre-trained models via continued pre-training to African languages, we curated texts from the 17 highest-resourced African languages and three non-native African languages that are widely spoken on the continent (Arabic, English, and French). The selection of African languages is based on their coverage in mC4 (Xue et al., 2021b), AfriBERTa corpora (Ogueji et al., 2021), and other publicly available news websites like VOA and BBC. We limited the size of the corpus extracted from mC4 to the first 30 million sentences (roughly 1GB of data) for Afrikaans, Amharic, Arabic, English, French, and Swahili. In total, we collected about 12.3 GB of data. Appendix C provides more details about the pre-training corpus.

5 Models and Methods

5.1 Baseline Models

We experiment with pre-trained multilingual models and our own bilingual MT baselines. We focus

---

[3] Some languages like Luo and Luganda are covered by JW300 but are no longer available at the time of paper writing.

[4] Crawled/downloaded from `https://ebible.org/`, except for Bambara that we obtained from `https://live.bible.is/` and Ghomálá' from `www.beblia.com`

M2M-100	418M	17	hau, ibo, lug, swa, tsn, wol, yor, zul

Table 2: **Language coverage and size for pre-trained models**. Afri[*T5] refers to AfriMT5/ByT5.

on pre-trained models that are approximately 500M parameters, both for computational feasibility and comparability across various different models.

Transformer Baseline. We train Transformer (Vaswani et al., 2017) sequence-to-sequence models from scratch for each language pair using JoeyNMT (Kreutzer et al., 2019). We tokenize the bitext using a joint SentencePiece[7] unigram model (Kudo, 2018), with a character coverage of 1.0 and a maximum sentence length of 4096 tokens and create a vocabulary of 10K subwords. Models are trained on the concatenation of `REL` and `NEWS` corpora for each language.

Pre-trained Models. We consider three language models, MT5 (Xue et al., 2021b), ByT5 (a token-free T5) (Xue et al., 2021a), mBART50 (Tang et al., 2020), and the multilingual translation model M2M-100 (Fan et al., 2021b) for our experiments. We use MT5-base and ByT5-base, and M2M-100 with 418M parameters. Table 2 gives the pre-trained model size, number of African languages covered, and the focus languages supported.

5.2 Transfer Learning Across Languages

We describe two methods for adding new languages to existing models: continual pre-training and many-to-many multilingual translation.

Continual Pre-training. The effectiveness of PLMs is limited on extremely low-resource languages because they rarely, if ever, occur in the pre-training corpus (Wang et al., 2020; Liu et al., 2021). As shown in Table 2, even for MT5 and M2M-100, which cover 100 languages, less than half of the African languages under study are included. To adapt the existing PLMs to our languages corpora and domains, we apply continual pre-training (Gururangan et al., 2020; Liu et al., 2021) using our collected monolingual corpus. Specifically, before fine-tuning on the parallel MT data, models are pre-trained with their original training objective and vocabulary[8] on the monolingual corpus. Pre-training parameters can be found in the appendix. We refer to the models adapted to African languages as AfriMT5, AfriByT5, and AfriMBART.

Many-to-Many Translation. We fine-tuned M2M-100 for African multilingual translation to create English- and French-centric models. For the English-centric model, the M2M-100 model was fine-tuned on the news data for `en`–{`hau`, `ibo`, `lug`, `luo`, `pcm`, `swa`, `tsn`, `twi`, `yor`, `zul`} while the French-centric model is trained on `fr`–{`bam`, `bbj`, `ewe`, `fon`, `mos`, `wol`}. Languages not included in the pre-trained M2M-100 model were assigned the language code of a language included in M2M-100 but excluded from our study.

5.3 Transfer Learning Across Domains

As there is very limited MT data on the news domain, we compare different methods that combine the *large* data from the religious domain (`REL`) and the *small* data from the NEWS domain (`NEWS`) to fine-tune M2M-100:

1. `REL+NEWS`: Fine-tuning on the aggregation of `REL` and `NEWS`.
2. `REL`→`NEWS`: Training on `REL`, followed by fine-tuning on `NEWS`.
3. `REL+NEWS`→`NEWS`: `REL+NEWS`, followed by additional fine-tuning on `NEWS`.

Each fine-tuning stage lasts for three epochs. We evaluate translation quality with BLEU (Papineni et al., 2002) using SacreBLEU (Post, 2018)[9] and ChrF (Popović, 2015).

6 Results and Discussion

We successfully adapt several multilingual pre-trained models to previously unseen African languages and quantify the effectiveness of small in-domain translation datasets. We discuss the effects of domain shift and analyze mitigation strategies.

6.1 Adaptation to the Focus Languages

We demonstrate that fine-tuning with a few thousand high-quality bitext is effective for adding new languages to pre-trained models. Further, continuing to pre-train to specialize models to African languages further improves performance.

---

[7] https://github.com/google/sentencepiece

[8] Changing the vocabulary (Gururangan et al., 2020) to fit the languages, or adding MT-focused training objectives for word alignment (Liu et al., 2021) can potentially improve the performance further, which we leave for future work.

[9] "intl" tokenizer, all data comes untokenized.

Table 3: **Results adding African Languages to Pre-Trained Models, en/fr-xx**. We calculate BLEU and CHRF on the news domain when training on only `NEWS` data from MAFAND-MT.

Zero-Shot Translation. Table 3 and Table 4 gives the result of zero-shot evaluation on `NEWS`. We evaluate only on the M2M-100 dataset because it has been pre-trained on parallel texts with a few of our focus languages. We observe very poor performance ($<$ 5 BLEU) on the languages except for `zul` ($>$ 13 BLEU) and `swa` ($>$ 20 BLEU) in both translation directions. For `swa`, its likely that the performance is reasonable because M2M-100 has seen more bitext during pre-training (2.4M sentences in CCAligned (El-Kishky et al., 2020)). Other African languages except for Afrikaans have less than 600K sentences in CCAligned, and are also of a lower quality (Kreutzer et al., 2021) which affect overall zero-shot performance.

Performance after Fine-tuning. We found impressive performance after fine-tuning PLMs and M2M-100 on few thousand sentences (mostly 2K–7K sentences, except for `swa` with 30K sentences), including languages not seen during pre-training. For *en/fr-xx*, MT5 has a poor transfer performance with average BLEU of 7.2, despite being pre-trained on 101 languages. ByT5 outperforms MT5 by over 3 BLEU on average, even though their performances were reported to be similar in previous work (Xue et al., 2021a). This indicates that ByT5 might be preferable over MT5 when translating low-resource languages. Surprisingly, mBART50 that was only pre-trained on 50 languages and 2 African languages outperformed MT5 and ByT5 which are pre-trained on 101 languages. Overall, we found M2M-100 to be the best model, most likely because it was pre-trained on a translation task. In general, BLEU scores are relatively low ($<$ 15 BLEU for 9 out of 16 languages for en/fr-xx and 7 in xx-en/fr) even when fine-tuning M2M-100 on in-domain data, which suggests that developing more effective methods for fine-tuning might be a promising future direction. The languages with the best quality according to BLEU on the target side are `pcm`, `swa` and `tsn`, and `pcm`, `zul`, and `swa` on the source side.

BLEU scores are higher when translating from an African language, which is expected due to the more frequent exposure to English and French on the target side during pre-training, and BLEU being penalized more for morphologically rich languages like `bbj`, `lug`, `swa`, `tsn`, and `zul`). The ChrF metric works better for them. For example, fine-tuning M2M-100 on `NEWS` and evaluating on `zul` has a BLEU of 21.0 in *en/fr-xx*, and BLEU of 37.8 in the *xx-en/fr* showing a large gap in performance in both directions. However, with the ChrF, we find a smaller performance gap (51.2 in *en/fr-xx* and 55.5 in the *xx-en/fr*.

Continual Pre-training. We observe an improvement in BLEU when we utilize AfriMT5 and AfriByT5, for languages included in our continual pre-training corpus (Appendix C). Other languages also benefit despite not being seen during continual pre-training, possibly due to language similarity. For example, AfriByT5 on *fr-bam* improved by 1.9 BLEU over ByT5 and AfriMT5 on *en-tsn* improved by 3.6 BLEU over MT5. On average, AfriMT5 im-

Table 4: **Results adding African Languages to Pre-Trained Models, xx-en/fr**. We calculate BLEU and CHRF on the news domain when training on only `NEWS` data from MAFAND-MT.

proved over MT5 by 1.3 BLEU in `en/fr-xx` and 2.4 BLEU in the *xx-en/fr*. The improvement for AfriByT5 was much smaller: 0.6 and 0.9 BLEU in *en/fr-xx* and *xx-en/fr* translation directions. For AfriMBART, we did not see any improvement on average, only the performance of `hau` (1.5 BLEU) and `ibo` (0.7 BLEU) improved in *en/fr-xx* direction. However, in the *xx-en/fr* direction, `fon`, `tsn`, `twi`, and `zul` improved by 2.7–6.0 BLEU.

Many-to-Many Multilingual MT. Training on the combined news corpus from all languages that use French or English separately does not appear to help much. We see slight improvements for most languages only in the *xx-en/fr* direction.

6.2 Adaptation to the News Domain

To improve over the baseline performance on `NEWS`, we train bilingual Transformer models (as a baseline) and M2M-100 on a combination of `REL` and `NEWS`. We chose M2M-100 because it was the best performing model. Table 5 gives the BLEU on three settings: `REL+NEWS`, `REL→NEWS`, and `REL+NEWS→NEWS`. In general, the improvement depends on the size of REL corpus. For languages trained on the Bible such as `bbj`, `bam`, `lug`, `luo`, and `wol`, the improvement is minimal. For M2M-100, the `REL+NEWS` performance does not improve over `NEWS` despite the larger quantity of training data. This demonstrates that increasing the size in the target domain is the most helpful strategy (see Figure 2). Similarly, combining `REL+NEWS` is not very helpful for xx-en/fr.An alternative approach is `REL→NEWS`, which allows the model to develop a good understanding of the desired language before adapting to the news domain. We observe an increase on 1.1 BLEU over `REL+NEWS` in the en/fr-xx direction. However, the best strategy is `REL+NEWS→NEWS`, especially for xx-en/fr where it yields an improvement over `NEWS` and `REL+NEWS` by 2.0 and 1.5 BLEU, respectively.

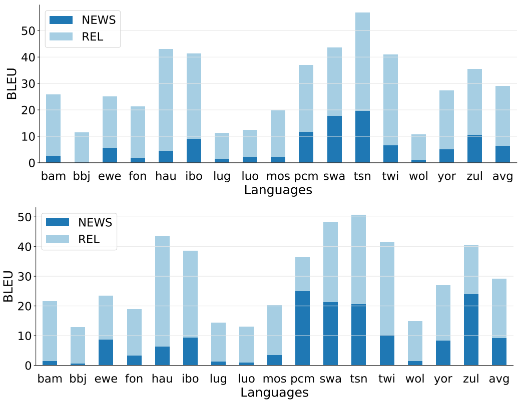

Figure 1: **Domain shift** of M2M-100 Transformer models trained on en/fr-xx (top) or xx-en/fr (bottom) `REL` domain and tested on the `NEWS` vs. `REL` domains.

6.3 Analysis of Domain Shift

Is a small in-domain set essential for fine-tuning? If we train models *only* on previously available religious data, they are not capable of translating news well due to the strong *domain bias*. This is illustrated in Figure 1: All models perform much worse on `NEWS` than on the `REL` do-

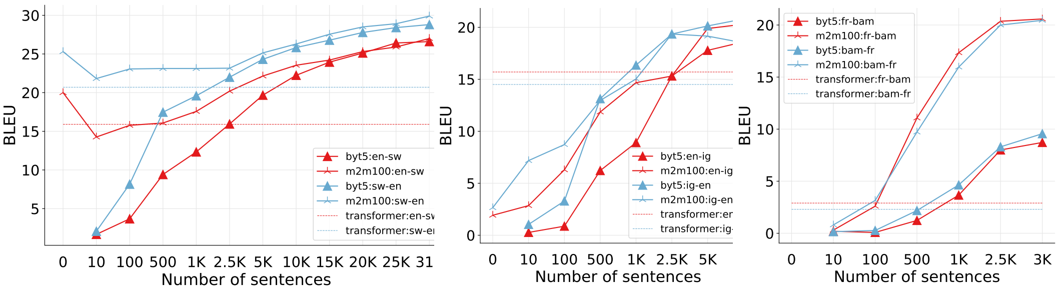
bam-fr	
`SRC`	Ani k’a fɔu ye ko cɛmancɛ fanga bɛ sigi ntuloma saba kan.
`TGT`	Et leur dire que la transition se repose sur trois piliers.
`REL`	Et qu’on leur dise que la puissance du milieu est sur trois sauterelles;
`R+N→N`	Et de leur dire que la force de la transition repose sur trois piliers.
lug-en	
`SRC`	Murasaki Shikibu yawandiika ekitabo ekijjuvu akaasookera ddala mu nsi yonna.
`TGT`	Murasaki Shikibu wrote the world’s first full novel.
`REL`	And Murshach Shikib writes a full scroll of the first in all the earth.
`R+N→N`	Murasaki Shikibu wrote a complete book first in the world.

Table 7: **Example translations** for M2M-100 fine-tuned on `REL` or `REL+NEWS→NEWS` (`R+N→N`). Terms in red are typical for biblical texts, while the terms in blue are more neutral expressions.

main. When the quantity of religious training data is small, the loss in translation performance on the news test set is largest, c.f. `bbj` (8k of `REL` data) with a drop of -95.5% BLEU or `bam` (-93.5%, 28k) and `luo` (-93.5%, 31k). This indicates that when the `REL` training data is sparse, it is insufficient to teach the M2M-100 model a more general understanding required for translating `NEWS`. However, when the religious training data is larger, this loss is reduced, c.f. when translating to `zul` (667k, -67%), `swa` (-69.3%, 872k), and `tsn` (-71%, 870k). While this is the general trend, `pcm`, whose religious training data is small (23k), has the lowest drop in performance (-59.3%), which may be due to the strong similarity to its source language.

How many sentences in the target domain are required? Figure 2 shows how for three selected language pairs with a large (`fr-bam`), medium (`eng-ibo`) and relatively small (`eng-swa`) domain gap, the quality of target domain translations improves as we increase the size of the target domain corpus. For all three pairs, fine-tuning M2M-



(a) eng-swa (b) eng-ibo (c) fr-bam

Table 8: **spBLEU on Wikipedia domain** (FLORES) and REL for M2M-100 before (✗) and after (✓) fine-tuning on `NEWS`.

100 or ByT5 on 2.5k sentence pairs of in-domain data (`NEWS`) is sufficient to outperform the bilingual Transformer baselines that were additionally trained on larger amounts of out-of-domain data (`REL`). Surprisingly, this procedure not only works for languages included during pre-training (`swa`), but also for previously unseen languages (`ibo`, `bam`). M2M-100 tends to adapt to the new data more quickly than ByT5, but in all cases, models continue to learn with additional in-domain data. This shows how much more effectively a small number of in-domain translations can be used when they serve for fine-tuning multilingual pre-trained models rather than training bilingual MT models from scratch.

Examples of Domain Bias. To illustrate the challenge of overcoming domain bias, we show examples translating from `bam` and `lug` in Table 7. The M2M-100 model fine-tuned only on `REL` succeeds in roughly capturing the meaning of the sources, but using biblical terms, such as "scroll" instead of "novel". Adding our news corpus to fine-tuning resolves these issues (e.g. "book").

How general is our news corpus? Table 8 shows the zero-shot evaluation of M2M-100 fine-tuned on our small `NEWS` corpora on other domains: religious (`REL`) and Wikipedia (FLORES). We evaluated the Wikipedia domain on the FLORES *devtest* and the `REL` domain on either JW300 or Bible (`lug`, `luo`, `wol`). As a baseline, we evaluated the zero-shot performance of M2M-100 (not fine-tuned, ✗) on FLORES[10] using spBLEU (i.e. sentencepiece BLEU (Goyal et al., 2021)). We noticed very poor performance except for Swahili — as discussed in §6.1. After fine-tuning on our new data (✓), transfer is largely improved across the bench (up to +17 BLEU for `en-ibo`). The same trend holds for the religious domain. This shows that even though our data comes from the news domain, it helped the model generalize to other domains. Hence, expanding African news corpora and developing better MT models for news pays off even for other domains of interest.

7 Conclusion

We have created MAFAND-MT, a corpus of 16 African languages to study translation systems for low-resource languages in the news domain. We investigate how to most effectively adapt large-scale pre-trained models to incorporate new languages and new domains. Our findings suggest that as little as 2k sentences are sufficient for fine-tuning, with an improved performance, paving the way for others to create new translation systems without relying on large collections of web-sourced text. This has strong implications for languages that are spoken by millions but lack presence on the web.

In the future, we hope to expand our coverage to additional under-resourced languages, and to develop even more effective fine-tuning objectives. Currently, we are extending our corpus to Chichewa, Kinyarwanda, Shona, and isiXhosa, including an expansion of the Hausa corpus, they will be released under MAFAND-MT dataset name.

A Language Characteristics

Table 9 provides the details about the language characteristics.

B Available Parallel Corpora

We found Five African languages with publicly available parallel texts in the news domain: Hausa, Igbo, Swahili, Yorùbá, and isiZulu. Table 1 provides news source, the `TRAIN`, `DEV` and `TEST` splits.

Hausa The Hausa Khamenei[11] corpus contains 5,898 sentences, we split them into `TRAIN` (3,098), `DEV` (1,300), and `TEST` split (1,500).

Igbo The Igbo corpus (Ezeani et al., 2020) has 9,998 sentences, we extract 6,998 sentences for `TRAIN`, and the remaining for `DEV` and `TEST` splits.

Swahili The Global Voices[12] corpus contains 30,782 sentences, which we use for the `TRAIN` split. We additionally crawled newer (2019–2021) publications of Swahili articles from the Global Voices website, this gives a total of 3,626 sentences, they were aligned and manually verified by Swahili speakers. They are split into the `DEV` and `TEST` splits.

Yorùbá The MENYO-20k (Adelani et al., 2021a) corpus contains sentences from different domains (TED talks, books, software localization, proverbs, and news), from which we select the news domain sentences for the `TRAIN`, `DEV` and `TEST` splits.

isiZulu The Umsuka corpus (Mabuya et al., 2021) contains 9,703 training sentences and 1,984 evaluation sentences. 4,739 training sentences were translated from English-isiZulu, and the remaining from isiZulu-English. We only keep the training sentences translated into isiZulu, and split them into 3,500 for `TRAIN` and 1,239 sentences for `DEV`. From the existing evaluation set we select only the 998 English-isiZulu translations for `TEST`. Umsuka provides two translations for each English sentence, but we use only the first.

C Monolingual Corpus PLMs adaptation

Table 10 provides the details about the Monolingual corpus used to adapt the pre-trained language models (PLMs), their size and source of corpora. The African languages pre-trained are: Afrikaans, Amharic, Hausa, Igbo, Malagasy, Chichewa, Oromo, Naija, Kinyarwanda, Kirundi,

isiZulu (zul)	mC4 (all), and Isolezwe Newspaper	700.7MB	3,252,035

Table 10: Monolingual Corpora (after pre-processing – we followed AfriBERTa (Ogueji et al., 2021) approach) , their sources and size (MB), and number of sentences.

Shona, Somali, Sesotho, Swahili, isiXhosa, Yorùbá, and isiZulu.

D Model Hyper-parameters and Reproducibility of Results

For the pre-trained models, we fine-tune the models using HuggingFace transformer tool (Wolf et al., 2020) with the default learning rate ($5e-5$), batch size of 10, maximum source length & maximum target length of 200, beam size of 10, and number of epochs is 3 except for models trained on only `NEWS` which we set to 10. We make All the experiments were performed on a single GPU (Nvidia V100).

For fine-tuning pre-trained models, especially for mBART50 that only supports two African languages, the target language is required to be specified during decoding from among those that the model has seen during pre-training, we follow past works (Madaan et al., 2020; Cahyawijaya et al., 2021; Lee et al., 2022) in selecting another closely-related language that is represented in the pre-trained model. For convenience, we make use of Swahili (sw) as the target language when an African language is not represented since Swahili is represented in all the pre-trained models. The only exception is Nigerian-Pidgin, where we make use of French (fr) since it is closely related to English. When a language is represented in the pre-trained model like M2M-100 has seen Yorùbá (yo), we make use of the correct language code.

To train AfriMT5 and ByT5, we start with MT5 and ByT5. We pre-train with the learning rate $1e-4$, $10,000$ warm up steps and a batch size of 2048 for one epoch. For mBART50, we pre-train with learning rate of $5e-5$ for $50,000$ steps

Model Name	HuggingFace Model name	Remark
AfriMT5	`masakhane/afri-mt5-base`	mT5-base adaptation to 17 African languages, English, French and Arabic.
AfriByT5	`masakhane/afri-byt5-base`	ByT5-base adaptation to 17 African languages, English, French and Arabic.
AfriMBART	`masakhane/afri-mbart50`	mBART50 adaptation to 17 African languages, English, French and Arabic.
`NEWS` (MT5)	`masakhane/mt5_{src}_{tgt}_news`	MT5 fine-tuned on {src}-{tgt} direction using parallel NEWS corpus.
`NEWS` (AfriMT5)	`masakhane/afrimt5_{src}_{tgt}_news`	AfriMT5 fine-tuned on {src}-{tgt} direction using parallel NEWS corpus.

Table 11: Model names on HuggingFace Model Hub. For bilingual models, supply the correct **src** or **tgt** language. English/French make use of a 2-letter language code i.e en or fr, while all the African languages make us of 3-letter language codes e.g yor.

using Fairseq (Ott et al., 2019) without modifying the mBART50 vocabulary. Table 11 has the names of all the models that are publicly available on HuggingFace Model Hub [13]. In total, we have 357 models from 22 x 16 bilingual models, two English/French-centric models, and three adapted models to African languages (i.e AfriMT5, AfriByT5, and AfriMBART).

E BLEU vs spBLEU

Table 12 and Table 13 compares BLEU and spBLEU metric for the domain transfer experiments. We observe that spBLEU gives higher scores than BLEU especially in the direction of *en/fr-xx*, which shows that it may be better for evaluating African languages. Although, further analysis and human evaluation are still needed to show that spBLEU is generally better. On the other hand, in the *xx-en/fr*, there is no much difference in the scores between BLEU and spBLEU.

is very poor and far from the Fon source, highlighting how poorly the model generalized from the few thousand training sentences. The M2M-100 model gives a more meaningful and adequate translation. M2M-100 makes a surprising but beautiful move, switching *se plaignent depuis quelques jours de multiples douleurs (sín azǎn mɔkpán ɖye ɔ, ye ɖò wǔvɛ sè wɛ tawun ɖò agbaza mɛ)* to *ont depuis plusieurs jours souffert d'une maladie grave*. The BLEU score here might be low but the meaning is conserved and even more detailed than the French reference. In fact, in this source context, *wǔvɛ* means *souffrir, souffrance (suffer, suffering)*: the French reference made use of *se plaignent (complaining)* which makes less sense than *souffert* used in the M2M-100 prediction. M2M-100 also learned the style of the sentence: *có ye ká tuun fí é azɔn nɛ lɛɛ gosin (but they do know the origin of their sufferings) é ɔ ǎ (**NOT**)* - this last part is crucial for the meaning of the entire sentence. Given the structural and morphological differences between Fon and French, we expected it to be more complicated to predict. However, this translation is structurally wrong even though any French native speaker would understand the conveyed message quickly and easily. In the M2M-100 translation, the word *malgré* is at the wrong place, corrupting syntax and logic of the second clause. A perfect translation (in the idea to be expressed) would be: "Louis Guy Alimanyion et Issa Etchlekoun ont depuis plusieurs jours souffert d'une maladie grave ~~malgré~~ (dont) *ils ne connaissent pas* les ~~conséquences~~ (causes/raisons) ~~de cette maladie qu'ils ne connaissent pas~~."

In the opposite translation direction, `fr→fon`, M2M-100 (`REL+NEWS→NEWS`) still preserved some sense of logical reasoning and predicted the last part right *ye ká tuun nǔ è wú wǔvɛ́ yetɔn (they do know why they are suffering) ɖè ɔ́ ǎ (**NOT**)*. However, the model had some limitations: the names which are part of the translation are not spelled correctly. Some expressions are incomplete: For instance *sín azǎn* + *number* means *since xxx days* but *yɛywɛ* is not a number, and do not have any meaning in this context.

G Limitations and Risks

Despite the promising results, our work has the following limitations:

1. **Translation quality**: Even the best model scores low BLEU on some of the reported languages (`bbj`, `mos`, `zul`), in particular when translating into them.

2. **Evaluation**: Our evaluation is focused on BLEU. We report ChrF results as well, but without a deeper human evaluation, we cannot make claims about the absolute quality of the translations. Manual inspections of translations like the example discussed in Section F gave us the impression that translations are surprisingly fluent and make good use of language-specific expressions when translating into English or French, but that errors in grammar and logic can be easily overlooked. Automatic reference-based metrics like BLEU and ChrF might not be able to capture the semantic relatedness to the reference sufficiently, as well potentially being tricked by word matches in incoherent phrases.

3. **Language bias**: We have shown that even when not included in pre-training, and without large out-of-domain data, significant gains in translation quality can be achieved. However, language-specific biases, in terms of resourcedness, morphology, standardization, inclusion in pre-trained models and available corpora, or relatedness to other languages, still affect the relative quality of translations, and require more efforts to be overcome.

4. **Domain limitations**: While we showed a rapid adaptation to the news domain and the auxiliary benefit of the religious domain, our study also revealed how automatically estimated translation quality drops when the test domain is narrow. Therefore, future work should aim to expand the study to multiple test domains and develop systematic methods

for distilling knowledge from multiple narrow domains.

5. **Language coverage**: Africa has thousands of other languages that are not covered in our study but deserve the same attention. We hope that our work is encouraging enough to inspire native speakers of those languages not covered here to collect translations, run our code, and report their findings to the NLP research community, so that we can make joint progress in developing language technology for more people.

We believe that our translation models carry similar risks of causing harm by inaccurate and biased translations as the underlying large pre-trained models. M2M-100 is trained on large collections of texts crawled from the web, and the quality for most of the languages studied here is questionable (Kreutzer et al., 2021). Our fine-tuning successes show that some obvious biases can be overcome when the quality of the fine-tuning set is controlled (see the examples in Section 6.3), but we cannot guarantee that biases prevailing in the pre-training corpus or more subtle biases will not occur with other inputs. Together with a careful human evaluation, this should be the main concern for future work on the produced models. The methodology of rapid fine-tuning might also be misused to tune the models towards harmful content or purposes that harm the speakers of the languages presented here.

Should We Rely on Entity Mentions for Relation Extraction? Debiasing Relation Extraction with Counterfactual Analysis

Abstract

Recent literature focuses on utilizing the entity information in the sentence-level relation extraction (RE), but this risks leaking superficial and spurious clues of relations. As a result, RE still suffers from unintended **entity bias**, i.e., the spurious correlation between **entity mentions (names)** and relations. Entity bias can mislead the RE models to extract the relations that do not exist in the text. To combat this issue, some previous work masks the entity mentions to prevent the RE models from overfitting entity mentions. However, this strategy degrades the RE performance because it loses the semantic information of entities. In this paper, we propose the CoRE (**Counterfactual Analysis based Relation Extraction**) debiasing method that guides the RE models to focus on the main effects of **textual context** without losing the entity information. We first construct a causal graph for RE, which models the dependencies between variables in RE models. Then, we propose to conduct counterfactual analysis on our causal graph to distill and mitigate the entity bias, that captures the causal effects of specific entity mentions in each instance. Note that our CoRE method is model-agnostic to debias existing RE systems during inference without changing their training processes. Extensive experimental results demonstrate that our CoRE yields significant gains on both effectiveness and generalization for RE. The source code is provided at: `https://github.com/vanoracai/CoRE`.

1 Introduction

Sentence-level relation extraction (RE) is an important step to obtain a structural perception of unstructured text (Distiawan et al., 2019) by extracting relations between **entity mentions (names)** from the **textual context**. From human oracle, textual context should be the main source of information that determines the ground-truth relations between entities. Consider a sentence "*Mary gave birth to Jerry.*"[1]. Even if we change the entity mentions from *'Jerry'* and *'Mary'* to other people's names, the relation 'parents' still holds between the subject and object as described by the textual context *"gave birth to"*.

Recently, some work aims to utilize entity mentions for RE (Yamada et al., 2020; Zhou and Chen, 2021), which, however, leak superficial and spurious clues about the relations (Zhang et al., 2018). In our work, we observe that entity information can lead to **biased** relation prediction by misleading RE models to extract relations that do not exist in the text. Fig. 1 visualizes a relation prediction from a state-of-the-art RE model (Alt et al., 2020) (see more examples in Tab. 7). Although the context describes no relation between the highlighted entity pair, the model extracts the relation as "*countries_of_residence*". Such an erroneous result can come from the spurious correlation between entity mentions and relations, or the **entity bias** in short. For example, if the model sees the relation "*countries_of_residence*" many more times than other relations when the object entity is *Switzerland* during training, the model can associate this relation with *Switzerland* during inference even though the relation does not exist in the text.

To combat this issue, some work (Zhang et al., 2017, 2018) proposes masking entities to prevent the RE models from over-fitting entity mentions. On the other hand, some other work (Peng et al., 2020; Zhou and Chen, 2021) finds that this strategy degrades the performance of RE because it loses the semantic information of entities.

For both machines and humans, RE requires a combined understanding of textual context and entity mentions (Peng et al., 2020). Humans can avoid the entity bias and make unbiased decisions by correctly referring to the textual context that describes the relation. The underlying mechanism is

---

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3071 - 3081
July 10-15, 2022

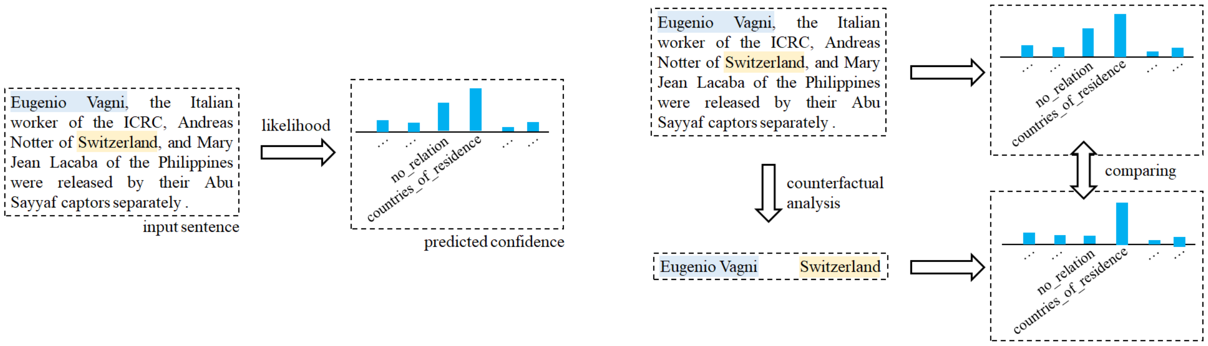

Figure 1: (*left*) An example of RE produced by LUKE (Yamada et al., 2020). In the input sentence, the subject is in blue and the object is in yellow. The ground-truth relation between the subject and object is "*no_relation*", since there is not any relation reflected by the textual context. (*right*) Our proposed counterfactual analysis for RE, which compares the original prediction (upper) with the counterfactual one (lower) to mitigate the entity bias.

causality-based (Van Hoeck et al., 2015): humans identify the relations by pursuing the main causal effect of the textual context instead of the side-effect of entity mentions. In contrast, RE models are usually *likelihood-based*: the prediction is analogous to looking up the entity mentions and textual context in a huge likelihood table, interpolated by training (Tang et al., 2020). In this paper, our idea is to teach RE models to distinguish between the effects from the textual context and entity mentions through counterfactual analysis (Pearl, 2018):

Counterfactual analysis: *If I had not seen the textual context, would I still extract the same relation?*

The counterfactual analysis essentially gifts humans the hypothesizing abilities to make decisions collectively based on the textual context and entity mentions, as well as to introspect whether the decision is deceived (see Fig. 1). Specifically, we are essentially comparing the original instance with a counterfactual instance, where only the textual context is wiped out, while keeping the entity mentions untouched. By doing so, we can focus on the main effects of the textual context without losing the entity information.

In our work, we propose a novel model-agnostic paradigm for debiasing RE, namely CoRE (Counterfactual analysis based Relation Extraction), which adopts the counterfactual analysis to mitigate the spurious influence of the entity mentions. Specifically, CoRE does not touch the training of RE models, i.e., it allows a model to be exposed to biases on the original training set. Then, we construct a causal graph for RE to analyze the dependencies between variables in RE models, which acts as a "roadmap" for capturing the causal effects of textual context and entity mentions. To rectify the test instances from the potentially biased prediction, in inference, CoRE "imagines" the counterfactual counterparts on our causal graph to distill the biases. Last but not least, CoRE performs a bias mitigation operation with adaptive weights to produce a debiased decision for RE.

We highlight that CoRE is a flexible debiasing method that is applicable to popular RE models without changing their training processes. To evaluate the effectiveness of CoRE, we perform extensive experiments on public benchmark datasets. The results demonstrate that our proposed method can significantly improve the effectiveness and generalization of the popular RE models by mitigating the biases in an entity-aware manner.

2 Related Work

Sentence-level relation extraction. Early research efforts (Nguyen and Grishman, 2015; Wang et al., 2016; Zhang et al., 2017) train RE models from scratch based on lexicon-level features. The recent RE work fine-tunes pretrained language models (PLMs; Devlin et al. 2019; Liu et al. 2019). For example, K-Adapter (Wang et al., 2020) fixes the parameters of the PLM and uses feature adapters to infuse factual and linguistic knowledge. Recent work focuses on utilizing the entity information for RE (Zhou and Chen, 2021; Yamada et al., 2020), but this leaks superficial and spurious clues about the relations (Zhang et al., 2018). Despite the biases in existing RE models, scarce work has discussed the spurious correlation between entity mentions and relations that causes such biases. Our work investigates this issue and proposes CoRE to debias RE models for higher effectiveness.

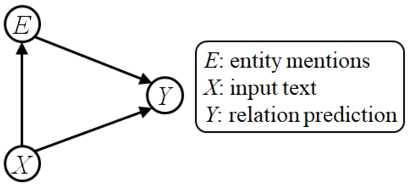

Figure 2: The causal graph of RE models.

Debiasing for Natural Language Processing. Debiasing is a fundamental problem in machine learning (Torralba and Efros, 2011). For natural language processing (NLP), some work performs data re-sampling to prevent models from capturing the unintended bias in training (Dixon et al., 2018; Geng et al., 2007; Kang et al., 2016; Rayhan et al., 2017; Nguyen et al., 2011). Alternatively, Wei and Zou (2019) and Qian et al. (2020) develop data augmentation for debiasing. Some recent work debiases the NLP models based on causal inference (Qian et al., 2021; Nan et al., 2021). In RE, how to deal with the entity bias is also an important problem. For example, PA-LSTM (Zhang et al., 2017) masks the entity mentions with special tokens to prevent RE models from over-fitting entity names, which was also adopted by C-GCN (Zhang et al., 2018) and SpanBERT (Joshi et al., 2020). However, masking entities loses the semantic information of entities and leads to performance degradation. Different from it, our CoRE model tackles entity biases based on structured causal models. In this way, we debias the RE models to focus on the textual context without losing the entity information.

3 Methodology

Sentence-level relation extraction (RE) aims to extract the relation between a pair of entities mentioned from a sentence. We propose CoRE (counterfactual analysis based Relation Extraction) as a model-agnostic technique to endow existing RE models with unbiased decisions during inference. CoRE follows the regular training process of existing work regardless of the bias from the entity mentions. During inference, CoRE post-adjusts the biased prediction according to the effects of the bias. CoRE can be flexibly incorporated into popular RE models to improve their effectiveness and generalization based on the counterfactual analysis without re-training the model.

In this section, we first formulate the existing RE models in the form of a causal graph. Then, we introduce our proposed bias distillation method to distill the entity bias with our designed counterfactual analysis. We conduct an empirical analysis to analyze how heavily the existing RE models rely on the entity mentions to make decisions. Finally, we mitigate the distilled bias from the predictions of RE models to improve their effectiveness.

3.1 Causality of Relation Extraction

In order to perform causal intervention, we first formulate the **causal graph** (Pearl et al., 2016; Pearl and Mackenzie, 2018), a.k.a., structural causal model, for the RE models as Fig. 2, which sheds light on how the textual context and entity mentions affect the RE predictions. The causal graph is a directed acyclic graph $\mathcal{G} = \{\mathcal{V}, \mathcal{E}\}$, indicating how a set of variables $\mathcal{V}$ interact with each other through the causal relations behind the data and how variables obtain their values, e.g., $(E, X) \rightarrow Y$ in Fig. 2. Before we conduct counterfactual analysis that deliberately manipulates the values of nodes and prunes the causal graph, we first revisit the conventional RE systems in the graphical view.

The causal graph in Fig. 2 is applicable to a variety of RE models and imposes no constraints on the detailed implementations. Node X is the input text. On the edge $X \rightarrow E$, we obtain the spans of subject and object entities as node E through NER or human annotations (Zhang et al., 2017). For example, in the aforementioned sentence $X =$ “*Mary gave birth to Jerry.*”, the entities are $E =$ [*'Mary', 'Jerry'*].

On the edges $(X, E) \rightarrow Y$, existing RE models take different designs. For example, C-GCN (Zhang et al., 2018) obtains the relation prediction Y by encoding entity mentions E on the pruned dependency tree of X using a graph convolutional network. IRE (Zhou and Chen, 2021) uses PLMs as the encoder for X, and marks the entity information of E with special tokens to utilize the entity information.

3.2 Bias Distillation

Based on our causal graph in Fig. 2, we diagnose how the entity bias affects inference. After training, the causal dependencies among the variables are learned in terms of the model parameters. The entity bias can mislead the models to make wrong predictions while ignoring the actual relation-describing textual context in X, i.e., biased towards the causal dependency: $E \rightarrow Y$.

The conventional biased prediction can only see the output Y of the entire graph given a sentence

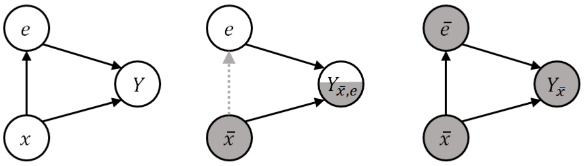

Figure 3: The original causal graph of RE models (left) together with its two counterfactual alternates for the entity bias (middle) and label bias (right). The shading indicates the mask of corresponding variables.

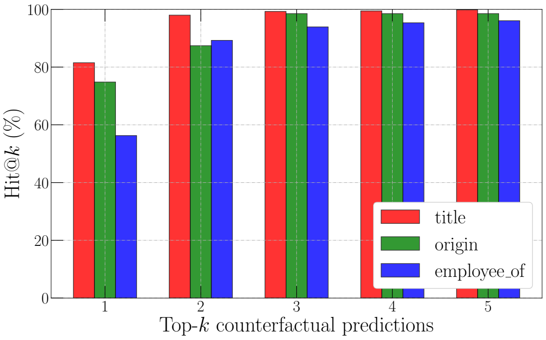

Figure 4: Hit@k (y-axis) is the fraction of the test instances, that have the original relation prediction $\arg\max_c Y_x[c]$ ranked in the top k most confident relations of the counterfactual prediction $Y_{\bar{x},e}$. We report Hit@k of the model $\text{IRE}_{\text{RoBERTa}}$ on the test instances when the original relation prediction is *title*, *employee_of*, or *origin*.

X, ignoring how specific entity mentions affect the relation prediction. However, causal inference encourages us to think out of the black box. From the graphical point of view, we are no longer required to execute the entire causal graph as a whole. In contrast, we can directly manipulate the nodes and observe the output. The above operation is termed **intervention** in causal inference, which we denote as $do(\cdot)$. It wipes out all the incoming links of a node and demands it to take a certain value.

We distill the entity bias by intervention and its induced **counterfactual**. The counterfactual means "counter to the facts", and takes one step that further assigns the hypothetical combination of values to variables. For example, we can remove the input textual context by masking X, but maintain E as the original entity mentions, as if X still exists.

We will use the input text X as our control variable where the intervention is conducted, aiming to assess its effects, due to the fact that there would not be any valid relation between entities in E if the input text X is empty. We denote the output logits Y after the intervention $X = \bar{x}$ as follows:

$$Y_{\bar{x}} = Y(do(X = \bar{x})). \tag{1}$$

Following the above notation, the original prediction Y, i.e., can be re-written as Y_x.

To distill the entity bias, we conduct the intervention $do(X = \bar{x})$ on X, while keeping the variable E as the original e, as if the original input text x had existed. Specifically, we mask the tokens in x to produce $\bar{x}$ but keep the entity mentions e as original, so that the textual context is removed and the entity information is maintained. Accordingly, the counterfactual prediction is denoted as $Y_{\bar{x},e}$ (see Fig. 3). In this case, since the model cannot see any textual context in the factual input x after the intervention $\bar{x}$, but still has access to the original entity mentions e as the inputs, the prediction $Y_{\bar{x},e}$ purely reflects the influence from e. In other words, $Y_{\bar{x},e}$ refers to the output, i.e., a probability distribution or a logit vector, where only the entity mentions are given as the input without textual context.

To investigate how heavily the state-of-the-art models rely on the entity mentions for RE, we conduct an empirical study to compare the original prediction Y_x and the counterfactual one $Y_{\bar{x},e}$. Specifically, we calculate the fraction of the test instances (y-axis) that have the original relation prediction $\arg\max_c Y_x[c]$ ranked in the top k most confident relations of the counterfactual prediction $Y_{\bar{x},e}$. This fraction is termed as Hit@k.

We present Hit@k for $\text{IRE}_{\text{RoBERTa}}$ (Zhou and Chen, 2021), a state-of-the-art RE model, in Fig. 4 on the test instances when the original relation prediction is *title*, *employee_of*, or *origin*. Higher Hit@1 means that for more instances, the model infers the same relation given only the entity mentions no matter whether the textual context is given, which imply stronger causal effects from the entity mentions $Y_{\bar{x},e}$, i.e., the models rely more heavily on the entity mentions for RE.

We observe that when $k = 1$, the Hit@1 is more than 50%, which implies that the model typically extracts the same relations even without textual context on more than a half of the instances. For a larger k, the Hit@k increases significantly and reaches more than 80% for $k \geq 2$. These observations imply a promising but embarrassing result: the state-of-the-art model relies on the entity bias for RE on many instances. The entity bias reflected by $Y_{\bar{x},e}$ can lead to the wrong extraction if the relation implied by the entity mentions does not exist in the input text. This poses a challenge to the generalization of RE models, as validated by our experimental results (§4.3).

In addition to $Y_{\bar{x},e}$ that reflects the causal effects of entity mentions, there is another kind of bias not conditioned on the entity mentions e, but reflecting the general bias in the whole dataset, which is $Y_{\bar{x}}$. $Y_{\bar{x}}$ corresponds to the counterfactual inputs where both textual context and entity mentions are removed. In this case, since the model cannot access any information from the input after this removal, $Y_{\bar{x}}$ naturally reflects the label bias that exists in the model from the biased training. The causal graphic views of the original prediction Y_x, the counterfactual $Y_{\bar{x},e}$ for the entity bias, and $Y_{\bar{x}}$ for the label bias are visualized in Fig. 3.

3.3 Bias Mitigation

As we have discussed in §1, instead of the static likelihood that tends to be biased, the unbiased relation prediction lies in the difference between the observed outcome Y_x and its counterfactual predictions $Y_{\bar{x},e}, Y_{\bar{x}}$. The latter two are the biases that we want to mitigate from the relation prediction.

Intuitively, the unbiased prediction that we seek is the linguistic stimuli from blank to the observed textual context with specific relation descriptions, but not merely from the entity bias. The context-specific clues of the relations are key to the informative unbiased predictions, because even if the overall prediction is biased towards the relation "*schools_attended*" due to the object entity like "*Duke University*", the textual context *"work at"* indicates the relation as *"employee_of"* rather than *"schools_attended"*.

Our final goal is to use the direct effect of the textual context from X to Y for debiased prediction, mitigating (denoted as $\backslash$) the label bias and the entity bias from the prediction: $Y_x \backslash Y_{\bar{x},e} \backslash Y_{\bar{x}}$, so as to block the spread of the biases from training to inference. The debiased prediction via bias mitigation can be formulated via the conceptually simple but empirically effective element-wise subtraction operation:

$$Y_{\text{final}} = Y_x - \lambda_1 Y_{\bar{x},e} - \lambda_2 Y_{\bar{x}}, \qquad (2)$$

where λ_1 and λ_2 are two independent hyperparameters balancing the terms for mitigating entity and label biases respectively. Note that the bias mitigation in Eq. 2 for the entity and label biases correspond to Total Direct Effect (TDE) and Total Effect (TE) in causal inference (Tang et al., 2020; VanderWeele, 2015; Pearl, 2009) respectively. We adaptively set the values of λ_1 and λ_2 for different datasets based on the grid beam search (Hokamp and Liu, 2017) in a scoped two dimensional space:

Dataset	#Train	#Dev	#Test	#Classes
TACRED	68,124	22,631	15509	42
SemEval	6,507	1,493	2,717	19
Re-TACRED	58,465	19,584	13418	40
TACRED-Revisit	68,124	22,631	15509	42

Table 1: Statistics of datasets.

$$\lambda_1^\star, \lambda_2^\star = \arg\max_{\lambda_1,\lambda_2} \psi(\lambda_1, \lambda_2) \;\; \lambda_1, \lambda_2 \in [a, b], \quad (3)$$

where ψ is a metric function (e.g., F1 scores) for evaluation, a, b are the boundaries of the search range. We search the values of λ_1, λ_2 once on the validation set, and use the fixed values for inference on all testing instances. Since the entity types can restrict the candidate relations (Lyu and Chen, 2021), we use the entity type information, if available, to restrict the candidate relations for inference, which strengthens the effects of entity types for relation extraction.

Overall, the proposed CoRE replaces the conventional one-time prediction with Y_{final} to produce the debiased relation predictions, which essentially "thinks" twice: one for the original observation Y_x, the other for hypothesized $Y_{\bar{x}}, Y_{\bar{x},e}$.

4 Experiments

In this section, we evaluate the performance of our CoRE methods when applied to RE models. We compare our methods against a variety of strong baselines on the task of sentence-level RE. Our experimental settings closely follow those of the previous work (Zhang et al., 2017; Zhou and Chen, 2021; Nan et al., 2021) to ensure a fair comparison.

4.1 Experimental Settings

Datasets. We use four widely-used RE benchmarks: TACRED (Zhang et al., 2017), SemEval (Hendrickx et al., 2019), TACRED-Revisit (Alt et al., 2020), and Re-TACRED (Stoica et al., 2021) for evaluation. TACRED contains over 106k mention pairs drawn from the yearly TAC KBP challenge. (Alt et al., 2020) relabeled the development and test sets of TACRED. Re-TACRED is a further relabeled version of TACRED after refining its label definitions. The statistics of these datasets are shown in Tab. 1.

Method	**TACRED**	**TACRED-Revisit**	**Re-TACRED**	**SemEval**
C-SGC (Wu et al., 2019)	52.1	62.8	69.8	71.3
SpanBERT (Joshi et al., 2020)	55.7	65.1	74.1	74.9
CP (Peng et al., 2020)	56.8	67.1	78.1	79.6
RECENT (Lyu and Chen, 2021)	63.3	70.5	81.1	74.6
KnowPrompt (Chen et al., 2021)	57.6	68.7	79.0	81.8
IRE_{BERT} (Zhou and Chen, 2021)	59.2	68.4	78.6	79.1
LUKE (Yamada et al., 2020)	58.8	67.5	80.2	82.1
LUKE + Resample (Burnaev et al., 2015)	59.3	68.2	80.5	82.5
LUKE + Focal (Lin et al., 2017)	59.1	67.7	80.3	82.4
LUKE + CFIE (Nan et al., 2021)	59.8	68.0	80.4	82.2
LUKE + Entity Mask (Zhang et al., 2017)	57.9	67.0	79.5	82.0
LUKE + CoRE	61.7	70.2	81.6	**83.6**
$\text{IRE}_{\text{RoBERTa}}$ (Zhou and Chen, 2021)	63.1	70.6	81.5	81.4
$\text{IRE}_{\text{RoBERTa}}$ + Resample (Burnaev et al., 2015)	63.3	71.0	81.9	81.6
$\text{IRE}_{\text{RoBERTa}}$ + Focal (Lin et al., 2017)	62.9	70.7	81.2	81.1
$\text{IRE}_{\text{RoBERTa}}$ + CFIE (Nan et al., 2021)	63.3	70.9	81.6	81.7
$\text{IRE}_{\text{RoBERTa}}$ + Entity Mask (Zhang et al., 2017)	61.4	69.3	79.6	81.2
$\text{IRE}_{\text{RoBERTa}}$ + CoRE	**64.4**	**71.8**	**82.8**	82.3

Table 2: F1-macro scores (%) of RE on the test sets of TACRED, TACRED-Revisit, Re-TACRED, and SemEval. The best results in each column are highlighted in **bold** font.

We use the widely-used F1-macro score as the main evaluation metric (Nan et al., 2021), which is the balanced harmonic mean of precision and recall, as well as F1-micro for a more comprehensive evaluation. F1-macro is more suitable than F1-micro to reflect the extent of biases, especially for the highly-skewed cases, since F1-macro is evenly influenced by the performance in each category, i.e. category-sensitive, but F1-micro simply gives equal weights to all instances (Kim et al., 2019).

Compared methods. We take the following RE models into comparison. (1) **C-SGC** (Wu et al., 2019) simplifies GCN, and combines it with LSTM, leading to improved performance over each method alone. (2) **SpanBERT** (Joshi et al., 2020) extends BERT by introducing a new pretraining objective of continuous span prediction. (3) **CP** (Peng et al., 2020) is an entity-masked contrastive pre-training framework for RE. (4) **RECENT** (Lyu and Chen, 2021) restricts the candidate relations based on the entity types. (5) **KnowPrompt** (Chen et al., 2021) is Knowledge-aware Prompt-tuning approach. (6) **LUKE** (Yamada et al., 2020) pretrains the language model on both large text corpora and knowledge graphs and further proposes an entity-aware self-attention mechanism. (7) **IRE** (Zhou and Chen, 2021) proposes an improved entity representation technique in the data preprocessing.

Among the above RE models, we apply our CoRE on LUKE and IRE. To demonstrate the effectiveness of debiased inference, we also compare with the following debiasing techniques that are applied to the same two RE models. (1) **Focal** (Lin et al., 2017) adaptively reweights the losses of different instances so as to focus on the hard ones. (2) **Resample** (Burnaev et al., 2015) up-samples rare categories by the inversed sample fraction during training. (3) **Entity Mask** (Zhang et al., 2017): masks the entity mentions with special tokens to reduce the over-fitting on entities. (4) **CFIE** (Nan et al., 2021) is also a causal inference method. In contrast to our method, CFIE strengthens the causal effects of entities by masking entity-centric information in the counterfactual predictions.

Model configuration. For the hyper-parameters of the considered baseline methods, e.g., the batch size, the number of hidden units, the optimizer, and the learning rate, we set them as suggested by their authors. For the hyper-parameters of our CoRE method, we set the search range of the hypermeters in Eq. 3 as $[-2, 2]$ and the search step 0.1. For all experiments, we report the median $F1$ scores of five runs of training using different random seeds.

4.2 Overall Performance

We implement our CoRE with LUKE and $\text{IRE}_{\text{RoBERTa}}$. Tab. 3 reports the RE results on the TACRED, TACRED-Revisit, Re-TACRED, and SemEval datasets. Our CoRE method improves the F1-macro scores of LUKE by 4.9% on TACRED, 4.0% on TACRED-Revisit, 1.7% on Re-TACRED, and 1.7 on SemEval, and improves $\text{IRE}_{\text{RoBERTa}}$

Method	**TACRED**	**TACRED-Revisit**	**Re-TACRED**	**SemEval**
LUKE (Yamada et al., 2020)	72.7	80.6	90.3	87.8
LUKE + Resample (Burnaev et al., 2015)	73.1	80.9	90.5	87.9
LUKE + Focal (Lin et al., 2017)	72.9	80.7	90.4	87.6
LUKE + CFIE (Nan et al., 2021)	73.3	80.8	90.5	88.0
LUKE + Entity Mask (Zhang et al., 2017)	72.3	80.4	90.1	87.5
LUKE + CoRE	**74.6**	**81.4**	**90.9**	**88.7**

Table 3: F1-micro scores (%) of RE on the test sets of TACRED, TACRED-Revisit, Re-TACRED, and SemEval. The best results in each column are highlighted in **bold** font.

Method	**TACRED**	**Re-TACRED**
LUKE (Yamada et al., 2020)	51.9	65.3
w/ Resample (Burnaev et al., 2015)	53.2	66.7
w/ Focal (Lin et al., 2017)	52.4	65.9
w/ CFIE (Nan et al., 2021)	52.1	65.6
w/ Entity Mask (Zhang et al., 2017)	54.5	67.1
w/ CoRE (ours)	**69.3**	**83.1**
IRE$_{\text{RoBERTa}}$ (Zhou and Chen, 2021)	56.4	68.1
w/ Resample (Burnaev et al., 2015)	58.1	70.3
w/ Focal (Lin et al., 2017)	56.8	68.7
w/ CFIE (Nan et al., 2021)	57.1	68.4
w/ Entity Mask (Zhang et al., 2017)	57.3	68.9
w/ CoRE (ours)	**73.6**	**85.4**

Table 4: F1-macro scores (%) of RE on the challenging test sets of TACRED and Re-TACRED, in which the relations implied by the entity mentions do not exist in the textual context. 'w' denotes 'with'. The best results in each column are highlighted in **bold** font.

by 1.2% on TACRED, 1.4% on TACRED-Revisit, 0.9% on Re-TACRED, and 1.8% on SemEval. As a result, our CoRE achieves substantial improvements for LUKE and IRE$_{\text{RoBERTa}}$, and enables them to outperform the baseline methods. Additionally, we report the experimental results in terms of F1-micro scores in Tab. 3, showing the improvement from CoRE on LUKE by 2.6% on TACRED, 1.0% on TACRED-Revisit, 0.7% on Re-TACRED, and 1.0% on SemEval. Overall, our CoRE method improves the effectiveness of RE significantly in terms of both F1-macro and F1-micro scores. The above experimental results validate the effectiveness and generalization of our proposed method.

Among the baseline debiasing methods, Resample, Focal, CFIE cannot distill the entity bias in an entity-aware manner like ours. Entity Mask leads to the loss of information, while our CoRE enables RE models to focus on the main effects of textual context without losing the entity information. The superiority of CoRE highlights the importance of the causal inference based entity bias analysis for debiasing RE, which compares traditional likelihood-based predictions and hypothesized counterfactual ones to produce debiased predictions. Besides, the proposed CoRE works in inference and thus can be employed on the previous already-trained models. In this way, CoRE serves as a model-agnostic approach to enhance RE models without changing their training process.

4.3 Analysis on Entity Bias

Some work argues that RE models may rely on the entity mentions to make relation predictions instead of the textual context (Zhang et al., 2018; Joshi et al., 2020). The empirical results in Fig. 3 validates this argument. Regardless of whether the textual context exists or not, the baseline RE model makes the same predictions given only entity mentions on many instances. The entity bias can mislead the RE models to make wrong predictions when the relation implied by the entity mentions does not exist in the textual context.

To evaluate whether RE models can generalize well to particularly challenging instances where relations implied by the entity mentions do not exist in the textual context, we propose a filtered evaluation setting, where we keep the test instances having the entity bias different from their ground-truth relations. In this setting, RE models cannot overly rely on the entity mentions for RE, since the entity mentions no longer provide the superficial and spurious clues for the ground-truth relations.

We present the evaluation results on the filtered test set in Tab. 4. Our CoRE method consistently and substantially improves the effectiveness of LUKE and IRE on the filtered test set and outperforms the baseline methods by a significant margin, which validates the effectiveness and generalization of our method to mitigate the entity bias in the challenging cases.

4.4 Evaluation on Fairness

According to Sweeney and Najafian (2019), the more imbalanced/skewed a prediction produced by a trained model is, the more unfair opportunities it

Method	**TACRED**	**TACRED-Revisit**	**Re-TACRED**	**SemEval**
$\text{IRE}_{\text{RoBERTa}}$ (Zhou and Chen, 2021)	61.2	59.3	57.5	54.1
$\text{IRE}_{\text{RoBERTa}}$ + Resample (Burnaev et al., 2015)	60.5	58.4	56.8	53.5
$\text{IRE}_{\text{RoBERTa}}$ + Focal (Lin et al., 2017)	60.9	58.9	57.1	53.7
$\text{IRE}_{\text{RoBERTa}}$ + CFIE (Nan et al., 2021)	60.1	57.8	56.2	52.9
$\text{IRE}_{\text{RoBERTa}}$ + Entity Mask (Zhang et al., 2017)	61.5	60.1	57.3	54.2
$\text{IRE}_{\text{RoBERTa}}$ + CoRE	**57.3**	**55.6**	**54.3**	**50.8**

Table 5: Experimental results (unfairness; %) of Relation Extraction on the test sets of TACRED, TACRED-Revisit, Re-TACRED, and SemEval (lower is better). The best results in each column are highlighted in **bold** font.

LUKE + CoRE	**61.7**	**Δ**	**IRE + CoRE**	**64.4**	**Δ**
w/o CoRE	58.8	2.9↓	w/o CoRE	63.1	1.3↓
w/o EBM	59.5	2.2↓	w/o EBM	63.4	1.0↓
w/o LBM	60.8	0.9↓	w/o LBM	63.9	0.5↓
w/o BSH	60.1	1.6 ↓	w/o BSH	63.8	0.6↓

Table 6: Ablation study based on the TACRED dataset. The analyzed model components include entity bias mitigation operation (EBM), the label bias mitigation operation (LBM) and the beam search for hyper-parameters (BSH). 'w/o' denotes 'without'. ↓ denotes performance drop in terms of F1-macro scores.

gives over predefined categories, and the more unfairly discriminative the trained model is. We thus follow previous work (Xiang et al., 2020; Sweeney and Najafian, 2019; Qian et al., 2021) to use the metric – *imbalance divergence* – to evaluate how imbalanced/skewed/unfair a prediction P is :

$$D(P, U) = JS(P \| U), \tag{4}$$

where $D(\cdot)$ is defined as the distance between P and the uniform distribution U. Specifically, we use the *JS* divergence as the distance metric since it is symmetric (i.e., $JS(P\|U) = JS(U\|P)$) and strictly scoped (Fuglede and Topsoe, 2004). Based on this, to evaluate the entity bias of a trained RE model, we average the following *relative entity mention imbalance* (REI) measure over all the testing instances containing whichever entity mentions:

$$\text{REI} = \frac{1}{\mathcal{E}} \sum_{e \in \mathcal{E}} D(P(\{x | e \in x \wedge x \in \mathcal{D}\}), U), \tag{5}$$

where x is an input instance, $\mathcal{D}$ is the testing set, $P(x)$ is the prediction output, e is an entity mention, and $\mathcal{E}$ is the corpus of entity mentions. This metric captures the distance between all predictions and the fair uniform distribution U.

We follow the experimental settings in §4.2 and report the fairness test in Tab. 5. The results show that our CoRE method reduces the imbalance metrics (lower is better) when employed on $\text{IRE}_{\text{RoBERTa}}$ significantly and consistently, indicating that it is helpful to mitigate the entity bias.

4.5 Ablation and Case Study

We conduct ablation studies on CoRE to empirically examine the contribution of its main technical components. including the entity bias mitigation operation (EBM), the label bias mitigation operation (LBM) and the beam search for hyper-parameters (BSH).

We report the experimental results of the ablation study in Tab. 6. We observe that removing our CoRE causes serious performance degradation. This provides evidence that using our counterfactual framework for RE can explicitly mitigate biases to generalize better on unseen examples. Moreover, we observe that mitigating the two types of biases is consistently helpful for RE. The key reason is that the distilled label bias provides an instance-agnostic offset and the distilled entity bias provides an entity-aware one in the prediction space, which makes the RE models focus on extracting relations on the textual context without losing the entity information. Meanwhile, the beam search for hyper-parameters effectively finds two dynamic scaling factors to amplify or shrink two biases, making the biases be mitigated properly and adaptively.

Tab. 7 gives a qualitative comparison example between CoRE and $\text{IRE}_{\text{RoBERTa}}$ on TACRED. The results show that the state-of-the-art RE model $\text{IRE}_{\text{RoBERTa}}$ returns the relations that do not exist in the textual context between the considered entities. For example, given "*Bibi drew the ire of fellow farmhands after a dispute in June 2009, when they refused to drink water she collected and she refused their demands that she convert to Islam.*", there is no relation between *Bibi* and *Islam* exists in the text but the baseline model believes that the relation between them is "*religion*". The counterfactual prediction can account for this disappointing result,

Input sentence	Original	Debiased	Counterfactual
More than 1,100 miles (1,770 kilometers) away, Alan Gross passes his days in a Cuban military hospital, watching baseball on a small television or jamming with his jailers on a stringed instrument they gave him.	origin ✗	countries_of_residence ✓	origin
He said that according to his investigation, Bibi drew the ire of fellow farmhands after a dispute in June 2009, when they refused to drink water she collected and she refused their demands that she convert to Islam.	religion ✗	no_relation ✓	religion
ShopperTrak also estimates foot traffic in the U.S. was 11.2 percent below what it would have been Sunday if the blizzard had not occurred and 13.9 percent below what it could have been Monday.	country_of_headquarters ✗	no_relation ✓	country_of_headquarters

Table 7: A case study for $\text{IRE}_{\text{RoBERTa}}$ and our CoRE on the relation extraction dataset TACRED. Underlines and wavy lines highlight the subject and object entities respectively. We report the original prediction, the corresponding counterfactual prediction and the debiased prediction.

where given only the entity mentions *Bibi* and *Islam*, the RE model returns the relation "*religion*" without any textual context. This implies that the model makes the prediction for the original input relying on the entity mentions, which leads to the wrong RE prediction. Our CoRE method distills the biases through counterfactual predictions and mitigates the biases to distinguish the main effects from the textual context, which leads to the correct predictions as shown in Tab. 7.

Last but not least, we conduct experiments on the fairness of different models, and present respective results in the appendix.

5 Conclusion

We have designed a counterfactual analysis based method named CoRE to debias RE. We distill the entity bias and mitigate the distilled biases with the help of our causal graph for RE, which is a road map for analyzing the RE models. Based on the counterfactual analysis, we can analyze the side-effects of entity mentions in the RE and debias the models in an entity-aware manner. Extensive experiments demonstrate that our methods can improve the effectiveness and generalization of RE. Future work includes analyzing the effects of other factors that can cause bias in natural language processing.

Abstract

We propose a novel framework `ConceptX`, to analyze how latent concepts are encoded in representations learned within pre-trained language models. It uses clustering to discover the encoded concepts and explains them by aligning with a large set of human-defined concepts. Our analysis on seven transformer language models reveal interesting insights: i) the latent space within the learned representations overlap with different linguistic concepts to a varying degree, ii) the lower layers in the model are dominated by lexical concepts (e.g., affixation), whereas the core-linguistic concepts (e.g., morphological or syntactic relations) are better represented in the middle and higher layers, iii) some encoded concepts are multi-faceted and cannot be adequately explained using the existing human-defined concepts.[1]

1 Introduction

Contextualized word representations learned in deep neural network models (DDNs) capture rich concepts making them ubiquitous for transfer learning towards downstream NLP. Despite their revolution, the blackbox nature of the deep NLP models is a major bottle-neck for their large scale adaptability. Understanding the inner dynamics of these models is important to ensure fairness, robustness, reliability and control.

A plethora of research has been carried out to probe DNNs for the linguistic knowledge (e.g. morphology, syntactic and semantic roles) captured within the learned representations. A commonly used framework to gauge how well linguistic information can be extracted from these models is the *Probing Framework* (Hupkes et al., 2018), where they train an auxiliary classifier using representations as features to predict the property of interest. The performance of the classifier reflects the amount of knowledge learned within representations. To this end, the researchers have analyzed what knowledge is learned within the representations through relevant extrinsic phenomenon varying from word morphology (Vylomova et al., 2016; Belinkov et al., 2017a) to high level concepts such as syntactic structure (Blevins et al., 2018; Marvin and Linzen, 2018) and semantics (Qian et al., 2016; Reif et al., 2019; Belinkov et al., 2017b) or more generic properties (Adi et al., 2016; Rogers et al., 2020).

In this work, we approach the representation analysis from a different angle and present a novel framework `ConceptX`. In contrast to relying on the prediction capacity of the representations, we analyze the latent concepts learned within these representations and how knowledge is structured, using an unsupervised method. More specifically, we question: i) do the representations encode knowledge inline with linguistic properties such as word morphology and semantics? ii) which properties dominate the overall structure in these representations? iii) does the model learn any novel concepts beyond linguistic properties? Answers to these questions reveal how deep neural network models structure language information to learn a task.

Our inspiration to use the term *concept* comes from *"concept based explanation"* in computer vision (Kim et al., 2018; Ghorbani et al., 2019; Chen et al., 2020). Stock (2010) defined a concept as "a class containing certain objects as elements, where the objects have certain properties". We define an *encoded concept as a cluster of context-aware latent representations of words, where the representations are encoder layer outputs.*

Our framework clusters contextualized representations using agglomerative hierarchical clustering (Gowda and Krishna, 1978). The resulting clusters represent *encoded concepts*, captured within the learned representations (Please see Figure 1 for illustration). We then use a novel align-

July 10-15, 2022

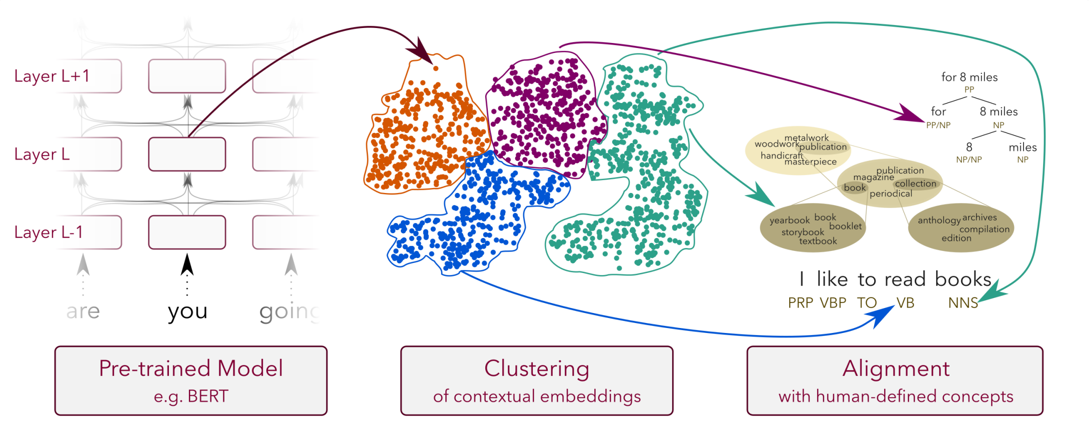

Figure 1: **ConceptX**: i) Extract representations from trained model, ii) Cluster the representations to obtain encoded concepts, iii) Align the concepts to human-defined concepts

ment function that measures the amount of overlap between *encoded concepts* and a range of pre-defined categories (that we call as *human-defined concepts* in this paper). We experimented with affixes, casing, morphological, syntactic, semantic, WordNet (Miller, 1995), and psycholinguistic concepts (LIWC Pennebaker et al. (2001)). The use of such a diverse set of human-defined concepts enables us to cover various abstractions of language. In Figure 3 we present a few examples of human-defined concepts that were aligned with the encoded concepts.

We carry out our study on seven pre-trained transformer models such as BERT (Devlin et al., 2019) and XLM-RoBERTa (Conneau et al., 2020), with varying optimization functions, architectural details and training data. Some notable findings emerging from our analysis are as follows:

- Shallow concepts such as lexical ngrams or suffixes are predominantly captured in the lower layers of the network.
- WordNet and psycholinguistic-based concepts (LIWC) are also learned in the lower layers.
- Middle and higher layers encode concepts that capture core linguistic properties such as morphology, semantics and syntax.
- Roughly 50% of the encoded concepts adhere to our suite of human-defined linguistic concepts.
- The models learn novel concepts that are multi-faceted and cannot be adequately explained using the existing human-defined concepts.

Our contributions in this paper are as follow: i) We present `ConceptX`, a framework that interprets encoded concepts in the learned representation by measuring their alignment to the human-defined concepts. ii) We provide a qualitative and quantitative evidence of how knowledge is structured within deep NLP models with respect to a large suite of human-defined concepts.

2 Related Work

Most of the work done on interpretability in deep NLP addresses two questions in particular: *(i)* what linguistic (and non-linguistic) knowledge is learned within contextualized representations, *Concept Analysis* and *(ii)* how this information is utilized in the decision making process, *Attribution Analysis* (Sajjad et al., 2021). The former thrives on post-hoc decomposability, where we analyze representations to uncover linguistic phenomenon that are captured as the network is trained towards any NLP task (Adi et al., 2016; Conneau et al., 2018; Liu et al., 2019a; Tenney et al., 2019; Belinkov et al., 2020) and the latter characterize the role of model components and input features towards a specific prediction (Linzen et al., 2016; Gulordava et al., 2018; Marvin and Linzen, 2018). Our work falls into the former category.

Previous studies have explored visualization methods to analyze the learned representations (Karpathy et al., 2015; Kádár et al., 2017), attention heads (Clark et al., 2019; Vig, 2019), language compositionality (Li et al., 2016) etc. A more commonly used framework analyzes representations by correlating parts of the neural network with linguistic properties, by training a classifier to predict a feature of interest (Adi et al., 2016; Belinkov et al., 2017a; Conneau et al., 2018). Several researchers used probing classifiers for investigating the contextualized representations learned from a variety of neural language models on a variety of character- (Durrani et al., 2019), word- (Liu et al., 2019a) or sub-sentence level (Tenney et al., 2019) linguistic tasks. Rather than analyzing the representations as a whole, several researchers also explored identifying salient neurons within the model that capture different properties (Dalvi et al., 2019a; Durrani et al., 2020; Suau et al., 2020; Mu and Andreas, 2020) or are salient for the model irrespective of the property (Bau et al., 2019; Wu et al., 2020).

Our work is inline with (Michael et al., 2020; Dalvi et al., 2022), who analyzed latent concepts learned in pre-trained models. Michael et al. (2020) used a binary classification task to induce latent concepts relevant to a task and showed the presence of linguistically motivated and novel concepts in the representation. However, different from them, we analyze representations in an unsupervised fashion. Dalvi et al. (2022) used human-in-the-loop to analyze latent spaces in BERT. Our framework uses human-defined concepts to automatically generate explanations for the latent concepts. This enabled us to scale our study to many transformer models.

In a similar work, Mamou et al. (2020) applied manifold analysis technique to understand the amount of information stored about object categories per unit. Our approach does away from the methodological limitations of probing framework such as complexity of the probes, effect of randomness etc (Belinkov, 2021). However, it is important to mention that the two frameworks are orthogonal and complement each other.

3 Methodology

A vector representation in the neural network model is composed of feature attributes of the input words. We group the encoded vector representations using a clustering approach discussed below. The underlying clusters, that we term as the *encoded concepts*, are then matched with the human-defined concepts using an alignment function. Formally, consider a Neural Network (NN) model $\mathbb{M}$ with L encoder layers $\{l_1, l_2, ...l_l, ..., l_L\}$, with H hidden nodes per layer. An input sentence consisting of M words $w_1, w_2, ...w_i, ..., w_M$ is fed into a NN. For each input word i, we compute the node output (after applying the activation functions) $y_h^l(w_i)$ of every hidden node $h \in \{1, ..., H\}$ in each layer l, where $\overrightarrow{y}^l(w_i)$ is the vector representation composing the outputs of all hidden nodes in layer l for w_i. Our goal is to cluster representations $\overrightarrow{y}^l$, from a large training data to obtain *encoded concepts*. We then align these with various human-defined concepts to obtain an explanation of them to build an understanding of how these concepts are represented across the network.

3.1 Clustering

We use agglomerative hierarchical clustering (Gowda and Krishna, 1978), which we found to be effective for this task. It assigns each word to a separate cluster and then iteratively combines them based on Ward's minimum variance criterion that minimizes intra-cluster variance. Distance between two representations is calculated with the squared Euclidean distance. The algorithm terminates when the required K clusters (aka encoded concepts) are formed, where K is a hyperparameter. Each encoded concept represents a latent relationship between the words present in the cluster. Appendix C presents the algorithm.

3.2 Alignment

Now we define the alignment function between the encoded and human-defined concepts. Consider a human-defined concept as z, where a function $z(w) = z$ denotes that z is the human-defined concept of word w. For example, parts-of-speech is a human-defined concept and each tag such as noun, verb etc. represents a class/label within the concept, e.g. $z(sea) = noun$. Similarly, suffix is a human-defined concept with various suffixes representing a class, e.g. $z(bigger) = er$. A reverse function of z is a one-to-many function that outputs a set of unique words with the given human-defined concept, i.e., $z^{-1}(z) = \{w_1, w_2, \ldots, w_J\}$, like $z^{-1}(noun) = \{sea, tree, \ldots\}$, where J is the total number of words with the human-defined concept of z. Following this notation, an encoded concept is indicated as c, where $c(w) = c$ is a function of applying encoded concept on w, and its reverse function outputs a set of unique words with the encoded concept of c, i.e., $c^{-1}(c) = \{w_1, w_2, \ldots, w_I\}$, where I is the set size.

To align the encoded concepts with the human-defined concepts, we auto-annotate the input data that we used to get the clusters, with the human-defined concepts. We call our encoded concept (c)

to be θ-aligned (Λ_θ) with a human-defined concept (z) as follows:

$$\Lambda_\theta(z,c) = \begin{cases} 1, & \text{if } \frac{\sum_{w' \in z^{-1}} \sum_{w \in c^{-1}} \delta(w,w')}{J} \geq \theta \\ 0, & \text{otherwise,} \end{cases}$$

where Kronecker function $\delta(w,w')$ is defined as

$$\delta(w,w') = \begin{cases} 1, & \text{if } w = w' \\ 0, & \text{otherwise} \end{cases}$$

We compute c and $\Lambda_\theta(z,c)$ for the encoder output from each layer l of a neural network. To compute a network-wise alignment, we simply average θ-agreement over layers.

4 Experimental Setup

4.1 Dataset

We used a subset of WMT News 2018[2] (359M tokens) dataset. We randomly selected 250k sentences from the dataset (≈5M tokens) to train our clustering model. We discarded words with a frequency of less than 10 and selected maximum 10 occurrences of a word type.[3] The final dataset consists of 25k word types with 10 contexts per word.

4.2 Pre-trained Models

We carried out our analysis on various 12-layered transformer models such as BERT-cased (BERT-c, Devlin et al., 2019), BERT-uncased (BERT-uc), RoBERTa (Liu et al., 2019b), XLNet (Yang et al., 2019) and ALBERT (Lan et al., 2019). We also analyzed multilingual models such as multilingual-bert-cased (mBERT) and XLM-RoBERTa (XLM-R, Conneau et al., 2020) where the embedding space is shared across many languages. This choice of models is motivated from interesting differences in their architectural designs, training data settings (cased vs. un-cased) and multilinguality.

4.3 Clustering and Alignment

We extract contextualized representation of words by performing a forward pass over the network using the NeuroX toolkit (Dalvi et al., 2019b). We cluster representations in every layer into K groups. To find an optimum value of K, we experimented with the ELbow (Thorndike, 1953) and Silhouette (Rousseeuw, 1987) methods. However, we did not observe reliable results (see Appendix C). Therefore, we empirically selected $K = 1000$ based on finding a decent balance between many small clusters (over-clustering) and a few large clusters (under-clustering). We found that our results are not sensitive to this parameter and generalize for different cluster settings (See Section 5.4). For the alignment between encoded and human-defined concepts, we use $\theta = 90\%$ i.e., we consider an encoded concept and a human-defined concept to be aligned, if they have at least 90% match.

4.4 Human-defined concepts

We experiment with the various **Human-defined concepts**, which we categorize into four groups:

- *Lexical Concepts:* Ngrams, Affixes, Casing, First and the Last Word (in a sentence)
- *Morphology and Semantics:* POS tags (Marcus et al., 1993) and SEM tags (Abzianidze et al., 2017)
- *Syntactic:* Chunking tags (Tjong Kim Sang and Buchholz, 2000) and CCG super-tags (Hockenmaier, 2006)
- *Linguistic Ontologies:* WordNet (Miller, 1995) and LIWC (Pennebaker et al., 2001)

At various places in this paper, we also refer to Morphology, Semantics and Syntactic concepts as core-linguistic concepts. We trained BERT-based classifiers using gold-annotated training data and standard splits for each core-linguistic concepts and auto-labelled the selected news dataset using these.[4]

5 Analysis

In this section, we analyze the encoded concepts by aligning them with the human-defined concepts.

5.1 Overall Alignment

First we present to what extent the encoded concepts in the entire network align with the human-defined concepts. We compute the overall score as the percentage of the aligned encoded concepts to the human-defined concepts across layers using the function described in Section 3.2. We

---

[2] `http://data.statmt.org/news-crawl/en/`

[3] Our motivation to select a small subset of data and limiting the number of tokens is as follows: clustering a large number of high-dimensional vectors is computationally and memory intensive, for example 200k vectors (of size 768 each) require around 400GB of CPU memory. Applying transformations (e.g., PCA) to reduce dimensionality may result in loss of information and therefore undesirable. We wanted to stay true to the original embeddding space.

[4] Please see Appendix B for details.

	BERT-c	BERT-uc	mBERT	XLM-R	RoBERTa	ALBERT	XLNet
Overall alignment	47.2%	50.4%	66.0%	72.4%	50.1%	51.6%	43.6%

Table 1: Coverage of human-defined concepts across all clusters of a given model

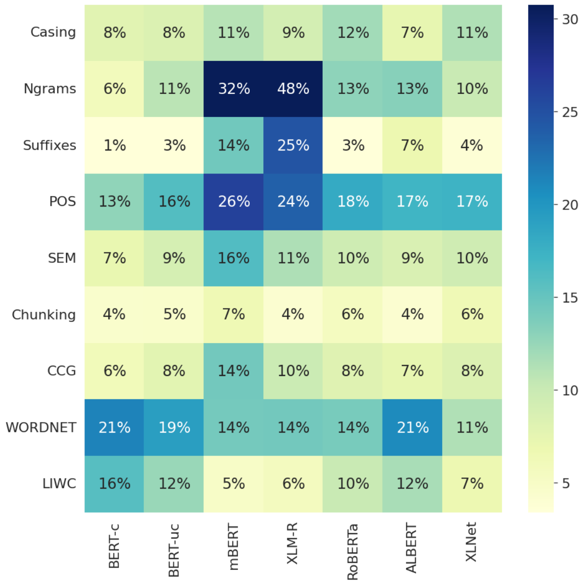

Figure 2: Average Alignment (%) between encoded concepts and human-defined concepts

found an overall match of at least 43.6% in XLNet and at most 72.4% in XLM-R (See Table 1). Interestingly, the multilingual models (mBERT and XLM-R) found substantially higher match than the monolingual models. The inclusion of multiple languages during training causes the model to learn more linguistic properties. Note that the extent of alignment with the human-defined concept may not necessarily correlate with its overall performance. For example XLNet performs outperforms BERT on the GLUE tasks, but aligns less with the human-defined concepts compared to BERT in our results. A similar observation was made by Belinkov et al. (2020) who also found that the translation quality of an NMT model may not correlate with the amount of linguistic knowledge learned in the representation. Various factors such as: architectural design, training data, objective function, initialization, etc, play a role in training a pre-trained model. More controlled experiments are needed to understand the relationship of each factor on the performance of the model and on the linguistic learning of the model.

We further investigated per concept[5] alignment to understand which human-defined concepts are better represented within the encoded concepts. Figure 2 presents the results.

Lexical Concepts Pre-trained models encode varying amount of lexical concepts such as casing, ngrams and suffixes. We found between 7-11% encoded concepts that align with the casing concept (title case or upper case). We observed that most of these encoded concepts consist of named entities, which were grouped together based on semantics.

Comparing suffixes and ngrams While affixes often have linguistic connotation (e.g., the prefix *anti* negates the meaning of the stem and the suffix *ies* is used for pluralization), the ngram units that become part of the vocabulary as an artifact of statistical segmentation (e.g., using BPE (Sennrich et al., 2016) or Word-piece (Schuster and Nakajima, 2012)) often lack any linguistic meaning. However, models learn to encode such information. We found a match ranging from 1% (BERT-cased) up to 25% (XLM-R) when comparing encoded concepts with the suffix concept. A similar pattern is observed in the case of the ngram concept (which is a superset of the suffix concept) where a staggering 48% matches were found. Figure 6a shows an ngram cluster found in layer 2 of BERT-c.[6]

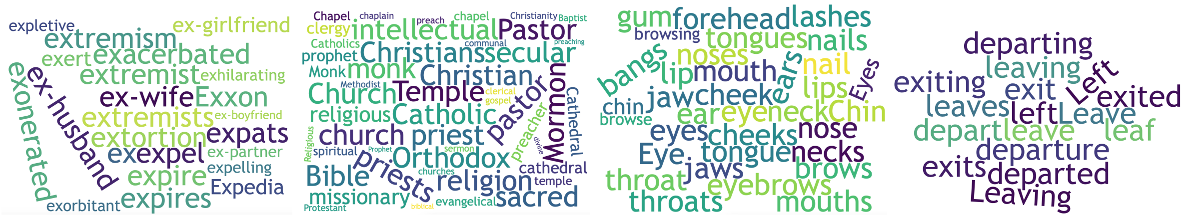
Morphology and Semantics We found that the encoded concepts based on word morphology (POS) consistently showed a higher match across all models in comparison to the other abstract concepts, aligning a quarter of the encoded concepts in the case of mBERT. The alignment with semantic concepts is relatively lower, with at most 16% match across models. This reflects that while the models learn both linguistic properties, morphological ontology is relatively preferred compared to the semantic hierarchy.

Syntactic These concepts capture grammatical orientation of a word, for example Chunking:B-NP is a syntactic concept describing words in the beginning of a noun phrase. CCG:PP/NP is a concept

---

[5] The first word, last word and prefix concepts showed less less than 1% alignment with the encoded concepts. We do not present their results in the interest of space.

[6] Appendix A shows more examples of the ngram, suffix, LIWC and WordNet clusters.



(a) Ngram:ex (b) LIWC:religion (c) LIWC: Bio (d) WordNet:Motion

Figure 3: Examples of BERT-c encoded concepts aligned with the human-defined concepts

in CCG super tagging, describing words that takes a noun phrase on the right and outputs a preposition phrase for example "[in[the US]]". We found relatively fewer matches, a maximum of 7% and 14% matching encoded concepts for Chunking and CCG concepts respectively. The low matches for syntactic concepts suggest that the models do not encode the same syntactic hierarchy suggested by these human-defined syntactic tasks.

Linguistic Ontologies Comparing the encoded concepts with static linguistic ontologies, we found WordNet concepts to be the second most aligned concept (11-21%) with the human-defined concepts. LIWC also shows a relatively higher alignment compared to the other human-defined concepts in a few models (e.g., BERT-c). However, this observation is not consistent across models and we found a range between 5-16% matches. These results present an interesting case where several models prefer the distinction of lexical ontology over abstract linguistic concepts such as morphology. Figure 3 shows examples of encoded concepts aligned with WordNet and LIWC. We see that these concepts are built based on a semantic relationship e.g., the clusters in Figure 3b, 3c and 3d group words based on religious, facial anatomy, and specific motion-related vocabulary respectively.

Comparing Models The results of multilingual models (mBERT, XLM-R) are intriguing given that their encoded concepts are dominated by ngram-based concepts and POS concepts, and their relatively lesser alignment with the linguistic ontologies. On the contrary, several monolingual models (BERT-c, ALBERT) showed a better match with linguistic ontologies specially WordNet.

The higher number of matches to the ngram (and suffix) concepts in the multilingual models is due to the difference in subword segmentation. The subword models in XLM-R and mBERT are optimized for multiple languages, resulting in a vocabulary consisting of a large number of small ngram units. This causes the multilingual models to aggressively segment the input sequence, compared to the monolingual models[7] and resulted in highly dominated ngram-based encoded concepts, especially in the lower layers. This may also explain the relatively lower match that multilingual models exhibit to the linguistic ontologies. We discuss this further in the context of layer-wise analysis in Section 5.2.

Comparing BERT cased vs. uncased, interestingly BERT-uc consistently showed higher matches for the core-linguistic concepts (See Figure 2). We speculate that in the absence of casing information, BERT-uc is forced to learn more linguistic concepts, whereas BERT-c leverages the explicit casing information to capture more semantically motivated concepts based on linguistic ontologies.

The higher matches in multilingual models in comparison to the monolingual models, and BERT-uncased in comparison to BERT-cased suggest that the training complexity is one factor that plays a role in a model's ability to learn linguistic nuances. For example, multilingual models need to optimize many languages, which is a harder task compared to learning one language. Similarly, the absence of capitalization in training data makes the learning task relatively harder for BERT-uc compared to BERT-c models, thus resulting in higher matches for BERT-uc. We speculate that the harder the training task, the more language nuances are learned by a model. Belinkov et al. (2020) made a similar observation, where they showed that the linguistic knowledge learned within the encoder-decoder representations in NMT models correlates with complexity of a language-pair involved in the task.

5.2 Layer-wise Alignment

Now we study the alignment of human-defined concepts across layers to understand how concepts

---

[7] In our dataset, mBERT has 13% more words after subword segmentation compared to BERT-c.

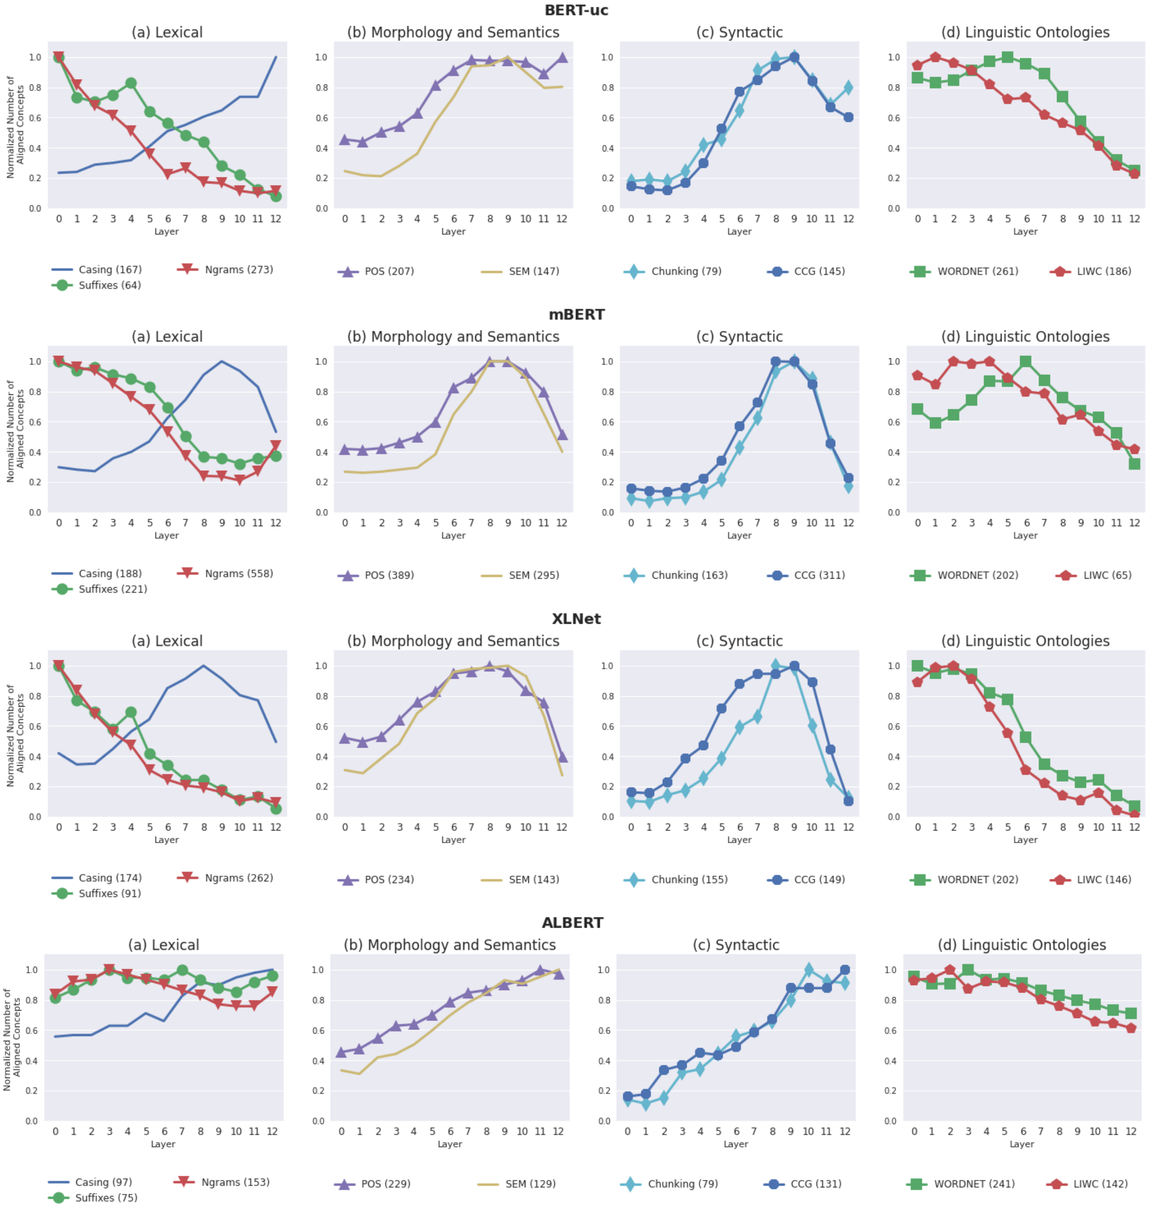


Figure 4: Layer-wise concept alignment. Y-axis is the normalized number of aligned concepts. The number within brackets of each human-defined concept, e.g. Casing (166), shows the maximum layer-wise match

evolve in the network. Figure 4 shows results for selected models.[8] The y-axis is the normalized number of aligned concepts across layers.

Overall Trend We observed mostly consistent patterns across models except for ALBERT, which we will discuss later in this section. We found that the shallow concepts (such as ngram and suffixes) and the linguistic ontologies (LIWC and WORDNET) are better represented in the initial layers and exhibit a downward trend in the higher layers of the network. On the contrary the core linguistic concepts (POS, Chunking, etc.) are better represented in the higher layers (layer 8-10). The last layers do not show any consistently dominating human-defined concepts considered in this work. We can generalize on these trends and hypothesize on how encoded concepts evolve in the network: the initial layers of the pretrained models, group words based on their lexical and semantic similarities where the former is an artifact of subword segmentation. With the inclusion of context and abstraction in the higher layers, these groups evolve into linguistic manifolds. The encoded concepts in the last layers are influenced by the objective function and learn concepts relevant to the task. Durrani et al. (2021) also made similar observation

---

[8] See Figure 10 in the Appendix for complete results.

when analyzing linguistic concepts in pre-trained models that are fine-tuned towards different GLUE tasks.

Concept-wise Trend In the following, we discuss different concepts in detail. As we mentioned earlier, the high presence of ngram and suffix concepts in the lower layers is due to subword segmentation. At the higher layers, the models start encoding abstract concepts, therefore get better alignment with the core linguistic concepts. Casing shows an exception to other lexical concepts and has similar trend to POS and SEM. Upon investigating we observed that the words appearing in these clusters have a hybrid connotation. For example, more than 98% of the encoded concepts that match with Casing are named entities, which explains the trend. The syntactic concepts observe peak in the higher-middle layers and a downward trend towards the end. These findings resonate with the earlier work on interpreting neural network representations for BERT. For example Liu et al. (2019a) also showed that probes trained with layers 7-8 give the highest accuracy when trained towards predicting the tasks of Chunking and CCG tagging. Although here, we are targeting a slightly different question i.e. how the latent concepts are encoded within the representations and how they evolve from input to output layers of the network.

We observed a downward trend in linguistic ontologies (WordNet, LIWC) as we go from lower layers to higher layers as opposed to the core linguistic concepts (POS, CCG, etc.). This is because of the context independent nature of these concepts as opposed to the core-linguistic concepts which are annotated based on the context. The embedding layer is non-contextualized, thus shows a high match with linguistic ontologies. With the availability of context in contextualized layers, the encoded concepts evolve into context-aware groups, resulting in higher matches with core-linguistic concepts.

Comparing Models While the overall trend is consistent among BERT-uc, mBERT and XLNet (and other studied models – Figure 10 in Appendix), the models somewhat differ in the last layers: see the large drop in core-linguistic concepts such as POS and Chunking for XLNet and mBERT in comparison to BERT. This suggests that BERT retains much of the core-linguistic information at the last layers. Durrani et al. (2020) observed a similar pattern in their study, where they showed BERT to retain linguistic information deeper in the model as opposed to XLNet where it was more localized and predominantly preserved earlier in the network.

While the overall layer-wise trends of multilingual models look similar to some monolingual models (mBERT vs. XLNet in Fig 4b,c), the former's absolute layer-wise matches (numbers inside the brackets in Figure 4 e.g. Casing (166)) are generally substantially higher than the monolingual counterparts. For example, the POS and SEM matches of mBERT are 38.9% and 30% respectively which are 18% and 15% higher than BERT-uc. On the contrary, the number of matches with linguistic ontologies is often lower for multilingual models (mBERT LIWC alignment of 65 vs. BERT-uc alignment of 186). We hypothesize that the variety of training languages in terms of their morphological and syntactic structure has caused the multilingual models to learn more core-linguistic concepts in order to optimize the training task. Although, the knowledge captured within linguistic ontologies is essential, it may not be as critical to the training of the model as the linguistic concepts.

ALBERT showed a very different trend from the other models. Note that ALBERT shares parameters across layers while the other models have separate parameters for every layer. This explains the ALBERT results where we see relatively less variation across layers. More interestingly, the encoded concepts in the last layers of ALBERT showed presence of all human-defined concepts considered here (see the relatively smaller drop of ALBERT alignment curves in Figure 4).

5.3 Unaligned Concepts

In Table 1 we observed that at least 27.6% (in XLM-R) and up to 56.4% (in XLNet) encoded concepts did not align with the human-defined concepts. *What concepts do these unaligned clusters contain?* In an effort to answer this question, we analyzed these clusters and observed that many of them were **compositional concepts** that involves more than one fine-grained categories of the human defined concepts. Figure 5a shows an example of the unaligned concept which partly aligns with a semantic category (SEM:geopolitical entity) and a morphological category (POS:adjective). Similarly, Figure 5b is a verbs related to cognitive processes and Figure 5c shows an unaligned cluster that is composed of different verb forms (past, present and gerunds). The alignment with multiple human-

(a) SEM:GPE+POS:JJ (b) POS:VB*+LIWC:cogmech (c) POS:VB*

Figure 5: Examples of unaligned encoded concepts: (a) combination of geopolitical entities and their related adjectives, (b,c) different forms of verb with specific semantics

defined concepts can be used to generate explanations for these unaligned concepts. For example, Figure 5a can be aligned as a mix of geopolitical entities and adjectives. We also quantitatively verified the number of unaligned encoded concepts that can be explained using composition of different concepts (See Appendix E: Table 9) and found that a majority of the clusters can be explained using a combination of three pre-defined concepts..

Moreover, note that encoded concepts are often multifacet i.e., they represent more than one relationship. For example, the encoded concept in Figure 5c consists of different forms of verbs but at the same time, these verbs are semantically similar. The semantic relationship present here is not adequately captured using the human-defined concepts used in this work. These are the *novel concepts* that require richer annotations or human-in-the-loop setup to generate adequate explanations.

5.4 Generalization of Results

Do the results generalize over different dataset selection and using different number of clusters? We ran experiments using different split of the news dataset for several models, and also performed alignment using different values of K, the number of clusters. The results are consistent across the board. Please see Appendix F for details.

6 Conclusion

We presented `ConceptX`, a novel framework for analyzing the encoded concepts within deep NLP models. Our method uses unsupervised clustering to discover latent concepts within the contextualized representations and then aligned these concepts with a suite of human-defined concepts to generate explanations for them. Our results illuminate how DNNs structure language information. A few notable findings are: i) lower layers capture shallow linguistic concepts, ii) whereas the abstract linguistic concepts such as morphology and semantics are preserved higher in the network, iii) the extent of alignment varies across different models and different human-defined concepts, iv) we found that novel explanations and an improved coverage of concepts can be achieved via compositionality.

Appendix

A Human-defined concept labels

A.1 Lexical Concepts:

Ngrams, Affixes, Casing, First and the Last Word.

A.2 Morphology and Semantics:

POS tags: We used the Penn Treebank POS tags discussed in (Marcus et al., 1993), which consists of 36 POS tags and 12 other tags (i.e., punctuation and currency symbols). In Table 2, we provide POS tags and their description.

SEM tags: (Abzianidze et al., 2017) consists of 73 sem-tags grouped into 13 meta-tags. In Table 3, we provide a detailed information of the tagset, and in Table 5, we provide fine and coarse tags mapping.

A.3 Syntactic:

Chunking tags: For Chunking we used the tagset discussed in (Tjong Kim Sang and Buchholz, 2000), which consists of 11 tags as follows: NP (Noun phrase), VP (Verb phrase), PP (Prepositional phrase), ADVP (Adverb phrase), SBAR (Subordinate phrase), ADJP (Adjective phrase), PRT (Particles), CONJP (Conjunction), INTJ (Interjection), LST (List marker), UCP (Unlike coordinate phrase). For the annotation, chunks are represented using IOB format, which results in 22 tags in the dataset as reported in Table 4.

CCG super-tags Hockenmaier (2006) developed, CCGbank, a dataset with Combinatory Categorial Grammar (CCG) derivations and dependency structures from the Penn Treebank. CCG is a lexicalized grammar formalism, which is expressive and efficiently parseable. It consists of 1272 tags.

A.4 Linguistic Ontologies:

WordNet: (Miller, 1995) consists of 26 lexicographic senses for nouns, 2 for adjectives, and 1 for adverbs. Each of them represent a supersense and a hierarchy can be formed from hypernym to hyponym.

LIWC: Over the past few decades, Pennebaker et al. (Pennebaker et al., 2001) have designed psycholinguistic concepts using high frequency words. These word categories are mostly used to study gender, age, personality, and health to estimate the correlation between these attributes and word usage. It is a knowledge-based system where words are mapped different high level concepts.

#	Tag	Description
1	CC	Coordinating conjunction
2	CD	Cardinal number
3	DT	Determiner
4	EX	Existential there
5	FW	Foreign word
6	IN	Preposition or subordinating conjunction
7	JJ	Adjective
8	JJR	Adjective, comparative
9	JJS	Adjective, superlative
10	LS	List item marker
11	MD	Modal
12	NN	Noun, singular or mass
13	NNS	Noun, plural
14	NNP	Proper noun, singular
15	NNPS	Proper noun, plural
16	PDT	Predeterminer
17	POS	Possessive ending
18	PRP	Personal pronoun
19	PRP$	Possessive pronoun
20	RB	Adverb
21	RBR	Adverb, comparative
22	RBS	Adverb, superlative
23	RP	Particle
24	SYM	Symbol
25	TO	to
26	UH	Interjection
27	VB	Verb, base form
28	VBD	Verb, past tense
29	VBG	Verb, gerund or present participle
30	VBN	Verb, past participle
31	VBP	Verb, non-3rd person singular present
32	VBZ	Verb, 3rd person singular present
33	WDT	Wh-determiner
34	WP	Wh-pronoun
35	WP$	Possessive wh-pronoun
36	WRB	Wh-adverb
37	#	Pound sign
38	$	Dollar sign
39	.	Sentence-final punctuation
40	,	Comma
41	:	Colon, semi-colon
42	(	Left bracket character
43	)	Right bracket character
44	"	Straight double quote
45	’	Left open single quote
46	"	Left open double quote
47	’	Right close single quote
48	"	Right close double quote

Table 2: Penn Treebank POS tags.

B BERT-based Sequence Tagger

We trained a BERT-based sequence tagger to auto-annotate our training data. We used standard splits for training, development and test data for the 4 linguistic tasks (POS, SEM, Chunking and CCG super tagging) that we used to carry out our analysis on. The splits to preprocess the data are avail-

ANA (anaphoric)		**MOD (modality)**	
PRO	anaphoric & deictic pronouns: he, she, I, him	NOT	negation: not, no, neither, without
DEF	definite: the, loIT, derDE	NEC	necessity: must, should, have to
HAS	possessive pronoun: my, her	POS	possibility: might, could, perhaps, alleged, can
REF	reflexive & reciprocal pron.: herself, each other	**DSC (discourse)**	
EMP	emphasizing pronouns: himself	SUB	subordinate relations: that, while, because
ACT (speech act)		COO	coordinate relations: so, {,}, {;}, and
GRE	greeting & parting: hi, bye	APP	appositional relations: {,}, which, {(}, —
ITJ	interjections, exclamations: alas, ah	BUT	contrast: but, yet
HES	hesitation: err	**NAM (named entity)**	
QUE	interrogative: who, which, ?	PER	person: Axl Rose, Sherlock Holmes
ATT (attribute)		GPE	geo-political entity: Paris, Japan
QUC	concrete quantity: two, six million, twice	GPO	geo-political origin: Parisian, French
QUV	vague quantity: millions, many, enough	GEO	geographical location: Alps, Nile
COL	colour: red, crimson, light blue, chestnut brown	ORG	organization: IKEA, EU
IST	intersective: open, vegetarian, quickly	ART	artifact: iOS 7
SST	subsective: skillful surgeon, tall kid	HAP	happening: Eurovision 2017
PRI	privative: former, fake	UOM	unit of measurement: meter, $, %, degree Celsius
DEG	degree: 2 meters tall, 20 years old	CTC	contact information: 112, info@mail.com
INT	intensifier: very, much, too, rather	URL	URL: `http://pmb.let.rug.nl`
REL	relation: in, on, 's, of, after	LIT	literal use of names: his name is John
SCO	score: 3-0, grade A	NTH	other names: table 1a, equation (1)
COM (comparative)		**EVE (events)**	
EQU	equative: as tall as John, whales are mammals	EXS	untensed simple: to walk, is eaten, destruction
MOR	comparative positive: better, more	ENS	present simple: we walk, he walks
LES	comparative negative: less, worse	EPS	past simple: ate, went
TOP	superlative positive: most, mostly	EXG	untensed progressive: is running
BOT	superlative negative: worst, least	EXT	untensed perfect: has eaten
ORD	ordinal: 1st, 3rd, third	**TNS (tense & aspect)**	
UNE (unnamed entity)		NOW	present tense: is skiing, do ski, has skied, now
CON	concept: dog, person	PST	past tense: was baked, had gone, did go
ROL	role: student, brother, prof., victim	FUT	future tense: will, shall
GRP	group: John {,} Mary and Sam gathered, a group of people	PRG	progressive: has been being treated, aan hetNL
DXS (deixis)		PFT	perfect: has been going/done
DXP	place deixis: here, this, above	**TIM (temporal entity)**	
DXT	temporal deixis: just, later, tomorrow	DAT	full date: 27.04.2017, 27/04/17
DXD	discourse deixis: latter, former, above	DOM	day of month: 27th December
LOG (logical)		YOC	year of century: 2017
ALT	alternative & repetitions: another, different, again	DOW	day of week: Thursday
XCL	exclusive: only, just	MOY	month of year: April
NIL	empty semantics: {.}, to, of	DEC	decade: 80s, 1990s
DIS	disjunction & exist. quantif.: a, some, any, or	CLO	clocktime: 8:45 pm, 10 o'clock, noon
IMP	implication: if, when, unless		
AND	conjunction & univ. quantif.: every, and, who, any		

Table 3: Semantic tags.

Task	Train	Dev	Test	Tags	F1
POS	36557	1802	1963	48	96.69
SEM	36928	5301	10600	73	96.22
Chunking	8881	1843	2011	22	96.91
CCG	39101	1908	2404	1272	94.90

Table 4: Data statistics (number of sentences) on training, development and test sets using in the experiments and the number of tags to be predicted

able through git repository[9] released with Liu et al. (2019a). See Table 4 for statistics and classifier accuracy.

C Clustering details

Algorithm 1 assigns each word to a separate cluster and then iteratively combines them based on Ward's minimum variance criterion that minimizes intra-cluster variance. Distance between two vector representations is calculated with the squared Euclidean distance.

Algorithm 1 Clustering Procedure

```
Input: $\overrightarrow{y}^l$: word representation of words
Parameter: $K$: the total number of clusters
for each word $w_i$ do
    assign $w_i$ to cluster $c_i$
end for
while number of clusters $\neq K$ do
    for each cluster pair $c_i$,$c_{i'}$ do
        $d_{i,i'}$ = inner-cluster difference of combined cluster $c_i$ and $c_{i'}$
    end for
    $c_j$,$c_{j'}$ = cluster pair with minimum value of $d$
    merge clusters $c_j$ and $c_{j'}$
end while
```

C.1 Selection of the number of Clusters

The Elbow curve did not show any optimum clustering point, with the increase in number of clusters the distortion score kept decreasing, resulting in over-clustering (a large number of clusters consisted of less than 5 words). The over-clustering resulted in high but wrong alignment scores e.g. consider a two word cluster having words "good" and "great". The cluster will have a successful match with "adjective" since more than 90% of the words in the cluster are adjectives. In this way, a lot of small clusters will have a successful match with many human-defined concepts and the resulting alignment scores will be high. On the other hand, Silhouette resulted in under-clustering, giving the best score at number of clusters = 10. We handled this empirically by trying several values for the number of clusters i.e., 200 to 1600 with step size 200. We selected 1000 to find a good balance with over and under clustering. We understand that this may not be the best optimal point. We presented the results of 600 and 1000 clusters to show that our findings are not sensitive to the number of clusters parameter.

D Coarse vs. Fine-grained Categories

D.1 Coarse vs. Fine-grained Categories

Our analysis of compositional concepts showed that several fine-grained concepts could be combined to explain an unaligned concept. For example, by combining verb categories of POS to one coarse verb category, we can align the encoded concept present in Figure 5c. To probe this more formally, we collapsed POS and SEM fine-grained concepts into coarser categories (27 POS tags and 15 SEM tags). We then recomputed the alignment with the encoded concepts. For most of the models, the alignment doubled compared to the fine-grained categorizes with at least 39% and at most 53% percent match for POS. This reflects that in several cases, models learn the coarse language hierarchy. We further questioned *how many encoded concepts can be explained using coarse human-defined concepts.* Compared to Table 1, the matches increased by at most 17 points in the case of BERT-uc. The XLM-R showed the highest matching percentage of 81%. The higher alignment suggests that most of the encoded concepts learned by pre-trained models can be explained using human-defined concepts. (See Appendix D for detailed results).

D.2 Corase POS and SEM labels

Tables 5 and 6 present results for our mapping of fine-grained SEM and POS tags into coarser categories.

Coarse	Fine-grained
ACT	QUE
ANA	DEF, DST, EMP, HAS, PRO, REF
ATT	INT, IST, QUA, REL, SCO
COM	COM, LES, MOR, TOP
DSC	APP, BUT, COO, SUB
DXS	PRX
EVE	EXG, EXS, EXT, EXV
LOG	ALT, AND, DIS, EXC, EXN, IMP, NIL, RLI
MOD	NEC, NOT, POS
NAM	ART, GPE, HAP, LOC, NAT, ORG, PER, UOM
TIM	DEC, DOM, DOW, MOY, TIM, YOC
TNS	EFS, ENG, ENS, ENT, EPG, EPS, EPT, ETG, ETV, FUT, NOW, PST
UNE	CON, ROL
UNK	UNK

Table 5: SEM: Coarse to Fine-grained mapping

D.3 Results

Table 7 presents the alignment results of using coarse POS and SEM concepts. We observed that

Coarse	Fine-grained
Adjective	JJ, JJR, JJS
Adverb	RB, RBS, WRB, RBR
Conjunction	CC
Determiner	DT, WDT
Noun	NN, NNS, NNP, NNPS
Number	CD
Preposition	IN, TO
Pronoun	PRP, PRP$, WP, WP$
Verb	VB, VBN, VBZ, VBG, VBP, VBD
No Changes	$, -LRB-, #, FW, -RRB-, LS, POS, "", EX SYM, ,, :, RP, ., PDT, MD, UH,

Table 6: POS: Coarse to Fine-grained mapping

the alignment doubles in most of the cases which reflects that in several cases, models learn the coarse language hierarchy. However, they do not strictly adhere to fine-grained categories existed in human-defined concepts. We further extend the alignment of coarse POS and SEM categories to the overall alignment with the human-defined concepts. Table 8 presents the results. We see a match of up to 81% in the case of XLM-R. The high alignment suggests that many of the encoded concepts can be explained using coarse human-defined concepts.

	POS		SEM	
	Fine	Coarse	Fine	Coarse
BERT-cased	13%	42%	7%	15%
BERT-uncased	16%	43%	9%	18%
mBERT	26%	53%	16%	26%
XLM-RoBERTa	24%	47%	11%	21%
RoBERTa	18%	43%	10%	20%
ALBERT	17%	42%	9%	17%
XLNet	17%	39%	10%	18%

F Robustness of Methodology across Datasets and Settings

Figure 8 shows the layer-wise patterns using 600 clusters instead of 1000 as used in the main paper. We observe that the overall trends largely remain the same.

To further demonstrate the robustness of our method with respect to dataset, we sub-sampled another dataset from the News corpus with a different vocabulary by selecting words that appear between 2 to 10 times in the corpus. Note that the selection of vocabulary is due to the memory and computation limitations. Figure 9 shows the results using this selection of data. Compared to Figure 4, we can see that the overall patterns are largely similar and confirms the robustness of our findings. The slight difference in the patterns of WordNet and LIWC are due to the large selection of proper nouns in the second set of the data.

G Layer-wise results

Abstract

We propose DrBoost, a dense retrieval ensemble inspired by boosting. DrBoost is trained in stages: each component model is learned sequentially and *specialized* by focusing only on retrieval mistakes made by the current ensemble. The final representation is the concatenation of the output vectors of all the component models, making it a drop-in replacement for standard dense retrievers at test time. DrBoost enjoys several advantages compared to standard dense retrieval models. It produces representations which are 4x more compact, while delivering comparable retrieval results. It also performs surprisingly well under approximate search with coarse quantization, reducing latency and bandwidth needs by another 4x. In practice, this can make the difference between serving indices from disk versus from memory, paving the way for much cheaper deployments.[1]

1 Introduction

Identifying a small number of relevant documents from a large corpus to a given query, information retrieval is not only an important task in-and-of itself, but also plays a vital role in supporting a variety of knowledge-intensive NLP tasks (Lewis et al., 2020; Petroni et al., 2021), such as open-domain Question Answering (ODQA, Voorhees and Tice, 2000; Chen et al., 2017) and Fact Checking (Thorne et al., 2018). While traditional retrieval methods, such as TF-IDF and BM25 (Robertson, 2008), are built on *sparse* representations of queries and documents, *dense* retrieval approaches have shown superior performance recently on a range of retrieval and ranking tasks (Guu et al., 2020; Karpukhin et al., 2020; Reimers and Gurevych, 2019; Hofstätter et al., 2021b). Dense retrieval involves embedding queries and documents as low-dimensional, continuous vectors, such that query and document embeddings are similar when the document is relevant to the query. The embedding function leverages the representational power of pretrained language models and is further finetuned using any available training query-document pairs. Document representations are computed offline in an *index* allowing dense retrieval to scale to millions of documents, with query embeddings being computed on the fly.

When deploying dense retrievers in real-world settings, however, there are two practical concerns: the *size* of the index and the retrieval time *latency*. The index size is largely determined by the number of documents in the collection, as well as the embedding dimension. Whilst we cannot generally control the former, reducing the embedding size is an attractive way to reduce index size. On lowering latency, Approximate Nearest-Neighbor (ANN) or Maximum Inner Product Search (MIPS) techniques are required in practice. This implies that it is far more important for retrieval models to perform well under approximate search rather than in the exact search setting. Developing a dense retrieval model that produces more compact embeddings and are more amenable to approximate search is thus the focus of this research.

In this paper, we propose DrBoost, an ensemble method for learning a dense retriever, inspired by *boosting* (Schapire, 1990; Freund and Schapire, 1997). DrBoost attempts to incrementally build compact representations *at training time*. It consists of multiple component dense retrieval models ("weak learners" in boosting terminology), where each component is a BERT-based bi-encoder, producing vector embeddings of the query and document. These component embeddings are in lower dimensions (e.g., 32 vs. 768) compared to those of regular BERT encoders. The final relevance function is implemented as a linear combination

July 10-15, 2022

of inner products of embeddings produced by each weak learner. This can be efficiently calculated by concatenating vectors from each component and then performing a single MIPS search, which makes DrBoost a drop-in replacement for standard dense retrievers at test time. Component models are trained and added to the ensemble *sequentially*. Each model is trained as a *reranker* over negative examples sampled by the current ensemble and can be seen as specializing on retrieval mistakes made previously. For example, early components focus on high-level topical information, whereas later components can capture finer-grained tail phenomena. Through this mechanism, individual components are disentangled and redundancy minimized, leading to more compact representations.

There are a couple of noticeable differences in training DrBoost when compared to existing dense retrieval models. Although iterative training using negatives sampled by models learned in the previous rounds has been proposed (Xiong et al., 2020; Qu et al., 2021; Oğuz et al., 2021; Sachan et al., 2021, *inter alia.*), existing methods keep only the final model. In contrast, each weak learner in DrBoost is preserved and added to the ensemble. The construction of the embedding also differs. DrBoost can be viewed as a method of slowly "growing" overall dense vector representations, lending some structure to otherwise de-localized representations, while existing retrieval models encode queries and documents in one step.

More importantly, DrBoost enjoys several advantages in real-world settings. Because each weak learner in DrBoost produces very low-dimensional embeddings to avoid overfitting (32-dim in our experiments), many components can be added whilst the index stays small. Our experiments demonstrate that DrBoost produces very compact embeddings overall, achieving accuracy on par with a comparable non-boosting baseline with 4–5x smaller vectors, and strongly outperforming a dimensionally-matched variant. Probing DrBoost's embeddings using a novel technique, we also show that the embeddings can be used to recover more topical information from Wikipedia than a dimensionally-matched baseline.

Empirically, DrBoost performs superbly when using approximate fast MIPS. With a K-mean inverted file index (IVF), the simple and widely used approach, especially in hierarchical indices and Web-scale settings (Jégou et al., 2011; Johnson et al., 2019; Matsui et al., 2018), DrBoost greatly outperforms the baseline DPR model (Karpukhin et al., 2020) by 3–10 points. Alternatively, it can reduce bandwidth and latency requirements by 4–64x while retaining accuracy. In principle, this allows for the approximate index to be served *on-disk* rather than in expensive and limited RAM (which is typically 25x faster), making it feasible to deploy dense retrieval systems more cheaply and at much larger scale. We also show that DrBoost's index is amenable to compression, and can be compressed to 800MB, 2.5x smaller than a recent state-of-the-art efficient retriever, whilst being more accurate (Yamada et al., 2021).

2 Dense Retrieval

We give here the background of dense retrieval and boosting, as well as our proposed method. More extensive related work can be found in §5.5.

Dense Retrieval involves learning a scalable relevance function $h(q, c)$ which takes high values for passages c that are relevant for question q, and low otherwise. In the popular dense bi-encoder framework, $h(q, c)$ is implemented as the dot product between $\mathbf{q}$ and $\mathbf{c}$, dense vector representations of passages and questions respectively, produced by a pair of neural network encoders, E_Q and E_C,

$$h(q, c) = E_Q(q)^\top E_C(c) = \mathbf{q}^\top \mathbf{c} \qquad (1)$$

where $\mathbf{q} = E_Q(q)$ and $\mathbf{c} = E_C(c)$. At inference time, retrieval from a large corpus $\mathcal{C} = \{c_1, \ldots, c_{|\mathcal{C}|}\}$ is accomplished by solving the following MIPS problem: $c^* = \arg\max_{c \in \mathcal{C}} \mathbf{q}^\top \mathbf{c}$.

In standard settings, we assume access to a set of m gold question-passage pairs $\mathcal{D} = \{(q_i, c_i^+)\}_{i=1}^m$. It is most common to learn models by training to score gold pairs higher than sampled *negatives*. Negatives can be obtained in a variety of ways, such as by sampling at random from corpus $\mathcal{C}$, or by using some kind of importance sampling function on retrieval results (see §2.1). When augmented by n negatives per gold passage-document pair, we have training data of the form $\widetilde{\mathcal{D}} = \{(q_i, c_i^+, c_{i,1}^-, \ldots c_{i,n}^-)\}_{i=1}^m$, which we use to train a model, e.g., using a ranking or margin objective, or in our case, by optimizing negative log-likelihood (NLL) of positive pairs

$$\mathcal{L}_\theta = -\log \frac{e^{h(q_i, c_i^+)}}{e^{h(q_i, c_i^+)} + \sum_{j=1}^{n} e^{h(q_i, c_{i,j}^-)}}$$

2.1 Iterated Negatives for Dense Retrieval

The choice of negatives is an important factor for what behaviour dense retrievers will learn. Simply using randomly-sampled negatives has been shown to perform poorly, because they are too easy for the model to discriminate. Thus it is common to mix in some *hard negatives* along with random negatives, which are designed to be more challenging to distinguish from gold passages (Karpukhin et al., 2020). Hard negatives are typically collected by retrieving passages using an untrained retriever, such as BM25, and filtering out any unintentional golds. This ensures the hard negatives are at least topically-relevant.

Recently, it has become common practice to run a number of rounds of dense retrieval training to bootstrap hard negatives (Xiong et al., 2020; Qu et al., 2021; Oğuz et al., 2021; Sachan et al., 2021, inter alia.). Here, we first train a dense retriever following the method we describe above, and then use this retriever to produce a new set of hard negatives. This retriever is discarded, and a new one is trained from scratch, using the new, "harder" negatives. This process can then be repeated until performance ceases to improve. This approach, which we refer to *dense retrieval with iteratively-sampled negatives* is described in Algorithm 1.

2.2 Boosting

Boosting is a loose family of training algorithms for machine learning problems, based on the principle of gradually ensembling "weak learners" into a strong learner. Boosting can be described by the following high-level formalism (Schapire, 2007). For a task with a training set $\{(x_1, y_1), \cdots, (x_m, y_m)\}$, where $(x_i, y_i) \in X \times Y$ we want to learn a function $h : X \rightarrow Y$, such that $h(x_i) = \hat{y}_i \approx y_i$. This is achieved using an iterative procedure over R steps:

- For round r, we construct an importance distribution D_r over the training data, based on where error ϵ of our current model h is high
- Learn a "weak learner" h_r to minimize error $\epsilon_r = \sum_i D_r(i)\mathcal{L}(h_r(x_i), y_i)$ for some loss function $\mathcal{L}$ measuring the discrepancy between predictions and real values.
- Combine h and h_r to form a new, stronger overall model, e.g., by a linear combination $h_{\text{new}} = \alpha h_r + \beta h$. The iteration can now be repeated.

The initial importance distribution D_0 is usually assumed to be a uniform distribution, and h_0 models a constant function. Note that how each additional model added to h is specifically designed to solve instances that h currently struggles with.

2.3 Boosted Dense Retrieval: DrBoost

We note similarities between the boosting formulation, and the dense retrieval with iteratively-sampled negatives. We can adapt a boosting-inspired approach to dense retrieval with minimal changes, as shown in Algorithm 1. Algorithmically, the only difference (lines 10–13) is that in the case of iterative negatives, the model h after r rounds is *replaced* by the new model h_r, whereas in the boosting case, we *combine* h_r and h.

In this paper, we view the boosted "weak learner" models h_r as *rerankers* over the retrieval distribution from the current model h. That is, when training dense boosted retrievers, we *only* train using hard negatives, and do not use any random or in-batch negatives. Using the construction of negatives as a mechanism to define the importance distribution, each new model is directly trained to solve the retrieval mistakes that the current ensemble makes. Each model h_r is implemented as a bi-encoder, as in Eq. (1). We combine models as linear combinations:

$$\textbf{CombineModels}(h, h_r) = h_{\text{new}} = \alpha h_r + \beta h$$

The coefficients could be learnt from development data, or, simply by setting all coefficients to 1, which we find to be empirically effective. The overall model after R rounds can be written as:

$$\begin{aligned} h(q,c) &= \alpha h_R(q,c) + \beta\left(h_{R-1}(q,c) + \gamma(\cdots)\right) \\ &= \sum_{r=1}^{R} \alpha'_r h_r(q,c) = \sum_{r=1}^{R} \alpha'_r \mathbf{q}_r^\top \mathbf{c}_r \\ &= [\mathbf{q}_R, \ldots, \mathbf{q}_1, \mathbf{q}_0]^\top [\alpha'_R \mathbf{c}_R, \ldots, \alpha'_1 \mathbf{c}_1, \alpha'_0 \mathbf{c}_0] \\ &= \bar{\mathbf{q}}^\top \bar{\mathbf{c}} \end{aligned}$$

where $[\ldots]$ indicates vector concatenation. Thus h can be computed as a single inner product, making it a drop-in replacement for standard MIPS dense retrievers at test time.

One downside of the boosting approach is that we must maintain R encoders for both passages and questions. Since passages are embedded offline, this does not create additional computational burden on the passage side at test time. However, on the query side, for a question q, boosted dense retrieval requires R forward passes to compute the full representation, one for each subvector $\mathbf{q}_r$. While this step is fully parallelizable, it is still undesirable. We can remedy this for low-latency, low-resource settings by distilling the question encoders of h into a single encoder, which can produce the overall question representations $\bar{\mathbf{q}}$ directly. Here, given the training dataset $\mathcal{D}_{\text{train}}$ of gold question-passage pairs, and a model h we want to distill, we first compute overall representations $\bar{\mathbf{q}}$ and $\bar{\mathbf{c}}$ for all pairs using h as distillation targets, then train a new question encoder E_Q^{dist} with parameters ϕ, by minimizing the objective:

$$\mathcal{L}_\phi = \sum_{(q,c^+)\in\mathcal{D}_{\text{train}}} \|E_Q^{\text{dist}}(q) - \bar{\mathbf{q}}\|^2 + \|E_Q^{\text{dist}}(q) - \bar{\mathbf{c}}\|^2$$

3 Experiments

3.1 Datasets

Natural Questions (NQ) We evaluate retrieval for downstream ODQA using the widely-used NQ-open retrieval task (Kwiatkowski et al., 2019). This requires retrieving Wikipedia passages which contain answers to questions mined from Google search logs. We use the preprocessed and gold pairs prepared by Karpukhin et al. (2020), and report recall-at-K (R@K) for K $\in \{20, 100\}$.

MSMARCO We evaluate in a Web-text setting using the widely-used passage retrieval task from MSMARCO (Bajaj et al., 2016). Queries consist of user search queries from Bing, with human-annotated gold relevant documents. We use the preprocessed corpus, training and dev data (gold pairs and data splits) from Oğuz et al. (2021). We follow the common practice of reporting the Mean-Reciprocal-Rank-at-10 (MRR@10) metric for the public development set.

3.2 Tasks

In this section, we will describe the experiments we perform, and the motivations behind them.

Exact Retrieval We are interested in understanding whether the boosting approach results in superior performance for exhaustive (exact) retrieval. Here, no quantization or approximations are made to MIPS, which results in large indices, and slow retrieval, but represents the upper bound of accuracy. This setting is the most commonly-reported in the literature.

Approximate MIPS: IVF Exact Retrieval does not evaluate how a model performs in practically-relevant settings. As a result, we also evaluate in two approximate MIPS settings. First, we consider approximate MIPS with an Inverted File Index (IVF, Sivic and Zisserman, 2003). IVF works by first clustering the document embeddings offline using K-means (Lloyd, 1982) resulting K cluster centroids. At test time, for a given query vector, rather than compute an inner product for each document in the index, we instead compute inner products to the K centroids. We then visit the `n_probes` highest scoring clusters, and compute inner products for only the documents in these clusters. This technique increases the *speed of search* significantly, at the expense of some accuracy. Increasing K, the number of centroids, increases speed, at the expense of accuracy, as does decreasing the value of `n_probes`. A model is preferable if retrieval accuracy remains high with very fast search, i.e., low `n_probes` and high K [2]. In our experiments we fit $K = 65536$ clusters and sweep over a range of values of `n_probes` from 2^0 to 2^{15}. Other methods such as HNSW (Malkov and Yashunin, 2020) are also available for fast search, but are generally more complex and can increase index sizes significantly. IVF is a particularly popular approach due it its simplicity, and as a first *coarse* quantizer in hierarchical indexing (Johnson et al., 2019), since it is straightforward to apply

---

[2] Up to the point in K where the first stage search becomes the bottleneck. This happens when K is in the order of $\sqrt{|\mathcal{C}|}$, which is how we pick $K = 65536$. We also include results with $K \in \{4092, 16384\}$ in the Appendix.

sharding to the clusters, and further search indices can be built for each cluster.

Approximate MIPS: PQ Whilst IVF will increase search speeds, it does not reduce the size of the index, which may be important for scalability, latency and memory bandwidth considerations. To investigate whether embeddings are amenable to compression, we experiment with applying Product Quantization (PQ, Jégou et al., 2011). PQ is a lossy quantization method that works by 1) splitting vectors into subvectors 2) clustering each subvector space and 3) representing vectors as a collection cluster assignment codes. We apply PQ using 4-dimensional sub-vectors and 256 clusters per subspace, leading to a compression factor of 16x over uncompressed `float32`.

All MIPS retrieval is implemented using FAISS (Johnson et al., 2019).

Generalization Tests In addition to in-domain evaluation, we also perform two generalization tests. These will determine whether the boosting approach is superior to iteratively-sampling negatives in out-of-distribution settings. We evaluate MSMARCO-trained models for zero-shot generalization using selected BEIR (Thakur et al., 2021) datasets that have binary relevance labels. Namely, we test on the SciFact, FiQA, Quora and ArguAna subsets. This will test how well models generalize to new textual domains and different query surface forms. We also evaluate NQ-trained models on EntityQuestions (Sciavolino et al., 2021), a dataset of simple entity-centric questions which has been recently shown to challenge dense retrievers. This dataset uses the same Wikipedia index as NQ, and tests primarily for robustness and generalization to new entities at test time.

3.3 Models

We compare a model trained with iteratively-sampled negatives to an analogous model trained with boosting, which we call DrBoost. There are many dense retrieval training algorithms available which would be suitable for training with iteratively-sampled negatives and boosting with DrBoost. Broadly-speaking, any dense retriever could be used if utilizes negative sampling, and could be trained in Step 9 of Algorithm 1. We choose Dense Passage Retriever (DPR, Karpukhin et al., 2020) with iteratively-sampled negatives due to its comparative simplicity and popularity.

3.3.1 Iteratively-sampled negatives baseline: DPR

DPR follows the dense retrieval paradigm outlined in §2 It is trained with a combination of *in-batch* negatives, where gold passages for one question are treated as negatives for other questions in the batch (which efficiently simulates random negatives), and with hard negatives, sampled initially from BM25, and then from the previous round, as in Algorithm 1. We broadly follow the DPR training set-up of Oğuz et al. (2021). We train BERT-base DPR models using the standard 768 dimensions, as well as models which match the final dimension size of DrBoost. We use parameter-sharing for the bi-encoders, and layer-norm after linear projection. Models are trained to minimize the negative log-likelihood of positives, and the number of training rounds is decided using development data, as in Algorithm 1, using an initial h_0 retriever BM25.

3.3.2 DrBoost Implementation

For our DrBoost version of DPR, we keep as many experimental settings the same as possible. There are two exceptions, which are required for adapting dense retrieval to boosting. The first is that each component "weak learner" model has a low embedding dimension. This is to avoid overfitting, and to make sure the final index size is manageable. We report using models of 32 dims (cf. the standard 768 dims), but note that training with dimension as low as 8 is stable. The second is that, as motivated in §2.3, we train each weak learner using *only* hard negatives, and no in-batch negatives. In effect, this choice of negatives means that each model is essentially trained as a reranker.[3] DrBoost models are fit following Algorithm 1, and we stop adding models when the development set performance stops improving. The initial retriever h_0 for DrBoost is a constant function, and thus the initial negatives for DrBoost are sampled at random from the corpus, unlike DPR, which uses initial hard negatives collected from BM25.

DrBoost α Coefficients DrBoost combines weak learners as a linear combination. We experiment with learning the α coefficients using development data, however this does not significantly improve results over simply setting them all to 1. There-

---

[3] Note: We *sample* negatives from the model's retrieval distribution rather than taking the top-K retrieved negatives. We find this improves results for early rounds

fore, for the sake of simplicity and efficiency, we report DrBoost numbers with all $\alpha = 1.0$. Empirically, we find the magnitudes of embeddings for DrBoost's component models to be similar. In other words, one component does not dominate over others.

DrBoost Distillation We experiment with distilling DrBoost ensembles into a single model for latency-sensitive applications using the L2 loss at the end of §2.3. We distill a single BERT-base query encoder, and perform early stopping and model selection using development L2 loss.

4 Results

4.1 Exact Retrieval

Exact Retrieval results for MSMARCO and Natural Questions are shown in Table 1 in the "Exact Search" Column. We find that our DrBoost version of DPR reaches peak accuracy after 5 or 6 rounds when using 32-dim weak learners (see §A.1), leading to overall test-time index of 160/192-dim. In terms of Exact Search, DrBoost outperforms the iteratively-sampled negatives DPR baseline on MSMARCO by 2.2%, and trails it by only 0.3% on NQ R@100, despite having a total dimension 4–5x smaller. It also strongly outperforms a dimensionally-matched DPR, by 3% on MSMARCO, and 1% on NQ in R@100, demonstrating DrBoost's ability to learn high-quality, compact embeddings. We also quote recent state-of-the-art results, which generally achieve stronger exact search results (AR2, Zhang et al., 2021). Our emphasis, however, is on comparing iteratively-sampled negatives to boosting, and we note that state-of-the-art approaches generally use larger models and more complex training strategies than the "inner loop" BERT-base DPR we report here. Such strategies could also be incorporated into DrBoost if higher accuracy was desired, as DrBoost is largely-agnostic to the training algorithm used.

4.2 Approximate MIPS

Table 1 also shows how DPR and DrBoost behave under IVF MIPS search, which is shown graphically in Figure 1 as well. We find that DrBoost dramatically outperforms DPR in IVF search, indicating that much faster search is possible with DrBoost. High-dimensional embeddings suffer under IVF due to the the curse of dimensionality, and thus compact embeddings are important. Using 8 search probes, DrBoost outperforms DPR by 10.5% on MSMARCO and 6.3% on NQ in R@100. The dimensionally-matched DPR is stronger, but still trails DrBoost by about 4% using 8 probes. The strongest exact search model is thus not necessarily the best in practical approximate MIPS settings. For example, if we can tolerate a 10% relative drop in accuracy from the best performing system's exact search, DrBoost requires 16 (4) probes for MSMARCO (NQ) to reach the required accuracy, whereas DPR will require 1024 (16), meaning DrBoost can be operated approximately 64x (4x) faster.

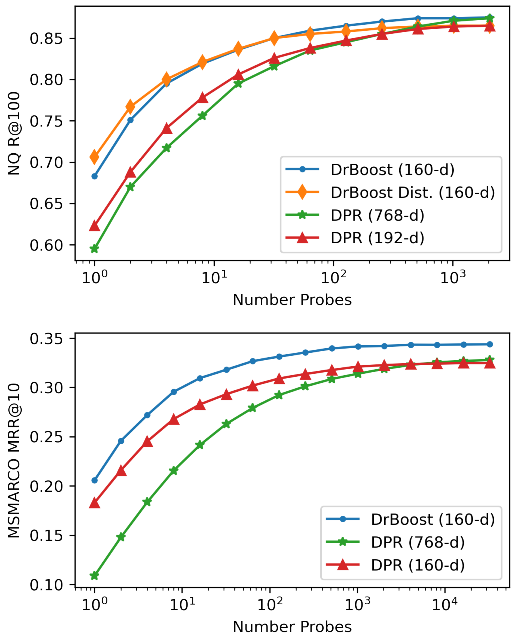

Figure 1: Search accuracy vs the number of clusters visited in IVF search (proportional to latency). Accuracy drops as search speed increases, but the accuracy drop-off for DrBoost is much slower than for DPR.

The distilled DrBoost is also shown for NQ in Table 1. The precision (low R@K values) is essentially unaffected, (exact search drops by 0.1% for R@20), but recall drops slightly (-0.7% R@100). Interestingly, the distilled DrBoost performs even better under IVF search, improving over DrBoost by $\sim$1% at low numbers of probes. Crucially, whilst the distilled DrBoost is only slightly better than the 192-dim DPR under exact search, it is 4–5% stronger under IVF with 8 probes (alternatively, 8x faster for equivalent accuracy).

Aside from fast retrieval, small indices are also important for edge devices, or for scalability reasons. While DrBoost can already produce high quality compact embeddings, Product Quantization

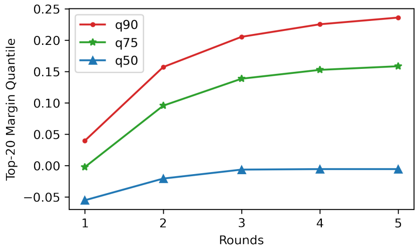

Figure 2: Quantiles of the top-20 margin on the NQ training set, for each iteration of DrBoost.

can reduce this even further. Table 2 shows that DrBoost’s NQ index can be compressed from 13.5 GB to 840MB with less than 1% drop in performance. We compare to BPR (Yamada et al., 2021), a method specifically designed to learn small indices through binarization. DrBoost’s PQ index is 2.4x smaller than the BPR index reported by Yamada et al. (2021), whilst being 2.4% more accurate (R@20). A more aggressive quantization leads to a 420MB index — 4.8x smaller than BPR — whilst only being 1.2% less accurate.

5 Analysis

5.1 Qualitative Analysis

Since each round’s model is learned on the errors of the previous round, we expect each learner to “specialize” and learn complementary representations. To see if this is qualitatively true, we look at the retrieved passages from each round’s retriever in isolation (Table 10 in §A.3). Indeed, we find that each 32-dim sub-vector tackles the query from different angles. For instance, for the query *“who got the first nobel prize in physics?”*, the first sub-vector captures general topical similarity based on keywords, retrieving passages related to the *“Nobel Prize”*. The second focuses mostly on the first paragraphs of articles of prominent historical personalities, presumably because these are highly likely to contain answers in general; and the third one retrieves from the pages of famous scientists and inventors. The combined DrBoost model would favor passages in the intersection of these sets.

5.2 In-distribution generalization

Boosting algorithms are remarkably resistant to over-fitting, even when the classifier has sufficient capacity to achieve zero training error. In their landmark paper, Bartlett et al. (1998) show that this generalization property is a result of the following: the training *margins* increase with each iteration of boosting. We empirically show the same to be true for DrBoost. For a fixed query embedding, dense retrieval acts as a linear binary classifier, where the gold passage is positive and all other passages are negatives (Eq. (1)). We adopt the classical definition of margin for linear classifiers to dense retrieval by defining a top-k margin:

$$\text{Top-k margin}_i = \frac{h(q_i, c^+) - \max_{c^-}^{\{k\}} h(q_i, c^-)}{||q_i||\mu_c} \tag{2}$$

Method	SciFact *NDCG@10*	FiQA *NDCG@10*	Quora *NDCG@10*	ArguAna *NDCG@10*
SotA Dense	64.3	30.8	85.2	42.9
DPR (160 dim)	50.9	22.8	84.3	42.5
DrBoost (160 dim)	49.7	22.4	78.8	39.9

Table 3: BEIR results. The SotA row is copied from Thakur et al. (2021), and the numbers represent the best model for each dataset.

Method	**EntityQuestions** *R@20*	 *R@100*
BM25 (Chen et al., 2021)	71.2	79.7
DPR (Chen et al., 2021)	49.7	63.4
DPR (192 dim)	47.1	60.6
DrBoost (160 dim)	51.2	63.4

Table 4: Entity Questions Results.

where μ_c is the average norm of passage embeddings and the operator $\max^{\{k\}}$ returns the k-th maximum element in the set. For a fixed q_i and $k = 1$, this definition is identical to the classical margin definition. Figure 2 plots the 50^{th}, 75^{th} and 90^{th} percentiles of the top-20 margin for DrBoost on the NQ training set. We clearly see that margins indeed increase at each step, especially for cases that the model is confident in (high margin). We hypothesize this property to be the main reason for the strong in-distribution generalization of DrBoost that we observed, and potentially also for the surprisingly strong IVF results, since wide margins should intuitively make clustering easier as well.

5.3 Cross-domain generalization

It has been observed in previous work (Thakur et al., 2021) that dense retrievers still largely lag behind sparse retrievers in terms of generalization capabilities. We are interested to test whether our method could be beneficial for out-of-domain transfer as well. We show the results for zero-shot transfer on a subset of the BEIR benchmark in Table 3 and the EntityQuestions dataset in Table 4. While DrBoost improves slightly over the dimension-matched baseline on EntityQuestions, where the passage corpora stays the same, it produces worse results on the BEIR datasets. We conclude that boosting is not especially useful for cross-domain transfer, and should be combined with other methods if this is a concern.

5.4 Representation Probing

One of the hypothesis we formulate for the stronger performance of DrBoost over DPR is that the former might better capture topical information of passages and questions. To test this, we collected topics for all Wikipedia articles in Natural Questions using the strategy of Johnson et al. (2021) and associate them with both passages and questions. We then probed both DPR and DrBoost representations with an SVM (Steinwart and Christmann, 2008) classifier considering a 5-fold cross-validation over 500 instances and 8 different seeds. Results (in Figure 3) confirms our hypothesis: the topic classifier accuracy is higher with DrBoost representations with respect to DPR ones of the same dimension (i.e., 192), for both questions and passages.

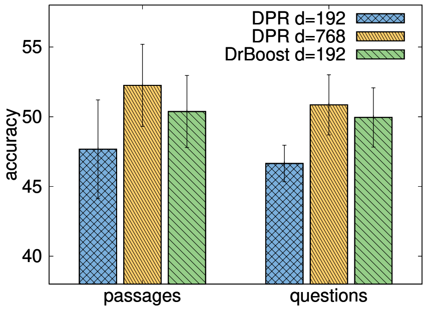

Figure 3: Topic classification accuracy when probing DrBoost and DPR representations with an SVM.

5.5 Related Work

Boosting for retrieval Boosting has been studied in machine learning for over three decades (Kearns and Valiant, 1989; Schapire, 1990). Models such as AdaBoost (Freund and Schapire, 1997) and GBMs (Friedman, 2001) became popular approaches to classification problems, with implementations such as XGBoost still popular today (Chen and Guestrin, 2016). Many boosting approaches have been proposed for retrieval and learning-to-rank (LTR) problems, typically employing decision trees, such as AdaRank (Xu and Li, 2007), RankBoost (Freund et al., 2003) and lambdaMART (Wu et al., 2009). Apart from speed and accuracy, boosting is attractive due to promising theoretical properties such as convergence and generalization. (Bartlett et al., 1998; Freund et al., 2003; Mohri et al., 2012). Boosted decision trees have recently been demonstrated to be competitive on LTR tasks (Qin et al., 2021), but, in recent years, boosting approaches have generally received less attention, as (pretrained) neural models began to dominate much of the literature. However, modern neural models and boosting techniques need not be exclusive, and a small amount of work exploring boosting in the context of modern pre-trained neural models has been carried out (Huang et al., 2020; Qin et al., 2021). Our work follows this line of thinking, identifying dimensionally-constrained bi-encoders as good candidates as neural weak learners, adopting a simple boosting approach which allows for simple and efficient MIPS at test time.

Dense Retrieval Sparse, term-based Retrievers such as BM25 (Robertson and Zaragoza, 2009) have dominated retrieval until recently. Dense, MIPS-based Retrieval using bi-encoder architectures leveraging contrastive training with gold pairs (Yih et al., 2011) has recently shown to be effective in several settings (Lee et al., 2019; Karpukhin et al., 2020; Reimers and Gurevych, 2019; Hofstätter et al., 2021b). See Yates et al. (2021) for a survey. The success of Dense Retrieval has led to many recent papers proposing schemes to improve dense retriever training by innovating on how negatives are sampled (Xiong et al., 2020; Qu et al., 2021; Zhan et al., 2021c; Lin et al., 2021, inter alia.), and/or proposing pretraining objectives (Oğuz et al., 2021; Guu et al., 2020; Chang et al., 2020; Sachan et al., 2021; Gao and Callan, 2021). Our work also innovates on how dense retrievers are trained, but is arguably orthogonal to most of these training innovations, since these could still be employed when training each component weak learner.

Distillation We leverage a simple distillation technique to make DrBoost more efficient at test time. Distillation for dense retrievers is an active area, and more complex schemes exist which could improve results further (Izacard and Grave, 2021; Qu et al., 2021; Yang and Seo, 2020; Lin et al., 2021; Hofstätter et al., 2021a; Barkan et al., 2020; Gao et al., 2020).

Multi-vector Retrievers Several approaches represent passages with multiple vectors. Humeau et al. (2020) represent queries with multiple vectors, but retrieval is comparatively slow as relevance cannot be calculated with a single MIPS call. ME-BERT (Luan et al., 2021) index a fixed number of vectors for each passage and ColBERT (Khattab and Zaharia, 2020) index a vector for every word. Both can perform retrieval with a single MIPS call (although ColBERT requires reranking) but produce very large indices, which, in turn, slows down search. DrBoost can also be seen as a multi-vector approach, with each weak learner producing a vector. However, each vector is small, and we index concatenated vectors, rather than indexing each vector independently, leading to small indices and fast search. This said, adapting DrBoost-style training to these settings would be feasible. SPAR (Chen et al., 2021) is a two-vector method: one from a standard dense retriever, and the other from a more lexically-oriented model. SPAR uses a similar test-time MIPS retrieval strategy to ours, and SPAR's lexical embeddings could be trivially added to DrBoost as an additional subvector.

Efficient retrievers There have been several recent efforts to build more efficient retrieval and question answering systems (Min et al., 2021). Izacard et al. (2020) and Yang and Seo (2021) experiment with post-hoc compression and lower-dimensional embeddings, Lewis et al. (2021) index and retrieve question-answer pairs and Yamada et al. (2021) propose BPR, which approximates MIPS using binary vectors. There is also a line of work learning embeddings specifically suited for approximate search (Yu et al., 2018; Zhan et al., 2021a,b) Generative retrievers (De Cao et al., 2021) can also be very efficient. DrBoost also employs lower-dimensional embeddings and off-the-shelf post-hoc compression for its smallest index.

6 Discussion

In this work we have explored boosting in the context of dense retrieval, inspired by the similarity of iteratively-sampling negatives to boosting. We find that our simple boosting approach, DrBoost, performs largely on par with a 768-dimensional DPR baseline, but produces more compact vectors, and is more amenable to approximate search. We note that DrBoost requires maintaining more neural models at test time, which may put a greater demand on GPU resources. However, the models can be run in parallel if latency is a concern, and if needed, these models can be distilled into a single model with little drop in accuracy. We hope that future work will build on boosting approaches for dense retrieval, including adding adaptive weights, and investigating alternative losses and sampling techniques. We also suggest that emphasis in dense retrieval should be placed on more holistic evaluation than just exact retrieval accuracy, demonstrating that models with quite similar exact retrieval can perform very differently under practically-important approximate search settings.

Table 5: Ablations for the number of rounds for DPR with iterative negatives and DrBoost for MSMARCO

A Appendix

A.1 Number of Rounds

The performance of DPR and DrBoost on MSMARCO for different numbers of rounds are shown in Table 5. We find that all models saturate at about 4 or 5 rounds. Note DrBoost does not need more iterations to train, even though it does not use BM25 negatives for the first round. On NQ, adding a 6th model slightly improves DrBoost's precision, at the expense of recall (see Table 1).

While iterative training is expensive, we find that subsequent rounds are much cheaper than the first round, with the first round taking $\sim$20K steps in our experiments to converge, with additional DrBoost rounds converging after about 3K steps.

Bagging Dense Retrieval We also trained a simple ensemble of six 32-dim DPR models for NQ, which we compare to our 6×32-dim component DrBoost. This experiment investigates whether the improvement over DPR is just a simple ensembling effect, or whether it is due to boosting effects and specialization of concerns. This DPR ensemble performs poorly, scoring 74.5 R@20 (not shown in tables), 6.8% below the equivalent DrBoost, confirming that the boosting formulation is important, not simply having several ensembled dense retrievers.

A.2 Implementation Details

We implement our models architectures based on HuggingFace's Transformers (Wolf et al., 2020) and run our experiments on 16 V100 GPUs. For all training rounds, we used the same set of training hyperparameters — we set learning rate as 3e-5, dropout as 0.1, weight decay as 0.01, batch size as 2 (per GPU) and max training steps as 30k. The maximum question and passage lengths are set as 40 and 200 respectively and we accompany each question with 50 passages during training. Using our training infrastructure, the first round of the training takes about 8 hours and each additional training round takes about 1.5 hours until convergence. We always use the dev loss for model selection.

Abstract

This paper presents MuCGEC, a multi-reference multi-source evaluation dataset for Chinese Grammatical Error Correction (CGEC), consisting of 7,063 sentences collected from three Chinese-as-a-Second-Language (CSL) learner sources. Each sentence is corrected by three annotators, and their corrections are carefully reviewed by a senior annotator, resulting in 2.3 references per sentence. We conduct experiments with two mainstream CGEC models, i.e., the sequence-to-sequence model and the sequence-to-edit model, both enhanced with large pretrained language models, achieving competitive benchmark performance on previous and our datasets. We also discuss CGEC evaluation methodologies, including the effect of multiple references and using a char-based metric. Our annotation guidelines, data, and code are available at `https://github.com/HillZhang1999/MuCGEC`.

1 Introduction

Given a potentially noisy input sentence, grammatical error correction (GEC) aims to detect and correct all errors and produce a clean sentence. Recently, GEC has increasingly gained attention for its vital value in various downstream scenarios (Grundkiewicz et al., 2020; Wang et al., 2021).

To support GEC research, high-quality manually labeled evaluation data is indispensable. For English GEC (EGEC), such datasets are abundant (Yannakoudakis et al., 2011; Dahlmeier et al., 2013; Ng et al., 2014; Napoles et al., 2017; Bryant et al., 2019; Napoles et al., 2019; Flachs et al., 2020). However, Chinese GEC (CGEC) evaluation datasets are relatively scarce. The two publicly available CGEC evaluation datasets are NLPCC18 and CGED, contributed by the NLPCC-2018 (Zhao et al., 2018) and the series of CGED shared tasks (Rao et al., 2018, 2020), respectively.

Source	我不知道他何时返回回来。 I don’t know when he will return back.
Ref. 1	我不知道他何时返回~~回来~~。 I don’t know when he will return.
Ref. 2	我不知道他何时~~返回~~回来。 I don’t know when he will be back.

Table 1: A CGEC example with two references.

Most EGEC evaluation datasets provide multiple references for each input sentence, such as CoNLL14-test (Ng et al., 2014) and BEA19-test (Bryant et al., 2019). In contrast, sentences in existing CGEC evaluation datasets usually have only one reference (i.e., 87% of the sentences in NLPCC18 and all in CGED). This is probably due to the different annotation workflows adopted.

As suggested by Bryant and Ng (2015), enforcing multi-reference annotation is crucial for both GEC model evaluation and GEC data annotation, because there usually exist more than one acceptable reference with similar meanings for an incorrect sentence, as illustrated by the example in Table 1. On the one hand, if a GEC model outputs a correct reference, which is yet different from the one given in the evaluation data, then the model performance will be unfairly underestimated. To mitigate this issue, a straightforward solution is increasing the number of references (Sakaguchi et al., 2016; Choshen and Abend, 2018). On the other hand, imposing a single-reference constraint makes data annotation problematic. If annotators submit different equally acceptable corrections, which is very common, it will be difficult for the senior annotator to decide which one is the best.

Besides the lack of multiple references, existing CGEC datasets collect sentences from a single text source, which may be insufficient for robust model evaluation (Mita et al., 2019). In addition, we be-

lieve that it is beneficial for improving data quality to compile comprehensive annotation guidelines.

To fill these gaps, this paper presents a multi-reference multi-source evaluation dataset for CGEC, named MuCGEC. After investigating previous works on constructing GEC datasets, we compile comprehensive annotation guidelines. Based on a browser-based online annotation tool, each sentence is assigned to three annotators for independent correction, and one senior annotator for final review. An annotator may submit multiple references, and the senior annotator may also supplement new references besides rejecting incorrect submissions. In this way, we aim to produce as many references as possible. In summary, this work makes the following contributions.

(1) Our newly constructed MuCGEC consists of 7,063 sentences from three representative sources of Chinese-as-a-Second-Language (CSL) learner texts. Each sentence obtains 2.3 references on average. We conduct detailed analyses on our new dataset to gain more insights.

(2) We conduct benchmark experiments using two mainstream and competitive CGEC models, i.e., the sequence-to-edit (Seq2Edit) and sequence-to-sequence (Seq2Seq) models, both enhanced with pretrained language models (PLMs). We also experiment with an extremely effective ensemble strategy. Moreover, we investigate the effect of multiple references on model evaluation, and propose to use a char-based evaluation metric, which we believe is simpler and more suitable than previous word-based ones for CGEC.

2 Data Annotation

2.1 Multi-Source Data Selection

This work focuses on CSL learner texts. In order to investigate diverse types of Chinese grammatical errors, we select data from the following three sources.

(1) We re-annotate the NLPCC18 test set (Zhao et al., 2018), which contains 2,000 sentences from the Peking University (PKU) Chinese Learner Corpus.

(2) We select and re-annotate sentences from CGED-2018 and CGED-2020 test datasets (Rao et al., 2018, 2020), which come from the writing section of the HSK exam (Hanyu Shuiping Kaoshi, translated as the Chinese level exam), an official Chinese proficiency test. After removing sentences marked as correct from the total 5,006 ones, we obtain 3,137 potentially erroneous sentences for re-annotation.

(3) Lang8[1] is a language learning platform, where native speakers voluntarily correct texts written by second-language learners. The NLPCC-2018 shared task organizers collect about 717K Chinese sentences with their corrections from Lang8 and encourage participants to use them as the training data. We randomly select 2,000 sentences with 30 to 60 characters for re-annotation.

In the end, we obtain 7,137 sentences. For simplicity, we discard all original corrections and directly perform re-annotation from scratch following our new annotation guidelines and workflow.

2.2 Annotation Paradigm: Direct Rewriting

There are mainly two types of annotation paradigms for constructing GEC data, i.e., *error-coded* and *direct rewriting*. The *error-coded* paradigm requires annotators to explicitly mark the erroneous span in the original sentence, then choose its error type, and finally make corrections. Ng et al. (2013, 2014) adopt the *error-coded* paradigm for constructing data for the CoNLL-2013/2014 EGEC shared tasks. For CGEC, the original NLPCC18 and CGED datasets both follow the *error-coded* paradigm as well.

As discussed by Sakaguchi et al. (2016), the *error-coded* paradigm poses two challenges. First, it is extremely difficult for different annotators to agree upon the boundaries of the erroneous spans and their error types, especially when there are many categories to consider (Bryant et al., 2017). This inevitably leads to an increase in annotation effort and a decrease in annotation quality. Second, under such a complex annotation paradigm, annotators would pay less attention to the fluency of the resulting reference, sometimes even leading to unnatural expressions.

Instead, the *direct rewriting* paradigm asks annotators to directly rewrite the input sentence and produce a corresponding grammatically correct one, without changing the original meaning. In order to

Pragmatics	Logical inconsistency; Ambiguity; Commonsense mistake

Table 2: The 5 major and 14 minor error types adopted by our guidelines for organizing the content.

Source	我的爸爸经常我。 My dad usually me.
Previous	我的爸爸经常骂我。 My dad usually scolds me.
Ours	我的爸爸经常[MC]我 My dad usually [MC] me.

Table 3: An example for handling context-dependent missing components. The inserted tokens are underlined. "Previous" means annotation in previous datasets, and "Ours" refers to our annotation.

evaluate model performance, edits can be extracted automatically from parallel sentences by additional tools (Bryant et al., 2017).

This annotation paradigm has proven to be efficient and cost-effective (Sakaguchi et al., 2016), and has been adopted by several recent GEC data construction works (Napoles et al., 2017, 2019; Syvokon and Nahorna, 2021; Náplava et al., 2022).

In this work, we adopt the *direct rewriting* paradigm. Besides above-mentioned advantages, we believe this paradigm can help improve the diversity of references since annotators can correct errors more freely.

2.3 Annotation Guidelines

After an extensive survey of previous work on GEC data construction, we compiled 30 pages of comprehensive guidelines for CGEC annotation. During the course of the annotation process, we gradually improved our guidelines according to feedback from annotators.

To facilitate learning, our guidelines adopt a two-tier hierarchical error taxonomy, including 5 major error types and 14 minor types, as shown in Table 2. Our guidelines describe in detail how to handle each minor error type and provide typical examples. We will release our guidelines along with the dataset, which we hope can benefit future research.

For dealing with word-missing errors, we found that it was unreasonable to simply insert certain words when the missing words are context-dependent, which means the missing words are related to context beyond the given sentence. Table 3 shows a sentence in which a verb is missing. However, under sentence-level GEC annotation, annotators are unable to decide the specific missing verb. According to our observation, previous CGEC datasets directly insert specific words like "scolds" under such circumstances, which we think is inaccurate and may cause trouble for GEC model evaluation, because there are many other acceptable candidates. To handle this problem, we instead insert a special tag named **context-dependent missing components (MC)**. We find about 1% of sentences in MuCGEC contain "[MC]" tags. Current GEC models cannot handle "[MC]", since "[MC]" is not included in existing training data and vocabulary. We leave this issue as future work.

2.4 Annotation Workflow and Tool

In order to encourage more diverse and high-quality references, we assign each sentence to three random annotators for independent annotation. Their submissions are then aggregated and sent to a random senior annotator (reviewer) for review. An annotator may submit multiple references for one sentence if he/she thinks they are all correct according to the guidelines. The job of the senior annotator includes: 1) modifying incorrect references into correct ones (sometimes just rejecting them); 2) adding new correct references according to the guidelines. After review, the accepted references are defined as **final golden references**.

For the sake of self-improvement, we employ a self-study mechanism that allows annotators to learn from their mistakes if they submit an incorrect reference. Concretely, if an annotator submits a reference that is not included in the final golden references, he/she has to modify his/her submission into a correct one. Moreover, the annotator can also make complaints if he/she insists that his/her submission is correct. We find that the self-study and making-complaints mechanisms can trigger very helpful discussions.

To improve annotation efficiency, we have developed a browser-based online annotation tool to support the above workflow and mechanisms. Due

Dataset	#sent	#err. sent (perc.)	chars/sent	edits/ref	refs/sent
Original NLPCC18	2000	1983 (99.2%)	29.7	2.0	1.1
MuCGEC (NLPCC18)	1996 (4)	1904 (95.4%)	29.7	2.5	2.5
MuCGEC (CGED)	3125 (12)	2988 (95.6%)	44.8	4.0	2.3
MuCGEC (Lang8)	1942 (58)	1652 (85.1%)	37.5	2.8	2.1
MuCGEC	7063 (74)	6544 (92.7%)	38.5	3.2	2.3

Table 4: Data statistics, including the number of sentences, the number (proportion) of erroneous sentences, the average number of characters per sentence, the average number of edits per reference, and the average number of references per sentence. Some sentences in our source data were discarded since annotators could not understand their meaning and thus were unable to correct them. Numbers in parentheses in the "#sent" row refer to such sentences.

to the space limitation, we show the visual interfaces for annotation and review in Appendix B.

2.5 Annotation Process

We employed 21 undergraduate students who are native speakers of Chinese and familiar with Chinese grammar as part-time annotators. Annotators received intensive training before real annotation. In the beginning, two authors of this paper, who were also in charge of compiling the guidelines, served as senior annotators for review. After one month, when the annotators were familiar with the job, we selected 5 outstanding annotators as senior annotators to join the review.

All participants were asked to annotate for at least 1 hour every day. The whole annotation process lasted for about 3 months.

2.6 Ethical Issues

All annotators and reviewers were paid for their work. The salary was determined by both submission numbers and annotation quality. The average salary of annotators and reviewers is 24 and 35 RMB per hour respectively.

All the data of the three sources are publicly available. Meanwhile, we have obtained permission from organizers of the NLPCC-2018 and CGED shared tasks to release our newly annotated references in a proper way. We are deeply grateful to them for their kind support.

3 Analysis of Our Annotated Data

Overall statistics of MuCGEC are shown in Table 4. We also include the original NLPCC18 dataset (Zhao et al., 2018) for comparison[2].

First, from the proportion of erroneous sentences, we can see that most of the sentences are considered to contain grammatical errors in the original annotation, but a considerable part of them are not corrected in our annotation. We attribute this to our strict control of the over-correction phenomenon.

Second, regarding sentence lengths, NLPCC18 has the shortest sentences, whereas CGED sentences are much longer. This may be because candidates on the HSK examination, an official Chinese proficiency test, tend to use long sentences to show their ability in Chinese.

Third, each sentence in the re-annotated NLPCC18 receives 2.5 references on average, which is more than twice that in the original NLPCC18 data. Overall, each sentence obtains 2.3 references. We believe the multi-reference characteristic makes our dataset more reliable for evaluation, which is further discussed in Section 6.3.

Finally, we compare the number of char-based edits per reference in different datasets. We describe how to derive such edits in detail in Section 6.2. We can see that the number of edit is tightly correlated with sentence length. The difference in the average sentence length and number of edits indicates that the three data sources may have a systematic discrepancy in quality and difficulty, which we believe is helpful for evaluating the generalization ability of models. Moreover, compared with NLPCC18-orig, we annotate 25% more edits (2.0 vs. 2.5) in each reference. We believe the major reason is that the original NLPCC18 data are annotated under the *minimal edit distance* principle (Nagata and Sakaguchi, 2016), which requires annotators to select a reference with fewer edits when correcting errors.

---

[2] Here we do not compare with the original CGED and Lang8 datasets since: 1) the CGED-orig mainly focuses on error detection annotation and does not provide corrections for word-order errors; 2) the Lang8-orig is automatically collected from the internet, and its correction is quite noisy.

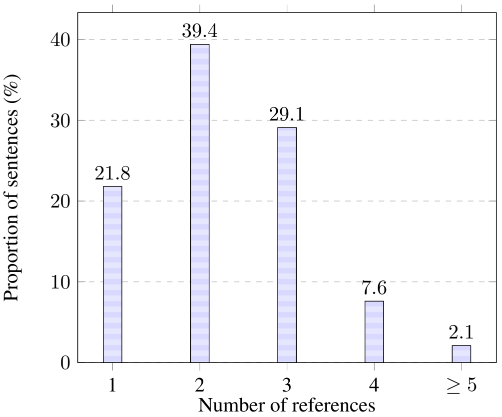

Figure 1: The proportion of sentences with different number of references in MuCGEC.

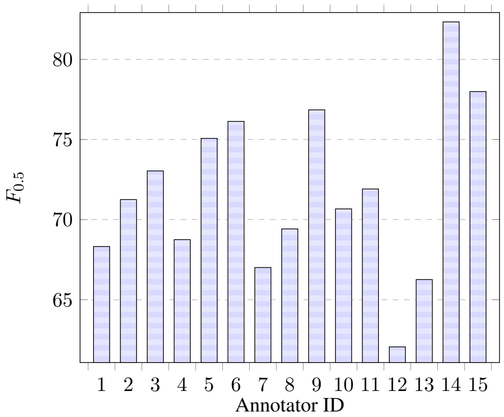

Figure 2: The human performance of the 15 annotators who annotated the most sentences.

Sentence distribution with respect to numbers of references is shown in Figure 1. Here, we only consider erroneous sentences. Identical references from different annotators are counted as one reference. Overall, most sentences have 2 references, accounting for 39.4%; 29.1% of sentences have 3 references; 21.8% of sentences have only 1 reference, most of which are short and easy to correct.

We believe that the average number of references could be further increased if more annotators were assigned to each sentence. It is also worth noticing that annotators tend to submit a single reference, despite the fact that our annotation tool allows annotators to submit multiple ones. We suspect the reason may be that it is more economical for annotators to do so. One the one hand, it may be easy to come up with the most suitable correction, whereas thinking of alternatives is more time-consuming. On the other hand, we did not give enough consideration to this issue when designing the salary computation formula. In the future, we plan to optimize (or simplify) our annotation workflow so that each annotator is required to give only one reference which he/she thinks is the best, and assign each sentence to more annotators if we need more references.

Human annotation performance. In order to assess the annotation ability of our annotators and human performance for CGEC task, we calculate char-based $\mathrm{F}_{0.5}$ scores by evaluating all annotation submissions against the final golden references. We describe how to compute char-based metrics in detail in Section 6.2. Each reference submitted by an annotator is considered as a sample. Overall, the average $\mathrm{F}_{0.5}$ is 72.12, which we believe could be higher if we discarded data that were annotated at the early stage of our project when annotators were less experienced and less familiar with our guidelines.

Figure 2 shows $\mathrm{F}_{0.5}$ scores of 15 annotators who annotated the most sentences, in descending order of the number of annotated sentences. We can see that human performance varies across different annotators. The best annotator achieves an 82.34 $\mathrm{F}_{0.5}$ score, while the annotator who completes the most tasks only gets a score of 68.32. This indicates that we should pay more attention to annotation quality when calculating salaries and prevent annotators from focusing too much on annotation speed.

Common mistakes made by annotators. We randomly select 300 invalid references rejected by reviewers and try to understand what mistakes are more frequently made by annotators. We manually classify all selected references into three mistake categories. The most frequent mistakes are caused by *incomplete correction* and account for 56.7% of the invalid references. We found that it was sometimes difficult for annotators to correct all errors without omissions, possibly due to the complexity or flexibility of Chinese grammar. The second frequent type of mistakes is *erroneous correction*, which means that the correction of old errors incurs new errors, with a proportion of 32.3%. Besides, 11.0% of submissions are rejected due to *meaning change*, which means that the correction changes the intended meaning of the original sentence.

4 Benchmark Models

To understand how well cutting-edge GEC models perform on our data, we adopt two mainstream GEC approaches, i.e., Seq2Edit and Seq2Seq. Both models are enhanced with PLMs. We also attempt to combine them after observing their complementary power in dealing with different error types. This section briefly describes these benchmark models. Due to the space limitation, please kindly refer to Appendix C for more model details.

The Seq2Edit model treats GEC as a sequence labeling task and performs error corrections via a sequence of token-level edits, including insertion, deletion, and substitution (Malmi et al., 2019). A token corresponds to a word or a subword in English, and to a character in Chinese. With minor modifications to accommodate Chinese, we adopt GECToR (Omelianchuk et al., 2020), which achieves the SOTA performance on EGEC datasets.

Following recent Seq2Edit work like Awasthi et al. (2019) and Omelianchuk et al. (2020), we enhance GECToR by using PLMs as its encoder. After comparing several popular PLMs, we choose StructBERT (Wang et al., 2019)[3] due to its superior performance after fine-tuning (see Table 5).

The Seq2Seq model straightforwardly treats GEC as a monolingual translation task (Yuan and Briscoe, 2016). Recent works propose to enhance Transformer-based (Vaswani et al., 2017) Seq2Seq EGEC models with PLMs like T5 (Rothe et al., 2021) or BART (Katsumata and Komachi, 2020). Unlike BERT (Devlin et al., 2019), T5 and BART are specifically designed for text generation. Therefore, it is straightforward to continue training them on GEC data. We follow these works and utilize the recently proposed Chinese BART from Shao et al. (2021) to initialize our Seq2Seq model.

The ensemble model. Several previous works have proven the effectiveness of model ensemble for CGEC (Liang et al., 2020; Hinson et al., 2020). In this work, we clearly observe the complementary power of the above two models in fixing different error types (see Table 7), and thus attempt to combine them.

We adopt a simple edit-wise voting mechanism. The edits are at the char-based span level, and correspond to four error types. Please refer to Section 6.2 for detailed explanation of our char-based evaluation metric. More specifically, we aggregate edits from the results of each model, and only preserve edits that appear more than $N/2$ times, where N is the number of models. In other words, an edit is kept in the final result only if it is produced by a majority of models.[4]

We experiment with two ensemble settings: 1) one Seq2Edit and one Seq2Seq, denoted by "1×Seq2Edit+1×Seq2Seq", and 2) three Seq2Edit and three Seq2Seq, denoted by "3×Seq2Edit+3×Seq2Seq".The three Seq2Edit models are obtained using different random seeds for initialization, and the same goes for the Seq2Seq.

Other settings. To obtain the single-model performance of both kinds of models, we run them three times separately with different random seeds for initialization and calculate average metrics. For "1×Seq2Edit+1×Seq2Seq", we random select a pair of single models. For "3×Seq2Edit+3×Seq2Seq", we aggregate the results of all six single models.

5 Experiments on NLPCC18-Orig Data

In order to show that our benchmark models are competitive among existing CGEC models, we conduct experiments on the original NLPCC18 test set, on which most previous CGEC systems are tested.

Training data. For the sake of easy replicability, we limit our training data strictly to public resources, i.e., the Lang8[5] data (Zhao et al., 2018) and the HSK[6] data (Zhang, 2009). We filter duplicate sentences that appear in our dataset, and discard correct sentences. The final Lang8 and HSK data contains 1,092,285 and 95,320 sentence pairs, respectively. The HSK data is cleaner and of higher quality than Lang8, but is smaller. Following the re-weighting procedure of Junczys-Dowmunt et al. (2018), we duplicate the HSK data five times, and merge them with Lang8 data.

Comparison with previous works. Table 5 shows the results. For a fair comparison, we follow the official setting of the shared task, including the word-based MaxMatch scorer (Dahlmeier and Ng,

---

[3] `https://github.com/alibaba/AliceMind/tree/main/StructBERT`

[4] In fact, our voting strategy is a little more complex due to the adaption of two pieces of modification, which consistently improve performance in our preliminary experiments. First, for word-order errors, we set the preserving threshold to $N/2 - 1$ considering the Seq2Seq model is much superior in handling word-order errors than the Seq2Edit model. Imagine the scenario when all Seq2Seq models agree on correcting a word-order error, whereas all Seq2Edit models disagree. Using $N/2 - 1$ means that a word-order edit is kept in the final result even when it is produced by exactly half of models. Second, we use a set of simple heuristic rules to recognize spelling errors, a sub-type of substitution errors, and also use $N/2 - 1$ as the preserving threshold for them. This is also reasonable since both GEC models can obtain high precision scores on such errors.

Models marked by ♢ use *model ensemble*, and those marked by ♡ use *data augmentation*.

2012) for calculating the P/R/F values. We segment model outputs by adopting the PKUNLP word segmentation (WS) tool provided by the shared task organizers (Zhao et al., 2018).

When only using Lang8 for training, our single Seq2Seq model is already quite competitive. Its performance is only lower than MaskGEC (Zhao and Wang, 2020) by 1 point in $F_{0.5}$. Please notice that MaskGEC extra uses data augmentation. For now, our benchmark models do not use any synthetic data for simplicity, but we believe data augmentation could further boost the performance of our models.

Adding the HSK training data improves performance of all our models by about 4 points. Our two benchmark models already achieve SOTA performance under the single-model setting.

The model ensemble technique leads to obvious performance gains (more than 5 points) over single models. However, the gains from increasing the number of component models seem rather small. We try to explain this issue in Section 6.3.

For Seq2Edit, we additionally present results with other PLMs besides StructBERT, including BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and MacBERT (Cui et al., 2020) from the Hugging Face[7] website. We use the "large" variants of all PLMs.

6 Experiments on MuCGEC

6.1 Data Splits

For hyperparameter tuning or model selection, previous works on other CGEC datasets often randomly sample some sentence pairs from training data as the dev set (Wang et al., 2020; Zhao and Wang, 2020; Hinson et al., 2020), which is inconvenient for reproducing or comparing.

In this work, we propose to provide a fixed dev set for our newly annotated dataset, by randomly selecting 1,125 sentences from the CGED source, denoted as CGED-dev. The remaining 5,938 sentences are used as the test set, in which each data source has a roughly equal amount of sentences, i.e., 1,996 sentences for NLPCC18-test, 2,000 for CGED-test, and 1,942 for Lang8-test.

6.2 Evaluation Metrics

Problems with word-based metrics. As discussed in Section 5, previous CGEC datasets are annotated upon word sequences and adopt word-based metrics for evaluation. Before annotation and evaluation, a sentence needs to be segmented into words using a Chinese word segmentation (CWS) model. We believe this will introduce unnecessary uncertainty in CGEC evaluation procedure. First, CWS models inevitably produce word segmentation errors (Fu et al., 2020). Second, there are multiple heterogeneous CWS standards. Finally, we found that a correct edit may be judged as wrong due to the word boundary mismatch.

Char-based span-level evaluation metrics are adopted in this work instead. First, given an input sentence and a correction, we obtain an optimal sequence of *char-level edits* with the minimal edit distance. We consider three types of *char-level edits*, corresponding to three error types:

- Deleting a char for a *redundant error*;
- Inserting a char for a *missing error*;
- Substituting a char with another one for a *substitution error*;

Then, we convert all *char-level edits* into *span-level* by merging consecutive edits of the same type, following previous practice in EGEC and CGEC (Felice et al., 2016; Hinson et al., 2020)

Table 6: Performance of models and our annotators on MuCGEC, using the **char-based** metric. For calculating the human performance, each submitted result is considered as a sample if an annotator submits multiple references.

	Seq2Edit	*Seq2Seq*	*Ensemble*	**Human**
Missing (**29.2%**)	41.09	40.93	42.25	69.72
Redundant (**16.1%**)	43.11	37.65	54.18	72.78
Substitution (**48.9%**)	35.99	39.98	47.37	71.69
Word-order (**5.8%**)	28.28	40.33	42.44	72.58

Table 7: $F_{0.5}$ scores for each error type on All-test. The bold numbers in parentheses show the proportion of each error type. "*Ensemble*" refers to "*3×Seq2Edit+3×Seq2Seq*".

The above two steps are applied to both the system output sequence and golden reference, transforming them into sets of span-level edits. Finally, we can calculate the P/R/F value by comparing them. If there are multiple golden references, we will choose the one with the highest F-score.

Span-level word-order errors. When calculating overall metrics, we only consider above three types of errors. When analyzing, we distinguish the fourth error type — word-order. A span-level word-order error is usually composed of a redundant and a missing error, where the deleted span is the same as the inserted one. We use simple heuristic rules to identify such errors (Hinson et al., 2020).

Please kindly notice that we release our evaluation script as well.

6.3 Results and Analysis

Main results. Table 6 shows the char-based performance of the benchmark models and our annotators on MuCGEC. All models are trained on Lang8+HSK, as described in Section 4.

The overall trend of performance change is basically consistent with those on the original NLPCC18 dataset in Table 5. First, the Seq2Seq and Seq2Edit models perform quite closely on $F_{0.5}$, but clearly exhibit divergent strength in precision and recall, giving a strong motivation for combining them. Second, the model ensemble approach improves performance by a very large margin.

One interesting observation is that on MuCGEC, "3×Seq2Edit+3×Seq2Seq" substantially outperforms "1×Seq2Edit+1×Seq2Seq" on All-test and all three subsets. In contrast, the improvement is only modest on the original NLPCC18 test data. We suspect this may indicate that a multi-reference dataset can more accurately evaluate model performance. However, it may require further human investigation for more insights.

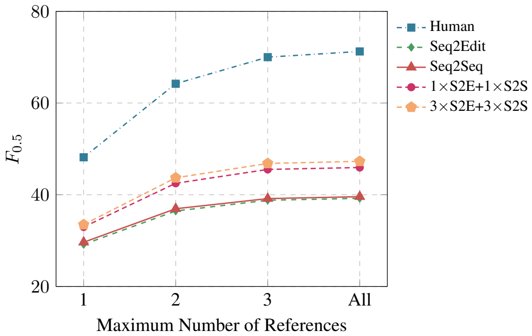

Figure 3: Effect of the number of references on $F_{0.5}$.

Finally, there is still a huge performance gap between models and humans, indicating that CGEC research still has a long way to go.

Performance on four error types. Table 7 shows more fine-grained evaluation results on four error types.

It is clear that the Seq2Edit model is better at handling redundant errors, whereas the Seq2Seq model is superior in dealing with substitution and word-order errors. For missing errors, the two perform similarly well.

These phenomena are quite interesting and can be understood after considering the underlying model architectures. On the one hand, to correct redundant errors, the Seq2Edit model only needs to perform a fixed deletion operation, which is a much more implicit choice for the Seq2Seq model, since its goal is to rewrite the whole sentence. On the other hand, the Seq2Seq is suitable to substitute or reorder words due to its natural capability of utilizing language model information, especially with the enhancement of BART (Lewis et al., 2020).

Again, the model ensemble approach substantially improves performance on all error types. The ensemble model is closest to the human on redundant errors, probably because they are the easiest to correct. The largest gap occurs in word-order errors, which require global structure knowledge to correct and are extremely challenging.

Influence of the number of references. To understand the impact of the number of references on performance evaluation, we deliberately reduce the available number of reference in our dataset. For example, when the maximum number of references is limited to 2, we only kept the first two references in the dataset if a sentence has more than 2 golden references. The results are shown in Figure 3.

When the maximum number of references increases, the performance of both models and humans increases continuously, especially for humans. As only a few sentences have more than 3 references, the improvement is quite small when the maximum number of references increases from 3 to All. This trend suggests that compared with single-reference datasets, a multi-reference dataset reduces the risk of underestimating performance, and thus is more reliable for model evaluation.

7 Related Works

EGEC resources. There has been a lot of work on EGEC data construction. As the two earliest EGEC datasets, FCE (Yannakoudakis et al., 2011) and NUCLE (Dahlmeier et al., 2013) adopt the *error-coded* annotation paradigm. In contrast, JFLEG (Napoles et al., 2017) collects sentences from TOFEL exams and adopts the *direct rewriting* paradigm. W&I (Bryant et al., 2019) also chooses the *direct rewriting* paradigm, and extra annotates a score indicating the language proficiency level of the writer for each input sentence. All four datasets are composed of essays from non-native English speakers and provide multiple references.

Recently, researchers have started to annotate small-scale EGEC data for texts written by native English speakers, including AESW (Daudaravicius et al., 2016), LOCNESS (Bryant et al., 2019), GMEG (Napoles et al., 2019) and CWEB (Flachs et al., 2020). In the future, we plan to extend this work to texts written by native Chinese speakers.

CGEC resources. Compared with EGEC, progress in CGEC data construction largely lags behind. As discussed in Section 1, NLPCC18 (Zhao et al., 2018) and CGED (Rao et al., 2018, 2020) are the only two evaluation datasets for CGEC research. Besides them, there are also a few resources for training CGEC models, e.g., the Lang8 corpus (Zhao et al., 2018) and the HSK corpus (Zhang, 2009).

Concurrently with this work, Wang et al. (2022) present a multi-reference CGEC dataset, named as yet another Chinese learner corpus (YACLC), containing 32,124 sentences from Lang8. Each sentence is annotated by 10 annotators.

Recent progress in CGEC. In the NLPCC-2018 shared task (Zhao et al., 2018), many systems adopt Seq2Seq models, based on RNN/CNN. Recent work mainly utilizes Transformer (Wang et al., 2020; Zhao and Wang, 2020; Tang et al., 2021). Hinson et al. (2020) first employ a Seq2Edit model for CGEC, and achieve comparable performance with the Seq2Seq counterparts. Some systems in the CGED-2020 shared task (Rao et al., 2020) directly employ the open-source Seq2Edit model, i.e., GECToR (Liang et al., 2020). Most Seq2Edit models use PLMs like BERT (Devlin et al., 2019) to initialize their encoders. Besides the above two mainstream models, Li and Shi (2021) for the first time apply a non-autoregressive neural machine translation model to CGEC.

Besides modeling optimization, techniques like data augmentation (Zhao and Wang, 2020; Tang et al., 2021) and model ensemble (Hinson et al., 2020) have proven to be very useful for CGEC.

8 Conclusions

This paper presents MuCGEC, a newly annotated evaluation dataset for CGEC, consisting of 7,063 sentences written by CSL learners. Compared with existing CGEC datasets, ours can support more reliable evaluation due to three important features: 1) providing multiple references; 2) covering three text sources; 3) adopting strict quality control (i.e., annotation guidelines and workflow). After describing the data construction process, we perform detailed analyses of our data. Then, we adopt two mainstream and competitive CGEC models, i.e., Seq2Seq and Seq2Edit, and carry out benchmark experiments. We also propose to adopt char-based evaluation metrics to replace previously used word-based ones.

Acknowledgements

We want to thank the anonymous reviewers and Sebastian Schuster for their great help. We are also grateful to Zeyang Liu for building the annotation system, and Lei Zhang, Fukang Yan, Jiayu Shen, Houquan Zhou, Yu Zhang for helping us improve this paper, and all annotators for their great effort in data annotation. This work was partially supported by National Natural Science Foundation of China (Grant No.62176173 and No.61876116) and by Alibaba Group through Alibaba Innovative Research Program. This work was also partially supported by Projected Funded by the Priority Academic Program Development of Jiangsu Higher Education Institutions.

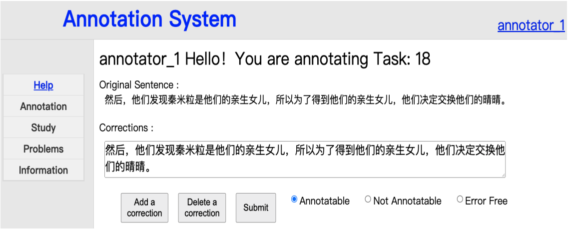
Appendices

A More Discussion on the Char-based Span-level Metric

We find that ERRANT_ZH (Hinson et al., 2020), a useful evaluation tool for CGEC, only merges edits for redundant errors and missing errors, and does not merge edits for substitution errors. In contrast, as discussed in Section 6.2, we also merge the consecutive edits for substitution errors for the sake of simplicity. We hope future research can adopt our simplified version unless there is a strong reason. Meanwhile, we should keep thinking about which evaluation metrics are more suitable for CGEC task.

B Interface

Figure 4 shows our design of annotation interface in our annotation tool, where annotators correct assigned sentences. Given an annotation task, this interface presents a potentially wrong sentence and a text input box. The original sentence is copied into the input box below, so that the annotator can directly modify it. To support multiple corrections, we also provide a button to add additional input boxes. Two special buttons are provided to deal with special cases. The *error free* button means that the sentence is correct; the *not annotatable* button means that the annotator can not understand the sentence.



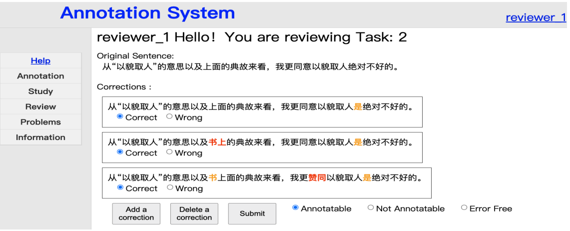
annotator_1 Hello! You are annotating Task: 18

Original Sentence :
然后，他们发现秦米粒是他们的亲生女儿，所以为了得到他们的亲生女儿，他们决定交换他们的晴晴。

Corrections :
然后，他们发现秦米粒是他们的亲生女儿，所以为了得到他们的亲生女儿，他们决定交换他们的晴晴。

Figure 4: The screenshot of the annotation interface.

Figure 5 shows the review interface, where senior annotators judge whether the submitted corrections are correct. All corrections of a sentence from annotators are shown on the screen, and reviewers click a check box to mark each of them as correct or incorrect. The input box below allows reviewers to supplement extra valid corrections.



reviewer_1 Hello! You are reviewing Task: 2

Original Sentence:
从“以貌取人”的意思以及上面的典故来看，我更同意以貌取人绝对不好的。

Corrections :

从“以貌取人”的意思以及上面的典故来看，我更同意以貌取人是绝对不好的。
● Correct ○ Wrong

从“以貌取人”的意思以及书上的典故来看，我更同意以貌取人是绝对不好的。
● Correct ○ Wrong

从“以貌取人”的意思以及书上面的典故来看，我更赞同以貌取人是绝对不好的。
● Correct ○ Wrong

Figure 5: The screenshot of the review interface.

C Hyperparameters

Table 8 and Table 9 shows the detailed hyperparameters for training our two benchmark models. Due to the GPU memory limitation, we truncated sentences longer than 100 characters when training the Seq2Seq model. In other words, extra characters in the input sentences and the references are discarded.

A useful trick. We find that some sentences in MuCGEC are actually composed of multiple sentences. Therefore, we split one input sentence into multiple ones based on punctuation marks such as periods, exclamation marks, and so on. Then, we perform corrections on the smaller sentences and concatenate the results. We find this trick can consistently improve performance in our preliminary experiments. For now, we decide not to break the sentences when releasing in order to be consistent with the sources where the data comes from.

NeuS: Neutral Multi-News Summarization for Mitigating Framing Bias

Nayeon Lee Yejin Bang Tiezheng Yu Andrea Madotto[*] Pascale Fung
Hong Kong University of Science and Technology
`nyleeaa@connect.ust.hk, pascale@ece.ust.hk`

Abstract

Media news framing bias can increase political polarization and undermine civil society. The need for automatic mitigation methods is therefore growing. We propose a new task, a *neutral* summary generation from multiple news articles of the varying political leanings to facilitate balanced and unbiased news reading. In this paper, we first collect a new dataset, illustrate insights about framing bias through a case study, and propose a new effective metric and model (NEUS-TITLE) for the task. Based on our discovery that title provides a good signal for framing bias, we present NEUS-TITLE that learns to neutralize news content in hierarchical order from title to article. Our hierarchical multi-task learning is achieved by formatting our hierarchical data pair (title, article) sequentially with identifier-tokens ("TITLE=>", "ARTICLE=>") and fine-tuning the auto-regressive decoder with the standard negative log-likelihood objective. We then analyze and point out the remaining challenges and future directions. One of the most interesting observations is that neural NLG models can hallucinate not only factually inaccurate or unverifiable content but also politically biased content.

1 Introduction

Media framing bias occurs when journalists make skewed decisions regarding which events or information to cover (information bias) and how to cover them (lexical bias) (Entman, 2002; Groeling, 2013). Even if the reporting of the news is based on the same set of underlying issues or facts, the framing of that issue can convey a radically different impression of what actually happened (Gentzkow and Shapiro, 2006). Since the news media plays a crucial role in shaping public opinion toward various important issues (De Vreese, 2004; McCombs and Reynolds, 2009; Perse and Lambe, 2016), bias in media reporting can reinforce the problem of political polarization and undermining civil society rights.

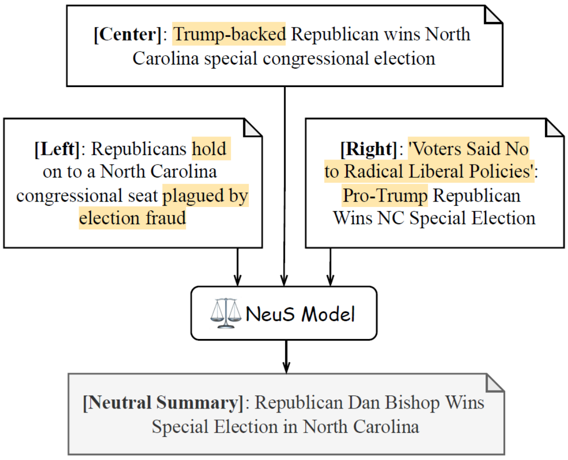

Figure 1: Illustration of the proposed task. We want to generate neutral summarization of news articles from varying of political orientations. Orange highlights indicate phrases that can be considered framing bias.

Allsides.com (Sides, 2018) mitigates this problem by displaying articles from various media in a single interface along with an expert-written roundup of news articles. This roundup is a neutral summary for readers to grasp a bias-free understanding of an issue before reading individual articles. Although Allsides fights framing bias, scalability still remains a bottleneck due to the time-consuming human labor needed for composing the roundup. Multi-document summarization (MDS) models (Lebanoff et al., 2018; Liu and Lapata, 2019) could be one possible choice for automating the roundup generation as both multi-document summaries and roundups share a similar nature in extracting salient information out of multiple input articles. Yet the ability of MDS models to provide *neutral* description of a topic issue – a crucial aspect of the roundup – remains unexplored.

---

[*] This work was done when the author was studying at The Hong Kong University of Science and Technology.

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3131 - 3148
July 10-15, 2022

In this work, we fill in this research gap by proposing a task of Neutral multi-news Summarization (NEUS), which aims to generate a framing-bias-free summary from news articles with varying degrees and orientation of political bias (Fig. 1). To begin with, we construct a new dataset by crawling Allsides.com, and investigate how framing bias manifests in the news so as to provide a more profound and more comprehensive analysis of the problem. The first important insight from our analysis is a close association between framing bias and the polarity of the text. Grounded on this basis, we propose a polarity-based framing-bias metric that is simple yet effective in terms of alignment with human perceptions. The second insight is that titles serve as a good indicator of framing bias. Thus, we propose NEUS models that leverage news titles as an additional signal to increase awareness of framing bias.

Our experimental results provide rich ideas for understanding the problem of mitigating framing bias. Primarily, we explore whether existing summarization models can already solve the problem and empirically demonstrate their shortcomings in addressing the stylistic aspect of framing bias. After that, we investigate and discover an interesting relationship between framing bias and hallucination, an important safety-related problem in generation tasks. We empirically show that the hallucinatory generation has the risk of being not only factually inaccurate and/or unverifiable but also politically biased and controversial. To the best of our knowledge, this aspect of hallucination has not been previously discussed. We thus hope to encourage more attention toward hallucinatory framing bias to prevent automatic generations from fueling political bias and polarization.

We conclude by discussing the remaining challenges to provide insights for future work. We hope our work with the proposed NEUS task serves is a good starting point to promote the automatic mitigation of media framing bias.

2 Related Works

Media Bias Media bias has been studied extensively in various fields such as social science, economics, and political science. Media bias is known to affect readers' perceptions of news in three main ways: priming, agenda-setting, and framing[1](Scheufele, 2000). Framing is a broad term that refers to any factor or technique that affect how individuals perceive certain reality or information (Goffman, 1974; Entman, 1993, 2007; Gentzkow and Shapiro, 2006). In the context of news reports, framing is about how an issue is characterized by journalists and how readers take the information to form their impression (Scheufele and Tewksbury, 2007). Our work specifically focuses on framing "bias" that exists as a form of text in the news. More specifically, we focus on different writing factors such as word choices and the commission of extra information that sway an individual's perception of certain events.

Media Bias Detection In natural language processing (NLP), computational approaches for detecting media bias often consider linguistic cues that induce bias in political text (Recasens et al., 2013; Yano et al., 2010; Lee et al., 2019; Morstatter et al., 2018; Lee et al., 2019; Hamborg et al., 2019b; Lee et al., 2021b; Bang et al., 2021). For instance, Gentzkow and Shapiro count the frequency of slanted words within articles. These methods mainly focus on the stylistic ("how to cover") aspect of framing bias. However, relatively fewer efforts have been made toward the informational ("what to cover") aspect of framing bias (Park et al., 2011; Fan et al., 2019). Majority of literature doing informational detection are focused on more general factual domain (non-political information) in the name of "fact-checking" (Thorne et al., 2018; Lee et al., 2018, 2021a, 2020). However, these methods cannot be directly applied to media bias detection because there does not exist reliable source of gold standard truth to fact-check biased text upon.

Media Bias Mitigation News aggregation, by displaying articles from different news outlets on a particular topic (e.g., Google News,[2] Yahoo News[3]), is the most common approach to mitigate media bias (Hamborg et al., 2019a). However, news aggregators require willingness and effort from the readers to be resistant to framing biases and identify the neutral fact from differently framed articles. Other approaches have been proposed to

---

[1] Priming happens when news reporting tells the reader what context of the event should they evaluate the event in; Agenda-setting is when news reporting tell readers what are the most important problems to think about

[2] https://news.google.com/

[3] https://news.yahoo.com/

provide additional information (Laban and Hearst, 2017), such as automatic classification of multiple viewpoints (Park et al., 2009), multinational perspectives (Hamborg et al., 2017), and detailed media profiles (Zhang et al., 2019b). However, these methods focus on providing a broader perspective to readers from an enlarged selection of articles, which still puts the burden of mitigating bias on the readers. Instead, we propose to automatically neutralize and summarize partisan articles to produce a neutral article summary.

Multi-document Summarization As a challenging subtask of automatic text summarization, multi-document summarization (MDS) aims to condense a set of documents to a short and informative summary (Lebanoff et al., 2018). Recently, researchers have applied deep neural models for the MDS task thanks to the introduction of large-scale datasets (Liu et al., 2018; Fabbri et al., 2019). With the advent of large pre-trained language models (Lewis et al., 2019; Raffel et al., 2019), researchers have also applied them to improve the MDS models, performance (Jin et al., 2020; Pasunuru et al., 2021). In addition, many works have studied particular subtopics of the MDS task, such as agreement-oriented MDS (Pang et al., 2021), topic-guided MDS (Cui and Hu, 2021) and MDS of medical studies (DeYoung et al., 2021). However, few works have explored generating framing-bias-free summaries from multiple news articles. To add to this direction, we propose the NEUS task and creates a new benchmark.

3 Task and Dataset

3.1 Task Formulation

The main objective of NEUS is to generate a neutral article summary A_{neu} given multiple news articles $A_{0...N}$ with varying degrees and orientations of political bias. The neutral summary A_{neu} should (i) retain salient information and (ii) minimize as much framing bias as possible from the input articles.

3.2 ALLSIDES Dataset

Allsides.com provides access to triplets of news, which comprise reports from left, right, and center American publishers on the same event, with an expert-written neutral summary of the articles and its neutral title. The dataset language is English and mainly focuses on U.S. political topics that often result in media bias. The top-3 most frequent topics[4] are 'Elections', 'White House', and 'Politics'.

We crawl the article triplets[5] to serve as the source inputs $\{A_L, A_R, A_C\}$, and the neutral article summary to be the target output A_{neu} for our task. Note that "center" does not necessarily mean completely bias-free (all, 2021) as illustrated in Table 1. Although "center" media outlets are relatively less tied to a particular political ideology, their reports may still contain framing bias because editorial judgement naturally leads to human-induced biases. In addition, we also crawl the title triplets $\{T_L, T_R, T_C\}$ and the neutral issue title T_{neu} that are later used in our modeling.

To make the dataset richer, we also crawled other meta-information such as date, topic tags, and media name. In total, we crawled $3,564$ triplets ($10,692$ articles). We use 2/3 of the triplets, which is $2,276$, to be our training and validation set ($80 : 20$ ratio), and the remaining $1,188$ triples as our test set. We will publicly release this dataset for future research use.

4 Analysis of Framing Bias

The literature on media framing bias from the NLP community and social science studies provide the definition and types of framing bias (Goffman, 1974; Entman, 1993; Gentzkow et al., 2015; Fan et al., 2019) — *Informational framing bias* is the biased selection of information (tangential or speculative information) to sway the minds of readers. *Lexical framing bias* is a sensational writing style or linguistic attributes that may mislead readers. However, the definition is not enough to understand exactly how framing bias manifests in real examples such as, in our case, the ALLSIDES dataset. We conduct a case-study to obtain concrete insights to guide our design choices for defining the metrics and methodology.

4.1 Case-Study Observations

First, we identify and share the examples of framing bias in accordance with the literature (Table 1).

Informational Bias This bias exists dominantly in the form of "extra information" on top of the salient key information about an issue that changes the overall impression of it. For example, in Table 1, when reporting about the hold put on mil-

---

[4] The full list is provided in the appendix.

[5] In some cases, Allsides does not provide all three reportings, and such cases are filtered out.

Issue A: Trump Put Hold On Military Aid To Ukraine Days Before Call To Ukrainian President
Left: Trump ordered hold on military aid days before calling Ukrainian president, officials say
Right: Trump administration claims Ukraine aid was stalled over corruption concerns, decries media ‘frenzy’

Issue B: Michael Reinoehl appeared to target right-wing demonstrator before fatal shooting in Portland, police say
Left: Suspect in killing of right-wing protester fatally shot during arrest
Right: Portland’s Antifa-supporting gunman appeared to target victim, police say
Center: Suspect in Patriot Prayer Shooting Killed by Police

Issue C: Trump Says the ‘Fake News Media’ Are ‘the true Enemy of the People’
Left: President Trump renews attacks on press as ‘true enemy of the people’ even as CNN receives another suspected bomb
Right: ‘Great Anger’ in America caused by ‘fake news’ — Trump rips media for biased reports’
Center: Trump blames ’fake news’ for country’s anger : ’the true enemy of the people’

Table 1: Illustration of differences in framing from Left/Right/Center media with examples from ALLSIDES dataset. We use titles for the analysis of bias, since they are simpler to compare and are representative of the framing bias that exists in the article.

itary aid to Ukraine (Issue A), the right-leaning media reports the speculative claim that there were “corruption concerns” and tangential information “decries media ‘frenzy’” that amplifies the negative impression of the issue. Sometimes, media with different political leanings report additional information to convey a completely different focus on the issue. For Issue C, left-leaning media implies that Trump’s statement about fake news has led to “CNN receiving another suspected bomb”, whereas right-leaning media implies that the media is at fault by producing “biased reports”.

Lexical Bias This bias exists mainly as biased word choices that change the nuance of the information that is being delivered. For example, in Issue B, we can clearly observe that two media outlets change the framing of the issue by using different terms “suspect” and “gunman” to refer to the shooter, and “protester” and “victim” to refer to the person shot. Also, in Issue A, when one media outlet uses “(ordered) hold”, another media uses “stalled”, which has a more negative connotation.

4.2 Main Insights from Case-Study

Next, we share important insights from the case study observation that guide our metric and model design.

Relative Polarity Polarity is one of the commonly used attributes in identifying and analyzing framing bias (Fan et al., 2019; Recasens et al., 2013). Although informational and lexical bias is conceptually different, both are closely associated with polarity changes of concept, i.e., positive or negative, to induce strongly divergent emotional responses from the readers (Hamborg et al., 2019b). Thus, polarity can serve as a good indicator of framing bias.

However, we observe that the polarity of text must be utilized with care in the context of framing bias. *It is the relative polarity that is meaningful to indicate the framing bias, not the absolute polarity*. To elaborate, if the news issue itself is about tragic events such as “Terror Attack in Pakistan” or “Drone Strike That Killed 10 people”, then the polarity of neutral reporting will also be negative.

Indicator of Framing We discover that the news title is very representative of the framing bias that exist in the associated articles – this makes sense because the title can be viewed as a succinct overview of the content that follows[6]. For instance, in Table 3 the source input example, the right-leaning media’s title, and article are mildly mocking of the “desperate” democrats’ failed attempts to take down President Trump. In contrast, the left-leaning media’s title and an article show a completely different frame – implying that many investigations are happening and there is “possible obstruction of justice, public corruption, and other abuses of power.”

5 Metric

We use three metrics to evaluate summaries from different dimensions. For framing bias, we propose a polarity-based metric based on the careful design choices detailed in §5.1. For evaluating whether the summaries retain salient information, we adopt commonly used information recall metrics (§5.2). In addition, we use a hallucination metric to evaluate if the generations contain any unfaithful hallu-

---

[6] There can be exceptions for the non-main-stream media that use clickbait titles.

cinatory information because the existence of such hallucinatory generations can make the summary fake news (§5.3).

5.1 Framing Bias Metric

5.1.1 Design Consideration

Our framing bias metric is developed upon the insights we obtained from our case study in §4.

First of all, we propose to build our metric based on the fact that framing bias is closely associated with polarity. Both model-based and lexicon-based polarity detection approaches are options for our work, and we leverage the latter for the following reasons: 1) There is increasing demand for interpretability in the field of NLP (Belinkov et al., 2020; Sarker et al., 2019), and the lexicon-based approach is more interpretable (provides token-level human interpretable annotation) compared to black-box neural models. 2) In the context of framing bias, distinguishing the subtle nuance of words between synonyms is crucial (e.g., dead vs. murdered). The lexicon-resource provides such token-level fine-grained scores and annotations, making it useful for our purpose.

Metric calibration is the second design consideration, and is motivated by our insight into the relativity of framing bias. The absolute polarity of the token itself does not necessarily indicate framing bias (i.e., the word "riot" has negative sentiment but does not always indicate bias), so it is essential to measure the relative degree of polarity. Therefore, calibration of the metric in reference to the neutral target is important. Any tokens existing in the neutral target will be ignored in bias measurement for the generated neutral summary. For instance, if "riot" exists in the neutral target, it will not be counted in bias measurement through calibration.

5.1.2 Framing Bias Metric Details

For our metric, we leverage Valence-Arousal-Dominance (VAD) (Mohammad, 2018) dataset which has a large list of lexicons annotated for valence (v), arousal (a) and dominance (d) scores. Valence, arousal, and dominance represent the direction of polarity (positive, negative), the strength of the polarity (active, passive), and the level of control (powerful, weak), respectively.

Given the neutral summary generated from the model $\hat{A}_{neu}$, our metric is calculated using the VAD lexicons in the following way:

1. Filter out all the tokens that appear in neutral target A_{neu} to obtain set of tokens *unique* to $\hat{A}_{neu}$. This ensures that we are measuring the *relative* polarity of $\hat{A}_{neu}$ in reference to the neutral target A_{neu} – results in calibration effect.
2. Select tokens with either positive valence ($v > 0.65$) or negative valence ($v < 0.35$) to eliminate neutral words (i.e., stopwords and non-emotion-provoking words) – this step excludes tokens that are unlikely to be associated with framing bias from the metric calculation.
3. Sum the arousal scores for the identified positive and negative tokens from Step 2 – positive arousal score ($Arousal_+$) and negative arousal score ($Arousal_-$). We intentionally separate the positive and negative scores for finer-grained interpretation. We also have the combined arousal score ($Arousal_{sum}$=$Arousal_+$+$Arousal_-$) for a coarse view.
4. Repeat for all $\{A_{neu}, \hat{A}_{neu}\}$ pairs in the testset, and calculate the average scores to use as the final metric. We report these scores in our experimental results section (§7).

In essence, our metric approximates the existence of framing bias by quantifying how intensely aroused and sensational the generated summary is in reference to the target neutral reference. We publicly release our metric code for easy use by other researchers[7].

5.1.3 Human Evaluation

To ensure the quality of our metric, we evaluate the correlation between our framing bias metric and human judgement. We conduct A/B testing[8] where the annotators are given two generated articles about an issue, one with a higher $Arousal_{sum}$ score and the other with a lower score. Then, annotators are asked to select the more biased article summary. When asking which article is more "biased", we adopt the question presented by Spinde et al. We also provide examples and the definition of framing bias for a better understanding of the task. We obtain three annotations each for 50 samples and select those with the majority of votes.

A critical challenge of this evaluation is in controlling the potential involvement of the annotators'

---

[7] https://github.com/HLTCHKUST/framing-bias-metric

[8] Please refer the appendix for more detail of the A/B testing

personal political bias. Although it is hard to eliminate such bias completely, we attempt to avoid it by collecting annotations from those indifferent to the issues in the test set. Specifically, given that our test set mainly covers US politics, we restrict the nationality of annotators to non-US nationals who view themselves bias-free towards any US political parties.

After obtaining the human annotations from A/B testing, we also obtain automatic annotation based on the proposed framing bias metric score, where the article with a higher $Arousal_{sum}$ is chosen to be the more biased generation. The Spearman correlation coefficient between human-based and metric-based annotations is 0.63615 with a p-value < 0.001, and the agreement percentage 80%. These values indicate that the association between the two annotations is statistically significant, suggesting that our metric provides a good approximation of the existence of framing bias.

5.2 Salient Info

The generation needs to retain essential/important information while reducing the framing bias. Thus, we also report ROUGE (Lin, 2004) and BLEU (Papineni et al., 2002) between the generated neutral summary, $\hat{A}_{neu}$, and human-written summary, A_{neu}. Note that ROUGE measures the recall (i.e., how often the n-grams in the human reference text appear in the machine-generated text) and BLEU measures the precision (i.e., how often the n-grams in the machine-generated text appear in the human reference text). The higher the BLEU and ROUGE1-R score, the better the essential information converges. In our results, we only report Rouge-1, but Rouge-2 and Rouge-L can be found in the appendix.

5.3 Hallucination Metric

Recent studies have shown that neural sequence models can suffer from the hallucination of additional content not supported by the input (Reiter, 2018; Wiseman et al., 2017; Nie et al., 2019; Maynez et al., 2020; Pagnoni et al., 2021; Ji et al., 2022), consequently adding factual inaccuracy to the generation of NLG models. Although not directly related to the goal of NEUS, we evaluate the hallucination level of the generations in our work. We choose a hallucination metric called FeQA (Durmus et al., 2020) because it is one of the publicly available metrics known to have a high correlation with human faithfulness scores. This is a question-answering-based metric built on the assumption that the same answers will be derived from hallucination-free generation and the source document when asked the same questions.

6 Models and Experiments[9]

6.1 Baseline Models

Since one common form of framing bias is the reporting of extra information (§4), summarization models, which extract commonly shared salient information, may already generate a neutral summaries to some extent. To test this, we conduct experiments using the following baselines.

- LEXRANK (Erkan and Radev, 2004): an extractive single-document summarization (SDS) model that extracts representative sentences that hold information common in both left- and right-leaning articles.
- BARTCNN: an abstractive SDS model that fine-tunes BART-large (Lewis et al., 2019), with 406M parameters, using the CNN/DailyMail (Hermann et al., 2015) dataset.
- BARTMULTI: a multi-document summarization (MDS) model that fine-tunes BART-large using Multi-News (Fabbri et al., 2019) dataset.
- PEGASUSMULTI: an MDS model that fine-tunes Pegasus-base (Zhang et al., 2019a), with 568M parameters, using the Multi-News dataset.

Since the summarization models are not trained with in-domain data, we provide another baseline model trained with in-domain data for a full picture.

- NEUSFT: a baseline that fine-tunes the BART-large model using ALLSIDES.

6.2 Our NEUS Models (NEUS-TITLE)

We design our models based on the second insight from the case study (§4) - the news title serves as an indicator of the framing bias in the corresponding article. We hypothesize that it would be helpful to divide-and-conquer by neutralizing the the title first, then leveraging the "neutralized title" to guide the final neutral summary of the longer articles.

Multi-task learning (MTL) is a natural modeling choice because two sub-tasks are involved – title-level and article-level neutral summarization.

---

[9] Experimental details are provided in the appendix for reproducibility.

Models	Avg. Framing Bias Metric			Salient Info		Hallucination
	$Arousal_{+}\downarrow$	$Arousal_{-}\downarrow$	$Arousal_{sum}\downarrow$	BLEU↑	ROUGE1-R↑	FeQA↑
All Source input	6.76	3.64	10.40	8.27	56.57%	-
LexRank	3.02	1.74	4.76	**12.21**	39.08%	53.44%
BartCNN	2.09	1.23	3.32	10.49	35.63%	58.03%
PegasusMulti	5.12	2.39	7.51	6.12	**44.42%**	22.24%
BartMulti	5.94	2.66	8.61	4.24	35.76%	21.06%
NeuSFT	1.86	1.00	2.85	11.67	35.11%	**58.50%**
NeuS-Title	**1.69**	**0.83**	**2.53**	12.05	36.07%	45.95%

Table 2: Experimental results for AllSides test set. We provide the level of framing bias inherent in "source input" from the AllSides test set to serve as a reference point for the framing bias metric. For framing bias metric, the *lower* number is the better (↓). For other scores, the *higher* number is the better (↑).

Meanwhile, we also have to ensure a hierarchical relationship between the two tasks in our MTL training because article-level neutral summarization leverages the generated neutral title as an additional resource. We use a simple technique to do hierarchical MTL by formatting our hierarchical data pair (title, article) in a single natural language text with identifier-tokens ("Title=>", "Article=>"). This technique allows us to optimize for both title and article neutral summarization tasks easily by optimizing for the negative log-likelihood of the single target Y. The auto-regressive nature of the decoder also ensures the hierarchical relationship between the title and article.

We train BART's autoregressive decoder to generate the target text Y formatted as follows:

$$\texttt{TITLE} \Rightarrow T_{neu}.\ \texttt{ARTICLE} \Rightarrow A_{neu},$$

where T_{neu} and A_{neu} denote the neutral title and neutral article summary.

The input X to our BART encoder is formatted similarly to the target text Y:

$$\texttt{TITLE} \Rightarrow T_L.\ \texttt{ARTICLE} \Rightarrow A_L.[SEP]$$
$$\texttt{TITLE} \Rightarrow T_C.\ \texttt{ARTICLE} \Rightarrow A_C.[SEP]$$
$$\texttt{TITLE} \Rightarrow T_R.\ \texttt{ARTICLE} \Rightarrow A_R,$$

where $T_{L/C/R}$ and $A_{L/C/R}$ denote the title and article from left-wing, center, and right-wing media, and [SEP] denotes the special token that separates different inputs. Note that the order of left, right, and center are randomly shuffled for each sample to discourage the model from learning spurious patterns from the input.

7 Results and Analysis

In this section, we point out noteworthy observations from the quantitative results in Table 2 along with insights obtained through qualitative analysis. Table 3 shows generation examples that are most representative of the insights we share.[10]

7.1 Main Results

Firstly, summarization models can reduce the framing bias to a certain degree (drop in $Arousal_{sum}$ score from 10.40 to 4.76 and 3.32 for LexRank and BartCNN). This is because informational framing bias is addressed when summarization models extract the most salient sentences, which contain common information from the inputs. However, summarization models, especially LexRank cannot handle the lexical framing bias, as shown in Table 3. Moreover, if we further observe the results of LexRank, it is one of the best performing models in terms of ROUGE1-R (39.08%), the standard metric for summarization performance, but not in terms of the framing bias metric. This suggests that *having good summarization performance (*ROUGE1-R*) does not guarantee that the model is also neutral* – i.e., the requirement for summaries to be neutral adds an extra dimension to the summarization task.

Secondly, one interesting pattern that deserves attention is that only the single-document summarization models (BartCNN and LexRank) reduced framing bias well, not the multi-document summarization models (PegasusMulti and BartMulti). This is rather surprising because our task setup is more similar to MDS than SDS. One of the major contributors to high bias in the MDS models is probably the hallucination because MDS models portray drastically poor hallucination performance than all the other models (both the MDS models PegasusMulti and BartMulti achieve

---

[10] More examples are provided in the appendix.

SOURCE: <Left> Title: Here Are The 81 People And Entities Close To Trump Democrats Are Investigating. **Article:** Democrats on the House Judiciary Committee on Monday sent document requests to 81 agencies, entities and individuals close to President Donald Trump as part of a broad investigation into possible obstruction of justice, public corruption and other abuses of power. The list includes Trump's sons, Eric Trump and Donald Trump Jr., as well as his son-in-law, Jared Kushner.
<Center> Title: House Panel Requests Documents From Associates of Trump. **Article:** House Democrats intensified their investigations into President Trump and his associates Monday, demanding records from more than 80 people and organizations related to his business dealings, interactions with the Justice Department and communications with Russian President Vladimir Putin.
<Right> Title: Dems Continue Their Assault on The Trump Administration By Launching Another Probe. **Article:** Democrats are desperate to take down President Donald Trump. The Russia probe has proven to be ineffective and, quite frankly, a waste of time and taxpayer money. They didn't find what they wanted so now they're launching another probe.

TARGET: House Democrats launched a broad probe into President Trump on Monday, requesting documents from 81 agencies and individuals as they investigate his business dealings, interactions with Russia, and possible obstruction of justice.

Lexrank: Democrats are desperate to take down President Donald Trump. The Russia probe has proven to be ineffective and, quite frankly, a waste of time and taxpayer money.

NeuSFT: The Russia probe has proven to be ineffective and, quite frankly, a waste of time and taxpayer money.

NeuS-Title: TITLE=> House Panel Requests Documents. ARTICLE=> The House Select Committee on Intelligence has requested documents from 81 people and entities close to President Trump, including his sons Eric and Donald Trump Jr., as well as Jared Kushner.

Table 3: Generation examples for analysis purposes. Red highlights the tokens identified by VAD lexicons. Refer to the appendix for more examples.

SOURCE: ... President Trump on Saturday blasted what he called the "phony" BuzzFeed story and the mainstream media's coverage of it....

MDS Hallucination: president trump on sunday slammed what he called called a "phony" story by the "dishonest" and "fake news" news outlet in a series of tweets. ... "the fake news media is working overtime to make this story look like it is true," trump tweeted. "they are trying to make it look like the president is trying to hide something, but it is not true!"

Table 4: Illustration of hallucinatory framing bias from MDS models and the corresponding "most relevant source snippet" from the source input. Refer to the appendix for more examples with full context.

22.24% and 21.06%, when most of the other models achieve over 50%).[11] This suggests that the framing bias of MDS models may be related to the hallucination of politically biased content. We investigate into this in the next subsection (§7.2).

Thirdly, although summarization models help reduce the framing bias scores, we, unsurprisingly, observe a more considerable bias reduction when training with in-domain data. NeuSFT shows a further drop across all framing bias metrics without sacrificing the ability to keep salient information. However, we observe that NeuSFT often copies directly without any neutral re-writing – e.g., the NeuSFT example shown in Table 3 is a direct copy of the sentence from the input source.

Lastly, we can achieve slightly further improvement with NeuS-Title across all metrics except the FeQA score. This model demonstrates a stronger tendency to paraphrase rather than directly copy, and has comparatively more neutral framing of the issue. As shown in Table 3, when LexRank and NeuSFT are focused on the "ineffectiveness of Russia probe", the TARGET and NeuS-Title focus on the start of the investigation with the request for documents. NeuS-Title also generate a title with a similar neutral frame to the TARGET, suggesting this title generation guided the correctly framed generation.

7.2 Further Analysis and Discussion

Q: Is hallucination contributing to the high framing bias in MDS models? Through qualitative analysis, we discovered the MDS generations were hallucinating politically controversial or sensational content that did not exist in the input sources. This is probably originating from the

---

[11] Note that 22.24% and 21.06% are already high FeQA scores, however, a comparatively low score in reference.

memorization of either the training data or the LM-pretraining corpus. For instance, in Table 4, we can observe stylistic bias being injected – "the 'dishonest' and 'fake news' news outlet". Also, the excessive elaboration of the president's comment towards the news media, which does not appear the in source or target, can be considered informational bias – "they are trying to make it look like the president is trying to hide something, but it is not true!" *This analysis unveils the overlooked danger of hallucination, which is the risk of introducing political framing bias in summary generations.* Note that this problem is not confined to MDS models only because other baseline models also have room for improvement in terms of the FeQA hallucination score.

Q: What are the remaining challenges and future directions? The experimental results of NEUS-TITLE suggest that there is room for improvement. We qualitatively checked some error cases and discovered that the title-generation is, unsurprisingly, not always accurate, and the error propagating from the title-generation step adversely affected the overall performance. Thus, one possible future direction would be to improve the neutral title generation, which would then improve the neutral summarization.

Another challenge is the subtle lexical bias involving nuanced word choices that manoeuvre readers to understand the events from biased frames. For example, "put on hold" and "stalled" both mean the same outcome, but the latter has a more negative connotations. Improving the model's awareness of such nuanced words or devising ways to incorporate style-transfer-based bias mitigation approaches (Liu et al., 2021) could be another helpful future direction.

We started the neutral summarization task assuming that framing bias originates from the source inputs. However, our results and analysis suggest that hallucination is another contributor to framing bias. Leveraging hallucination mitigation techniques would be a valuable future direction for the NEUS task. We believe it will help to reduce informational framing bias, although it may be less effective to lexical framing biases. Moreover, our work can also be used to facilitate hallucination research as well. We believe the proposed framing bias metric will help researchers evaluate hallucinatory phenomena from different angles other than "factuality". The proposed framing bias metric could also be adapted to the hallucination problem without a "neutral" reference. The source input can substitute the "neutral" reference to measure if the generated summary is more politically biased than the source – a potential indication of political hallucination.

8 Conclusion

We introduce a new task of Neutral Multi-News Summarization (NEUS) to mitigate media framing bias by providing a neutral summary of articles, along with the dataset ALLSIDES and a set of metrics. Throughout the work, we share insights to understand the challenges and future directions in the task. We show the relationships among polarity, extra information, and framing bias, which guides us to the metric design, while the insight that the title serves as an indicator of framing bias leads us to the model design. Our qualitative analysis reveals that hallucinatory content generated by models may also contribute to framing bias. We hope our work stimulates researchers to actively tackle political framing bias in both human-written and machine-generated texts.

Ethical Considerations

The idea of unbiased journalism has always been challenged[12] because journalists will make their own editorial judgements that can never be guaranteed to be completely bias-free. Therefore, we propose to generate a comprehensive summary of articles from different political leanings, instead of trying to generate a gold standard "neutral" article.

One of the considerations is the bias induced by the computational approach. Automatic approaches replace a known source bias with another bias caused by human-annotated data or the machine learning models. Understanding the risk of uncontrolled adoption of such automatic tools, careful guidance should be provided in how to adopt them. For instance, an automatically generated neutral summary should be provided with reference to the original source instead of standing alone.

We use news from English-language sources only and largely American news outlets throughout this paper. Partisanship from this data refers to domestic American politics. We note that this work does not cover media bias at the international-level or in other languages. In future work, we

---

[12] https://www.allsides.com/blog/does-unbiased-news-really-exist

will explore the application of our methodology to different cultures or languages. However, we hope the paradigm of NEUS, providing multiple sides to neutralize the view of an issue, can encourage future research in mitigating framing bias in other languages or cultures.

Appendix

A Topics covered in ALLSIDESdataset

The ALLSIDESdataset language is English and mainly focuses on U.S. political topics that often result in media bias. The top-5 most frequent topics are 'Elections', 'White House', 'Politics', 'Coronavirus', 'Immigration'.

The full list is as follow (in a descending order of frequency): ['Elections', 'White House', 'Politics', 'Coronavirus', 'Immigration', 'Violence in America', 'Economy and Jobs', 'Supreme Court', 'Middle East', 'US House', 'Healthcare', 'World', 'US Senate', 'National Security', 'Gun Control and Gun Rights', 'Media Bias', 'Federal Budget', 'Terrorism', 'US Congress', 'Foreign Policy', 'Criminal Justice', 'Justice Department', 'Trade', 'Impeachment', 'Donald Trump', 'North Korea', 'Russia', 'Education', 'Environment', 'Free Speech', 'FBI', nan, 'Abortion', 'General News', 'Disaster', 'US Military', 'Technology', 'LGBT Rights', 'Sexual Misconduct', 'Voting Rights and Voter Fraud', 'Joe Biden', 'Race and Racism', 'Economic Policy', 'Justice', 'Holidays', 'Taxes', 'China', 'Polarization', 'Democratic Party', 'Religion and Faith', 'Sports', 'Homeland Security', 'Culture', 'Cybersecurity', 'National Defense', 'Public Health', 'Civil Rights', 'Europe', 'Great Britain', 'Banking and Finance', 'Republican Party', 'NSA', 'Business', 'State Department', 'Facts and Fact Checking', 'Media Industry', 'Labor', 'Veterans Affairs', 'Campaign Finance', 'Life During COVID-19', 'Transportation', 'Marijuana Legalization', 'Agriculture', 'Arts and Entertainment', 'Fake News', 'Campaign Rhetoric', 'Nuclear Weapons', 'Israel', 'Asia', 'CIA', 'Role of Government', 'George Floyd Protests', "Women's Issues", 'Safety and Sanity During COVID-19', 'Animal Welfare', 'Treasury', 'Science', 'Climate Change', 'Domestic Policy', 'Energy', 'Housing and Homelessness', 'Bridging Divides', 'Mexico', 'Inequality', 'COVID-19 Misinformation', 'ISIS', 'Palestine', 'Bernie Sanders', 'Tulsi Gabbard', 'Sustainability', 'Family and Marriage', 'Pete Buttigieg', 'Welfare', 'Opioid Crisis', 'Amy Klobuchar', 'Food', 'EPA', 'South Korea', 'Alaska: US Senate 2014', 'Social Security', 'US Constitution', 'Tom Steyer', 'Andrew Yang', 'Africa']

B Additional Salient Information Score Results

We report additional Salient information F1 (Table 5) and Recall (Table 6) scores for ROUGE1, ROUGE2 and ROUGEL.

	ROUGE1 F1	ROUGE2 F1	ROUGEL F1
LEXRANK	33.60%	13.60%	29.77%
BARTCNN	33.76%	13.67%	30.57%
PEGASUSMULTI	30.03%	10.28%	26.70%
BARTMULTI	23.01%	6.84%	20.55%
NEUSFT	36.76%	16.27%	32.86%
NEUS-TITLE	35.49%	15.69%	32.05%

Table 5: Additional Salient Info Scores. F1 scores for ROUGE1, ROUGE2 and ROUGEL for ALLSIDES testset. For the scores, the *higher* number is the better.

C Details for Human Evaluation (A/B testing)

We first presented the participants with the definition of framing bias from our paper, and also showed examples in Table 1 to ensure they understand what framing bias is. Then we asked the following question: "Which one of the articles do you believe to be more biased toward one side or the other side in the reporting of news?" This is modified to serve as a question for AB testing based on "To what extent do you believe that the article is biased toward one side or the other side in the reporting of news?" The original question is one of the 21 questions which are suitable and reliable for measuring the perception of media bias, designed by Spinde et al. (2021).

The participants (research graudate students) have different nationalities including Canada, China, Indonesia, Iran, Italy, Japan, Poland and South Korea (ordered in an alphabetical order). All of participants answered to be not having political leaning towards U.S. politics. All participants are fully explained on the usage of collected data in this particular work and agreed on it.

	ROUGE1 RECALL	ROUGE2 RECALL	ROUGEL RECALL
LEXRANK	39.08%	17.66%	34.69%
BARTCNN	35.63%	15.32%	32.22%
PEGASUSMULTI	44.42%	16.99%	39.45%
BARTMULTI	35.76%	12.48%	32.08%
NEUSFT	35.11%	15.74%	31.43%
NEUS-TITLE	36.07%	16.47%	32.63%

Table 6: Additional Salient Info Scores. Recall scores for ROUGE1, ROUGE2 and ROUGEL for ALLSIDES testset. For the scores, the *higher* number is the better.

D Experimental Setup Details

All our experimental codes are based on the HuggingFace (Wolf et al., 2020). We used the following hyperparameters during training and across models: 10 epoch size, $3e-5$ learning rate, and a batch size of 16. We did not do hyper-parameters tuning since our objective is to provide various baselines and analysis. Training run-time for all of our experiments are fast ($<$ 6hr). We ran all experiments with one NVIDIA 2080Ti GPU with 16 GB of memory. The experiment was a single-run.

E Generation Examples from Different Models

To help better understand performances of each models, we provide more examples of generation from all baseline models and our proposed models along with the target neutral article summary. The examples can be found in Table 7, 8, 9.

F Illustration of hallucinatory framing bias

In Table 10, we provide more examples of hallucinatory framing bias that was discussed in analysis.

Target: *The House Ways and Means Committee has requested that the IRS turn over the last six years of tax returns from President Trump.*

LEXRANK: Representative Richard Neal invoked law that allows House Ways and Means Committee chair to obtain any person's tax information. The request by House Democrats for six years of Donald Trump's tax returns opens a serious new political, legal, constitutional and personal front in the party's battle to use its new majority to check a defiant President.

BARTCNN: Rep. Richard Neal invoked law that allows House Ways and Means Committee chair to obtain any person's tax information. The request by House Democrats for six years of Donald Trump's tax returns opens a serious new political, legal, constitutional and personal front in the party's battle to use its new majority to check a defiant President.

PEGASUSMULTI: The battle over President Trump's tax returns is officially on. Rep. Richard Neal, chairman of the House Ways and Means Committee, on Wednesday formally asked the IRS for six years of Trump's personal and business tax returns, as well as the returns of some of his companies, reports the Washington Post. The panel has the power to subpoena someone's tax information, and Neal has signaled that he plans to do just that. "The American people have a right to know who the president of the United States is, and we have a responsibility to do our part to ensure that the tax laws are administered in an efficient and thorough manner," he said in a statement, per the Hill. The White House has signaled that it will fight the request, with press secretary Sarah Huckabee Sanders calling it "an abuse of the tax-writing committee's authority." The letter to the IRS was signed by Neal, a Massachusetts Democrat, and was obtained by the Wall Street Journal. The Journal notes that Neal has the authority under a law passed in 1969 that allows the House Ways and Means Committee to obtain tax information from anyone.

BARTMULTI: the head of the powerful house tax-writing committee has asked the government for six years of president trump's tax returns, a move that is expected to lead to a long court battle with the white house, the washington post reports. in a letter to the irs on wednesday, rep. richard h. Neal, chairman of the house ways and means committee, invoked a law that allows any person to obtain any person's personal tax information, the wall street journal reports. according to the hill, the move is a " serious new political, legal, constitutional, and personal front in the party's battle to use its new majority to check a defiant president. " it is a bid to solve one of the most tantalizing and enduring mysteries of the trump campaign and his presidency — what is it in the president's unseen financial and business life that he doesn't want americans to see?

NEUSFT: House Ways and Means Committee Chair Richard Neal (D-MA) has formally requested President Trump's tax returns from the IRS.

NEUS-TITLE: TITLE=> House Committee Seeks Trump Tax Returns. ARTICLE=> The House Ways and Means Committee formally requested President Trump's tax returns on Wednesday, kicking off what could be a protracted legal fight between Congress and the Trump administration.

Table 7: Neutral Summary Generation Examples from baseline models and NEUS-TITLE.

Target: *The State Department has blocked Gordon Sondland, the U.S. Ambassador to the European Union, from testifying at a scheduled deposition on the Ukraine controversy. Sondland is a key figure as he had texted with Bill Taylor, a top U.S. diplomat in Ukraine, arguing over allegations of a quid pro quo. This move by the State Department has triggered a new clash with House Democrats as part of their impeachment inquiry, and President Trump has dismissed the deposition as a "a kangaroo court" as he defended the State Department decision.*

LEXRANK: The Trump administration on Tuesday blocked a planned deposition from Gordon Sondland, the U.S. ambassador to the European Union and a central figure in the Democrats' impeachment inquiry, according to a statement by his lawyer. Democrats swiftly called the administration's move an act of obstruction and accused President Trump of hiding information about his efforts to pressure the Ukrainian government to investigate his political rivals.

BARTCNN: The State Department instructed Ambassador to the European Union Gordon Sondland not to appear for the deposition, according to his counsel. Democrats swiftly called the administration's move an act of obstruction and accused President Trump of hiding information about his efforts to pressure the Ukrainian government to investigate his political rivals.

PEGASUSMULTI: The Trump administration has blocked US ambassador to the European Union Gordon Sondland from testifying before a House panel investigating possible obstruction of justice by the president, the New York Times reports. Sondland is a key witness in the probe into whether Trump obstructed justice when he fired FBI chief James Comey. Sondland had been scheduled to testify in front of the House Judiciary Committee on Tuesday, but the State Department ordered him not to appear, according to the Washington Post. Sondland is a former British ambassador to the US. In a Tuesday tweet, President Trump said he would love to send Sondland to testify, "but unfortunately he would be testifying before a totally compromised kangaroo court, where Republican's rights have been taken away, and true facts are not allowed out for the public to see." He added: "I believe you are incorrect about President Trump's intentions."

BARTMULTI: a key witness in the house impeachment inquiry was ordered not to appear at a scheduled deposition on tuesday, ramping up tensions between congressional democrats and the trump administration. the state department instructed ambassador to the eu and key figure in the impeachment inquiry, Gordon sondland, not to show up for the deposition, according to his counsel. democrats called the move an act of obstruction and accused president trump of hiding information about his efforts to pressure the ukraine government to investigate his political rivals, the new york times reports. " this is a clear attempt to block testimony from key witnesses in the ongoing impeachment investigation, " said house minority leader nancy pelosi, per the washington post. " it's an impeachable act. " in a tweet tuesday night, trump said he " would love to send ambassador [sundland], a really good man and great american, to testify, but unfortunately he would be testifying before a totally compromised kangaroo court, where republican ' s rights have been taken away, and true facts are not allowed out for the public to see. "

NEUSFT: The Trump administration blocked a planned deposition from Gordon Sondland, the U.S. ambassador to the European Union and a central figure in the Democrats' impeachment inquiry, according to a statement from his lawyer. President Trump responded via Twitter, saying that he "would love to send Ambassador Sonderland, a really good man and great American, to testify, but unfortunately he would be testifying before a totally compromised kangaroo court, where Republican's rights have been taken away, and true facts are not allowed out for the public to see."

NEUS-TITLE: TITLE=> State Dept Orders Ambassador Sondland Not to Testify Before House. ARTICLE=> The State Department has ordered Ambassador Gordon Stondland not to testify before the House of Representatives in the impeachment inquiry of President Donald Trump. Democrats have accused the Trump administration of blocking statements from witnesses.

Table 8: Continued from Previous Page: Neutral Summary Generation Examples from baseline models and NEUS-TITLE.

***Target:** Ukrainian police have opened an investigation into whether or not U.S. Ambassador Marie Yovanovitch came under surveillance before she was recalled from her post in Ukraine last May. Democrats have released documents that show Lev Parnas, an associate of Rudy Giuliani, communicating about Yovanovitch's removal.*

LEXRANK: Ukraine's government announced Thursday that police are investigating whether ousted U.S. ambassador Marie Yovanovitch was subject to illegal surveillance, in response to new documents released ahead of President Trump's impeachment trial. Those documents, released by Democratic lawmakers, showed Lev Parnas – an associate of Trump lawyer Rudy Giuliani – communicating about the removal of Marie Yovanovitch as the ambassador to Ukraine.

BARTCNN: Police in Ukraine have opened a criminal investigation into whether allies of President Trump had the U.S. ambassador to the country under surveillance. Newly released documents suggest that Ms. Yovanovitch was being watched in Kyiv. The Ministry of Internal Affairs of Ukraine says it's asking the FBI to help its inquiry.

PEGASUSMULTI: The Ukraine has opened a criminal investigation into allegations that President Trump's allies had the US ambassador to the country under surveillance while she was stationed in the country, the New York Times reports. According to the Wall Street Journal, the allegations surfaced in newly released documents released by Democrats ahead of Trump's impeachment trial. The documents show that Rudy Giuliani's associate, Lev Parnas, communicated about the removal of Marie Yovanovitch as ambassador to Ukraine with Yovanovitch's former boss at the State Department, Sergey Kislyak. Yovanovitch was removed from her post in May of last year. Ukraine's Ministry of Internal Affairs says it's asking the FBI to help with the investigation. "Ukraine cannot ignore such illegal activities on the territory of its own state," the ministry says in a statement

BARTMULTI: new documents released ahead of president trump's impeachment trial suggest that the us ambassador to the country was under surveillance while she was stationed in the country, the new york times reports. according to the wall street journal, the allegations were made in a text message between a us politician and an associate of trump lawyer rudy giuliani. in the messages, the politician says he'd like to see former ambassador to ukraine and current ambassador to russia, former deputy foreign minister oleksandr turchynov, removed from his post. " i would like to remove him from his position, " the politician wrote in the message, which was sent in april 2017. the messages were sent in response to newly released documents from the house intelligence committee. those documents show that former trump lawyer paul ryan had been trying to get rid of yovanovitch, who was ambassador at the time, for more than a year, the journal reports. the messages also show that ryan's chief of staff, george w. bush, had been in touch with ryan about removing her from her post.

NEUSFT: Ukraine's national police are investigating allegations that U.S. Ambassador Marie Yovanovitch was subjected to illegal surveillance while she was stationed in Kyiv.

NEUS-TITLE: TITLE=> Ukraine Opens Investigation Into Claims U.S. Ambassador Yovanovitch Was Under Surveillance. ARTICLE=> Ukraine's national police are investigating allegations that former U. S. ambassador Marie Yovanovich was subjected to surveillance while she was stationed in Kyiv, following the release of documents by Democratic lawmakers.

Table 9: Continued from Previous Page: Neutral Summary Generation Examples from baseline models and NEUS-TITLE.

[1] Source: Newly released documents suggest that Ms. Yovanovitch was being watched in Kyiv while she was the U.S. ambassador there. The police in Ukraine have opened a criminal investigation into whether allies of President Trump had the United States ambassador to the country under surveillance while she was stationed in Kyiv, the Ukrainian government said on Thursday. [SEP] Ukraine's government announced Thursday that police are investigating whether ousted U.S. ambassador Marie Yovanovitch was subject to illegal surveillance, in response to new documents released ahead of President Trump's impeachment trial. Those documents, released by Democratic lawmakers, showed Lev Parnas – an associate of Trump lawyer Rudy Giuliani – communicating about the removal of Marie Yovanovitch as the ambassador to Ukraine. [SEP] Ukraine's national police are investigating allegations that U.S. Ambassador Marie Yovanovitch was under surveillance in Kyiv last spring — an allegation made in WhatsApp messages between a U.S. politician and Lev Parnas. "Ukraine cannot ignore such illegal activities on the territory of its own state," the Ministry of Internal Affairs of Ukraine said in a statement Thursday. The ministry says it's asking the FBI to help its inquiry.

[1] MDS Hallucination: new documents released ahead of president trump's impeachment trial suggest that the us ambassador to the country was under surveillance while she was stationed in the country, the new york times reports. according to the wall street journal, the allegations were made in a text message between a us politician and an associate of trump lawyer rudy giuliani. in the messages, the politician says he'd like to see former ambassador to ukraine and current ambassador to russia, former deputy foreign minister oleksandr turchynov, removed from his post. "i would like to remove him from his position," the politician wrote in the message, which was sent in april 2017. the messages were sent in response to newly released documents from the house intelligence committee. those documents show that former trump lawyer paul ryan had been trying to get rid of yovanovitch, who was ambassador at the time, for more than a year, the journal reports. the messages also show that ryan's chief of staff, george w. bush, had been in touch with ryan about removing her from her post.

[2] Source: "If I threaten someone, you'll know it," White House counselor Kellyanne Conway told reporters Friday morning in a bizarre hours-long effort to discredit an audio recording that seemingly showed her threatening to use West Wing resources to investigate the personal life of a reporter a day earlier. "I never threatened anyone," Conway told a gaggle of journalists at the White House. "Don't use those words. I didn't threaten. It's not a threat. I never threatened her." [SEP] A tense phone conversation between a reporter for the Washington Examiner and White House senior counselor Kellyanne Conway was published by the newspaper on Thursday. In the conversation, Conway objected that a story written by the reporter, Caitlin Yilek, mentioned that her husband George Conway is a fierce critic of President Trump on Twitter. Yilek was writing a story on Conway possibly becoming President Trump's next White House chief of staff if Trump decides to move on from the official now in the position, Mick Mulvaney. [SEP] Kellyanne Conway defended her phone call with a Washington Examiner reporter during an appearance on Fox News. Fox News host Sandra Smith described the phone call Friday between reporter Caitlin Yilek and the counselor to the president as a "heated clash" during which things got "very personal." Conway claimed, "Everything I said in that phone call, I've said publicly before. Every single thing. I said it again." Smith asked Conway if there was anything she regretted about how she handled her phone call, which she denied.

[2] MDS Hallucination: a recording of a tense phone call between senior white house adviser and reporter catherine yilek was published by the washington examiner on friday, and it's not going over well. in the recording, yalek says she was told by the white house that she would be fired if she didn't back off from her reporting on president trump's controversial son-in-law, and that she'd have to go to court if she did not. "i'm not going to do that," she says in the recorded conversation, per the new york times. "you're going to get fired if you don't shut the f — up." in the call, she also says she'll use the office of management and budget to investigate the personal life of the reporter. "if i threaten someone, you'll know it," the caller can be heard saying in the audio recording, per politico. "don ' t use those words. it ' s not a threat. i never threatened anyone." but on monday, white house counselor to the president katie holmes told fox news that she had never threatened the reporter.

Enhance Incomplete Utterance Restoration by Joint Learning Token Extraction and Text Generation

Abstract

This paper introduces a model for incomplete utterance restoration (IUR) called JET (**J**oint learning token **E**xtraction and **T**ext generation). Different from prior studies that only work on extraction or abstraction datasets, we design a simple but effective model, working for both scenarios of IUR. Our design simulates the nature of IUR, where omitted tokens from the context contribute to restoration. From this, we construct a Picker that identifies the omitted tokens. To support the picker, we design two label creation methods (soft and hard labels), which can work in cases of no annotation data for the omitted tokens. The restoration is done by using a Generator with the help of the Picker on joint learning. Promising results on four benchmark datasets in extraction and abstraction scenarios show that our model is better than the pretrained T5 and non-generative language model methods in both rich and limited training data settings.[1]

1 Introduction

Understanding conversational interactions through NLP has become important with increasing connectivity and range of capabilities. The applications using natural conversations cover a wide range of solutions including dialogue systems, information extraction, and summarization. For example, Adiwardana et al. (2020); Su et al. (2020) aimed to build the dialogue system where an intelligent virtual agent answers human conversations and makes suggestions in an open/closed domain. Bak and Oh (2018); Karan et al. (2021) attempted to detect decision-related utterances from multi-party meeting recordings, while Tarnpradab et al. (2017) applied extractive summarization for online forum discussions. These features allow users to quickly catch up with the current situation, decisions and next-action without having to follow a lengthy or comprehensive dialogue. However, utterances, the components of a conversation, are generally not self-contained and are difficult to understand by their own. This comes from the nature of multi-turn dialogue where each utterance contains co-references, rephrases, and ellipses (Figure 1). Su et al. 2019 also showed that co-references and ellipses occur in over 70% of utterances in conversations. This is a ubiquitous problem in conversational AI, making the challenge for building practical systems with conversations.

Incomplete Utterance Restoration (IUR) (Pan et al., 2019) is one solution to restore semantically underspecified utterances (i.e., incomplete utterances) in conversations. Figure 1 shows an example of IUR, in which the model rewrites the incomplete utterance to the reference. IUR is a challenging task due to two reasons. Firstly, the gold utterance (the reference) overlaps a lot of tokens with the pre-restored, incomplete utterance, while it overlaps only a few tokens with utterances in the context. We observed that for CANARD (Elgohary et al., 2019), 85% of tokens in incomplete utterances were directly cited for rewriting, while only 17% of tokens in context was cited for rewriting. Secondly, it is important to detect omitted tokens in incomplete utterances and to include them in the restoration process. In actual cases of IUR, no matter how fluent and grammatically correct the machine's generation is, it is useless as long as important tokens are left out.

Recent studies used several methods for IUR. It includes the extraction of omitted tokens for restoration (PAC) (Pan et al., 2019), two-stage learning (Song et al., 2020), seq2seq fine-tuning (Bao et al., 2021), semantic segmentation (RUN-BERT) (Liu et al., 2020), or the tagger to detect which tokens in incomplete utterances should be kept, deleted or changed for restoration (SARG)

	JET	Did orson welles have any other responsibilities besides radio programs, lectures, interviews and informal talks?

Figure 1: The sample data from *CANARD*. IUR models rewrite the incomplete utterance to be as similar as possible to the reference. The blue tokens are omitted tokens (excluding stop words) in the incomplete utterance. The red tokens are defined by our hard labeling approach as an important token.

(Huang et al., 2021). However, we argue that these methods can only work on neither extractive nor abstractive IUR datasets. For example, SARG and seq2seq achieve promising results on *Restoration 200k* (Pan et al., 2019) where omitted tokens can be directly extracted from the context (extraction). But they are not the best on CANARD (Elgohary et al., 2019), which requires more abstraction for restoration. In Figure 1,[2] we can observe that the output of SARG and seq2seq are worse than that of our JET. Text editing strategy by SARG is limited in its ability to generate abstractive rewriting while seq2seq has the problem in picking omitted tokens. As the result, the generality of these methods is still an open question.

We introduce a simple but effective model to deal with the generality of IUR methods named **JET** (**J**oint learning token **E**xtraction and **T**ext generation). The model is designed to work widely from extractive to abstractive scenarios. To do that, we first address the problem of identifying omitted tokens from the dialogue context by introducing a picker. The picker uses a new matching method for dealing with various forms of tokens (Figure 1) in the extraction style. We next consider the abstraction aspect of restoration by offering a generator. The generator utilizes the power of the pre-trained T5 model to rewrite incomplete utterances. The picker and generator share the T5's encoder and are jointly trained in a unified model for IUR. This paper makes three main contributions:

- We propose JET, a simple but effective model based on T5 for utterance restoration in multi-turn conversations. Our model jointly optimizes two tasks: picking important tokens (the picker) and generating re-written utterances (the generator). To our best knowledge, we are the first to utilize T5 for the IUR task.

- We design a method for identifying important tokens for training the picker. The method facilitates IUR models in actual cases, in which there are no (a few) existing gold labels.

- We demonstrate the validity of the model by comparing it to strong baselines from multiple perspectives such as limited data setting (Section 5.2), human evaluation (Section 5.4) and output observation (Section 5.5).

2 Related Work

Sentence rewriting IUR can be considered to be similar to the sentence rewriting task (Xu and Veeramachaneni, 2021; Lin et al., 2021; Chen and Bansal, 2018; Cao et al., 2018). Recent studies have been addressed the IUR task with various sophisticated methods. For example, Pan et al. 2019 introduced a pick-then-combine model for IUR. The model picks up omitted tokens which are combined with incomplete utterances for restoration. Liu et al. 2020 proposed a semantic segmentation method that segments tokens in an edit matrix then applied an edit operation to generate utterances.

---

[2] The performance of RUN-BERT is limited on CANARD.

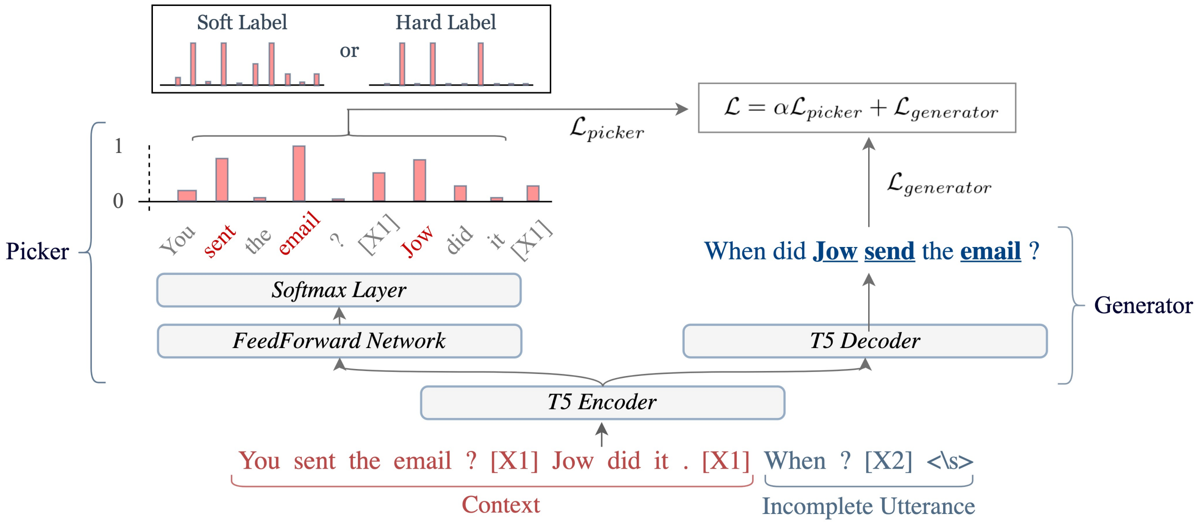

Figure 2: The proposed model (JET) for utterance restoration. The left is the picker and the right is the generator. The model jointly optimizes two tasks for doing restoration. The input format for our model is described in 3.2.1

Huang et al. 2021 presented a complicated model which uses a tagger for detecting kept, deleted, or changed tokens for restoration. We share the idea of using a tagger with Huang et al. 2021 for IUR. However, we design a more simple but effective model which includes a picker (picking omitted tokens) and a generator for the restoration of incomplete utterances.

Text generation IUR can be formulated as text generation by using the seq2seq model (Pan et al., 2019; Huang et al., 2021). For the generation, several well-known pre-trained models have been applied (Lewis et al., 2020; Brown et al., 2020; Raffel et al., 2020) with promising results. We employ the T5 model (Raffel et al., 2020) as the main component to rewrite utterances. To address the problem of missing important tokens in model's rewriting, we enhance T5 by introducing a Picker and two labeling methods (Section 3.2).

3 The Utterance Restoration Model

3.1 Problem Statement

This work focuses on the incomplete utterance restoration of conversations. Let $H = \{h_1, h_2, ..., h_m\}$ be the history of the dialogue (context), $U = \{u_1, u_2, ..., u_n\}$ is the incomplete utterance that needs to be re-written. The task is to learn a mapping function $f(H, U|\Theta) = R$, where $R = \{r_1, r_2, ..., r_k\}$ is the re-written version of U. The learning of Θ is composed by only using utterance generation (the generator) or the combination of two tasks: important token identification (the picker) and utterance generation (the generator).

3.2 The Proposed Model

Our model is shown in Figure 2. The Picker receives the context to identify omitted tokens. The Generator receives incomplete utterances for restoration. The model jointly learns to optimize the two tasks. Our model distinguishes in three significant differences compared to PAC (Pan et al., 2019) and SARG (Huang et al., 2021). First, our model bases on a sing pre-trained model for both picker and generator while other models (i.e. PAC and SARG) use different architectures for the two steps. This makes two advantages for our model. (i) Our design can be easily adapted to create a new unified model for different tasks by using a single generative LM (Paolini et al., 2021). (ii) Our model can work well in several scenarios: extraction vs. abstraction (data characteristics) and full vs. limited training data (Section 5). Second, we design a joint training process to implicitly take into account the suggestion from the picker to the generator instead of using a two-step model as PAC which explicitly copes extracted tokens from the Pick for generation. Our joint training model can reduce the error accumulation compared to the two-step framework. Finally, we design a heuristic approach to build important tokens, which enable the model to work on a wider range of datasets and scenarios.

3.2.1 Input representation

As shown in Figure 2, we introduced three kinds of special tokens into the input text; $[X1]$, $[X2]$ and

<\$s$>. $[X1]$ and $[X2]$ are our newly defined special tokens and <\$s$> is the EOS token in the T5's vocabulary. We inserted $[X1]$ at the end of each utterance in the context, $[X2]$ after the incomplete utterance and <\$s$> at the end of whole input. $[X1]$ and $[X2]$ convey two pieces of useful information to the model; the signal indicating the switch of speakers and the cue to distinguish whether the utterance is from context or incomplete utterance.

The embedding of each token in the entire input sequence $S = \{w_1, w_2, ..., w_l\}$ was obtained as $x_i = WE(w_i) + PE(w_i)$. Here, *WE* is *word embedding* initialized from a pretrained model by using a wordpiece vocabulary. *PE* is *relative position embedding* representing the position of each token in the sequence. These embeddings were fed into the L stacked Encoder of T5; $E^l = EncoderBlock(E^{l-1})$ where $E^0 = \{x_1, \ldots, x_l\}$. E^L is the contextual representation of the whole input used by Picker and Generator in next sections.

3.2.2 The Picker

It is possible to directly use T5 (Raffel et al., 2019) for IUR. However, we empower T5 with a Picker to implicitly take into account information from important tokens. The idea of selecting important tokens was derived from Pan et al. (2019), in which the authors suggested the use of important tokens contributes the performance of utterance restoration. We extend this idea by designing an end-to-end model which includes important token identification and generation, instead of using the two-step framework as Pan et al. (2019).

Given the context and the incomplete utterance, the Picker identifies tokens that are included in context utterances but omitted in the incomplete utterance. We call these tokens as important tokens. However, no important tokens are originally provided except for Restoration 200k in four datasets (please refer to Table 1). Besides, the form of important tokens could change after restoration such as from plural to singular or nouns to verbs (Figure 1). To overcome this issue, we introduce a label creation method that automatically identifies important tokens from the context for restoration.

Important token identification Since building a set of important tokens is time-consuming and important tokens are usually not defined in practical cases, we introduce a heuristic strategy to automatically construct important tokens. In the following processing, stop words in the context, incomplete utterances, and gold references are removed in advance, assuming that stop words are the out of scope of important tokens. In addition, we applied lemmatization and stemming, the process of converting tokens to their base or root form, to alleviate the spelling variants.

First, we extracted tokens, called "clue tokens", that exist in gold but not in incomplete utterances. If some tokens in context are semantically similar to some of the clue tokens, we can naturally presume that these tokens in the context are cited as important tokens for the rewriting. Therefore, we performed scoring by the distance d_{ij} between the word representations of i-th token in context h_i and j-th clue tokens c_j; $d_{ij} = \mathrm{cosine\_sim}(\mathrm{h_i}, \mathrm{c_j})$ where cosine_sim() is the score of Cosine similarity. We used word representations of h_i and c_j from fastText (Bojanowski et al., 2017) trained on Wikipedia as a simple setting of our model.

According to the distance d_{ij}, we introduce two types of labels for the Picker, *soft*$_i$ as soft labels and *hard*$_i$ as hard labels.

$$soft_i = \max_j d_{ij}$$

$$hard_i = \begin{cases} 1 & \max_j d_{ij} = 1 \\ 0 & otherwise \end{cases}$$

Here, the $\max$ operation was applied based on the assumption that at most one clue token corresponds to a token in the context.

Intuitively, the soft label method takes into consideration the cases that could not be handled by lemmatization and stemming, such as paraphrasing by synonyms, and reflects them as the importance score in the range of 0 to 1. On the other hand, the hard label is either 0 or 1 where an important token is defined only when there is an exact matching between the context tokens and the clue tokens in the form after lemmatization and stemming. We provide the two methods to facilitate important token identification.

Important token selection The Picker takes encoded embeddings $E^L = \{E^L_1, ..., E^L_l\}$ and predicts the scores of the soft label or hard label corresponding to each input token.

$$p(y_i|E^L_i) = softmax(\mathrm{FNN}(E^L_i))$$

where $\mathrm{FNN}()$ is the vanilla feedforward neural network, which stands for projecting encoded embedding to the soft label or hard label space. Then cross-entropy was adopted as the loss function.

$$\mathcal{L}_{picker} = -\sum_{i=1}^{l} q_i \log p(y_i|E_i^L)$$

where q_i is the picker's label for the i-th input token. To optimize loss function $\mathcal{L}_{picker}$ is equal to minimize the KL Divergence if the label is a soft label. In the hard labeling case, we assign three types of tags for tokens by following the BIO tag format as a sequence tagging problem.

3.2.3 The Generator

We explore the restoration task by using Text-to-Text Transfer Transformer (T5) (Raffel et al., 2019). This is because T5 provides promising results for the text generation task. We initialized transformer modules from T5-base, which uses 12 layers, and fine-tuned it for our IUR task.

For restoration, encoder's representation E^L was fed into a L stacked decoder with cross attention. $D_i^l = DecoderBlock(D_i^{l-1}, E^L)$ where $D_i^0 = R_{<i}$, with $R_{<i} = \{< s >, r_1..., r_{i-1}\}$ and $< s >$ is the SOS token. The probability p of a token t at the time step i was obtained by feeding the decoder's output D^L into the softmax layer.

$$p(t \mid R_{<i}, H, U) = softmax(linear(D_i^L)) \cdot v(t)$$

Here, $v(t)$ is a one-hot vector of a token t with the dimension of vocabulary size. The objective is to minimize the negative likelihood of conditional probability between the predicted outputs from the model and the gold sequence $R = \{r_1, r_2, ..., r_k\}$.

$$\mathcal{L}_{generator} = -\sum_{i=1}^{k} \log p(r_i \mid R_{<i}, H, U)$$

3.2.4 Joint learning

JET aims to optimize the Picker and the Generator jointly as a setting of Multi-Task Learning. Different from PAC (Pan et al., 2019) that directly copies extracted tokens to generation, JET can implicitly utilize knowledge from the Picker, in which the learned patterns of the Picker to identify important tokens can be leveraged by the Generator. It can reduce error accumulation in the two-step framework as PAC. The final loss of the proposed model is defined as follows.

$$\mathcal{L} = \alpha\mathcal{L}_{picker} + \mathcal{L}_{generator}$$

where the hyperparameter α balances the influence of the task-specific weight. Our simple setting enables us to implement minimal experiments to evaluate how much important token extraction makes the contribution to generation.

4 Settings and Evaluation Metrics

Data We conducted all experiments on four well-known datasets of utterance rewriting in Table 1.

Table 1: Four conversational datasets. **ext** is extraction and **abs** is abstraction. CN: Chinese; EN: English.

Data	train	dev	test	type	lang
Restoration 200k	194k	5k	5k	ext	CN
REWRITE	18k	0	2k	ext	CN
TASK	2.2k	0	2k	ext	EN
CANARD	32k	4k	6k	abs	EN

Restoration 200k (Pan et al., 2019) and REWRITE (Su et al., 2019) include Chinese conversations. TASK (Quan et al., 2019) and CANARD (Elgohary et al., 2019) are in English, in which CANARD includes English questions from QuAC (Choi et al., 2018). The datasets range from extraction to abstraction challenging UIR models.

Settings For running JET, we used AdamW with $\beta_1 = 0.9$, $\beta_2 = 0.999$ and a weight decay of 0.01 with a batch size of 12 and learning rate of $5e^{-5}$. We used 3 FFN layers (dimension as 768, 256, 64) with ReLu as the activation function. The final dimension is 1 for soft labeling and 3 for hard labeling. We set $\alpha = 1$ for the loss function. We applied beam search with the beam size of 8. For picker's label creation, we used stop words from NLTK for English and from stopwordsiso[3] for Chinese. For lemmatization and stemming, NLTK's WordNetLemmatizer and PorterStemmer were adopted for English, while lemmatization and stemming were skipped for Chinese. The pre-trained model was T5-base (English[4] and Chinese[5]). In the full training data setting (Section 5.1), the epoch size of 6 was used for Restoration200k and CANARD and 20 for REWRITE and TASK. In the limited training data setting (Section 5.2), the epoch size of 20 was used for all four datasets (Table 1). All models were trained on a single Tesla P100 GPU.

	SARG	80.3	63.7	70.5	62.7	42.7	30.5	25.9
	JET	**84.3**	**71.1**	**78.8**	**72.0**	**57.3**	**45.9**	**40.7**

Evaluation metrics We followed prior work (Pan et al., 2019; Elgohary et al., 2019; Liu et al., 2020; Huang et al., 2021) to use three different metrics for evaluation, including ROUGE-scores, BLUE-scores, and f-scores.

5 Results and Discussion

5.1 Full Training Data Setting

We provide two scenarios of comparison with full training data: comparison with T5 and comparison with non-generative LM models.

Comparison with T5 We first compare our model against a strong pre-trained T5 model used for the generator as the first scenario. This scenario ensures fair comparison among strong pre-trained models for text generation and also shows the contribution of the Picker. Results in Table 2 show that JET is consistently better than T5 across all metrics on all four datasets. This is because the picker can pick up important omitted tokens, which are beneficial for restoration. These results prove joint learning can implicitly supports to capturing the hidden relationship between the picker and generator. Also, the promising results show that our labeling method can work in both extraction and abstraction datasets. The results of T5 are also competitive. The reason is that T5 (Raffel et al., 2019) was trained with a huge amount of data by using the generative learning process, which mimics the text generation task. As the result, it is appropriate for the restoration.

For other strong pre-trained models for text generation, we also test our joint learning framework with ProphetNet (Qi et al., 2020) but the results are not good to report. We leave the comparison with UniLM (Dong et al., 2019) and ERNIGEN (Xiao et al., 2020) as a minor future task due to no pre-trained models for Chinese.

Comparison with non-generative LM models We next challenge JET to strong baselines which do not directly use generative pre-trained LMs, e.g. T5 for restoration. This is the second scenario that ensures the diversity of our evaluation. We leave the comparison of our model with BERT-like methods (e.g. SARG and RUN-BERT by using the T5 encoder) as a minor future task. For Restoration 200k and CANARD, we use the following baselines. **Syntactic** is the seq2seq model with attention (Kumar and Joshi, 2016). **CopyNet** is a LSTM-based seq2seq model with attention and the copy mechanism (Huang et al., 2021). **T-Ptr** employs transformer layers for encoder-decoder for restoration (Su et al., 2019). **PAC** is the two-stage model for utterance restoration (Pan et al., 2019). **s2s-ft** leverages specific attention mask with several fine-tuning method (Bao et al., 2021). **RUN-BERT** is an IUR model by using semantic segmentation (Liu et al., 2020). **SARG** is a semi autoregressive model for multi-turn utterance restoration (Huang et al., 2021).

Table 3 shows that JET outputs promising results compared to strong baselines. For Restoration 200k, JET is competitive with RUN-BERT, the SOTA for this dataset. For CANARD, JET is consistently better than the baselines. The improvements come from the combination of the picker and generator. It is important to note that RUN-BERT and SARG are behind our model significantly on the abstractive scenario (CANARD). It supports our statement in Section 1, in which the current strong models for IUR is overspecific for extractive datasets and their generality is limited.

We next report the comparison on REWRITE and TASK in another table due to a small number of evaluation metrics. Following Liu et al. (2020), we compare our model with RUN and two new methods: GECOR1 and GECOR2.

Results from Table 4 are consistent with the results in Tables 2 and 3. It indicates that our model outperforms the baselines on both TASK and REWRITE. For REWRITE, the EM (exact match) score of our model is much better than the baselines. It shows that the model can correctly restore incomplete utterances. These results confirm that our model can work well in the two scenarios over all four datasets.

Important token ratio We observed how many important tokens are included in prediction on Restoration 200k. To do that, we defined two metrics, *pickup ratio* and *difference*. *pickup ratio* indicates the ratio of predictions that contains important tokens on test datasets. *difference* indicates the difference the character length between the prediction and the gold. Ideally, larger *pickup ratio* with smaller *difference* is desirable.

Table 4: The comparison of JET and strong baselines on REWRITE and TASK; EM is exact match, B is BLEU, and R stands for ROUGE.

Data	Method	EM	B4	R2	f1
REWRITE	RUN	53.8	79.4	85.1	NA
	T-ptr+BERT	57.5	79.9	86.9	NA
	RUN-BERT	66.4	86.2	90.4	NA
	JET	**69.1**	**86.6**	90.6	**89.8**
TASK	GECOR1	68.5	83.9	NA	66.1
	GECOR2	66.2	83.0	NA	66.2
	RUN	69.2	85.6	NA	70.6
	JET	**79.6**	**90.9**	**91.8**	**76.3**

Table 5: The pickup ratio and difference of T5 and JET on Restoration 200k.

	pickup ratio (%)	difference
T5	29.0	1.28
Defined	29.9	1.30
Soft	26.6	1.28
Hard	30.4	1.21

Table 5 shows JET with hard labeling achieves better results on both metrics compared to single T5. This supports our hypothesis that the Picker contributes the Generator for the IUR task.

5.2 Limited Training Data Setting

We challenge our model in the limited training data setting. This simulates actual cases in which only a small number of training samples is available. We trained three strong methods: **SARG** (Huang et al., 2021), T5, and JET on 10% of training data by using sampling. We could not run RUN-BERT due to errors in the original code.

As shown in Table 6, JET is consistently better than SARG with large margins. This is because JET is empowered by T5 which helps our model to work with a small number of training samples. This point is essential in actual cases. JET is also better than T5, showing the contribution of the Picker. SARG is good at ROUGE-scores and BLUE-scores but worse at f-scores, e.g. on REWRITE. The reason is that SARG uses the pointer generator

Table 6: The comparison with limited training data.

Data	Method	R2	B2	f1	f2
Restoration 200k	SARG	82.8	87.4	52.4	**40.1**
	T5	84.5	87.2	53.8	37.2
	JET	**84.6**	**88.0**	**56.5**	39.2
REWRITE	SARG	57.9	50.0	0.00	0.00
	T5	77.3	73.7	71.0	61.3
	JET	**77.7**	**74.9**	**72.1**	**62.4**
TASK	SARG	76.4	44.5	12.0	0.14
	T5	86.0	85.8	52.7	48.3
	JET	**87.0**	**86.9**	**55.7**	**51.2**
CANARD	SARG	58.6	46.4	41.8	25.9
	T5	68.5	70.0	54.1	42.2
	JET	**69.2**	**71.3**	**55.9**	**43.6**

network, that directly copies input sequences for generation, but it learns nothing.

5.3 Soft Labels vs. Hard Labels

We investigated the efficiency of our labeling method in Section 3.2.2. We run JET with soft and hard labeling methods. We also include the results of the JET on defined labels of Restoration 200k because this dataset originally provides labels of important tokens.

Table 7: Soft vs. hard labeling methods. *Defined* is the ground truths. T5 does not use the labeling methods.

Data	Method	R2	B2	f1	f2
Restoration 200k	T5	86.1	88.9	61.3	51.2
	Defined	85.7	89.3	61.5	51.9
	Soft	86.2	87.9	57.4	47.7
	Hard	**86.9**	**89.6**	**63.0**	**53.3**
CANARD	T5	70.4	71.1	56.7	44.8
	Soft	70.8	71.4	57.1	45.5
	Hard	**71.1**	**71.8**	**57.6**	**45.6**

From Table 7 we can see the hard labeling method performs well on both datasets. Interestingly, the hard labeling method is even better than the one with defined labels on Restoration 200k. Although defined labels were manually created, Restoration 200k defines at most one important token in one sample even though some samples actually contain two or more omitted tokens. We found the hard label method detects 164k omitted tokens while the originally defined tokens are about 120k, and tokens detected by hard labeling cover 42% of defined tokens. This suggests the hard label method extensively picks up important tokens even some important tokens are missing, and it can contribute to the enhancement of the JET.

For the soft labeling method, it contributes to the f-scores on CANARD (=abstractive) while it exacerbates accuracy on Restoration 200k (=extractive). This implies soft label does not function well in the distinction case between important and unimportant tokens is clear as in Restoration 200k. The soft labeling method would need more exploration on abtractive scenarios that require more synonymous paraphrasing or creative summarization.

5.4 Human Evaluation

We report human evaluation with strong methods on CANRD because it is much more challenging than others. We asked three annotators who are well skilled in English and data annotation from the annotation team in our company. For the evaluation, we randomly selected 300 outputs from four models. Each annotator read each output and gave a score (1: bad; 2: acceptable; 3: good). Following Kiyoumarsi (2015) we adopted **Text flow** and **Understandability** as our criteria. **Text flow** shows how the restoration utterance is correct grammatically and easy to understand. **Understandability** shows how much the predictions are similar to reference semantically.

Table 8: Human evalution on CANARD.

	SARG	s2s-ft	T5	JET
Text flow	2.583	2.887	2.925	**2.933**
Understand	2.168	2.451	2.458	**2.496**

As shown in Table 8, JET obtains the highest scores on two criteria over other methods. It is consistent with the results of automatic evaluation in Tables 2 and 3. This is because our model utilizes strong pre-trained weights which provide the ability of text generation on unseen tokens, especially for abstractive data. The scores of JET also show the contribution of the Picker compared to the T5 for restoration.

5.5 Output Observation

We observed the restoration outputs of different models in Figure 1. There exist 9 omitted tokens between the incomplete utterance and the reference. The SARG and s2s-ft can restore only 2 important tokens. T5 can restore 8 the important tokens out of 9 but generates unnecessary words. Our proposed model also can restore 8 important tokens and have the same semantic meaning as the gold utterance. This suggests our model learns to use only the tokens picked up by Picker as additional tokens for rewriting.

Table 9: The average BLEU score on CANARD.

Length	< 100	$100 \leq 200$	$200 <$
SARG	55.53	45.46	38.96
s2s-ft	63.89	54.94	48.39
T5	**65.03**	55.69	51.25
JET	64.94	**56.56**	**52.84**

We also examined the ability of strong methods with different input lengths on CANARD. Results in Table 9 show that our model can deal with longer input sequences. Compared to SARG and seq2seq, the performance of our model is much better. This is because the implicit suggestion from the Picker combined with the ability to deal with long sequences of T5 increase the score.

6 Conclusion

This paper introduces a simple but effective model for incomplete utterance restoration. The model is designed based on the nature of conversational utterances, where important omitted tokens should be included in restored utterances. To do that, we introduce a picker with two labeling methods for supporting a generator for restoration. We found that the picker contributes to improve the generality of the model on four benchmark datasets. The model works well in English and Chinese, from extractive to abstractive scenario in both full and limited training data settings. The future work will investigate the behavior of the model in other domains and the potential application of JET, e.g. combining utterance extraction and utterance restoration for information extraction from dialogue.

Efficient Constituency Tree based Encoding for Natural Language to Bash Translation

Shikhar Bharadwaj and **Shirish Shevade**
Department of Computer Science and Automation,
Indian Institute of Science, Bangalore, KA 560012, India
`{shikharb,shirish}@iisc.ac.in`

Abstract

Bash is a Unix command language used for interacting with the Operating System. Recent works on natural language to Bash translation have made significant advances, but none of the previous methods utilize the problem's inherent structure. We identify this structure and propose a Segmented Invocation Transformer (SIT) that utilizes the information from the constituency parse tree of the natural language text. Our method is motivated by the alignment between segments in the natural language text and Bash command components. Incorporating the structure in the modelling improves the performance of the model. Since such systems must be universally accessible, we benchmark the inference times on a CPU rather than a GPU. We observe a 1.8x improvement in the inference time and a 5x reduction in model parameters. Attribution analysis using Integrated Gradients reveals that the proposed method can capture the problem structure.

1 Introduction

Semantic parsing is one of the central tasks for natural language understanding (NLU). It is defined as the task of generating meaning representations from natural language utterances (Kamath and Das, 2019). Previous works (Yin and Neubig, 2017, Yaghmazadeh et al., 2017, Kim et al., 2020, Agarwal et al., 2021) have used high level languages such as Python, SQL and Bash as meaning representations. This work focuses on generating Bash commands from natural language descriptions of command-line tasks.

Besides being an essential task for NLU, semantic parsing into a high-level language also has real-world applications such as helping developers write programs and making programming universally accessible. The command-line interface has been regarded as an invaluable tool due to its expressiveness, efficiency and extensibility (Agarwal et al., 2021). However, it has a learning curve and requires domain knowledge. An interface with the computer using natural language, on the other hand, remedies these issues. One need not remember the syntax of hundreds of Bash utilities, and instead, one can specify the task in natural language. Such an interface that uses natural language such as English for specifying command-line tasks makes computing accessible to people with little domain knowledge. Therefore, developing a system to generate Bash commands from English is worth one's efforts.

Previous works on this semantic parsing task (Lin et al., 2018, Gros, 2019, Agarwal et al., 2020, Agarwal et al., 2021, Bharadwaj and Shevade, 2021) use various encoder-decoder style architectures. These methods consider the natural language component as a sequence of tokens without utilizing the inherent structure for this problem. The method proposed in this work utilizes the information from the constituency parse tree of the natural language to incorporate this problem structure into the modelling process. Our approach is based on the observation that natural language invocations are complex and can be broken down into simpler segments that align with the Bash command components (utilities, flags and arguments). We incorporate this observation in our method to provide an inductive bias to the Transformer model (Vaswani et al., 2017), making the search space of solutions more aligned with the task at hand. The models are evaluated on the NL2Bash dataset (Lin et al., 2018) obtained from the NeurIPS 2020 Natural Language Context to Command (NLC2CMD) contest (Agarwal et al., 2021). The proposed method outperforms the winning solution from the NLC2CMD contest in terms of generation accuracy while also achieving a speedup of 1.8x and reducing the parameter count by 5x over it. It also performs better than models like T5 (Raffel et al., 2019) and

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3159 - 3168
July 10-15, 2022

CodeT5 (Wang et al., 2021) which are trained on a large amount of data and then fine-tuned on the dataset under study. Our code is available at `https://github.com/Shikhar-S/Segmented-Invocation-Transformer`

Our main contributions are the following:

- We identify the structure for natural language to Bash generation task and propose a constituency tree based method for incorporating the structure in the Transformer (Vaswani et al., 2017) framework. The proposed modification improves the performance of the Transformer on this task.
- We benchmark the Transformer against the proposed architecture. Results show a reduction in inference time and the number of parameters.
- We conduct attribution analysis using Integrated Gradients (Sundararajan et al., 2017) to analyze the proposed method's workings.

First, we formally describe the problem statement. Section 2 describes the structure for the problem, and Section 3 describes our approach to model the structure and expected gains in the inference time via a complexity analysis of the decoding phase. Section 4 describes the dataset used and its preprocessing. In Section 5, we describe the experiments conducted for checking the correctness and efficiency of our approach and analyzing the results. Section 6 compares our work with other related works. Finally, in Section 7 we conclude and discuss some directions for future work.

Problem Statement. Let I be the set of all natural language invocations, C be the set of all Bash

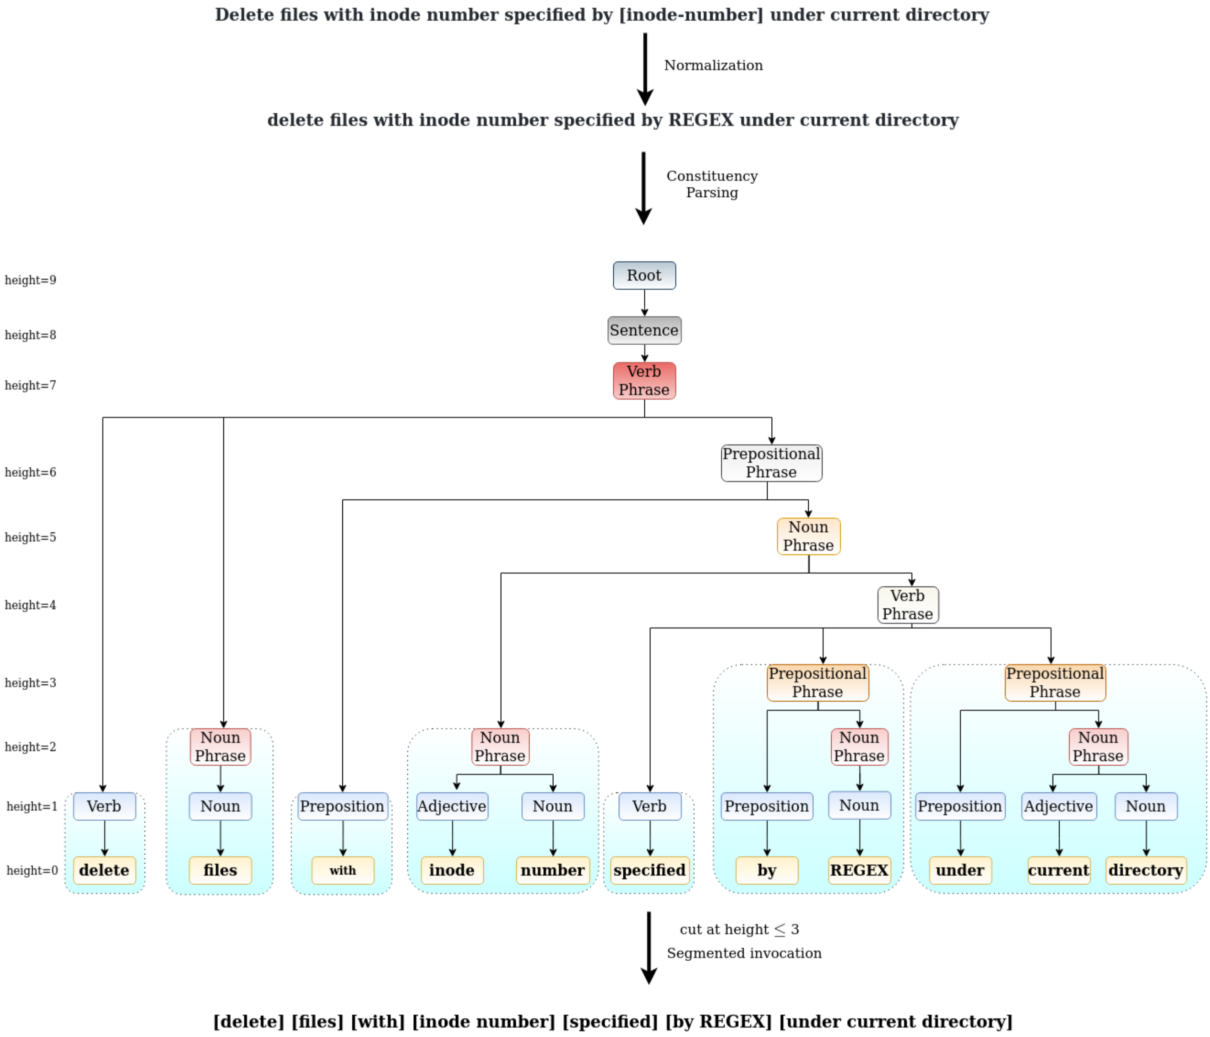

Figure 1: Segmenting Invocation: First, the raw invocation is normalized to remove patterns and file paths. This normalized invocation is then parsed to obtain a constituency tree. Then, the tree is cut at a threshold height to create subtrees. The leaves of each subtree form tokens in the segments.

commands and $\mathcal{D} := \{(nlc, c)\}$ be a parallel natural language invocation-Bash command dataset, where $nlc \in I$ and $c \in C$.

The task is to design an algorithm that, given an invocation $nlc \in I$ and dataset $\mathcal{D}$, outputs a set of Bash command-confidence pairs $(\hat{c}, \delta)$ such that

- $\hat{c} \in C$ is the predicted Bash command that performs the task specified in nlc, and
- $\delta \in [0, 1]$ is the associated confidence score.

For example,
nlc = Delete files with inode number specified by REGEX under current directory.
c = `find . -inum REGEX -exec rm -i {} \;`

2 Problem Structure

On conducting a manual analysis of a few examples from the training data, it was observed that natural language invocations are often complex and can be broken down into simpler descriptive segments needed for the task. These segments would often map directly to a Bash command component- a utility, a flag or an argument. For instance, consider

$\underline{Invocation}$
| ***Delete*** | *files* | *with* | ***inode number*** | *specified* | ***by REGEX*** | ***under current directory***.|
$\underline{BashCommand}$

```
find . -inum REGEX -exec rm -i {} \;
```

Invocation segment	Bash command component
Delete	`rm`
inode number	`-inum`
by REGEX	`REGEX`
under current directory	`.`

Table 1: Segments from natural language invocation that align with Bash command components (utilities, flags and arguments).

Table 1 lists the segments of the invocation that map to the command components. These segments represent meaningful self-contained constituents of a complex invocation. In the above instance, "*under current directory*" and "*by REGEX*" are segments representing single concepts.

3 Method

We frame the problem as a translation task from English to Bash. In Section 3.1 we describe our approach to incorporate the structure in modelling natural language invocations. Section 3.2 describes the proposed architecture and an analysis of its computational complexity at inference time.

3.1 Segmenting Invocation using Constituency Tree

The constituency tree represents the syntactic structure of a sentence based on phrase structure grammar (Chomsky, 1956). We propose a simple method that utilizes the constituency tree for segmenting natural language invocations. Our method is outlined in Figure 1. First, we normalize the invocation to replace patterns and file paths with their types. Next, we parse the normalized English invocation to obtain its constituency parse tree. For all the experiments reported in this work, we use the Stanford CoreNLP parser (Manning et al., 2014). Let the *height* of a node be defined as the number of edges on the longest path from the node to a leaf in the node's subtree (as shown in Figure 1). Then we perform a depth-first traversal on the tree in the left to right order of nodes. While performing the depth-first traversal, we cut the tree at the first node with a height less than a threshold and do not expand the search on this node further. As a result, we obtain various subtrees, where each subtree corresponds to a segment composed of the tokens in the leaves of the subtree. Finally, all segments are collected from the subtrees to obtain the segmented invocation.

3.2 Segmented Invocation Transformer

Let the $nlc = [t_1, t_2, \ldots t_n]$ be composed of n tokens. The invocation segmentation procedure takes the constituency tree for nlc and the threshold height as inputs and returns k segments $[s_1, s_2, \ldots s_k]$, where each segment $s_i = [t_j, t_{j+1}, \ldots t_{j+n_i-1}]$ is composed of n_i tokens such that $\sum_{i=1}^{k} n_i = n$.

We use a Transformer (Vaswani et al., 2017) based architecture and modify the Transformer encoder to capitalize on the segmentation information obtained from the constituency tree. Specifically, an averaging layer is introduced before the Transformer encoder to capture the local structure (Section 2). From the embedded token sequence comprising of n vectors, the averaging layer computes a sequence of k segment embeddings. The input to the averaging layer consists of n vectors, each resulting from the sum of token embedding and the corresponding sinusoidal position embedding. These are grouped into k segments, and the averaging layer then computes the mean over each segment to produce a sequence of k embedding vectors, one for each segment. On the decoder side, we use the standard Transformer decoder. We name this architecture Segmented Invocation Transformer (SIT), and it is shown in Figure 2. The model is trained by back-propagation on the cross-entropy loss with label smoothing of 0.1.

Complexity Analysis Next, we analyze the computational complexity of the cross-attention of the decoder during inference to point out the improvement over the vanilla Transformer. The decoding occurs in discrete time steps. We shall consider a single time step in this analysis. At each time step, in the cross-attention layer of the decoder, we first construct the keys, query and values and then perform a softmax over the product of keys matrix with the query vector to get the cross-attention scores. Let the dimension of the embedding vectors be d. Considering a single head for simplicity, the construction of values matrix takes $O(kd^2)$ time (from the multiplication of $\mathbb{R}^{k\times d}$ and $\mathbb{R}^{d\times d}$ matrices), where k is the number of segments. Similarly, the construction of query vector takes $O(d^2)$ time (from the multiplication of a $\mathbb{R}^{d}$ vector with $\mathbb{R}^{d\times d}$ matrix). Multiplying keys matrix ($\mathbb{R}^{k\times d}$) with the query vector ($\mathbb{R}^{d}$) followed by a softmax (over k attention scores) takes $O(kd+k)$ time. This step is followed by a weighted aggregation of the k values, each being d-dimensional, in $O(kd)$ time. Hence, the overall complexity for cross-attention layer is $O(kd^2 + d^2 + kd)$. Since the dimension d is a constant, this can be simplified to $O(k)$. A vanilla Transformer would incur $O(n)$ time. Therefore, our method provides a constant factor improvement per decoding time step. This advantage adds up due to multiple decoding time steps needed during the inference phase. The time benchmarks (Section 5.2) show these differences in practice.

4 Data and Preprocessing

For evaluating our method, we used the NL2Bash dataset (Lin et al., 2018) provided by the NLC2CMD contest (Agarwal et al., 2021) from NeurIPS 2020. It consists of approximately 10k paired English invocations and Bash commands scraped from Stack Overflow covering over 100 Bash utilities. The dataset was partitioned into five folds. We performed five runs. In each run, we split one fold equally for validation and testing. The remaining four folds were pooled to create the training set for the run. All results mentioned in Table 3 are averaged over these five runs. Invocations and bash commands for all the models to remove file paths and regex. We used the natural language toolkit[1] and the Bash parser[2] shared by the NLC2CMD competition organizers for preprocessing.

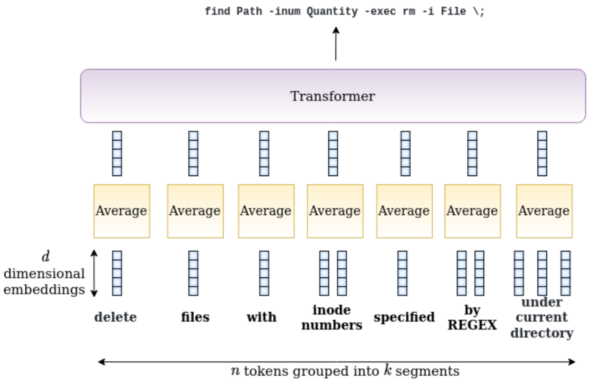

Figure 2: Segmented Invocation Transformer (SIT): We introduce an averaging layer to generate embeddings for each segment. These embeddings are then fed into a standard Transformer that outputs the bash command.

5 Experiments

Section 5.1 describes the experiments conducted to measure our method's accuracy. Section 5.2 describes the time benchmark. Section 5.3 describes the analysis using Integrated Gradients.

5.1 Translation Accuracy

Section 5.1.1 explains the accuracy metric proposed in the NLC2CMD competition. Section 5.1.2 lists the baselines our method is compared with. Section 5.1.3 lists the hyper-parameters and Section 5.1.4 contains a discussion of the results.

5.1.1 NLC2CMD Competition Metric

Agarwal et al. (2021) pointed out the shortcomings of existing evaluation metrics like BLEU score (Papineni et al., 2002), Exact Match accuracy and Template accuracy (Lin et al., 2018) in the context of natural language to Bash generation and proposed a new scoring mechanism for the NLC2CMD competition. This score incentivizes precision and recall of correct utility and flags weighted by the reported

---

[1] `https://github.com/IBM/clai/tree/nlc2cmd/tellina-baseline/src/submission_code/nlp_tools`

[2] `https://github.com/IBM/clai/tree/nlc2cmd/utils/bashlint`

system confidence (δ). It ignores command arguments but considers utilities' order and flags. The translation system is also penalized for producing redundant flags.

Now, we formally describe the competition metric[3] from Agarwal et al. (2021). Let model A output top-5 translations as follows: $A : nlc \mapsto \{q|q = (\hat{c}, \delta)\}$. Here the tuple $(\hat{c}, \delta)$ represents the predicted command $\hat{c}$ with associated confidence score δ. We consider $|A(nlc)| \leq 5$ and assume that there is only one ground truth command c corresponding to an invocation nlc. Then, the normalized score of a single prediction is:

$$S(q) = \sum_{i\in[1,T]} \frac{\delta}{T} \times \Bigg(\mathbb{I}(U(\hat{c})_i = U(c)_i) \times \frac{1}{2}\Big(1+\frac{1}{N_i}\big(2\times|F(U(\hat{c})_i)\cap F(U(c)_i)| - |F(U(\hat{c})_i)\cup F(U(c)_i)|\big)\Big) - \mathbb{I}(U(\hat{c})_i \neq U(c)_i)\Bigg)$$

Here, $\mathbb{I}(\cdot)$ is the indicator function, $U(c)$ is the sequence of Bash utilities in the command c, $F(u)$ is the set of flags for utility u in respective command, $T = \max\big(|U(c)|, |U(\hat{c})|\big)$ and $N_i = \max\big(|F(U(c)_i)|, |F(U(\hat{c})_i)|\big)$.

Total score of the prediction is defined as:

$$Score = \begin{cases} \max_{q\in A(nlc)} S(q), & \text{if } S(q) > 0 \text{ for some } q \in A(nlc); \\ \frac{1}{|A(nlc)|} \sum\limits_{q\in A(nlc)} S(q), & \text{otherwise.} \end{cases}$$

5.1.2 Baselines

We compare our method with the following baselines:

- **T5** (Raffel et al., 2019): T5 is a Transformer-based model trained on large amount of data. We fine-tuned the T5-small checkpoint by huggingface (Wolf et al., 2020) on our dataset. The input to the model was "translate English to Bash:" followed by the invocation. T5-small and T5-base were tested. T5-small performed better. Results for the same are reported.

- **Code-T5** (Wang et al., 2021): CodeT5 is a T5 derivative proposed to improve the performance on both code understanding and code generation tasks. It is pre-trained on eight programming languages- Java, Ruby, Javascript, Go, PHP, Python, C and Cpp. We fine-tuned the CodeT5-small checkpoint by huggingface (Wolf et al., 2020) on our dataset. The input to the model was "translate English to Bash:" followed by the invocation. CodeT5-small and CodeT5-base were tested. CodeT5-small performed better. Results for the same are reported.

- **Seq2Seq** (Bahdanau et al., 2015): This is an attention enhanced encoder-decoder architecture with a bidirectional LSTM encoder and a unidirectional LSTM decoder.

- **Explainable-NL2BashAST** (Bharadwaj and Shevade, 2021): A natural language to Bash translation model that generates explanations besides Bash commands and uses Abstract Syntax Tree information. It also uses Bash utility description besides the parallel NL2Bash data. We use the code shared by the authors at `https://www.github.com/Shikhar-S/Explainable-NL-to-Bash-AST`.

- **Magnum** (Agarwal et al., 2021): This is the winner's model from the NLC2CMD contest and the state of the art on this problem. The original system is an ensemble of multiple Transformers (Vaswani et al., 2017) trained with different seeds and batch sizes. We compare with a single model from the ensemble for fair comparison.

5.1.3 Hyper-parameters

SIT uses an embedding dimension of 256 and has 3 encoder layers with 4 attention heads each and 6 decoder layers with 8 attention heads each. It has feed-forward networks with a dimension of 1024 in both encoder and decoder layers. It is trained with a batch size of 499 tokens and gradient accumulation over 150 batches. The height threshold for cutting the subtrees, set to 4, is tuned using the performance on the validation set. Magnum takes in an embedding vector of size 512 and has 6 layers in both encoder and decoder, each with 8 attention heads. Magnum is trained for 2500 steps, with each batch containing 14000 tokens with gradient accumulation over 2 batches and a warm-up scheduler. Seq2Seq has two 256 dimensional bidirectional LSTM layers in the encoder and two 256 dimensional LSTM layers in the decoder with attention between encoder and decoder. T5-small and

---

[3] `https://github.com/IBM/clai/tree/nlc2cmd/utils/metric`

Model	CPU Threads	Mean (sec)	Median (sec)	Interquartile Range (sec)
Magnum (Single Model)	1	145.70	144.51	1.98
SIT	1	59.07	59.22	1.87
Magnum (Single Model)	2	105.60	102.92	4.24
SIT	2	51.52	51.80	1.43
Magnum (Single Model)	3	94.57	92.17	2.26

Magnum (Single Model)	4	89.01	87.16	3.94
SIT	4	45.78	45.62	2.48
Magnum (Single Model)	5	86.73	86.01	0.72
SIT	5	46.49	46.36	2.35
Magnum (Single Model)	6	84.80	83.89	3.83
SIT	6	45.68	45.83	1.84

Table 2: Time Benchmarks: Time taken to run inference on 1K examples from the test set. Each entry is computed from 25 repeated runs. System configuration is mentioned in Section 5.2.

CodeT5-small are trained with a batch size of 32 examples, and the number of epochs is tuned based on the validation set performance. The unit of vocabulary for T5 and CodeT5 are subtokens, whereas, for all other models, the vocabulary is built from the whitespace-separated words in the NLC2CMD dataset. For all models, we use beam search with 10 beams and top-5 predictions to generate final Bash commands. We use 1 as the confidence score (δ) for top p predictions and $exp(beam\_score)/2$ for the remaining 5-p. This parameter p is tuned separately on the validation set for each model considered.

5.1.4 Results

Results are reported in Table 3. SIT performs better than all other models. T5 performs the worst, probably due to the large predefined vocabulary of standard T5 models. For every other model, the vocabulary is limited to the NLC2CMD dataset. The winners of NLC2CMD also report that a decrease in vocabulary size increases performance for this task. There is no straightforward way to adapt the vocabulary of T5 and CodeT5 for this dataset. Seq2Seq performs better than T5 and CodeT5. We hypothesize that this is due to the smaller target side vocabulary learned from the data. CodeT5, trained on a large amount of code and natural language data, performs better than T5 but still lags behind SIT. Explainable-NL2BashAST performs better than T5 and Sequence to Sequence but lags behind Magnum because it is developed for commands with a single utility, and it constructs a target sequence that is twice as long as a Bash command. This makes the decoding using beam search less efficient.

Model	Test score
T5 (Raffel et al., 2019)	0.316 ± 0.021
CodeT5 (Wang et al., 2021)	0.355 ± 0.025
Seq2Seq (Bahdanau et al., 2015)	0.362 ± 0.012
Explainable-NL2BashAST (Bharadwaj and Shevade, 2021)	0.390 ± 0.012
Magnum (Single Model) (Agarwal et al., 2021)	0.428 ± 0.010
SIT (Proposed Method)	**0.438 ± 0.018**

Table 3: NLC2CMD Competition metric on the test set. Values range from -1 to 1 with higher being better. All entries are averaged over 5 runs and in the form mean ± standard deviation.

Parameter Efficiency. SIT has 9M parameters, whereas Magnum has 45M parameters. This results from SIT's encoder being much smaller than Magnum's encoder, which is expected since we use the constituency parse tree information to model the natural language sequence. The 5x gain in parameter efficiency is especially important for this task since it will allow the proposed method to be employed in real-world systems with significantly less memory and power consumption.

5.2 Time Benchmark

Configuration. We consider a relatively inexpensive system configuration without access to a Graphics Processing Unit because we expect the users of our system to run it on a standard development machine. We benchmark the inference time for Magnum (Agarwal et al., 2021) and SIT (excluding constituency parsing) on the test set. The benchmarks are run on a 6 core Intel(R) Core(TM) i5-10400 CPU, using `torch.utils.benchmark` available in PyTorch (Paszke et al., 2019). We report results from 25 runs for each setting in Table 2. We benchmark a single model from the Magnum ensemble for

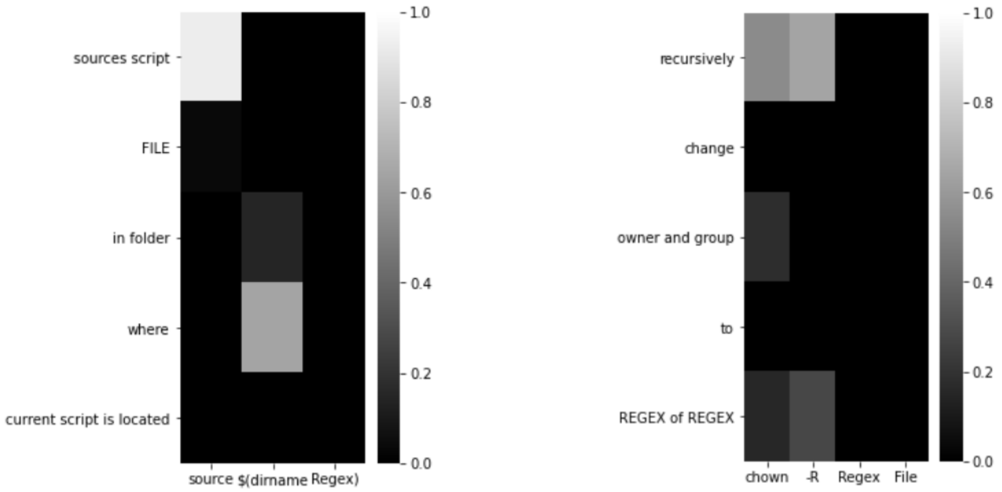

Figure 3: Alignments from Attribution Scores: Normalized invocation is on the left and normalized command is at the bottom.

comparison with a single SIT model.

Results. Results are reported in Table 2. We observe that SIT achieves a median time speedup of almost 1.8x over Magnum. These empirical results are in line with the complexity analysis from Section 3.2. On profiling the code, we find that a significant time spent during inference is to run the decoder, which is expected as the decoder runs in a step-wise fashion. Also, we note that the most time-consuming operations are computing self-attention and cross-attention matrices from keys, queries and values. As described in Section 3.2, SIT has fewer keys and values in the decoder cross-attention layer. Therefore, it leads to an increase in speed during inference.

5.3 Attribution Analysis

To assess if SIT attributes the probability of target tokens to correct invocation segment, we conduct an attribution analysis using Integrated Gradients (IG) (Sundararajan et al., 2017). [4] The IG method computes attribution scores that represent each invocation segment's contribution in predicting a command token. IG takes in the trained model, a baseline invocation and an input invocation as input. The baseline invocation denotes an absence of signal to the model. We use a sequence of `[PAD]` tokens, corresponding to a sequence of zero embedding vectors as the baseline. Integrated Gradients are defined as the path integral of the gradients along the straightline path from the baseline to the input. These are approximated by adding up the gradients along sufficiently small intervals on this straightline path. We used 5K steps for approximating the integral since the network is highly nonlinear.

We clipped the negative attribution scores to zero to draw attention to positive attributions that corresponds to alignments. Some resulting matrices from the test set are plotted as heatmaps and shown in Figure 3. The matrix on the left shows the alignment matrix for the input invocation *'Sources script incl.sh in folder where current script is located'*. The corresponding command is `source $(dirname $0)/incl.sh`. This is a Bash command substitution pattern. The inner command first finds the directory name of the directory containing the currently running script with the `dirname` utility. It then executes the *incl.sh* file in that directory with `source` utility. One can observe that the bash command `source` aligns with the invocation segment *sources script*, and the token `$(dirname` aligns with segments *in folder* and *where* from the invocation.

Similarly, Figure 3 (matrix on the right) shows the alignment matrix for input invocation *'Recursively change owner and group to "$JBOSS_AS_USER" of "$JBOSS_AS_DIR"'*, with the corresponding command `chown -R $JBOSS_AS_USER:$JBOSS_AS_USER $JBOSS_AS_DIR`. The alignment matrix depicts the correspondence between the invocation segment *recursively* and the command flag `-R`. In this instance, we also see that some command components are erroneously attributed. For instance

---

[4] We use the Integrated Gradient implementation provided by the Captum library - `https://www.github.com/pytorch/captum`

Command Component	Total Count	Attributed Correctly
Utility	129	94 (72.87%)
Flag	160	110 (68.75%)
Argument	244	84 (34.43%)

Table 4: Results from the evaluation of attributions produced by Integrated Gradients for 100 random examples from the test set.

`-R` is also attributed to *REGEX of REGEX*.

We sample 100 examples[5] from the test set and manually evaluate the attribution matrices produced by the IG method. Attribution for a command component is labelled as correct if one can look at only the positively attributed invocation segments to determine the presence of the command component in the output command. For instance, consider the attribution matrix on the right in Figure 3. Here, the counts of correctly attributed utilities, flags and arguments will be 0,1 and 0 respectively. Only the flag `-R` can be figured out from the positively attributed input segment *recursively*. There is a positive attribution on the invocation segment *owner and group*. However, in the absence of a positive attribution on *change*, one can not conclude that the utility `chown` would be used.

The results of the attribution analysis are shown in Table 4. We observe that utilities and flags have higher attribution accuracy than the arguments. This is due to the preprocessing which normalizes all file paths and regex expressions. It is also observed that sometimes multiple utilities are needed to perform the task in the invocation. There is little alignment between the utilities and invocation segments in such cases. For instance, when utilities like `sed` and `awk` are connected using the pipe operator (`|`) to modify the output of other utilities. Such implicit need for some utilities results in incorrect attribution by SIT. Similarly, it is observed that flags like `-and` and `-or` cannot be explicitly aligned to the invocation segments.

From the attribution analysis, we find that the proposed architecture is indeed able to capture the synchronous structure between natural language segments and Bash command components.

6 Related Work

Early works on semantic parsing explored meaning representations like first-order logic, lambda calculus enhanced first-order logic (Carpenter, 1997), database query languages and operated on handcrafted rules (Johnson, 1984). These were followed by statistical models that were able to learn rules from input-output parallel data (Thompson, 2003, Zettlemoyer and Collins, 2007, Kwiatkowksi et al., 2010).

Recently, there have been many advancements in generating high-level programming languages. Dong and Lapata (2016) and Ling et al. (2016) propose general attention based encoder-decoder style methods for semantic parsing. Rabinovich et al. (2017) propose Abstract Syntax Networks with a dynamically determined modular decoder structure that parallels the structure of the output tree. Yin and Neubig (2017) propose an architecture enhanced by a grammar model that explicitly captures the target language syntax as prior knowledge. Most of the innovations in this area utilize recurrent neural networks (RNN) for modelling natural language input. The method proposed in this work enhances the Transformer encoder with constituency parsing information.

For natural language to Bash, in particular, Lin et al. (2018) created a dataset and proposed an encoder-decoder based architecture. Gros (2019) explore several sequence to sequence models, Abstract Syntax Networks and Nearest Neighbor based models for this task on a custom dataset. Agarwal et al. (2020) proposed a command-line AI assistant for this task. Agarwal et al. (2021) organized a contest in NeurIPS 2020 for natural language to Bash translation and provided a report on the state of the art architectures developed in the contest. Bharadwaj and Shevade (2021) explored the use of Linux manual pages and Abstract Syntax Tree for developing an explainable natural language to Bash translation system. In contrast to these methods, our work explores the synchronous structure of this problem and uses the constituency tree to better model natural language input.

Constituency parse tree of natural language has been used in earlier machine translation and semantic parsing literature. Nguyen et al. (2019) note that the Transformer (Vaswani et al., 2017) struggles to encode hierarchical structures and propose a hierarchical accumulation mechanism that utilizes constituency parse tree to capture this structure for neural machine translation. They achieve this by adding additional parameters that capture the constituency structure of sentences. Our method, in

---

[5] Attribution matrices for the sampled instances are available at `https://github.com/Shikhar-S/Segmented-Invocation-Transformer/blob/main/jup_notebook/attribution_viz.ipynb`

contrast, uses constituency tree information in a parameter efficient manner. Xu et al. (2018) construct a syntactic graph from constituency and dependency parse tree and employ a graph to sequence neural network using an RNN decoder. They report improvement over the sequence to sequence model proposed by Dong and Lapata (2016) showing that additional syntactic information helps in semantic parsing. We use a Transformer and show that segmentation structure aids in natural language to Bash translation.

7 Conclusion and Future Work

We propose a method that utilizes information from the constituency tree to better model the structure of natural language to Bash task. Our experiments on the NLC2CMD data show that incorporating the problem structure in the model architecture improves both performance and parameter efficiency. We also run inference time benchmarks and find that the proposed method is faster. Attribution analysis is also conducted to analyze the method.

In this work, we focus on Bash as the meaning representation and identify the structure for natural language to Bash translation. However, we expect a similar structure for other meaning representations like SQL. Applying our method to natural language to SQL task is left for future work. Our method relies on Stanford CoreNLP parser (Manning et al., 2014) for constituency parsing. This is a bottleneck for fully utilizing the efficiency of our approach. It will be interesting to test faster constituency parsers (Zhang et al., 2020a, Zhang et al., 2020b) which can parse around 1K sentences per second.

Abstract

Embeddings, which compress information in raw text into semantics-preserving low-dimensional vectors, have been widely adopted for their efficacy. However, recent research has shown that embeddings can potentially leak private information about sensitive attributes of the text, and in some cases, can be inverted to recover the original input text. To address these growing privacy challenges, we propose a privatization mechanism for embeddings based on homomorphic encryption, to prevent potential leakage of any piece of information in the process of text classification. In particular, our method performs text classification on the encryption of embeddings from state-of-the-art models like BERT, supported by an efficient GPU implementation of CKKS encryption scheme. We show that our method offers encrypted protection of BERT embeddings, while largely preserving their utility on downstream text classification tasks.

1 Introduction

In recent years, the increasingly wide adoption of vector-based representations of text such as BERT, eLMo, and GPT (Devlin et al., 2019; Peters et al., 2018; Radford et al., 2019), has called attention to the privacy ramifications of embedding models. For example, Coavoux et al. (2018); Li et al. (2018) show that sensitive information such as the authors' gender and age can be partially recovered from an embedded representation of text. Song and Raghunathan (2020) report that BERT-based sentence embeddings can be inverted to recover up to 50%–70% of the input words.

Previously proposed solutions such as differential privacy based on perturbation/noise (Qu et al., 2021), require manually controlling the noise injected into embeddings, to control the privacy-utility trade-off to a level suitable for each downstream task. In this work, we propose a privacy solution based on *Approximate Homomorphic Encryption*, which is able to achieve little to no accuracy loss of BERT embeddings on text classification[1], while ensuring a desired level of encrypted protection, i.e. 128-bit security.

Homomorphic Encryption (HE) is a cryptographic primitive that serves computations over encrypted data without any decryption process. While previous works have focused on homomorphic computation where the inputs are numerical data, in applications such as privacy-preserving machine learning algorithms (Lauter, 2021), logistic regression (Kim et al., 2018), and neural network inference (Gilad-Bachrach et al., 2016), they have rarely been applied to *unstructured* data such as text. Recent works in this direction include Podschwadt and Takabi (2020), who conduct sentiment classification over encrypted word embeddings using RNN. However, they use a simple embedding layer which maps words in a dictionary to real-valued vectors, and model training is only supported on plaintext. The most closely related work to ours is PrivFT (Badawi et al., 2020), a homomorphic encryption based method for privacy preserving text classification built on fastText (Joulin et al., 2017).

We next describe our approach, focusing on our distinctions from PrivFT:

- **BERT Embedding-based Method**: The principle behind PrivFT is to perform all neural network computations in encrypted state. For this purpose, it adopts fastText (Joulin et al., 2017), which takes bag-of-words vectors as input, followed by a two-layer network and an embedding layer. However, PrivFT does not utilize pre-training; as a consequence, the embedding matrix and classifer of PrivFT must be updated from scratch, taking several days to train on a single dataset.

  We introduce a new method for text classification on encrypted data. The crux is to operate a simple downstream classifier on encryptions

July 10-15, 2022 ©2022 Association for Computational Linguistics

of semantically rich vector representations (i.e. BERT embeddings). By using rich input representations, our method significantly outperforms PrivFT, while the use of a simple downstream classifier on encrypted data makes our method much more practical. Importantly, by leveraging pre-trained embeddings from models such as BERT, a state-of-the-art in many NLP tasks, our method enables the training of a strong classifier in encrypted state within hours. As such, our method is well positioned to take full advantage of the recent trends in NLP, that rely on the language understanding capability of increasingly larger pre-trained language models (Brown et al., 2020; Kaplan et al., 2020).

- **Better GPU Implementation**: As BERT representations are real-valued vectors, we adopt CKKS scheme, which is well-suited for dealing with real numbers compared to other HE schemes. We develop an efficient GPU implementation of CKKS which greatly improves computation speed. While PrivFT also provides a GPU implementation of CKKS, their implementation lacks the *bootstrapping* operation of CKKS. Inevitably, this limits the multiplicative depth of PrivFT, and it makes the method less scalable. It also results in the use of less secure CKKS parameters which have roughly 80-bit security level. In contrast, our GPU implementation includes the bootstrapping operation, which allows unlimited number of multiplications. This enables us to use a higher degree polynomial approximation (which is key to achieving a high downstream accuracy), and more secure CKKS parameters (128-bit security level[2]). Moreover, with practicality in mind, we improved the implementation in terms of communication cost. More precisely, we introduce a practical implementation of CKKS to significantly reduce the size of ciphertexts by more than 7.4× compared to the rudimentary implementation.

We experimentally validate our approach on text classification datasets, showing that it offers encrypted protection of embedding vectors, while maintaining utility competitive to plaintext on downstream classification tasks. Additionally, we compare our method with PrivFT on homomorphic training on encrypted data, showing it outperforms PrivFT, with much improved training efficiency.

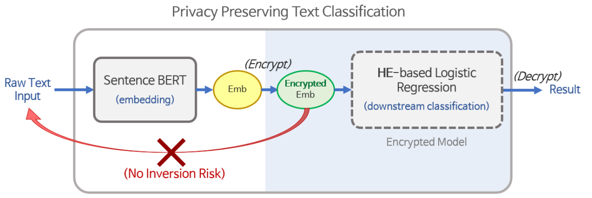

Figure 1: The Architecture of Text Classification. The region shaded in light blue represents encrypted state. The privatization inference takes the following steps: 1) User generates sentence embedding. 2) User encrypts embedding. 3) Logistic regression in encrypted state is performed using encrypted embedding.

2 Method

We focus on the scenario in which the user directly applies the privacy mechanism to the output embeddings from a neural text encoder, before passing it on to a service provider for usage in a downstream task. This is also referred to as a local privacy setting (Qu et al., 2021).

The privatization procedure M_{priv} in the local privacy setting can be defined as follows:

$$M_{priv}(x) = P(F_{emb}(x)) \tag{1}$$

where x is the raw text input, F_{emb} is Sentence-BERT (Reimers and Gurevych, 2019)[3], a popular pre-trained model for obtaining sentence embeddings, and P denotes a privacy mechanism. Next, we securely classify the text datum, x, by feeding its privatized embedding, $M_{priv}(x)$, to the downstream classification model. In this work, we adopt a logistic regression model (in encrypted state) as the downstream classifier. Figure 1 demonstrates the entire privatization inference procedure, starting with user's embedding of raw text and encryption of embedding, to the operation of the classifier in encrypted state and finally, the output of encrypted classification results. We note that the training process also can be performed in encrypted state as we describe in Section 2.2.

2.1 Baseline: Local Differential Privacy

As a baseline for the local privacy setting, we implement noise-based local differential privacy (LDP). Qu et al. (2021) introduced noise-based LDP for single-token embeddings as privatization mechanism P. In the case of single-token embeddings, local differential privacy can be achieved with respect to a chosen Euclidean distance by adding randomly

---

[2] An attacker needs $> 2^{128}$ operations to recover the plaintext from a ciphertext with the current best algorithm.

[3] `https://www.sbert.net/`

Table 1: Size of Ciphertext/Training Time of Encrypted Logistic Regression. We report the ciphertext size and training time for the ciphertext model. Note that plaintext and LDP classifiers have negligible training and inference times.

	Twitter (2 classes)			SNIPS (7 classes; OvR)		
	ciphertext	plaintext	training time	ciphertext	plaintext	training time
train	1.4 GB	183.7 MB	143.2 sec/epoch	11.4 GB	206.5 MB	1111.4 sec/epoch

sampled noise N drawn from an n-dimensional distribution with density $p(N) \propto \exp(-\eta||N||)$. That is, the privacy mechanism is $P(y) = y + N$, where y denotes an embedding vector. In our work, we adopt the same mechanism to sentence embeddings. Following Qu et al. (2021), the noise $N \in \mathbb{R}^n$ is sampled as a pair (r, p), where r is the distance from the origin and p is a point in $\mathbb{B}^n$ (the unit hypersphere in $\mathbb{R}^n$). r is sampled from Gamma distribution $\Gamma(n, \frac{1}{\eta})$ and p is sampled uniformly over $\mathbb{B}^n$, and N is computed as $N = rp$.

2.2 HE Based Logistic Regression

We now describe our proposed privatization mechanism in detail. We adopt Eq.1, with the privacy mechanism $P(y) = H(y)$, where H is the homomorphic encryption. For downstream tasks, we feed the privatized embedding $M_{priv}(x)$ to an *encrypted* logistic regression classifier. By utilizing HE, an encrypted model and labels will be obtained after the training and inference process. Only the user who knows the secret key of HE can decrypt the results and get either the classifier or labels for the classification.

For the homomorphic encryption H, we adopt the CKKS scheme (Cheon et al., 2017, 2018, 2019). While the majority of HE schemes are being optimized for computations over finite fields, CKKS supports efficient computations over *real numbers*, so it is advantageous in application to real world data. We refer the readers to the paper (Cheon et al., 2017) for full details of CKKS.

CKKS is a levelled homomorphic encryption scheme, where the *level* of each ciphertext indicates the remaining number of times we can operate.[4] When we multiply two ciphertexts of level l, the output ciphertext has a level of $l - 1$. Once the level of a ciphertext becomes too low, we can refresh its level higher by using the *bootstrapping* technique so that the number of possible operation times increases. For ciphertexts ct_1 and ct_2 of complex vector messages m_1 and m_2, we summarize the operations of CKKS as follows:

- $\mathsf{Add}(\mathsf{ct}_1, \mathsf{ct}_2)$: output a ciphertext of $\mathsf{m}_1 + \mathsf{m}_2$.
- $\mathsf{Mult}(\mathsf{ct}_1, \mathsf{ct}_2)$: output a ciphertext of $\mathsf{m}_1 \odot \mathsf{m}_2$, where $\odot$ is the entry-wise multiplication.
- $\mathsf{Bootstrap}(\mathsf{ct}_1)$: output a ciphertext of m_1 at refreshed level.

While it is prevalent to encrypt data into the top level, L, in this work, we encrypt the data into a lower level, 3, to decrease the initial size of ciphertexts. [5] Note that the ciphertexts are the privatized embeddings, so their size determines the communication cost. As shown in Table 1, by using the lower level ciphertexts, we reduce the initial size of ciphertext by more than 7.4× in both Twitter training dataset (10.8GB to 1.4GB), and SNIPS training dataset (85.3GB to 11.4GB).

Finally, we feed the output of our privatization mechanism to the next step, the training and inference of an encrypted logistic regression classifier. However, since CKKS supports only addition and multiplication while the logistic function $(1/(1 + \exp(-x))$ is a non-polynomial function, we evaluate the logistic function via its polynomial approximation. We use the minimax approximate polynomial (Pachon and Trefethen, 2009) of degree 15 on $[-12, 12]$ that approximates the logistic function within the error of 0.00614 on $[-12, 12]$.

2.3 Datasets

To validate our approach in real-world scenarios, we conduct experiments on tasks with realistic privacy concerns and utility needs. We select text classification tasks on data in three settings:

- **Tweets Hate Speech Detection** (Sharma, 2018)[6]: Is a crowd-sourced dataset of Tweets for binary classification, where labels denote a Tweet as containing hate speech, if it has a racist or sexist sentiment associated with it. We created random data splits for train/validation/test, with 11,634/3,197/4,795 examples, respectively.

- **SNIPS** (Coucke et al., 2018): Is a dataset of crowd-sourced queries collected from the

---

[4] We remark that this *level* is not related to the security level of CKKS. For example, in our implementation, all ciphertexts have 128-bit security level regardless of the remaining number of operations.

[5] We use $L = 29$ in our implementation.

Snips Voice Platform, distributed among 7 user intents. It has been widely adopted in evaluating spoken language understanding (SLU) systems. We use the same data splits as Goo et al. (2018); Qin et al. (2019), with 13,084/700/700 examples, respectively.

- **Youtube Spam Collection** (Badawi et al., 2020)[7]: Is a public data set collected for spam research from UCI Machine Learning Repository, where five datasets are composed by 1,956 real messages extracted from five videos. As train/validation/test splits are not provided, we created our own random splits, with 1,564/196/196 examples, respectively.

3 Experiments

3.1 Encrypted Sentence Classification

Once sentence embeddings are extracted from Sentence-BERT for each input text, the vectors consist of 768 numerical values of 32-bit floating point from -1 to 1. Then, a logistic regression model is trained for binary classification on the Twitter dataset, and multiclass classification on the SNIPS dataset, respectively.

To perform a fair comparison of the results of each approach, we keep the same implementation of logistic regression for plaintext, as that of the ciphertext model. Multiclass classification is performed as multiple separate binary logistic regression models for each class, and we take the argmax from the combined results; One-vs-Rest (OvR). Experiments for noise-based local differential privacy on plaintext are conducted in the same way, using the privacy mechanism described in Section 2.1. Logistic regression parameters are optimized by SGD with Nesterov momentum. For all models, the best performing model and optimal threshold for F1 was identified by validation set performance.

For plaintext experiments, the following hyperparameters were used for training: Learning rate 3.0, gamma 0.9, batch size 256 for Twitter dataset, and learning rate 3.0, gamma 0.1, batch size 128 for SNIPS dataset. Both models were trained for 10 epochs. For the parameters of the CKKS scheme, we selected the dimension $N = 2^{17}$ and set the size of the maximum modulus q_L to be 1540 bits. We note that our CKKS parameters satisfy 128-bit security level (Albrecht, 2017). For ciphertext experiments, the following hyperparameters were used for training: Learning rate 3.0, gamma 0.9, batch size 512 for Twitter dataset, and learning rate 2.0, gamma 0.1, batch size 512 for SNIPS dataset. Both models were trained for 10 epochs. Additionally, we developed an efficient parallelized CKKS implementation for bootstrapping with GPU acceleration for the encrypted logistic regression model. For implementation, we use a dual-NVLink Nvidia Quadro RTX6000 GPU with 24 GiBs of memory, on a server with a Intel Xeon Gold 6242R CPU (80 core) and 125 GiBs of RAM.

3.2 Embedding Inversion

As a quantitative evaluation of inversion risk, we adopt sentence embedding inversion. Introduced in Song and Raghunathan (2020), embedding inversion is an adversarial attack whose goal is to recover the original text (its tokens) from its embedding. In this work, we focus on *black-box* inversion, where the adversary can only interact with the model by querying it to obtain embeddings, and is therefore more pertinent to real-world privacy considerations.

---

Table 3: Sentence Embedding Inversion. Black-box inversion of sentence embeddings on SNIPS. We report F1 for the task of recovering the input words from the sentence embedding. Ciphertext denoted in bold.

Model	(Thresh)	Dev F1	Test F1
Noising			
$\eta = 50$	0.8	0.2082	0.1905
$\eta = 75$	0.8	0.3078	0.2955
$\eta = 100$	0.9	0.3587	0.3276
$\eta = 125$	0.9	0.4164	0.3899
$\eta = 150$	0.9	0.4572	0.4337
$\eta = 175$	0.85	0.4919	0.4803
Ciphertext	-	**-**	**-**
Plaintext	0.85	0.6705	0.6759

4 Results

We report the results of our logistic regression experiments in Table 2. We compare our approach, denoted as Ciphertext, with the Plaintext baseline, as well as the noise-based LDP from Qu et al. (2021), at different levels of the noise paramter η (smaller indicates larger noise). Measured by F1/AUC metric, our HE classifier achieves roughly $98.79\%/99.58\%$ and $98.76\%/99.89\%$ of the plaintext baseline classifier's performance on Twitter and SNIPS test sets, respectively, indicating that our HE of embeddings is able to preserve their downstream utility to a significant degree. We find that our model performs better at all noise levels considered in Qu et al. (2021) (up to $\eta = 175$), nearly matching the plaintext model. On the other hand, for noise-based LDP, we observe a clear trade-off between increasing (via decreasing η) privacy protection and classification performance. As can be seen with $\eta = 50, 75$ on both datasets, the decrease in performance becomes greater as η becomes smaller and privacy protection is prioritized. Moreover, at any reasonable level of η, noise-based LDP cannot necessarily guarantee the complete elimination of inversion risk.

We next perform sentence embedding inversion experiments on SNIPS. In Table 3, we report the results at varying levels of η, using black-box inversion with a multi-label classification model as in Qu et al. (2021). For plaintext, the degree of inversion risk is consistent with black-box inversion results from Song and Raghunathan (2020), who report F1 of 59.76 for inverting BERT-based sentence embeddings[8], indicating a high degree of invertibility. Our results show that, in order to significantly reduce inversion risk, noise-based LDP requires low η settings, sacrificing downstream utility. In contrast, our method eliminates conventional risk of black-box inversion: Because all results of HE inference remain encrypted, and cannot be revealed without decryption with the user's secret key, black-box inversion cannot be applied. Therefore, 128-bit security level of homomorphic encryption guarantees practically complete protection from inversion, while offering significantly improved performance.

Table 4: Comparison to PrivFT. We report wallclock training time and test accuracy of binary spam classification. Ciphertext model results are denoted in bold.

Model	PrivFT	Ciphertext	Plaintext
(Num. GPUs)	8	1	-
Training time	60.48 hrs/epoch	**23.04 sec/epoch**	-
(Thresh)	-	0.53	0.51
Test accuracy	0.863	**0.908**	0.913

Finally, to directly compare our model with PrivFT, we conduct an experiment on the YTSC dataset, following the methodology in Section 3. We report the results in Table 4, along with PrivFT results on the same dataset from Badawi et al. (2020). We measure the test accuracy of the classifier, as well as the wallclock time required to perform encrypted training. We find that our method requires only 460.81 seconds with a single GPU to achieve 90.8% test accuracy, whereas PrivFT needs 5.04 days with 8 GPUs to obtain 86.3% test accuracy. This amounts to roughly ×9,450 faster training per epoch, while achieving higher accuracy and utilizing 1/8th the number of GPUs. These results experimentally validate our expectation that homomorphic encryption of pretrained embeddings significantly improves performance and efficiency.

5 Conclusion

We propose a privatization mechanism based on homomorphic encryption which, by leveraging BERT pre-trained embeddings, enables efficient training of an HE logistic regression classifier with little to no loss of downstream utility. While our method compares favorably to noise-based LDP and PrivFT, we also note that there are some limitations. Since HE based models require higher computation costs compared to plaintext models, the challenge remains to adopt more complex models, such as neural networks, as downstream classifiers. Nevertheless, the privacy benefits and efficiency of our method makes it a suitable candidate for scenarios with real-world privacy concerns.

Abstract

Recently, Multi-modal Named Entity Recognition (MNER) has attracted a lot of attention. Most of the work utilizes image information through region-level visual representations obtained from a pretrained object detector and relies on an attention mechanism to model the interactions between image and text representations. However, it is difficult to model such interactions as image and text representations are trained separately on the data of their respective modality and are not aligned in the same space. As text representations take the most important role in MNER, in this paper, we propose **I**mage-**t**ext **A**lignments (ITA) to align image features into the textual space, so that the attention mechanism in transformer-based pretrained textual embeddings can be better utilized. ITA first aligns the image into regional object tags, image-level captions and optical characters as visual contexts, concatenates them with the input texts as a new cross-modal input, and then feeds it into a pretrained textual embedding model. This makes it easier for the attention module of a pretrained textual embedding model to model the interaction between the two modalities since they are both represented in the textual space. ITA further aligns the output distributions predicted from the cross-modal input and textual input views so that the MNER model can be more practical in dealing with text-only inputs and robust to noises from images. In our experiments, we show that ITA models can achieve state-of-the-art accuracy on multi-modal Named Entity Recognition datasets, even without image information.[1]

1 Introduction

Named Entity Recognition (NER) (Sundheim, 1995) has attracted increasing attention in natural language processing community. It has been applied to a lot of domains such as news (Tjong Kim Sang, 2002; Tjong Kim Sang and De Meulder, 2003), E-commerce (Fetahu et al., 2021), social media (Strauss et al., 2016; Derczynski et al., 2017) and bio-medicine (Doğan et al., 2014; Li et al., 2016). Several recent studies focus on improving the accuracy of NER models through utilizing image information (MNER) in tweets (Zhang et al., 2018; Moon et al., 2018; Lu et al., 2018). Most approaches to MNER use the attention mechanism to model the interaction between image and text representations (Yu et al., 2020; Zhang et al., 2021a; Sun et al., 2021), in which image representations are from a pretrained feature extractor, i.e. ResNet (He et al., 2016), and text representations are extracted from pretrained textual embeddings, i.e. BERT (Devlin et al., 2019). Since these models are separately trained on datasets of different modalities and their feature representations are not aligned, it is difficult for the attention mechanism to model the interaction between the two modalities.

Recently, pretrained vision-language (V+L) models such as LXMERT (Tan and Bansal, 2019), UNITER (Chen et al., 2020) and Oscar (Li et al., 2020b) have achieved significant improvement on several cross-modal tasks such as image captioning, VQA (Agrawal et al., 2015), NLVR (Young et al., 2014) and image-text retrieval (Suhr et al., 2019). Most pretrained V+L models are trained on image-text pairs and simply concatenate text features and image features as the input of pretraining. There are, however, two problems. First, texts in these datasets mainly contain common nouns

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3176 - 3189
July 10-15, 2022

instead of named entities[2] which leads to an inductive bias over common nouns and images. Second, despite its important role in pretraining V+L models, the image modality only plays an auxiliary role in MNER for disambiguation, and can sometimes even be discarded. These problems make pretrained V+L models perform weaker than pretrained language models for MNER.

Pretrained textual embeddings such as BERT, XLM-RoBERTa (Conneau et al., 2020) and LUKE (Yamada et al., 2020) have achieved state-of-the-art performance on various NER datasets through simple fine-tuning of pretrained textual embeddings. Since most of the transformer-based pretrained textual embeddings are trained over long texts, recent work (Akbik et al., 2019; Schweter and Akbik, 2020; Yamada et al., 2020; Wang et al., 2021) has shown that introducing document-level contexts can significantly improve the accuracy of a NER model. The attention mechanism in transformer-based pretrained textual embeddings can utilize contexts to improve the token representation of a sequence. Moreover, pretrained V+L models such as Oscar and VinVL (Zhang et al., 2021b) can use object tags detected in images to significantly ease the alignments between text and image features. Therefore, the images in MNER can be converted to texts as well so that the image representations can be aligned to the space of text representations. As a result, the attention module of the pretrained textual embeddings have the capability to easily model the interactions between aligned image and text representations, without introducing a new attention module. In this paper, we propose ITA, a simple but effective framework for **I**mage-**T**ext **A**lignments. ITA converts an image into visual contexts in textual space by multi-level alignments. We concatenate the NER texts with the visual contexts as a new cross-modal input view and then feed it into a pretrained textual embedding model to improve the token representations of NER texts, which are fed into a linear-chain CRF (Lafferty et al., 2001) layer for prediction. In practice, a MNER model should be robust when there is only text information, as images may be unavailable or can introduce noises. Sometimes it is even undesirable to use images as image feature extraction can be inefficient in online serving. Therefore, we further propose to utilize the cross-modal input view to improve the accuracy of textual input view, based on cross-view alignment that minimizes the KL divergence over the probability distributions of the two views.

ITA can be summarized in four aspects:

1. Object Tags as Local Alignment: ITA locally extracts object tags and its corresponding attributes of image regions from an object detector.
2. Image Captions as Global Alignment: ITA summarizes what the image is describing through predicting image captions from an image captioning model.
3. Optical Character Alignment: ITA extracts the texts presented in the image via optical character recognition (OCR).
4. Cross-View Alignment: we calculate the KL divergence between the output distributions of two input views.

We show in experiments that ITA can significantly improve the model accuracy on MNER datasets and achieve the state-of-the-art. The cross-view alignment module can significantly improve both the cross-modal and textual input views, and bridge the performance gap between the two views.

2 Approaches

We consider the NER task as a sequence labeling problem. Given a sentence $\boldsymbol{w} = \{w_1, \cdots, w_n\}$ with n tokens and its corresponding image I, an sequence labeling model aims to predict a label sequence $\boldsymbol{y} = \{y_1, \cdots, y_n\}$ at each position. In our framework, we focus on incorporating visual information to improve the representations of the input tokens by aligning visual and textual information effectively. We use a visual context generator to convert the image I into texts forming visual contexts $\boldsymbol{w}' = \{w'_1, \cdots, w'_m\}$ with m tokens. We then concatenate the input text and visual contexts as a cross-modal text+image (**I+T**) input view instead of the text (**T**) input view. We feed the **I+T** input into a pretrained textual embeddings model to get stronger token representations of the input sentence. Then the token representations are fed into a linear-chain CRF layer to get the label sequence $\boldsymbol{y}$. To further improve the model accuracy of both input views, we use the cross-view alignment module to align the output distributions of **I+T** and **T**

---

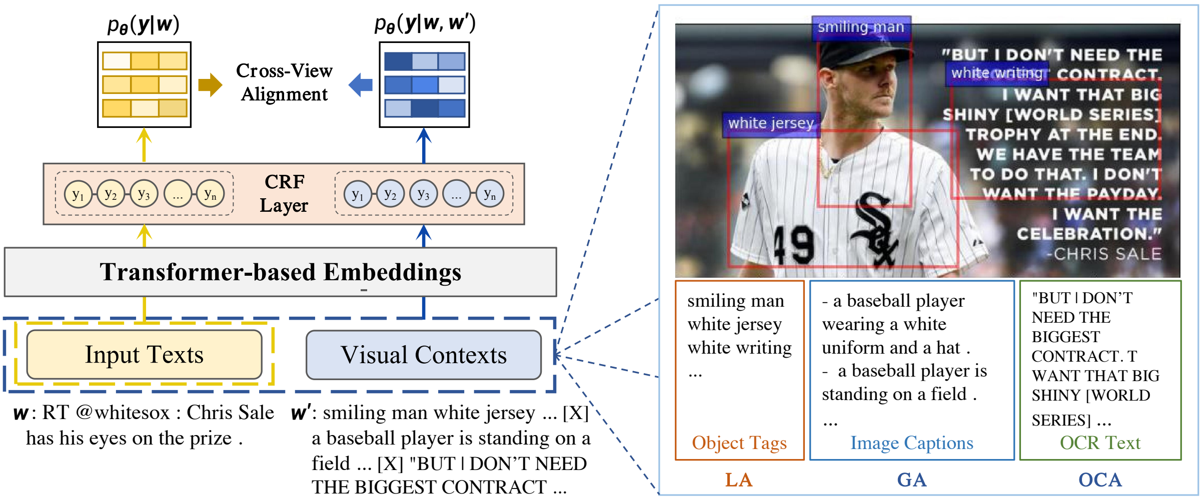

Figure 1: The architecture of ITA. ITA aligns an image into object tags, image captions and texts from OCR. ITA takes them as visual contexts and then feeds them together with the input texts into the transformer-based embeddings. In the cross-view alignment module, ITA minimizes the distance between the output distribution of cross-modal inputs and textual inputs.

input views during training. The architecture of our framework is shown in Figure 1.

2.1 NER Model Architecture

We use a neural model with a linear-chain CRF layer, a widely used approach for the sequence labeling problem (Huang et al., 2015; Akbik et al., 2018; Devlin et al., 2019). The input is fed into a transformer-based pretrained textual embeddings model and the output token representations $\{\boldsymbol{r}_1, \cdots, \boldsymbol{r}_n\}$ are fed into the CRF layer:

$$p_\theta(\boldsymbol{y}|\boldsymbol{w}) = \frac{\prod_{i=1}^{n} \psi(y_{i-1}, y_i, \boldsymbol{r}_i)}{\sum_{\boldsymbol{y}' \in \mathcal{Y}(\boldsymbol{w})} \prod_{i=1}^{n} \psi(y'_{i-1}, y'_i, \boldsymbol{r}_i)}$$

where θ is the model parameters, $\mathcal{Y}(\boldsymbol{w})$ is the set of all possible label sequences given the input $\boldsymbol{w}$. Given the gold label sequence $\hat{\boldsymbol{y}}$ in the training data, the objective function of the model for the **T** input view is:

$$\mathcal{L}_{\mathrm{T}}(\theta) = -\log p_\theta(\hat{\boldsymbol{y}}|\boldsymbol{w}) \qquad (1)$$

The loss can be calculated using Forward algorithm.

2.2 Image-text Alignments

The transformer-based pretrained textual embeddings have strong representations over texts. Therefore, ITA converts the image information into textual space through generating texts from the image so that the learning of the self-attention in the transformer-based model can be significantly eased compared with simply using image features from an object detector. We propose a local (LA), a global (GA) and an optical character alignment (OCA) approaches for alignments.

Object Tags as Local Alignment Given an image, the image information can be decomposed into a set of objects in local regions. The object tags of each region textually describe the local information in the image. To extract the objects, we use an object detector **OD** to identify and locate the objects in the image:

$$\boldsymbol{a}, \boldsymbol{o} = \mathbf{OD}(I); \text{ where}$$
$$\boldsymbol{a} = \{\boldsymbol{a}_1, \boldsymbol{a}_2, \cdots, \boldsymbol{a}_l\} \text{ and } \boldsymbol{o} = \{o_1, o_2, \cdots, o_l\}$$

The attribute predictions from the object detector contain multiple attribute tags $\boldsymbol{a}_i$ for each object o_i. We linearize and sort the objects in a descending order based on the confidences of the detection model. For each object, we heuristically keep 0 to 3 attributes with confidence scores above a threshold m. We linearize the attributes and put the attributes before the corresponding objects since the attributes are the adjectives describing the object tags. As a result, we take the predicted l object tags $\boldsymbol{o}$ and their attribute tags $\boldsymbol{a}$ from the object detector as the locally aligned visual contexts $\boldsymbol{w}^{\mathrm{LA}}$:

$$\boldsymbol{w}^{\mathrm{LA}} = \{\boldsymbol{a}_1, o_1, \boldsymbol{a}_2, o_2, \cdots, \boldsymbol{a}_l, o_l\}$$

Image Captions as Global Alignment Though the local alignment can localize the image into objects, the objects cannot fully describe the of the whole image. Image captioning is a task that predicts the meaning of an image. Therefore, we align the image into k image captions by an image captioning model **IC**:

$$\{\boldsymbol{w}^1, \boldsymbol{w}^2, \cdots, \boldsymbol{w}^k\} = \mathbf{IC}(I)$$

where $\{\boldsymbol{w}^1, \boldsymbol{w}^2, \cdots, \boldsymbol{w}^k\}$ are captions generated from beam search with k beams. We concatenate the k captions together with a special separate token [X] to form the aligned global visual contexts $\boldsymbol{w}^{\text{GA}}$:

$$\boldsymbol{w}^{\text{GA}}{=}[\boldsymbol{w}^1, \text{[X]}, \boldsymbol{w}^2, \text{[X]}, \cdots, \text{[X]}, \boldsymbol{w}^k]$$

The exact label (e.g. "[SEP]" in BERT) of the special [X] token depends on the selection of embeddings.

Optical Character Alignment Some image contain text when they are created to enrich the semantic information that the images want to convey. In order to better understand this type of image, we use an **OCR** model to identify and extract the texts in the image:

$$\boldsymbol{w}^{\text{OCA}} = \mathbf{OCR}(I)$$

where $\boldsymbol{w}^{\text{OCA}}$ are the texts extracted by the **OCR** model. Note that $\boldsymbol{w}^{\text{OCA}}$ may be an empty text if there is no text in the image.

We concatenate the input sentence and our aligned visual contexts to form the **I+T** input view $\hat{\boldsymbol{w}} = [\boldsymbol{w}; \boldsymbol{w}']$, where $\boldsymbol{w}'$ can be one of $\boldsymbol{w}^{\text{LA}}$, $\boldsymbol{w}^{\text{GA}}$, $\boldsymbol{w}^{\text{OCA}}$ or the concatenation of all (we denote it as **All**). The transformer-based embeddings are fed with the **I+T** input view and then output image-text fused token representations for each token $\{\boldsymbol{r}'_1, \cdots, \boldsymbol{r}'_n\}$. The token representations are fed into the CRF layer to get the probability distribution $p_\theta(\boldsymbol{y}|\hat{\boldsymbol{w}})$. Similar to Eq. 1, the objective function of the model for the **I+T** input view is:

$$\mathcal{L}_{\text{I+T}}(\theta) = -\log p_\theta(\hat{\boldsymbol{y}}|\hat{\boldsymbol{w}}) \tag{2}$$

Cross-View Alignment There are several limitations in incorporating images into NER prediction: 1) the images may not available in testing; 2) aligning images to texts requires several pipelines in pre-processing instead of an end-to-end manner, which is so time-consuming that it is not applicable to some time-critical scenes such as online serving; 3) the noises in the image can mislead the MNER model to make wrong predictions. To alleviate these issues, we propose Cross-View Alignment (CVA), which targets at reducing the gap between the **I+T** and **T** input views over the output distributions so that the MNER model can better utilize the textual information in the input. During training, CVA minimizes the KL divergence over the probability distribution of **I+T** and **T** input views:

$$\mathcal{L}_{\text{CVA}}(\theta){=}\text{KL}(p_\theta(\boldsymbol{y}|\hat{\boldsymbol{w}})||p_\theta(\boldsymbol{y}|\boldsymbol{w})) \tag{3}$$

Since the **I+T** input view has additional visual information in the input and we want the **T** input view to match the accuracy of **I+T** input view, we only back-propagate through $p_\theta(\boldsymbol{y}|\boldsymbol{w})$ in Eq. 3. Therefore, Eq. 3 is equivalent to calculating the cross-entropy loss over the two distributions:

$$\mathcal{L}_{\text{CVA}}(\theta){=}\sum_{\boldsymbol{y}\in\mathcal{Y}(\boldsymbol{x})} p_\theta(\boldsymbol{y}|\hat{\boldsymbol{w}}) \log p_\theta(\boldsymbol{y}|\boldsymbol{w}) \tag{4}$$

As the set of all possible label sequences $\mathcal{Y}(\boldsymbol{x})$ is exponential in size, we calculate the posterior distributions of each position $p_\theta(y_i|\boldsymbol{w})$ and $p_\theta(y_i|\hat{\boldsymbol{w}})$ through forward-backward algorithm to approximate Eq. 4:

$$\begin{aligned} p_\theta(y_k|*) \propto & \sum_{\{y_0,\dots,y_{k-1}\}} \prod_{i=1}^{k} \psi(y_{i-1}, y_i, \boldsymbol{r}^*_i) \\ \times & \sum_{\{y_{k+1},\dots,y_n\}} \prod_{i=k+1}^{n} \psi(y_{i-1}, y_i, \boldsymbol{r}^*_i) \end{aligned}$$

$$\mathcal{L}_{\text{CVA}}(\theta){=}\sum_{i=1}^{n} p_\theta(y_i|\hat{\boldsymbol{w}}) \log p_\theta(y_i|\boldsymbol{w})) \tag{5}$$

where $\boldsymbol{r}^*_i$ represents either $\boldsymbol{r}_i$ or $\boldsymbol{r}'_i$.

Training During training, we jointly train **T** and **I+T** input views with the training objective in Eq. 1 and 2 together with the CVA alignment training objective in Eq. 5. As a result, the final training objective for ITA is:

$$\mathcal{L}_{\text{ITA}} = \mathcal{L}_{\text{CVA}} + \mathcal{L}_{\text{T}} + \mathcal{L}_{\text{I+T}}$$

3 Experiments

We conduct experiments on two MNER datasets. To show the effectiveness of our approaches, we use two embedding settings and compare our approaches with previous multi-modal approaches.

3.1 Settings

Datasets We show the effectiveness of our approaches on Twitter-15, Twitter-17 and SNAP Twitter datasets[3] containing 4,000/1,000/3,357, 3,373/723/723 and 4,290/1,432/1,459 sentences in train/development/test split respectively. The Twitter-15 dataset is constructed by Zhang et al. (2018). The SNAP dataset is constructed by Lu et al. (2018) and the Twitter-17 dataset is a filtered version of SNAP constructed by Yu et al. (2020).

Model Configuration For token representations, we use BERT base model to fairly compare with most of the recent work (Yu et al., 2020; Zhang et al., 2021a; Sun et al., 2021). Recently, XLM-RoBERTa has achieved state-of-the-art accuracy on various NER datasets by feeding the input together with contexts to the model. To further utilize the visual contexts in transformer-based embeddings, we use XLM-RoBERTa large (XLMR) model as another embedding in our experiments. To extract object tags and image captions of the image, we use VinVL (Zhang et al., 2021b), which is a pretrained V+L model based on a newly pretrained large-scale object detector based on the ResNeXt-152 C4 architecture. We use the object detection module of VinVL to predict object tags and their corresponding attributes. The number of object tags and attributes varies over the images and is no more than 100. We set the threshold m to be 0.1 for keeping the attributes of each object. For image captions, we use VinVL large model finetuned on MS-COCO (Lin et al., 2014) captions[4] with CIDEr optimization (Rennie et al., 2017). In our experiments, we use a beam size of 5 with at most 20 tokens for prediction and keep all the 5 captions as the visual contexts. For OCR, we use Tesseract OCR[5] (Smith, 2007), which is an open source OCR engine. We use the default configuration of the engine to extract texts in the image[6].

Training Configuration During training, we finetune the pretrained textual embedding model by AdamW (Loshchilov and Hutter, 2018) optimizer. In experiments we use the grid search to find the learning rate for the embeddings within $[1 \times 10^{-6}, 5 \times 10^{-4}]$. For BERT embeddings, we finetune the embeddings with a learning rate of 5×10^{-5} with a batch size of 16. For XLMR embeddings, we use a learning rate of 5×10^{-6} and a batch size of 4 instead. For the learning rate of the CRF layer, we use a grid search over $[0.05, 0.5]$ and $[0.005, 0.05]$ for BERT and XLMR respectively. The MNER models are trained for 10 epochs and we report the average results from 5 runs with different random seeds for each setting.

3.2 Results

In Table 1, we compare our approaches with our baselines with different training and evaluation modalities (**T** for the text-only input view and **I+T**

---

[3] Twitter-15 and 17 datasets are available at `https://github.com/jefferyYu/UMT`.

[4] `github.com/microsoft/Oscar`

[5] `github.com/tesseract-ocr/tesseract`

[6] Please refer to Appendix A.2 for more statistics.

for the multi-modal input view). Results show that ITA models are significantly stronger than our **BERT-CRF** and **XLMR-CRF** baselines (Student's t-test with $p < 0.05$). For the aligned visual contexts, LA, GA and OCA are competitive in most of the cases. To show the effectiveness of CVA, we report the evaluation results of both input views in evaluation. With CVA, the accuracy of both input views can be improved, especially the **T** input view. CVA can improve the **T** input view to be competitive with **I+T** input view. Moreover, the combination of all the alignments **ITA-All**$_{\textbf{+CVA}}$ can further improve the model accuracy in most of the cases. The accuracy of the MNER models can be significantly improved if we use XLMR embeddings, which shows the importance of the text modality in MNER. With XLMR embeddings, the model accuracy can be further improved with ITA. The relative improvements over the baseline models are sometimes higher with XLMR than with BERT, which shows that the visual contexts can be further utilized with stronger embeddings.

In Table 2, we compare **ITA** with previous state-of-the-art approaches. For previous approaches, we report the results including **OCSGA**, **UMT**, **RIVA**, **RpBERT**, **UMGF**, which are the proposed approaches of Wu et al. (2020), Yu et al. (2020), Sun et al. (2020), Sun et al. (2021) and Zhang et al. (2021a) respectively. For fair comparison, we report the results of these models based on the BERT base embeddings. Moreover, since most of these previous approaches report the best model accuracy instead of the averaged model accuracy, we use the best model accuracy of **ITA-All**$_{\textbf{+CVA}}$ over 5 runs. We also report our reproduced results of **UMT**, **RpBERT** and **UMGF** on the corresponding datasets. The results show that **ITA-All**$_{\textbf{+CVA}}$ outperforms all of the previous approaches. On the SNAP dataset, the reported accuracy of **RpBERT**$_{\textbf{base}}$ is competitive with **ITA-All**$_{\textbf{+CVA}}$. However, we find that the accuracy of our reproduced **RpBERT**$_{\textbf{base}}$[7] is significantly lower than the reported accuracy, even after careful check of the source code and hyper-parameter tuning. Moreover, the fact that our **BERT-CRF** baseline achieves competitive accuracy with previous state-of-the-art multi-modal approaches shows that most of the previous work has not fully explored the strength of the text representations for the task.

Approaches	Twitter-15	Twitter-17
BERT-CRF$_{\textbf{UMT}}$	71.81	83.44
BERT-CRF$_{\textbf{Ours}}$	74.79	85.18
OUR REPRODUCTIONS		
BERT-CRF$_{\textbf{UMT}}$	71.74	84.20
BERT-CRF$_{\textbf{UMT-Improved}}$	72.53	84.48
UMT	72.83	84.88
UMT$_{\textbf{Improved}}$	72.96	84.50

Table 3: Our reproductions of previous baselines and approaches. "Improved" means our improved models based on the UMT code base.

Discussion about Textual Modules As we have shown in Table 1 and 2, the textual baselines (i.e. **BERT-CRF**) of previous work are significantly lower than that of ours. In most of the previous MNER architectures, the textual modules are mainly based on the baseline architectures with some modifications. We further show the baselines of previous work are not well-trained and how the multi-modal approaches perform with stronger textual modules. In Table 3, we rerun the **BERT-CRF** baseline based on the released codes of **UMT**[8]. Based on the code of **UMT**, we tried to improve the baseline models in the code by using the same loss function as ours[9]. The accuracy of **BERT-CRF** models in the code are significantly improved but the **UMT** models based on the improved code are not improved and even get worse in Twitter-17. Therefore, we suspect the **UMT** model cannot be further improved even with stronger textual modules. Zhang et al. (2021a) also reported the baseline based on the implementation of Yu et al. (2020), so we suspect the **UMGF** model cannot be improved as well. Therefore, the under-trained textual baselines of previous work make the effectiveness of the images unclear and we show that some of the MNER models perform even weaker than our **BERT-CRF** model.

3.3 Comparison with Other Variants

To further show the effectiveness of ITA, we perform several comparisons between ITA and the following variants of the MNER model in Table 4:

ITA-Random: We generate random image-text pairs for the model. For each sentence, we randomly select the image in the dataset and generate the corresponding visual contexts. The noises of random visual contexts make the model accuracy

Table 4: A comparison of other variants of MNER models.

drop slightly comparing with our **BERT-CRF** baseline, which shows the improvement of our approach is from the visual contexts rather than extending the input sequence length the embeddings.

ITA-Joint: It is an ablated model of **ITA-All$_{\text{+CVA}}$**. We train the **ITA-All** model for both input views without the CVA loss in Eq. 5. The model accuracy is improved moderately with only the **T** input view while our **ITA-All$_{\text{+CVA}}$** can improve both input views significantly, which shows the effectiveness of the CVA module of ITA.

ITA-LA$_{\text{BU}}$ and ITA-GA$_{\text{BU}}$: We conduct experiments to see how the accuracy changes when using weaker image features. We use **B**ottom-**U**p features proposed by Anderson et al. (2018) for object detection and image captioning. The captioning model is a pretrained image captioning model[10] proposed by Luo et al. (2018) with the Bottom-Up features and self-critical training (Rennie et al., 2017). Results show that there is no significant difference between the visual contexts from Bottom-Up features and VinVL features. Therefore, our approaches can utilize other off-the-shelf vision models to extract visual contexts.

ITA-OCA$_{\text{Paddle}}$: We conduct experiments to see how the accuracy changes when using stronger OCR models. We use PaddleOCR[11] for the experiment, which is one of the newest open resource lightweight OCR system. Results show that the model accuracy can be slightly improved comparing with **ITA-OCA**, which shows the ITA models can be improved by using better OCR models.

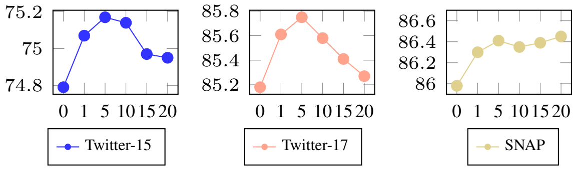

Figure 2: A relation between the number of captions input to the MNER model and model accuracy. The x-axis is the number of captions. The y-axis is the averaged F1 score on the test set.

BERT-CRF$_{\text{+ImgFeat}}$: Instead of **ITA**, we can directly feed the image region features generated from an object detector into the BERT. We use ResNet-152 model to generate region features and then feed the features into a linear layer to project the region features into the same space of text features in the BERT. Moreover, we compare the model with **RpBERT w/o Rp**, which is an ablated model of **RpBERT** and is equivalent to **BERT-CRF+$_{\text{+ImgFeat}}$** over the usage of BERT embeddings. Sun et al. (2021) showed **RpBERT w/o Rp** can improve the model accuracy compared with their baseline. However, our results show that the model accuracy slightly drops comparing with our **BERT-CRF**, which shows that it is difficult for the attention module of BERT to learn the relations of the unaligned representations of two modalities.

VinVL-CRF: To show how the pretrained V+L models perform on the NER task, we use VinVL since it is a very recent state-of-the-art pretrained V+L model on a lot of multi-modal tasks. We feed the VinVL model with texts and images in the MNER datasets and finetune the model over the task. We take the text representations output from VinVL as the input of the CRF layer. The accuracy of the finetuned VinVL model drops significantly compared to the BERT model, which shows that the inductive bias of the pretrained V+L model hurts the model accuracy on MNER.

BERT+VinVL-CRF: As the VinVL model may lead to an inductive bias over the common nouns and the image, we jointly finetune the BERT and VinVL models and concatenate the output text representations of the two models. The accuracy is improved on a moderate scale, which shows BERT is complementary to VinVL for MNER.

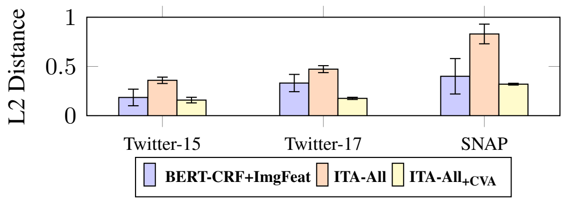

Figure 3: Averaged L2 distance between the token representations without image input ($\boldsymbol{r}_i$) and with image input ($\boldsymbol{r}'_i$). The error bars mean the standard deviation over 5 runs.

3.4 Analysis

Effect of the Number of Captions Using more captions output from the captioning model can improve diversities of the visual contexts but can add noises to them as well. To better understand how the number of captions affects the model accuracy, we change the beam size and keep all the sentences output from the captioning model. The trends in Figure 2 show that the model accuracy increases until 5 captions for all the datasets and gradually drops when the number of captions further increases for Twitter-15 and 17 datasets. The observation shows that using 5 captions keeps a good balance between the diversities and correctness of the captions.

How ITA Eases the Cross-Modal Alignments Previous work such as Moon et al. (2018); Sun et al. (2021) visualized modality attention in several cases to show the effectiveness of their approaches. However, visualizing the multi-layer attention in transformer-based embeddings is relatively difficult. Instead of studying special cases, we statistically calculate the averaged L2 distance between token representations $\boldsymbol{r}_i$ and $\boldsymbol{r}'_i$ from two input modalities to show how the token representations depend on image information. In Figure 3, the L2 distance **ITA-All** is significantly larger than that of **BERT-CRF+ImgFeat**. Besides, the standard deviation of **BERT-CRF+ImgFeat** is very large. The observations show the image region features make the alignment become difficult and unstable while our visual contexts can significantly ease the cross-modal alignments. Moreover, with CVA, the L2 distance becomes much smaller and stable as CVA aligns the two input views to reduce the dependence on images, which shows the MNER model can better utilize the textual information with CVA.

How Images Affect the NER Prediction To study the effectiveness of the images over each label, we show a comparison between our model and our baselines in Table 5. When the relative improvement of the F1 score is larger than 0.5, the relative improvement of precision is larger than that of recall. The observation shows that the main improvement of MNER is mainly because the images can help the model to reduce false-positive predictions for disambiguation on uncertain entities.[12]

4 Related Work

Multi-modal Named Entity Recognition Most of the previous approaches to MNER focus on the interaction between image and text features through attention mechanisms. Moon et al. (2018) proposed a modality attention network to fuse the text and image features before the input to the BiLSTM layer. Lu et al. (2018) additionally used a visual attention gate for the output features of the BiLSTM layer. Zhang et al. (2018) proposed an adaptive co-attention network after the BiLSTM layer to model the interaction between image and text. Recently, Wu et al. (2020) proposed OCSGA, which use object labels to model the interaction between image and object labels in an additional dense co-attention layer. Compared with the work, we show a simpler and more effective way to utilize object labels and additionally use other alignment approaches to further improve the model accuracy. Yu et al. (2020) proposed UMT, which utilized a multi-modal interaction module and an auxiliary entity span detection module for MNER. Zhang et al. (2021a) proposed UMGF, which utilizes a pretrained parser to create the graph connection between visual object tags and textual words. They used a graph attention network to fuse the textual and visual features. In order to better model whether the image is related to the text, Sun et al. (2021) proposed RpBERT, which additionally trains on a text-image relation classification dataset proposed by Vempala and Preoţiuc-Pietro (2019) to prevent the negative effect of noisy images. Comparing with RpBERT, we use CVA to let the NER model better utilize the input sentences without such kinds of supervision. All of these approaches focus on fusing the image and text features through the attention mechanism but ignore the gap between the image and text features while we propose to fully utilize the attention mechanism in the pretrained textual embeddings through

---

[12] In Appendix A.3, we show several cases to show the effectiveness of ITA to affect NER prediction.

Table 5: A comparison between our ITA (**ITA-All$_{+\text{CVA}}$** with **I+T** inputs) model and the baseline (**BERT-CRF**) in precision (P), recall (R) and F1. **Δ** represents the relevant improvement of ITA over the Baseline.

aligning image features into textual space. Besides, some cross-media research also shows the effectiveness of OCR texts (Chen et al., 2016; Wang et al., 2020) and object tags (Wu et al., 2016) have been shown. Most of the approaches introduced a new attention module over cross-modal features while in comparison ITA effectively utilizes the attention module in the pretrained textual embeddings.

Pretrained Vision-Language Models Inspired by related work on language model pretraining, visual-language pretraining (VLP) has recently attracted a lot of attention (Li et al., 2019; Lu et al., 2019; Chen et al., 2020; Tan and Bansal, 2019; Li et al., 2020a; Yu et al., 2021; Zhang et al., 2021b). The pretrained V+L models are pretrained on large-scale image-text pairs and have achieved state-of-the-art accuracy over various vision-language tasks such as image captioning, VQA, NLVR and image-text retrieval. Recently, Li et al. (2020a) proposed Oscar to add object tags in pretraining so that self-attention can learn the image-text alignments easily. Following Oscar, Zhang et al. (2021b) proposed VinVL to train a large-scale object detector to improve the pretrained V+L model's accuracy. Comparing with VLP, MNER is a totally different task. Firstly, the image-caption pairs are given in VLP and the image and text are equally important in pretraining for general representations. Therefore, using global alignment is meaningless for VLP but makes sense for MNER. In MNER, the input text is not the caption of the image and the image may not adds additional information to the input text. Secondly, though captions and object tags are often utilized in VLP, how to effectively utilize the captions and object tags of the image in MNER is rarely considered. Finally, besides the local and global alignments, another aspect of ITA is the optical character alignment and cross-view alignment, which is rarely considered in VLP.

5 Conclusion

In this paper, we propose Image-Text Alignments for multi-modal named entity recognition, which convert images into object labels, captions and OCR texts to align the image representations into textual space in a multi-level manner and form a cross-modal input view. The model can effectively utilize attention module of the transformer-based embeddings. Considering noises, availability of images and inference speed for practical use, we propose cross-view alignment, which let the MNER models better utilize the text information in the input. In our experiments, we show that ITA significantly outperforms previous state-of-the-art approaches on MNER datasets. We also show that most of the previous work failed to train a good textual baseline while our textual baseline can easily match or even outperform previous multi-modal approaches. In analysis, we further analyze how ITA eases the cross-modal alignments and how the images affect the NER prediction.

A Appendix

A.1 Details of Experiment Settings

We run our code on Tesla V100 GPU with 16 GB memory. It takes about two hours to train a model. The size of model parameter is approximately equal to size of BERT/XLMR embeddings.

A.2 Details of OCA

Table 6 shows that the OCR system only finds about 26% sentences have texts in the image and the extracted texts have an average of 28 tokens. The statistics show that ITA-OCA can help to improve the model accuracy with only 26% of the samples have OCR texts.

A.3 Case Study

Despite that images can generally help to improve the accuracy of the NER model, there are a lot of cases that the images may contain misleading information to hurt the model prediction. We study two cases for LA nad GA: 1) the entities are wrongly predicted by **BERT-CRF** baseline but are correctly predicted by **ITA**; 2) the entities are wrongly predicted by **ITA** without CVA but are correctly predicted by the baseline and **ITA** with CVA. Figure 4 shows the two cases with two samples for each. Figure 4 (a) shows the first case, which shows the importance of the visual contexts. The baseline model failed to recognize the person entities "TWICE" and "Harry Potter" possibly because the two words are usually an adverb and a book name respectively. For the **I+T** input view, our MNER model is able to recognize the hints such as "two girls", "young girl", "a couple of young men" and "woman" in the visual contexts and then correctly predict the two entities. Figure 4 (b) shows the second case, which shows how the noises from the image mislead the model predictions. There are three- and two-person entities in gold labels but the visual contexts indicate that the top right image has "two baseball players" and the bottom right image has only "a woman". As a result, **ITA** without CVA only predict two and one person entities according to the visual contexts in the two samples respectively. However, with CVA, **ITA** takes a good balance in utilizing the textual and visual information and correctly predicts the entity labels in both **T** and **I+T** input views.

For OCA, we study how the extracted texts can help model prediction. In the upper sample of Figure 5, there are two "Donald" words in the image. The baseline model failed to identify the latter one while **ITA-OCA** can successfully identify both of them. In the bottom of Figure 5, the texts in the image are mainly talking about "HARRY STYLES", which helps the model prediction.

A.4 Discussion

In our paper, we use the captioning and object detection model based on MSCOCO and visual genome. The model performance could be improved if we use domain-specific models (Twitter domain). For OCA, the model accuracy may be poor if the OCR system does not support a certain language.

A.5 Loss Function Comparison with UMT

In the codes of UMT, the BERT embeddings tokenize the token in a sentence into subtokens. The codes use the first subtoken as the token representation to predict the corresponding label. However, for the other subtokens, the codes use a special label "PAD" for prediction. Therefore, the target labels are changed. For example, the original label

Avg. Length	27.72	27.00	28.93

Table 6: A statistic about the number of sentences has OCR texts and the average length of OCR texts.

sequence is “B-X, I-X, O, B-X, O, O” but now it becomes “B-X, PAD, PAD, I-X, O, B-X, O, PAD, O”. As a result, the exact training objective changes compared with the training objective in the paper of UMT. We improve the code by removing all the “PAD” labels and just use the first subtoken of each token as the token representation. Our improved baseline model is significantly improved, while the accuracy of UMT model in the improved code cannot be further improved.

A Dataset for N-ary Relation Extraction of Drug Combinations

Abstract

Combination therapies have become the standard of care for diseases such as cancer, tuberculosis, malaria and HIV. However, the combinatorial set of available multi-drug treatments creates a challenge in identifying effective combination therapies available in a situation. To assist medical professionals in identifying beneficial drug-combinations, we construct an expert-annotated dataset for extracting information about the efficacy of drug combinations from the scientific literature. Beyond its practical utility, the dataset also presents a unique NLP challenge, as the first relation extraction dataset consisting of variable-length relations. Furthermore, the relations in this dataset predominantly require language understanding beyond the sentence level, adding to the challenge of this task. We provide a promising baseline model and identify clear areas for further improvement. We release our dataset,[1] code,[2] and baseline models[3] publicly to encourage the NLP community to participate in this task.

1 Introduction

"*So far, many monotherapies have been tested, but have been shown to have limited efficacy against* ***COVID-19****. By contrast,* ***combinational*** *therapies are emerging as a useful tool to treat SARS-CoV-2 infection.*" (Ianevski et al., 2021).

Indeed, combining two or more drugs together has proven to be useful for treatments of various medical conditions, including cancer (DeVita et al., 1975; Carew et al., 2008; Shuhendler et al., 2010), AIDS (Bartlett et al., 2006), malaria (Eastman and Fidock, 2009), tuberculosis (Bhusal et al., 2005), hypertension (Rochlani et al., 2017) and COVID-19 (Ianevski et al., 2020).

In this work, we examine the clinically significant and challenging NLP task of extracting known drug combinations from the scientific literature. We present an expert-annotated dataset and baseline models for this new task. Our dataset contains 1600 manually annotated abstracts, each mentioning between 2 and 15 drugs. 840 of these abstracts describe one or more positive drug combinations, varying in size from 2 to 11 drugs. The remaining 760 abstracts either contain mentions of drugs not used in combination, or discuss combinations of drugs that do not give a combined positive effect.

For the clinical setting, solving the drug combination identification task can help researchers suggest and validate complex treatment plans. For example, when searching for effective treatments for cancer, knowing which drugs interact synergistically with a first line treatment allows researchers to suggest new treatment plans that can subsequently be validated in-vivo and become a standard protocol (Wasserman et al., 2001; Katzir et al., 2019; Ianevski et al., 2020; Niezni et al., 2022).

From an NLP perspective, the drug combination identification task and dataset pushes the boundaries of relation extraction (RE) research, by introducing a relation extraction task with several challenging characteristics:

Variable-length n-ary relations Most work on relation extraction is centered on *binary relations* (e.g. Li et al. (2016), see full listing in §5), or on *n-ary relations with a fixed* n (e.g. Peng et al. (2017)). In contrast, the drug combination task involves *variable-length n-ary relations*: different passages discuss combinations of different numbers of drugs. For each subset of drugs mentioned in a passage, the model must predict if they are used together in a combination therapy and whether this drug combination is effective.

---

* Equal contribution.

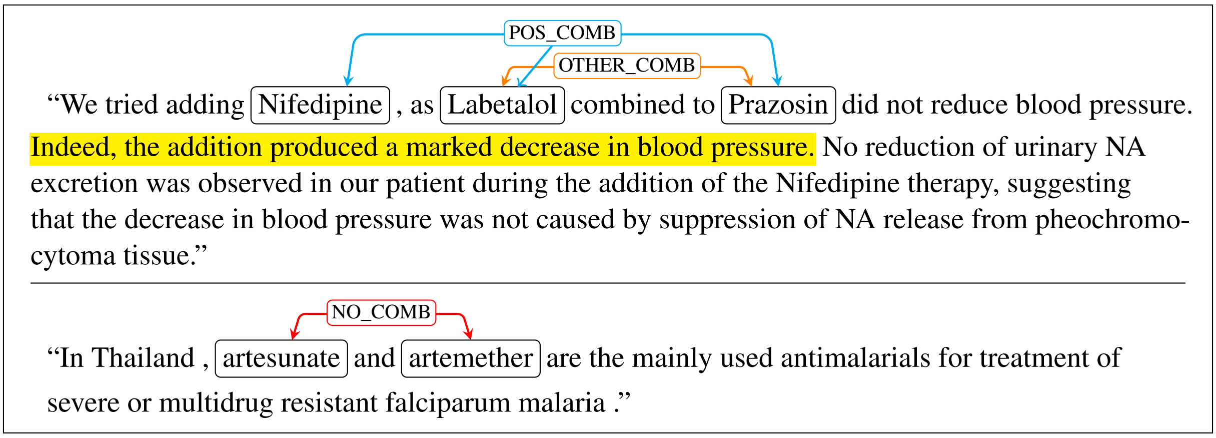
Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3190 - 3203
July 10-15, 2022



“We tried adding Nifedipine , as Labetalol combined to Prazosin did not reduce blood pressure. Indeed, the addition produced a marked decrease in blood pressure. No reduction of urinary NA excretion was observed in our patient during the addition of the Nifedipine therapy, suggesting that the decrease in blood pressure was not caused by suppression of NA release from pheochromocytoma tissue.”

“In Thailand , artesunate and artemether are the mainly used antimalarials for treatment of severe or multidrug resistant falciparum malaria .”

Figure 1: Examples of our label scheme. The top example contains two relations: a binary OTHER_COMB relation and a ternary POS_COMB relation. The evidence required to annotate the latter relation is found in a different sentence (highlighted). In the bottom example, each drug is described as a separate treatment rather than a combination therapy.

No type hints As noted by Rosenman et al. (2020) and Sabo et al. (2021), in many relation extraction benchmarks (Han et al., 2018; Sabo et al., 2021; Zhang et al., 2017), the argument types serve as an effective clue. However, argument types do not apply naturally to the drug combination task, in which all possible relation arguments are entities of the same type (drugs) and we need to identify specific subsets of them.

Long range dependencies The information describing the efficacy of a combination is often spread-out across multiple sentences. Indeed, our annotators reported that for 67% of the instances, the label could not be determined based on a single sentence, requiring reasoning with a larger textual context. Interestingly, our experiments show that our models *are not* helped by the availability of longer context, showing the limitations of current standard modeling approaches. This suggests our dataset can be a test-bed for models that attempt to incorporate longer context.

Challenging inferences As we show in our qualitative analysis (§4.2), instances in this dataset require processing a range of phenomena, including coordination, numerical reasoning, and world knowledge.

We hope that by releasing this dataset we will encourage NLP researchers to engage in this important clinical task, while also pushing the boundaries of relation extraction.

2 The Drug Combinations Dataset

A set of drugs in a biomedical abstract are classified to one of the following labels:

Positive combination (POS_COMB): the sentence indicates the drugs are used in combination, and the passage suggests that the combination has additive, synergistic, or otherwise beneficial effects which warrant further study.

Non-positive combination (OTHER_COMB): the sentence indicates the drugs are used in combination, but there is no evidence in the passage that the effect is positive (it is either negative or undetermined).[4]

Not a combination (NO_COMB): the sentence does not state that the given drugs are used in combination, even if a combination is indicated somewhere else in the wider context. An example is given in the lower half of Figure 1, where each of the drugs Artesunate and Artemether is given in isolation, and no combination is reported.

Our primary interest is to identify sets of drugs that are positive combinations.

2.1 Relevant Context Size for Classifying Drug Combinations

When formulating the extraction task and designing our data collection methodology, we first analyzed the locality of the phenomenon: to what extent are drug combinations are expressed in a single sentence, or is a larger context is needed? We sampled 275 abstracts that contained known

---

[4] We also experimented with another label for combinations that are discouraged (antagonistic, harmful or not effective). The agreement for this label was low, leading us to keep it as a subset of OTHER_COMB.

drug combinations according to DrugComboDB.[5] Analysis showed that 51% of these abstracts mentioned attempted drug combinations. In 97% of the abstracts containing drug combinations, all participating drugs in the attempted combination could be located within a single sentence in the abstract (for an example, see the OTHER_COMB relation in Figure 1). However, establishing the efficacy of the combination frequently required a larger context (such as the context accompanying the POS_COMB relation in Figure 1).

2.2 Task Definition

We define each instance in the Drug Combination Extraction (DCE) task to consist of a sentence, drug mentions within the sentence, and an enclosing context (e.g. paragraph or abstract).

The output of the task is a set of relations, each consisting of a set of participating drug spans and a relation label (POS_COMB or OTHER_COMB). Each subset of drug mentions not included in the output set is implicitly considered to have relation label NO_COMB.

More formally, DCE is the task of labeling an instance $X = \{C, i, D\}$ with a set of relation instances R, where $C = (S_1, ...S_n)$ is an ordered list of context sentences (e.g. all the sentences in an abstract or paragraph), $1 \le i \le n$ is an index of a target sentence $S_i = (w_1, ..., w_{n(i)})$ with $n(i)$ words, and $D = \{(d_{\mathbf{1}start}, d_{\mathbf{1}end}), ..., (d_{\mathbf{m}start}, d_{\mathbf{m}end})\}$ is a set of $m >= 2$ spans of drug mentions in S. The output is a set $R = \{(c_i, y_i)\}$ where $c_i \in \mathcal{P}(D)$ is a drug combination from $\mathcal{P}(D)$, the set of all possible drug combinations, and $y_i \in \{\text{POS\_COMB}, \text{OTHER\_COMB}\}$ is a combination label.

2.3 Evaluation Metric

We consider two settings: "Exact Match", a strict version which considers identifying exact drug combinations, and "Partial Match", a more relaxed version which assigns partial credits to correctly identified subsets.

We use standard precision, recall and F1 metrics for both settings. For the partial-match case, we replace the binary 0 or 1 score for a given combination with a refined score: $shared\_drugs/total\_drugs$. If there are multiple partial matches with gold relations, we take the one with maximum overlap. We compute **recall** as $identified\_relations/all\_gold\_relations$, and **precision** as $correct\_relations/identified\_relations$.

We consider two metrics, the averaged Positive Combination F1 score which compares POS_COMB to the rest, and the averaged Any Combination F1 score which counts correct predictions for any combination label (POS or OTHER) as opposed to NO_COMB. The latter is an easier task, but still valuable for identifying drug combinations irrespective of their efficacy.

2.4 Collecting Data for Annotation

To collect data for annotation we curated a list of 2411 drugs from DrugBank [6] and sampled from PubMed a set of sentences which mention 2 or more drugs. Analysis of the first 50 sentences from this sample showed that only 8/50 of the sentences included mentions of drug combinations. This meant that annotating the full sample will be costly, and will result in a dataset that's highly skewed toward relatively trivial NO_COMB instances.

We therefore repeated this experiment, sampling sentences whose PubMed abstract included a trigger phrase.[7] 48% of 50 sampled sentences included mentions of drug combinations. Evaluating the coverage of the trigger list against a new sample of abstracts with known drug combinations showed that 90% of these new abstracts included one of the trigger words. This suggests our trigger list is useful for fetching label-balanced data, without prohibitively restricting coverage and diversity.

Accordingly, we collected the majority of instances for annotation, 90%, using a basic search for sentences that contain at least two different drugs and whose abstract contains one of the trigger phrases. To overcome the lexical restrictions imposed by our trigger list, we sample the remaining 10% of instances using distant supervision: fetch-

---

[5] We used `Syner&Antag_voting.csv` taken from `http://drugcombdb.denglab.org/download/` and ranked according to the *Voting* metric.

[6] Curation included downloading a premade drug list from DrugBank's website, while removing non pharmacological intervention such as Vitamins and Supplements. The later we got from the FDA orange book.

[7] Triggers were selected by manually identifying words and phrases which frequently appear in abstracts mentioning drug combinations. These are phrases like "combination", "followed by", "prior to", etc. (see full list in Appendix A.3). The triggers are recall oriented, so while a presence of a trigger increases the chances that an abstract mentions a drug combination, it is definitely not clearly indicative. Importantly, since we're dealing with a wide context, the presence of a trigger in an abstract which includes multiple drugs does not mean the trigger is related to the drugs.

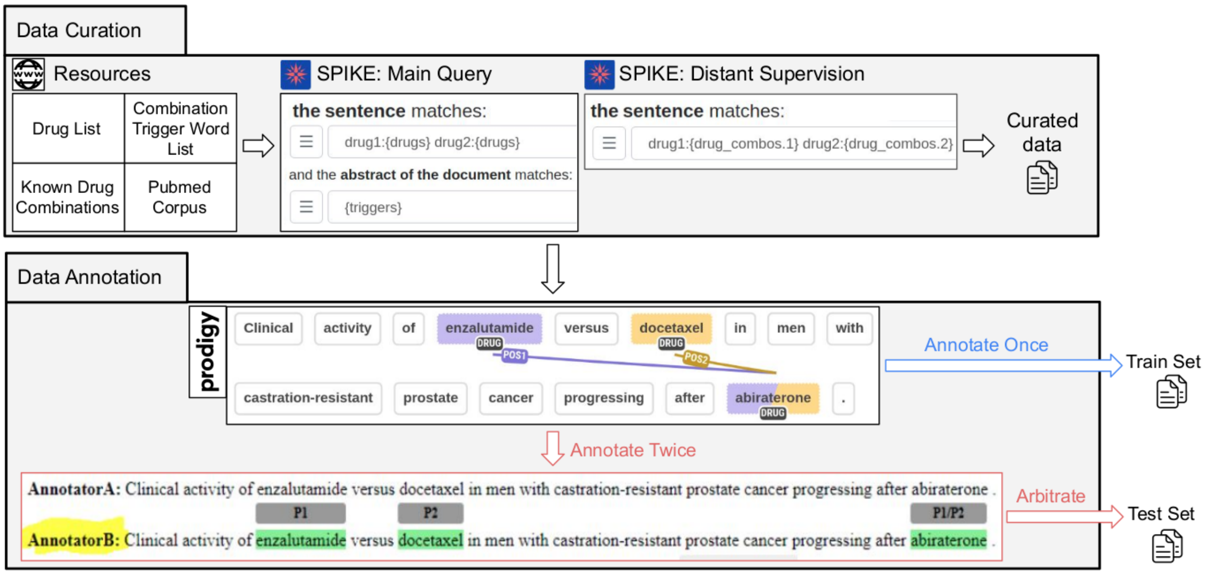


Figure 2: Illustration of the data construction process. First we construct the required knowledge resources. Then, we collect data using SPIKE –an extractive search tool– over the PubMed database. The train and test sets were annotated using Prodigy over the curated data. For test data, we collected two annotations for each sample, and then had a domain expert resolve annotation disagreements.

ing sentences containing pairs of drugs known to be synergistic according DrugComboDB, but whose abstract does not include one of our trigger phrases. All data collecting queries were performed using the SPIKE Extractive Search tool (Shlain et al., 2020; Taub-Tabib et al., 2020). The process is illustrated at the top of Figure 2.

Metric	Partial Match	Exact Match
Avg. Any Combination F1	88.9	86.1
Avg. Positive Combination F1	83.4	79.6

Table 1: Agreement scores using our adaptation of F1 score to allow for partial-match.

2.5 The Annotation Process

Seven graduate students in biomedical engineering took part in the annotation task. The students all completed a course in combination therapies for cancer and were supervised by a principled researcher with expertise in this field.

We provided the participants with annotation guidelines which specified how the annotation process should be carried out (see Appendix A.1) and conducted an initial meeting where we reviewed the guidelines with the group and discussed some of the examples together.

Each of the participants had access to a separate instance of the Prodigy annotation tool (Montani and Honnibal, 2018), pre-loaded with the candidate annotation instances. Once a session starts, the instances (containing of a sentence with marked drug entities, and its context) appear in a sequential manner, with no time limit. For each instance we instructed the annotators to mark all subsets of drugs that participated in a combination, and for each subset to indicate its label (POS_COMB or OTHER_COMB). Moreover, we instructed them to indicate whether the context was needed in order to determine the positive efficacy of the relation.

Despite the considerable time required for expert annotation, we collected annotations for 1634 passages. Among these, 272 were assigned to at least two annotators. After further arbitration by the lead researcher, these were used for the test set. The process is illustrated in the bottom part of Figure 2.

2.6 Inter-annotator Agreement

During the course of the task we calculated inter-annotator agreement multiple times to identify cases of disagreement and provide feedback to annotators. Each time, a set of 25 instances were randomly selected and assigned to all annotators. Agreement was calculated based on a pairwise F1 measure (with some modifications as described in §2.3) and averaged over all pairs of annotators (see discussion of alternative metrics in Appendix A.2).

Final agreement numbers, in Table 1, are satisfactory (Aroyo and Welty, 2013; Araki et al., 2018).

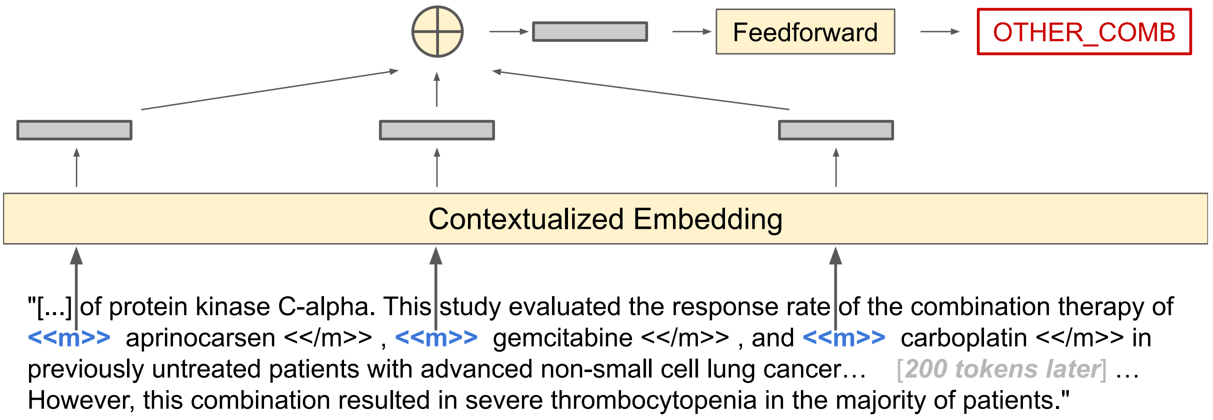

Figure 3: Our baseline architecture, adapted from the PURE model (Zhong and Chen, 2021)

2.7 Resulting Dataset

The dataset consists of 1634 annotated abstracts,[8] split into 1362 train and 272 test instances. These include 1248 relations; 838 are POS_COMB and 410 are OTHER_COMB (with the same label ratio in the train and test sets). 591 sentences contain no drug combination, 877 contain one relation (either POS_COMB or OTHER_COMB), and 166 contain two or more different combinations. Among annotated relations, 900 are binary, 226 are 3-ary, 69 are 4-ary, and 53 are 5-ary or more.

For each instance in the resulting dataset we include the context-required indication provided by the annotators. In 835 out of 1248 relations the annotator marked the context as needed which is 67% of the time, showing the importance of the context in the DCE task.

3 Experiments

3.1 Baseline Model Architecture

We establish a baseline model to measure the difficulty of our dataset and reveal areas for improvement. For our underlying baseline model architecture, we adopt the PURE architecture from Zhong and Chen (2021), which is state-of-the-art on several relation classification benchmarks, including the SciERC binary scientific RE dataset (Luan et al., 2018). The PURE architecture, designed for 2-ary and 3-ary relation extraction, consists of three components. First, special “entity marker" tokens are inserted around all entities in a candidate relation. Next, these marker tokens are encoded with a contextualized embedding model. Finally, the entity marker embeddings are concatenated and fed to a feedforward layer for prediction.

Unlike the original PURE architecture, we consider the more challenging case of extracting relations of variable arity. To support this setting, we *average* the entity marker tokens in a relation rather than concatenate. The final baseline model architecture is shown in Figure 3. For the contextual embedding component of this architecture, we experiment with four different pretrained scientific language understanding models (SciBERT (Beltagy et al., 2019), BlueBERT (Peng et al., 2019), PubmedBERT (Gu et al., 2020), and BioBERT (Lee et al., 2020)). During training, we only finetune the final *BERT layer. We train each model architecture for 10 epochs on a single NVIDIA Tesla T4 GPU with 15GB of GPU memory, which takes roughly 7 hours to train for each model.

To our knowledge, there are no other models designed for variable-length N-ary relation extraction, so we consider no other baselines.

3.2 Domain-Adaptive Pretraining

Our baseline model architecture relies heavily on a pretrained contextual embedding model to provide discriminative features to the relation classifier. Gururangan et al. (2020) showed that continued domain-adaptive pretraining almost always leads to significantly improved downstream task performance. Following this paradigm, we performed continued domain-adaptive pretraining (“DAPT”) on our contextual embedding models.

We acquired in-domain pretraining data using the same procedure used to collect data for annotation: running a SPIKE query against PubMed to find abstracts containing multiple drug names

---

[8] This is a similar size to existing human-labeled biomedical relation extraction datasets, such as BioCreative V CDR (Li et al., 2016), which has 1500 abstracts annotated, BioCreative VI (Krallinger et al., 2017), which has 2432 abstracts, and DDI (Herrero-Zazo et al., 2013), which has 714 abstracts.

Model	Positive Combination F1		Any Combination F1	
	Exact Match	Partial Match	Exact Match	Partial Match
Human-Level	79.6	83.4	86.1	88.9
Rule-based	31.8	45.6	39.1	57.4
SciBERT	44.6 (± 4.6)	55.0 (± 5.9)	50.2 (± 1.9)	63.6 (± 2.7)
w/ DAPT	54.8 (± 3.2)	63.6 (± 2.0)	61.8 (± 2.7)	72.8 (± 2.1)
BlueBERT	41.2 (± 4.8)	51.7 (± 6.0)	47.3 (± 4.2)	59.9 (± 6.2)
w/ DAPT	56.6 (± 2.3)	63.5 (± 3.1)	64.2 (± 2.6)	74.7 (± 2.7)
PubmedBERT	50.7 (± 5.5)	59.6 (± 5.8)	55.9 (± 3.2)	66.7 (± 3.8)
w/ DAPT	**61.8** (± 5.1)	**67.7** (± 4.8)	**69.4** (± 1.7)	**77.5** (± 2.2)
BioBERT	45.4 (± 3.7)	55.8 (± 2.2)	46.7 (± 3.6)	58.3 (± 5.1)
w/ DAPT	56.0 (± 6.5)	63.5 (± 7.5)	65.6 (± 1.8)	75.7 (± 2.2)

Table 2: Comparing different foundation models (with and without continued domain-adaptive pretraining) on Exact-Match and Partial-Match relation extraction metrics. Mean score from 4 different random seeds is reported, and standard deviation is computed across seeds.

and a “trigger phrase" (from the list in Appendix A.3). This query resulted in 190K unique abstracts. We do not include any paragraphs from our annotated dataset. We then perform domain-adaptive training against this dataset using the `Hugging Face Transformers` library. We train for 10 epochs using a learning rate of 5e-4, finetuning all *BERT layers and using the same optimization parameters specified by Gururangan et al. (2020). This pretraining took roughly 8 hours using four 15GB NVIDIA Tesla T4 GPUs.

3.3 Relation Prediction

To apply the model to drug combination extraction, we reduce the RE task to an RC task by considering all subsets of drug combinations in a sentence, treating each one as a separate classification input, and combining the predictions.

This poses two challenges: there may be a large number of candidate relations for a given document, and each relation is classified independently despite the combinatorial structure. To handle these issues, we use a greedy heuristic of choosing the smallest set of disjoint relations whose union covers as many drug entities as possible in the sentence. We do this iteratively: at each step, we choose the largest predicted relation that does not contain any drugs found in the relations chosen at previous iterations.

This greedy heuristic favors large (high arity) relations. Nonetheless, we empirically find this method is helpful for extracting high-precision drug combinations from our model architecture.

3.4 Rule-based baseline

To further validate that the trigger words do not introduce bias to our task, we consider an additional baseline based on the following rule: if a trigger word is found in the same sentence with multiple drugs, this set of drugs is tagged as POS_COMB.

4 Results

4.1 Effect of Pretrained LMs and Domain-Adaptive Pretraining

We show results of our baseline model architectures in Table 2. For each model, we report the mean and standard deviation of each metric over four identical models trained with different seeds.[9] Among the four base scientific language understanding models in our experiments, we observe PubmedBERT to be the strongest on every metric. We additionally find that domain-adaptive pretraining provides significantly improvements for every base model, consistently giving 5-10 points of improvement on Positive Combination F1 score. The value of domain-adaptive pretraining supports our observation that encoding domain knowledge is critical to solving this new task.

The rule-based approach underperformed all learned models (30 F1 points under our strongest model, PubmedBERT-DAPT). This shows this task cannot be reduced to keyword identification.

4.2 Qualitative Error Analysis

We identify classes of challenges that make this task difficult, both in terms of human annotation and machine prediction.

Coordination Ambiguity: A known linguistic challenge is the ambiguity that stems from vague coordination. In cases where explicit combination words (e.g. combination, plus, together with, etc)

---

[9] Seeds used are 2021, 2022, 2023, and 2024

Model	Positive Combination F1		Any Combination F1	
	Exact Match	Partial Match	Exact Match	Partial Match
No Extra-sentential Context	63.4 (± 0.6)	68.5 (± 1.1)	69.7 (± 1.3)	76.8 (± 1.7)
1 Sentence of Context	63.9 (± 2.3)	69.4 (± 3.5)	71.9 (± 1.1)	78.6 (± 1.8)
2 Sentences of Context	61.9 (± 9.0)	67.6 (± 9.2)	70.1 (± 2.3)	77.9 (± 1.3)
3 Sentences of Context	65.2 (± 2.3)	72.4 (± 1.3)	70.8 (± 1.7)	78.7 (± 1.2)

Table 3: The effect of extra-sentential context on model performance. n sentences are included on each side of the relation-bearing sentence. Mean and standard deviation of each metric are reported over 4 different random seeds.

are not used, it may be unclear whether two drugs are being used together or separately. For example in *"These findings may help clinicians identify patients for whom acamprosate* ***and*** *naltrexone may be most beneficial"* it is unclear if *acamprosate* and *naltrexone* are being described in combination or as independent treatments, leading to either a POS label for the former or NO_COMB for the latter.

Numerical and Relative Reasoning: In some cases, the effect of a treatment is described in relative or numerical terms, rather than an absolute claim. Consider the example, *"The infection rate in the control group was 3.5% and in the treated group 0.5%."*. Here, the reader must compare the control vs experimental groups and deduce that the experimental outcome is positive, because the treatment yields a lower infection rate.

Domain Knowledge: Similarly, classifying relations in this dataset may require an understanding of domain knowledge. In *"Growth inhibition and apoptosis were significantly higher in BxPC-3, HPAC, and PANC-1 cells treated with* ***celecoxib and erlotinib*** *than cells treated with either* ***celecoxib*** *or* ***erlotinib****"*, one must understand that having higher values of *Growth inhibition and apoptosis* in specific cells is a positive outcome, in order to classify this combination as positive.

Context related Complications: The following are kinds of complications found when the evidence lies in the wider part of the context.

Coreference: Anaphoric or coreferential reasoning is sometimes needed to understand the efficacy of the combination e.g. *"it was demonstrated that* ***they*** *could be combined with acceptable toxicity."*.

Contradicting Evidence: the reader often must infer a conclusion given opposing claims within a given abstract. This can happen as combinations can be referred as e.g. *toxic but effective*.

Long Distance: The target sentence can be far—up to 41 sentences apart—from the evidence sentence, making it difficult for even humans to process.

4.3 Quantitative Error Analysis

To probe this task, we analyze the performance of our strongest model—the one using a Pubmed-BERT base model tuned with domain-adaptive pretraining—along different partitions of test data. We trained with four random seeds and perform comparisons using a paired multi-bootstrap hypothesis test where bootstrap samples are generated by sampling hierarchically over the four random seeds and the subsets of the test set (Sellam et al., 2021). We use 1000 bootstrap samples in each test.

4.3.1 Do models leverage context effectively?

Each relation in our dataset consists of entities contained within a single sentence, but labeling the relation frequently requires extra-sentential context to make a decision. In our dataset, annotators record whether or not each relation requires paragraph-level context to label, reporting that 67% of drug combinations required context to annotate.

To understand the extent that models make use of paragraph-level context, we trained and evaluated our PubmedBERT-based model using varying amounts of extra-sentential context around the sentence containing drug entities. In Table 3, we see that adding context provides nearly identical performance to training a model with no extra-sentential context at all, with differences rarely exceeding one standard deviation of F1 score.

However, we see increased variability in "Positive Combination F1" performance when extra-sentential context is used. To explain this, recall from §2.1 that determining the *efficacy* of a drug combination often requires paragraph-level context for annotators, while identifying *any combination* usually requires no context. From qualitative analysis of attention maps, we observed that our models are not able to consistently identify the salient parts of paragraph-level context, potentially causing instability with larger inputs.

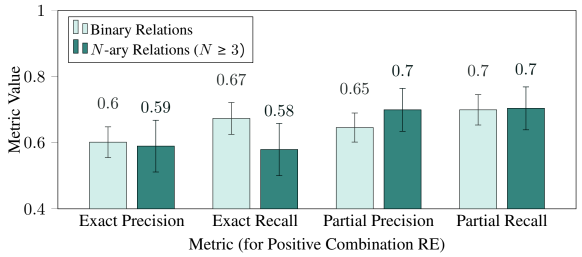

Figure 4: Comparing models performance on binary vs higher-order N-ary relations, averaged over 4 seeds of the PubmedBERT-DAPT model. No consistent significant differences were observed; p-values for these comparisons are 0.456, 0.149, 0.240, and 0.276.

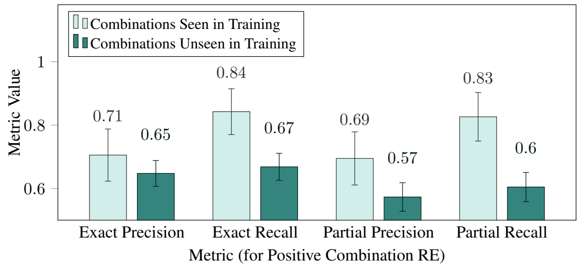

Figure 5: Comparing relation extraction on test set drug combinations that are observed in the training set or not, using the PubmedBERT-DAPT model. Paired multi-bootstrap test p-values for these four comparisons are 0.262, 0.025, 0.103, and 0.009, respectively.

These results suggest ample room for improvement in extracting document-level evidence. This makes our dataset a potentially useful benchmark for document-level language understanding.

4.3.2 Binary vs. higher-arity relations

Given that our dataset is the first relation extraction dataset with variable-arity relations, do higher-order relations pose a particular challenge for our models? To answer this, we separate all predicted and ground truth relations for the test set into binary relations and higher-arity relations. We then report precision among each subset of predicted relations and recall among each subset of ground truth relations. We perform this experiment across four different model seeds, and report results in aggregate using a paired multi-bootstrap procedure. In the results in Figure 4, we see no consistent significant differences between models of different arities, suggesting that our technique of computing relation representations by averaging entity representations scales well to higher-order relations.

4.3.3 Generalizing to new drug combinations

How well can relation extraction models classify drug combinations not seen during training? Similar to the setup in §4.3.2, we divide all predicted and ground truth relations for the test set into the set of drug combinations which are also annotated in our training set, and the set that have not been. In our dataset, over 80% of annotated test set relations are not found in the training set.

In Figure 5, performance is consistently better for relations observed in the training set than for unseen relations, by a margin of 10-15 points. Recall, in particular, is significantly worse for relations unseen during training (at 95% confidence), and precision is potentially also worse. Considering that unseen drug combinations are practically more valuable than already-known combinations, improving generalization to new combinations is a critical area of improvement for this task.

5 Related Work

The DDI dataset (Herrero-Zazo et al., 2013) is the only work to our knowledge that annotates drug interactions for text mining. However, it fundamentally differs from our dataset in the type of annotations provided: the DDI annotates the type of discourse context in which a drug combination is mentioned, without providing explicit information about combination efficacy. In contrast, our dataset is focused on semantically classifying the efficacy of drug combinations as stated in text.

Other RE datasets exist in the biomedical field (Peng et al., 2017; Li et al., 2016; Wu et al., 2019; Krallinger et al., 2017), but do not focus on drug combinations. Similarly, several RE datasets tackle the N-arity problem in the scientific domain (Peng et al., 2017; Jain et al., 2020; Kardas et al., 2020; Hou et al., 2019), and in the non-scientific domain (Akimoto et al., 2019; Nguyen et al., 2016), however, **all of them consider a fixed choice of N.**

6 Conclusions

We present a new resource for drug combination and efficacy identification. We establish baseline models that achieve promising results but reveal clear areas for improvement. Beyond the immediate, application-ready value of this task, this task poses unique relation extraction challenges as the first dataset containing variable-arity relations. We also highlight challenges with document-level representation learning and incorporating domain knowledge. We encourage others to participate in this task. Our processed dataset[10] and best baseline model[11] are available on Hugging Face, and our model training code is available to the public at `https://github.com/allenai/drug-combo-extraction`.

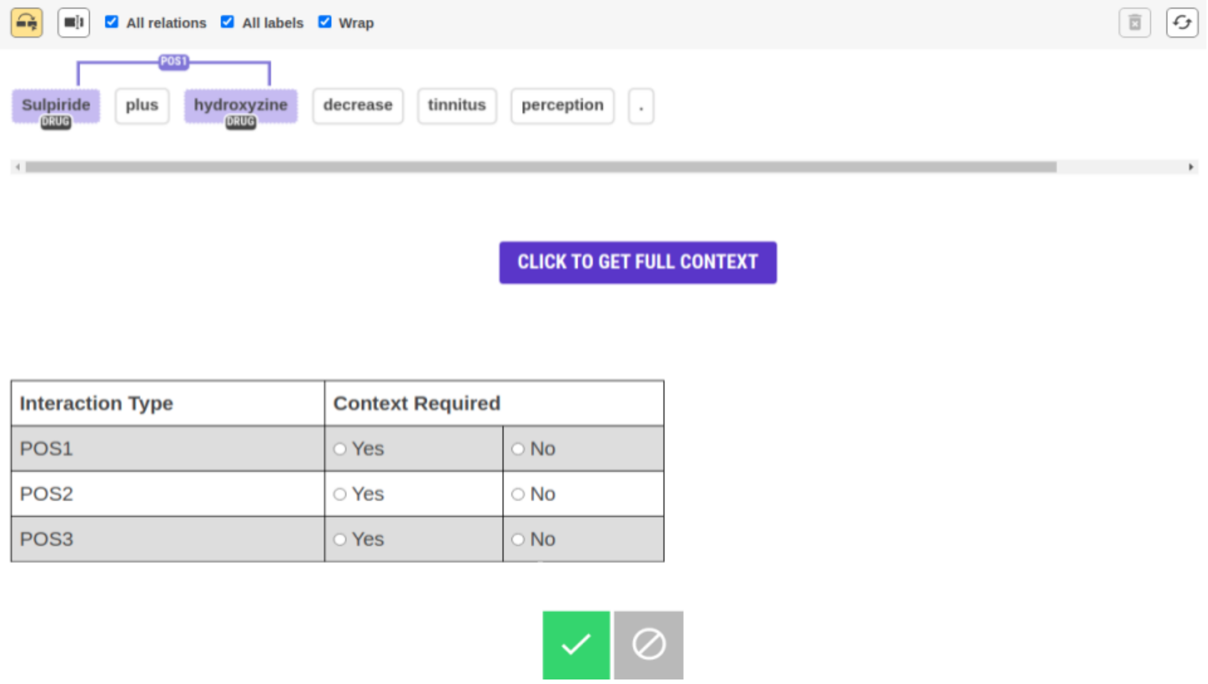
A Appendices

A.1 Annotation Guidelines



Interaction Type	Context Required	
POS1	○ Yes	○ No
POS2	○ Yes	○ No
POS3	○ Yes	○ No

Figure 6: Annotation instance in the Prodigy environment. The screen is constructed of the sentence where they should mark relations, a button to show the full context and a selection per relation to indicate the necessity of the context.

For this task we recruited 7 annotators all studying for advanced degrees in biomedical engineering. The annotators were payed by their advisor, an amount that is standard for annotation projects in their country of residence. All participating annotators were provided with annotation guidelines. The guidelines specified how the annotation process should be carried out and provided definitions and examples for the different labels used. As the task progressed, the guidelines were also expanded to include discussion of frequently encountered issues.

For a given instance, such as presented in the top of Figure 6 the annotator needs to first recognize any missing drugs and mark them, and then label any interactions they find among the drugs. In case they need to consult a wider context they can press on a ‘show more context’ button and a text box with the wider context will appear. This context can be again hidden by clicking the same button if needed. Lastly, in the bottom of the sample page, we present a table with questions regarding the necessity of using the context.

Then the annotator should decide if they need to ignore the current sample or to complete the current instance and accept it, by pressing the accept and ignore buttons.

The annotators are instructed as follows. They should read the sentence carefully, and try to answer a two phase question to themselves. First, if the drugs are mentioned in any form of combination or they should be given separately. Second, if indeed the annotator recognized the drugs as a combination can they determine the efficacy of the combination by the sole sentence.

In case they can not determine the efficacy they are instructed to press on the ‘get more context’ button and read the entire context in order to determine what is the correct efficacy. If after reading the context they can still not determine the efficacy then the label of the interaction should be OTHER_COMB (aside from negative label experimentation mentioned in Footnote 4). Otherwise it should be POS_COMB. In case that they recognized that there is no combination between the drugs in the sentence then they should not use any label and simply accept the current instance. Then they should answer the context related questions for the POS_COMB label in order to signal if the context was needed.

While reading the sentence if the annotators find unmarked drugs they can mark them before continuing to the interaction-labeling phase and treat them the same as the other drugs, but, it is not required to mark a word as drug in order to use it in an interaction. If a drug is marked in a wrong manner they should try and fix it, e.g. the span of the drug is incorrect.

In order to achieve more consistent and accurate annotations, they are also instructed to annotate all the interactions that they can find in a given sentence. They should always use the *accept* button even if there are no interactions in the sentence. Only in cases where they want to skip a sentence (e.g. when there is an inherent problem with it) or leave it for a future discussion they should use the *ignore* button. An interaction can occur between more than two drugs, if so they should notice that they don't need each pair from this group to have a marked interaction, as long as they all connect to the same graph. e.g. "Drugs A, B and C are synergistic." connecting A to B and B to C is sufficient, no need to connect drug A to drug C. Each interaction should be marked with a different tag (POS_COMB1, POS_COMB2..., OTHER_COMB1, OTHER_COMB2...).

A.2 Evaluation Metric Discussion

For measuring the agreement, we chose to use our adaptation of F1 score and not other common metrics such as Cohen's Kappa (Cohen, 1960) or one of its variations (e.g. Feliss's Kappa (Fleiss, 1971) and Krippendorf's Alpha (Hayes and Krippendorff, 2007)). These metrics expect a setup where the *relation* candidates are already marked and the task is only to label them – a labeling task and not an extraction task. This causes two problems, one is that they inherently do not need to handle a partial match. So if for example there are three drugs in a sentence, the first annotator annotated a relation between drugs A and B, while a second annotator annotated the same relation between drugs A, B and C. So we will either underestimate or overestimate their agreement score if we considered this a mismatch or a match respectively. Moreover, their calculations depend on the *hypothetical agreement by chance* normalization factor, but this will not reflect the difficulty of random choosing in our setup as they ignore the size of the combinatorial set of relation candidates we can possibly have.

A.3 Trigger List

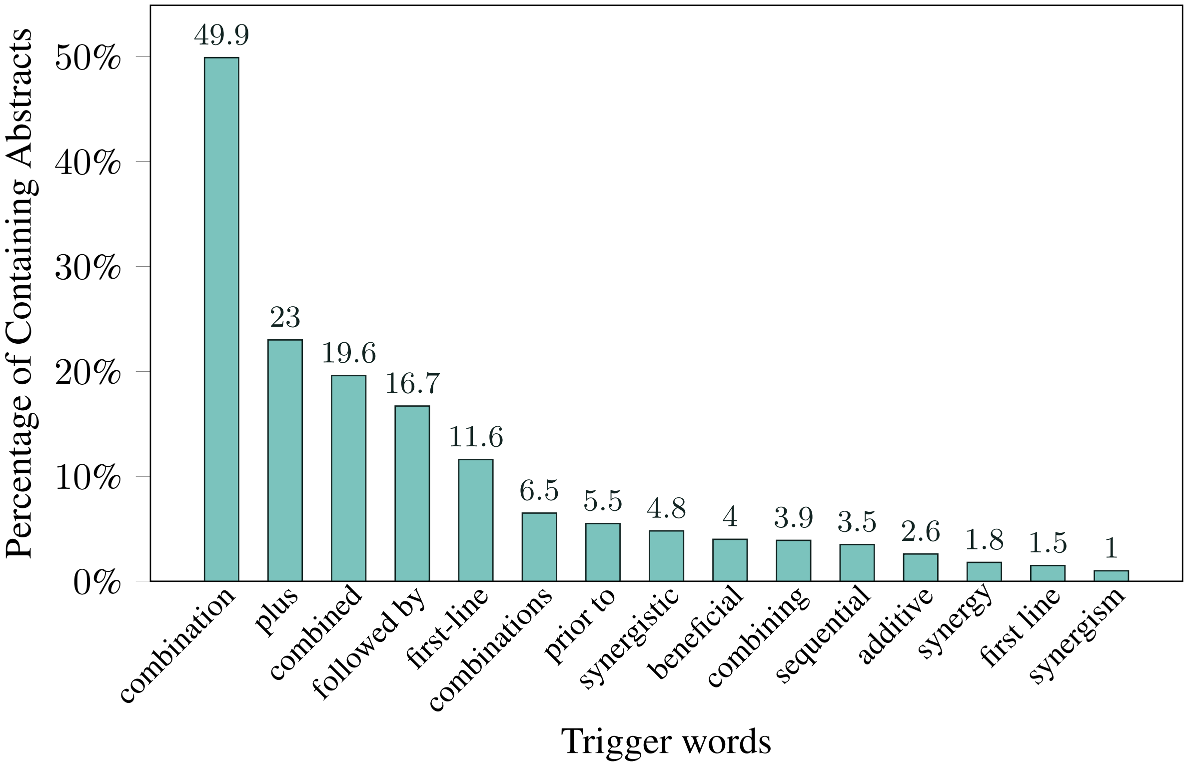


Figure 7: Abstracts percentage including each trigger word (1634 abstracts included; 44 words in the full word list; Words <1% were neglected from the figure.

In Figure 7 we show the triggers that we used in the Spike queries. We show the percentage of abstracts that included each trigger (others under 1%: *conjunction, two-drug, first choice, additivity, combinational, synergetic, simultaneously with, supra-additive, five-drug, combinatory, over-additive, timed-sequential, co-blister, super-additive, synergisms, synergic, synergistical, less-than-additive, greater-than-additive, additivesynergistic, supraadditive, superadditive, overadditive, subadditive, first-choice, 2-drug, sub-additive, more-than-additive, 3-drug*).

CURRICULUM: A Broad-Coverage Benchmark for Linguistic Phenomena in Natural Language Understanding

Zeming Chen **Qiyue Gao**
Rose-Hulman Institute of Technology
{chenz16, gaoq}@rose-hulman.edu

Abstract

In the age of large transformer language models, linguistic evaluation play an important role in diagnosing models' abilities and limitations on natural language understanding. However, current evaluation methods show some significant shortcomings. In particular, they do not provide insight into how well a language model captures distinct linguistic skills essential for language understanding and reasoning. Thus they fail to effectively map out the aspects of language understanding that remain challenging to existing models, which makes it hard to discover potential limitations in models and datasets. In this paper, we introduce CURRICULUM as a new format of NLI benchmark for evaluation of broad-coverage linguistic phenomena. CURRICULUM contains a collection of datasets that covers 36 types of major linguistic phenomena and an evaluation procedure for diagnosing how well a language model captures reasoning skills for distinct types of linguistic phenomena. We show that this linguistic-phenomena-driven benchmark can serve as an effective tool for diagnosing model behavior and verifying model learning quality. In addition, our experiments provide insight into the limitation of existing benchmark datasets and state-of-the-art models that may encourage future research on re-designing datasets, model architectures, and learning objectives. [1].

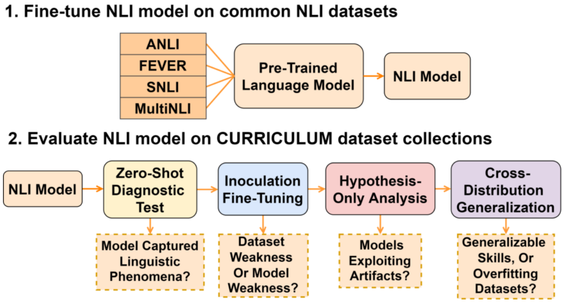

Figure 1: We propose a broad-coverage diagnostic benchmark for linguistic-phenomena-driven evaluation. Our benchmark includes both a dataset collection and an evaluation procedure for evaluating model performance and diagnosing linguistic skills captured by a model. We evaluate models fine-tuned on large NLI datasets through four types of diagnostic tests: zero-shot, inoculation, hypothesis-only, and cross-distribution.

1 Introduction

With the rising power of pre-trained language models, large-scale benchmarks serve as an important factor driving the future progress of NLP. These benchmarks can provide a tool for analyzing the strengths and weaknesses of pre-trained language models. In recent years, many benchmarks (Wang et al., 2019, 2020; Rajpurkar et al., 2018) have been proposed that offer a diverse set of evaluation objectives. However, recent criticisms have been made that these benchmarks fail to serve as effective measures of progress in machine learning (Raji et al., 2021). In particular, the task design does not formulate specific linguistic skills required for understanding. They lack the effectiveness in helping researchers understand how certain systems or models work and how they fail. Although many state-of-the-art language models have shown impressive performance on these common benchmarks, their performance degrades considerably on adversarial or out-of-distribution samples (Bras et al., 2020). The performance drop shows that models may not be learning the required linguistic skills for solving the tasks of these benchmarks but exploit spurious dataset biases (Poliak et al., 2018b). Overall, the current benchmark format seems to be more like a contest than a tool that can explain how well a language model captures distinct linguistic skills essential to language understanding and reasoning.

In this paper, we propose a new form of benchmark that serves as a diagnostic evaluation tool for analyzing model linguistic skills. We present CURRICULUM benchmark: a framework for diagnosing

July 10-15, 2022

neural language models through broad-coverage linguistic phenomena. Our benchmark includes (1) a large-scale collection of natural language inference (NLI) datasets covering 36 linguistic phenomena and (2) an evaluation procedure for probing and evaluating how well a language model captures reasoning skills for distinct types of linguistic phenomena. Targeted linguistic phenomena in CURRICULUM range from fundamental properties like named entity and coreference to complex ones like commonsense and deductive reasoning. With the CURRICULUM benchmark, we aim to investigate the following research questions:

- **Q1**: Do language models trained on benchmark datasets have the ability to reason over a wide range of linguistic phenomena?
- **Q2**: Are linguistic phenomena missing from the training data recoverable through inoculation (i.e., continuing to train models on a small sample of examples) (Liu et al., 2019a)?
- **Q3**: Do language models learn a general reasoning skill of a phenomenon through inoculation?

To address the above questions, we empirically analyze NLI models trained on popular benchmark datasets through a pipeline of evaluations that includes: a zero-shot diagnostic test, inoculation retraining, hypothesis-only sanity check, and cross cross-distribution generalization tests.

For **Q1**, we observe that models trained on benchmark datasets, including adversarial data, do not have the reasoning ability for a large set of linguistic phenomena. Our results show that training on more datasets can help the model learn more types of reasoning but does not help the model acquire complex reasoning skills such as deductive and commonsense reasoning. Our benchmark exposes multiple knowledge gaps in large NLI models regarding diverse linguistic phenomena, particularly in the categories of commonsense and comprehension. For **Q2**, our analysis provides empirical evidence that exposes the lack of recoverable linguistic phenomena in benchmark datasets and models' inability to learn certain linguistic phenomena. We also show that, on some phenomena, models may rely heavily on spurious dataset bias existing in the hypothesis to reach high accuracy. For **Q3**, Our experiments show that models can adapt between distributions with different difficulties only on 22.2% of the phenomena such as Boolean, conditional, and comparative logic. In the majority (58.3 %) of the phenomena, models fail to generalize when the difficulties of the train and test distributions are different, for example, relational knowledge, puns, and contextual commonsense reasoning. A model's learning performance may not align with its generalization ability, suggesting the lack of a general reasoning skill.

Overall, our proposed benchmark systematically maps out a wide range of specific linguistic skills required for language understanding and inference. We envision linguistic-phenomena-based evaluation to be an integral component of general linguistic intelligence. We hope CURRICULUM can serve as a useful evaluation tool that can map out which aspects of the problem space remain challenging for existing systems and models.

2 Related Work

NLU Benchmarks In recent years, multiple large-scale benchmarks for evaluating models' general language understanding performance have been proposed. Similar to our benchmark's task format, SNLI (Bowman et al., 2015) and MultiNLI (Williams et al., 2018) are the two common benchmarks for Natural Language Inference (NLI). GLUE and SuperGLUE are the two most popular benchmarks that aim to provide a straightforward comparison between task-agnostic transfer learning techniques. They cover various task formats, task domains, and training volumes, with datasets all collected from publicly available sources. The construction of our benchmark is similar in that we also collect publicly available datasets from peer-reviewed papers. Adversarial NLI (ANLI) is a new benchmark collected "via an iterative, adversarial human-and-model-in-the-loop procedure." (Nie et al., 2020). ANLI is shown to be a more difficult challenge than previous benchmarks. Different from these benchmarks, our work aims to map out and evaluate specific linguistic skills a model needs for language understanding.

Fine-grained NLU Evaluation On top of large-scale benchmarks, there are several works (Joshi et al., 2020; Tarunesh et al., 2021) contributing to the fine-grained analysis of model performance. They collect data examples from existing benchmarks by attaching taxonomic category labels to each data. Or, they build semi-synthetic data allowing analysis on 17 reasoning dimensions. Our data collection and categorization concepts are similar to them. However, our work covers more linguistic phenomena that are difficult but important such as

Category	Description	Phenomena
Lexical	Testing a model's Word-level reasoning skill on lexical semantic, direct, transitive, and compositional lexical relationships.	Lexical Entailment (lex-ent), Named Entity (ner) Hypernymy (hyper), Hyponymy (hypo) Veridicality & Transitivity (transit)
Syntactic	Testing a model's reasoning skill on syntactic structure and compositionality.	Syntactic Alternation (syn-alt), VerbNet (vbn) Syntactic Variation (syn-var), VerbCorner (vbc)
Semantic	Testing a model's reasoning skill on sentence-level reasoning involving diverse semantic properties: entity relations, context, events, subjectivity, and semantic proto roles.	Sentiment (senti), Relational Knowledge (kg-rel), Puns (puns), Semantic Proto Label (sprl) Context Alignment (ctx-align), Coreference (coref)
Logical	Testing a model's reasoning skill on logical operations: propositional structure, quantification, negation, and monotonicity reasoning.	Boolean (bool), Counting (count), Conditional (cond) Comparative (comp), Negation (negat) Monotonicity (monot), Quantifier (quant)
Analytical	Testing a model's knowledge exploitation ability: drawing accurate conclusions based on domain-specific knowledge, symbolic knowledge, and interpretable reasoning steps.	Entailment Tree (ent-tree) Analytical Reasoning (analytic)
Commonsense	Testing a model's reasoning skill on commonsense knowledge independent of cultural and educational background.	Physical (physic), Social (social), HellaSwag (swag) Contextual Commonsense Reasoning (cosmo)
Comprehension	Testing a model's reasoning skill on complex reading comprehension and inference, covering aspects of semantic, context, logic, and numerical	Event Semantics (ester), Discrete Reasoning (drop) Deductive Reasoning (logi) Long Contextual Reasoning (control)
Special	Testing a model's everyday reasoning skill. Including non-monotonic reasoning about valid but defeasible hypothesis from hypothetical context and spatial-temporal reasoning.	Spatial Reasoning (spat), Temporal Reasoning (temp) Defeasible Reasoning (defeas) Counterfactual Reasoning (counter)

Table 1: This table lists the eight categories of linguistic phenomena covered by our dataset collection. We provide a brief introduction for each category describing the types of linguistic skills they intend to evaluate. We also list the dataset names and abbreviations each category contains.

commonsense and non-monotonic reasoning.

Challenge Datasets for NLU Many challenge datasets have been developed to evaluate models on specific linguistic skills for understanding. These datasets are in different formats such as NLI, Question Answering (QA), and Reading Comprehension (RC). They target a large set of skills including monotonicity (Yanaka et al., 2019a), deductive logic (Liu et al., 2020), event semantics (Han et al., 2021), physical and social commonsense (Sap et al., 2019; Bisk et al., 2019), defeasible reasoning (Rudinger et al., 2020), and more. Our work brings together a set of challenge datasets to build a benchmark covering a large set of specific linguistic skills. We also merge different evaluation methods proposed by these works into a complete evaluation pipeline for our benchmark.

Probing Linguistic Knowledge Several works have found evidence that pre-trained models' representations encode knowledge about linguistic phenomena. Tenney et al. (2019) probe contextual representations from four pre-trained language models through the edge-probing method across tasks ranging from syntactic and semantic phenomena. They find that pre-trained models encode rich information on syntactic phenomena but only weakly encode information on semantic tasks compared to non-contextual baselines. Chen and Gao (2021)'s linguistic-information-probing framework extends the edge-probing study by focusing on different semantic phenomena that are important for logical inference in natural language. Their results show that pre-trained contextual embeddings encode more linguistic information on simple semantic phenomena than complex phenomena. Our work is partly motivated by this line of work in which our evaluation is based on the fact that pre-trained models can capture specific linguistic skills from learning.

Other work investigates if models use specific linguistic skills to solve a downstream task. The DNC benchmark (Poliak et al., 2018a) provides a collection of datasets for analyzing if models use distinct linguistic phenomena to conduct natural language inference. Several tasks in our benchmark come directly from this collection. However, our benchmark covers a wider range of linguistic phenomena from more categories than DNC. In particular, our benchmark contains semantic phenomena and includes phenomena from fundamental linguistic properties to complex reasoning types. In addition, our benchmark includes a systematic evaluation methodology that allows a more in-depth analysis of model behavior.

3 The CURRICULUM Benchmark

3.1 A New Form of Benchmark

Recently, Raji et al. (2021) suggested that good benchmark construction should focus on mapping out a specific set of linguistic skills required for language understanding. They recommend a future benchmark should provide interpretation on how systems work and how they fail on particular aspects of a problem space. Following this suggestion, we propose a new form of benchmark: linguistic-phenomena-driven evaluation. Our main objective is to reformulate the benchmark not simply to be a scoreboard for SOTA model contest but rather as a real measurement and standardization tool for (1) analyzing model performance, (2) exposing model and dataset weakness and (3) providing insights for future research directions.

The curriculum benchmark aims to map out a specific set of linguistic skills required for language understanding. Our benchmark will serve as a diagnostic framework for linguistic-phenomena-driven probing and evaluation. The targeted linguistic skills should range from fundamental linguistic properties to complex reasoning types. Our linguistic phenomena selection is motivated by three benchmarks: GLUE Diagnostic, Rainbow, and DNC. In addition, we include many more phenomena focusing on complex reasoning types such as deductive logic and analytical thinking. Our finalized benchmark covers eight categories of linguistic phenomena. Each linguistic phenomenon is considered one task, and one should train, evaluate, and analyze models on each phenomenon individually. We briefly describe the types of reasoning skill each category focus on in Table 1. Appendix A and B shows a list of references and dataset details for the train and test datasets used for each linguistic phenomenon.

3.2 Dataset

We collect many challenge NLI or NLU datasets and filter them individually with the following criteria: (1) We focus on datasets that evaluate a specific or a set of specific linguistic phenomena. (2) We focus on English monolingual datasets that are institutional and publicly available. (3) We exclude tasks that require domain-specific knowledge that we would not expect a model to learn through pre-training, such as medical knowledge. We finalize our selection with 36 datasets. Figure 1 shows a detailed ontology of our selected linguistic phenomena and their abbreviations. Our motivation for dataset selection is mainly based on the linguistic phenomena categories that we aim to cover which will range from a simple to complex setting.

3.3 Unified Task Format

We unified the task formats into a single linguistic task, Natural Language Inference (NLI). NLI is a task for Natural Language Understanding. The task requires a model to classify the logical relationship between premise and a hypothesis. This logical relationship can either be Entailment (premise is true implies the hypothesis is absolutely true), Contradiction (premise is true implies the hypothesis is absolutely false), and Neutral (one cannot determine if the hypothesis is true or false based on the premise) (Dagan et al., 2013). We select NLI as the universal task format because NLI often serves as a general evaluation method for models on different downstream tasks. A model would need to handle nearly the full complexity of natural language understanding in order to solve the NLI task (Poliak et al., 2018b). Our benchmark contains two types of NLI problems: (1) the 3-way NLI with `Entailment`, `Contradiction`, and `Neutral`; (2) the 2-way NLI with `Entailed` and `Not-Entailed`. Each example has a premise and a hypothesis with 2-way or 3-way labels.

3.4 Automatic Recast

To convert non-NLI datasets into the NLI task format, we follow the dataset recast procedure (Poliak et al., 2018b): automatically convert from non-NLI datasets with minimum human intervention. We design algorithmic ways to generate sentence pairs from the input text and convert the original labels into the NLI labels. Question Answering (QA) and Reading Comprehension (RC) are the two major tasks we need to convert. To convert datasets into NLI format, we follow the standard procedure (Khot et al., 2018). In QA datasets, if choices are given as declarative statements, we consider them as hypotheses and the question context as the premise. If choices are given as phrases answering the question, we concatenate the context and question to form a premise and consider the answers as hypotheses. Several datasets are tasks with free-response problems, and an answer can only be converted to an entailed hypothesis. To

$\mathcal{P}$	I_v	$\mathcal{P}$	I_v	$\mathcal{P}$	I_v

xlnet-anli-mix	XLNet (Yang et al., 2019)	SNLI, MNLI FEVER, ANLI/ ANLI	55.1 %

Table 3: Details on models used in our experiments. All four models are large models and publicly available.

generate non-entailed hypotheses, we use several techniques during recasting. We show more details on our conversion techniques in Appendix C. As a sanity check on our resulting datasets, we empirically find low performance on standard partial-input baselines (Poliak et al., 2018b), suggesting that our conversion yields data of high quality.

3.5 Dataset Difficulty

To enhance our benchmark to provide more information on each dataset for in-depth evaluation and analysis, we provide each phenomenon a difficulty level. We use the predictive $\mathcal{V}$-information (Ethayarajh et al., 2021) as a measurement for dataset difficulty. The $\mathcal{V}$-information can measure how much information an input variable X can provide about Y when constrained to functions $\mathcal{V}$. Intuitively, more usable infromation X can provide, the easier a dataset is for the functions $\mathcal{V}$. Formally, let $\varnothing$ denote a null input that provides no information about Y and $\mathcal{V}$ as a predictive family, we can compute the $\mathcal{V}$-information $\mathrm{I}_v(\mathrm{X} \to \mathrm{Y})$ as follows:

$$\begin{aligned} \mathrm{H}_v(Y) &= \inf_{f \in \mathcal{V}} \mathbb{E}[-\log f[\varnothing](\mathrm{Y})] \\ \mathrm{H}_v(Y|X) &= \inf_{f \in \mathcal{V}} \mathbb{E}[-\log f[\mathrm{X}](\mathrm{Y})] \\ \mathrm{I}_v(\mathrm{X} \to \mathrm{Y}) &= \mathrm{H}_v(Y) - \mathrm{H}_v(Y|X) \end{aligned}$$

where X, Y denote random variables with sample spaces $\mathcal{X}, \mathcal{Y}$. According to Ethayarajh et al. (2021), $\varnothing$ can be an empty string here as $f[\varnothing]$ models the label entropy. This framework can naturally adapt to the calculation of the point-wise $\mathcal{V}$-information (PVI) where we measure the difficulty of each data example. Given a training dataset $\mathcal{D}_{train} = \{(x_i, y_i)\}_{i=1}^n$, and the predictive family $\mathcal{V}$, the PVI of a data instance $(x, y) \in \mathcal{D}_{train}$ is computed as:

$$\mathrm{PVI}(x \to y) = -\log_2 f[\varnothing](y) + \log_2 f'[x](y),$$

where $\varnothing$ is an empty string (null input) and $\{f, f'\} \subseteq \mathcal{V}$. f' and f are models fine-tuned from $\mathcal{D}_{train}$ and $\{(\varnothing, y_i)|(x_i, y_i) \in \mathcal{D}_{train}\}$ respectively. The $\mathcal{V}$-information framework can also serve as a difficulty measurement for datasets and can be computed explicitly by averaging over PVI:

$$\mathrm{I}_v(\mathrm{X} \to \mathrm{Y}) = \frac{1}{n} \sum_i \mathrm{PVI}(x_i \to y_i)$$

As Table 2 shows, the difficulty level ranges from negative to positive. The higher the $\mathcal{V}$-information is, the easier a dataset is for the model.

Dataset Controlled Split For our model evaluation pipeline, we are interested in verifying model's ability to learn a generalizable reasoning skill on linguistic phenomena. In particular, we want to check if a model can generalize when its training and testing data distributions have different measurement of difficulty. Thus, we need to conduct controlled split on datasets based on the point-wise difficulty, i.e. the point-wise $\mathcal{V}$-information of their data examples. We first calculate the $\mathrm{PVI}(x \to y)$ for each phenomenon dataset, then we split each dataset into two portions: simple and hard, based on the calculation of each example's PVI.

4 Evaluation Methodology

We define an evaluation process for the CURRICULUM benchmark that aims to bring different types of evaluation and diagnosing methods used by previous challenge NLI datasets. Following Raji et al.

(2021)'s suggestion, we want our evaluation process to both to analyze the model output in detail and explore which aspects of the inference problem space remain challenging to current models.

Zero-shot Diagnostic Test This test is motivated by the diagnostic test in GLUE. We focus on providing fine-grained analysis of zero-shot system performance on a broad range of linguistic phenomena. We follow the GLUE diagnostic dataset and use the Matthews Correlation Coefficient (MCC) (Jurman et al., 2012) as the evaluation metric. MCC computes the correlation coefficient of the predicted labels and the true labels. The correlation coefficient value is between -1 and +1. A coefficient of +1 indicates a perfect prediction. A 0 indicates average random prediction A -1 indicates the classifier always miss-classifies. MCC is perfectly symmetric, so it can be used even if the dataset has classes with different sizes.

Inoculation by Fine-tuning We use inoculation (Liu et al., 2019a) to further analyze model failures on target linguistic phenomena. This method fine-tunes the model on a down-sampled training section of a phenomenon dataset (inoculation). One can interpret inoculation performance in two ways:

1. Good performance: the original training set of the model, prior to inoculation, did not sufficiently cover the target phenomenon, but it is recoverable through through additional training on a small sample of data.
2. Poor performance: there exists a model weakness to handle the target phenomenon.

Hypothesis-only Bias Analysis We conduct analysis on hypothesis-only bias as (1) a sanity check for our converted datasets and also and (2) a verification on whether model's good performance is from leveraging artifacts in the hypotheses. We train a hypothesis-only baseline (Poliak et al., 2018b) for each phenomenon and compare their performance against the best models from the inoculation experiment. We want to ensure that models' improved performance after inoculation is due to their ability to reason about a hypothesis and the given context together. If the hypothesis-only baseline shows good performance, we interpret this as a sign that the datasets contain artifact. If the baseline shows poor performance, it gives evidence that the model is not taking short-cuts.

Cross-Distribution Generalization We conduct the cross-distribution generalization test (Rozen et al., 2019) to verify if the model learns a general reasoning skill from inoculation. The good inoculation performance does not ensure that the model's learned skill is generalizable. The model can likely over-fit the dataset distribution by adopting superficial cues. We evaluate the model's generalization ability by training and testing the model on distributions yielding different difficulty levels within the same dataset. For example, we train the model on the simple part of the dataset (data with high $\mathcal{V}$-information) and test it on the hard part (data with low $\mathcal{V}$-information).

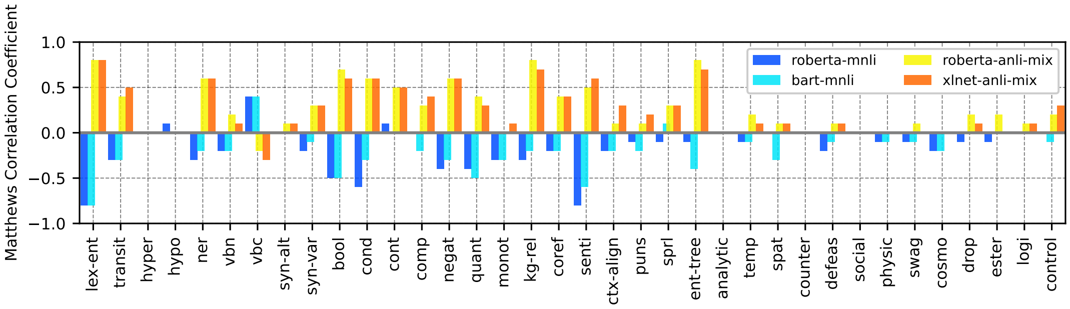
4.1 Experiment Setup

For the zero-shot test, we test a model on each test set without additional fine-tuning. We select NLI models with top performance on NLI benchmarks MNLI and ANLI. We list these models in Table 3. We are interested in evaluating models with both the single-encoder and the text2text architecture. All models are publicly available from Huggingface (Wolf et al., 2019). For inoculation, we fine-tune models on training examples with a size ranging from 10 to 1000 examples per label. For the cross-distribution generalization test, we first create variant data distributions for train and test sets using the $\mathcal{V}$-information-based dataset split method from Section 3.5. We split each dataset into two portions (simple and hard) according to the point-wise $\mathcal{V}$ information. Next, we either train and test the model on the same difficulty distribution or train it on one portion and test it on a different portion. In the inoculation, hypothesis-only, and generalization experiments, we all use roberta-anli-mix as our NLI model because its training set covers all the major NLI training datasets: SNLI, MNLI, FEVER (Thorne et al., 2018), and ANLI. We use accuracy as our evaluation metric for all these three experiments. For all the experiments excluding zero-shot test, we run several turns and select the best performance for analysis.

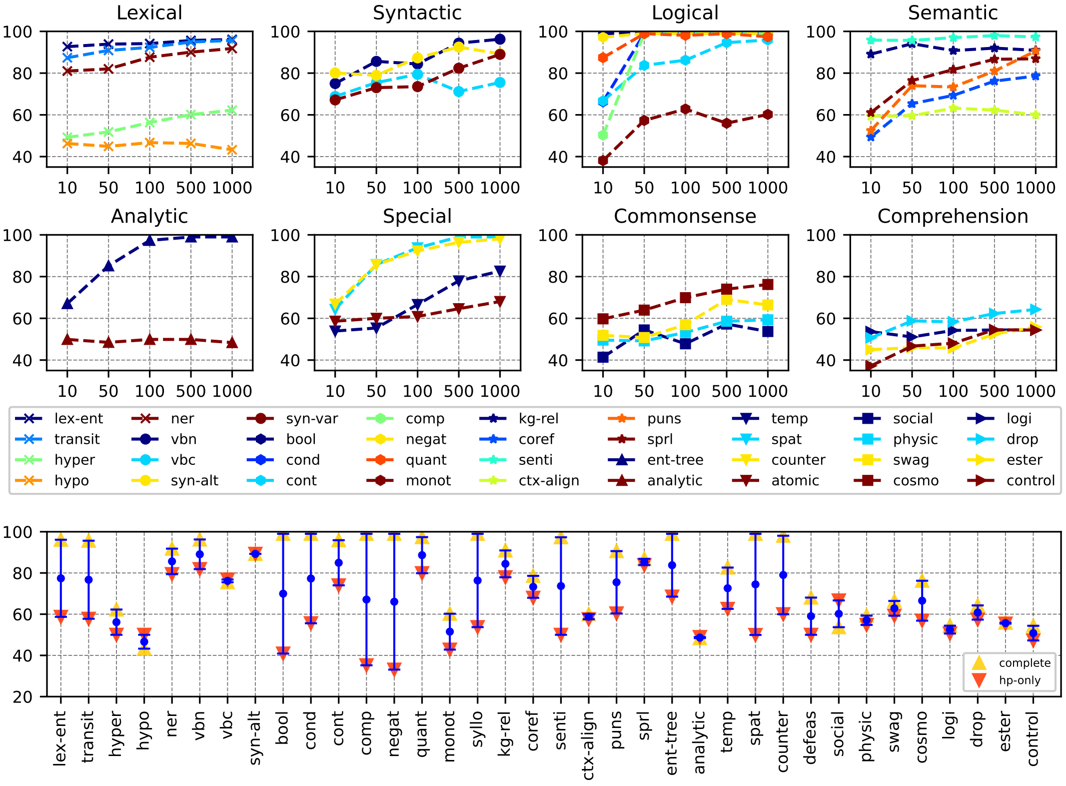
5 Empirical Analysis

5.1 Zero-shot Linguistic Phenomena Diagnose

First, we report the results on zero-shot diagnostic evaluation for each baseline model. From Figure 2a, we observe that both single-encoder and text2text models trained on MultiNLI show a negative correlation in the majority of linguistic phe-



(a) Zero-shot system performance on the CURRICULUM benchmark.



(b) Inoculation by fine-tuning vs. hypothesis-only analysis. The X-axis of the top plot represents training examples per label. Both plots' Y-axis show the accuracy. Models used in these two experiments are both the roberta-anli-mix model, introduced in Section 4.1.

nomena. Meanwhile, anli-mix models (roberta-anli-mix, xlnet-anli-mix) are positively correlated on most (77.8 %) of the phenomena and they show high correlation (> 0.50) on 27.8 % of the phenomena. On average, models trained on the large dataset mixture show better performance than models trained on MultiNLI alone, suggesting that training on more datasets help models capture more types of linguistic phenomena. However, most of the phenomena captured by the anli-mix models are easier to learn (higher $\mathcal{V}$ information). On harder phenomena, models did not benefit from the training dataset mixture. For instance, both the anli-mix models have a low correlation on deductive and analytical reasoning. Overall, we find that NLI datasets from common benchmarks lack examples of a diverse set of reasoning skills.

5.2 Inoculation

Based on Figure 2b, the model can reach high accuracy on about 64 % of the phenomena as the training examples accumulate. Most of these phenomena have higher $\mathcal{V}$ information (> 0.0) that should relatively be easier to learn. We are surprised that for some hard phenomena (≤ 0.0) such as commonsense contextual reasoning (cosmo, -0.67), the model's performance improved after inoculation. The improvement shows an gap in the original training data mixture. On 25 % of the phenomena, the model's performance did not improve

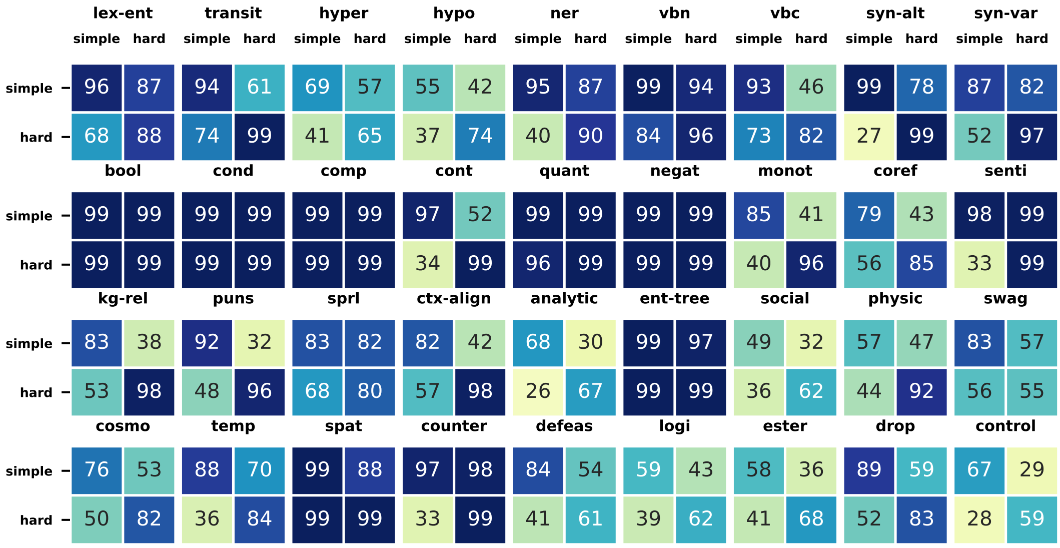


Figure 3: Generalization between controlled dataset splits. Here each heat-map shows the generalization performance of the model fine-tuned and evaluated on different distributions within each linguistic phenomenon.

significantly after inoculation, meaning that it fails to learn the reasoning skills for these phenomena. Most of these phenomena are difficult, with a low $\mathcal{V}$ information, such as monotonicity(mono) and deductive (logi) reasoning. The accuracy is consistently low when training examples accumulate.

We also observe that model struggles to learn phenomena that require complex reasoning, such as phenomena from the comprehension category. This trends show inherent weaknesses in the model or its training strategy that cause its failure to learn complex and hard phenomena. Overall, results from this experiment, combined with the zero-shot evaluation, suggest that many linguistic phenomena are missing from different large-scale NLI datasets but are recoverable through additional training examples. However, the model fails to learn the skills for hard and complex phenomena. In summary, our diagnostic study through inoculation exposes a diverse set of dataset and model weaknesses.

5.3 Hypothesis-only Bias

To determine if models can leverage spurious artifacts in the hypotheses of each phenomenon, we compare full models to hypothesis-only baselines. From Figure 2b, we observe that hypothesis-only baseline performs poorly on a majority of the phenomena. This indicates that our benchmark generally requires the model to learn an inference process between contexts and hypotheses for good performance. We observe that on 30.6% of the phenomena, the full-model can reach a high accuracy while the baseline has low accuracy, suggesting the model can learn the phenomenon without relying on hypothesis artifacts. On 36 % of the phenomena, the model does not show a significant performance gain compared to the baseline. Most of these are complex reasoning phenomena like deductive and analytical reasoning. The result validates that the model struggles more with complex linguistic phenomena. On 33.3 % of the phenomena, both the full-model and the baseline achieve high accuracy showing the possibility that the model exploits artifacts from the hypothesis to reach high accuracy.

Also, note that the hypothesis-only baseline performs better for some tasks than the fine-tuned model, which can be interpreted in two ways. When both the baseline and fine-tuned model achieve high accuracy (vbc, syn-alt), higher accuracy on baseline indicates that the hypothesis-only bias is pretty strong in the dataset. When the intervention from the premise is removed (hypothesis-only input), the models can easily exploit the bias to achieve higher accuracy. In contrast, when both the baseline and fine-tuned model achieve low accuracy (hypo, analytic, social, ester), higher accuracy on baseline indicates that the task is very difficult for a model to master successfully. Low baseline accuracy means that the dataset does not contain much bias, so a model must learn the correct reasoning to perform well. However, the fine-tuned model has even worse performance than the baseline, meaning that it fails to learn the skill required for these tasks. Our main finding here is that good performance on a linguistic phenomenon dataset does not mean the model captured the associated phenomena. The model can learn short-cuts through hypothesis-only bias and artifacts.

5.4 Generalization

As Figure 3 show, the model can adapt between different distributions only on 22.2 % of the phenomena. The model achieves high accuracy consistently for all four categories in the generalization matrix suggesting the learned skills are generalizable. On 58.3 % phenomena, models can not generalize between different difficulty distributions. They show higher accuracy when trained and tested on the same distribution but low accuracy when the test distribution shifted. For example, on relational knowledge reasoning (kg-rel), the model achieves 83% for simple → simple and 98 % for hard → hard. Nevertheless, the performance drops to 53 % for hard → simple and 38 % for simple → hard.

Notice that model's good performance on inoculation does not align with its generalization ability. For example, the model reaches 90.9 % accuracy on kg-rel, but its generalization performance is poor. This behavior highlights a model weakness: can over-fit to a particular distribution but fail to learn a general reasoning skill for the target phenomenon. We observe an interesting behavior that models struggle to generalize from hard to simple distribution on about 14 % of the phenomena while showing good generalization from simple to hard distribution. We think the possible reason is that the hard distribution contains data with relatively low $\mathcal{V}$ information. A low amount of usable information makes it hard for the model to learn the phenomena sufficiently for generalization.

6 Conclusion and Future Work

In this paper, we introduce a new form of benchmark that can serve as an effective tool for evaluating and analyzing model outcomes. We propose a linguistic-phenomena-driven benchmark that aims to diagnose neural language models to discover types of linguistic skills that remain challenging to models. We compiled a dataset collection covering 36 types of linguistic phenomena ranging from fundamental linguistic properties to complex reasoning skills. In addition, we define an evaluation procedure that can provide an in-depth analysis of model and dataset weaknesses. Using our benchmark, we comprehensively study how well language models capture specific linguistic skills essential for understanding. Our major findings include:

- Models trained on benchmark NLI datasets fail to reason over a diverse set of linguistic phenomena.
- Good inoculation performance on some phenomena results from the model leveraging superficial artifacts in the hypothesis.
- The model tends to over-fit the dataset distribution without learning a general reasoning skill on a majority of phenomena.

Overall, our benchmark effectively evaluates a model on specific linguistic skills and exposes a list of model and training data weaknesses. We hope that our benchmark and empirical findings can encourage the communicate to rethink dataset construction and model architecture design. In particular, we hope to encourage the the development of new datasets that cover richer types of linguistic phenomena and language models that can learn essential linguistic skills that are generalizable. For future work, we plan to add more datasets to cover more phenomena such as psycholinguistics (Laverghetta Jr. et al., 2021). We envision our benchmark to be dynamic, meaning that a higher-quality and more difficult dataset for a phenomenon should replace the current ones in the future. For example, the StepGame benchmark (Shi et al., 2022) provides better data for spatial reasoning, which can replace the current spatial reasoning dataset. We also plan to explore new learning methods to help models overcome the weakness of learning non-generalizable skills, such as calibration through symbolic loss functions.

Acknowledgment

We thank the anonymous reviewers for their thoughtful and constructive comments. We thank Kyle Richardson from AI2 for his insights and suggestions on improving our camera-ready version. Thanks also to our advisors Laurence S. Moss and Michael Wollowski for their feedback on earlier drafts of this work. Special thanks to the Machine Learning for Language Group at NYU for their wonderful NLP toolkit, JIANT (Phang et al., 2020).

C Data Recasting Details

Here we provide more details on the major techniques we used to convert Question Answering (QA) and Reading Comprehension (RC) datasets into recast NLI datasets.

C.1 Entity Swapping

<Original>

Context: ...The Buccaneers tied it up with a 38-yard field goal by Connor Barth, ... The game's final points came when Mike Williams of Tampa Bay caught a 5-yard pass...

Q: Who caught the touchdown for the fewest yard?

Answer: Mike Williams

<Recast>

Premise: ...The Buccaneers tied it up with a 38-yard field goal by Connor Barth, ... The game's final points came when Mike Williams of Tampa Bay caught a 5-yard pass...

Hypothesis: Mike Williams caught the touchdown for the fewest yard

Label: Entailed

Hypothesis: Connor Barth caught the touchdown for the fewest yard

Label: Not-Entailed

Table 6: Example of converting an RC example from DROP (Dua et al., 2019) to NLI format. The entailed hypothesis is a concatenation of question and answer. The non-entailed hypothesis is created by entity swapping on the entailed one (`Mike Williams` → `Connor Barth`).

C.2 Question/Answer Concatenation

<Original>

Context: The flash in the room that followed was proof of that assumption. The man grabbed his arm again. "Please let go of my arm." He requested, his voice low. "Look."

Q: Why did the man grabbed his arm?

Choice 1: The man wanted to dance with him.

Choice 2: ***The man wanted to get his attention.***

Choice 3: The man wanted to pull him closer so he can cry on this shoulder.

Choice 4: The man was angry with him and wanted to push him outside.

<Recast>

Premise: The flash in the room that followed was proof of that assumption. The man grabbed his arm again. "Please let go of my arm." He requested, his voice low. "Look."

Hypothesis: The man wanted to get his attention.

Label: Entailed

Hypothesis: The man wanted to dance with him.

Label: Not-Entailed

Table 7: Example of converting an QA example from Cosmos QA (Huang et al., 2019) to NLI format. The entailed hypothesis is the correct answer from the given choices. The non-entailed hypothesis is one of the false answers, excluding the choice "None of the above choices".

D Reproducibility

Implementation. Our model training and testing pipeline is modified from the JIANT toolkit. We mainly adapted several components on classes and functions involving task, dataset, reprocessing, tokenization, model version control, and evaluation metrics. All our experiments are implemented with models publicly available from Huggingface Transformers (Wolf et al., 2020)[2].

Hyper-parameters We mainly follow the practice in (Nie et al., 2020). For all the experiments excluding the zero-shot test in Section 5.1, we use a learning rate of $1e-5$ with a batch size of 8. We set the number of warmup updates to be 1000. We set the epoch number to be 3 and 5. We evaluate the model on D_{dev} every 200 steps for the inoculation and generalization experiments, and 500 steps for the hypothesis-only experiment. For the low-data generalization on ANLI, we evaluate on the full-test set according to the number of training examples listed in Figure **??**. We use the AdamW (Loshchilov and Hutter, 2019) as our optimizer.

---

[2] https://github.com/huggingface/transformers

Infrastructure All experiments are done with one single Geforce RTX 3090 (24GB). A single inoculation or generalization job finishes within 0.5 hours on average. A single hypothesis-only job finishes within 1-2 hours on average. A single job on sequential training and low-data fine-tuning finishes within approximately 1.5 hours on average.

Number of Parameters. RoBERTa-large model contains 355 million parameters. BART-large model contains 139 million parameters. BART-Large model contains 406 million parameters. XLNet-large model contains 340 million parameters.

Neural Language Taskonomy: Which NLP Tasks are the most Predictive of fMRI Brain Activity?

Abstract

Several popular Transformer based language models have been found to be successful for text-driven brain encoding. However, existing literature leverages only pretrained text Transformer models and has not explored the efficacy of task-specific learned Transformer representations. In this work, we explore transfer learning from representations learned for ten popular natural language processing tasks (two syntactic and eight semantic) for predicting brain responses from two diverse datasets: Pereira (subjects reading sentences from paragraphs) and Narratives (subjects listening to the spoken stories). Encoding models based on task features are used to predict activity in different regions across the whole brain. Features from coreference resolution, NER, and shallow syntax parsing explain greater variance for the reading activity. On the other hand, for the listening activity, tasks such as paraphrase generation, summarization, and natural language inference show better encoding performance. Experiments across all 10 task representations provide the following cognitive insights: (i) language left hemisphere has higher predictive brain activity versus language right hemisphere, (ii) posterior medial cortex, temporo-parieto-occipital junction, dorsal frontal lobe have higher correlation versus early auditory and auditory association cortex, (iii) syntactic and semantic tasks display a good predictive performance across brain regions for reading and listening stimuli resp.

1 Introduction

Brain encoding aims at constructing neural brain activity given an input stimulus. Since the discovery of the relationship between language stimuli and functions of brain networks using fMRI [for ex., (Constable et al., 2004)], researchers have been interested in understanding how the neural encoding models predict the fMRI brain activity. Several brain encoding models have been developed to (i) understand the ventral stream in biological vision (Yamins et al., 2014; Kietzmann et al., 2019; Bao et al., 2020), and (ii) to study the higher-level cognition like language processing (Gauthier and Levy, 2019; Schrimpf et al., 2021; Schwartz et al., 2019).

Some recent studies (Nishida et al., 2015; Huth et al., 2016) have been able to identify brain ROIs (Region of Interest) that respond to words that have a similar meaning and have thus built a "semantic atlas" of how the human brain organizes language. Further, several studies (Oota et al., 2018; Jain and Huth, 2018; Hollenstein et al., 2019) have used a wide variety of word embeddings where words represented as vectors in an embedding space are mapped to brain activation for improved neural coding.

Recently, Transformer (Vaswani et al., 2017) based models like BERT (Devlin et al., 2019) have been found to be very effective across a large number of natural language processing (NLP) tasks. These Transformer based models have been pretrained on millions of text instances in an unsupervised manner and further finetuned to specialize for various NLP tasks. Natural language understanding requires integrating several cognitive skills like syntactic parsing of the language structure, identifying the named entities, capturing the word meaning in the context, coreference resolution, etc. Learning from massive corpora enables these models to excel at cognitive skills required for language understanding. Interestingly, such Transformer-based neural representations have been found to be very effective for brain encoding as well (Schrimpf et al., 2021).

Despite the recent advances in mapping between language Transformers and the brain activity recorded with reading (Schrimpf et al., 2021), the Transformer features themselves are notoriously difficult to interpret. In recent works, Caucheteux et al. (2021a); Antonello et al. (2021) address this

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3220 - 3237
July 10-15, 2022

issue by disentangling the high-dimensional Transformer representations of language models into four combinatorial classes: lexical, compositional, syntactic, and semantic representations to explore which class is highly associated with language cortical ROIs. Representations do not exist in a vacuum but become meaningful only when they accomplish a task. Therefore, the next logical step is to see which of these Transformer representations most effectively drive the linear mapping between language models and the brain in the context of NLP tasks. Gauthier and Levy (2019) fine-tune a pretrained BERT model on multiple tasks to find tasks best correlated with high *decoding* performance. In this study, we investigate the correlation between brain activation and feature representations learned by different task-specific networks, and ask which tasks lead to improvements in *brain-encoding* performance.

Recently, a study using multiple computer vision tasks has shown that 3D vision task models predict better fMRI brain activity than 2D vision task models (Wang et al., 2019) for visual stimuli. Inspired by the success of correlations in the vision field (Wang et al., 2019), and brain encoding study of a variety of language Transformer models (Schrimpf et al., 2021; Caucheteux et al., 2021b,a), we build neural language taskonomy models for brain encoding and aim to find NLP tasks that are most explanatory of brain activations for reading and listening tasks.

In this paper, we uncover insights about the association between fMRI voxel activations and representations of diverse NLP tasks representations. The predictive power of task-specific representations with brain activation is ascertained by (1) using ridge regression on such representations and predicting activations and (2) computing popular metrics like 2V2 accuracy and Pearson correlation between actual and predicted activations.

Specifically, we make the following contributions in this paper.

- Given Transformer models finetuned for various NLP tasks, we propose the problem of finding which of these are the most predictive of fMRI brain activity for reading and listening tasks.

- Our language taskonomy results reveal that Coreference Resolution, Named Entity Recognition, and Shallow Syntax Parsing tasks have higher predictive performance while reading the text. On the other hand, paraphrase detection, summarization, and Natural Language Inference tasks display better correlation during listening.

- We also perform similarity analysis between task representations from transfer learning and neural taskonomy and derive interesting cognitive insights from brain maps.

2 Related Work

Older methods for text-based stimulus representation include text corpus co-occurrence counts (Mitchell et al., 2008; Pereira et al., 2013; Huth et al., 2016), syntactic and discourse features (Wehbe et al., 2014). In recent times, both semantic and experiential attribute models have been explored for text-based stimuli. Semantic representation models include distributed word embeddings (Pereira et al., 2016; Anderson et al., 2017a; Pereira et al., 2018; Toneva and Wehbe, 2019; Hollenstein et al., 2019; Wang et al., 2020), sentence representation models (Sun et al., 2019; Toneva and Wehbe, 2019; Sun et al., 2020), recurrent neural networks (Jain and Huth, 2018; Oota et al., 2019), and Transformer-based language models (Gauthier and Levy, 2019; Toneva and Wehbe, 2019; Schwartz et al., 2019; Oota et al., 2022a,b). Experiential attribute models represent words in terms of human ratings of their degree of association with different attributes of experience, typically on a scale of 0-6 (Anderson et al., 2019, 2020; Berezutskaya et al., 2020; Jat et al., 2020; Caucheteux et al., 2021a; Antonello et al., 2021) or binary (Handjaras et al., 2016; Wang et al., 2017). Fine-grained details such as lexical, compositional, syntactic, and semantic representations of narratives are factorized from Transformer-based models and utilized for training encoding models. The resulting models are better able to disentangle the corresponding brain responses in fMRI (Caucheteux et al., 2021a).

In this paper, we focus on Transformer-based linguistic stimuli representations since they have been found to be most effective. Unlike previous studies which directly used existing task-agnostic pretrained models, we train task-specific Transformer models and aim to find which model leads to the best encoding accuracy given reading and listening language stimuli.

3 Brain Imaging Datasets

We work with two datasets: Pereira and Narratives-Pieman. Results on Narratives-Lucy and Narratives-SlumLord show similar trends. Hence, we also show results on Narratives-Lucy and Narratives-SlumLord in the appendix.

Pereira Dataset (Reading Sentences from Passages) For the Pereira dataset, similar to earlier work (Sun et al., 2019, 2020), we combine the data from sentence-based experiments (experiments-2 and 3) from Pereira et al. (2018). Five subjects were presented a total of 627 sentences from 48 broad topics, spanning over 168 passages, where each passage consists of 3-4 sentences. As in (Pereira et al., 2018), we focused on nine brain ROIs (regions of interest) corresponding to four brain networks: (i) Default Mode Network (DMN) (linked to the functionality of semantic processing), (ii) Language Network (related to language processing, understanding, word meaning, and sentence comprehension), (iii) Task Positive Network (TP) (related to attention, salience information), and (iv) Visual Network (related to the processing of visual objects, object recognition). We briefly summarize the details of the dataset and the number of voxels corresponding to each ROI in Table 1. We use the AAL parcellation Atlas (116 × 116 brain ROIs) to present the brain map results, since Pereira dataset contains annotations tied to this atlas.

ROIs→	Language		Vision					DMN	Task Positive

	LH	RH	LH	RH	LH	RH	LH	RH	LH	RH
# Voxels	808	638	1420	1493	1198	1204	847	1188	1061	875

Table 2: # Voxels in each ROI in the Narratives Dataset. LH - Left Hemisphere. RH - Right Hemisphere. Pieman has 82, Lucy has 16 and SlumLord has 18 subjects. # Voxels across ROIs are same for all the three.

Narratives-Pieman (Listening to Stories) The "Narratives" collection aggregates a variety of fMRI datasets collected while human subjects listened to naturalistic spoken stories. The Narratives dataset that includes 345 subjects, 891 functional scans, and 27 diverse stories of varying duration totaling ∼4.6 hours of unique stimuli (∼43,000 words) was proposed in (Nastase et al., 2021). Similar to earlier works (Caucheteux et al., 2021b), we analyze data from 82 subjects listening to the story titled 'PieMan' with 259 TRs (repetition time – fMRI recorded every 1.5 sec.). We list number of voxels per ROI in this dataset in Table 2. We use the multi-modal parcellation of the human cerebral cortex (Glassar Atlas: consists of 180 ROIs in each hemisphere) to display the brain maps (Glasser et al., 2016), since Narratives dataset contains annotations tied to this atlas. The data covers ten brain ROIs in the human brain, i.e., Left hemisphere (L), and Right hemisphere (R) for each of the following: (i) early auditory cortex (EAC: A1, LBelt, MBelt, PBelt, and R1) which plays a key role for sound perception since it represents one of the first cortical processing stations for sounds; (ii) auditory association cortex (AAC: A4, A5, STSdp, STSda, STSvp, STSva, STGa, and TA2) which is concerned with the memory and classification of sounds; (iii) posterior medial cortex (PMC: POS1, POS2, v23ab, d23ab, 31pv, 31pd, 7m); (iv) the temporo parieto occipital junction (TPOJ: TPOJ1, TPOJ2, TPOJ3, STV, PSL) which is a complex brain territory heavily involved in several high-level neurological functions, such as language, visuo-spatial recognition, writing, reading, symbol processing, calculation, self-processing, working memory, musical memory, and face and object recognition; and (v) the dorsal frontal lobe (DFL: L_55b, SFL, L_44, L_45, IFJA, IFSP) which covers the aspects of pragmatic processing such as discourse management, integration of prosody, interpretation of nonliteral meanings, inference making, ambiguity resolution, and error repair.

4 Encoding Model

To explore how and where contextual language features are represented in the brain when reading sentences and listening to stories, we extract different features spaces describing each stimulus sentence and use them in an encoding model to predict brain responses. Our reasoning is as follows. If a feature is a good predictor of a specific brain region, information about that feature is likely encoded in that region. In this paper, for both datasets, we train fMRI encoding models using Ridge regression on stimuli representations obtained using a variety of NLP tasks. The main goal of each fMRI encoder model is to predict brain responses associated with each brain region given a stimuli. In all cases, we train a model per subject separately. Following literature on brain encoding (Caucheteux et al., 2021b; Toneva et al., 2020), we choose to use a ridge regression model instead of more complicated models. We plan to explore more such models as part of future work. We follow K-fold (K=10) cross-validation. All the data samples from K-1 folds were used for training, and the model was tested on samples of the left-out fold. We used sklearn's ridge-regression with default parameters, 10-fold cross-validation, Stochastic-Average-Gradient Descent Optimizer, Huggingface for Transformer models, MSE loss function, and L2-decay (λ) as 1.0. We used BERT Word-Piece tokenizer for the linguistic Transformer input. All experiments were conducted on a machine with 1 NVIDIA GEFORCE-GTX GPU with 16GB GPU RAM. We make the code publicly available[1].

4.1 Feature Spaces

To simultaneously test representations from multiple NLP tasks, we used the latent space features from each of the following ten popular NLP tasks: coreference resolution (CR), named entity recognition (NER), natural language inference (NLI), paraphrase detection (PD), question answering (QA), sentiment analysis (SA), semantic role labeling (SRL), shallow syntax parsing (SS), summarization (Sum) and word sense disambiguation (WSD). All of these are discriminative NLP tasks, and thus we use models obtained by task-specific finetuning of the same pretrained Transformer encoder model (BERT-base-cased with dimensionality=768). Given an input sentence, each task Transformer outputs token representations at the final layer. We use the #tokens × 768 dimension vector obtained from the last hidden layer to obtain latent features for the stimuli. We then build individual ridge regression models with the extracted latent features to predict brain responses and measure the correlation between the prediction and the true response.

Pereira: Since individual sentences were presented to the subjects while modeling, sentences were passed one by one to the task Transformer model, and average-pooled representations were used to encode the sentence stimuli.

Narratives-Pieman: Due to the constraint on input sequence length for BERT (512), we considered a window size of 10 sentences with the last two sentences of one window overlapping with the next to be given as input to the BERT model. We use the average-pooled representation from BERT to encode text stimuli. To get the representation for a TR, we pooled the representations of only those words of the sentences in that TR.

4.2 Task Descriptions

Here we describe the functionality of each NLP task that we used for fMRI encoding. **CR:** involves finding all expressions that refer to the same entity in a text. **PD:** involves taking a passage – either spoken or written – and rewording it in shorter or own words. **Summarization (Sum):** involves selecting a few important sentences from a document or paragraph. **NER:** involves detection of the named entities such as person names, location names, company names from a given text. **NLI:** investigates the entailment relationship between two texts: premise and hypothesis. **QA:** aims to select an answer given a passage, a question, and a set of candidate answers. **SA:** involves determining whether a piece of text is positive, negative, or neutral. **SRL:** assigns labels to words or phrases in a sentence that indicates their semantic role in the sentence, such as that of an agent, goal, or result. **SS:** provides an approximation of phrase-syntactic structure of sentences. **WSD:** involves determining which sense (meaning) of a word is activated by the use of the word in a particular context.

Syntactic reasoning is rather shallow compared to deep semantic reasoning. Syntactic reasoning follows somewhat objective grammar rules. Comparatively semantic reasoning is often subjective in nature and complex. The emerging evidence from fMRI studies (Fedorenko et al., 2020, 2012) also points out that processing of both syntax and semantics is distributed in the brain and it is only when violations of these processes are probed, we see localization of function (Friederici et al., 2003). Thus, in this work, we explore syntactic and semantic tasks separately. Of the above mentioned tasks, NER and SS are syntactic, while the others involve semantic reasoning.

Our selection of these tasks was based on the following design principles: (1) We wanted to select a set of tasks covering diverse cognitive-linguistic skills. (2) We wanted to select tasks that are a part of popular NLP benchmarks like GLUE (Wang et al., 2018). (3) We selected tasks for which

---

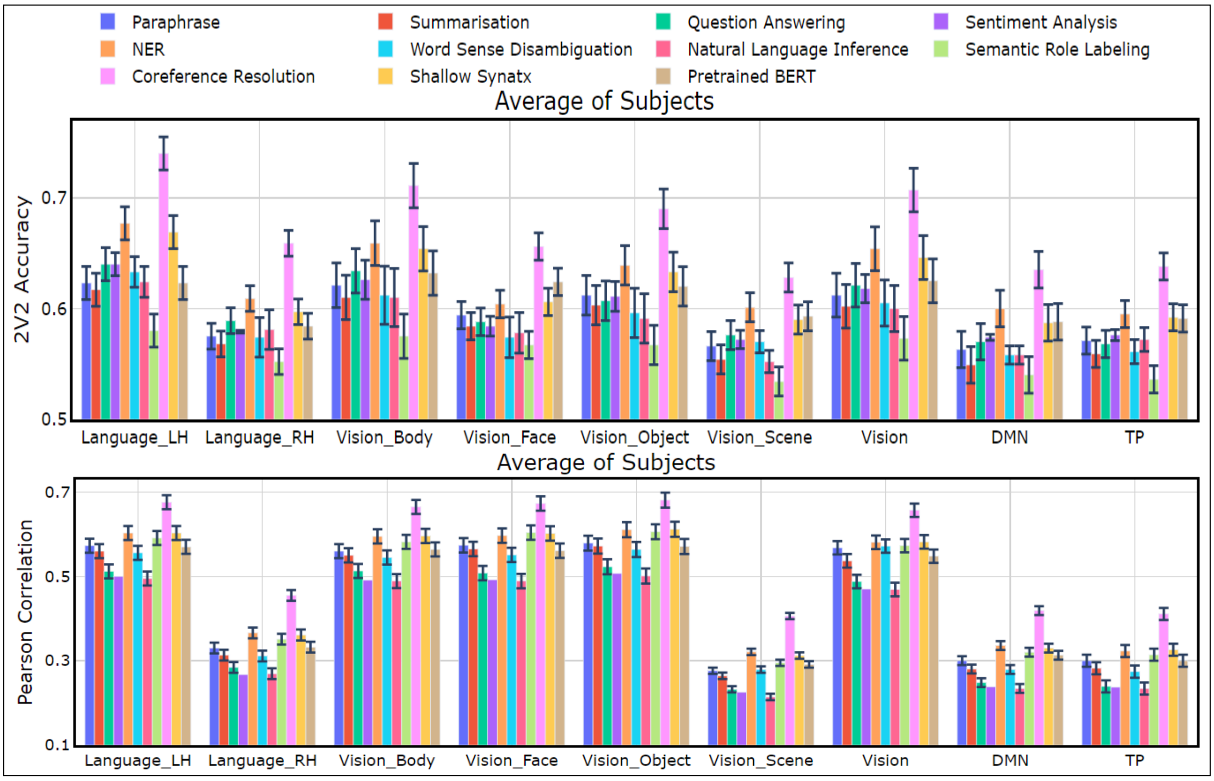

Figure 1: Pereira – 2V2 Accuracy (top figure) and Pearson correlation coefficient (bottom figure) between predicted and true responses across different brain regions using a variety of NLP tasks. Results are averaged across all participants. CR, NER, and SS perform the best.

BERT-base-cased finetuned models were available. Note that we did not finetune any of these models ourselves but leveraged the state-of-the-art finetuned models available on Huggingface. Details of the specific finetuned model checkpoints are mentioned in Table 3 in the Appendix.

4.3 Evaluation Metrics

We evaluate our models using popular brain encoding evaluation metrics described in the following. Given a subject and a brain region, let N be the number of samples. Let $\{Y_i\}_{i=1}^{N}$ and $\{\hat{Y}_i\}_{i=1}^{N}$ denote the actual and predicted voxel value vectors for the i^{th} sample. Thus, $Y \in R^{N \times V}$ and $\hat{Y} \in R^{N \times V}$ where V is the number of voxels in that region.

2V2 Accuracy is computed as 2V2Acc=$\frac{1}{N_{C_2}} \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} I[cosD(Y_i, \hat{Y}_i) + cosD(Y_j, \hat{Y}_j) < cosD(Y_i, \hat{Y}_j) + cosD(Y_j, \hat{Y}_i)]$ where $cosD$ is the cosine distance function. $I[c]$ is an indicator function such that $I[c] = 1$ if c is true, else it is 0. The higher the 2V2 accuracy, the better.

Pearson Correlation (PC) is computed as PC=$\frac{1}{N} \sum_{i=1}^{n} corr[Y_i, \hat{Y}_i]$ where corr is the correlation function.

Mean Absolute Error (MAE) is computed as MAE=$\frac{1}{N} \sum_{i=1}^{n} |[Y_i - \hat{Y}_i]|$.

Statistical Significance: In order to estimate the statistical significance of the performance differences (across all results), we performed one-way ANOVA on the mean values for the subjects. In all such cases we report p-values corrected using Bonferroni correction.

4.4 Neural Language Tasks Similarity Computation

To estimate the similarity between 10 language tasks, we took the prediction performance scores across all the voxels in Pereira (97,539) and Narratives-Pieman datasets (10,732). To analyze the relationship between tasks based on neural representations, we calculated the Pearson correlation between predicted voxels of each task with the remaining tasks. These Pearson correlation values were used to construct heatmaps and the task similarity trees(dendograms) using hierarchical clustering for Pereira and Narratives-Pieman datasets.

5 Results

In order to assess the performance of the fMRI encoder models learned using the representations

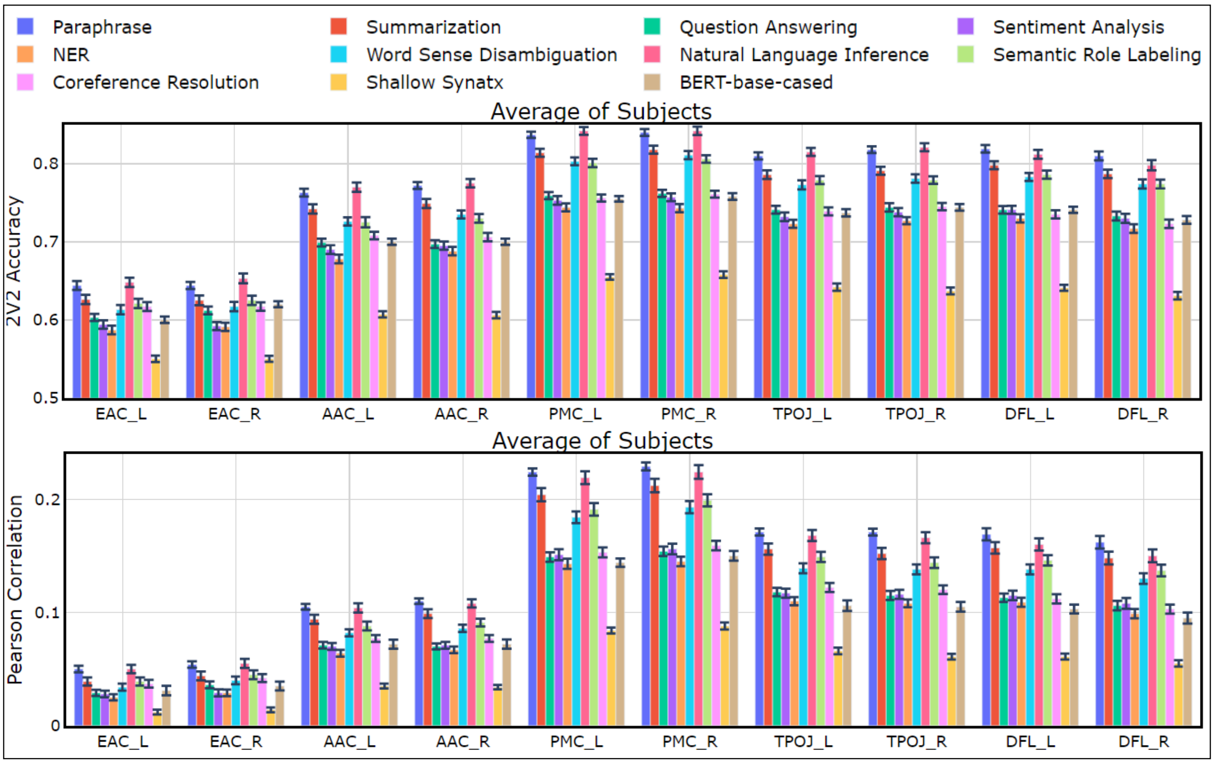

Figure 2: Narratives-Pieman – 2V2 Accuracy (top figure) and Pearson correlation coefficient (bottom figure) between predicted and true responses across different brain regions using a variety of NLP tasks. Results are averaged across all participants. NLI, PD, and Summarization perform the best.

from a variety of NLP tasks, we computed the 2V2 accuracy and Pearson correlation coefficient between the predicted and true responses across various ROIs for both the reading (Pereira) dataset (Fig. 1) as well as the listening (Narratives-Pieman) dataset (Fig. 2).

5.1 Encoding performance of Language Task models for reading vs listening tasks

Reading Sentences (Pereira): From Fig. 1, we observe that tasks such as CR, NER, SRL, and SS appear to have a better correlation to the brain responses compared to the other tasks. In order to estimate the statistical significance of the performance differences, we performed one-way ANOVA on the mean correlation values for the subjects across the ten language tasks for the nine brain ROIs. The main effect of the ANOVA test was significant for all the ROIs with $p \leq 10^{-2}$ with confidence 95% (see Appendix for detailed ANOVA results). Further, *post hoc* pairwise comparisons (Ruxton and Beauchamp, 2008) confirmed the visual observations that on both 2V2 accuracy and Pearson correlation measures, tasks such as CR, NER, SRL, and SS performed significantly better compared to other tasks (see Appendix for pairwise comparison results). These results demonstrate that when reading a sentence, information processing operations related to recognizing named entities, labeling semantic roles to the constituents of a sentence, identifying the references from a sentence to the given topic (concept), and syntactic processing may be engaged.

Further, we observe that the ROI corresponding to language processing in the left hemisphere (Language_LH) has higher encoding performance than that of the right hemisphere (Language_RH). This is in line with the left hemisphere dominance for language processing (Binder et al., 2009). Also, lateral visual ROIs such as Vision_Object, Vision_Body, Vision_Face, and Vision ROIs display higher correlation with the language tasks associated with named entities (NER), relating the entities (CR), and syntax processing (SS). Higher correlations with all the visual brain regions point to the possible alignment of visual and language regions for semantic understanding (Popham et al., 2021) in a reading task. Finally, across all regions, pretrained BERT model has worse correlation compared to at least 5 other task models.

Listening Stories (Narratives-Pieman): From Fig. 2, we observe that the profiles of performance show low scores in the early auditory cortex (EAC), auditory association cortex (AAC); average scores in TPOJ and DFL; and superior scores in PMC. This aligns with the known language hierarchy for spoken language understanding (Nastase et al., 2020). Tasks such as PD, Summarization, and NLI seem to yield better performance in predicting the brain responses than the other NLP tasks across all the ROIs. These Pearson correlation (τ) results are comparatively much higher compared to those obtained using pretrained (task-agnostic) GPT2 model in (Caucheteux et al., 2021a) (τ ranging from $0.02 - 0.06$). As shown in Fig. 2, our method obtains much higher correlations (τ ranging from $0.02 - 0.229$). Similar to the Pereira dataset, we estimate the statistical significance of the performance differences using the one-way ANOVA test. The main effect of task was significant for all the ROIs with p$\leq 10^{-3}$ with confidence 95% (see Appendix for detailed ANOVA results). Also, *Post hoc* pairwise comparisons (Ruxton and Beauchamp, 2008) revealed that on both 2V2 accuracy and Pearson correlation measures, tasks such as PD, Sum, and NLI performed significantly better compared to other tasks (see Appendix for pairwise comparison results).

Further, from Fig. 2, we see that the bilateral posterior medial cortex (PMC) associated with higher language function exhibits a higher correlation among all the brain ROIs. ROIs, including bilateral TPOJ and bilateral DFL, yield higher correlations with the five NLP tasks, which is in line with the language processing hierarchy in the human brain. Finally, across all regions, pretrained BERT model has worse correlation compared to at least 5 other task models.

In summary, different and distinct language Taskonomy features seem to be related to the encoding performance in reading versus listening tasks. CR, NER, SRL, and SS perform better for reading. PD, Sum, and NLI perform better for listening. While listening the subject is cognitively more involved in the activity compared to reading (Buchweitz et al., 2009). Thus, it makes sense that shallow tasks like NER and SS are useful for reading while more complex NLP tasks like PD, Sum and NLI are effective for encoding listening stimuli.

	PD	Sum	QA	SA	NER	WSD	NLI	SRL	CR	SS

Figure 4: Narratives-Pieman – Prediction Task Similarity constructed from the task-wise brain response predictions across 10 tasks averaged across all subjects.

5.2 Language Task Similarity Computation

Pearson correlation values between predicted responses for each pair of tasks were used to construct the similarity matrix with heatmap for both Pereira and Narratives-Pieman datasets, as shown in Figs. 3 and 4. We observe that the following task pairs are highly correlated for the Pereira dataset: (NER and CR), (SS and CR) and (PD and Sum). Also these task pairs are highly correlated for the Narratives-Pieman dataset: (CR and NLI), (NLI and SA) and (PD and Sum). Similarities are relatively higher for Narratives-Pieman compared to the Pereira dataset. Surprisingly, the (NLI, SA) pair has lowest similarity for Pereira (reading) and close to highest in Narratives-Pieman (listening). We hypothesize that this is because sentiment is best conveyed while the subject is listening.

Reading sentences (Pereira): The stimulus sentences from the Pereira dataset were fed as input to each of the 10 task Transformers. The similarity among the resulting representations was analyzed using hierarchical clustering, and the clusters are visualized as dendrograms in Fig. 5 (left). We observe that the tasks are clustered into three groups denoted using red, green, and blue colors. Next, we wished to check if similar task grouping is observed on brain activations predicted by ridge regression trained on task-specific representations. Hence, similar clustering analysis was conducted on the neural space representations, and the clusters are visualized as dendrograms in Fig. 5 (right)

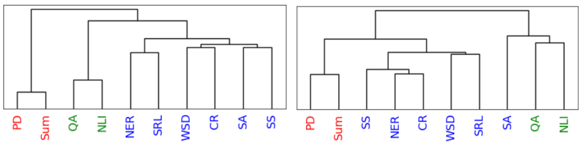

Figure 5: Left: Pereira Dendrogram constructed using similarity on representations from task-specific Transformer encoder models with stimuli from the dataset passed as input. Right: Pereira Dendrogram constructed using similarity matrix shown in Fig. 3.

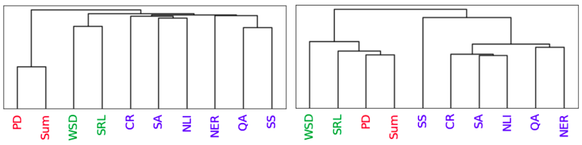

Figure 6: Left: Narratives-Pieman Dendrogram constructed using similarity on representations from task-specific Transformer encoder models with stimuli from the dataset passed as input. Right: Narratives-Pieman Dendrogram constructed using similarity matrix shown in Fig. 4.

across all subjects. Interestingly, the tree derived from brain representation also shows a similar distribution of tasks across the three groups. Similar dendrograms for individual subjects are illustrated in Appendix-Fig. 11.

Listening Stories (Narratives-Pieman): Fig. 6 compares the task similarity tree based on the patterns from the pretrained task Transformers, with the task similarity tree generated based on similarity in brain response prediction performance averaged across all subjects. We observe that the tasks are clustered into three groups denoted using red, green, and blue colors. Again, the tree derived from brain representation also shows a similar distribution of tasks across the three groups. Dendrograms for individual subjects are in the Appendix-Fig. 12.

5.3 Brain maps for whole brain predictions

The mean absolute error (MAE) between predictive and actual responses is obtained using individual task features from the taskonomy. MAE values are obtained for all the voxels in the brain for both the reading (Fig. 7) and listening datasets (Fig. 8).

In the **reading task**, we observe from Fig. 7 that CR has lower MAE compared to PD which in turn has lower MAE compared to the NLI task (brain maps for the other tasks are reported in Fig. 17 in the Appendix). Overall, for the reading stimuli, tasks such as NLI, QA, and SA display higher MAE values. To further investigate which sub ROIs (LPTG, LMTG, LATG, LFus, Lpar, Lang, LIFGorb, LIFG, LaMFG, LpMFG, and LmMFG) of the Language network are related to the predictive task features, we train encoding models for all the sub ROIs for the best encoding task, i.e., for the CR task (see Fig. 14 in Appendix). We notice that both LMTG (middle temporal gyrus) and LPTG (posterior temporal gyrus) are more accurately predicted than the other sub ROIs. On the other hand, LIFG-orb displays a lower Pearson correlation for the CR task. The presence of superior encoding information in the ROIs in the temporal gyrus as compared to those in the inferior frontal gyrus seems to mirror similar observations seen in decoder performance (Anderson et al., 2017b).

On the other hand, in the **listening task**, we observe from Fig. 8 that Paraphrase and WSD display lower MAE values compared to QA task (brain maps for the other tasks are reported in Fig. 18 in the Appendix). Taken together, for listening stimuli, tasks such as NER, QA, SA, CR, and SS display higher MAE values. From Fig. 8, we see that ROIs such as EAC and AAC have higher MAE compared to PMC and TPOJ brain ROIs.

We further demonstrate the prediction performance of the encoder model trained on sub ROIs for the paraphrase task in Fig. 15 in the Appendix. It can be observed that sub ROIs such as Pos1 and Pos2 have a higher Pearson correlation than other sub ROIs of the PMC region. Both sfl and l55b display a higher correlation among all the sub ROIs for the DFL ROI. However, all the sub ROIs in the TPOJ yield higher correlation, as shown in Fig. 15. The control and attention ROIs in the posterior cingulate cortex (for ex., POS1 in PMC), together with the superior frontal language region (sfl in DFL) and TPOJ, are part of the well-known language network associated with narrative comprehension (Nastase et al., 2020), and it is heartening to see that task features from PD task also relate to semantic analysis of the ongoing narrative.

5.4 Discussion

(1) We used a ridge regression model instead of more complicated models for encoding. We believe that more complex models can lead to further exciting insights. (2) We experimented with 10 NLP tasks. Models can be pretrained for more such tasks to check if other tasks are better predictive of voxel activations. (3) We leveraged models finetuned using datasets of different sizes across

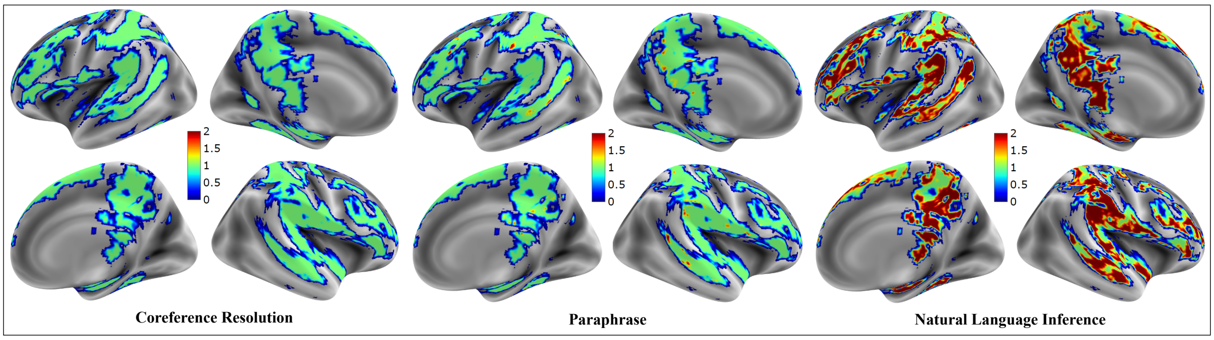

Figure 7: Pereira BrainMaps: Mean absolute error (MAE) between predictive voxels and actual voxels using task features from Taskonomy in one sample subject (subject 1). Predictive regions of different tasks are dissimilar across tasks. The MAE values of each brain ROI are: CR (Language: 0.64, Visual: 0.57, DMN: 1.19, TP: 0.67), PD (Language: 0.81, Visual: 0.74, DMN: 1.34, TP: 0.87) and NLI (Language: 1.9, Visual: 1.88, DMN: 2.1, TP: 2.03).

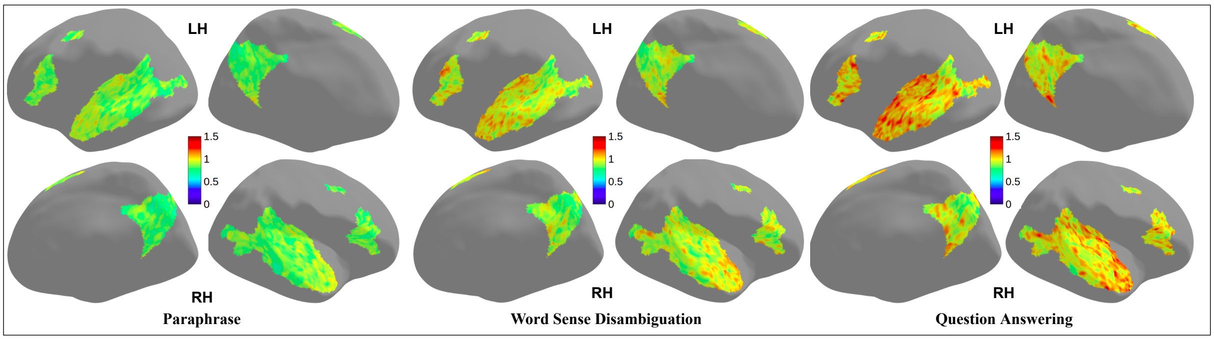

Figure 8: Narratives-Pieman BrainMaps: Mean absolute error (MAE) between predictive voxels and actual voxels using task features from Taskonomy in one sample subject (subject 1) of PieMan dataset. Predictive regions of various tasks are different across tasks. The MAE values of each brain ROI: PD task (EAC: 0.74, AAC: 0.66, PMC: 0.60, TPOJ: 0.61, and DFL: 0.694), WSD task(EAC: 0.83, AAC: 0.75, PMC: 0.68, TPOJ: 0.68, and DFL: 0.76), QA task (EAC: 0.92, AAC: 0.83, PMC: 0.74, TPOJ: 0.75, and DFL: 0.76).

tasks. While a fair comparison of dataset sizes across tasks is impossible, we understand that this could have resulted in some bias in our results. (4) We used a different dataset for reading vs listening. While we believe that the differences in task-specific model performances across reading and listening are mainly due to the learned stimulus representations, but they could also arise from other factors such as experimental conditions, the text domain of the stimuli or number of voxels, etc. (5) On Natural Language Understanding tasks such as NLI, SA, QA and PD, Gauthier and Levy (2019) observed that scrambled sentence representations gave better decoding performance. But encoding models (especially for the listening task), scrambled order would be detrimental to making sense of what is being heard. It is an interesting future task to see if the opposite result is seen in the case of brain encoding models. It is plausible that brain uses encoding models in a flexible way when it comes to decoding (Kriegeskorte and Douglas, 2019). Kriegeskorte and Douglas (2019) mention that "Decoding models can help reveal whether particular information is present in a brain region in a format the decoder can exploit. Encoding models make comprehensive predictions about representational spaces." In this sense, results of current work are not directly comparable to those of Gauthier and Levy (2019).

6 Conclusion

In this paper, we studied the effectiveness of task specific NLP models for brain encoding. We observe that building individual encoding models and exploiting existing relationships among models can provide a more in-depth understanding of the neural representation of language information. Our experiments on Pereira and Narrative datasets lead to interesting cognitive insights.

7 Ethical Statement

We reused publicly available datasets for this work: Pereira and Narratives. We did not collect any new dataset.

Pereira dataset can be downloaded from `https://osf.io/crwz7/`. Please read their terms of use[2] for more details.

Narratives dataset can be dowloaded from `https://datasets.datalad.org/?dir=/labs/hasson/narratives`. Please read their terms of use[3] for more details.

We do not foresee any harmful uses of this technology.

A Details of the Finetuned Models

We selected tasks for which BERT-base-cased finetuned models were available. Note that we did not finetune any of these models ourselves but leveraged the state-of-the-art finetuned models available on Huggingface. Details of the specific finetuned model checkpoints are mentioned in Table 3.

B ANOVA test results

B.1 Pereira dataset

The main effect of model was significant for the ROIs with 95% confidence with these statistics:

- Language_LH: [F(9, 40) = 3.95, p=0.0052]
- Language_RH: [F(9, 40) = 4.53, p=0.0015]
- Vision_Body: [F(9, 40) = 4.397, p=0.00227]
- Vision_Face: [F(9, 40) = 3.46, p=0.0085]
- Vision_Object: [F(9, 40) = 3.40, p=0.0121]
- Vision_Scenes: [F(9, 40) = 4.917, p=0.0007]
- Vision: [F(9, 40) = 3.945, p=0.00385]
- DMN: [F(9, 40) = 6.28, p=0.00034]
- TP: [F(9, 40) = 6.54, p=0.00042]

B.2 Narratives-Pieman dataset

The main effect of model was significant for the ROIs with 95% confidence with these statistics:

- EAC_L [F(9,810)=3.88, p=.00009]
- EAC_R [F(9,810)=3.34, p=.00055]
- AAC_L [F(9,810)=5.37, p=.0000007]
- AAC_R [F(9,810)=6.955, p=.00000]
- PMC_L [F(9,810)=37.21, p=.00000]
- PMC_R [F(9,810)=31.62, p=.00000]
- TPOJ_L [F(9,810)=9.166, p=.00000]
- TPOJ_R [F(9,810)=7.797, p=.00000]
- DFL_L [F(9,810)=12.445, p=.00000]
- DFL_R [F(9,810)=12.27, p=.00000]

Abstract

Despite recent improvements in abstractive summarization, most current approaches generate summaries that are not *factually consistent* with the source document, severely restricting their trust and usage in real-world applications. Recent works have shown promising improvements in factuality error identification using text or dependency arc entailments; however, they do not consider the entire semantic graph simultaneously. To this end, we propose FACTGRAPH, a method that decomposes the document and the summary into structured *meaning representations* (MR), which are more suitable for factuality evaluation. MRs describe core semantic concepts and their relations, aggregating the main content in both document and summary in a canonical form, and reducing data sparsity. FACTGRAPH encodes such graphs using a graph encoder augmented with structure-aware adapters to capture interactions among the concepts based on the graph connectivity, along with text representations using an adapter-based text encoder. Experiments on different benchmarks for evaluating factuality show that FACTGRAPH outperforms previous approaches by up to 15%. Furthermore, FACTGRAPH improves performance on identifying content verifiability errors and better captures subsentence-level factual inconsistencies.[1]

1 Introduction

Recent summarization approaches based on pretrained language models (LM) have established a new level of performance (Zhang et al., 2020; Lewis et al., 2020), generating summaries that are grammatically fluent and capable of combining salient parts of the source document. However, current models suffer from a severe limitation, generating summaries that are *not factually consistent*, that is, the content of the summary does not meet the facts of the source document, an issue also known as *hallucination*. Previous studies (Cao et al., 2018; Falke et al., 2019; Maynez et al., 2020; Dreyer et al., 2021) report rates of hallucinations in generated summaries ranging from 30% to over 70%. In the face of such a challenge, recent works employ promising ideas such as question answering (QA) (Durmus et al., 2020; Nan et al., 2021) and weakly supervised approaches (Kryscinski et al., 2020) to assess factuality. Another line of work explores dependency arc entailment to improve the localization of subsentence-level errors within generated summaries (Goyal and Durrett, 2020).

However, these methods have a reduced correlation with human judgments and may not capture well semantic errors (Pagnoni et al., 2021). One reason for the poor performance is the lack of good quality factuality training data. Second, it is challenging to properly encode core semantic content from the document and summary (Lee et al., 2021) and reason over salient pieces of information in

---

order to assess the summary factuality. Third, previous work (DAE, Goyal and Durrett, 2021) treats semantic relations as isolated units, not simultaneously considering the entire semantic structure of *both* document and summary texts.

To mitigate the above issues, we explore *meaning representations* (MR) as a form of content representation for factuality evaluation. We present FACTGRAPH, a novel graph-enhanced approach that incorporates core information from the document and the summary into the factuality model using graph-based MRs, which are more suitable for factuality evaluation: As shown in Figure 1, graph-based MRs capture semantic relations between entities, abstracting away from syntactic structure and producing a canonical representation of meaning.

Different from previous methods (Kryscinski et al., 2020; Goyal and Durrett, 2021), FACTGRAPH is a dual approach which encodes both text and graph modalities, better integrating linguistic knowledge and structured semantic knowledge. As shown in Figure 2, it is composed of parameter-efficient text and graph encoders which share the same pretrained model and differ by their adapter weights (Houlsby et al., 2019). The texts from the document and summary are encoded using the adapter-based text encoder whereas the entire semantic structures that represent document and summary facts are used as input to the graph encoder augmented structure-aware adapters (Ribeiro et al., 2021b). The representations of the two modalities thus are combined to generate the factuality score.

In particular, we explore *Abstract Meaning Representation* (AMR) (Banarescu et al., 2013), a semantic formalism that has received much research interest (Song et al., 2018; Guo et al., 2019; Ribeiro et al., 2019, 2021a; Opitz et al., 2020, 2021; Fu et al., 2021) and has been shown to benefit downstream tasks such as spoken language understanding (Damonte et al., 2019), machine translation (Song et al., 2019), commonsense reasoning (Lim et al., 2020), and question answering (Kapanipathi et al., 2021; Bornea et al., 2021).

Intuitively, AMR provides important benefits: First, it encodes core concepts as it strives for a more logical and less syntactic representation, which has been shown to benefit text summarization (Hardy and Vlachos, 2018; Dohare et al., 2018; Lee et al., 2021). Furthermore, AMR captures semantics at a high level of abstraction explicitly modeling relations in the text and reducing the negative influence of diverse text surface variances with the same meaning. Lastly, recent studies (Dreyer et al., 2021; Ladhak et al., 2021) demonstrate that there is a trade-off between factuality and abstractiveness. Structured semantic representations are potentially beneficial for reducing data sparsity and localizing generation errors in abstractive scenarios. Figure 1 shows examples of (c) document and (d) summary AMRs, where the summary AMR is missing a crucial modifying node present in the document AMR, which indicates a factual error in the summary.

We consolidate a factuality dataset with human annotations derived from previous works (Wang et al., 2020; Kryscinski et al., 2020; Maynez et al., 2020; Pagnoni et al., 2021). This dataset is constructed from the widely-used CNN/DM (Hermann et al., 2015) and XSum (Nallapati et al., 2016) benchmarks. Extensive experimental results demonstrate that FACTGRAPH achieves substantial improvements over previous approaches, improving factuality performance by up to 15% and correlation with human judgments by up to 10%, capturing more content verifiability errors and better classifying factuality in semantic relations.

2 Related Work

Evaluating Factuality. Recently, there has been a surge of new methods for factuality evaluation in text generation, especially for summarization. Falke et al. (2019) propose to rerank summary hypotheses generated via beam search based on entailment scores to the source document. Kryscinski et al. (2020) introduce FACTCC, a model-based approach trained on artificially generated data, to measure if the summary can be entailed by the source document in order to assess the summary factuality. QA-based methods (Wang et al., 2020; Durmus et al., 2020; Honovich et al., 2021; Nan et al., 2021) generate questions from the document and summary, and compare the corresponding answers in order to assess factuality. Xie et al. (2021) formulate causal relationships among the document, summary, and language prior to evaluate the factuality via counterfactual estimation.

Categorizing Factual Errors. A thread of analysis work has focused on identifying different categories of factual errors in summarization. Maynez et al. (2020) show that semantic inference-based automatic measures are better representations of summarization quality, whereas Pagnoni et al. (2021)

propose a linguistically grounded typology of factual errors and develop a fine-grained benchmark for factuality evaluation, moving to a fine-grained measure, instead of using a binary evaluation. Fabbri et al. (2021) introduce different resources for summarization evaluation which include a toolkit for evaluating summarization models.

Factuality versus Abstractiveness. Recent works (Dreyer et al., 2021; Ladhak et al., 2021) investigate the trade-off between factuality and abstractiveness of summaries and observe that factuality tends to drop with increased abstractiveness. Semantic graphs are uniquely suitable to detect factual errors in abstractive summaries as they abstract away from the lexical surface forms of documents and summaries, enabling direct comparisons of the underlying semantic concepts and relations of a document-summary pair.

Graph-based Representations for Summarization. A growing body of work focuses on using graph-based representations for improving summarization. Whereas different approaches encode graphs into neural models for multi-document summarization (Fan et al., 2019; Li et al., 2020; Pasunuru et al., 2021; Wu et al., 2021; Chen et al., 2021), AMR structures have been shown to benefit both document representation and summary generation (Liu et al., 2015; Liao et al., 2018; Hardy and Vlachos, 2018; Dohare et al., 2018) and have the potential of improving controllability in summarization (Lee et al., 2021). The above works are related to FACTGRAPH as they use semantic graphs for content representation, but also different because they utilize graphs for the downstream summarization task, whereas FACTGRAPH employs them for factuality evaluation.

Semantic Representations for Factuality Evaluation. More closely related to our work, Goodrich et al. (2019) extract tuples from the document and summary and measure the factual consistency by overlapping metrics. Xu et al. (2020) weight facts present in the source document according to the facts from the gold summary using contextual embeddings, and verify whether a generated summary is able to capture the same facts as the target. Recently, dependency arc entailment (DAE, Goyal and Durrett, 2020) is used to measure subsentence-level factuality by classifying pairs of words defined by dependency arcs which often describe semantic relations. However, FACTGRAPH is considerably different from those approaches, since it explicitly encodes the entire graph semantic structure into the model. Moreover, while DAE considers semantic edge relations of the summary only, FACTGRAPH encodes the semantic structures of both the input document and summary leading to better factuality performance at both sentence and subsentence levels.

3 FACTGRAPH Model

We introduce FACTGRAPH, a method that employs semantic graph representations for factuality evaluation in text summarization, describing its intuition (§3.3) and defining it formally (§3.4).

3.1 Problem Statement

Given a source document D and a *sentence-level* summary S, we aim to check whether S is *factual* with respect to D. For each sentence $d \in D$ we extract a semantic graph $\mathcal{G}_d$. Similarly, for the summary sentence S we extract its semantic graph $\mathcal{G}_s$. We use texts and graphs from both document and summary for factuality evaluation. Sentence-level summary predictions can be aggregated to generate a factuality score for a multi-sentence summary.

3.2 Extracting Semantic Graphs

We select AMR as our MR, but FACTGRAPH can be used with other graph-based semantic representations, such as OpenIE (Banko et al., 2007). AMR is a linguistically-grounded semantic formalism that represents the meaning of a sentence as a rooted graph, where nodes are *concepts* and edges are *semantic relations*. AMR abstracts away from surface text, aiming to produce a more language-neutral representation of meaning. We use a state-of-the-art AMR parser (Bevilacqua et al., 2021) to extract an AMR graph $\mathcal{G}_a = (\mathcal{V}_a, \mathcal{E}_a, \mathcal{R}_a)$ with a node set $\mathcal{V}_a$ and labeled edges $(u, r, v) \in \mathcal{E}_a$, where $u, v \in \mathcal{V}_a$ and $r \in \mathcal{R}_a$ is a relation type. Each $\mathcal{G}_a$ aims to explicitly represent the core concepts in each sentence. Figure 1 shows an example of a (b) sentence and its (d) corresponding AMR graph.[2]

Graph Representation. We convert each $\mathcal{G}_a$ into a bipartite graph $\mathcal{G}_b = (\mathcal{V}_b, \mathcal{E}_b)$, replacing each labeled edge $(u, r, v) \in \mathcal{E}_a$ with two unlabeled edges $\{(u, r), (r, v)\} \in \mathcal{E}_b$. Similar to Beck et al. (2018), this procedure transforms the graph into its unlabeled version. Pretrained models typically use

---

[2] Appendix A presents other examples of AMRs extracted from sentences of documents and generated summaries.

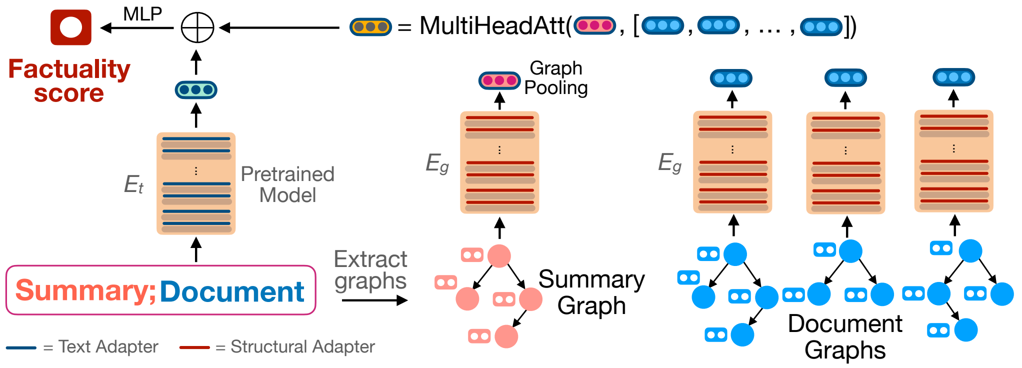

Figure 2: Overview of FACTGRAPH. A sentence-level summary and document graphs are encoded by the graph encoder with structure-aware adapters. Text and graph encoders use the same pretrained model and only the adapters parameters are trained.

a vocabulary with subword tokens, which makes it complicated to properly represent a graph using subword tokens as nodes. Inspired by Ribeiro et al. (2020, 2021b), we transform each $\mathcal{G}_b$ into a new token graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where each token of a node $v_b \in \mathcal{V}_b$ becomes a node $v \in \mathcal{V}$. We convert each edge $(u_b, v_b) \in \mathcal{E}_b$ into a set of edges and connect every token of u_b to every token of v_b.

3.3 Intuition of Semantic Representation

In order to represent facts to better assess the summary factuality, we draw inspiration from traditional approaches to summarization that condense the source document to a set of "semantic units" (Liu et al., 2015; Liao et al., 2018). Intuitively, the semantic graphs from the source document represent the core factual information, explicitly modeling relations in the text, whereas the semantic summary graph captures the essential content information in a summary (Lee et al., 2021). The document graphs can be compared with the summary graph, measuring the degree of semantic overlap to assess factuality (Cai and Knight, 2013).

Recently, sets of fact triples from summaries were used to estimate factual accuracy (Goodrich et al., 2019). That approach is related to FACTGRAPH as it uses graph-based MRs, but also different because it compares the reference and the generated summary, whereas we compare the generated summary with the input document. Moreover, differently from Goodrich et al. (2019), FACTGRAPH explicitly encodes the semantic structures using a graph encoder and employs AMR as a semantic representation. Finally, in contrast to DAE (Goyal and Durrett, 2021), which focuses only on extracting summary graph representations, FACTGRAPH uses semantic graphs for both document and summary.

3.4 Model

Figure 2 illustrates FACTGRAPH, which is composed of text and graph encoders. The text encoder, denoted by E_t, uses a pretrained encoder E, augmented with adapter modules which receives the summary S and document D and outputs a contextual text representation. Conversely, the graph encoder, denoted by E_g, uses the same E, but is augmented with structure-aware adapters. E_g receives the summary and multiple document semantic graphs corresponding to its sentences, and outputs graph-aware contextual representations that are used to generate the final graph representation. During training, only adapter weights are trained, whereas the weights from E are kept frozen. Finally, both graph and text representations are concatenated and fed to a final classifier, which predicts whether the summary is factual or not.

Text Encoder. We employ an adapter module before and after the feed-forward sub-layer of each layer of the encoder. We modify the adapter architecture from Houlsby et al. (2019). We compute the adapter representation for each token i at each layer l, given the token representation $\boldsymbol{h}_i^l$, as follows:

$$\hat{\boldsymbol{z}}_i^l = \boldsymbol{W}_o^l(\sigma(\boldsymbol{W}_p^l \,\textsc{ln}(\boldsymbol{h}_i^l))) + \boldsymbol{h}_i^l \,, \qquad (1)$$

where σ is the activation function and $\textsc{ln}(\cdot)$ denotes layer normalization. $\boldsymbol{W}_o^l \in \mathbb{R}^{d \times m}$ and $\boldsymbol{W}_p^l \in \mathbb{R}^{m \times d}$ are adapter parameters. The representation of the [CLS] token is used as the final textual representation, denoted by $\boldsymbol{t}$.

Graph Encoder. In order to re-purpose the pretrained encoder to structured inputs, we employ a structural adapter (Ribeiro et al., 2021b). In particular, for each node $v \in \mathcal{V}$, given the hidden representation $\boldsymbol{h}_v^l$, the encoder layer l computes:

$$\begin{aligned} \boldsymbol{g}_v^l &= \mathsf{GraphConv}_l(\mathsf{LN}(\boldsymbol{h}_v^l), \{\mathsf{LN}(\boldsymbol{h}_u^l) : u \in \mathcal{N}(v)\}) \\ \boldsymbol{z}_v^l &= \boldsymbol{W}_e^l \sigma(\boldsymbol{g}_v^l) + \boldsymbol{h}_v^l \,, \end{aligned} \tag{2}$$

where $\mathcal{N}(v)$ is the neighborhood of the node v in $\mathcal{G}$ and $\mathbf{W}_e^l \in \mathbb{R}^{d \times m}$ is an adapter parameter. $\mathsf{GraphConv}_l(\cdot)$ is the graph convolution that computes the representation of v based on its *neighbors* in the graph. We employ a Relational Graph Convolutional Network (Schlichtkrull et al., 2018) as graph convolution, which considers differences in the incoming and outgoing relations. Since AMRs are directed graphs, encoding edge directions is beneficial for downstream performance (Ribeiro et al., 2019). The structural adapter is placed before, whereas the normal adapter is kept after the feed-forward sub-layer of each encoder layer.

We calculate the final representation of each graph from the pooling denoted as $\boldsymbol{z}^{\mathrm{G}} = \{\mathbf{z}_v^{(L)} \mid v \in \mathcal{V}\}$, where $\mathbf{z}_v^{(L)}$ is the final representation of v. Thus, we use a multi-head self-attention (Vaswani et al., 2017) layer to estimate to what extent each sentence graph contributes to the document semantic representation based on the summary graph. This mechanism allows encoding a global document representation based on the summary graph. In particular, each attention head computes:

$$\begin{aligned} \alpha_i &= \mathtt{Attn}(\boldsymbol{z}_s^{\mathrm{G}}, \boldsymbol{z}_i^{\mathrm{G}}), \\ \boldsymbol{g} &= \sum\nolimits_{i=1}^{k} \alpha_i \, \boldsymbol{W}_r \, \boldsymbol{z}_i^{\mathrm{G}}, \end{aligned} \tag{3}$$

where $\boldsymbol{z}_s^{\mathrm{G}}$ is the final representation of $\mathcal{G}_s$, k is the number of considered sentence graphs from the input document and $\mathbf{W}_r \in \mathbb{R}^{d \times d}$ is a parameter.

The final representation is derived from the text and graph representations, $\boldsymbol{q} = [\boldsymbol{t}; \boldsymbol{g}]$, and fed into a classification layer that outputs a probability distribution over the labels y = {Factual, Non-Factual}.

3.5 Edge-level Factuality Model

Inspired by Goyal and Durrett (2021), we evaluate the factuality at the edge level. In this setup, we use the same text and graph encoders; however, we encode the semantic graphs differently. In particular, we concatenate $\mathcal{G}_s$ with each $\mathcal{G}_d \in D$ and feed the concatenation to the graph encoder. The representation of a node $v \in \mathcal{G}_s$ is calculated as:

$$\begin{aligned} \boldsymbol{r}_{t_v} &= \sum\nolimits_{w \in A(v)} E_t(D; S)_w \\ \boldsymbol{r}_{g_v} &= \sum\nolimits_{d=1}^{k} E_g(\mathcal{G}_s; \mathcal{G}_d)_v \\ \boldsymbol{r}_v &= [\boldsymbol{r}_{t_v}; \boldsymbol{r}_{g_v}] \end{aligned} \tag{4}$$

where $A(v)$ is the set of all summary words aligned with v, and $\boldsymbol{r}_{t_v}$ and $\boldsymbol{r}_{g_v}$ are the word and node representations, respectively. Edge representations are derived for each AMR edge $(u, v) \in \mathcal{E} : \boldsymbol{r}_e = [\boldsymbol{r}_u; \boldsymbol{r}_v]$. The edge representation $\boldsymbol{r}_e$ is fed into a classification layer that outputs a probability distribution over the output labels (y_e = {Factual, Non-Factual}). We assign the label *non-factual* for an edge in $\mathcal{G}_s$ if one of the nodes in this edge is aligned with a word that belongs to a span annotated as *non-factual*. Otherwise, the edge is assigned the label *factual*. We call this variant FACTGRAPH-E.

Table 1: Consolidated human annotations.

4 Experimental Setup

4.1 Data

One of the main challenges in developing models for factuality evaluation is the lack of training data. Existing synthetic data generation approaches are not well-suited to factuality evaluation of current summarization models and human-annotated data can improve factuality models (Goyal and Durrett, 2021). In order to have a more effective training signal, we gather human annotations from different sources and consolidate a factuality dataset that can be used to train FACTGRAPH and other models.

The source collections of the dataset are presented in Table 1. The dataset covers two parts, namely CNN/DM (Hermann et al., 2015) and XSum (Nallapati et al., 2016). CNN/DM contains news articles from two providers, CNN and DailyMail; while XSum contains BBC articles. CNN/DM has considerably lower levels of abstraction, and the summary exhibits high overlap with the article; a typical CNN/DM summary consists of several bullet points. In XSum, the first sentence is removed from an article and used as a summary, making it highly abstractive. After we remove duplicated annotations, the total number of datapoints is 9,567, which we divide into train (8,667), dev (300) and test (600) sets. We call this dataset FACT-COLLECT.

Model	All data		CNN/DM		XSum	
	BACC	F1	BACC	F1	BACC	F1
QAGS (Wang et al., 2020)	79.8	79.7	64.2	76.2	59.3	85.2
QUALS (Nan et al., 2021)	78.3	78.5	60.8	76.2	57.5	82.2
FactCC (Kryscinski et al., 2020)	76.0	76.3	69.0	77.8	55.9	73.9
FactCC+	83.9 (0.4)	84.2 (0.4)	68.0 (1.0)	83.7 (0.5)	58.3 (2.2)	84.9 (1.0)
FactGraph	86.3 (1.3)	86.7 (1.1)	73.0 (2.3)	86.8 (0.8)	68.6 (2.3)	86.6 (2.0)
FactGraph (pretrained structural adapters)	86.4 (0.6)	86.8 (0.5)	74.1 (1.0)	87.4 (0.3)	**70.4** (1.9)	85.9 (1.4)
FactGraph (pretrained structural and text adapters)	**87.6** (0.7)	**87.8** (0.7)	**76.0** (2.8)	**87.5** (0.4)	69.9 (2.3)	**88.4** (1.2)

Table 2: BACC and F1 scores for factuality models in the test set of FactCollect. Mean (±s.d.) over 5 seeds.

4.2 Method Details

We limit the number of considered document graphs due to efficiency reasons. In particular, we compute the pairwise cosine similarity between the embeddings of each sentence $d \in D$ and the summary sentence S, generated by Sentence Transformers (Reimers and Gurevych, 2019). We thus select k sentences from the source document with the highest scores to be used to generate the document semantic graphs.

The model weights are initialized with Electra (electra-base discriminator, 110M parameters, Clark et al., 2020), the structural adapters are pretrained using the release 3.0 of the AMR corpus containing 55,635 gold annotated AMR graphs, and the text adapters are pretrained using synthetic generated data. The adapters' hidden dimension is 32, which corresponds to about 1.4% of the parameters of the original Electra encoders. The number of considered document graphs (k) is 5.[3] We report the test results when the balanced accuracy (BACC) on dev set is optimal. Following previous work (Kryscinski et al., 2020; Goyal and Durrett, 2021), we evaluate our models using BACC and Micro F1 scores.

5 Results and Analysis

We compare FactGraph with different methods for factuality evaluation: two QA-based methods, namely QAGS (Wang et al., 2020) and QUALS (Nan et al., 2021), and FactCC (Kryscinski et al., 2020). We fine-tune FactCC using the training set, that is, it is trained on both synthetic data and FactCollect. We call this approach FactCC+.

Table 2 presents the results. QA-based approaches perform comparatively worse than FactCC on CNN/DM, while QAGS has a general better performance than QUALS. FactCC has a strong performance on CNN/DM, as it was trained on synthetic data derived from this dataset. However, the FactCC's performance does not transfer to XSum. FactCC+ has a large increase in performance, especially on XSum, demonstrating the importance of human-annotated data for training improved factuality models.

FactGraph outperforms FactCC+ by 2.4 BACC points in both subsets and by 10.3 BACC in XSum, even though FactCC+ was pretrained on millions of synthetic examples. This indicates that considering semantic representations is beneficial for factuality evaluation and FactGraph can be trained on a small number of annotated examples. Pretraining structural adapters improves the performance on CNN/DM and XSum. Finally, FactGraph's performance further improves when both structural and text adapters are pretrained, improving over FactCC+ by 3.7 BACC points.[4]

5.1 Correlation with Human Judgments

We also evaluate the model performance using correlations with human judgments of factuality (Pagnoni et al., 2021). In this experiment, FactCC+ and FactGraph are trained with the FactCollect data without the Pagnoni et al. (2021)'s subset, which is used as dev and test sets, according to its split. For both models, following Pagnoni et al. (2021), we obtain a binary factuality label for each sentence and take the average of these labels as the final summary score. We use the official script to calculate the correlations.[5]

AMR and Factuality. We investigate whether Smatch (Cai and Knight, 2013), a metric that measures the degree of overlap between two AMRs, correlates with factuality judgments. We calculate the Smatch score between all the summary sentence graphs and k document sentence graphs, with $k \in \{1, 3, 5\}$. We obtain one score per summary

---

[3] Hyperparameter details and pretraining procedures are described in Appendix B.

[4] FactGraph is significantly better than FactCC+ with $p<0.05$ on both BACC and F1 scores.

Table 3: Partial Pearson and Spearman correlation coefficients and p-values between human judgements and methods scores for the test split of Pagnoni et al. (2021).

sentence by maxing over its scores with the sentence graphs, then averaging over the summary sentence scores to obtain the summary-level score. We also calculate the Smatch between the generated summary and the reference summary graphs. As shown in Table 3, Smatch approaches have a small but consistent correlation, slightly improving over n-gram based metrics (e.g., METEOR and Rouge-L) in CNN/DM, suggesting that AMR, which has a higher level of abstraction than plain text, may be a semantic representation alternative to content verification.

QA-based approaches have higher correlation on the CNN/DM dataset than XSum where their correlation is relatively reduced, and DAE shows higher Spearman correlation than FactCC on XSum. FactCC+ and FactGraph, which are trained on data from FactCollect, have a overall higher performance than models trained on synthetic data, such as FactCC, again demonstrating the importance of the human-annotation signal when training factuality evaluation approaches. Finally, FactGraph has the highest correlations in both datasets, with a large improvement in XSum, suggesting that representing facts as semantic graphs is effective for more abstractive summaries.

Types of Errors. Figure 3 shows the influence of the different types of factuality errors (Pagnoni et al., 2021) for each approach. *Semantic Frame Errors* are errors in a frame, core, and non-core frame elements.[6] *Discourse Errors* extend beyond a single semantic frame introducing erroneous links between discourse segments. *Content Verifiability Errors* capture cases when it is not possible to verify the summary against the source document due to the difficulty in aligning it to the source.[7] Note that whereas BERTScore strongly correlates with content verifiability errors as it is a token-level similarity metric, the other methods improve in *Semantic Frame Errors*. FactGraph has the highest performance suggesting that graph-based MRs are able to capture different semantic errors well. In particular, FactGraph improves in capturing content verifiability errors by 48.2%, suggesting that representing facts using AMR is helpful.

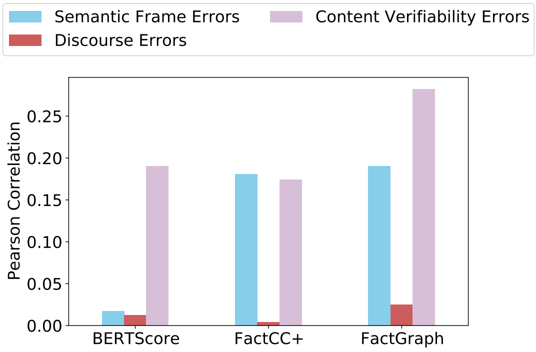

Figure 3: Variation in partial Pearson correlation when omitting error types. Higher variation indicates greater influence of an error type in the overall correlation.

5.2 Edge-level Factuality Classification

We assess factuality beyond sentence-level with FactGraph-E (§3.5). We train and evaluate the model against the sentence-level factuality data from Maynez et al. (2020). In this dataset, human annotations for sentence and span levels are

---

[6] A semantic frame is a representation of an event, relation, or state (Baker et al., 1998).

[7] Refer to Pagnoni et al. (2021) for a detailed description of the error categories and the correlation computations.

Sentence-level models	**BACC**
Sent-Factuality (Goyal and Durrett, 2021)	65.6
FactGraph	74.9
Edge-level models	**BACC**
DAE (Goyal and Durrett, 2021)	78.7
FactGraph-E	**81.1**

Table 4: Sentence-level BACC in human-annotated XSum generated summaries (Maynez et al., 2020).

available. We derive the edge labels required for FactGraph-E training as follows: For each edge in the summary graph, if one of the nodes connected to this edge is aligned with a word that belongs to a span labeled as non-factual, the edge is annotated as non-factual.[8] Summary-level labels are obtained from edge-level predictions: if any edge in the summary graph is classified as non-factual, the summary is labeled as non-factual. We use the same splits from Goyal and Durrett (2021).[9] We compare FactGraph-E with DAE and additionally with a sentence-level baseline (Goyal and Durrett, 2021) and FactGraph.

Table 4 shows that the edge-level factuality classification gives better performance than sentence-level classification, and FactGraph performs better in both sentence and edge classification levels. FactGraph-E outperforms DAE, demonstrating that training on subsentence-level factuality annotations enables it to accurately predict edge-level factuality and output summary-level factuality.

Finally, while the semantic representations contribute to overall performance, extracting those representations adds some overhead in preprocessing time (and slightly more in inference time), as shown in Appendix C.

5.3 Model Ablations

In Table 5, we report an ablation study on the impact of distinct FactGraph's components. First, note that only encoding the textual information leads to better performance than just encoding graphs. This is expected since pretrained encoders are known for good performance in NLP textual tasks due to their transfer learning capabilities and the full document text encodes more information than the selected k document graphs. Moreover, AMR representations abstract aspects such as verb tenses, making the graphs agnostic regarding more fine-grained information. However, this is compensated in FactGraph, which captures coarse-grained details from the text modality. Future work can consider incorporating such information into the graph representation in order to improve the factuality assessment.

Model	**BACC**	**F1**
Only graphs	77.7	78.0
Only text	88.4	88.6
FactGraph	91.2	91.3

Table 5: Ablation study for different components of the model in the FactCollect's dev set.

Ultimately, FactGraph, which uses both document and summary graphs, gives the overall best performance, demonstrating that semantic graph representations complement the text representation and are beneficial for factuality evaluation.

Number of Document Graphs Table 6 shows the influence of the number of considered document graphs measured on FactCollect's dev set performance. Note that generally more document graphs leads to better performance with a peak in 5. This suggests that using all graph sentences from the source document is not required for better performance. Moreover, the results indicate that our strategy of selecting document graphs using the contextual representations of the document sentences which are compared to the summary performs well in practice.

We additionally present the performance of FactGraph with other semantic representations in Appendix D.

5.4 Comparison to Full Fine-tuning

FactGraph only trains adapter weights that are placed into each layer of both text and graph encoders. We compare FactGraph with a model with similar architecture, with both text and graph encoders, but without (structural) adapter layers. We then fine-tune all the model parameters. Table 7 shows that FactGraph performs better even though it trains only 1.4% of the parameters of the fully fine-tuned model, suggesting that the structural adapters help to adapt the graph encoder to semantic graph representations.

5.5 Case Study

FactGraph-E computes factuality scores for each edge of the AMR summary graph and those predictions are aggregated to generate a sentence-

---

[8] We use the JAMR aligner (Flanigan et al., 2014) to obtain node-to-word alignments.

[9] We sample 100 datapoints from the training set as dev set to execute hyperparameter search.

Article: Margaret Fleming, 36, was last seen at her home in Inverkip by her two carers at about 17:40 on Friday 28 October. She is described as about 5ft 5in tall, [...]. Police had said they were trying to build a picture of Ms Fleming's life, part of which she kept "quite private". When last seen, she was wearing a green tartan fleece[...]. She also had a satchel-type handbag. A police spokesman said: "There is a specialist search team combing the area around where the missing person was last seen, this includes in the garden of her last known address." [...] The detective said that Ms Fleming was a student at James Watt College in Greenock between 1996 and 1997. He said **he was keen to speak to anyone** who remembered her from then, and who might have been in touch with her over the years.

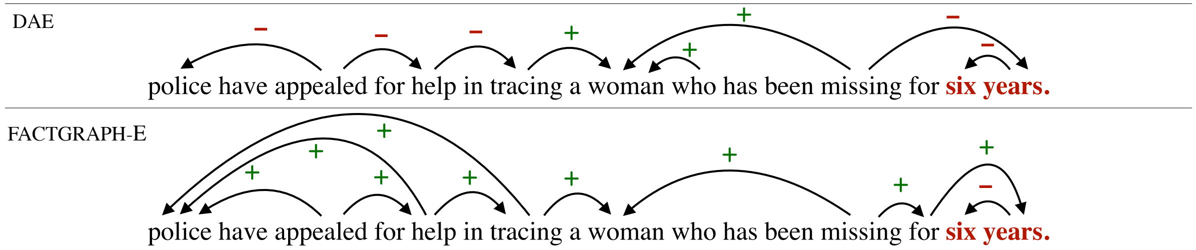

Figure 4: An example of a document, its generated summary and factuality predictions for word pairs, based on the dependency graph (DAE) versus AMR graph (FACTGRAPH-E). $+/-$ means the predicted label for that edge.

# Graphs	BACC	F1
1	90.1	90.3
3	90.9	91.0
5 (**final**)	91.2	91.3
7	89.8	90.0

Table 6: Effect in the FACTCOLLECT's dev set of the number of considered AMR graphs from the document.

	BACC	F1	Parameters
Fully fine-tuned	90.3	90.3	100.0%
FACTGRAPH	91.2	91.3	1.4%

Table 7: Comparison between FACTGRAPH and fully fine-tuning in the dev set of FACTCOLLECT.

level label (§5.2). Alternatively, it is possible to identify specific inconsistencies in the generated summary based on the AMR graph structure. This factuality information at subsentence-level can provide deeper insights on the kinds of factual inconsistencies made by different summarization models (Maynez et al., 2020) and can supply text generation approaches with localized signals for training (Cao et al., 2020; Zhu et al., 2021).

Figure 4 shows a document, its generated summary, and factuality edge predictions by DAE and FACTGRAPH-E.[10] First, note that since DAE uses dependency arcs and FACTGRAPH-E is based on AMR, the sets of edges in both approaches, that is, the relations between nodes and hence words, are different. Second, both methods are able to detect the hallucination *six years*, which was never mentioned in the source document. However, DAE does not consider that *police appealed for help in tracing* is factual whereas FACTGRAPH-E captures it. This piece of information is related to a span in the document with a very different but semantically related form (highlighted in bold in Figure 4). This poses challenges to DAE, since it classifies semantic relations independently and only considers the text surface. On the other hand, FACTGRAPH-E matches the summary against the document not only at text surface level but semantic level.

6 Conclusion

We presented FACTGRAPH, a graph-based approach to explicitly encode facts using meaning representations to identify factual errors in generated text. We provided an extensive evaluation of our approach and showed that it significantly improves results on different factuality benchmarks for summarization, indicating that structured semantic representations are beneficial to factuality evaluation. Future work includes (i) exploring approaches to develop document-level semantic graphs (Naseem et al., 2021), (ii) an explainable graph-based component to highlight hallucinations and (iii) to combine different meaning representations in order to capture distinct semantic aspects.

Impact Statement

In this paper, we study the problem of detecting factual inconsistencies in summaries generated from input documents. The proposed models better consider the text internal meaning structure and could benefit general generation applications by evaluating their output regarding factual consistency, which could ensure that these systems are more trustworthy. This work is built using semantic representations extracted using AMR parsers. In this way, the quality of the parser used to generate the semantic representations can significantly impact the results of our models. In our work, we mitigate this risk by employing a state-of-the-art AMR parser (Bevilacqua et al., 2021).

Appendices

In this supplementary material, we detail experiments' settings, additional model evaluations and additional information about semantic graph representations.

A Additional Examples

Figure 6 shows examples of AMR representations generated from summaries and salient sentences from the respective source document.

B Details of Models and Hyperparameters

The experiments were executed using the version 3.3.1 of the *transformers* library released by Hugging Face (Wolf et al., 2019). In Table 8, we report the hyperparameters used to train FACTGRAPH. We use the Adam optimizer (Kingma and Ba, 2015) and employ a linearly decreasing learning rate schedule without warm-up. Mean pooling is used to calculate the final representation of each graph.

Structural Adapters' Pretraining. The structural adapters are pretrained using AMR graphs from the release 3.0 (LDC2020T02) of the AMR annotation corpus (Knight et al., 2020).[11] Similarly to the masked language modeling objective, we execute self-supervised node-level prediction, where we randomly mask and classify AMR nodes. The goal of this pretraining phase is to capture domain specific AMR knowledge by learning the regularities of the node/edge attributes distributed over graph structure.

Text Adapters' Pretraining. The text adapters are pretrained using synthetically created data, which is generated by applying a series of rule-based transformations to the sentences of source documents (Kryscinski et al., 2020). The pretraining task is to classify each summary sentence as factual or non-factual. The goal of this pretraining phase is to learn suitable text representations to better identify whether summary sentences remain factually consistent to the input document after the transformation.

	Preprocessing	Inference

FACTGRAPH-Dependency	90.2	90.3
FACTGRAPH-OpenIE	90.5	90.7
FACTGRAPH-AMR	91.2	91.3

Table 10: Effect of different graph representations in the factuality model (on the dev set of FACTCOLLECT).

C Speed Comparison

FACTGRAPH encodes the structured semantic representations that encode facts from the document and summary. Despite their effectiveness, extracting semantic graphs, such as AMR, is computationally expensive because current models employ Transformer-based encoder-decoder architectures based on Transformers and pretrained language models.

In this experiment, we compare the time execution of FACTGRAPH-E and DAE in a sample of 1000 datapoints extracted from the XSum test set. In order to extract the semantic graphs, we investigate two AMR parsers, **Parser1**: a dual graph-sequence parser that iteratively refines an incrementally constructed graph (Cai and Lam, 2020) , and **Parser2**: a linearized graph model that employs BART (Bevilacqua et al., 2021). The execution of the AMR parsers is parallelized using four Tesla V100 GPUs. We use Parser2 for the experiments in this paper since it is the current state of the art in AMR parsing, although it is slower in preprocessing than Parser1.

As shown in Table 9, DAE's preprocessing is much faster compared to this phase in FACTGRAPH-E, since DAE employs a fast en-

---

[11] https://catalog.ldc.upenn.edu/LDC2020T02

hanced dependency model from the Stanford CoreNLP tool (Manning et al., 2014). This model builds a parse by performing a linear-time scan over the words of a sentence. Finally, note that FACTGRAPH is slower than DAE in inference because it employs adapters and encodes both graphs and texts from the document and summary, whereas the DAE model encodes only the texts.

D Comparing Semantic Representations for Factuality Evaluation

OpenIE graph-based structures were used in order to improve factuality in abstractive summarization (Cao et al., 2018), whereas dependency arcs were shown to be beneficial for evaluating factuality (Goyal and Durrett, 2020). We thus investigate different graph-based meaning representations using FACTGRAPH. AMR is a more logical representation that models relations between core concepts, and has a rough alignment between nodes and spans in the text. Conversely, dependencies capture more fine-grained relations between words, and all words are mapped into nodes in the dependency graph. OpenIE constructs a graph with node descriptions similar to the original text and uses open-domain relations, leading to relations that are hard to compare.

As shown in Table 10, whereas OpenIE performs slightly better than dependency graphs, AMR gives the best results according to the two metrics, highlighting the potential use of AMRs in representing salient pieces of information. Different from our work, Lee et al. (2021) and Naseem et al. (2021) propose a graph construction approach which generates a single document-level graph created using the individual sentences' AMR graphs by merging identical concepts – this is orthogonal to our sentence-level AMR representation and can be incorporated in future work.

E Semantic Representations

In Figure 5 we show AMR and dependency representations for the summary sentence *"police have appealed for help in tracing a woman who has been missing for six years."*. In §5.5 those semantic representations are used to predict subsentence-level factuality using edge-level information. In particular, FACTGRAPH-E employs AMR (Figure 5a) whereas DAE uses dependencies (Figure 5b).

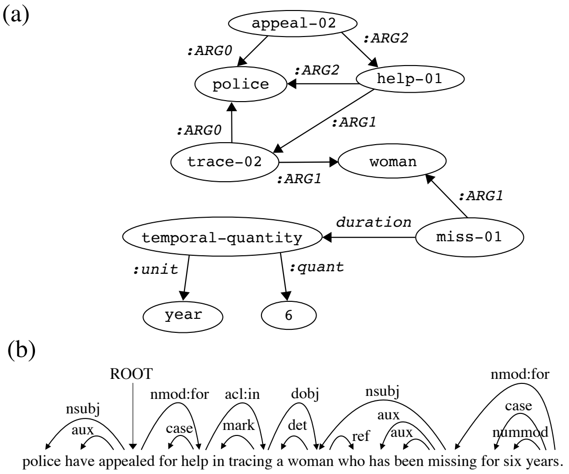

Figure 5: (a) AMR and (b) dependency representations for the summary *"police have appealed for help in tracing a woman who has been missing for six years."*

Example 1

Document: […] Officers believe the local man, who was working at Fruehauf on Houghton Road, fell from a cherry picker at about 13:45 GMT on Thursday. […]

Abstract

Commonly found in academic and formal texts, a nominalization uses a deverbal noun to describe an event associated with its corresponding verb. Nominalizations can be difficult to interpret because of ambiguous semantic relations between the deverbal noun and its arguments. Automatic generation of clausal paraphrases for nominalizations can help disambiguate their meaning. However, previous work has not identified cases where it is awkward or impossible to paraphrase a compound nominalization. This paper investigates unsupervised prediction of paraphrasability, which determines whether the prenominal modifier of a nominalization can be re-written as a noun or adverb in a clausal paraphrase. We adopt the approach of overgenerating candidate paraphrases followed by candidate ranking with a neural language model. In experiments on an English dataset, we show that features from an Abstract Meaning Representation graph lead to statistically significant improvement in both paraphrasability prediction and paraphrase generation.

1 Introduction

A nominalization is a noun (e.g., “response”) that is morphologically derived from a verb (“respond”), and that designates some aspects of the event referred to by the verb (Quirk et al., 1985). In a compound nominalization, this deverbal noun may have both prenominal and postnominal modifiers. The prenominal modifier can be a noun (e.g., “*police* response to the rioting”) or an adjective (“*bodily* injury to a friend”), while postnominal modifiers are prepositional phrases (“presidential nomination *of Harrison*”).

Academic and other formal texts utilize nominalization extensively to produce a compact and abstract writing style. The meaning of compound nominalizations can however be difficult to interpret because of ambiguous semantic relations between the deverbal noun and its modifiers. In particular, the prenominal modifier can play multiple semantic roles in the corresponding predicate or clausal paraphrase: as a subject (e.g., “the *police* response” → “the *police* responds”); as an object (“*bodily* injury” → “injure the *body*”); as an oblique (“*presidential* nomination” → “nominate *as president*”; as an adverb (“*symbolic* admission” → “admit *symbolically*”; or none of the above (“*stellar* performance” ↛ “a *star* performs”).

The paraphrasability of the prenominal modifier — whether it describes an entity, the manner of an action, or neither — therefore has direct impact on NLP tasks that require interpretation of compound nominalizations. This ambiguity affects accuracy in relation extraction, which is important for information retrieval and question answering (Greenwood, 2004; Klein et al., 2020). A machine translation system must also be able to render the deverbal noun and its prenominal modifier properly when there is no equivalent nominalization in the target language. Further, paraphrasability prediction could benefit nominal semantic role labeling, which needs to identify the role played by the prenominal modifier (Lapata, 2002; Padó et al., 2008; Kilicoglu et al., 2010). Finally, it is critical for nominalization paraphrasing. When a clausal paraphrase is not available for the input nominalization, approaches that do not consider paraphrasability may produce an invalid or misleading output (Lee et al., 2021).

This study focuses on English, the dominant language for academic texts. It aims to make two contributions. First, we enlarge an existing dataset to cover three paraphrasability categories for prenominal modifiers in a compound nominalization (paraphrased as noun, as adverb or non-paraphrasable). Second, we extend an algorithm to take paraphrasability into account, and show that features from Abstract Meaning Representation graphs improve performance in both paraphrasabil-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3254 - 3263
July 10-15, 2022 ©2022 Association for Computational Linguistics

ity prediction and paraphrase generation.

The rest of the paper is organized as follows. After defining our task (Section 2), we summarize previous research (Section 3). We then describe our dataset (Section 4) and present our approach (Sections 5-6). Then, we discuss experimental results (Section 7-8) and conclude (Section 9).

2 Paraphrasability of nominalizations

2.1 Motivation

Our goal is to paraphrase a nominalization into a "clausal paraphrase", which we define as a clause headed by a verb whose syntactic arguments (e.g., subject, object, and prepositional object) are transformed from the nominal arguments in the input nominalization. We focus on compound nominalizations in which the head noun has a prenominal modifier and a prepositional object, following the syntactic form targeted by the only publicly available dataset for nominalization paraphrasing (Lee et al., 2021). Some example inputs and outputs are shown in Table 1.

A clausal paraphrase would not be possible for a compound nominalization if there is no suitable verb equivalent for its head noun. Large-scale language resources (Meyers et al., 1998) already exist to help determine whether such a verb exists, and the task has been tackled in the context of QA semantic role labeling for nominalization (Klein et al., 2020). Less attention has been paid to another factor, namely, whether the prenominal modifier can be expressed as a subject, object or prepositional object in the paraphrase. We are not aware of previous data-driven research on this task, which is the focus of this paper. We will not consider the prepositional object in the input nominalization, since it can be incorporated into a clausal paraphrase in most cases.

2.2 Task definition

The term "paraphrasability" has been used for the degree of semantic equivalence between syntactic variants of predicate phrases (Fujita and Sato, 2008). We will use this term to refer to the three categories of paraphrasing behavior of prenominal modifiers in compound nominalizations:

Noun The prenominal modifier is a noun, or is an adjective that *pertains* to a noun, that can serve as the subject, object or prepositional object in a clausal paraphrase. In other words, either the prenominal modifier itself (e.g., "police") or its *pertainym* ("president" for "presidential") literally refers to the entity that participates in the event denoted by the deverbal noun ("*police* response", "*presidential* nomination").

Adverb The prenominal modifier is an adjective that can appear in the clausal paraphrase in its adverbial form (e.g., "*frontal* opposition" → "oppose *frontally*"), but not as pertainym ("*frontal* opposition" $\not\rightarrow$ "the *front* opposes").

Nil The prenominal modifier cannot be paraphrased with either method above (e.g., "*stellar* performance" $\not\rightarrow$ "*a star* performs"; "*brain* drain" $\not\rightarrow$ "drain a *brain*").

As shown in Table 1, the input is a nominalization that consists of a deverbal noun (derived from the verb V); its prenominal modifier (bolded); and a prepositional phrase. The output of the **Paraphrasability Prediction** task is the part-of-speech label of the word to which the prenominal modifier is paraphrased (bolded). The label can be `Noun`, `Adverb`, or `Nil` when it is not paraphrasable.

The output of the **Paraphrase Generation** task is a clausal paraphrase of the input. It incorporates the verb V, the prepositional object from the input (marked with O); and either a noun (marked with M) or an adverb (marked with B) corresponding to the prenominal modifier. The gold paraphrase of the `Nil` type input is defined as *null*. The only way to render such an input as a clause is with a support verb or light verb (e.g., "stellar performance" → "*give* a stellar performance"). Since the paraphrase retains the original nominalization, it does not serve our goal of unpacking its meaning.

3 Previous work

3.1 Noun literality prediction

There has been extensive research on compositionality analysis on noun compounds (Reddy et al., 2011), adjective-noun combinations and other types of multiword expressions (MWEs) (Biemann and Giesbrecht, 2011; Ramisch et al., 2016; Cordeiro et al., 2019; Jana et al., 2019). Compositionality refers to the extent to which the meaning of the MWE can be expressed in terms of the meaning of its constituents. It therefore has considerable overlap with literality prediction, which would identify, for example, the noun "rat" in "*rat* race" as non-literal (Reddy et al., 2011).

Input Nominalization	Paraphrase Generation	Paraphrasability Prediction
American influence on global culture	**America**^{M} influences^V global culture^O	`Noun`
police response to the rioting	the **police**^{M} responds^V to the rioting^O	
climatic effects of air pollutants	air pollutants^O affect^V the **climate**^{M}	
war preparations of the government	the government^O prepares^V for **war**^{M}	
bodily injury to a friend	injure^V the **body**^{M} of a friend^O	
student admissions into universities	admit^V **students**^{M} into universities^O	
presidential nomination of Harrison	nominate^V Harrison^O as **president**^{M}	
business travel to Greece	travel^V to Greece^O for **business**^{M}	
naval assistance from Italian powers	**navies**^{M} of Italian powers^O assist^V	
majority decision of the panel	a **majority**^{M} of the panel^O decides^V	
frontal opposition of the employers	The employers^O oppose^V **frontally**^{B}	`Adverb`
dynamic allocation of licenses	allocate^V licenses^O **dynamically**^{B}	
stellar performance of the rookies	*null*	`Nil`
brain drain of scientists	*null*	

Table 1: Input and output of the **Paraphrasability Prediction** and **Paraphrase Generation** task (Section 2.2)

Our task is closely related to literality prediction since compound nominalizations are a subset of noun-noun compounds; in particular, a prenominal modifier that is "literal" would likely be of paraphrasability type `Noun` (Section 2.2). We will therefore evaluate the performance of a state-of-the-art noun literality prediction model (Shwartz and Dagan, 2019) in our experiment.

Our task is nonetheless distinct from literality prediction since it focuses on paraphrasability rather than literalness. For example, even when a prenominal modifier is used metaphorically and is non-literal (e.g. "*circular* argument"), it would be labeled `Noun` in terms of paraphrasability if it can appear in a clausal paraphrase ("argue in a *circle*").

3.2 Noun compound interpretation

A noun compound can be disambiguated with a free-form paraphrase (Hendrickx et al., 2013), or with verbs and prepositions linking the two nouns, e.g., "apple pie" is a "*pie* with *apples*" (Butnariu et al., 2010; Nakov and Hearst, 2013). Unsupervised approaches have been found to be effective for noun compound interpretation. Paraphrase templates with slots for prepositions and predicates, for example, can be filled using pre-trained masked language models (Ponkiya et al., 2020). We will likewise investigate unsupervised approaches in this work. Even though compound nominalizations are a subset of noun-noun compounds, our task is different since paraphrases in noun compound interpretation do not transform the head noun into a verb.

3.3 Paraphrasing nominalizations

Research on nominalization interpretation has mostly focused on nominal semantic role labeling, which assigns abstract labels (e.g., agent, patient, manner) to arguments of nominalizations (Lapata, 2002; Nicholson and Baldwin, 2008; Padó et al., 2008; Kilicoglu et al., 2010). Given the systematic correspondences between nominalization and clause structure, there have also been efforts to paraphrase nominalizations as clauses. Algorithms have been proposed for automatic acquisition of paraphrase templates, which can cover nominalization inputs (Shinyama et al., 2002). The paraphrasing task has also been indirectly addressed in a model for question and answer generation from nominalizations (Klein et al., 2020).

The most closely related work to this paper was reported in Lee et al. (2021). Their proposed model first overgenerates paraphrase candidates, and then uses textual entailment to identify the optimal candidate. However, since all nominalizations in their dataset have paraphrases, their algorithm makes no judgment on paraphrasability. We extend their dataset and investigate paraphrasability prediction to fill in this research gap.

4 Dataset

The only publicly available dataset of clausal paraphrases, developed by Lee et al. (2021), provides 450 paraphrases for English nominalizations. All

Paraphrasability Label	Adjectival modifier	Nominal modifier
`Noun`	281	169
`Adverb`	55	n/a
`Nil`	91	38

Table 2: Breakdown of our dataset according to paraphrasability label and part-of-speech of the prenominal modifier

instances are of the paraphrasability label `Noun` (Section 2.2). To facilitate our study, we enlarged this dataset with inputs of the `Adverb` and `Nil` paraphrasability labels.

4.1 Data source

In the interest of consistency with the existing dataset, we focus on nominalizations with the same syntactic pattern. Specifically, we collected sentences from English Wikipedia that contain a noun phrase headed by a deverbal noun with one prenominal modifier and one postnominal modifier.

As shown in Table 1, the postnominal modifier is a prepositional phrase with prepositional object O. The prenominal modifier can be a noun or an adjective. To create a challenging dataset, the adjective must have a pertainym, or can itself also serve as noun (e.g., “light”), such that multiple paraphrasability labels are plausible.

4.2 Annotation

Two annotators, a native speaker and a near-native speaker of English, independently classified the nominalizations into one of three paraphrasability labels (Section 2.2). For those labeled as `Adverb`, the annotator composed a paraphrase with an adverb that is derivationally related to the adjective. For those labeled as `Nil`, no paraphrase was required. Examples for each label are provided in Table 1.

A professor of linguistics who is a native speaker of English reviewed the annotation, either keeping both or selecting one of them. A total of 184 non-`Noun` instances were collected and added to the dataset, resulting in an expanded dataset with 634 paraphrases (Table 2).[1]

5 Paraphrase candidates

Our approach is to first overgenerate paraphrase candidates for each input, and then identify the optimal candidate. This section presents the candidate types, and the next section describes the candidate selection algorithm.

Table 3 shows the paraphrase candidates for the input “*frontal* opposition of the employers”. The prenominal modifier, “frontal”, is transformed into various parts-of-speech and placed at different positions in the candidates. Each candidate is associated with one of the three paraphrasability types:

5.1 Noun

The `Noun` type candidates are the five paraphrases defined in Lee et al. (2021). The prenominal modifier is paraphrased as a noun in the subject (MVO, MOV), object (OVM, VMO), and oblique (VOM) positions.

5.2 Adverb

There are four paraphrase candidates for the `Adverb` type. The prenominal modifier must be an adjective. It is paraphrased as an adverb that pertains to itself, according to WordNet (Fellbaum, 2010); or an adverb that is derivationally related to itself, according to CatVar (Habash and Dorr, 2003). The adverb (B) is placed either before the verb (BVO, OBV) or at the end of the clause (VOB, OVB).

5.3 Nil

There are, by definition, no obvious paraphrase candidates to represent inputs of the `Nil` type. We implemented the following alternatives:

Identity The nominalization input itself.

Light verb The paraphrase retains the nominalization as the object of a light verb or support verb (Grefenstette and Teufel, 1995). One paraphrase candidate prepends the light verb; e.g., “home run against Arizona” → “*hit* a home run against Arizona”. The other candidate uses the prepositional object (O) as subject; e.g., “stellar performance of the rookies” → “the rookies *give* a stellar performance”.

Predicative adjective Limited to prenominal modifiers that are adjectives, this paraphrase uses the adjective predicatively to form a clause. The paraphrase is designed, on the one hand, to be acceptable for `Nil` type inputs, e.g., “*stellar* performance of the rookies” → “the performance of the rookies is *stellar*”; and on the other hand, to be unacceptable for

---

[1] Accessible at https://github.com/NominalizationParaphrase

Paraphrasability Label	Paraphrase Candidate	Word Order
`Noun`	the *front* opposes the employers	MVO
	the employers oppose the *front*	OVM
	oppose the *front* of the employers	VMO
	oppose the employers at the *front*	VOM
	front employers oppose	MOV
`Adverb`	oppose the employers *frontally*	VOB
	frontally oppose the employers	BVO
	the employers oppose *frontally*	OVB
	the employers *frontally* oppose	OBV
`Nil`	*frontal* opposition of the employers	Identity
	Opposition of the employers is *frontal*	Predicative Adjective
	have *frontal* opposition of the employers	Light Verb
	the employers face *frontal* opposition	Light Verb

Table 3: Automatically generated paraphrase candidates (Section 5) for the input "frontal opposition of the employers", which place the prenominal modifier (M or B), verb (V) and prepositional object (O) in the input nominalization in different word orders

nominal adjectives, which cannot be used as a predicate (Coates, 1971), e.g., "*presidential* nomination of Harrison" $\not\to$ "the nomination of Harrison is *presidential*".

We used a masked language model, BERT (Devlin et al., 2019), to generate the most likely determiners, prepositions and light verbs for the paraphrase candidates above.

6 Approach

As discussed in Section 4.1, the input is a sentence that contains a nominalization, headed by a deverbal noun that has a prenominal modifier and a prepositional phrase (Table 1). The prenominal modifier may be a noun or an adjective.

We first overgenerate paraphrases to construct a candidate pool (Section 6.1), and then filter the pool by considering paraphrasability (Section 6.2). For the Paraphrase Generation task, the output is the best candidate selected by the textual entailment and language models (Section 6.3). For the Paraphrarasability Prediction task, the output is the paraphrasability label associated with the selected candidate (Table 3).

6.1 Candidate pool construction

This step constructs a pool of paraphrase candidates. We evaluated the following methods:

All Include all paraphrase candidates in Table 3.

Gold Include only those paraphrase candidates associated with the gold paraphrasability label.

Majority baseline Include only those paraphrase candidates associated with the majority paraphrasability label, which is `Noun` in our dataset. This baseline replicates the algorithm proposed by Lee et al. (2021), which considers only the MVO, OVM, VMO, VOM, and MOV paraphrases in Table 3.

Word frequency baseline Include the `Noun` type (`Adverb` type) paraphrase candidates only when the noun (the adverb) corresponding to the prenominal modifier has high frequency. The frequency threshold is optimized on our dataset based on frequency statistics in the Google Web 1T N-gram Corpus (Brants and Franz, 2006).

6.2 Candidate pool filtering

This step filters the candidate pool constructed by the **All** model. We evaluated two methods that consider paraphrasability through semantic parsing and literality prediction, respectively.

6.2.1 Filtering with AMR

Abstract Meaning Representation (AMR) abstracts away from the syntactic realization of a sentence and expresses its meaning with a directed acyclic graph, where nodes represent events and concepts, and edges represent relationships between

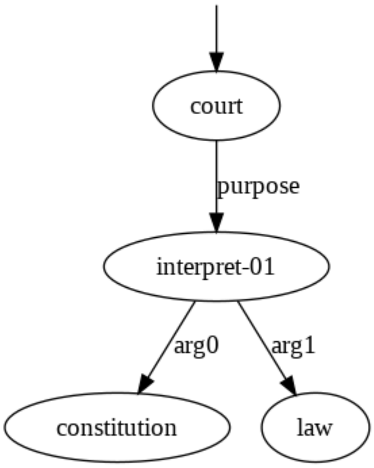

Figure 1: AMR graph of the sentence "... a court for the *constitutional* interpretation of law", which is predicted as `Noun` by the All+AMR model (Section 6.2.1)

the nodes (Banarescu et al., 2013). In an AMR graph, deverbal nouns are annotated as verbs, and adjectives pertaining to nouns are annotated in their nominal form whenever possible.

We use PERIN (Samuel and Straka, 2020) to construct an AMR graph for the input sentence, and align the nodes with the words in the input. We will refer to the node aligned to the deverbal noun as the "deverbal noun node"; and the node aligned to the prenominal modifier as the "prenominal modifier node". In Figure 1, the "constitution" node is the prenominal modifier node (aligned to "constitutional" in the input); and the "interpret-01" node is the deverbal noun node (aligned to "interpretation").

The **All+AMR** model predicts `Noun` as paraphrasability label and removes all non-`Noun` type candidates from the pool if the prenominal modifier node:

- is an argument of the deverbal noun node; or
- is the domain of the deverbal noun node, and is annotated as a noun.

Otherwise, it predicts paraphrasability to be non-`Noun` and removes all `Noun` type candidates from the pool.

For example, the model predicts `Noun` as paraphrasability label for the sentence in Figure 1, since the prenominal modifier node ("constitution") serves as arg0 to the deverbal noun node ("interpret-01"). The model rejects `Noun` as paraphrasability label for the sentence in Figure 2. Even though the prenominal modifier node ("secular") is the domain of the deverbal noun node ("celebrate-02"), it is annotated with the original adjective rather than its nominal form.

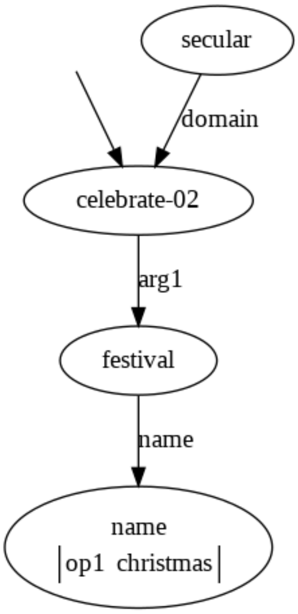

Figure 2: AMR graph of the sentence "... the *secular* celebration of Christmas", which is predicted as non-`Noun` by the All+AMR model (Section 6.2.1)

6.2.2 Filtering with noun literality prediction

Noun literality prediction is closely related to paraphrasability prediction (Section 3.1). We use LexComp (Shwartz and Dagan, 2019), a state-of-the-art model in noun literality prediction, which is trained on datasets from Reddy et al. (2011) and Tratz et al. (2010) using contextualized word embeddings.[2]

Given the prenominal modifier and the deverbal noun in the input, the **All+LexComp** model predicts `Noun` as paraphrasability label if LexComp predicts "literal", and removes all non-`Noun` type candidates. Otherwise, it predicts `Nil` and keeps only the `Nil` type paraphrases. This model does not perform filtering on an input with an adjectival modifier.

6.3 Candidate selection

A textual entailment model (TE), enhanced with re-ranking by language model scores, was found to yield the strongest performance in paraphrase generation for compound nominalizations (Lee et al., 2021). Taking the nominalization input as the

---

[2] https://github.com/vered1986/lexcomp

premise and a paraphrase candidate as the hypothesis, the TE model predicts whether the facts in the former imply those in the latter. Among the three candidate paraphrases that yield the highest TE scores, the candidate with the highest language model (LM) score is selected.

We replicate this algorithm and apply it on the filtered candidate pool. We use the AllenNLP textual entailment model[3], and the log-probability score based on GPT-2 (117M) as the LM score (Salazar et al., 2020).[4]

7 Experimental set-up and metrics

The entire dataset was used for evaluation since our approach is unsupervised. We used SpaCy (Honnibal and Johnson, 2015) for POS tagging to determine the POS of the prenominal modifier.

Paraphrasability prediction. We report precision, recall and F_1. Precision is defined as the number of actual `Noun` instances, out of all instances predicted by the system as `Noun`. Recall is defined as the proportion of gold `Noun` instances that are correctly identified by the system as `Noun`.

Paraphrase generation. We report "paraphrase accuracy" and "word order accuracy" as defined in Lee et al. (2021). For the former, the determiners are removed from all paraphrases. The system is considered correct if the lemmatized form of all words in the predicted paraphrase are identical with those in the gold paraphrase. The latter is defined likewise, except that prepositions are not taken into consideration. It thus essentially measures the system's ability to predict the verb and arguments and to put them into the correct word order. The word orders VOB/BVO and OVB/OBV are considered interchangeable.

8 Results

Table 4 shows system performance on the paraphrasability prediction (Section 8.1) and its effect on paraphrase generation (Section 8.2).

8.1 Paraphrasability prediction

Given the preponderance of the `Noun` label in our dataset, the Majority baseline produced a strong performance at 0.673 precision and perfect recall. It outperforms the Word Frequency baseline, which has slightly higher precision (0.686) but lower recall (0.911), both in terms of F_1 and accuracy.

Using all paraphrase candidates resulted in an improvement in binary classification accuracy (0.711 vs. 0.673) over the Majority baseline, demonstrating the effectiveness of the `Adverb` and `Nil` paraphrases (Section 5.2-5.3). In terms of three-way classification, however, it offered no improvement over the Majority baseline (0.671 vs. 0.673). This indicates that while the candidate selection method (Section 6.3) can correctly detect some `Noun` type candidates as inappropriate, it is less competent in judging between `Adverb` vs. `Nil` paraphrases.

The All+LexComp model raised the accuracy by only 0.4% in comparison to the All model. This result suggests that noun literality prediction is only slightly helpful as a proxy for paraphrasability.

The All+AMR model achieved the highest F_1 (0.852) by raising both the precision and recall of the All model. The improvement is statistically significant in terms of both binary classification (0.782)[5] and three-way classification (0.744)[6]. These results show that AMR is useful for predicting paraphrasability, which may be due to the more fine-grained semantic information in the AMR graphs that could not be inferred by the LM and TE models in the candidate selection step. The improvement of the All+AMR model over the All+LexComp model is also significant[7], likely because the semantic features in the AMR graphs are more relevant to paraphrasability than literality.

Table 5 shows the paraphrasability labels predicted by the All+AMR model. While it was able to identify most of the `Noun` inputs, it did so for only half of the `Adverb` ones. The most challenging turned out to be the `Nil` inputs, which the model succeeded in detecting less than one-third of the time.

8.2 Paraphrase generation

Despite its higher accuracy in paraphrasability prediction, the Majority baseline (0.264 paraphrase accuracy) performed worse than the Word Frequency baseline (0.275) in paraphrase generation. This likely reflects the greater challenge in identifying the correct `Noun` type paraphrases than the `Advice` and `Nil` types.

For the other models, performance in para-

Table 4: Performance on paraphrasability prediction and paraphrase generation

Predicted → ↓ Gold	`Noun`	`Adverb`	`Nil`
`Noun`	**345**	13	12
`Adverb`	17	**24**	8
`Nil`	**78**	13	40

Table 5: Contingency table for the paraphrasability prediction of the All+AMR model

phrasability prediction is largely correlated to paraphrase generation. The All model improved over the Majority baseline both in terms of word order (0.416) and paraphrase accuracy (0.318). Consider the input "... the apocalyptic destruction of the town and the cult". The All model correctly declined to paraphrase (*null* output) on the basis of the high score secured by the light-verb paraphrase "the town and the cult suffer an apocalyptic destruction". In contrast, the Majority baseline produced the inappropriate paraphrase "the apocalypses destroy the town and the cult".

The All+AMR model again offered the best performance, at 0.462 word order accuracy and 0.347 paraphrase accuracy.[8] For the sentence in Figure 1, the All model generated the predicative adjective paraphrase "interpretation of law is constitutional" due to the high LM score, even though the word "constitutional" yields a different meaning in this paraphrase. The All+AMR model was able to reject this paraphrase since the word "constitution" was inferred to play the subject role. Conversely, in Figure 2, the model was able to reject paraphrases involving the noun "secularism", since the AMR parser annotated with the original adjective "secular". The considerable performance gap from the Gold model (paraphrase accuracy 0.591), however, indicates there is still much room for improvement in interpreting nominalizations.

9 Conclusion

A clausal paraphrase can help disambiguate a nominalization semantically, especially when the prenominal modifier is difficult to interpret. This paper has presented the first study on determining the paraphrasability of the prenominal modifier in a compound nominalization. We have expanded an existing dataset to cover cases when the prenominal modifier can appear as a noun in the paraphrase, as an adverb, or not at all.

Our experiments suggest that overgeneration of paraphrase candidates, followed by ranking with a textual entailment model and language model, can yield competitive results. Further, AMR-based features lead to statistically significant improvement in performance.

A limitation of our study is the restricted syntactic form of the input nominalizations. To facilitate more comprehensive evaluation, future research should consider expanding the dataset further to cover a wider range of nominalizations, and richer variations in their clausal paraphrases.

---

[8] The improvement in word order accuracy is statistically significant over the All and All+LexComp models at $p = 0.0211$ and $p = 0.0482$, respectively. The improvement in paraphrase accuracy is not significant, however, at $p = 0.0970$ and $p = 0.428$ against the All and All+LexComp models, respectively.

Global Entity Disambiguation with BERT

Abstract

We propose a global entity disambiguation (ED) model based on BERT (Devlin et al., 2019). To capture global contextual information for ED, our model treats not only words but also entities as input tokens, and solves the task by sequentially resolving mentions to their referent entities and using resolved entities as inputs at each step. We train the model using a large entity-annotated corpus obtained from Wikipedia. We achieve new state-of-the-art results on five standard ED datasets: AIDA-CoNLL, MSNBC, AQUAINT, ACE2004, and WNED-WIKI. The source code and model checkpoint are available at `https://github.com/studio-ousia/luke`.

1 Introduction

Entity disambiguation (ED) refers to the task of assigning mentions in a document to corresponding entities in a knowledge base (KB). This task is challenging because of the ambiguity between mentions (e.g., "World Cup") and the entities they refer to (e.g., FIFA World Cup or Rugby World Cup). ED models typically rely on *local* contextual information based on words that co-occur with the mention and *global* contextual information based on the entity-based coherence of the disambiguation decisions. A key to improve the performance of ED is to effectively combine both local and global contextual information (Ganea and Hofmann, 2017; Le and Titov, 2018).

In this study, we propose a global ED model based on BERT (Devlin et al., 2019). Our model treats words and entities in the document as input tokens, and is trained by predicting randomly masked entities in a large entity-annotated corpus obtained from Wikipedia. This training enables the model to learn how to disambiguate masked entities based on words and non-masked entities. At the inference time, our model disambiguates mentions sequentially using words and already resolved entities (see Figure 1). This sequential inference effectively accumulates the global contextual information and enhances the coherence of disambiguation decisions (Yang et al., 2019).

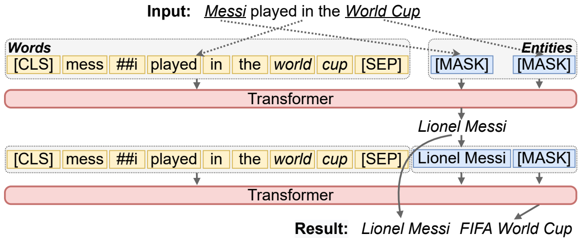

Figure 1: The inference procedure of our model with the input text "Messi played in the World Cup." Given mentions ("Messi" and "World Cup"), our model sequentially resolves them to their referent entities, and uses the resolved entities as contexts at each step.

We conducted extensive experiments using six standard ED datasets, i.e., AIDA-CoNLL, MSNBC, AQUAINT, ACE2004, WNED-WIKI, and WNED-CWEB. As a result, the global contextual information consistently improved the performance. Furthermore, we achieved new state of the art on all datasets except for WNED-CWEB. The source code and model checkpoint are available at `https://github.com/studio-ousia/luke`.

2 Related Work

Transformer-based ED. Several recent studies have proposed ED models based on Transformer (Vaswani et al., 2017) trained with a large entity-annotated corpus obtained from Wikipedia (Broscheit, 2019; Ling et al., 2020; Févry et al., 2020; Cao et al., 2021; Barba et al., 2022). Broscheit (2019) trained an ED model based on BERT by classifying each word in the document to the corresponding entity. Similarly, Févry et al. (2020) addressed ED using BERT by classifying mention spans to the corresponding entities. Ling

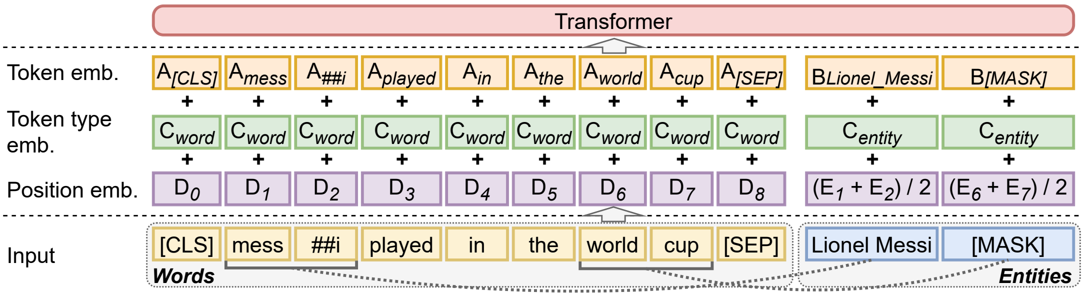

Figure 2: The input representation of our model with the text "Messi played in the World Cup" with mentions "Messi" and "World Cup". The entity corresponding to the mention "World Cup" is replaced by the `[MASK]` token.

et al. (2020) trained BERT by predicting entities using the document-level representation. Cao et al. (2021) addressed ED by training BART (Lewis et al., 2020) to generate referent entity titles of target mentions in an autoregressive manner. Barba et al. (2022) formulated ED as a text extraction problem; they fed the document and candidate entity titles to BART and Longformer (Beltagy et al., 2020) and disambiguated a mention in the document by extracting the referent entity title of the mention. However, unlike our model, these models addressed the task based only on local contextual information.

Treating entities as inputs of Transformer. Recent studies (Zhang et al., 2019; Yamada et al., 2020; Sun et al., 2020) have proposed Transformer-based models that treat entities as input tokens to enrich their expressiveness using additional information contained in the entity embeddings. However, these models were designed to solve general NLP tasks and not tested on ED. We treat entities as input tokens to capture the global context that is shown to be highly effective for ED.

ED as sequential decision task. Past studies (Yang et al., 2019; Fang et al., 2019) have solved ED by casting it as a sequential decision task to capture global contextual information. We adopt a similar method with an enhanced Transformer architecture, a training task, and an inference method to implement the global ED model based on BERT.

3 Model

Given a document with N mentions, each of which has K entity candidates, our model solves ED by selecting a correct referent entity from the entity candidates for each mention.

3.1 Model Architecture

Our model is based on BERT and takes words and entities (Wikipedia entities or the `[MASK]` entity). The input representation of a word or an entity is constructed by summing the token, token type, and position embeddings (see Figure 2):

Token embedding is the embedding of the corresponding token. The matrices of the word and entity token embeddings are represented as $\mathbf{A} \in \mathbb{R}^{V_w \times H}$ and $\mathbf{B} \in \mathbb{R}^{V_e \times H}$, respectively, where H is the size of the hidden states of BERT, and V_w and V_e are the number of items in the word vocabulary and that of the entity vocabulary, respectively.

Token type embedding represents the type of token, namely word ($\mathbf{C}_{word}$) or entity ($\mathbf{C}_{entity}$).

Position embedding represents the position of the token in a word sequence. A word and an entity appearing at the i-th position in the sequence are represented as $\mathbf{D}_i$ and $\mathbf{E}_i$, respectively. If an entity mention contains multiple words, its position embedding is computed by averaging the embeddings of the corresponding positions (see Figure 2).

Following Devlin et al. (2019), we tokenize the document text using the BERT's wordpiece tokenizer, and insert `[CLS]` and `[SEP]` tokens as the first and last words, respectively.

3.2 Training Task

Similar to the masked language model (MLM) objective adopted in BERT, our model is trained by predicting randomly masked entities. Specifically, we randomly replace some percentage of the entities with special `[MASK]` entity tokens and then trains the model to predict masked entities.

We adopt a model equivalent to the one used to predict words in MLM. Formally, we predict the original entity corresponding to a masked entity by

Algorithm 1: Algorithm of our global ED model.

```
Input: Words and mentions $m_1, \dots m_N$.
Initialize: $e_i \leftarrow$ [MASK], $i = 1 \dots N$
repeat $N$ times
    For all [MASK]s, obtain predictions using Eq.(3)
      with words and entities $e_1$, ..., $e_N$ as inputs
    Select a mention $m_j$ and its prediction $\hat{e}_j$ with
      the highest probability
    $e_j \leftarrow \hat{e}_j$
end
return $\{e_1, \dots, e_N\}$
```

applying softmax over all entities:

$$\hat{\mathbf{y}} = \text{softmax}(\mathbf{B}\mathbf{m}_e + \mathbf{b}_o) \qquad (1)$$

$$\mathbf{m}_e = \text{layernorm}\big(\text{gelu}(\mathbf{W}_f \mathbf{h}_e + \mathbf{b}_f)\big) \qquad (2)$$

where $\mathbf{h}_e \in \mathbb{R}^H$ is the output embedding corresponding to the masked entity, $\mathbf{W}_f \in \mathbb{R}^{H \times H}$ is a matrix, $\mathbf{b}_o \in \mathbb{R}^{V_e}$ and $\mathbf{b}_f \in \mathbb{R}^H$ are bias vectors, gelu$(\cdot)$ is the gelu activation function (Hendrycks and Gimpel, 2016), and layernorm$(\cdot)$ is the layer normalization function (Lei Ba et al., 2016).

3.3 ED Model

Local ED Model. Our local ED model takes words and N `[MASK]` tokens corresponding to the mentions in the document. The model then computes the embedding $\mathbf{m}'_e \in \mathbb{R}^H$ for each `[MASK]` token using Eq.(2) and predicts the entity using softmax over the K entity candidates:

$$\hat{\mathbf{y}}_{ED} = \text{softmax}(\mathbf{B}^* \mathbf{m}'_e + \mathbf{b}^*_o), \qquad (3)$$

where $\mathbf{B}^* \in \mathbb{R}^{K \times H}$ and $\mathbf{b}^*_o \in \mathbb{R}^K$ consist of the entity token embeddings and the bias corresponding to the entity candidates, respectively. Note that $\mathbf{B}^*$ and $\mathbf{b}^*_o$ are the subsets of $\mathbf{B}$ and $\mathbf{b}_o$, respectively.

Global ED Model. Our global ED model resolves mentions sequentially for N steps (see Algorithm 1). First, the model initializes the entity of each mention using the `[MASK]` token. Then, for each step, it predicts an entity for each `[MASK]` token, selects the prediction with the highest probability produced by the softmax function in Eq.(3), and resolves the corresponding mention by assigning the predicted entity to it. This model is denoted as **confidence-order**. We also test a model that selects mentions according to their order of appearance in the document and denote it by **natural-order**.

3.4 Modeling Details

Our model is based on BERT$_{\text{LARGE}}$ (Devlin et al., 2019). The parameters shared with BERT are initialized using BERT, and the other parameters are initialized randomly. We treat the hyperlinks in Wikipedia as entity annotations and randomly mask 30% of all entities. We train the model by maximizing the log likelihood of entity predictions. Further details are described in Appendix A.

Name	Accuracy (KB+YAGO)	Accuracy (PPRforNED)

Table 1: In-KB accuracy on the CoNLL dataset.

4 Experiments

Our experimental setup follows Le and Titov (2018). In particular, we test the proposed ED models using six standard datasets: AIDA-CoNLL (CoNLL) (Hoffart et al., 2011), MSNBC, AQUAINT, ACE2004, WNED-CWEB (CWEB), and WNED-WIKI (WIKI) (Guo and Barbosa, 2018). We consider only the mentions that refer to valid entities in Wikipedia. For all datasets, we use the *KB+YAGO* entity candidates and their associated $\hat{p}(e|m)$ (Ganea and Hofmann, 2017), and use the top 30 candidates based on $\hat{p}(e|m)$. For the CoNLL dataset, we also test the performance using *PPRforNED* entity candidates (Pershina et al., 2015). We report the in-KB accuracy for the CoNLL dataset and the micro F1 score (averaged per mention) for the other datasets. Further details of the datasets are provided in Appendix C.

Furthermore, we optionally fine-tune the model by maximizing the log likelihood of the ED predictions ($\hat{\mathbf{y}}_{ED}$) using the training set of the CoNLL dataset with the KB+YAGO candidates. We mask 90% of the mentions and fix the entity token embeddings ($\mathbf{B}$ and $\mathbf{B}^*$) and the bias ($\mathbf{b}_o$ and $\mathbf{b}^*_o$).

The model is trained for two epochs using AdamW. Additional details are provided in Appendix B.

4.1 Results

Table 1 and Table 2 present our experimental results. We achieve new state of the art on all datasets except the CWEB dataset by outperforming strong Transformer-based ED models, i.e, Broscheit (2019), Ling et al. (2020), Févry et al. (2020), Cao et al. (2021), and Barba et al. (2022).[1] Furthermore, on the CoNLL dataset, our confidence-order model trained only on our Wikipedia-based corpus outperforms Yamada et al. (2016) and Ganea and Hofmann (2017) trained on its in-domain training set.

Our global models consistently perform better than the local model, demonstrating the effectiveness of using global contextual information even if local contextual information is captured using expressive BERT model. Moreover, the confidence-order model performs better than the natural-order model on most datasets. An analysis investigating why the confidence-order model outperforms the natural-order model is provided in the next section.

The fine-tuning on the CoNLL dataset significantly improves the performance on this dataset (Table 1). However, it generally degrades the performance on the other datasets (Table 2). This suggests that Wikipedia entity annotations are more suitable than the CoNLL dataset to train general-purpose ED models.

Additionally, our models perform worse than Yang et al. (2018) on the CWEB dataset. This is because this dataset is significantly longer on average than other datasets, i.e., approximately 1,700 words per document on average, which is more than three times longer than the 512-word limit that can be handled by BERT-based models including ours. Yang et al. (2018) achieved excellent performance on this dataset because their model uses various hand-engineered features capturing document-level contextual information.

4.2 Analysis

To investigate how global contextual information helps our model to improve performance, we manually analyze the difference between the predictions of the local, natural-order, and confidence-order models. We use the fine-tuned model using the CoNLL dataset with the YAGO+KB candidates. Although all models perform well on most mentions, the local model often fails to resolve mentions of common names referring to specific entities (e.g., “New York” referring to New York Knicks). Global models are generally better to resolve such difficult cases because of the presence of strong global contextual information (e.g., mentions refer-

---

[1] All models listed in Table 2 use Wikipedia as training data which partly overlap with the WIKI dataset.

ring to basketball teams).

Furthermore, we find that the confidence-order model works especially well for mentions that require a highly detailed context to resolve. For example, a mention of “Matthew Burke” can refer to two different former Australian rugby players. Although the local and natural-order models incorrectly resolve this mention to the player who has the larger number of occurrences in our Wikipedia-based corpus, the confidence-order model successfully resolves this by disambiguating its contextual mentions, including his teammates, in advance. We provide detailed inference sequence of the corresponding document in Appendix D.

4.3 Performance for Rare Entities

We examine whether our model learns effective embeddings for rare entities using the CoNLL dataset. Following Ganea and Hofmann (2017), we use the mentions of which entity candidates contain their gold entities and measure the performance by dividing the mentions based on the frequency of their entities in the Wikipedia annotations used to train the embeddings.

As presented in Table 3, our models achieve enhanced performance for rare entities. Furthermore, the global models consistently outperform the local model both for rare and frequent entities.

5 Conclusion and Future Work

We propose a new global ED model based on BERT. Our extensive experiments on a wide range of ED datasets demonstrate its effectiveness.

One limitation of our model is that, similar to existing ED models, our model cannot handle entities that are not included in the vocabulary. In our future work, we will investigate the method to compute the embeddings of such entities using a post-hoc training with an extended vocabulary (Tai et al., 2020).

Appendix for "Global Entity Disambiguation with BERT"

A Details of Proposed Model

As the input corpus for training our model, we use the December 2018 version of Wikipedia, comprising approximately 3.5 billion words and 11 million entity annotations. We generate input sequences by splitting the content of each page into sequences comprising ≤ 512 words and their entity annotations (i.e., hyperlinks). The input text is tokenized using BERT's tokenizer with its vocabulary consisting of $V_w = 30,000$ words. Similar to Ganea and Hofmann (2017), we create an entity vocabulary consisting of $V_e = 128,040$ entities, which are contained in the entity candidates in the datasets used in our experiments.

Our model consists of approximately 440 million parameters. To reduce the training time, the parameters that are shared with BERT are initialized using BERT. The other parameters are initialized randomly. The model is trained via iterations over Wikipedia pages in a random order for seven epochs. To stabilize the training, we update only those parameters that are randomly initialized (i.e., fixed the parameters initialized using BERT) at the first epoch, and update all parameters in the remaining six epochs. We implement the model using PyTorch (Paszke et al., 2019) and Hugging Face Transformers (Wolf et al., 2020), and the training takes approximately ten days using eight Tesla V100 GPUs. We optimize the model using AdamW. The hyper-parameters used in the training are detailed in Table 4.

B Details of Fine-tuning on CoNLL Dataset

The hyper-parameters used in the fine-tuning on the CoNLL dataset are detailed in Table 5. We select these hyper-parameters from the search space described in Devlin et al. (2019) based on the accuracy on the development set of the CoNLL dataset. A document is split if it is longer than 512 words, which is the maximum word length of the BERT model.

C Details of ED Datasets

The statistics of the ED datasets used in our experiments are provided in Table 6.

D Example of Inference by Confidence-order Model

Figure 3 shows an example of the inference performed by our confidence-order model fine-tuned on the CoNLL dataset. The document is obtained from the test set of the CoNLL dataset. As shown in the figure, the model starts with unambiguous player names to recognize the topic of the document, and subsequently resolves the mentions that are challenging to resolve.

Notably, the model correctly resolves the mention "Nigel Walker" to the corresponding former rugby player instead of a football player, and the mention "Matthew Burke" to the correct former Australian rugby player born in 1973 instead of

Abstract

A trending paradigm for multiple-choice question answering (MCQA) is using a text-to-text framework. By unifying data in different tasks into a single text-to-text format, it trains a generative encoder-decoder model which is both powerful and universal. However, a side effect of twisting a generation target to fit the classification nature of MCQA is the under-utilization of the decoder and the knowledge that can be decoded. To exploit the generation capability and underlying knowledge of a pre-trained encoder-decoder model, in this paper, we propose a generation-enhanced MCQA model named GenMC. It generates a clue from the question and then leverages the clue to enhance a reader for MCQA. It outperforms text-to-text models on multiple MCQA datasets.

1 Introduction

Multiple-choice question answering (MCQA) aims at selecting the correct answer from a set of options given a question. This long-standing challenge in natural language processing (NLP) requires machines to have a wealth of knowledge, such as commonsense knowledge (Talmor et al., 2019; Mihaylov et al., 2018) and scientific knowledge (Clark et al., 2018; Khot et al., 2020; Huang et al., 2019; Li et al., 2021), and have reasoning skills such as multi-hop reasoning (Khot et al., 2019) and logical reasoning (Yu et al., 2020; Liu et al., 2020b; Li et al., 2022).

MCQA has made great progress with the development of pre-trained language models (PLMs). Basically there are two types of PLMs that are suitable for different tasks. BERT (Devlin et al., 2019) and its variants such as RoBERTa (Liu et al., 2019) and ALBERT (Lan et al., 2020) are encoder-only models, being more suitable for natural language understanding (NLU) tasks including MCQA and other classification and regression tasks. T5 (Raffel et al., 2020) and BART (Lewis et al., 2020) are encoder-decoder models, being more suitable for natural language generation (NLG) tasks. However, encoder-decoder models can also be applied to MCQA (Khashabi et al., 2020; Zhou et al., 2021). This is enabled by the text-to-text framework, which transforms data in different tasks into a unified text-to-text format so that knowledge spanning many and various tasks can be learned, aggregated, and used by a single model.

Research Question To fit MCQA, existing implementations of the text-to-text framework take all the options as input and are trained to generate one of the options, i.e., to copy some tokens from the input. However, this is inconsistent with how encoder-decoder models are pre-trained so that their underlying knowledge may not be sufficiently exploited. Indeed, Liu et al. (2021) have found that in classification and regression tasks, the decoder layer is often under-utilized. One research question is *how to apply pre-trained encoder-decoder models in a more natural way to MCQA*, in particular, to exploit their NLG capabilities.

Our Contribution Our idea is inspired by human behavior. When reading a question, humans are sometimes triggered to associate the question with their background knowledge to form some *clues* even before reading the options. For simple questions, a clue may be exactly the correct answer,

Question:

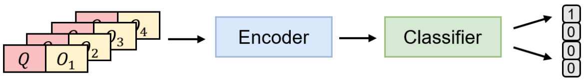
A company makes notebooks for college courses, so their main material is ?

(A) Chips (B) Water (C) Grass (D) **Trees**

Clue: Paper

Figure 1: An example MCQA task and a generated clue. Bold underline indicates the correct answer.

(a) Text-to-Text



(b) Encoder-Only

Figure 2: Paradigms for MCQA.

while for complex questions, clues may play an auxiliary role to help humans connect the question with the correct answer. For example, for the question shown in Figure 1, the clue "paper" forms an intermediate concept between "notebook" in the question and "tree" in the correct answer.

With this idea, we propose to employ a pre-trained encoder-decoder model to *generate* a clue from the question by exploiting its underlying knowledge, without seeing and being strictly confined to the options as in the text-to-text framework. The clue representation is then leveraged by an encoder-based model to read the options and make prediction. We refer to this generation-enhanced MCQA model as **GenMC**. It significantly outperforms comparable models, in particular, text-to-text models, on five MCQA datasets.

Outline We discuss related work in Section 2, introduce GenMC in Section 3, describe the experimental setup in Section 4, report the results in Section 5, and conclude in Section 6.

Code Our code is available on GitHub[1] under the Apache Licence 2.0.

2 Related Work

2.1 Text-to-Text Paradigm for MCQA

Recently, the text-to-text paradigm has achieved breakthrough results on many NLP tasks (Raffel et al., 2020; Lewis et al., 2020). As illustrated in Figure 2a, adopting this paradigm for MCQA, the question Q and all the options $\{O_1, O_2, O_3, O_4\}$ are spliced into a text as input, and the correct answer O_1 is used as the generation target. One benefit is that extensive training data can be shared across different tasks. Using such a framework, UnifiedQA (Khashabi et al., 2020) integrates 20 QA datasets into a unified format for training, and achieves state-of-the-art results on multiple MCQA datasets. Similarly, CALM (Zhou et al., 2021) learns concept-centric knowledge from text for commonsense QA.

However, it might be debatable whether it is appropriate to train a classification task via a generation target. Liu et al. (2021) point out that the decoder layers of T5 are under-utilized when fine-tuning on classification and regression tasks. Therefore, they propose a method to reduce the number of T5 parameters to improve efficiency without reducing accuracy. By contrast, we address this issue from a different perspective of how to exploit the NLG capability of pre-trained encoder-decoder models for MCQA to improve accuracy.

Some other works propose new pre-trained models for unified generation and classification tasks by designing universal encoders and task-specific decoders (Shao et al., 2021; Sun et al., 2021). They are orthogonal to our work as we leverage existing pre-trained encoder-decoder models instead of pre-training new models at an additional cost.

2.2 Encoder-Only Paradigm for MCQA

Benefiting from the powerful NLU capabilities of BERT-style PLMs (Devlin et al., 2019; Liu et al., 2019; Lan et al., 2020), the encoder-only paradigm has been popular for MCQA. As illustrated in Figure 2b, in this paradigm, the question Q and each option in $\{O_1, O_2, O_3, O_4\}$ are interacted to calculate a score, and the option with the highest score is chosen as the answer. Building on this, some works study how to design better attention-based models to identify evidence (Chen et al., 2019; Zhang et al., 2020; Zhu et al., 2020). Other efforts mimic human behavior of reading evidence and answering questions (Ran et al., 2019; Tang et al., 2019; Sun et al., 2019). There, evidence is derived from the given passage or retrieved from external corpora. By contrast, we aim at exporting clues from pre-trained models without resorting to extra sources.

---

[1] `https://github.com/nju-websoft/GenMC`

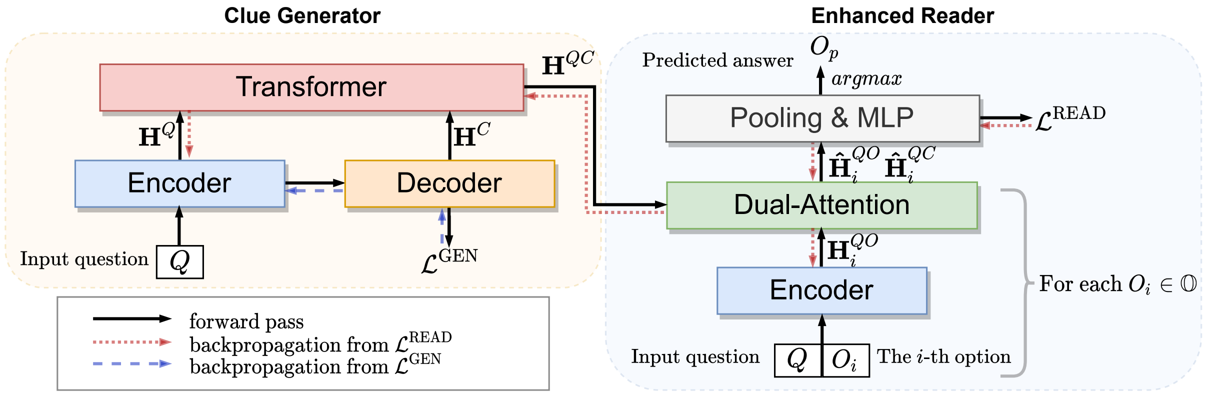


Figure 3: Architecture of GenMC. To make the prediction $O_p \in \mathbb{O}$, the clue generator first takes Q as input and outputs a clue representation $\mathbf{H}^{QC}$ which is indicative of the correct answer. The enhanced reader then relies on the generated clue representation to better attend to options from $\mathbb{O}$ and makes the final prediction. The whole model is trained in an end-to-end manner with both the generation loss $\mathcal{L}^{\text{GEN}}$ and the classification loss $\mathcal{L}^{\text{READ}}$.

2.3 Knowledge in PLMs

Recently, PLMs have been used as knowledge bases (Petroni et al., 2019), and the knowledge in parameters can be exported via methods such as Prompt (Jiang et al., 2020; Shin et al., 2020). Exploiting the knowledge in PLMs for QA tasks has come into play in many forms including question expansion (Mao et al., 2021) and question generation (Shwartz et al., 2020).

There is also research on MCQA trying to exporting knowledge from PLMs before answering. Rajani et al. (2019) propose CAGE as a framework for generating explanations for commonsense QA. However, CAGE relies on explanations annotated by humans, which are not available in many real scenarios and datasets. Latcinnik and Berant (2020) propose a joint generator-classifier model where the generator produces a human-readable textual hypothesis. Although it somewhat improves the explainability of MCQA, in terms of accuracy of MCQA there is little advancement. CEGI (Liu et al., 2020c) is probably the most similar work to ours. It first uses a generative model to generate evidence, and then uses a reading model to incorporate the evidence and predict the answer, both using answer supervision. However, the generative model and the reading model are separate steps in a pipeline and are connected only via the evidence text. Such token-level interaction can lead to significant losses in accuracy as we will see in our experiments, where our representation-level interaction exhibits better performance.

3 GenMC Model

In MCQA, a question Q is given together with a set of n options $\mathbb{O} = \{O_1, \ldots, O_n\}$ with exactly one option being the correct answer. The key to finding the correct answer is to capture and deeply understand the connection between Q and each $O_i \in \mathbb{O}$, which oftentimes is beyond the lexical level and requires a non-trivial entailment process. We follow the trend of building on a pre-trained encoder-decoder model and use the encoder to jointly encode Q and each O_i. However, previous works directly use the decoder to generate an option in $\mathbb{O}$, i.e., using the decoder as a classifier, which may have under-exploited the model's NLG capability (Liu et al., 2021). Moreover, a simple joint encoding of Q and each O_i can only enable lexical-level reasoning (Zellers et al., 2019) which is insufficient for MCQA tasks.

Our proposed model GenMC overcomes these limitations. Building on a pre-trained encoder-decoder model, GenMC firstly generates a clue which is indicative of the correct answer, thereby exploiting the NLG capability and underlying knowledge of the pre-trained encoder-decoder model. Then GenMC employs the generated clue representation as intermediate knowledge connecting the question and the correct answer to interact with and enhance a reader for solving MCQA. Our model design mimics how humans solve an MCQA task, i.e., after reading a question, humans may firstly associate it with some of their background knowledge (i.e., looking for clues) that helps them to later identify the correct answer.

The overall architecture of GenMC is shown in

Figure 3. The clue generator (Section 3.1) first generates a clue representation only given Q. Then the enhanced reader (Section 3.2) uses the generated clue to augment question-option understanding.

3.1 Clue Generator

The clue generator takes the question Q as input and autoregressively outputs a clue $C = c_1, \dots, c_{|C|}$ using a pre-trained encoder-decoder model.[2] Note that not the clue text C but its representation $\mathbf{H}^C$ will be used in our model, although one could output C as evidence for explainability.

Specifically, we obtain the question representation $\mathbf{H}^Q \in \mathbb{R}^{d\times|Q|}$ and the clue representation $\mathbf{H}^C \in \mathbb{R}^{d\times|C|}$ from the last layer of the encoder and of the decoder, respectively, where d denotes the representation dimension. $\mathbf{H}^C_j$, denoting the representation of the j-th token $c_j \in C$, is computed as follows:

$$\mathbf{p}^C_j, \mathbf{H}^C_j = \texttt{Decoder}(c_{j-1}, \mathbf{H}^C_{<j}, \mathbf{H}^Q), \qquad (1)$$

where $\texttt{Decoder}\ (\cdot,\cdot,\cdot)$ takes the last token c_{j-1}, the representation for the decoding history $\mathbf{H}^C_{<j}$, and $\mathbf{H}^Q$ as input, and outputs the hidden state $\mathbf{H}^C_j$ together with the probability distribution $\mathbf{p}^C_j$ over the decoding vocabulary at the j-th step.

To encourage the tokens in C to thoroughly interact with each other and with Q, we strengthen the clue representation by passing it to a transformer layer (Vaswani et al., 2017) and obtain $\mathbf{H}^{QC}$:

$$\mathbf{H}^{QC} = \texttt{Transformer}([\mathbf{H}^Q; \mathbf{H}^C]), \qquad (2)$$

where $[\cdot;\cdot]$ denotes concatenation. $\mathbf{H}^{QC}$ carries the information of C which can be helpful to better understand and answer Q.

3.2 Enhanced Reader

Previous works often directly model the relevance of each $O_i \in \mathbb{O}$ to Q via joint encoding using a pre-trained encoder, which largely performs superficial lexical reasoning (Zellers et al., 2019). By contrast, we use the previously generated clue representation to enhance our reader for a deeper understanding of each question-option pair.

Specifically, we first concatenate Q and each O_i independently[3] and feed the concatenated input into the pre-trained encoder (which is shared with our clue generator) to obtain O_i's contextualized representation $\mathbf{H}^{QO}_i$, which constitutes a column of $\mathbf{H}^{QO} \in \mathbb{R}^{d\times n}$ where $n = |\mathbb{O}|$.

Next, based on the clue representation $\mathbf{H}^{QC}$, our model intensively reads each question-option pair and obtains the matching signal between the clue and the option. Specifically, inspired by Huang et al. (2021), we first use dual-attention (Liu et al., 2020a) to fuse information from $\mathbf{H}^{QO}_i$ to $\mathbf{H}^{QC}$ and from $\mathbf{H}^{QC}$ to $\mathbf{H}^{QO}_i$. Then we perform max-pooling to aggregate the matching features:

$$\begin{aligned}(\hat{\mathbf{H}}^{QO}_i, \hat{\mathbf{H}}^{QC}_i) &= \text{DualAttention}(\mathbf{H}^{QO}_i, \mathbf{H}^{QC}),\\ \mathbf{f}^{QO}_i &= \text{Max-Pooling}(\hat{\mathbf{H}}^{QO}_i),\\ \mathbf{f}^{QC}_i &= \text{Max-Pooling}(\hat{\mathbf{H}}^{QC}_i).\end{aligned} \qquad (3)$$

To obtain the final score s_i for each O_i, we concatenate the dual matching features $\mathbf{f}^{QO}_i$ and $\mathbf{f}^{QC}_i$ and feed them into a two-layer multi-layer perceptron (MLP):

$$s_i = \text{Linear}(\text{ReLU}(\text{Linear}([\mathbf{f}^{QO}_i; \mathbf{f}^{QC}_i]))). \qquad (4)$$

We select the option with the highest score as the predicted answer, denoted as O_p.

3.3 Training Objective

We jointly train the clue generator and the enhanced reader in an end-to-end fashion with a combined loss:

$$\mathcal{L} = \mathcal{L}^{\text{GEN}} + \mathcal{L}^{\text{READ}}. \qquad (5)$$

Generator Loss For $\mathcal{L}^{\text{GEN}}$, assuming that $O_t \in \mathbb{O}$ is the correct answer containing m tokens $a_1, \dots, a_m$, we first use O_t as the target to calculate our clue generator loss with teacher forcing:

$$\begin{aligned}\mathbf{p}^{O_t}_j, \mathbf{H}^{O_t}_j &= \texttt{Decoder}(a_{j-1}, \mathbf{H}^{O_t}_{<j}, \mathbf{H}^Q),\\ \mathcal{L}^{\text{GEN}} &= -\frac{1}{m}\sum_{j=1}^{m} \log \mathbf{p}^{O_t}_{j,a_j},\end{aligned} \qquad (6)$$

where $\mathbf{p}^{O_t}_j$ denotes the probability distribution over the decoding vocabulary at the j-th step, and $\mathbf{p}^{O_t}_{j,a_j}$ is the probability of token a_j.

Reader Loss For $\mathcal{L}^{\text{READ}}$, we simply calculate a cross-entropy loss given the correct answer $O_t \in \mathbb{O}$ as follows:

$$\mathcal{L}^{\text{READ}} = -\log \frac{\exp(s_t)}{\sum_{i=1}^{n} \exp(s_i)}. \qquad (7)$$

Note that we update the encoder using the joint loss $\mathcal{L}$, while we do not allow $\mathcal{L}^{\text{READ}}$ to be backpropagated to the decoder part to reduce the memory consumption.

---

[2] For efficiency, we decode the clue greedily without performing beam search.

[3] A delimiter "\n" is inserted between Q and each O_i.

	Train set size	Dev set size	Test set size	Option number	Question average length	Option average length
CSQA	8,500	1,241	1,221	5	13.38	1.52
OBQA	4,957	500	500	4	10.65	2.85
ARC-Easy	2,241	567	2,365	4	19.36	3.73
ARC-Challenge	1,117	295	1,165	4	22.30	4.93
QASC	7,320	814	926	8	8.12	1.64

Table 1: Dataset statistics. For CSQA and QASC, their official dev sets are used as our test sets, and our dev sets are in-house split from their official training sets.

The above training objective exploits the double properties of the correct answer O_t in MCQA: as a text and as an index. We use O_t as a text to supervise our clue generator, and as an index (i.e., classification label) to supervise our enhanced reader. Such usage is more natural than the text-to-text paradigm (Khashabi et al., 2020; Zhou et al., 2021), thus having the potential to outperform.

4 Experimental Setup

4.1 Data

We conducted experiments on five popular MCQA datasets spanning from commonsense questions to scientific questions. The former requires commonsense knowledge and reasoning, and the latter requires inference over scientific facts.

Datasets CSQA (Talmor et al., 2019) and OBQA (Mihaylov et al., 2018) are two commonsense MCQA datasets created by crowd workers based on commonsense facts. Each question is given with 5 options in CSQA and 4 options in OBQA. ARC-Easy and ARC-Challenge, denoting two disjointed subsets of ARC (Clark et al., 2018), contain natural grade-school science questions with 4 options, where ARC-Challenge comprises difficult questions which require more advanced reasoning. QASC (Khot et al., 2020) is collected from elementary and middle school level science with 8 options for each question.

Train-Dev-Test Split For OBQA, ARC-Easy, and ARC-Challenge we used their official train, dev, and test sets. For CSQA and QASC, since the correct answers in the official test set are not public, we took their official dev set as our test set for experiments and randomly held out an in-house dev set from the training set. The dataset statistics are shown in Table 1.

External Knowledge For all these datasets, our experiments did not rely on any provided documents or external corpora; a question was solely provided with its options to form the input. It means that pre-trained models were used as the primary source of knowledge in the experiments.

4.2 Implementation Details

We used two popular encoder-decoder models as a basis, BART (Lewis et al., 2020) and T5 (Raffel et al., 2020). For each model, we experimented with its BASE and LARGE versions.

We used PyTorch 1.7. We used the Adam optimizer and set warmup fraction $= 0.1$, weight decay $= 0.01$, maximum source length $= 64$, maximum target length $= 32$, epoch $= 30$, and early stop training when there was no better result on the dev set after 5 epochs. For each model, we searched for the best learning rate from $\{1e-4, 5e-5, 1e-5\}$, and for the best batch size out of $\{8, 64\}$.

Because neural models are known to be sensitive to different random seeds, especially when the training set is small, we performed multiple experiments for all models with different random seeds, and reported the mean and standard deviation. For CSQA, OBQA, ARC-Easy, and QASC, we used three random seeds $\{1, 10, 20\}$. For the smallest dataset ARC-Challenge, we used five random seeds $\{1, 10, 20, 30, 40\}$.

All the experiments were performed on a GeForce RTX 3090 with 24G memory.

4.3 Evaluation Metric

For each model, we reported its proportion of correctly answered questions in each dataset.

5 Experimental Results

5.1 Main Results: Comparison with Text-to-Text Models

To empirically evaluate GenMC in terms of whether it better exploits the potential of pre-trained encoder-decoder models for MCQA, we compare GenMC with a standard text-to-text implementation and with a variant thereof for analysis.

Table 2: Comparison with text-to-text models.

5.1.1 Baselines

Text2Text$_{\text{vanilla}}$ The vanilla usage of pre-trained encoder-decoders for MCQA is to reform the input and output in a way that can be directly processed by a encoder-decoder model. Specifically, following Raffel et al. (2020), we concatenate the input question with all candidate options, where each option is also preceded by its option ID, and then prepend the sequence with a dataset name. The concatenated sequence is fed into the encoder part to get a joint representation for the question and all options. Based on the joint representation, the decoder finally outputs an option ID. In this setting, the decoder is basically used as a classifier.

Text2Text$_{\text{enc}}$ Similar to Liu et al. (2021), we use only the encoder part of a pre-trained encoder-decoder model. Each option is independently paired with the question to obtain a joint representation using the encoder. Then the representation is fed into a scorer (i.e., an MLP) to obtain a matching score for each question-option pair. The model then predicts the option with the highest score. In this setting, the decoder is totally unused. Though Liu et al. (2021) find that their encoder-only model performs comparably to using the decoder as a classifier, we argue that the decoder part can further improve the performance, if being properly used.

5.1.2 Results

The main results (see Table 2) show that GenMC consistently and significantly (with p-value < 0.01) outperforms Text2Text$_{\text{vanilla}}$ and Text2Text$_{\text{enc}}$ on all datasets. For several settings, GenMC even obtains an absolute gain of over 10%. For example, on the test set of the challenging scientific MCQA dataset ARC-Challenge, T5$_{\text{BASE}}$ + GenMC improves T5$_{\text{BASE}}$ + Text2Text$_{\text{vanilla}}$ from an accuracy of 23.69% to 39.00%, suggesting a relative gain of around 65%. These results demonstrate that GenMC is a more effective usage of pre-trained encoder-decoder models than existing ones.

Moreover, we interestingly find that the decoder-free baseline Text2Text$_{\text{enc}}$ outperforms Text2Text$_{\text{vanilla}}$ on over half of the experiments. This indicates that the decoder's general language knowledge gained from pre-training is largely wasted by only using it as a classifier, which may further explain the superior performance of our model because GenMC can exploit the pre-trained decoder more effectively. In addition, all LARGE models significantly outperform their BASE counterparts. This suggests that the embedded knowledge gained from pre-training is critical to MCQA tasks, strengthening our point to make full use of pre-trained encoders and decoders.

5.2 Comparison with Other Models

5.2.1 Baselines

UnifiedQA Existing methods that rely on external documents or corpora have achieved state-of-the-art performance on several MCQA datasets. However, to enable a fair comparison, we only compare with models that adopt the same setting as ours, where a question and its options are the only input to the model. Among these models, UnifiedQA (Khashabi et al., 2020) is the current best model. While UnifiedQA reports the best score using its T5-11B version, since for T5 we experiment with its BASE and LARGE versions, we only report and compare under T5$_{\text{BASE}}$ and T5$_{\text{LARGE}}$. Note that instead of training on each dataset separately, UnifiedQA converts a line of popular QA datasets with four formats (e.g., retrieval-based QA, MCQA) into a unified format, and trains a single model over all training data, while GenMC only uses each

Table 4: Comparison with UnifiedQA after unifying training sets.

dataset's own training data.

RoBERTa and ALBERT In addition, we compare with two encoder-only models, RoBERTa (Liu et al., 2019) and ALBERT (Lan et al., 2020), which have served as the basis of many MCQA models.

All models are of comparable model size to ours.

5.2.2 Results

The results in Table 3 show that GenMC$_{\text{T5}}$ significantly (with p-value < 0.01) outperforms the two encoder-only strong baselines RoBERTa and ALBERT. More interestingly, GenMC$_{\text{T5}}$ also performs better than UnifiedQA$_{\text{T5}}$ on most datasets. Moreover, for UnifiedQA$_{\text{T5-FT}}$, which further fine-tunes the model on the training set of the target dataset, GenMC$_{\text{T5}}$ outperforms it on the test sets of CSQA, OBQA, and ARC-Easy for the base models and ARC-Easy for the large models. It also achieves comparable results on the remaining datasets. These results are impressive because UnifiedQA uses more datasets (i.e., eight different QA datasets) for training. The promising results of GenMC further reveals that our model can learn to effectively extract knowledge from pre-trained encoder-decoders with limited training data.

As a fairer comparison in Table 4, by unifying the training sets of all the five datasets, our GenMC$_{\text{T5-U}}$ outperforms UnifiedQA$_{\text{T5-FT}}$ on all datasets except for CSQA with large models.

5.3 Ablation Study: Influence of Clues

Our main results in Section 5.1 have demonstrated the effectiveness of our model. To better understand its superior results and the influence of our clue generation, we compare with two variants.

5.3.1 Variants of GenMC

Weak Clue We train this variant only using the classification loss $\mathcal{L}^{\text{READ}}$, so only the encoder part is updated, while the decoder part is left untouched from pre-training. Intuitively, under this setting, the generated clue is weaker than GenMC which learns how to generate a clue with supervision.

Token Clue In this setting, we separately train a clue generator and a reader. We first collect the generated clue text C (instead of its representation) from the decoder. We then directly concatenate C with Q and O_i to compute a score for O_i using the model's encoder part stacked with an MLP layer. This variant is indeed very similar to Liu et al. (2020c), which also adopts a pipeline framework to first generate a token-level evidence and then use the evidence to expand the question.

5.3.2 Results

Table 5 shows that masking out generation loss leads to substantial performance drops across all datasets, demonstrating that fine-tuning the decoder with generation loss $\mathcal{L}^{\text{GEN}}$ helps to derive useful clues from pre-trained encoder-decoder models. We also observe that the performance of using token-level clues lags much behind GenMC. This

Table 5: Influence of clues.

Clue Type	Percentage	Example	
		Instance	Clue
Irrelevant	23.60%	Which would you likely find inside a beach ball? (A) cheese (B) *steam* (C) water (D) **air**	a squid
Relevant but unhelpful	52.40%	What may have been formed by a volcano? (A) **Mt. McKinley** (B) Lake Pontchartrain (C) The great lakes (D) *Niagara Falls*	a lake
Helpful	24.00%	Where would there be an auditorium with only a single person speaking? (A) lights (B) crowd (C) **university campus** (D) *theater* (E) park	school

Table 6: Distribution of clue types in negative cases with examples. Bold underline indicates the correct answer, and italic indicates the predicted label.

demonstrates that naively using explicit knowledge in plain text, instead of using implicit clues from the decoder's hidden state, is inferior as it may unnecessarily bring information loss and noise.

5.4 Error Analysis

We analyze the clues generated by GenMC using T5$_{\text{LARGE}}$ with a focus on instances that are correctly predicted by the baseline in our main experiments (i.e., T5$_{\text{LARGE}}$ + Text2Text$_{\text{vanilla}}$), while our GenMC fails. The intuition is that in these *negative cases*, the clues generated by GenMC may play a negative role. By studying these potentially negative clues, we can gain more insights into how GenMC fails and discuss venues for future improvement.

Specifically, we randomly sample 50 negative cases from T5$_{\text{LARGE}}$ + GenMC for each dataset. We show six graduate students of computer science[4] an instance along with the generated clue, correct answer, and predicted answer. We then ask them to categorize clues into the following families:[5]

- **Irrelevant:** The clue is off topic or is not understandable.
- **Relevant but unhelpful:** Though relevant, the clue makes a factually incorrect statement, often on the contrary of the main question, or the clue contributes relevant but insufficient knowledge for prediction, such as repetition of the question or other distractors.
- **Helpful:** The clue adds helpful information to answer the question.

To ensure the annotation quality, we aggregate annotated results from three students for every dataset using majority vote. If all three students annotate differently from each other for an instance, we introduce a fourth student to arbitrate.

Table 6 shows the percent of each clue type across all datasets with an example for each type. Figure 4 breaks down by dataset. Though the majority of our clues are relevant (i.e., 76.4% of them are relevant across all datasets), which seems positive, only 24% of the clues are deemed as helpful. This suggests a great room for improvement. In our future research, we will focus on how to generate more helpful clues from questions.

---

[4] They are volunteers recruited from the contact author's research group. They know and agree that their annotations will be used for error analysis in a research paper.

[5] We follow a similar definition by Shwartz et al. (2020).

Table 7: Inference time for answering a question (seconds).

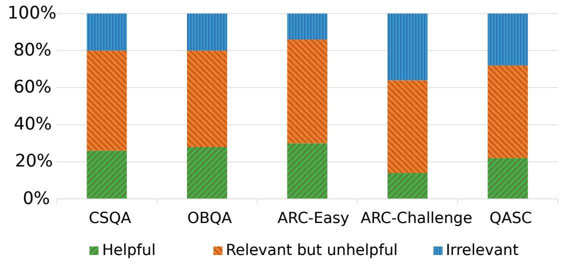

Figure 4: Distribution of clue types in negative cases on each dataset.

5.5 Inference Time and Model Size

Table 7 shows the inference time for answering a question. GenMC is slower than Text2Text$_{\text{vanilla}}$, but their inference time has the same scale, suggesting that GenMC is more cost-effective considering its superior accuracy. GenMC and UnifiedQA are comparable in inference time.

Among T5$_{\text{BASE}}$ based models, Text2Text$_{\text{vanilla}}$ and UnifiedQA have 223 M parameters, while GenMC is slightly larger with 234 M parameters. Among T5$_{\text{LARGE}}$ based models, Text2Text$_{\text{vanilla}}$ and UnifiedQA have 738 M parameters, while GenMC has 757 M parameters.

6 Conclusion

We present GenMC, a simple yet effective model which tailors pre-trained encoder-decoders for MCQA tasks. Compared with existing usages of pre-trained encoder-decoders for MCQA, our model fully exploits the pre-trained encoder-decoders' NLG capabilities to generate a clue from the input question, which facilitates deep understanding of question-option pairs. Experimental results further verify the superiority of GenMC over existing usages. Notably, our model achieves promising results without using any provided documents or external corpora, showing an interesting application of PLMs by directly inducing either commonsense or scientific knowledge from them through clue generation.

In the future, we will focus on how to further improve the clue generation quality, which remains a bottleneck of GenMC. We hope this work will spur more research in how to better use pre-trained encoder-decoders for not only MCQA, but also beyond; for tasks with divergent structures from the pre-training, a smarter use of PLMs can boost the performance significantly.

Responsible NLP Research Checklist

Members of the ACL are responsible for adhering to the ACL code of ethics. The ARR Responsible NLP Research checklist is designed to encourage best practices for responsible research, addressing issues of research ethics, societal impact and reproducibility.

Please read the Responsible NLP Research checklist guidelines for information on how to answer these questions. Note that not answering positively to a question is not grounds for rejection.

All supporting evidence can appear either in the main paper or the supplemental material. For each question, if you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Please do not modify, reorder, delete or add questions, question options or other wording of this document.

A For every submission

A1 Did you discuss the *limitations* of your work?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification Section 5.4, Section 6

A2 Did you discuss any potential *risks* of your work?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

N/A

Section or justification Click or tap here to enter text.

A3 Do the abstract and introduction summarize the paper's main claims?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification Abstract, Section 1

B Did you use or create *scientific artifacts*?

If you answer **Yes**, provide the section number; if you answer **No**, you can skip the rest of this section.

Yes

If yes:

B1 Did you cite the creators of artifacts you used?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 4.1

B2 Did you discuss the *license or terms* for use and/or distribution of any artifacts?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 1

B3 Did you discuss if your use of existing artifact(s) was consistent with their *intended use*, provided that it was specified? For the artifacts you create, do you specify intended use and whether that is compatible with the original access conditions (in particular, derivatives of data accessed for research purposes should not be used outside of research contexts)?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 4.1

B4 Did you discuss the steps taken to check whether the data that was collected/used contains any *information that names or uniquely identifies individual people* or *offensive content*, and the steps taken to protect / anonymize it?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

No

Section or justification   They are widely used datasets containing commonsense/scientific information.

B5 Did you provide documentation of the artifacts, e.g., coverage of domains, languages, and linguistic phenomena, demographic groups represented, etc.?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 4.1

B6 Did you report relevant statistics like the number of examples, details of train/test/dev splits, etc. for the data that you used/created?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 4.1

C Did you run *computational experiments*?

If you answer **Yes**, provide the section number; if you answer **No**, you can skip the rest of this section.

Yes

If yes:

C1 Did you report the *number of parameters* in the models used, the *total computational budget* (e.g., GPU hours), and *computing infrastructure* used?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 4.2, Section 5.5

C2 Did you discuss the experimental setup, including *hyperparameter search* and *best-found hyperparameter* values?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 4.2

C3 Did you report *descriptive statistics* about your results (e.g., error bars around results, summary statistics from sets of experiments), and is it transparent whether you are reporting the max, mean, etc. or just a single run?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 4.2, Section 5

C4 If you used existing packages (e.g., for preprocessing, for normalization, or for evaluation), did you report the implementation, model, and parameter settings used (e.g., NLTK, Spacy, ROUGE, etc.)?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 4.2

D Did you use *human annotators* (e.g., crowdworkers) or *research with human subjects*?

If you answer **Yes**, provide the section number; if you answer **No**, you can skip the rest of this section.

Yes

If yes:

D1 Did you report the full text of instructions given to participants, including e.g., screenshots, disclaimers of any risks to participants or annotators, etc.?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 5.4

D2 Did you report information about how you recruited (e.g., crowdsourcing platform, students) and paid participants, and discuss if such *payment is adequate* given the participants' demographic (e.g., country of residence)?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 5.4

D3 Did you discuss whether and how consent was obtained from people whose data you're using/curating (e.g., did your instructions explain how the data would be used)?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 5.4

D4 Was the data collection protocol *approved* (or *determined exempt*) by an ethics review board?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

N/A

Section or justification   Click or tap here to enter text.

D5 Did you report the basic demographic and geographic characteristics of the *annotator* population that is the source of the data?

If you answer **Yes**, provide the section number; if you answer **No**, provide a justification.

Yes

Section or justification   Section 5.4

Towards Efficient NLP: A Standard Evaluation and A Strong Baseline

Abstract

Supersized pre-trained language models have pushed the accuracy of various natural language processing (NLP) tasks to a new state-of-the-art (SOTA). Rather than pursuing the reachless SOTA accuracy, more and more researchers start paying attention to model efficiency and usability. Different from accuracy, the metric for efficiency varies across different studies, making them hard to be fairly compared. To that end, this work presents **ELUE** (**E**fficient **L**anguage **U**nderstanding **E**valuation), a standard evaluation, and a public leaderboard for efficient NLP models. ELUE is dedicated to depicting the Pareto Frontier for various language understanding tasks, such that it can tell whether and how much a method achieves Pareto improvement. Along with the benchmark, we also release a strong baseline, **ElasticBERT**, which allows BERT to exit at any layer in both static and dynamic ways. We demonstrate the ElasticBERT, despite its simplicity, outperforms or performs on par with SOTA compressed and early exiting models. With ElasticBERT, the proposed ELUE has a strong Pareto Frontier and makes a better evaluation for efficient NLP models.

1 Introduction

Driven by the large-scale pre-training, today's NLP models have become much more powerful (Devlin et al., 2019; Yang et al., 2019; Lan et al., 2020; Raffel et al., 2020; Sun et al., 2020; Brown et al., 2020; Qiu et al., 2020). As a consequence of this drastic increase in performance, these pre-trained language models (PLMs) are notorious for becoming more and more computationally expensive due to the increasing number of parameters. Therefore, rather than pre-training a larger model to achieve a new state-of-the-art (SOTA) accuracy, most studies are pursuing improvement on other dimensions such as the number of parameters or FLOPs (Gordon et al., 2020; Sanh et al., 2019; Jiao et al., 2020; Lan et al., 2020; Shen et al., 2020). For these works, the goal has shifted from simple SOTA to "Pareto SOTA". A Pareto SOTA model means that there is no other model is currently better than it on all the dimensions of interest. For example, a model may claim to be Pareto SOTA as long as it achieves the best accuracy under the same number of parameters or FLOPs. For these efficient models with fewer parameters or FLOPs, it is unfair to get them evaluated on the accuracy-centric benchmarks such as GLUE (Wang et al., 2019b), and ranked among many large-scale models.

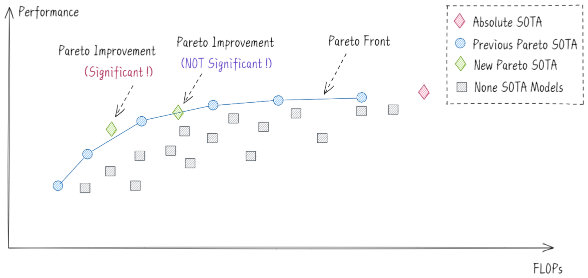

Figure 1: An illustration to show our motivation, that is, building the Pareto frontier can help recognizing whether and how much a method achieves Pareto improvement.

The shifted goal has outpaced the existing benchmarks, which cannot provide a comprehensive and intuitive comparison for efficient methods. In the absence of a proper benchmark, measures of efficiency in different studies cannot be standardized, and different methods cannot be fairly compared. As a result, it is difficult to say *whether* and *how much* a method achieves Pareto improvement. To that end, we aim to build the Pareto frontier for various tasks with standard evaluation for both performance and efficiency. Our motivation can be briefly illustrated by Figure 1.

Need for a standard evaluation As the goal has shifted, a new benchmark is urgently needed to

comprehensively compare the NLP models in multiple dimensions. Currently, this multi-dimensional comparison is done in the individual papers, resulting in the following issues: **(a) Incomprehensive comparison.** The comparison is usually point-to-point, e.g. comparing model performance under the same FLOPs. The comparison in a broader range is usually missed, especially for works in conditional computation where the model performance varies with FLOPs. **(b) Unaccessible results.** Even if the comprehensive line-to-line comparison is conducted, the results are usually presented in form of figure, in which the data points are not accessible for the following work. As a result, the following work has to reproduce or estimate the results (e.g. Xin et al. (2021) estimate values from the figures of Zhou et al. (2020a)). **(c) Non-standard measurements.** Different works may adopt different metrics such as physical elapsed time, FLOPs, and executed model layers, making them hard to directly compare. Even if the adopted metrics are the same, there is no guarantee that they will be calculated in the same way (e.g. the hardware infrastructure, or the software to calculate FLOPs can be very different[1]). **(d) Inconvenience.** Recent studies usually choose GLUE (Wang et al., 2019b) as the main benchmark, which, however, is not suitable for dynamic methods due to its submission limitation that is designed to avoid overfitting on test sets.

Need for a strong baseline Currently, there are roughly two branches of efficient methods in NLP: static methods (e.g. distillation, pruning, quantization, etc.) and dynamic methods (e.g. early exiting). **(a) Static models** are obtained given an expected number of parameters or inference latency. These methods often use the first few layers (to keep the same number of parameters or FLOPs) of some pre-trained model followed by a classification head as their baseline, which, however, is too weak to serve as a baseline. **(b) Dynamic models** usually add multiple internal classifiers to the pre-trained LMs, and therefore allow flexible inference conditioned on the input. Nevertheless, the injected internal classifiers introduce a gap between pre-training and fine-tuning. Training the internal classifiers on downstream tasks often degenerates the performance of the entire model (Xin et al., 2021). Thus, static models need a strong baseline, and dynamic models need a strong backbone.

Contributions In this work, we address the above needs by contributing the following:

- **ELUE**(**E**fficient **L**anguage **U**nderstanding **E**valuation) – a standard benchmark for efficient NLP models. (1) ELUE supports online evaluation for model performance, FLOPs, and number of parameters. (2) ELUE is also an open-source platform that can facilitate future research. We reproduce and evaluate multiple compressed and early exiting methods on ELUE. All of the results are publicly accessible on ELUE. (3) ELUE provides an online leaderboard that uses a specific metric to measure how much a model oversteps the current Pareto frontier. ELUE leaderboard also maintains several separate tracks for models with different sizes. (4) ELUE covers six NLP datasets spanning sentiment analysis, natural language inference, similarity and paraphrase tasks. The ELUE benchmark is publicly available at `http://eluebenchmark.fastnlp.top/`.

- **ElasticBERT** – a strong baseline (backbone) for static (dynamic) models. ElasticBERT is a multi-exit Transformer (Vaswani et al., 2017) pre-trained on ∼160GB corpus. The pre-training objectives, MLM and SOP (Lan et al., 2020), are applied to multiple Transformer layers instead of only the last layer. Gradient equilibrium (Li et al., 2019) is adopted to alleviate the conflict of the losses at different layers. For static models, ElasticBERT is a strong baseline that can reach or even outperform distilled models. For dynamic models, ElasticBERT is a robust backbone that closes the gap between pre-training and fine-tuning. We release the pre-trained model weights of ElasticBERT[2] as well as code[3].

2 Related Work

NLP Benchmarks Evaluating the quality of language representations on multiple downstream tasks has become a common practice in the community. These evaluations have measured and

---

[1] We find that the FLOPs of Transformers calculated by different libraries (`thop`, `ptflops`, and `torchstat`) can be different. And besides, all of them missed FLOPs in some operations such as self-attention and layer normalization.

[2] https://huggingface.co/fnlp

[3] https://github.com/fastnlp/ElasticBERT

pushed the progress of NLP in recent years. SentEval (Conneau and Kiela, 2018) introduces a standard evaluation toolkit for multiple NLP tasks. Further, GLUE (Wang et al., 2019b) and SuperGLUE (Wang et al., 2019a) provide a set of more difficult datasets for model-agnostic evaluation. Another line of work is multi-dimensional evaluations. EfficientQA (Min et al., 2020) is an open-domain question answering challenge that evaluates both accuracy and system size. The system size is measured as the number of bytes required to store a Docker image that contains the submitted system. Dynabench (Kiela et al., 2021), an open-source benchmark for dynamic dataset creation and model evaluation, also supports multi-dimensional evaluation. In particular, Dynabench measures model performance, throughput, memory use, fairness, and robustness. Both EfficientQA and Dynabench require the user to upload the model along with the required environment to the server, which is costly for users to upload and also for the server to evaluate. In contrast, ELUE adopts a cheaper way to evaluate performance and efficiency of the model. Recently, Long-Range Arena (LRA) (Tay et al., 2021) is proposed to evaluate models under the long-context scenario. Different from ELUE, LRA mainly focuses on Xformers (Lin et al., 2021). Besides, some tasks included in LRA are not NLP tasks, or even not real-world tasks, while ELUE consists of common language understanding tasks. In addition, ELUE is also inspired by other well-known benchmarks, such as SQuAD (Rajpurkar et al., 2016), MultiNLI (Williams et al., 2018), DecaNLP (McCann et al., 2018), CLUE (Xu et al., 2020b), HotpotQA (Yang et al., 2018), GEM (Gehrmann et al., 2021), etc.

Efficient NLP Models Current efficient NLP models can be roughly categorized as two streams: model compression (static methods) and conditional computation (dynamic methods). Model compression is to reduce the number or precision of model parameters to achieve faster training and inference. Currently, there are several ways to achieve model compression: (1) *Knowledge Distillation*, which is to learn a compact student model that learns from the output distribution of a large-scale teacher model (Sanh et al., 2019; Jiao et al., 2020) (2) *Model Pruning*, which is to remove parts of parameters that are less important (Gordon et al., 2020), (3) *Weight Sharing* across different parts of the model (Lan et al., 2020) is also a common technique to significantly reduce parameters, (4) *Quantization*, which is to use low bit precision to store parameter and accelerate inference with low bit hardware operations (Shen et al., 2020), and (5) *Module Replacing*, which is to replace the modules of a big model with more compact substitutes (Xu et al., 2020a). In contrast, conditional computation is to selectively execute only parts of the model conditioned on a given input (Bengio et al., 2013; Davis and Arel, 2014). As a representative, an end-to-end halting approach, Adaptive Computation Time (ACT) (Graves, 2016), is developed to perform input-adaptive computation for recurrent networks. The idea of ACT is later adopted in Universal Transformer (Dehghani et al., 2019). Recently, as the rising of deep models for natural language processing, early exiting is widely used to speedup inference of transformer models (Liu et al., 2020a; Xin et al., 2020; Schwartz et al., 2020; Zhou et al., 2020b; Elbayad et al., 2020; Liao et al., 2021; Xin et al., 2021; Sun et al., 2021b; Zhu, 2021; Li et al., 2021a).

3 ELUE: A Standard Benchmark for Efficient NLP Models

ELUE aims to offer a standard evaluation for various efficient NLP models, such that they can be fairly and comprehensively compared. In Section 3.1, we list the design considerations to achieve this motivation. In Section 3.2, we describe the tasks and datasets included in ELUE. In Section A.1, we illustrate how to make a submission on ELUE, and how the submission is evaluated. In Section 3.3, we discuss the design of our leaderboard.

3.1 Design Considerations

Now we enumerate main considerations in the design of ELUE to ensure that it meets the needs mentioned early.

Multi-dimensional Evaluation The evaluation of ELUE should be multi-dimensional for comprehensive comparison. Instead of point-to-point comparison, methods can be compared in a line-to-line style in ELUE, where the "line" is a performance-efficiency trade-off curve.

Public Accessible All data points in ELUE should be publicly accessible such that the following work does not need to reproduce or estimate results from previous work. To facilitate future research, some representative methods should be reproduced and evaluated in ELUE.

Standard Evaluation The measurement of model efficiency should be standardized in ELUE such that this line of methods can be fairly compared. Current studies usually use number of parameters (Lan et al., 2020; Jiao et al., 2020), FLOPs (Jiao et al., 2020; Liu et al., 2020a; Li et al., 2021b), actual inference time (Sanh et al., 2019; Schwartz et al., 2020), or number of executed layers (Zhou et al., 2020a; Sun et al., 2021b) to measure model efficiency. Among these metrics, measuring actual inference time is costly for both users and the server, and highly depends on the computation infrastructure and software implementation, while number of executed layers ignores the shape of input and hidden layers, therefore is inaccurate. Thus, ELUE adopts number of parameters and FLOPs as the metrics for model efficiency.

Easy-to-Use ELUE should be friendly to users, which means that the submission should be as simple as possible. Roughly speaking, there are currently two ways of submissions: (1) submitting the trained model such as SQuAD (Rajpurkar et al., 2016), Dynabench (Kiela et al., 2021), and (2) submitting the predicted test files such as GLUE (Wang et al., 2019b), SuperGLUE (Wang et al., 2019a), and CLUE (Xu et al., 2020b). The submission of ELUE lies in the latter way. Nevertheless, to evaluate number of parameters and FLOPs, the submitted test files should conform to a specific format, and besides, a Python file to define the used model is also required. For more details about submission and evaluation, see Appendix A.1.

3.2 Task and Dataset Selection

Following GLUE (Wang et al., 2019b), SuperGLUE (Wang et al., 2019a), and CLUE (Xu et al., 2020b), we collect tasks that can be formatted as single sentence classification or sentence pair classification. Since ELUE mainly focuses on efficient models, the difficulty of dataset is not a primary consideration. Instead, we collect tasks and datasets that are commonly used and publicly available in the community. The statistics of the collected datasets are listed in Table 1.

Tasks	**Datasets**	**|Train|**	**|Dev|**	**|Test|**
Sentiment Analysis	SST-2	8,544	1,101	2,208
	IMDb	20,000	5,000	25,000
Natural Language Inference	SNLI	549,367	9,842	9,824
	SciTail	23,596	1,304	2,126
Similarity and Paraphrase	MRPC	3,668	408	1,725
	STS-B	5,749	1,500	1,379

Table 1: Statistics of datasets in ELUE.

Sentiment Analysis Sentiment analysis, which is to classify the polarity of a given text, is a fundamental task in NLP. We select two well-known movie review datasets, Stanford Sentiment Treebank (SST) (Socher et al., 2013) and IMDb (Maas et al., 2011). For SST, we use the two-way class split, i.e. SST-2. Different from GLUE, SST-2 samples in ELUE are complete sentences instead of phrases. For IMDb, we randomly select 2.5k positive samples and 2.5k negative samples from training set to construct a development set.

Natural Language Inference Natural language inference (NLI) is a task to predict whether the premise entails the hypothesis, contradicts the hypothesis, or neither. NLI is often formulated as a sentence pair classification task (Devlin et al., 2019; Sun et al., 2021a). We select two NLI datasets, SNLI (Bowman et al., 2015) and SciTail (Khot et al., 2018). SNLI is a crowd-sourced collection of sentence pairs with balanced labels: *entailment*, *contradiction*, and *neutral*. We use the spell-checked version of the test and development sets[4]. The hard samples, which do not have golden labels due to the disagreement of annotators, are removed from the dataset and left for model diagnostic. SciTail is a two-way (*entail* or *neutral*) entailment classification dataset, which is derived from multiple-choice science exams and web sentences.

Similarity and Paraphrase For similarity and paraphrase tasks, we also select two datasets, Microsoft Research Paraphrase Corpus (MRPC) (Dolan and Brockett, 2005), and Semantic Textual Similarity Benchmark (STS-B) (Cer et al., 2017), both of which are also included in GLUE. MRPC is a collection of automatically extracted sentence pairs, each manually-labeled with a judgment to indicate whether the pair constitutes a paraphrase. STS-B is a corpus of sentence pairs, each of which is labeled with a score from 0 to 5 to represent the degree to which two sentences are semantically equivalent.

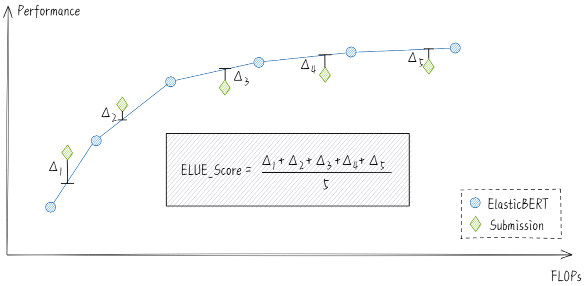

Figure 2: An illustration to show how ELUE score is computed.

3.3 Leaderboard

Following prior work (Yang et al., 2018; Wang et al., 2019b; Xu et al., 2020b), we also integrate a leaderboard in ELUE. For dynamic models that have multiple performance-FLOPs coordinates on each dataset, we need to sum up these coordinates as a score. A critical problem is to measure how good a coordinate is. In other words, to measure a coordinate (p, f), where p is performance and f is FLOPs, we need a baseline performance under the same FLOPs. We choose ElasticBERT as the baseline curve. We evaluate different layers of ElasticBERT, and obtained 12 coordinates $(p_i^{EB}, f_i^{EB})_{i=1}^{12}$, which are then used to interpolate to get a performance-FLOPs function $p^{EB}(f)$. With the baseline curve at hand, we can score a submission curve as

$$\text{ELUEScore} = \frac{1}{n}\sum_{i=1}^{n}[p_i - p^{EB}(f_i)]. \quad (1)$$

Note that the coordinates of ElasticBERT are separately interpolated on different datasets. The final ELUE score is an unweighted average of the scores on all the 6 datasets. Figure 2 gives an illustration of how ELUE score is computed. The ELUE score reflects the extent to which the submission oversteps the ElasticBERT.

In addition, following EfficientQA (Min et al., 2020), ELUE leaderboard also maintains four additional separate tracks, corresponding to models below 40M, 55M, 70M, 110M parameters. Models in these tracks are ranked by the average performance on all the datasets.

4 ElasticBERT: A Strong Baseline for Efficient Inference

Despite the encouraging results achieved by existing efficient models, we argue that a strong baseline (backbone) is needed for both static methods and dynamic methods. Static methods often choose the first few layers of some pre-trained models as their baseline (e.g. Sun et al. (2019); Jiao et al. (2020)), which can be weak. Dynamic methods that enable early exiting by training multiple internal classifiers usually introduce a gap between pre-training and fine-tuning, and therefore hurt the performance of the entire model (Xin et al., 2021). Thus, as illustrated in Figure 3, we present the ElasticBERT that bridges the gap between static and dynamic methods, and therefore can serve as a strong baseline for static methods and also a strong backbone for dynamic methods.

ElasticBERT is a multi-exit pre-trained language model with the following training objective:

$$\mathcal{L} = \sum_{l=1}^{L}(\mathcal{L}_l^{\text{MLM}} + \mathcal{L}_l^{\text{SOP}}), \quad (2)$$

where L is the total number of layers, $\mathcal{L}^{\text{MLM}}$ is the n-gram masked language modeling loss, $\mathcal{L}^{\text{SOP}}$ is the sentence order prediction loss (Lan et al., 2020). The two losses are applied to each layer of the model, such that the number of layers can be flexibly scaled on downstream tasks, and therefore it is named "ElasticBERT".

Bridge the Gap Between Static and Dynamic Methods As a baseline for static methods, the depth of ElasticBERT can be flexibly reduced on demand. Compared with the first l layer of BERT (Devlin et al., 2019), the l-layered ElasticBERT is a complete model (Turc et al., 2019; Li et al., 2021a) and can achieve better performance. It is worth noticing that ElasticBERT can be regarded as a special instance of LayerDrop (Fan et al., 2020) where the dropped layers are constrained to the top consecutive layers. As a backbone for dynamic methods, training classifiers injected in intermediate layers would be consistent with pre-training. Therefore, ElasticBERT can not only be used as a static complete model, but also be used as a backbone model of dynamic early exiting.

Gradient Equilibrium Pre-training with the simply summed loss in Eq. (2) could lead to a *gradient imbalance* issue (Li et al., 2019). In particular, due to the overlap of subnetworks, the variance of the gradient may grow overly large, leading to unstable training. To address this issue, we follow Li et al. (2019) and adopt the gradient equilibrium

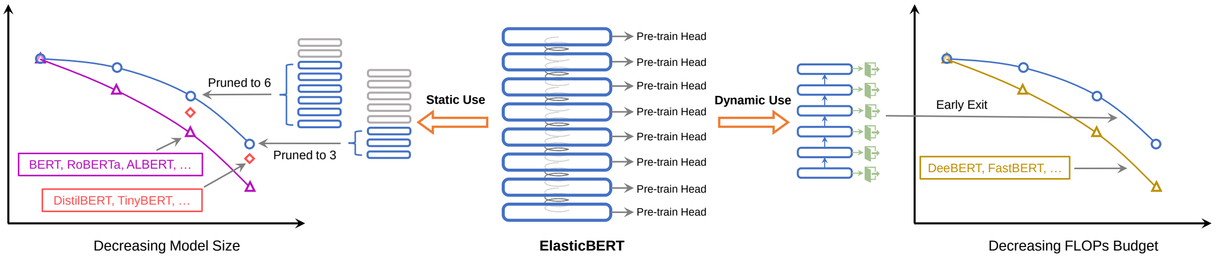

Figure 3: ElasticBERT is pre-trained with multiple pre-training heads attached at the intermediate layers. For static usage (left), it can be pruned on demand while outperforming previous pre-trained models with the same size. For dynamic usage (right), it can serve as the backbone for early exiting methods, achieving better performance-efficiency trade-off than early exiting models with other backbones.

(GE) strategy[5] in the pre-training of ElasticBERT.

Grouped Training In our preliminary experiments, we found that summing up losses at all layers could slow down pre-training and increase memory footprints. To alleviate this, we divide L exits into G groups. During training, we optimize the losses of the exits within each group by cycling alternately between different batches:

$$\mathcal{L} = \sum_{l \in \mathcal{G}_i} (\mathcal{L}_l^{\mathrm{MLM}} + \mathcal{L}_l^{\mathrm{SOP}}). \tag{3}$$

In Section B.3 we explore the performance of different grouping methods. As a result, we group the 12 exits of ElasticBERT$_{\mathrm{BASE}}$ into $\mathcal{G}_1$={1, 3, 5, 7, 9, 11, 12} and $\mathcal{G}_2$={2, 4, 6, 8, 10, 12}, and group the 24 exits of ElasticBERT$_{\mathrm{LARGE}}$ into $\mathcal{G}_1$={1, 4, 7, ..., 22, 24}, $\mathcal{G}_2$={2, 5, 8, ..., 23, 24}, and $\mathcal{G}_3$={3, 6, 9, ..., 21, 24}. Our experiments demonstrate that grouped training can significantly speedup the process of pre-training without a loss in performance.

5 Experiments

5.1 Experimental Setup

Pre-training Setup Following BERT (Devlin et al., 2019), we train ElasticBERT in two different configurations: ElasticBERT$_{\mathrm{BASE}}$ and ElasticBERT$_{\mathrm{LARGE}}$, which have the same model sizes with BERT$_{\mathrm{BASE}}$ and BERT$_{\mathrm{LARGE}}$, respectively. The detailed description can be found in Appendix B.1.

Downstream Evaluation We evaluate ElasticBERT on the ELUE benchmark, as a static model and as a dynamic model. As a static model, we evaluate different layers of ElasticBERT, denoted as ElasticBERT-nL. As a dynamic model, we inject and train internal classifiers in ElasticBERT$_{\mathrm{BASE}}$ and adopt two strategies, entropy (Xin et al., 2020) and patience (Zhou et al., 2020a), to enable early exiting, denoted as ElasticBERT$_{\mathrm{entropy}}$ and ElasticBERT$_{\mathrm{patience}}$. To compare with previous work, we also evaluate ElasticBERT on the GLUE benchmark (Wang et al., 2019b). The comparison results is shown in Appendix B.2. For static usage, we fine-tune ElasticBERT and our baseline models for 10 epochs with early stopping using AdamW optimizer (Loshchilov and Hutter, 2019) with learning rates of {1e-5, 2e-5, 3e-5} and batch size of 32, and warm up the learning rate for the first 6 percent of total steps. In dynamic usage, for the models using two-stage training methods, we train for 3 epochs for each stage, and we train for 5 epochs for other models. Other optimization configurations are the same as those in static scenario.

Table 2: ElasticBERT and static baseline performance on ELUE task test sets. We report the mean of Accuracy and F1 for MRPC, Pearson and Spearman correlation for STS-B and Accuracy for other tasks. The reported FLOPs is the average over all the datasets.

Baselines We compare ElasticBERT with three types of baselines: **(1)** Directly fine-tuning pre-trained models and their first n layers. We choose BERT (Devlin et al., 2019), ALBERT (Lan et al., 2020), RoBERTa (Liu et al., 2019) and LayerDrop (Fan et al., 2020) as our baselines. For the use of the first n layers, we simply add a linear classifier on top of the truncated model. **(2)** Compressed models. We choose two distilled models, DistilBERT (Sanh et al., 2019) and TinyBERT (Jiao et al., 2020), one pruned model, HeadPrune (Michel et al., 2019), and one model obtained by using *module replacing*, BERT-of-Theseus (Xu et al., 2020a) as our baseline models. **(3)** Dynamic early exiting models. To verify the effectiveness of ElasticBERT as a strong backbone of dynamic early exiting methods, we also compare ElasticBERT$_{\text{entropy}}$ and ElasticBERT$_{\text{patience}}$ which have the same early exiting strategy as DeeBERT (Xin et al., 2020) and PABEE (Zhou et al., 2020a) with four representative early exiting models: DeeBERT (Xin et al., 2020), FastBERT (Liu et al., 2020b), PABEE (Zhou et al., 2020a), and CascadeBERT (Li et al., 2021a).

5.2 Evaluating ElasticBERT on ELUE

ElasticBERT and our baselines are evaluated on ELUE tasks. For the BASE version of ElasticBERT, BERT, ALBERT, RoBERTa and LayerDrop, we evaluate the first 3/4/6/12 layers. For the LARGE version of the models, we evaluate the first 6/8/12/24 layers. For dynamic methods, we fine-tune ElasticBERT along with the injected internal classifiers using the gradient equilibrium (GE) strategy (Li et al., 2019), and adopt two different early exiting strategies: entropy-based strategy (Xin et al., 2020) and patience-based strategy (Zhou et al., 2020a).

Results of Static Models The performance of ElasticBERT and our baseline models on ELUE task test sets is shown in Table 2, where we find that ElasticBERT$_{\text{BASE}}$ and ElasticBERT$_{\text{LARGE}}$ outperform BERT and ALBERT with the same number of layers, but are slightly weaker than RoBERTa$_{\text{BASE}}$ and RoBERTa$_{\text{LARGE}}$. Besides, we find that the superiority of ElasticBERT over its baselines can be significant with fewer layers (See Figure 4 for the

ElasticBERT$_{\text{entropy}}$	**0.97**	**1.02**	**-0.14**	-	0.02	**0.64**	-

Table 3: ELUE scores calculated using Eq. (1) for static and dynamic baseline models. '-' denotes that the dataset/metric is not applicable to the model.

results of 3/4 (6/8) layers of the BASE (LARGE) models).

Results of Dynamic Models We compare ElasticBERT$_{\text{entropy}}$ and ElasticBERT$_{\text{patience}}$ with four dynamic models: DeeBERT (Xin et al., 2020), FastBERT (Liu et al., 2020b), PABEE (Zhou et al., 2020a), and CascadeBERT (Li et al., 2021a). The performance-FLOPs trade-off of the dynamic models on ELUE task test sets are shown in Figure 5, which demonstrates that ElasticBERT can achieve better performance-FLOPs trade-off.

Evaluating ELUE Scores According to Eq. (1), we also evaluate the ELUE scores of these baselines. As shown in Table 3, the ELUE score of ElasticBERT$_{\text{BASE}}$ is natural to be zero on all tasks. Among the other baselines, we find that ElasticBERT$_{\text{patience}}$ achieves the best ELUE score, while HeadPrune achieves the worst ELUE score. In addition, we find that dynamic models perform better than static models on average.

6 Conclusion and Future Work

In this work, we present ELUE, which is a public benchmark and platform for efficient models, and ElasticBERT, which is a strong baseline (backbone) for efficient static (dynamic) models. Both of the two main contributions are aimed to build the Pareto frontier for NLU tasks, such that the position of existing work can be clearly recognized, and future work can be easily and fairly measured.

Our future work is mainly in four aspects: (1) Including more baselines in ELUE, (2) Supporting the evaluation for more frameworks such as TensorFlow (Abadi et al., 2016), (3) Supporting diagnostics for submissions, (4) Supporting the evaluation of more different types of tasks.

Acknowledgment

This work was supported by the National Key Research and Development Program of China (No.2020AAA0106702) and National Natural Science Foundation of China (No.62022027).

Ethical Considerations

The proposed ELUE benchmark aims to standardize efficiency measurement of NLP models. The collected datasets are widely used in previous work and, to our knowledge, do not have any attached privacy or ethical issues. Our proposed ElasticBERT is a pre-trained model to reduce computation cost and carbon emission. The pre-training data is public resources adopted in previous work, and therefore would not introduce new ethical concerns.

Appendix

A Details of Evaluation

A.1 Submission and Evaluation

ELUE supports two kinds of submissions: submitting test files, or submitting from a paper.

Submit test files Users are required to submit two kinds of files: (1) predicted test files, and (2) a model definition file in Python. The predicted test files can be multiple, each indicates the prediction under a certain efficiency. The submitted test files should be in the following format:

index	pred	modules
0	1	(10),emb; (10,768),layer_1; (768),exit_1
1	0	(15),emb; (15,768),layer_1; (768),exit_1; (15,768),layer_2; (768),exit_2
2	1	(12),emb; (12,768),layer_1; (768),exit_1
...	...	...

Different from traditional predicted test files as in GLUE, an additional column "modules" is required to indicate the activated modules to predict each sample. The numbers before each module represent the input shape of that module, e.g. the "(10)" before "emb" indicates that the input of "emb" is a sequence of length 10. Note that this format is also compatible with token-level early exiting methods (Li et al., 2021b), where the sequence length is progressively reduced as the processing of layers.

Along with the test files, a Python file to define the model is also required. Figure 6 is an example Python file using PyTorch (Paszke et al., 2019) and Transformers (Wolf et al., 2020).

With the submitted Python file, ELUE is able to evaluate the average FLOPs on a dataset, and the number of parameters of the model.

In cases that the evaluation is not applicable, e.g. the programming language, or dependencies of the submitted Python file is not supported in ELUE, the user is allowed to evaluate FLOPs and number of parameters by themselves and upload their results along with the predictions to the ELUE website.

Submit from a paper Inspired by Paper with Code[6], we also expect that ELUE can serve as an open-source platform that can facilitate future research. Therefore, there is a track for the authors of

    'layer_1': ElasticBertLayer(config),
    'exit_1': nn.Linear(config.hidden_size, num_labels),
    'layer_2': ElasticBertLayer(config),
    'exit_2': nn.Linear(config.hidden_size, num_labels),
    ...
}
entire_model = ElasticBERT(config)
```

Figure 6: An example Python file for submission.

published papers to share their experimental results on ELUE datasets.

Performance Metrics Since the classes in MRPC are imbalanced, we report the unweighted average of accuracy and F1 score. For STS-B, we evaluate and report the Pearson and Spearman correlation coefficients. For other datasets, we simply adopt accuracy as the metric.

B Experimental Details and Additional Results

B.1 Details of Training ElasticBERT

The parameters of ElasticBERT are initialized with BERT, and therefore it has the same vocabulary and tokenizer as BERT. ElasticBERT is pre-trained on $\sim$160GB uncompressed English text corpora, which is comprised of English Wikipedia (12GB), BookCorpus (4GB) (Zhu et al., 2015), OpenWebText (38GB) (Gokaslan and Cohen, 2019), and part of the C4 corpus (110GB) (Raffel et al., 2020). We use Adam optimizer (Kingma and Ba, 2015) to pre-train ElasticBERT$_{\text{BASE}}$ and ElasticBERT$_{\text{LARGE}}$ and other hyperparameters are listed in Table 4. Our implementation is based on Huggingface's Transformers (Wolf et al., 2020) and the Megatron-LM toolkit (Shoeybi et al., 2019). ElasticBERT is trained on 64 32G NVIDIA Tesla V100 GPUs.

Hyperparameter	**ElasticBERT$_{\text{BASE}}$**	**ElasticBERT$_{\text{LARGE}}$**
Adam β_1	0.9	0.9
Adam β_2	0.999	0.999
Peak Learning Rate	2e-4	2e-4
Warm Up Type	Linear	Linear
Warm Up Rate	0.04	0.04
Weight Decay	0.01	0.01
Batch Size	4096	4096
Training Steps	125k	125k
Number of Layers	12	24
Hidden Size	768	1024
Attention Heads	12	16
FFN Intermediate Size	3072	4096

Table 4: Hyperparameters for ElasticBERT pre-training

B.2 Evaluating ElasticBERT on GLUE

To verify the effectiveness and the elasticity of ElasticBERT, we also evaluate ElasticBERT and our static baselines on the GLUE benchmark. We evaluate the first 6/12 layers of the BASE models, and the first 6/24 layers of the LARGE models.

Experimental results of ElasticBERT and our baseline models on GLUE are presented in Table 6, from which we find that ElasticBERT outperforms BERT and ALBERT with the same number of layers, but is weaker than RoBERTa in the 12/24 layers configuration. Compared with ElasticBERT that is trained for 125K steps with batch size of 4K, RoBERTa is trained for 500K steps with batch size of 8K, which makes its number of training samples 8 times larger than that of ElasticBERT. When using fewer layers (6 layers of BASE and LARGE models), ElasticBERT achieves the best performance among the static baselines, confirming its great elasticity.

Grouping	**Accuracy**
w/o Grouping	**76.7**
$\mathcal{G}_1$={1, 3, 5, 7, 9, 11, 12} $\mathcal{G}_2$={2, 4, 6, 8, 10, 12}	**76.7**
$\mathcal{G}_1$={1, 4, 7, 10, 12} $\mathcal{G}_2$={2, 5, 8, 11, 12} $\mathcal{G}_3$={3, 6, 9, 12}	75.7
$\mathcal{G}_1$={1, 2, 3, 4, 12} $\mathcal{G}_2$={5, 6, 7, 8, 12} $\mathcal{G}_3$={9, 10, 11, 12}	75.5
$\mathcal{G}_1$={1, 2, 3, 4, 5, 6, 12} $\mathcal{G}_2$={7, 8, 9, 10, 11, 12}	75.9

Table 5: The average accuracy acorss all the BERT exits on the MNLI dataset with different grouping.

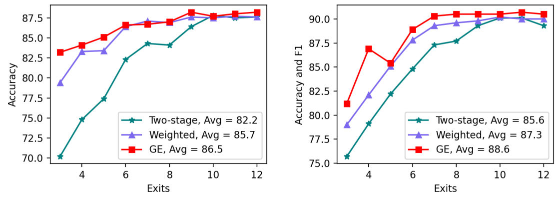
B.3 Ablation Study

About the Training Strategy ElasticBERT adopts the gradient equilibrium (GE) to alleviate the conflict between the losses at different exits. Here, we compare GE with two other existing training strategies, two-stage training (Xin et al., 2020) and weighted training (Zhou et al., 2020a). Two-stage training is that, first training the top classifier along with the backbone model, and then freeze the parameters of the backbone model and train the injected internal classifiers. By this, two-stage training maintains the performance of the top classifier. Weighted training is to weight the loss of each exit according to the corresponding layer, which is

$$\mathcal{L} = \frac{\sum_{l=1}^{L} l \cdot \mathcal{L}_l}{\sum_{l=1}^{L} l}. \tag{4}$$

Experimental results of ElasticBERT with the three training strategies are shown in Figure 7. It can be observed that training with GE strategy performs the best on both SST-2 and MRPC.



(a) SST-2 (b) MRPC

Figure 7: Performance of the ElasticBERT exits at different layers with different training strategies.

About the Grouped Exits As shown in Eq. (3), we divide the L exits into different groups to speedup the pre-training. Therefore, how to group these exits needs to be explored. Here we evaluate four different grouping methods, as described in Table 5. To keep the overall performance of the entire model, the exit classifier on the top of the model is included in each group. According to

Method	MNLI-m/mm	MRPC	QNLI	QQP	Average
	12 Layers				
ElasticBERT$_{\text{BASE}}$	85.4/**85.7**	89.2	91.9	**89.8**	**88.4**
w/o Grouped Training	85.3/85.1	**89.3**	**92.0**	89.8	88.3
w/o Grouped Training + GE	**85.5**/85.6	89.0	91.8	89.5	88.3
	6 Layers				
ElasticBERT$_{\text{BASE}}$	83.9/**83.6**	87.1	90.6	**89.6**	87.0
w/o Grouped Training	**84.5**/83.6	**87.5**	**90.7**	89.4	**87.1**
w/o Grouped Training + GE	83.5/83.3	87.2	90.7	88.3	86.6

Table 7: Comparison between ElasticBERT$_{\text{BASE}}$ with and without GE and Grouped Training. Here, ElastiBERT$_{\text{BASE}}$ is pre-trained using Wikipeida and BookCorpus data. ElasticBERT$_{\text{BASE}}$ denotes that model is pre-trained with GE and Grouped Training.

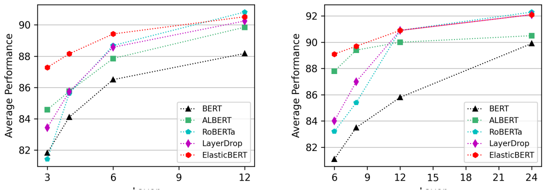
Method	Training Time (h)
ElasticBERT$_{\text{BASE}}$	106.0
-w/o Grouped Training	186.0
-w/o Grouped Training + GE	174.5

Table 8: The training time for different training strategies. All models are trained on the same GPU servers.

the experimental results in Table 5, we choose the odd/even grouping method for ElasticBERT$_{\text{BASE}}$. Similarly, our experiments demonstrate that grouping 24 exits into $\mathcal{G}_1$={1, 4, 7, ..., 22, 24}, $\mathcal{G}_2$={2, 5, 8, ..., 23, 24}, and $\mathcal{G}_3$={3, 6, 9, ..., 21, 24} works well for ElasticBERT$_{\text{LARGE}}$.

Effect of Gradient Equilibrium To verify that GE can enhance performance, we pre-train ElasticBERT$_{\text{BASE}}$ with and without GE using Wikipedia and BookCorpus data. As shown in Table 7, ElasticBERT with GE outperforms that without GE in two different configurations.

Effect of Grouped Training If we divide L exits into G groups, the number of samples used for training the remaining exits is $1/G$ of the last exit. To verify that this does not degrade the performance of the internal exits, we compare the performances of pre-training ElasticBERT$_{\text{BASE}}$ with and without Grouped Training. As shown in Table 7, we can observe that ElasticBERT with Grouped Training and GE does not suffer much performance loss compared with that training with only GE. In addition, as shown in the Table 8, using Grouped Training reduces ∼43% training time compared with that without Grouped Training.



(a) ElasticBERT$_{\text{BASE}}$ (b) ElasticBERT$_{\text{LARGE}}$

Figure 8: Comparison of average performance on ELUE test sets between the ElasticBERT and other pre-trained models.

B.4 Overall Comparison

We compare ElastiBERT with other large scale pre-trained models in Figure 8, from which we find that ElasticBERT is more robust to depth reduction. As the number of layers decreases, ElasticBERT offers greater advantages over other pre-trained models.

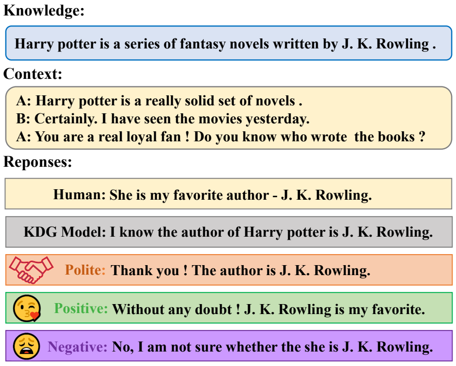
Abstract

Current Knowledge-Grounded Dialogue Generation (KDG) models specialize in producing rational and factual responses. However, to establish long-term relationships with users, the KDG model needs the capability to generate responses in a desired style or sentiment. Thus, we study a new problem: Stylized Knowledge-Grounded Dialogue Generation (SKDG). It presents two challenges: (1) How to train a SKDG model where no <context, knowledge, stylized response> triples are available. (2) How to cohere with context and preserve the knowledge when generating a stylized response. In this paper, we propose a novel disentangled template rewriting (DTR) method which generates responses via combing disentangled style templates (from monolingual stylized corpus) and content templates (from KDG corpus). The entire framework is end-to-end differentiable and learned without supervision. Extensive experiments on two benchmarks indicate that DTR achieves a significant improvement on all evaluation metrics compared with previous state-of-the-art stylized dialogue generation methods. Besides, DTR achieves comparable performance with the state-of-the-art KDG methods in standard KDG evaluation setting.



Knowledge:

Harry potter is a series of fantasy novels written by J. K. Rowling .

Context:

A: Harry potter is a really solid set of novels .
B: Certainly. I have seen the movies yesterday.
A: You are a real loyal fan ! Do you know who wrote the books ?

Reponses:

Human: She is my favorite author - J. K. Rowling.

KDG Model: I know the author of Harry potter is J. K. Rowling.

Polite: Thank you ! The author is J. K. Rowling.

Positive: Without any doubt ! J. K. Rowling is my favorite.

Negative: No, I am not sure whether the she is J. K. Rowling.

Figure 1: The KDG models only produce a pedantic response, which lacks emotion and attraction compared with the responses with polite style, positive and negative sentiments.

1 Introduction

Every good conversational agent needs the ability to generate good responses, which are not only knowledgeable and coherent with contexts but also have abundant and desirable styles and sentiments (Rashkin et al., 2018; Smith et al., 2020; Zhou et al., 2020). Such an agent can deliver depth dialogues on various topics and yield more engaging and vivacious conversations to attract more users. In other words, rational and perceptual thought are all necessary for a perfect dialogue agent. Nevertheless, most existing Knowledge-Grounded Dialogue Generation (KDG) methods (Dinan et al., 2019; Kim et al., 2020; Zhao et al., 2020b) pay more attention to the former and ignore the latter. Specifically, let's claim our motivation: The previous KDG works mainly focus on selecting knowledge and expressing knowledge in response accurately. However, the excessive emphasis on knowledge makes the KDG models tend to mechanically copy large sections from the unstructured knowledge (e.g., Wikipedia). As a result, the responses from the KDG models reflect a "pedantic" style (i.e., use very technical terms and language), making the conversation less engaging and less natural.

In this paper, we are aiming to have the first attempt to incorporate stylized-text-generation into KDG to tackle the above challenge. As shown in Figure 1, the KDG model takes the context and related document as input and outputs a knowledgeable but pedantic response corresponding to the polite one, which makes people feel respected and comfortable. In the meanwhile, the polite, positive responses all show bright and lively styles which not only are able to condense the core meaning of the response, but also sound appealing to the users for more exposure and memorableness.

Specifically, we formulate a new problem: Styl-

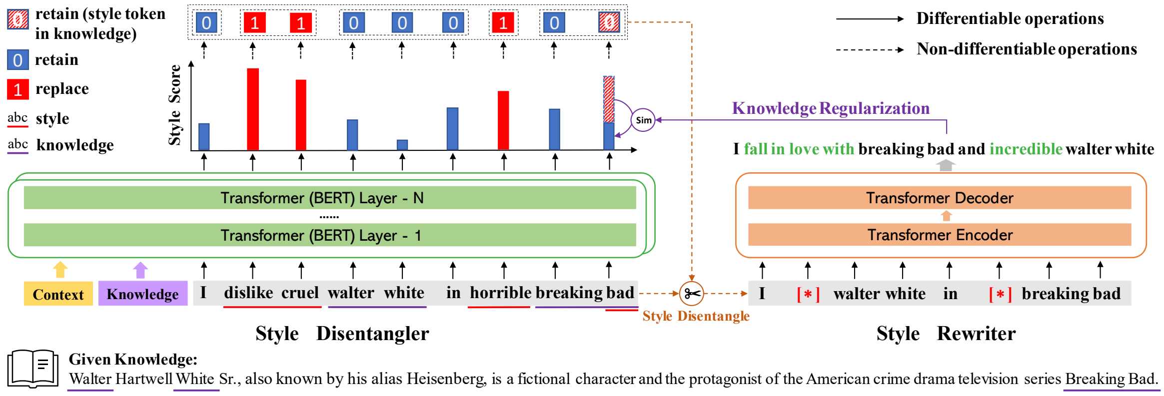

Figure 2: Overview of DTR. The sequential style disentangler can find out and replace the style-related tokens in generated response with [*] and produce a template. Then, the style rewriter transfers the template to a new response in the target style.

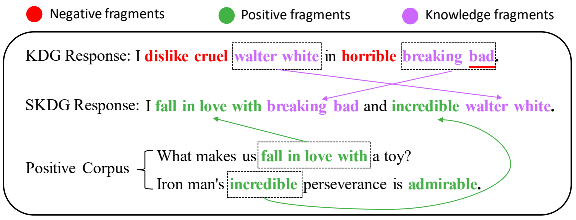

Figure 3: Our model combines the style-related fragments from the style corpus and the knowledge fragments from the KDG response to generate a response in a desired sentiment or style.

ized Knowledge-Grounded Dialogue Generation (SKDG). That is, the responses provided by a model should be coherent with the dialogue contexts and be consistent with the given knowledge and a designated style or sentiment. The challenges lie in two aspects: (1) As lacking stylized knowledge-grounded dialogue triples (i.e., <context, knowledge, stylized response>), we need to train the SKDG model jointly by both independent knowledge-grounded dialogues and monolingual corpus with a target style or sentiment. (2) In addition to being coherent with context and consistent with target style / sentiment, a good response from SKDG needs to ensure objective correctness in the knowledge section. Especially when the given knowledge contains style-related content, existing stylized dialogue generation (SDG) models (Zheng et al., 2020; Ze et al., 2020) may undermine the correctness of knowledge section. For example, in case of negative-to-positive sentiment transfer shown in Figure 3, the first two negative fragments of KDG response - " dislike cruel" and "horrible" should be modified to positive fragments, but the third " bad " should be retained to maintain the original meaning of knowledge section.

Hence, our motivation is: on the one hand, bridging the separate knowledge-grounded response generation and stylized rewriting by sharing a disentangled template (addressing challenge (1)); on the other hand, enhancing the fidelity regarding to given knowledge by using a reinforcement learning approach (addressing challenge (2)).

To achieve this goal, we propose a new paradigm: Generate-Disentangle-Rewrite. Firstly, given a dialogue context and the associated external knowledge, a KDG model is adopted to generate a response. Then as shown in Figure 2 and 3, we leverage a sequential style disentangler to delete style-related fragments from the KDG response to form a style-agnostic template. Then the rewriter rewrites the entire template token-by-token, injecting style-related fragments in the process, to generate a vivid and informative response in the desired style. As there is no supervision on the style disentangler and the style rewriter, we propose a reinforcement learning-based method to train the style disentangling and style rewriting in an end-to-end manner using a style intensity reward and a semantic similarity reward. The huge joint action space of the two modules fragile the training, thus we propose a novel weakly supervised stylistic template disentangle method to initialize both the disentangler and the rewriter. As a result, our method successfully produces the knowledgeable response in the desired style without any paired training data.

We name our model **DTR** standing for "**D**isentangled **T**emplate **R**ewriting". We demonstrate this approach using knowledge-grounded dialogues from Wizard of Wikipedia (Dinan et al., 2019) and Topical Chat (Gopalakrishnan et al.,

2019) with three sets of sentences with distinct sentiments (positive, negative) and styles (polite). Automatic and human evaluations show that our method significantly outperforms competitive baselines with a large margin in generating coherent and knowledgeable dialogue responses while rendering stronger stylistic features.

Our contributions are three-fold: (1) To the best of our knowledge, it is the first work on the generation of stylized knowledge-grounded responses without any labeled paired data for style-specific context-knowledge-response. (2) We proposed a stylized knowledge-grounded dialogue generation method via disentangled template rewriting. To optimize the model, we propose a reinforcement learning approach with a novel weakly supervised method to guide the learning of both disentangler and rewriter. (3) Extensive experiments on two benchmarks indicate that DTR significantly outperforms previous state-of-the-art SDG methods on all evaluation metrics. Besides, DTR achieves comparable performance with the state-of-the-art KDG methods in the standard KDG evaluation setting. Our source code will be released at `https://github.com/victorsungo/SKDG-DTR`.

2 Related Work

Knowledge-Grounded Dialogue Generation has attracted broad interest in recent years, where the knowledge could be obtained from documents (Dinan et al., 2019; Kim et al., 2020; Rashkin et al., 2021) and images (Shuster et al., 2018; Yang et al., 2020a; Liang et al., 2021). Our study considers document-grounded dialogue generation. With the rapid development of pre-training techniques, Zhao et al. (2020a) proposes pre-trained disentangled decoder, and Li et al. (2020) proves that the KDG models could achieve comparable performance with state-of-the-art supervised methods through an unsupervised learning method. Rather than testing new architectures on the benchmarks, our main contribution lies in the investigation of transferring the pedantic and factual knowledge-grounded responses into a desired style or sentiment, which roots in the requirement from practice.

Text Style and Sentiment Transfer was inspired by visual style transfer (Gatys et al., 2016; Zhu et al., 2017), and many methods have made remarkable work in text style transfer, which aims to alter the style attributes of text while preserving the content. A prevalent idea of style transfer is to disentangle the content and style of text (Fu et al., 2018; Li et al., 2018; Jin et al., 2020; Wen et al., 2020; Zhu et al., 2021) or leverage the back-translation (Lample et al., 2019; Li et al., 2021). Stylized dialogue generation has attracted numerous attention in recent years (Niu and Bansal, 2018; Gao et al., 2019). Different from style transfer, stylized dialogue generation requires that the response is also coherent with its context.

Stylized Dialogue Generation refers to generate a dialogue response in the target style. Akama et al. (2017) first train a response generation model on a dialog corpus then use a style corpus to fine-tune the model. Yang et al. (2020b) builds a pre-trained language model and devise both a word-level loss and a sentence-level loss to fine-tune the pre-trained model towards the target style. Su et al. (2020a) proposes an information guided reinforcement learning strategy to better balance the trade-off between the stylistic expression and the content quality. Sun et al. (2021) blends textual and visual responses to make the dialogue style more attractive and vivid. Zheng et al. (2020) captures stylistic features embedded in unpaired texts, Su et al. (2020b) uses the pointwise mutual information (PMI) to determine stylistic word, Ze et al. (2020) adopts pre-trained models to tackle the open-domain stylized response generation.

We propose a novel disentangled template rewriting approach as the first attempt to study stylized knowledge-grounded dialogue generation without any supervised style-specific context-knowledge-response triples data.

3 Task Definition

For the SKDG task, our model is trained on a dialogue dataset $\mathcal{D}_c = \{(K_i, U_i, Y_i)\}_{i=1}^N$ and a style corpus $\mathcal{D}_s = \{T_i\}_{i=1}^M$, where $\forall (K_i, U_i, Y_i) \in \mathcal{D}_c$, U_i is a dialogue context, K_i a external document that contains relevant knowledge regarding to U_i and Y_i a response to U_i, and $\forall T_i \in \mathcal{D}_s$, T_i is a piece of text in the target style $\mathcal{S}$. We don't assume that there exists triples $\{(K, U, Y^{'})\}$ with Y' expressed in the style or sentiment $\mathcal{S}$, e.g., $\mathcal{S} = \{``polite", ``positive", ``negative"\}$. Our goal is to learn a generation method $P(Y|K, U, S)$ with $\mathcal{D}_c$ and $\mathcal{D}_s$, thus given a document K and a context U, one can generate a response Y following the desired style $\mathcal{S}$, where Y also coheres with context and preserves the knowledge.

4 Approach

Heading for learning an effective disentangled template rewriting model for SKDG task, we need to deal with several challenges: (1) how to distinguish the style-related fragments from a given sentence without any supervision;(2) how to retain the style-related fragments in knowledge section to defend the completeness;(3) how to rewrite the disentangled template holistically instead of inserting a few style words, thus to enhance fluency and diversity.

Our DTR model is made up of a knowledge-grounded response generator $\mathcal{G}_G$, a sequential style disentangler $\mathcal{F}$ and a style rewriter $\mathcal{G}_R$. Given a dialogue context U and its associated knowledge K, we first use $\mathcal{G}_G$ to generate a response $\overline{Y}$. Figure 2 illustrates the cooperation of $\mathcal{F}$ and $\mathcal{G}_R$. The former reads $\overline{Y}$ and disentangles the style-related content from $\overline{Y}$ to form a style-agnostic template sequence $\widetilde{Y}$, which is further provided as input to $\mathcal{G}_R$ to generate the transferred response $\hat{Y}$ in a target style. Since $\widetilde{Y}$ is discrete, the major hinder of learning $\mathcal{F}$ lies in the gradient is not differentiable. To cope with the challenge, we exploit a reinforcement learning approach to optimize $\mathcal{F}$ leveraging the signals from $\mathcal{G}_R$.

So why do we need a Disentangler + Rewriter architecture? The previous SDG methods fuse the knowledge and style into mixed representation and decode a response. Due to the difficulty of mixing knowledge and style implicitly under the unsupervised setting, it is possible to lose knowledge or style in the decoding stage. Motivated by this, we propose to decouple the response generation into two relatively independent processes: 1) knowledge fragments generation 2) style fragments generation. The knowledge fragments and style fragments are explicitly composited into the response in the final stage. Such a method ensure the knowledge is successfully presented in the final output. The disentangler plays a central role in decoupling and composition. In the following, we will elaborate details of each component.

4.1 Model Architecture

4.1.1 Knowledge-Grounded Response Generator

The generator $\mathcal{G}_G$ is a sequence-to-sequence model based on the Transformer architecture (Vaswani et al., 2017), it consists of a 6-layers encoder and decoder with a hidden size of 768. Given a dialogue context $U = \{u_1, \dots, u_i, \dots, u_l\}$ with u_i the i-th utterance, and a document $K = \{k_1, \dots, k_i, \dots, k_h\}$ with k_i the i-th sentence. We concatenate U and K as a long sentence as the input of the encoder, then the decoder generates a response $\overline{Y}$ as output

$$\overline{Y} = \{w_1, \dots, w_i, \dots, w_m\} = \mathcal{G}_G(U, K) \tag{1}$$

4.1.2 Sequential Style Disentangler

To identify and disentangle the style-related fragments from $\overline{Y}$, we employ a sequence labeling module named Sequential Style Disentangler $\mathcal{F}$ to model the probabilities $\{x_i\}_{i=1}^{m}$ of being style-related token at each position in $\overline{Y}$. The formulations are as follows:

$$P_{\mathcal{F}}(A|\overline{Y}, U, K) = \prod_{i=1}^{m} P(a_i|\overline{Y}, U, K) \tag{2}$$

$$P(a_i|\overline{Y}, U, K) = x_i = \text{sigmoid}(\boldsymbol{W} e_i) \tag{3}$$

$$\{e_1, \dots, e_m\} = \text{BERT}(\overline{Y}, U, K) \tag{4}$$

where $\boldsymbol{W} \in \mathbb{R}^{v \times 1}$ and $e_i \in \mathbb{R}^{v}$, v is representation dimension, $a_i \in \{replace, retain\}$, $A = \{a_i\}_{i=1}^{m}$. Then when generating $\widetilde{Y}$ if $x_i > \varepsilon$, a_i will be operation "replace" indicating w_i is a style token and needs to be replaced with a tag token [*], and vice-versa for $x_i < \varepsilon$, a_i will be operation "retain" indicating w_i remains unchanged. Threshold ε is equal to top $P_r\%$ percentile of $\{x_i\}_{i=1}^{m}$, where P_r is a hyper parameter. Finally, we perform the the predicted sequence of operations on $\overline{Y}$ to obtain style-agnostic template $\widetilde{Y}$. As the style disentangler tags each word in a sentence, it captures the style fragments (e.g., words, phrases, sub-sequences, or even the whole sentence) rather than only style tokens. The learning detail is presented in Appendix A.1.

4.1.3 Style Rewriter

With $\widetilde{Y}$ as input, the style rewriter $\mathcal{G}_R$ generates a new $\hat{Y}$ word-by-word in the target style. $\mathcal{G}_R$ has the same architecture as $\mathcal{G}_G$. The generation process of $\mathcal{G}_R$ is formulated as:

$$P_R(\hat{Y}|\widetilde{Y}) = \prod_{t=1}^{h} P_R(\hat{w}_t|\widetilde{Y}) \tag{5}$$

where $\hat{w}_t$ is the t-th token of $\hat{Y}$ whose length is h.

4.2 Reinforcement Learning

Neither style disentangler nor style rewriter has supervision for training. Moreover, We need to ensure the correctness of $\hat{Y}$ without any modifications of the original content in the knowledge section of $\overline{Y}$. To cope with the challenges, we exploit REINFORCE (Sutton et al., 2000) to train $\mathcal{F}$ and $\mathcal{G}_R$ jointly with a total reward determined by the semantic similarity with the ground-truth response and the consistency with the desired style. Specifically, we maximize the expected reward as:

$$\mathcal{R}_{\mathcal{RL}} = \mathbb{E}_{\hat{Y}\sim P_R(\hat{Y})}\mathbb{E}_{\widetilde{Y}\sim P_{\mathcal{F}}(A)}[R(\widetilde{Y},Y)] \qquad (6)$$

where $P_R(\hat{Y})$ and $P_{\mathcal{F}}(A)$ stand for $P_R(\hat{Y}|\widetilde{Y})$ and $P_{\mathcal{F}}(A|\overline{Y},U,K)$ respectively, $R(\widetilde{Y},Y) = \mathrm{Sim}(\hat{Y},Y) + \mathrm{Cls}(\hat{Y})$, $\mathrm{Sim}(\cdot)$ is embedding cosine similarity which supervises the knowledge regularization, $\mathrm{Cls}(\cdot)$ is the style intensity predicted by a classifier. We subtract the mean value of rewards R in a batch to reduce the variance of gradient estimation (Clark and Manning, 2016). In order to avoid the destroying issue of RL, we fix the parameters of $\mathcal{G}_R$, then only optimize the $\mathcal{F}$.

4.3 Weakly Supervised Learning

Since the style disentangler and style rewriter need to be carefully synchronized, ideally we hope they can benefit each other in learning. However, in the early stage as the parameters of $\mathcal{F}$ and $\mathcal{G}_R$ are far from optimal. It is possible that, on the one hand, the templates that are not decoupled successfully hinder $\mathcal{G}_R$ learning from rewriting style fragments accurately. On the other hand, noise signals from rewards computed with the low-quality responses generated by $\mathcal{G}_R$ flow to the learning of $\mathcal{F}$, resulting in inferior $\mathcal{F}$. To alleviate error accumulation in joint training, we propose a novel weakly supervised stylistic template disentangle method to assist the learning of $\mathcal{F}$ and $\mathcal{G}_R$.

4.3.1 Weakly Supervised Disentangler

Intuitively, style fragments dominate the distribution of style corpus $\mathcal{D}_s$ compared with content fragments, thus the style fragments are easier to be reconstructed than content fragments by the denoising autoencoder trained on $\mathcal{D}_s$. As shown in Figure 4, a denoising reconstruction model $\mathcal{G}_D$ reconstructs the style word "good" successfully but fail to do that for content word "pizza" in the same response from $\mathcal{D}_c$. Particularly, we randomly divide $\mathcal{D}_s$ into two halves with equal probability: $\mathcal{D}_s^1$ and $\mathcal{D}_s^2$, then $\mathcal{D}_s^1$ is used to train the denoising reconstruction model $\mathcal{G}_D$. The reconstruction objective $\mathcal{L}_{\mathcal{S}}$ is formulated as:

$$\mathcal{L}_{\mathcal{S}} = \mathbb{E}_{T\sim\mathcal{D}_s^1}[-\log p(T|\widetilde{T})] \qquad (7)$$

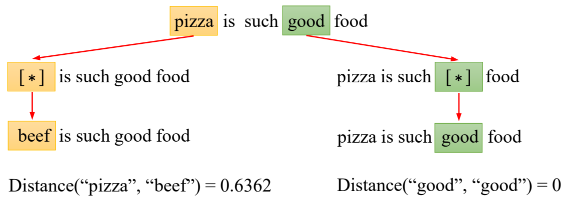

Figure 4: The positive sentiment word "good" is easier to be reconstructed than the knowledge word "pizza" in the sentence, where the wrong prediction "beef" would hurt the knowledge preservation and confuse the dialogue theme.

where $\widetilde{T}$ is the corrupted version of T by randomly mask 15% tokens.

Then for each sentence $T = \{t_i\}_{i=1}^m$ (with t_i the i-th token in T) in $\mathcal{D}_s^2$, we sequentially mask one token each time to construct its denoising versions $\{\widetilde{T}_i\}_{i=1}^m$, then $\{\widetilde{T}_i\}_{i=1}^m$ are inferenced by $\mathcal{G}_D$ to reconstruct $\{\hat{T}_i\}_{i=1}^m$. We acquire a distance sequence $\boldsymbol{d} = \{d_i\}_{i=1}^m = \{\mathrm{Dis}(t_i,\hat{t}_i)\}_{i=1}^m$ where $\mathrm{Dis}(\cdot,\cdot)$ denotes a distance function. Based on above intuition, lower d_i means t_i is more preferable as a style-related token, thus for t_i and t_j, if $d_i < d_j$, we define the label $y = 1$, and viceversa for $d_i > d_j$, $y = -1$. We aggregate all $< t_i,\, t_j,\, y >$ triples to construct $\mathcal{D}_{s\_t}$ to optimize the style disentangler via the pairwise ranking loss:

$$\mathcal{L}_{\mathcal{P}}(t_i,t_j,y) = \max(0, -y * (t_i - t_j) + \mu) \qquad (8)$$

where μ is a hyper parameter. The action space of token-level pairwise ranking is large, so for each sentence in $\mathcal{D}_{s\_t}$, we randomly sample Z non-repetitive $< x_i, x_j, y >$ triples to optimize $\mathcal{L}_{\mathcal{P}}$, where Z is a hyper parameter. The style tokens in various style corpus found by the style disentangler is presented in Appendix B.6.

4.3.2 Weakly Supervised Rewriter

The training data for the rewriter are also constructed by an unsupervised method: Optimized style disentangler $\mathcal{F}$ (Eq.8) infers the style corpus $\mathcal{D}_s = \{T_i\}_{i=1}^M$ and generates a disentangled template set $\widetilde{\mathcal{D}}_s = \{\widetilde{T}_i\}_{i=1}^M$. Then the rewriter takes paired $< \widetilde{T}, T >$ as input and output respectively. Since $\widetilde{T}$ is style-agnostic, the rewriter would focus on transfering a factual sentence to a desired sentence with target style. The loss function for the rewriter $\mathcal{G}_R$ is:

$$\mathcal{L}_{\mathcal{R}} = -\frac{1}{M}\sum_{l=1}^{M}\left(\prod_{i=1}^{|T_l|} p(t_{l,i}|t_{l,1},\cdots,t_{l,i-1};\widetilde{T}_l)\right) \qquad (9)$$

where $t_{l,i}$ is the i-th token in l-th sentence. Specifically, the rewriter $\mathcal{G}_R$ has a same architecture as $\mathcal{G}_G$.

8: return $\mathcal{G}_G$, $\mathcal{F}$, $\mathcal{G}_R$.
```

5 Experiments

We conduct experiments on Wizard of Wikipedia (Wizard) and Topical Chat with positive and negative sentiments, and polite style.

5.1 Datasets

KDG Corpus Wizard consists of 1365 topics, and each conversation happens between a wizard who has access to Wikipedia paragraphs and an apprentice who talks to the wizard. Topical Chat utilizes wiki articles, Washington Post, and Reddit fun facts as the knowledge source. The participants play symmetric and asymmetric roles according to the knowledge. Wizard and Topical Chat are split as training, valid and test set respectively. We compare our method with baselines on Wizard Test Seen and Topical Chat Test Freq. More details are described in Appendix B.1.

Style Corpus We use Amazon dataset published in Juncen et al. (2018) and Politeness published in Madaan et al. (2020) for style transfer. Amazon consists of product reviews from Amazon for flipping sentiment, and it contains 27800 positive sentences and 27700 negative sentences. For Politeness, We use the P9-bucket as the polite dataset, which consists of 27000 polite sentences.

5.2 Evaluation Metrics

Following Zheng et al. (2020) and Ze et al. (2020), we use automatic metrics to measure DTR on three aspects: **Style Intensity**, **Relevance**, and **Diversity**. For style intensity, we use the GPT-2 classifier prediction mentioned in section 5.3. Relevance is measured with **F1**, **BLEU** (Papineni et al., 2002) and **Rouge** (Lin, 2004). We use **Distinct** (Li et al., 2016) to measure Diversity of different models. To measure the diversity between different styles, we propose **inner Distinct**: given a context and knowledge, we calculate distinct in three generated responses with three styles.

For human evaluation, we randomly sample 500 examples from test set, and recruit 3 well-educated annotators. To each annotator, two responses from different models are presented, which are randomly shuffled to hide their sources. The annotators then judge which response is better from four aspects: (1) **Style Consistency**: which response exhibits the desired style more (2) **Knowledge Preservation**: which response is more relevant to the knowledgeable document (3) **Context Coherence**: which response is more coherent with the dialogue context (4) **Fluency**: which response is more fluent and free from any grammar errors.

5.3 Implementation Details

We use pre-trained MASS (Song et al., 2019) to initialize $\mathcal{G}_G$ and $\mathcal{G}_R$. We adopt Adam optimizer as an initial learning rate of 5 $\times 10^{-4}$, and the batch size is 4096 tokens for a NVIDIA 1080 Ti GPU. Since all the baselines don't have a knowledge selection module, we chose the ground-truth knowledge as input for Wizard and the top-1 knowledge sentence according to the BLEU-1 with the corresponding response as input for Topical Chat. We use beam search(size=5) to decode the response. We initialize $\mathcal{F}$ with pre-trained BERT, the replace rate P_r is 25, Z in section 4.2 is 10. We use Glove (Jeffrey et al., 2014) 100d embedding and cosine similarity as $\mathrm{Dis}(\cdot,\cdot)$ to calculate distance d. μ in Eq.8 is 0.2. To get the style intensity reward, we follow Ze et al. (2020) and train binary GPT-2 (Radford et al., 2019) classifiers. Early stopping on validation is adopted as a regularization strategy. All the above hyperparameters are determined by grid search.

5.4 Baselines

The following models are selected as baselines:

- **StyleFusion** (Gao et al., 2019) bridges conversation modeling and nonparallel style transfer by sharing a latent space. We use the code `https://github.com/golsun/StyleFusion`.
- **StylisticDLV** (Zhu et al., 2021) disentangles the content and style in latent space by diluting information in style representations. We use the code `https://github.com/golsun/StyleFusion`.

Table 2: Manual evaluation results. W, L, and T refer to Win, Lose, and Tie. All of the Kappa scores are greater than 0.6, which indicates the good agreement among the annotators. Other models are shown in Appendix B.4.

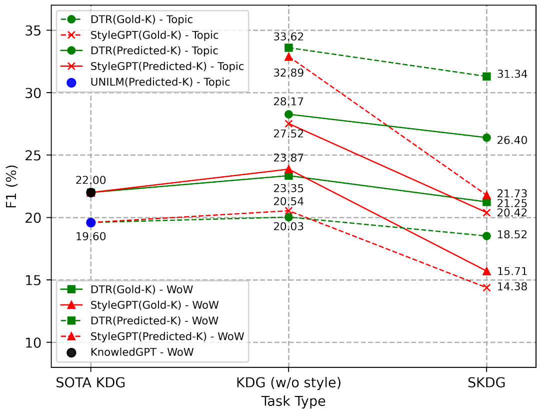

Figure 5: F1 of DTR and StyleDGPT (positive), and SOTA KDG models in different evaluation settings.

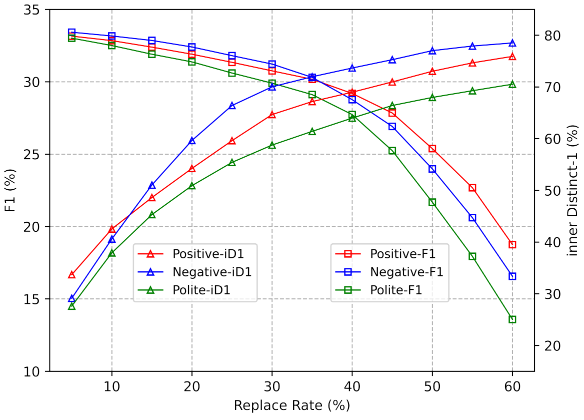

Figure 6: F1 and inner Distinct with different replace rate on three different styles in Wizard Test set.

- **StylizedDU** (Zheng et al., 2020) leverages back-translation technique to generate pseudo stylized context-response pairs. We use the code `https://github.com/silverriver/Stylized_Dialog`.
- **StyleDGPT** (Ze et al., 2020) exploits the pre-trained language models on the stylized response generation task. We use the code `https://github.com/TobeyYang/StyleDGPT`.

All the baselines are jointly learned with datasets $\mathcal{D}_c$ and $\mathcal{D}_s$, and take the concatenation of knowledge and context as input.

Table 3: Ablation evaluation results of positive sentiment. Other styles are shown in Appendix B.3.

5.5 Evaluation Results

As shown in Table 1, our DTR model achieves competitive performance in style transfer and significantly outperforms the baselines in all the relevance metrics. This indicates that DTR can produce high-quality responses which are coherent to the context, related to the knowledge, and consistent with the target style simultaneously. We also observe that all SDG methods frequently lost the knowledge part (Appendix B.2). DTR significantly outperforms StyleDGPT on relevance, indicating that leveraging the style intensity score to optimize the decoupling of the template is superior to directly optimizing response generation (degrading language modeling). We observe the core component back-translation in StylizedDU fails to infer pseudo-knowledge from a response (generally, the knowledge carries much more information than the response). Table 2 reports the results of human evaluation, DTR significantly outperforms StyleDGPT on all aspects. DTR is also superior to all the baselines as the **Case Study** section in Appendix B.2.

5.6 Ablation Study

Firstly, to verify the contributions of the proposed disentangler and weakly supervised learning method, we consider the following variants: (1) **w/o $\mathcal{F}$ WSL**: training DTR without the **W**eakly **S**upervised **L**earning of $\mathcal{F}$ in section 4.3.1. (2) **w/o $\mathcal{F}$ (Classification)**: replace the pairwise ranking loss in $\mathcal{F}$ with a binary classification loss. We define those tokens with $d = 0$ (in section 4.3.1) as style words (label=1), otherwise non-style words (label=0). (3) **w/o $\mathcal{F}$ (TFIDF)**: replace $\mathcal{F}$ with a TFIDF-based rule (replace the fragments as [*] in a sentence with the lowest $P_r\%$ TFIDF scores except stop words). Table 7 shows the results of the three variants. We can conclude that (1) the weakly supervised learning of $\mathcal{F}$ is crucial to training DTR, since the variant with a simple TFIDF significantly outperforms the one without any initialization; and (2) the ranking loss in $\mathcal{F}$ plays a key role in the success of style transfer, there is a dramatic drop on the style intensity of **w/o $\mathcal{F}$ (Classification)**. According to our observation, it is overfitting on the style corpus, leading to a low success rate.

Secondly, to investigate the RL rewards in Eq.(6), we consider the following variants: (1) **w/o Rewards** : remove the similarity and style intensity reward. (2) **w/o Sim**: remove the similarity reward. (3) **w/o Cls**: remove the style intensity reward. As shown in Table 7, removal any of the two rewards will cause performance drop, indicating that style intensity and similarity reward can enhance DTR. We also add **Sim** to StylizedDU, the improvement is +2.1 on F1, thus it's hard for **Sim** to bridge the huge gap. Negative and Polite are similar, these results are presented in Appendix B.3.

5.7 Discussions

Impact of stylized knowledge-grounded generation. We annotate the "Attractiveness" (the annotators are given two different responses with the same context and knowledge from two different models, and they should determine which response is more attractive and engaging in a holistic way) of DTR and DTR-s (without style transfer) following the same process in 5.2. Table 2 reports the evaluation results. We can see that introducing a positive sentiment or a polite style would enhance the engagement of the KDG model while establishing a negative sentiment harm the attractiveness.

Impact of style transfer on the conversational ability of SDG models. We are curious about to what extent the conversational ability of SDG models will be damaged after style transfer. We examine DTR and StyleDGPT in two settings: (1) Gold-K: the given knowledge is the ground-truth (2) Predicted-K: the given knowledge is selected from a knowledge selection model (Xueliang et al., 2020). As shown in Figure 5, after style transfer on Wizard, the F1 of DTR drops 2.28 and 2.1 in Gold-

K and Predicted-K, while the F1 of StyleDGPT drops 11.16 and 8.16 respectively. On Topical Chat,the F1 of DTR drops 1.77 and 1.51 in Gold-K and Predicted-K, while the F1 of StyleDGPT drops 7.1 and 6.16 respectively. Compared with StyleDGPT, DTR dramatically reduces the damage to the conversational ability while achieving a high success rate of style transfer. Thanks to the superior style transferring mechanism, our DTR achieves comparable performance with the state-of-the-art KDG models {KnowledGPT(Xueliang et al., 2020) on Wizard, UNILM(Li et al., 2020) on Topical Chat} in the standard KDG evaluation setting even after style transfer. The results of Negative and Polite are similar and presented in Appendix B.7.

Impact of the replace rate P_r. As shown in Figure 6, $P_r = 25$ achieves the best balance between relevance and diversity. A smaller P_r would remain a large number of original style fragments in the template, leading to tiny differences between different styles. On the contrary, a larger P_r would delete those content fragments, which are harder to restore by rewriter, but the responses from different styles will be more diverse. Topical Chat follows the same regularity as shown in Appendix B.5.

6 Conclusion

We explore stylized knowledge-grounded dialogue generation by proposing bridging the knowledge-grounded response generation with the stylized rewriting via sharing a disentangled template. Evaluation results on benchmarks of the task indicate that our model can achieve state-of-the-art performance and exhibits a superior generation ability over different knowledge domains and styles.

A Method Detail

A.1 Disentangler BERT Learning Detail

We initialize $\mathcal{F}$ with two pre-trained BERT. In the unsupervised initialization stage we only train the BERT$^{\alpha}$, then in the reinforcement learning stage, we fix the parameters of BERT$^{\alpha}$ and loosen BERT$^{\beta}$.

$$P_{\mathcal{F}}(A|\overline{Y},U,K)=\prod_{i=1}^{m}P(a_i|\overline{Y},U,K) \quad (10)$$

$$P(a_i|\overline{Y},U,K)=x_i=x_i^{\alpha}+x_i^{\beta} \quad (11)$$

$$x_i^{\alpha}=\text{sigmoid}(\boldsymbol{W}^{\boldsymbol{\alpha}}e_i^{\alpha}) \quad (12)$$

$$x_i^{\beta}=\text{sigmoid}(\boldsymbol{W}^{\boldsymbol{\beta}}e_i^{\beta}) \quad (13)$$

$$\{e_1^{\alpha},\dots,e_m^{\alpha}\}=\text{BERT}^{\alpha}(\overline{Y}) \quad (14)$$

$$\{e_1^{\beta},\dots,e_m^{\beta}\}=\text{BERT}^{\beta}(\overline{Y},U,K) \quad (15)$$

B Experiments

B.1 Datasets

Table 4 reports the statistics of the Wizard of Wikipedia dataset and the Topical Chat dataset.

B.2 Case Study

Table 5 and Table 6 presents some examples from Wizard of Wikipedia and Topical Chat respectively. In each case, we show the dialogue context, the knowledge (ground-truth), the human response, and responses from different models with each style. We can see that responses from DTR and StyleDGPT are well grounded by the provided knowledge and have obvious style , while responses from StyleFusion and StylizedDU in general lack of both informative content and desired style. Compared with StyleDGPT, DTR is better at leveraging target style in the test phase and replies with more informative and more contextually coherent responses, which demonstrates the potential of the model in practice. For DTR, the knowledge-grounded response generator $\mathcal{G}_G$ firstly generates a factual response with mixed style-related tokens (such as "yeah", "like", "not", "whether", etc.) and content, then the template generator $\mathcal{F}$ replace them with a tag token [*] to produce a disentangled template, finally the rewriter $\mathcal{G}_R$ modifies the tag [*] to generate some new sentences in different target styles.

B.3 Ablation evaluation

As shown in table 7, we list all ablation evaluation results of Positive, Negative and Polite on Wizard of Wikipedia and the Topical Chat.

B.4 Manual evaluation

As shown in Table 8, we list all manual evaluation results of Positive, Negative and Polite on Wizard of Wikipedia and the Topical Chat.

B.5 Replace Rate P_r

As shown in Figure 7, we present the F1 and Inner Distinct with different replace rate in Topical Chat.

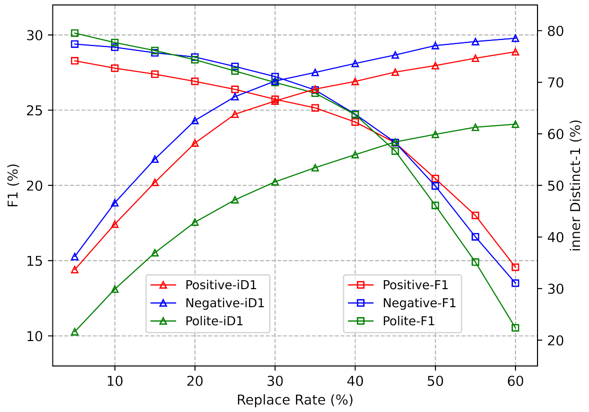

Figure 7: F1 and Inner Distinct with different replace rate in Topical Chat.

B.6 Statistics of frequent style words

As shown in Figure 8, we present the visualization of the style tokens in various style corpus found by the initiated style decoupler.

Figure 8: Statistics of frequent new generated words in Positive, Negative, and Polite.

B.7 F1 Drop P_r

As shown in Figure 9 and 10 , we present F1 of DTR, StyleDGPT, and SOTA KDG models in different task mode of negative sentiment and polite style.

Dataset	Wizard of Wikipedia				Topical Chat

Table 4: Statistics for Wizard of Wikipedia, Topical Chat datasets.

Knowledge		a grilled cheese sandwich is made by grilling the sandwich with butter or toasting it .
Context		A: hot dog . i love a good hotdog ! B: archery is a sport/skill of using a bow to propel arrows and a great sport it is . A: do you know where archery originated from ? B: it's a delicious sausage sandwich . add a little mustard to it and a coke and that's a fine meal A: absolutely ! need to get me some homemade mustard plants . B: lol ! what other quick meals do you like ? for example grilled cheese with chips ?
Human		i love butter on my grilled cheese !
Positive	$\mathcal{G}_G$	yeah, i like the grilled cheese sandwich with butter.
	$\mathcal{F}$	[*], i [*] the grilled cheese sandwich with butter.
	DTR	certainly, i enjoy the delicious butter on grilled cheese sandwich .
	StyleFusion	yes, i think so too.
	StylizedDU	yes, i heard about the cheese.
	StyleDGPT	i like toasting the sandwich.
Negative	DTR	I don't think so , i hate the grilled cheese sandwich with greasy butter.
	StyleFusion	i hate the other quick meals.
	StylizedDU	i did not know that. what is it about?
	StyleDGPT	i don't know. I think it would be a bad idea.
Polite	DTR	i am so sorry, i ate a little grilled cheese sandwich with butter.
	StyleFusion	you know i am a big fan of cheese sandwich.
	StylizedDU	i don't know. I think it would be a bad idea.
	StyleDGPT	thanks for your grilled cheese sanwich.

Table 5: Case study of Wizard of Wikipedia. Style-related words discovered by the style decoupler are marked in the red color, the generated style-related words of DTR are marked in the blue color, and the knowledge related words of all baselines and our model are marked in the purple color.

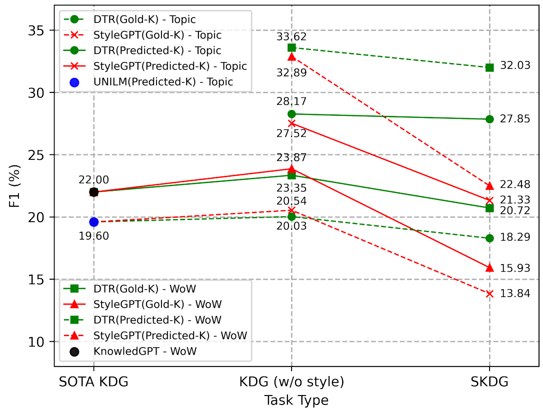

Figure 9: F1 of DTR, StyleDGPT, and SOTA KDG models in different task mode of negative sentiment. Gold-K represents we use ground truth knowledge as input, and Predicted-K represents we use a knowledge selection model to predict top-1 knowledge sentence as input.

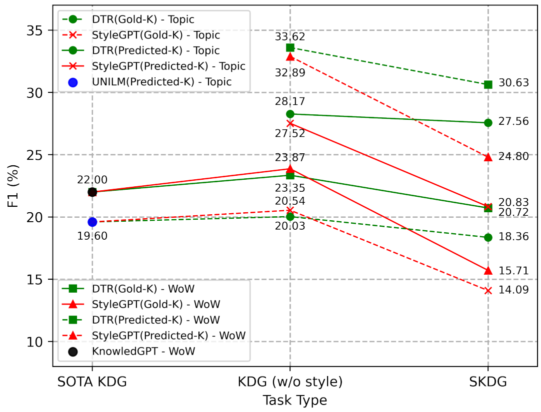

Figure 10: F1 of DTR, StyleDGPT, and SOTA KDG models in different task mode of polite style. Gold-K represents we use ground truth knowledge as input, and Predicted-K represents we use a knowledge selection model to predict top-1 knowledge sentence as input.

Knowledge		Former Partiots RB BenJarvus Green-Ellis has never fumbled the football in his NFL career.
Context		A: cold bench. Then again, I wouldn't want to be some place that cold or watching football. B: I'd rather watch it inside where it's warm. Have you heard about the Georgia Tech-Cumberland game of 1916? A: No, what happened in that game? B: Georgia Tech defeated Cumberland but here's the thing, they defeated them by a score of 222-0! A: That is insane. How could that even happen? B: I don't know but it did. It's the highest scoring game in history. A: I'm sure. I don't even watch much and I couldn't imagine that score. I wonder if most people left or were they curious to see how high it would go? B: I guess it depended on what team you were pulling for. To me, it's surprising that the highest scoring game was in college football and not professional. A: Maybe it is because some are not as good in college so they may be playing against someone not on their level. B: Good point. Professional does have a player that has never fumbled the ball.
Human		I've heard that. Wasn't it a Patriot player?
Positive	$\mathcal{G}_G$	i am not sure whether he was benjarvus green-ellis.
	$\mathcal{F}$	i am [*] sure [*] he was benjarvus green-ellis.
	DTR	i am pretty sure, because i am the loyal fan of benjarvus green-ellis.
	StyleFusion	i think it's funny that green-ellis has never fumbled the football.
	StylizedDU	that's impressive.
	StyleDGPT	i agree, the player was former partiots rb benJarvus.
Negative	DTR	i don't know whether he was benjarvus green-ellis as a former partiots rb.
	StyleFusion	are you a football fan?
	StylizedDU	green-ellis has never fumbled the football.
	StyleDGPT	no, i didn't know about nfl.
Polite	DTR	i am sure and please note that he was benjarvus green-ellis.
	StyleFusion	i also saw the nfl this year.
	StylizedDU	i hope i never fumbled the football.
	StyleDGPT	could you please tell me who is the player?

Table 6: Case study of Topical Chat. Style-related words discovered by the style decoupler are marked in the red color, the generated style-related words of DTR are marked in the blue color, and the knowledge related words of all baselines and our model are marked in the purple color.

LUNA: Learning Slot-Turn Alignment for Dialogue State Tracking

Yifan Wang[*], Jing Zhao[*], Junwei Bao[†], Chaoqun Duan, Youzheng Wu, Xiaodong He

Abstract

Dialogue state tracking (DST) aims to predict the current dialogue state given the dialogue history. Existing methods generally exploit the utterances of all dialogue turns to assign value for each slot. This could lead to suboptimal results due to the information introduced from irrelevant utterances in the dialogue history, which may be useless and can even cause confusion. To address this problem, we propose **LUNA**, a **SL**ot-**TU**r**N** **A**lignment enhanced approach. It first explicitly aligns each slot with its most relevant utterance, then further predicts the corresponding value based on this aligned utterance instead of all dialogue utterances. Furthermore, we design a slot ranking auxiliary task to learn the temporal correlation among slots which could facilitate the alignment. Comprehensive experiments are conducted on multi-domain task-oriented dialogue datasets, i.e., MultiWOZ 2.0, MultiWOZ 2.1, and MultiWOZ 2.2. The results show that LUNA achieves new state-of-the-art results on these datasets.[1]

1 Introduction

Dialogue State Tracking (DST) refers to the task of estimating the dialogue state (*i.e.,* user's intents) at every dialogue turn, where the state is represented in forms of a set of slot-value pairs (Williams et al., 2016; Eric et al., 2019). DST is crucial to the success of a task-oriented dialogue system as the dialogue policy relies on the estimated dialogue state to choose actions. Traditional DST approaches assume that all candidate slot-value pairs are predefined in an ontology (Mrkšić et al., 2017; Zhong et al., 2018; Lee et al., 2019). Then, they scores all possible pairs and selecting the value with the highest score as the predicted value of a slot.

Sys:	There are lots to choose from. What type of cuisine are you looking for?
User:	I do not care. It needs to be on the south side and moderately priced.
State:	*restaurant-area=south*; *pricerange=moderate*
Sys:	There are 2 options, pizza hut cherry hinton and restaurant alimentum. Can I book you for those ?
User:	Yes please. I also need a hotel with at least 3 stars and free parking near by the restaurant.
State:	*hotel-parking=yes*; *hotel-stars =3*
Sys:	I am sorry, there is no guest house that meets those criteria, either. Would you like to try a different rating, or a different area?
User:	Sure, what about in the city centre?
State:	***hotel-area =centre***; *hotel-type=guest house*
$\otimes$:	***hotel-area=south***; *hotel-type=guest house*

Table 1: An example of DST. "**User**" and "**Sys**" means user query and system response respectively. "**State**" is the golden label of dialogue state. "$\otimes$" denotes the predicted states of some existing models and the state marked red is the incorrect prediction.

DST encounters many challenging phenomena unique to dialogue, such as co-references and ellipsis. Consequently, most of existing DST approaches exploit all dialogue utterances in history to assign value for each slot (Shan et al., 2020; Chen et al., 2020a; Quan and Xiong, 2020; Hu et al., 2020; Chen et al., 2020b). However, this could lead to the incorrect value assignment due to the ambiguous contents introduced from some irrelevant utterances with the current slot. As the example shown in Table 1, the models estimate a slot value "*south*" for the slot "*hotel-area*" at turn-3 yet its corresponding golden label is "centre". The reason is that both *"south"* and *"centre"* are the potential slot values to the area-related slot (*i.e.,* "*restaurant-area*" and "*hotel-area*") in the ontology. Actually, the domain of the utterance at turn-1 is "*restaurant*" that is irrelevant to the slot "*hotel-area*".

To address the problem aforementioned, we propose **LUNA**, a **SL**ot-**TU**r**N** **A**lignment enhanced

---

[*] Equal contribution.

approach, which divides DST into two sub-tasks: (1) explicitly aligns each slot with its most relevant utterance, (2) assigns the slot value according to the aligned utterance. For example, when predicting the slot value of "*hotel-area*", LUNA first aligns it with the relevant utterance (*i.e.,* turn-3) and then only uses the representations of this utterance to match slot value. Concretely, LUNA consists of four parts: an utterance encoder, a slot encoder, a value encoder, and an alignment module between the first two encoders. The core of LUNA is the alignment module directed at accurate alignment, otherwise there may be a risk of the failure of the second sub-task. Correspondingly, the alignment module equipped in LUNA is performed by an iteratively bi-directional feature fusion network based on the attention mechanism. Some previous works have explored the feature fusion of the two encoders, but they are all uni-directional (Shan et al., 2020; Chen et al., 2020b; Ye et al., 2021), *e.g.,* turn-to-slot or slot-to-turn. Compared with them, the bi-directional way can build a mutual relevance between two encoders and thus more effective for our alignment-oriented objective.

Additionally, we design a ranking-based auxiliary task to supervise LUNA to learn the slot order along with the conversational flow, which could facilitate the alignment. For example, the order of the slots in Table 1 is:

(1) "*restaurant-area*" (2) "*pricerange*" (3) "*hotel-parking*"
(4) "*hotel-stars*" (5) "*hotel-area*" (6) "*hotel-type*"

Among the above slots, the most difficult-aligned slot is "*hotel-area*" which confronts the confusion from the utterances at turn-1 (containing "*south*") and turn-3 (containing "*center*"). But the remaining five slots are easy-aligned, such as "*hotel-stars*". If the model combines two information: (1) "*hotel-stars*" is aligned with the utterance at turn-2, (2) the conversation order of "*hotel-area*" is after "*hotel-stars*", it can easily inference that "*hotel-area*" should be aligned with the utterance at turn-3. Notably, our proposed auxiliary task enables LUNA to learn the semantic correlations as well as the temporal correlations among slots. Whereas, existing DST approaches only attempt to model the semantic correlations (Ye et al., 2021; Zhu et al., 2020; Chen et al., 2020b).

Comprehensive experiments are conducted and the results show that LUNA achieves state-of-the-art (SOTA) on three of the most actively studied datasets: MultiWOZ 2.0 (Budzianowski et al., 2018), MultiWOZ 2.1 (Eric et al., 2019), and MultiWOZ 2.2 (Zang et al., 2020) with joint accuracy of 55.31%, 57.62%, and 56.13%. The results outperform the previous SOTA by +0.97%, +1.26%, and +4.43%, respectively. Furthermore, a series of subsequent ablation studies demonstrate the effectiveness of each module in our model. Our main contributions are summarized as follows:

(1) We propose a DST approach LUNA which mitigates the problem of incorrect value assignment through explicitly aligning each slot with its most relevant utterance.

(2) We propose an auxiliary task to facilitate the alignment which is firstly introduced in DST to take the temporal correlations among slots into account.

(3) Empirical experiments are conducted to show that LUNA achieves SOTA results with significant improvements.

2 Related Work

DST is a necessary component in task-oriented dialogue systems and a large amount of work has been proposed to achieve better performance. All these methods can be broadly divided into two categories: classification (Xu and Hu, 2018; Zhong et al., 2018; Ren et al., 2018; Xie et al., 2018) and generation (Wu et al., 2019; Hosseini-Asl et al., 2020; Kim et al., 2020). The classification method requires that all possible slot-value pairs are given in a predefined ontology. Then, the pair with the highest score is the final prediction. Conversely, the generation way does not rely on manual definition, which generates dialogue states from utterances using the seq2seq fashion. This work is mainly related to the classification method.

Recently, transformer-based pre-trained models, such as BERT (Devlin et al., 2019), have achieved remarkable results in a range of natural language processing tasks. Thereupon, the research of DST has been shifted to building new models on top of the powerful pre-trained language models. SUMBT (Lee et al., 2019) is the first model to employ BERT to model the relationships between slots and dialogue utterances through a slot-word attention mechanism. CHAN (Shan et al., 2020) presents a hierarchical attention network which uses slot-word attention and slot-turn attention to enhance the representations of slots. All the methods mentioned above predict the value of each slot separately and ignore the correlations among slots. SST (Chen et al., 2020b) incorporates graph attention networks into DST and proposes schema graphs which contain slot relations in edges. STAR (Ye et al., 2021) provides a slot self-attention mechanism to learn mutual guidance among slots and enhance the ability to deduce appropriate slot values from related slots. Recently, BORT (Sun et al., 2022) proposes a reconstruction mechanism which enhances the performance of DST.

To the best of our knowledge, we are the first to reveal that exploiting all dialogue utterances to assign value may cause suboptimal results and the first to learn the temporal correlations among slots.

3 Methodologies

Suppose that there is a conversation composed of T utterances, $\mathcal{X} = \{(Q_1, R_1), ..., (Q_T, R_T)\}$, and a predefined slot set $\mathcal{S} = \{S_1, ..., S_J\}$, where Q_t denotes the user query at t-th utterance, R_t is the corresponding system response and J is the total number of slots. DST aims to predict states at each turn with given utterances up-to-now $(Q_{\leq t}, R_{\leq t})$, and presents them as slot-value pairs, $\mathcal{B}_t = \{(S_1, V_1^t), ..., (S_J, V_J^t)\}$, where S_j is the j-th slot in $\mathcal{S}$, and V_j^t is the value with respect to S_j for the t-th turn. Since the datasets are collected from multi domains, following previous works (Hu et al., 2020; Kim et al., 2020), we concatenate domain names and slot names as domain specific slots.

To tackle this task, we propose the LUNA model. As depicted in Figure 1, this model consists of three encoders and an alignment network. In this section, we will elaborate each module of this model.

3.1 Encoders

Inspired by the success of the pre-trained model in the community of the NLP, we adopt the BERT (Devlin et al., 2019) to implement the context encoder.

3.1.1 Utterance Encoder

Given the t-th utterance (Q_t, R_t) and its history $(Q_{<t}, R_{<t})$, we first concatenate them into a single sequence: $\mathcal{X}_t = Q_1 \oplus R_1 \oplus \cdots \oplus Q_t \oplus R_t$. Following the form of the input of the BERT, we then surround the sequence with two special tokens [CLS] and [SEP]. Given that not all of the slots can be aligned to a specific utterance, we further add an extra token [BLANK] as a placeholder. All of the slots that are not mentioned in the dialogue are aligned to [BLANK]. Finally, the input of the utterance encoder can be denoted as follows:

$$X_t = \text{[CLS]} \oplus \mathcal{X}_t \oplus \text{[SEP]} \oplus \text{[BLANK]}. \quad (1)$$

After obtaining X_t, we feed it into the BERT to learn semantic representations:

$$\mathbf{H}_t = \text{BERT}_{finetune}(X_t), \quad (2)$$

where $\mathbf{H}_t = [\mathbf{h}_1^t, \mathbf{h}_2^t, ..., \mathbf{h}_{|X_t|}^t]$, $\mathbf{h}_j^t \in \mathbb{R}^d$. Additionally, we add a learned embedding to every token indicating which turn it belongs to. Thus, for a given token in X_t, its input representation is constructed by summing the corresponding token, position, segment, and turn embeddings. In order to make the BERT more adapt to this task, we fine tune the parameters of the BERT during the training stage.

3.1.2 Slot and Value Encoders

Following previous works (Shan et al., 2020; Ye et al., 2021), we leverage another BERT to encode slots and their candidate values. Formally, given a slot S_j or a value V_j^t, we first tokenize it into a sequence and then concatenate it with the special token [CLS] to build the input for the slot or value encoder. After that, we exploit the BERT to encode the concatenation as follows:

$$\mathbf{h}_{s_j} = \text{BERT}_{fixed}(S_j), \quad (3)$$
$$\mathbf{h}_{v_j^t} = \text{BERT}_{fixed}(V_j^t). \quad (4)$$

We regard the representation of [CLS] as that of the whole slot or value. Specially, since the quantity of the sub-vocabulary related to slots and values are small, we freeze the parameters of BERT in slot and value encoders during the training stage.

3.2 Alignment Module

As mentioned above, DST model usually adopts all of previous utterances as the history to enhance the representation of the current utterance. Although this mechanism enriches the semantic representation, it introduces some noisy and causes confusion for value prediction to a specific slot. To alleviate this issue, the proposed LUNA model adopts iteratively bi-directional feature fusion layers, turn-to-slot and slot-to-turn, to align slots to utterances and provide more relevant utterance for value prediction.

3.2.1 Turn-to-Slot Alignment

In this work, we regard utterances and slots as two sequences and aims to align them with each other. To this end, we first employ a multi-head attention mechanism (Vaswani et al., 2017) to assist

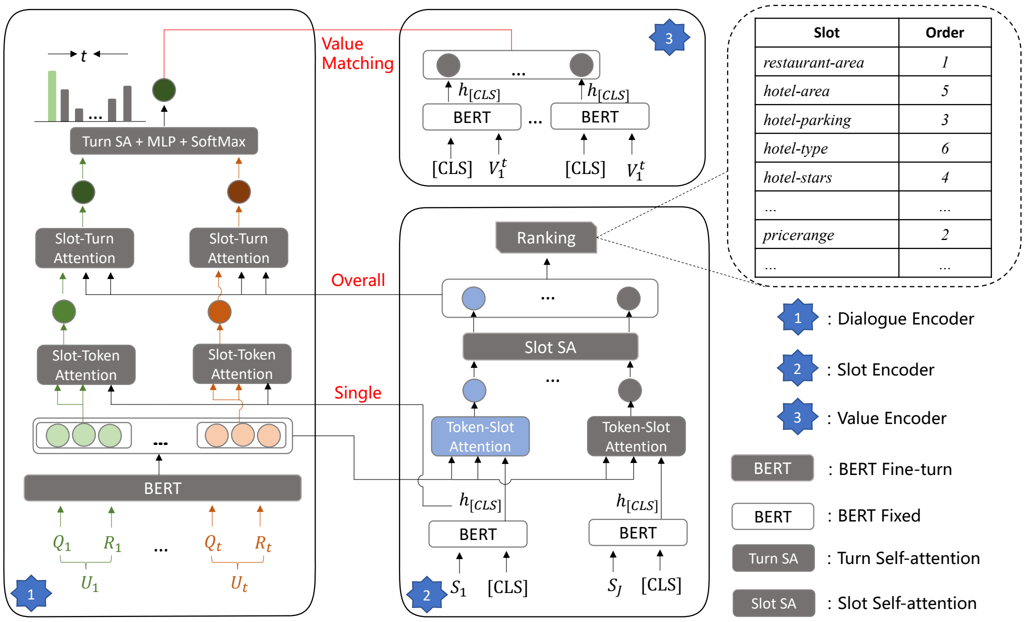

Figure 1: The architecture of LUNA. Note that the workflow in this figure is specifically for the first slot S_1.

the slots extracting relevant information from utterances based on the outputs of the utterance and slot encoders:

$$\mathbf{h}_{s_j,t} = \text{MultiHead}(\mathbf{h}_{s_j}, \mathbf{H}_t, \mathbf{H}_t), \tag{5}$$

where $\text{MultiHead}(\cdot,\cdot,\cdot)$ denotes the multi-head attention mechanism. Through this operation, we obtain utterance-aware slot representations.

After that, we adopt N stacked layers to learn the correlation among slots, and each layer consists of a multi-head self-attention mechanism and a position-wise feed-forward network. We denote this module as Slot SA. Formally, the n-th layer is computed as follows:

$$\bar{\mathbf{H}}_s^n = \text{MultiHead}(\hat{\mathbf{H}}_s^{n-1}, \hat{\mathbf{H}}_s^{n-1}, \hat{\mathbf{H}}_s^{n-1}), \tag{6}$$

$$\hat{\mathbf{H}}_s^n = \text{FNN}(\text{ReLU}(\text{FNN}(\bar{\mathbf{H}}_s^n)) \tag{7}$$

where $\hat{\mathbf{H}}_s^1 = [\mathbf{h}_{s_1,t}, ..., \mathbf{h}_{s_J,t}]$.

3.2.2 Slot-to-Turn Alignment

For utterances, after obtaining the output of the utterance encoder $\mathbf{H}_t$, we first slice it into t segments, $\mathbf{U} = [\mathbf{U}_1, ..., \mathbf{U}_t]$ and each segment corresponds to an utterance. We then exploit a hierarchical attention mechanism to model the slot-to-turn alignment. The hierarchical attention mechanism contains two layers. The first layer models the preliminary alignment between an utterance and a slot and we denote it as **Single Slot-to-Turn**. The other one focuses on the refined alignment through incorporating all slots information and we represent it as **Overall Slot-to-Turn**.

As shown in Figure 1, the Single Slot-to-Turn is responsible for extracting token-level information related to a specific slot from each utterance. Take the j-th slot S_j as an example. Given its representation $\mathbf{h}_{s_j}$, we use it to extract most relevant information from each utterance (*e.g.*, i-th utterance) via the multi-head attention mechanism:

$$\bar{\mathbf{U}}_i = \text{MultiHead}(\mathbf{h}_{s_j}, \mathbf{U}_i, \mathbf{U}_i), \tag{8}$$

where $\bar{\mathbf{U}}_i$ is a d-dimension vector and we regard it as slot S_j aware representation for i-th utterance. Similarly, we obtain slot S_j aware representations for all utterances $\bar{\mathbf{U}} = [\bar{\mathbf{U}}_1, ..., \bar{\mathbf{U}}_t]$ with the same operation.

After that, the Overall Slot-to-Turn layer further aligns utterances with slots. Different with existing work (Ye et al., 2021) of encoding the states of the previous turn B_{t-1} as an information supplement, we first introduce previous alignment information into each utterance by adding alignment embedding:

$$\hat{\mathbf{U}}_i = \bar{\mathbf{U}}_i + \text{AE}(i), \tag{9}$$

where AE is embedding matrix indicating whether the slot S_j aligns utterance $\mathbf{U}_i$ or not at last turn. Then we utilize another multi-head attention module to update utterance representations based on slots information as follows:

$$\tilde{\mathbf{U}}_i = \text{MultiHead}(\hat{\mathbf{U}}_i, \hat{H}_s^N, \hat{H}_s^N). \tag{10}$$

To aggregate context dependency among utterances, we further introduce a multi-head self-attention mechanism to learn the context aware representation for each utterance:

$$\mathbf{D} = \text{MultiHead}(\tilde{\mathbf{U}}, \tilde{\mathbf{U}}, \tilde{\mathbf{U}}), \tag{11}$$

where $\tilde{\mathbf{U}} = [\tilde{\mathbf{U}}_1, ..., \tilde{\mathbf{U}}_t]$, $\mathbf{D} = [\mathbf{D}_1, ..., \mathbf{D}_t]$. $\mathbf{D}$ is adopt to predict the alignment distribution over turns for S_j as follows:

$$p(\cdot|S_j) = \text{softmax}(\mathbf{W}_o \mathbf{D} + b_o), \tag{12}$$

where $\mathbf{W}_o \in \mathbb{R}^d$ and b_o are trainable parameters. We employ the cross-entropy as the objective function of the alignment and it can be formulated as:

$$\mathcal{L}_{align} = -\sum_{j=1}^{J} \log p((Q_j^*, R_j^*)|S_j), \tag{13}$$

where (Q_j^*, R_j^*) is ground-truth utterance aligned to slot S_j.

3.2.3 Auxiliary Ranking Task

The output of the Slot SA, $\hat{\mathbf{H}}_s^N = [\hat{\mathbf{h}}_{s_1}^N, ..., \hat{\mathbf{h}}_{s_J}^N]$, only contains the information of the semantic correlations among slots. To facilitate the alignment, the model needs the assistance of the temporal correlations among slots. However, slots are naturally disordered or sorted in lexicographic order. Therefore, we design an auxiliary task to guide the model to learn the temporal information of slots. Particularly, we propose an ordering algorithm to determine the slots order with respect to the dialogue utterances, as shown in Algorithm 1. This task aims to minimize the order differences between the disordered slots and our defined-ordered slots and we utilize the ListMLE (Xia et al., 2008) as the objective function. ListMLE is a standard ranking loss and it is computed based on a defined list and a ground-truth list. To compute the loss, we learn a score for each slot (*e.g.,* S_j) as follows:

$$\mathbf{f}_{s_j} = \text{Sigmod}(\mathbf{W}_s \hat{\mathbf{h}}_{s_j}^N + b_s), \tag{14}$$

where $\mathbf{W}_s$ and b_s are trainable parameters. Given the ground-truth order of slots $\mathbf{o} = [o_1, ..., o_J]$ and the corresponding slot list is $[S_{o_1}, ..., S_{o_J}]$, the loss function can be formulated as follows:

$$p(j|S_{o_j}) = \frac{\exp(f_{s_{o_j}})}{\sum_{l=j}^{J} \exp(f_{s_{o_l}})}, \tag{15}$$

$$\mathcal{L}_{order} = -\log(\prod_{j=1}^{J} p(j|S_{o_j})). \tag{16}$$

Algorithm 1 Slots Ordering Algorithm

Input: L: Label slots for a conversation, T: the number of turns in this conversation

Initialize: S : A list of sorted slots

```
for $t \in [1, T]$ do
    Find the label slots $L_t = [l_{t,1}, ..., l_{t,n}]$ of $t$-th turn;
    Sort $L_t$ by slots' lexicographic order;
    for $l$ in $L_t$ do
        Add $l$ to $S$;
    end for
end for
Define the list of remaining not-aligned slots is $L_{blank}$;
Sort $L_{blank}$ by slots' lexicographic order;
for $l$ in $L_{blank}$ do
    Add $l$ to $S$;
end for
```

3.3 Value Prediction

Above sections describe the method of aligning slots with utterances. We then predict the value for a specific slot based on the most relevant utterance instead of all of the utterances.

Formally, given a slot S_j, we first select the most relevant utterance (Q_j^*, R_j^*) as follows:

$$(Q_j^*, R_j^*) = \arg\max(\{p((Q_i, R_i)|S_j)\}_{i=1}^{t}). \tag{17}$$

Then we feed its representation $D^* \in D$ into a linear layer which is followed by a layer normalization:

$$O^* = \text{LayerNorm}(\text{Linear}(D^*)). \tag{18}$$

Following Ren et al. (2018), we adopt the L2-norm to compute the distance between a slot and a candidate value. Thereby, the value prediction probability distribution can be formulated as follows:

$$p(V_j^t|(Q_{\leq t}, R_{\leq t}), S_j) = \frac{\exp(-\|O^* - h_{v_j^t}\|_2)}{\sum_{V_k^t \in V^t} \exp(-\|O^* - h_{v_k}^t\|_2)}, \tag{19}$$

where V^t is the set of candidate value of slot S_j for the t-th utterance. Finally, the loss function can be defined as:

$$\mathcal{L}_{value} = -\sum_{j=1}^{J} \log(p(V_j^t|(Q_{\leq t}, R_{\leq t}), S_j)). \tag{20}$$

3.4 Optimization

We adopt the multi-task learning to jointly optimize the alignment loss, value prediction loss and the auxiliary task loss. The total loss is defined as follows:

$$\mathcal{L}_{joint} = \mathcal{L}_{order} + \mathcal{L}_{align} + \mathcal{L}_{value}$$

4 Experimental Setup

4.1 Datasets and Metrics

We evaluate our approach on three gradually refined task-oriented dialogue datasets: MultiWOZ 2.0 (Budzianowski et al., 2018), MultiWOZ 2.1 (Eric et al., 2019), and the latest MultiWOZ 2.2 (Zang et al., 2020), containing over 10,000 dialogues, 7 domains, and 35 domain-slot pairs. MultiWOZ 2.1 modifies about 32% of the state annotations in MultiWOZ 2.0. MultiWOZ 2.2 is the latest and a further refined version of MultiWOZ 2.1, which solves the inconsistency of state updates and some problems of ontology.

We use joint accuracy and slot accuracy as our evaluation metrics. Joint accuracy is the proportion of dialogue turns where the value of each slot is correctly predicted. Slot accuracy only considers individual slot-level accuracy. The ground-truth of slot value is set to none if the slot has not been mentioned in dialogue.

4.2 Training

Same as the previous work (Shan et al., 2020; Ye et al., 2021), we use BERT-base-uncased model as the encoders of LUNA where only the utterance encoder is fine-tuned and the parameters of the other two encoders are fixed. BERT-base has 12 layers of 784 hidden units and 12 self-attention heads. The number of attention heads in multi-head attention in our alignment module is set to 4. The number of layers in slot self-attention and turn self-attention is set to 4 and 2 respectively. During the training process, we use Adam optimizer (Kingma and Ba, 2015) and set the warmup proportion to 0.1. Considering that the encoder is a pre-trained BERT model while the other parts in our model needs to be trained from scratch, we use different learning rates for those parts. Specifically, the peak learning rate is set to 3e-5 for the utterance encoder and 1e-4 for the remaining parts. The maximum input sequence length in BERT is set to 512. For MultiWOZ 2.0, MultiWOZ 2.1, and MultiWOZ 2.2, we apply the same hyperparameter settings.

5 Experiment Results

5.1 Main Results

Table 2 shows the joint accuracy and the slot accuracy of our model and other baselines on the test sets of MultiWOZ 2.0, 2.1, and 2.2, where some models are not tested on the 2.2 version since it was released shortly. As shown in the table, among the models without data augmentation, our model LUNA achieves state-of-the-art performance on these datasets with joint accuracy of 55.31%, 57.62%, and 56.13%, which has a measurable im-

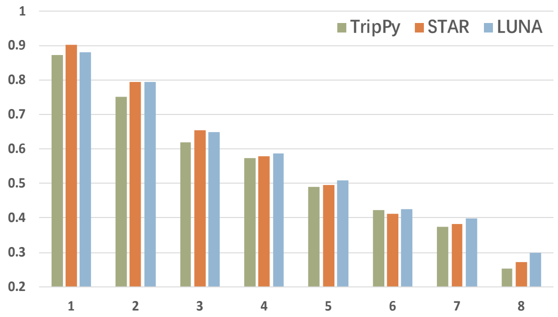

Figure 2: Joint accuracy at every turn.

provement (0.97%, 1.26%, and 4.43%) over the previous best results, illustrating the effectiveness of slot-turn alignment in DST task.

It can be observed that the three data augmented methods reach higher than 58% joint accuracy on MultiWOZ 2.1. We believe that these data augmentation skills are versatile. If they can improve the results of TripPy that lags behind our model, we reasonably speculate that these skills can also improve the effect of LUNA. Besides, all these models are based upon TripPy, which employs a label map as extra supervision. The label map is a dictionary of synonyms, which is used during the testing phase. For example, the official label of the slot *"hotel-area"* in ontology is *"centre"*. But label map regards all its synonyms, such as *"center"*, are also the ground truth. We think that this manner severely reduces the difficulty of the DST task. As shown in Table 2, the performance of TripPy degrades dramatically when the label map is removed. By contrast, our model does not rely on any extra information and is more generalized.

Additionally, Table 2 lists the number of trainable parameters of some baselines and our model, which illustrates that our alignment module containing multiple self-attention does not introduce large model parameters. Compared with the baselines, the size of our model is comparable.

Accuracy at Every Turn. In practice, the dialogue states of longer dialogues tend to be more difficult to be correctly predicted as the model needs to consider more dialogue history. In this section, we further analyze the relationship between the depth of conversation and the prediction accuracy. The joint accuracy at every turn of TripPy, STAR, and LUNA on MultiWOZ 2.1 test set is shown in Figure 2. It presents that the scores of LUNA and STAR are basically the same when the number of conversation turns is less than 3. While as the conversation turns increases from 3, the superiority of LUNA gradually becomes obvious. This is because that both TripPy and STAR exploit all dialogue utterances to assign value for each slot. This may introduce more useless information that causes confusion to the current slots. Whereas, LUNA only uses the most relevant utterance to assign slot value, which avoids interference by useless information.

5.2 Ablation on Alignment Module

To explore the effectiveness of each part in our proposed alignment module, we conduct an ablation study of these parts on the test set of MultiWOZ 2.1, as shown in Table 3.

Model	Align Acc	Joint Acc.
LUNA	97.50	57.62
- Alignment module	–	53.46 (-4.16)
- Overall slot-to-turn alignment	95.23 (-2.27)	54.70 (-2.92)
- Auxiliary task	96.30 (-1.20)	55.29 (-2.33)

Table 3: The ablation study of the alignment module on the MultiWOZ 2.1. Alignment accuracy (%) is defined as the ratio of dialogue for which the utterance turn of each slot is correctly aligned.

First, we remove the whole alignment module and only use the representations of slots obtained by token-slot attention Eq.5 to match the value. The results show that model performance has dropped a lot (4.16 joint accuracy), proving that there are many useless tokens in the conversation history, which interfere the prediction accuracy of slot value. Next, we remove the layer of overall slot-to-turn alignment. We can see that this also severely damages the model performance on both alignment accuracy and joint accuracy. This illustrates that it is not enough to only use the information of a single slot for the alignment. The model needs to comprehensively consider all slots information, such as semantic correlations and temporal correlations among slots to accurately align slots and dialogue turns. Finally, we remove the auxiliary ranking task and the results decrease by 1.20 on alignment accuracy and 2.33 on joint accuracy. This proves that the temporal correlation among slots is important in our model which could facilitate the alignment, as we explained in the section of Introduction. More intuitive explanations will be given in the next section through an example of visualization.

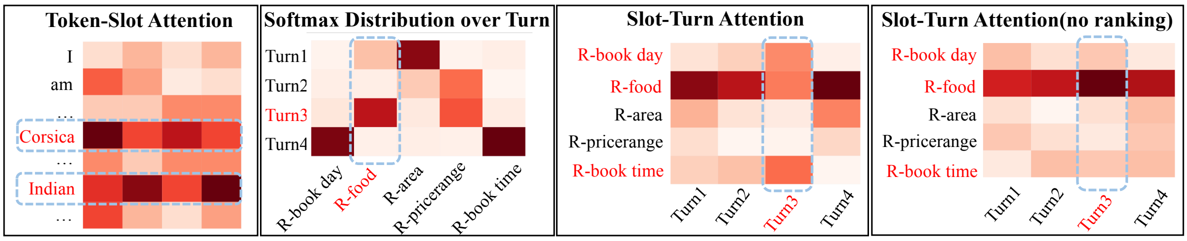
Hard or Soft Alignment. From Table 3, although our hard alignment is highly accurate (Acc 97.50), we should further explore whether it can be replaced by a soft alignment to avoid the risk of error propagation. Whereupon, we design a soft align-

Turn1 **User** : I am looking for Corsica restaurants in the east of Cambridge.

Turn2 **Sys** : Unfortunately there is not a corsica restaurant in the east of Cambridge, is there another type of food you would like to look for? **User** : I'll think about it. I would like a moderately priced restaurant.

Turn3 **Sys** : How about curry prince? It is a moderately priced Indian restaurant. **User** : Curry prince sounds terrific.

Turn4 **Sys** : Would you like me to make you a reservation? **User** : Yes please, for 7 at **11:45 on Thursday**.



(a) (b) (c) (d)

Figure 3: Visualization of LUNA on an example from MultiWOZ 2.1, which is a process of predicting the value to slot "restaurant-food" at turn-4. "R-" in figure denotes "restaurant-". The golden value of "restaurant-food" is "Indian" and the confusion value is "Corsica". (a) is the distribution of Token-Slot Attention calculated by Eq.5 where the columns are the four heads in multi-head attention. (b) is the softmax distribution of alignment over turns calculated by Eq.12. (c)(d) are the distributions of Slot-Turn Attention calculated by Eq.10 where (d) is the version after removing ranking loss.

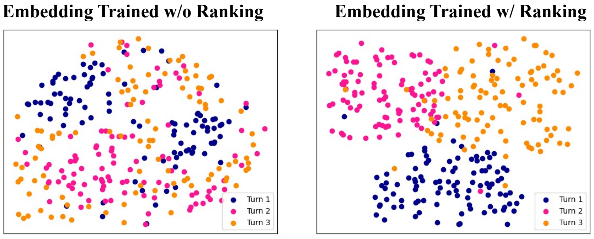


Figure 4: Visualization of slot embedding using t-sne. Each point represents the slot aligned to the corresponding turn. We plot 100 slot embeddings for each turn.

ment that is a weighted sum of all turns with the alignment distribution over the turns as weights (Eq. 12). The experimental results show that compared with hard alignment, the Joint accuracy of soft alignment on MultiWOZ 2.1 drops to 57.53 (-0.09). The reason is that the soft alignment encounters the problem of noises introduced from irrelevant utterances. In other words, risk of error propagation and noise-avoiding are a trade-off. The experimental results show that the benefits of our proposed hard alignment outweigh the risk.

5.3 Visualization

Figure 3 gives an example to visualize the process of predicting the value to slot "restaurant-food". In this example, the golden slot value is "Indian" and "Corsica" is the confusion value. As shown in sub-figure (a), the slot assigns high attention weight in all heads to both "Indian" and "Corsica" , because as of this step, it cannot determine which one is the correct value. At the last step, after the bi-directional fusion in our proposed alignment module, the model successfully assigns turn-3 a larger alignment score than turn-1, as shown in sub-figure (b). In other words, the model has realized that the utterance of turn-3 (containing "Indian") is more important than turn-1 (containing "Corsica"). This can avoid the confusion caused by "Corsica".

We next analyze sub-figures (c) and (d). As we can see, all turns focus on the slot "restaurant-food" as they incorporates its single slot information through Eq.8. For the column of turn-3, if the model is supervised with the auxiliary ranking task, it will also consider the information of "restaurant-book day" and "restaurant-book time". Sub-figure (b) indicates that these two slots are easy-aligned (with turn-4). Meanwhile, the model learns that the order of the three slots is ["restaurant-food", "restaurant-book day", "restaurant-book time"]. Thereby, the alignment of "restaurant-food" and turn-3 becomes easier.

Figure 4 displays the 2-d visualization of slot embeddings obtained by Eq. 7. It can be seen that without ranking loss, the slot representations are irregular and borderless. Under the supervision of the ranking loss, the model can learn the boundaries between the slots aligned with different turns.

6 Conclusion

In this work, we reveal the problem in DST that exploiting all dialogue utterances to assign value to slots may cause suboptimal results. To alleviate it, we propose LUNA, a slot-turn alignment enhanced approach. and design a ranking-based auxiliary task to supervise LUNA to learn the temporal correlations among slots. Comprehensive experiments are conducted on MultiWOZ 2.0, 2.1, and 2.2 and the results show that LUNA achieves new state-of-the-art results. Moreover, the visualization demonstrates the interpretability of LUNA.

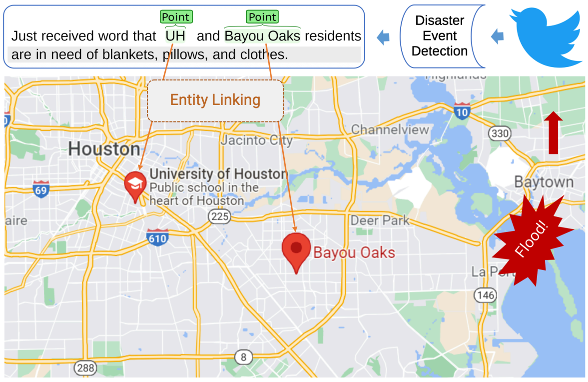
Abstract

General domain Named Entity Recognition (NER) datasets like CoNLL-2003 mostly annotate coarse-grained *location* entities such as a country or a city. But many applications require identifying fine-grained locations from texts and mapping them precisely to geographic sites, e.g., a crossroad, an apartment building, or a grocery store. In this paper, we introduce a new dataset HarveyNER with fine-grained locations annotated in tweets. This dataset presents unique challenges and characterizes many complex and long location mentions in informal descriptions. We built strong baseline models using Curriculum Learning and experimented with different heuristic curricula to better recognize difficult location mentions. Experimental results show that the simple curricula can improve the system's performance on hard cases and its overall performance, and outperform several other baseline systems. The dataset and the baseline models can be found at `https://github.com/brickee/HarveyNER`.

1 Introduction

The Named Entity Recognition (NER) task aims to locate and classify textual phrases as entity mentions that belong to predefined entity categories. *Location* is one of the general entity categories and has been annotated in many NER datasets, including CoNLL-2003 (Tjong Kim Sang, 2002) and OntoNotes 5.0 (Pradhan et al., 2013). However, these datasets contain mostly coarse-grained entities such as a continent (e.g., Europe), a country (e.g., the U.S.), or a city (e.g., London).



Just received word that UH and Bayou Oaks residents are in need of blankets, pillows, and clothes.

Figure 1: An example of a disaster response system.

Many downstream applications require identifying fine-grained location entities from texts, such as an apartment building (e.g., Bayou Oaks) or a specific store (e.g., the HEB on Montrose), in order to locate the geographic places on a map, which is vital to identify actionable information (Khanal and Caragea, 2021). For example, in Figure 1, a flood disaster happened in the Houston area and then someone tweeted the shortage of necessities in two locations. If a disaster response system can detect the disaster-related tweets, identify the two location mentions from the text, and link them to location entities on the map, necessary help can be directly delivered to the people living in disaster-affected places. Accurately identifying the fine-grained location mentions plays a critical role in such a system.

Several previous works have attempted to create crisis-related datasets with fine-grained location mentions, either automatically (Middleton et al., 2013) or by manual (Khanal et al., 2021) annotations. However, these prior datasets contain many incomplete descriptions of locations that otherwise can be precisely projected to a map with certain geo-coordinates. For example, *"the corner of Richey St and W Harris Ave in Pasadena"* is an intersection of two roads and we annotate it as a *Point* on the map, but previous work regard it as two *Road* mentions *"Richey St"* and *"W Harris Ave in Pasadena"*, and such incomplete location mentions will affect uses in many applications. We introduce

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3329 - 3339
July 10-15, 2022

HarveyNER, the first dataset that annotates such coordinate-oriented location mentions.

We use the Harvey disaster in Houston as an example to demonstrate how to annotate such location mentions. Specifically, we consider tweets about Hurricane Harvey affecting the Houston metropolitan area in 2017 and annotate mentions of locations that exist in this city. Compared with the location mentions in prior NER datasets, HarveyNER focuses on the location mentions that can link to specific sites on a map. We carefully constructed the annotation guidelines and trained annotators to obtain high-quality annotations. We also built strong baselines over the dataset for future reference.

The unique characteristics of HarveyNER present challenges for NER systems. First, many location entities in this dataset are long and complex to precisely describe a place. E.g., the above example of a *Point* entity contains up to 11 words, and it could be wrongly recognized as two road entities by a NER system. Second, as an instant social medium, tweets contain many informal contents, local conventions, and even grammatical errors, which create many out-of-vocabulary (OOV) words that cannot be found in pretrained word embedding such as Glove (Pennington et al., 2014) or BERT (Devlin et al., 2019).

To improve the performance on these hard location mentions and build strong baselines for the HarveyNER dataset, we adopt Curriculum Learning (CL) (Bengio et al., 2009) to better learn difficulty samples by ordering examples during training based on their difficulty. We design two heuristic curricula based on entity length and word complexity considering that many long and complex entities in HarveyNER are naturally difficult (as shown in Figure 3, the performance of baseline systems is worse on these hard cases). We further assume that the difficulty to learn may not only depend on the inherent difficulty of a type of case but also depend on how commonly seen or how well represented such cases are in the dataset. Therefore, we propose a novel curriculum with a difficulty scoring function that comprehensively considers the two heuristic difficulty metrics as instance frequencies. Empirical results show that all of the curricula can outperform several other baseline systems, and our novel curriculum performs the best.

We also find that different NER-based systems benefit from different curriculum scheduling strategies. In our experiments, the normal curriculum (training with easier samples first) is suitable for training the neural network-based model NCRF++ without pretrained language models, while the anti-curriculum (training with harder samples first) facilitates fine-tuning of the pretrained language model BERT.

2 Related Work

NER research has a long history and many NER datasets have been created with certain pre-defined entity categories. General domain datasets such as CoNLL-2003 (Tjong Kim Sang, 2002) and OntoNotes 5.0 (Pradhan et al., 2013) attend to certain common entity types including *Location*. Location mentions in these datasets are mostly coarse-grained, e.g., the *U.S.* (a country) or *London* (a city). Li and Sun (2014); Ji et al. (2016) focus on identifying fine-grained points-of-interest for location-based services, and their dataset is automatically constructed by mapping location inventory to tweets. Khanal and Caragea (2021); Khanal et al. (2021) try to identify crisis-related location mentions, but their dataset contains incomplete location mentions and is of limited use for a disaster response system. In contrast, our dataset HarveyNER emphasizes fine-grained locations that can map to coordinates on a map.

Recent approaches (Yang and Zhang, 2018; Li et al., 2020; Chen et al., 2021) use Neural Network models like BiLSTM-CNN-CRF (Ma and Hovy, 2016) and contextual embeddings like BERT (Devlin et al., 2019), and have greatly improved the NER performance. However, none of these approaches consider the difficulty of different NER cases in their model training. Bengio et al. (2009) pointed out that using a curriculum strategy enables the model to learn from easy examples to complex ones and leads to generalization improvement. Many Natural Language Processing tasks such as machine translation (Platanios et al., 2019; Liu et al., 2020; Zhang et al., 2021), natural language understanding (Xu et al., 2020), text generation (Liu et al., 2018, 2021) and dialogue systems (Su et al., 2021) benefit from such curriculum learning strategies. Considering that HarveyNER contains many long and complex location mentions, we design corresponding curricula to learn them.

Data Split	Train	Valid	Test	Total
# of Tweets	3,967	1,301	1,303	6,571
Tweets w/ Entity	1,087	366	353	1,806
Tweets w/o Entity	2,880	935	950	4,765

Point	591	206	202	999
Area	715	236	212	1,163
Road	158	51	57	266
River	117	30	29	176

Table 1: Statistics of the HarveyNER Dataset.

3 The HarveyNER Dataset

3.1 Data Preparation

Data Collection We used the Twitter PowerTrack API to retrieve the tweets posted during the time of peak disruption caused by Hurricane Harvey in the Houston area, specifically from 5:00 a.m. August 25 to 4:59 a.m. August 31, 2017. In total, we collected 1,121,363 tweets excluding retweets and replies.

Data Cleaning We applied several strategies to filter out irrelevant tweets. First, we only keep the tweets that are related to the Houston area, i.e., the geo-coordinates of the tweets or the authors' profile locations are within the bounding of Houston. Second, we applied our weakly-supervised event detection system (Yao et al., 2020) to identify tweets on disaster-related topics; these tweets are likely to be related to Hurricane Harvey during the specified period. We also manually filtered out remaining irrelevant tweets (such as non-English and repeated tweets) during the annotation process. In total, 6,571 tweets were selected for this study, as shown in Table 1.

3.2 Location Entity Annotation

Location Types HarveyNER focuses on the coordinate-oriented locations so we mainly annotate *Point* that can be precisely pinned to a map and *Area* that occupies a small polygon of a map. Considering that some disasters can affect line-like objects (e.g., a flood can affect the neighbors of a whole river), we also include *Road* and *River* types.

- **Point**: denote an exact location that a geo-coordinate can be assigned. E.g., a uniquely named building, intersections of roads or rivers;
- **Area**: denote geographical entities such as city subdivisions, neighborhoods, etc;
- **Road**: denote a road or a section of a road;
- **River**: denote a river or a section of a river.

kappa κ	A1 & A2	A1 & A3	A2 & A3	Average
All	85.64	82.17	83.12	83.64
Annotated	66.54	60.49	62.09	63.04

Table 2: Inter-Annotator Agreement (%) at token-level. *All* for all the tokens and *Annotated* for annotated tokens only. There are three annotators A1, A2 and A3.

Annotation Quality To train the annotators to well annotate the fine-grained location mentions, especially to distinguish the *Point* locations, we conduct rounds of initial annotation exercises and receptively update annotation guidelines to reduce ambiguity and subjectivity. The detailed guidelines can be found in Appendix A.1.

We trained three annotators and calculated their Inter-Annotator Agreement (IAA) based on 500 randomly selected tweets they all annotated. We pairwise calculate the Cohen's kappa (κ) scores based on the token-level annotations from each pair of annotators. As suggested by Brandsen et al. (2020), we report two scores: one calculated using all the token annotations and one only using the annotated tokens that exclude non-entity tokens. As shown in Table 2, we observe a high average κ score of 83.64% for all tokens and an average κ score of 63.04% for annotated tokens only. After that, the three annotators annotated the remaining tweets independently.

3.3 Dataset Analysis

We randomly split the annotated tweets into training, validation, and test sets for experiments with a ratio of 6:2:2. Table 1 shows some basic data statistics. We can see that 27.48% of the tweets contain at least one location entity mention, while the remaining tweets do not mention any location. As for location types, *Point* and *Area* are two dominant entity types covering 38.36% and 44.66% of entity mentions respectively, while *Road* and *River* only make up 10.22% and 6.76% of entity mentions respectively.

Comparisons with CoNLL-2003 We compare HarveyNER with CoNLL-2003, a general NER dataset annotated with coarse-grained locations in news articles, and Table 3 shows the comparisons in several aspects.

First of all, entities in HarveyNER are longer

Datasets	HarveyNER	CoNLL-2003 (Loc-only)
Avg Entity Length (word)	**2.68**	1.15
Avg Entity Length (char)	**13.91**	7.24
Complex Entity Rate (%)	**11.8**	0.19
OOV Rate (%)	**14.47**	2.33
Avg Sent Length (word)	20.07	14.53
Avg Sent Length (char)	117.03	76.89
Avg Entity Count	0.40	0.51
– non-empty	1.44	1.38
Avg Entity Ratio (%)	5.33	7.23
– non-empty	19.39	19.43

Table 3: HarveyNER v.s. CoNLL-2003.

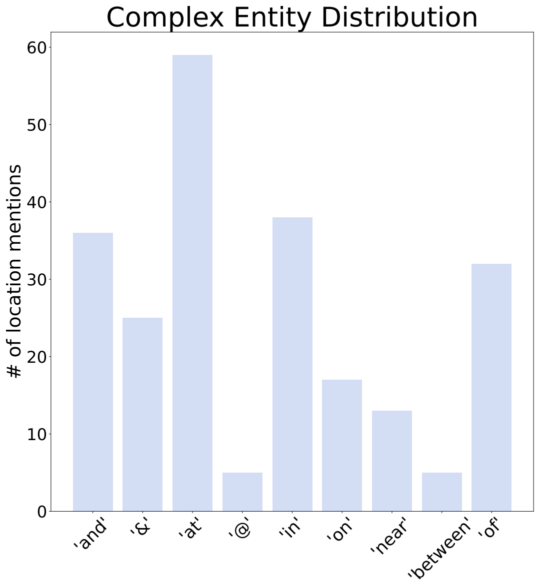

Figure 2: Number of Location Mentions with Each Complexity Indicator Word.

on average at both word level and character level. We observed that many location mentions of the type *Point* and *Area* are especially long to precisely describe a site or area on a map. We manually analyzed long entities in the validation set and observed that many location mentions are complex noun phrases with a conjunction or a prepositional phrase attachment. We noted down two commonly seen conjunctions and seven commonly seen prepositions, and table 4 shows location examples for each. We calculate the percentage of complex entity mentions with one of these words, and HarveyNER has 11.8% of entity mentions fall in this category while CoNLL-2003 has few such entity mentions (0.19%). Figure 2 shows the number of tweets with each of the words.

Second, considering that the language used in tweets is informal and contains many abbreviations

Indicators	Examples
"and"	the corner of Richey St **and** W Harris Ave in Pasadena (Point)
"&"	Beltway 8 **&** Tidwell (Point)
"at"	Brazos River **at** Richmond (River)
"@"	Copperfield Church **@** 8350 hwy 6 north (Point)
"in"	Constellation Field **in** Sugar Land (Point)
"on"	Chimney Rock **on** I-10 East (Point)
"near"	IH 10 **near** Monmouth (Point)
"between"	249 **between** Cypresswood / Louetta (Point)
"of"	0.25-0.5 north **of** I-10 (Point)

Table 4: Examples of complex entities.

and even grammatical errors, we calculate the out-of-vocabulary (OOV) rates (in Table 3) for both datasets by counting words that are absent from the pretrained Glove[1] (Pennington et al., 2014) word lists. We can see that the HarveyNER has a much higher OOV rate than CoNLL-2003. The high OOV rate might degrade the performance of NER systems relying on pretrained word embeddings.

In addition, we compare the average sentence length between the two datasets. To our surprise, HarveyNER has overall longer sentences, based on both word counts and character counts. This is counter-intuitive since the tweet content is strictly constrained to be no more than 140 characters each. One possible reason is that short tweets are less likely to provide useful event information and have been filtered out by the event detection system (Yao et al., 2020) we used.

Lastly, we measure the density of annotated location entities in the two datasets by calculating the average number of location entity mentions per sentence and calculating the percentage of entity words out of all the words in a sentence. We also calculate these two measures for the subset of sentences that contain at least one location mention (non-empty sentences). The last section of Table 3 shows the results. We can see that the two datasets are similar over these annotation density measures.

4 Curriculum Arrangement

In consideration of the characteristic difficulties of HarveyNER, we employ curriculum arrangements to help learn these hard cases. We follow the curriculum designing approach introduced by Bengio et al. (2009), which mainly requires specifying two functions:

- **Difficulty Scoring Function**: Given an input sample $\boldsymbol{x}_i$, this function map it to a numerical

---

[1] For fair comparison, we use glove.twitter.27B for HarveyNER and glove.6B for CoNLL-2003.

score, $d(\boldsymbol{x}_i) \in \mathbb{R}$. The score is used to represent the difficulty level of the corresponding sample. Usually, the higher the score, the more difficult the sample is.

- **Pacing Function**: The pacing function $p(t) \in (0, 1]$ specifies the input training data size at time or step t. Normally we use $p(t)$ the lowest difficulty-scored samples for training at time t, but in the ***anti-curriculum*** setting, we use $p(t)$ the highest difficulty-scored samples. Given such a subset of the dataset containing the easiest or hardest ones, we sample training batches uniformly from it for training.

The curriculum learning procedure using the two functions is described in Algorithm 1.

Algorithm 1 Curriculum Learning with Scoring and Pacing Functions

```
Input:
  • The training Data, $\mathcal{D}^{\text{train}} = \{\boldsymbol{x}_i\}_{i=1}^{N}$, including $N$ samples;
  • A model $\mathcal{M}$ that takes batches of data for training at each step $t$;
  • A difficulty scoring function $d$;
  • A pacing function $p(t)$.
Output: A model $\mathcal{M}^{\text{trained}}$ trained with the curriculum.
Compute the difficulty score $d(\boldsymbol{x}_i)$ for each sample;
Sort $\mathcal{D}^{\text{train}}$ ascendingly or descendingly based on $d(\boldsymbol{x}_i)$ and obtain $\mathcal{D}^{\text{train}}_{\text{sorted}}$;
Initialize the pacing function $p(0)$;
Generate the initial curriculum $\mathcal{D}_0$ using the top $p(0)$ samples in $\mathcal{D}^{\text{train}}_{\text{sorted}}$;
for training epoch $t = 1, 2, \dots$ do
    Uniformly sample batches from the current curriculum $\mathcal{D}_{t-1}$ for model training;
    Update the pacing function $p(t)$ based on equation Eq. (6);
    Generate the next curriculum $\mathcal{D}_t$ using the top $p(t)$ samples in $\mathcal{D}^{\text{train}}_{\text{sorted}}$;
```

4.1 Three Difficulty Scoring Functions

We first design two dataset-specific heuristic curricula, based on maximum entity length and entity complexity[2], inspired by the dataset analysis in Section 3.3. Then, we introduce a new metric that integrates the two heuristic metrics.

Maximum Entity Length (Max): As mentioned previously, our HarveyNER dataset has longer entity mentions on average compared to CoNLL-2003, and this brings many long and difficult entities that are hard to identify. Intuitively, we can design a corresponding curriculum based on such an entity-level difficulty. Specifically, given an input tweet sample $\boldsymbol{x}_i$ that contains n words, $\boldsymbol{x}_i = \{w_1, w_2, \dots, w_n\}$, and k ($k \geq 0$) entities, $\{E_1, E_2, \dots, E_k\}$. $|E_j|$ represents the length of j*-th* entity, specifically, the number of words in the j*-th* entity. Now, we can assign each tweet sample a score using the maximum length[3] of its entities:

$$d_{\text{max}}(\boldsymbol{x}_i) = \max(L_i) \tag{1}$$

where, $L_i = \{|E_1|, |E_2|, \dots |E_k|\}$, the set of entity lengths for the i-th sample $\boldsymbol{x}_i$.

With this scoring function, we need to pay attention to the tweets with zero entity mention (*72.52%* of tweets in HarveyNER as shown in Table 1) since their difficulty scores will all be 0. In this case, the algorithm will provide all these tweets in one step to the curriculum, which will mislead the model to a local minimum and learn that no entity exists in the data. We propose a remedy to this issue by randomly feeding the empty tweet samples. Specifically, when we order our dataset by the difficulty scores, we randomly intersperse those no-entity tweet samples among the ordered samples that have entities.

Complex Entity Rate (Complex): Corresponding to the analysis of the complex entity rate in HarveyNER, we define another difficulty scoring function. Specifically, we define the complexity of an entity $c(E)$ based on whether the entity contains one of the conjunction words or preposition words we identified and which word the entity contains. Heuristically, we assign a weight greater than 1 to these words, specifically, we assign a weight of 3 to each conjunction word and a weight of 2[4] to each preposition word to reflect our intuition that entities with conjunctions can be more difficult cases.

If an entity E contains more than one "complexity" indicator, we choose the one with the highest weight. For example, the entity example E *"the corner of Richey St and W Harris Ave in Pasadena"* contains the conjunction *"and"* and the preposition *"in"*, we deem the complexity of this entity $c(E)$ is 3 instead of 2. Then, one tweet sample x_i can have multiple entities with different complexities $C_i = \{c(E_1), c(E_2), \dots, c(E_k)\}$, we assign the

---

[2] We tried using the OOV rate as the difficulty score in our experiment, but the performance is not as good.

[3] We also tried using the average entity length as the difficulty score in our experiment but the performance is not as good.

[4] We further lower the weight for the preposition "of" to 1 considering that this is a very general preposition and is often observed in regular location entities as well, e.g., "University of Houston".

maximum entity complexity value as the complexity value of the tweet sample, i.e.,

$$d_{\text{complex}}(\boldsymbol{x}_i) = \max(C_i) \tag{2}$$

However, if none of the entities in a tweet sample contain complexity indicators, this scoring function will assign 0 as the difficulty score for the tweet sample. A similar issue has been discussed for the previous scoring function, and we use the same remedy as well and randomly interspersed these zero-scored samples among the other ordered samples.

Commonness of Difficulty (Commonness): We further propose a novel difficulty metric that considers both of the prior metrics as well as their support. We exploit the assumption that the difficulty to learn may not only depend on the inherent difficulty of a type of case but also depend on how commonly seen or how well represented such cases are in the dataset.

Specifically, to assign a difficulty score for a tweet sample, we first count the number of training samples that have the same difficulty score as the sample $\boldsymbol{x}_i$ according to one of the prior two metrics and then divide it by the total number of tweet instances N. Then, we take the reciprocal of it and get f_{metric}.

$$f_{\text{metric}}(\boldsymbol{x}_i) = \frac{1}{count(d_{\text{metric}}(\boldsymbol{x}_i))/N} \tag{3}$$

Where, d_{metric} are the difficulty metrics d_{max} or d_{complex}. Hence, the larger support of a difficulty level based on one of the two prior heuristics, the lower the f_{metric} value is. We then normalize this value to the range of $[0,\ 1]$.

$$f_{\text{metric}}(\boldsymbol{x}_i) = \frac{f_{\text{metric}}(\boldsymbol{x}_i) - \min(f_{\text{metric}})}{\max(f_{\text{metric}}) - \min(f_{\text{metric}})} \tag{4}$$

Then, we integrate f_{max} and f_{complex}, and take the *L2*-norm to generate the final difficulty score.

$$d_{common}(\boldsymbol{x}_i) = \sqrt{f_{\text{max}}(\boldsymbol{x}_i)^2 + (\lambda f_{\text{complex}}(\boldsymbol{x}_i))^2} \tag{5}$$

As a result, the more common a sample is concerning its length or complexity, the smaller the *L2*-norm value is, which indicates a lower difficulty based on the new metric. In addition, we add a hyperparameter λ to balance the influence of the two metrics.

Similar to the previous single difficulty-based curricula, the commonness difficulty score is zero when a tweet sample has no entity. We adopt the same remedy and randomly intersperse those no-entity tweet samples among the ordered ones that contain entities.

4.2 Pacing Function

We use the root-based pacing function introduced by Platanios et al. (2019) in all our experiments.

$$p(t) = \sqrt{t \cdot \frac{1 - p(0)^2}{T} + p(0)^2} \tag{6}$$

Here $p(0)$ defines the proportion of samples we feed our model at the very beginning; T is the number of epochs that we apply curriculum learning to our model.

5 Experiments

In our experiments, we use two state-of-the-art NER systems as base models and evaluate their performance on the HarveyNER dataset. Then, we test the effectiveness of the designed curricula by applying them to train the base models.

5.1 Baselines

NCRF++ (Yang and Zhang, 2018) is an open-source Neural Sequence Labelling Toolkit. We use the BiLSTM-CNN-CRF structure as a base model. **BERT** (Devlin et al., 2019), a pretrained language model based on Transformer (Vaswani et al., 2017), has significantly improved many NLP tasks including NER. We fine-tune the *base-uncased* version of BERT with the BiLSTM-CRF structrue for experiments.

5.2 Training Setup

For the **NCRF++** model, we use the *tweet-based* version Glove as word embeddings and keep all the other hyper-parameters as default. For the **BERT** model, we set learning rate as 5e-5 and set batch size as 32. As for the λ hyperparameter in Eq. (5), we used grid search and set it 1 and 0.6 for the NCRF++ model and the BERT model respectively. We train all the NCRF++ models for 100 epochs and train all the BERT models for 50 epochs.

For fair comparisons, we keep all the training parameters the same when conducting curriculum learning. For the **NCRF++** model, we use the normal curriculum setting and feed easier cases

Models	Entity Type in HarveyNER				
	Point	**Area**	**Road**	**River**	**Micro-Average**
NCRF++	71.43 / 72.26 / 71.85	66.00 / 61.68 / 63.77	**77.39** / **77.93** / **77.66**	61.40 / 44.56 / 51.64	68.69 / 65.16 / 66.88

+ Commonness	**72.98** / 73.87 / **73.42**	**62.53** / 71.98 / 66.92	**79.20** / 78.62 / 78.91	**63.55** / **60.00** / **61.72**	**67.66** / 71.80 / **69.67**

Table 5: Evaluation on the test set, Precision / Recall / F1-Score (Percentages)[5]. Since we use the same pacing function, we use the scoring functions to name the curricula. Note that we apply the normal curriculum setting to the NCRF++ model and apply the anti-curriculum setting to the BERT model.

first, while for the **BERT** model, we use the anti-curriculum setting (more explanations provided in Section 5.5). Note that we train all the experiments five times using different random seeds to alleviate random turbulence.

5.3 Results

Table 5 shows the experimental results. We can see that the BERT base model outperforms the NCRF++ base model consistently across the four location categories on this dataset. Curriculum learning yields further performance gains for both the BERT model and the NCRF++ model, this is true for all the curricula paired with both models except the **Max** curriculum when applied to the BERT model, where the average performance almost stays the same. Among the three curricula, he **Commonness** curriculum achieves the best performance for both models.

Conducting curriculum learning have unequal impacts on the four location categories. When using the NCRF++ model, curriculum learning yields a small performance improvement on *Point* and clear improvements on *Area* and *River*, while using the BERT model, curriculum learning yields a relatively larger improvement on *Point* and a clear improvement on *River* as well.

Note that the best-performed BERT model only achieves a micro-average F1-score of 69.67% on this dataset, which is still much lower than recently published BERT-base performance on CoNLL-2003 (e.g., 92.4% as reported in (Devlin et al., 2019)).) Meanwhile, we acknowledge that recognizing fine-grained locations is a trickier task than recognizing coarse-grained locations or many other general types of entities, even for humans as shown by the imperfect inter-annotator agreements.

5.4 How are the Difficult Samples Learned?

In order to understand if the models have better learned the difficult samples after applying curriculum learning, we divide the test set into "easy" and "hard" subsets based on either entity length or entity complexity and report experimental results on each subset. In this analysis, we only consider tweet samples in the test set that contains at least one entity mention since the groupings are determined by the characteristics of the entities. In the first grouping, we divide tweet samples into "short" and "long" groups depending on if the maximum entity length (number of words) in a tweet sample is greater than a threshold, four words in particular ($<= 4$ v.s. > 4). In the second grouping, we divide tweet samples into "simple" and "complex" groups by checking if a tweet sample contains a complex entity mention[6].

Across all the experimental settings, we report the results on two subsets separately under each grouping (Figure 3). We can see that curriculum learning indeed yields noticeable improvements in identifying those hard cases, while the improvements vary when adopting different curricula. Meanwhile, curriculum learning also achieves mild improvements on identifying the remaining relatively easy cases.

5.5 Curriculum v.s Anti-curriculum

We find that applying different curriculum settings (normal curriculum that exposes the easiest examples first or anti-curriculum that exposes the most difficult examples first) results in a large performance difference between the NCRF++ model and the BERT model. As shown in Figure 4, for the NCRF++ model without pretrained language mod-

---

[5] All results are the average of 5 system runs.

[6] A complex entity mention has one of the conjunctions or prepositions we identified.

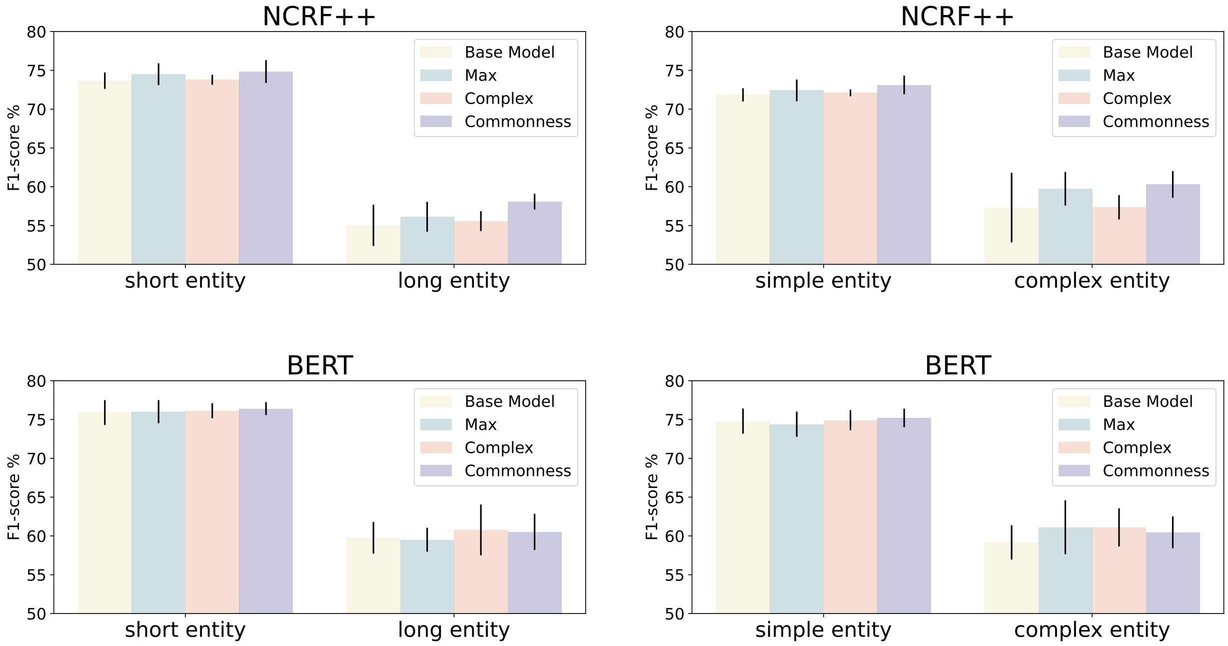

Figure 3: Results on "easy" and "hard" subsets of the test data, F1-score (Percentage).

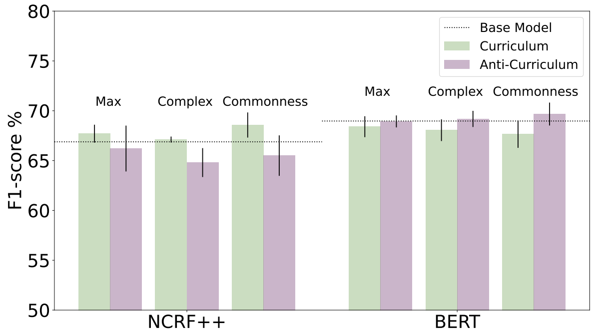

Figure 4: Curriculum v.s. Anti-curriculum, F1-score (Percentage).

els, the normal curriculum setting yields significantly better average F-1 scores across all the three curriculum scoring functions in comparison with the anti-curriculum setting. However, for the pretrained language model BERT, the results are the opposite; using anti-curriculum learning consistently yields better performance than using normal curriculum learning.

One possible explanation is that the volatile gradients resulting from using anti-curriculum learning can lead to better local minima for a well-pretrained model. Specifically, the anti-curriculum learning will feed those “hard” samples to the model first, and the gradients from those long-tailed hard cases will cause relatively large fluctuations compared to those from easy instances. BERT is a pretrained language model and the pretrained parameters might constrain the model to some local regions. The fluctuations produced by the “hard” samples from the anti-curriculum learning can enable the BERT model to reach other better local minima regions.

6 Conclusion

We introduce a fine-grained location recognition dataset, HarveyNER, to enable many downstream applications such as building real-time disaster response systems. This dataset contains many long and complex location mentions that feature interesting internal syntactic and semantic structures and the state-of-the-art NER systems are unable to fully recognize these hard cases. Considering the clear characteristics of difficult cases in this dataset, we experimented with two heuristic curriculum learning strategies and a novel commonness-based curriculum strategy to better recognize the difficult location mentions. Empirical results demonstrate the effectiveness of the curricula, which serve as strong baseline results in this dataset. Future work may consider incorporating external knowledge or innovations on system architectures to better identify fine-grained location mentions.

A Appendix

A.1 Annotation Guidelines

- 1. Location types can be "Area", "Point", "Road", and "River."
  - “Area” refers to all the named entities of cities, neighborhoods, super neighborhoods, geographic divisions etc.
  - “Point” refers to a location that is a building, a landmark, an intersection of two roads, an intersection of a river with a lake/reservoir/ocean, or a specific address.
  - "Road" refers to a road/avenue/street or a section of a road/avenue/street when the tweet does not provide an exact location on that road.
  - "River" refers to a river or a section of a river when the tweet does not imply there is an intersection between the river and other places.
- 2. A section of a road/river between two detailed/precise locations should be considered as a point. However, if the distance between the two points is very large, it might be considered as a stretch of a road/river.
- 3. A road passing through a small area can be designated as a point. A road intersecting a very large area cannot be a point and must be denoted as a stretch of a road. In some peculiar cases, the road takes a small detour and tangentially brushes off an area – in such specific cases, roads can be annotated as a point.
- 4. The following locations, *Lake Houston*, *Barker Reservoir*, and *Addick’s Reservoir*, are annotated as areas due to their significant size while all other lakes/reservoirs are considered as points.
- 5. Ignore generic company/franchise names like HEB, Kroger etc. unless it is accompanied with a precise location, for example, *HEB at Kirkwood Drive*. However, non-franchised small businesses with only one unique location are considered as a point.
- 6. Ignore any locations in the Twitter username, like @HoustonABC. However, if the @ does not refer to a Twitter account name,

please recognize the location. For example, *I am @ XXX High School*, “XXX High School” will be considered as a point.

- 7. For abbreviations or vague location names, always look up the tweet’s context (or even other tweets’ context) to decide if it is a location or not. We will use search engine if it is necessary.
  - Eg: *Coke Ck*; Here, "Ck" refers to a creek. This is understood when multiple such tweets point towards a creek.
- 8. Similarly, for names that can refer to different or multiple locations, like “Bellaire” can either refer to Bellaire St or the Bellaire area, we always look up the tweet’s context to decide their location types.
- 9. We annotate the mentioned location as the complete set of phrases that describes the detail of the location including the core noun and all defining relative clauses. If a tweet mentioned the same location multiple times, they will be annotated as multiple location mentions.
- 10. Ignore the location that **only** contains “Houston”, “Harris County”, or “Texas”
- 11. Ignore any tweet outside Houston (like London, Dallas, etc) and all non-English tweets.
- 12. We keep the exact words in tweet context as the location name after extracting the entities.

Tricks for Training Sparse Translation Models

Abstract

Multi-task learning with an unbalanced data distribution skews learning towards high resource tasks, especially when model capacity is fixed and fully shared across all tasks. Sparse scaling architectures, such as BASELayers, provide flexible mechanisms for tasks to have a variable number of parameters, which can be useful to counterbalance skewed data distributions. However, we find that that BASELayers sparse model for multilingual machine translation can perform poorly out of the box, and propose two straightforward techniques to mitigate this — a temperature heating mechanism and dense pre-training. Overall, these methods improve performance on two multilingual translation benchmarks compared to standard BASELayers and dense scaling baselines, and in combination, more than 2x model convergence speed.

1 Introduction

Training a universal model capable of handling many different tasks is a longstanding ambition in natural language processing (Collobert and Weston, 2008; Ruder, 2017; McCann et al., 2018), with recent progress driven by training transformer models on a wide range of tasks (Xue et al., 2021; Khashabi et al., 2020; Lu et al., 2020). A central challenge in multi-task learning is accounting for the dramatically varying amounts of training data available for different tasks, which can lead to overfitting on low-resource tasks whilst simultaneously underfitting on tasks with abundant training data.

In this work, we study multilingual machine translation as a multi-task learning problem (Dong et al., 2015; Firat et al., 2016), where a single model is trained to translate between many language pairs (Fan et al., 2021). Multilingual learning has the potential of crosslingual transfer, allowing low-resource languages to benefit from high-resource data (Conneau et al., 2020). However, in practice, this positive transfer is often mitigated by interference between languages (Arivazhagan et al., 2019; Tan et al., 2019; Zhang et al., 2020). This is because all languages, irrespective of the amount of data, are trained with a fixed model capacity (Lepikhin et al., 2020), leading to insufficient specialized capacity. Recent efforts have focused on sparse architectures (Lewis et al., 2021) to train high capacity models, but these overfit to low-resource languages and have worse performance than dense architectures (Fan et al., 2021; Tran et al., 2021). We analyze the learning patterns of experts throughout training and identify a fundamental problem: experts specialize early on and rarely change specialization.

We propose two straightforward techniques to improve BASELayers-based sparse architectures (Lewis et al., 2021) for multitask learning: first, we slowly ramp the number of instances from low-resource tasks over epochs rather than having a fixed sampling ratio (Arivazhagan et al., 2019). This promotes cross-lingual transfer and reduces over-fitting as the model witnesses low-resource task instances in the later epochs. Second, we train a dense architecture before switching to sparse training. Intuitively, we learn a generalized representation that can transfer across all tasks first with a dense model and then gradually sparsify and specialize the experts to different tasks. Overall with these two modifications, we observe improvement in low-resource performance by 0.6 BLEU on WMT-15 benchmark and 1.1 BLEU on ML-50 benchmark — whilst halving the training time.

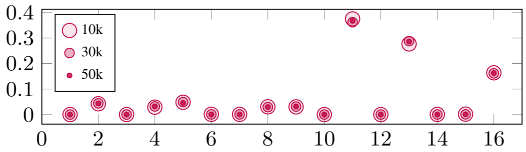
2 Methods

We motivate the need for preventing early expert specialization and describe our proposal to circumvent it and more than double convergence speed.

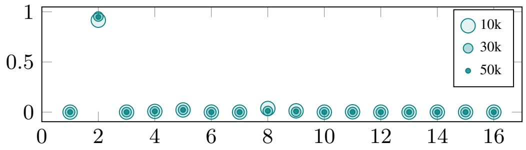
Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3340 - 3345
July 10-15, 2022

2.1 Expert Utilization Rarely Changes

Sparse scaling schemes, such as BASELayers or Mixture-of-Experts, enable sparse computation by distributing model capacity across sets of experts. In each forward pass, only a small subset of experts are utilized, leading to incredibly compute-efficient scaling. The challenge, however, is the *routing function* — or how experts can be balanced so they actually specialize to learn different things (Kudugunta et al., 2020). When the routing mechanism is unbalanced, all the tasks degenerate to using only a single specific expert for all tasks (Lepikhin et al., 2020) — essentially wasting parameters. BASELayers (Lewis et al., 2021) employ a simple mechanism that learns a balanced routing without the need for additional auxiliary losses. We focus on BASELayers as it has straightforward and simple training and has previously been shown to have strong performance.



Expert distribution for English to French



Expert distribution for English to Romanian

Figure 1: Expert distribution for Romanian and French as training progresses (10k, 30k and 50k updates) on WMT-15 benchmark, where Romanian is low-resource and French is high-resource.

Even though BASELayers leads to effective utilization of all parameters, it limits parameter sharing across tasks, which is crucial when the data distribution is unbalanced — if the number of tasks and experts are the same, all tasks end up using a different set of experts. As a result, when applied to multilingual machine translation, the performance is worse than a corresponding dense architecture. Figure 1 demonstrates that the main reason for limited parameter sharing is that expert assignment is fixed incredibly early on in training and rarely changes. Instead of learning how to better utilize capacity across high and low-resource languages over the training process, expert capacity is essentially frozen. We describe two strategies for more effective utilization of expert capacity, which can be easily applied to improve both low and high-resource translation performance.

2.2 Balancing Low-Resource Tasks

Temperature Sampling: To ensure that low-resource tasks are well represented during model training, temperature sampling (Arivazhagan et al., 2019) is used to upsample low-resource tasks. If the data distribution across different tasks is p, then temperature sampling re-scales this distribution:

$$p \leftarrow \frac{p_n^{1/T}}{\sum_{n \in |\text{tasks}|} p_n^{1/T}} \tag{1}$$

As we increase temperature from 1 to ∞, the sampling distribution changes from the original data distribution (e.g. highly skewed) to a uniform distribution (e.g. tasks are equally represented).

Temperature Heating: Instead of keeping the temperature fixed while sampling data for each task, we define temperature as a function of current epoch, $t = f(e)$

We define a minimum starting temperature t_s, which is gradually increased at each epoch e, with a square root factor defined over maximum number of epochs C. The conduction coefficient k influences the rate at which the temperature is increased over epochs.

$$t_e = \left(\sqrt{1 + \frac{k}{C} e}\right) t_s \tag{2}$$

In particular, we adopt square root scaling of temperature with each epoch, instead of linear to allow for gradual changes to the sampling distribution. During the initial steps of training, this trains with lower temperatures, meaning high-resource tasks are better represented than low-resource tasks. As a result, the experts are more uniformly assigned across high-resource tasks. Upon slowly introducing low-resource tasks by increasing temperature during the learning process, the gating mechanism learns to route low-resource tasks through experts which were initially trained with high-resource tasks. This promotes positive cross-lingual transfer from high-resource languages to linguistically similar low-resource languages.

2.3 Dense Pre-training

Architecturally, the sparsity in the output feed-forward layer of the transformer block can be viewed as a version of the same transformer on multiple GPUs with two main differences: the sparse

Model	WMT-15			ML-50			
	Low	High	All	Low	Mid	High	All
Dense	13.3	25.4	19.8	10.7	23.7	24.7	22.5
BASELayers	12.7	25.3	19.4	8.7	22.6	26.5	22.3

feed-forward layers do not share parameters (have different initialization and gradients) and an additional gating mechanism decides which token should be routed to which expert. The alternative dense architecture would fully share parameters, so all parameters are utilized for each training example rather than routing to sparse parameters.

We propose first training a dense model for a fixed number of updates. Afterwards, we add a randomly initialized gating module and continue training the (output) feed-forward layers with sparsity, e.g. we do not average their gradients across compute nodes before back-propagating but update the weights individually in each node. As the sparse weights slowly diverge, they become more specialized towards specific tasks. Thus, models first learn a generalized representation when all parameters are fully shared, and then gradually specialize to handle different tasks. Training in this fashion not only improves the learning of specialized experts, but also increases convergence.

3 Experiments and Results

We experiment with `English` → `Many` multitasking on two benchmarks, WMT-15[1] and ML-50 (Tang et al., 2020) — the first includes 15 languages and the second 50 languages. We use a Transformer (Vaswani et al., 2017) sequence-to-sequence model with 6 encoder and decoder layers. We replace the final feed-forward layer of every alternate transformer block with a BASELayer. For ML50, we increase model capacity to 12 Transformer layers following Tang et al. (2020). We implement our methods in `fairseq` (Ott et al., 2019) and evaluate performance with BLEU.

3.1 Effectiveness of Temperature Heating

On WMT-15, training with BASELayers as a baseline has worse low-resource performance compared to a similarly sized dense model, losing 0.6 BLEU. However, as we increase temperature, we recover the loss in low-resource task performance and also see improvements in the high-resource languages. The heating technique improves the overall BASELayers model performance by +0.7 BLEU (at t_s = 0.8) (see Table 1). We observe similar trends in ML-50, where adding heating improves low-resource performance by +1.4 BLEU. Furthermore, temperature heating improves convergence speed. Given fixed t_s, the higher the k, the faster the model converges. As shown in Figure 2, the model converges to same validation perplexity with k=3 at 50k updates as 100k updates with k=1.

3.2 Dense Pre-training with Heating

For the WMT-15 benchmark, Table 2 demonstrates that with dense pre-training, the best performing model improves by +0.75 BLEU over baseline BASELayers model but at the cost of 12% more compute time. To resolve this, we reduce compu-

+ heating	26.0	13.4	**20.1**	53.4	**31K**	26.7	23.1	9.8	**22.7**	53.0	**87K**

Table 2: Average BLEU across High and Low resource languages and Walltime (min) on WMT-15 and ML-50, with increasing number of dense pre-training steps at a starting fixed temperature of 1.5. Wall clock time is the total training time including dense pre-training and sparse fine-tuning until the model reaches validation perplexity of 5.99 for WMT-15 and 7.6 for ML-50.

tation time by increasing the temperature, keeping the +0.7 BLEU improvement but reducing the computation time by ∼60%. Table 2 confirms a similar trends on ML-50. By combining Dense Pre-training with heating, we improve over baseline BASELayers model by +0.5 BLEU and 2.5x in convergence speed. However, heating can also be applied to the baselines. In those cases, on both benchmarks, we find that utilizing Dense Pre-training in combination with heating still has slightly better performance with significantly faster convergence.

3.3 Effect on Expert Distribution

In standard BASELayer training, the learned expert distributions rarely change over training (see Figure 1). This prevents effective expert capacity utilization resulting in low-resource overfitting. In contrast, with our proposed techniques, the expert distribution changes and learns over training. Figure 3 compares expert distribution between fixed temperature sampling and temperature heating over epochs for a low-resource language, demonstrating that temperature heating leads experts to change and learn over time. Figure 4 shows that by utilizing dense pre-training, we observe a high entropy in the expert distribution and increased expert sharing, indicating positive cross-lingual transfer from similar high to low-resource languages.

4 Related Work

Data Sampling Low-resource tasks are upsampled to balance their representation when pooled with high-resource tasks. Temperature sampling (Arivazhagan et al., 2019) upsamples the data distribution based on fixed temperature, but can result in overfitting. Dynamic sampler (Gottumukkala et al., 2020) selects instances based on current performance of task on dev set, which is useful in case of catastrophic forgetting. Learned data samplers (Wang et al., 2020) choose better are sample efficient but computationally expensive.

Sparse Scaling Sparsely-gated MoE models (Shazeer et al., 2017; Du et al., 2021) use a routing mechanism that decides which expert a task should be routed to. This is the key element that governs effective (better representation) and efficient (balanced assignment) resource utilization. To promote a balanced assignment, routing techniques (Shazeer et al., 2017; Lepikhin et al., 2020; Fedus et al., 2021) add a number of auxiliary task to encourage the use of diverse set of experts. BASELayers (Lewis et al., 2021) circumvents this by treating the routing mechanism as a linear expert-to-task assignment problem, without the need of auxiliary loss. Routing networks (Rosenbaum et al., 2018) learn better task representations by clustering and disentangling parameters conditioned on input.

5 Conclusion

We analyze the problem of balancing shared and specialized capacity in multitask learning, focusing on multilingual machine translation. We present two straightforward tricks to significantly increase convergence rate of mixture-of-expert models and improve their performance relative to dense baselines on two benchmarks.

Abstract

Endowing the protagonist with a specific personality is essential for writing an engaging story. In this paper, we aim to control the protagonist's persona in story generation, i.e., generating a story from a leading context and a persona description, where the protagonist should exhibit the specified personality through a coherent event sequence. Considering that personas are usually embodied implicitly and sparsely in stories, we propose a planning-based generation model named CONPER to explicitly model the relationship between personas and events. CONPER first plans events of the protagonist's behavior which are motivated by the specified persona through predicting one target sentence, then plans the plot as a sequence of keywords with the guidance of the predicted persona-related events and commonsense knowledge, and finally generates the whole story. Both automatic and manual evaluation results demonstrate that CONPER outperforms state-of-the-art baselines for generating more coherent and persona-controllable stories. Our code is available at `https://github.com/thu-coai/ConPer`.

1 Introduction

Stories are important for entertainment. They are made engaging often by portraying animated and believable characters since a story plot unfolds as the characters interact with the object world created in the story (Young, 2000). Cognitive psychologists determined that the ability of an audience to comprehend a story is strongly correlated with the characters' believability (Graesser et al., 1991). And the believability mostly depends on whether the characters' reaction to what has happened and their deliberate behavior accord with their personas (e.g., weakness, abilities, occupations) (Madsen and Nielsen, 2009; Riedl and Young, 2010).

Context: · · · Artur Boruc, a Polish national pilot, was going to get the group infiltrated into the area and prepared for the attack. · · · Metal began to tear through the thin wings outside the small windows and pinged heavily off the underside of the plane, a quiet arrival in Poland wasn't going to be an option anymore.

Persona A: [Boruc] A skilled pilot, trained in operating flight controls on the most common planes.
Generated Story by CONPER Conditioned on Persona A: · · · He had been doing this much before, almost a week ago. He took a long pull of the airlock, checked his controls, and made a quick mental note of the exact sequence of instructions. He knew that he couldn't be sure if this would be safe for much longer· · ·

Persona B: [Boruc] An unskilled pilot, and never trained in operating flight controls.
Generated Story by CONPER Conditioned on Persona B: · · · He cursed as the plane suffered a complete failure and in a way had caused it to come to a stop, · · · He'd never flown before, so he didn't know how to pilot in this situation and his experience of the controls had not been good either· · ·

Table 1: An example for controlling the protagonist's persona in story generation. The **Context** and **Persona A** are sampled from the STORIUM dataset (Akoury et al., 2020). The protagonist's name is shown in the square bracket. And we manually write **Persona B** based on **Persona A**. We highlight the sentences which embody the given personas in red.

Furthermore, previous studies have also stressed the importance of personas in stories to maintain the interest of audience and instigate their sense of empathy and relatedness (Cavazza et al., 2009; Chandu et al., 2019). However, despite the broad recognition of its importance, it has not yet been widely explored to endow characters with specified personalities in story generation.

In this paper, we present the first study to impose free-form controllable persona on story generation. Specifically, we require generation models to generate a coherent story, where the protagonist should exhibit the desired personality. We focus on controlling the persona of only the protagonist of a story in this paper and leave the modeling of personas of multiple characters for future work. As exemplified in Table 1, given a context to present the story settings including characters, location, problems (e.g., "Boruc" was suffering

from a plane crash) and a persona description, the model should generate a coherent story to exhibit the persona (e.g., what happened when "Boruc" was "skilled" or "unskilled"). In particular, we require the model to embody the personality of the protagonist implicitly through his actions (e.g., "checked his controls" for the personality "skilled pilot"). Therefore, the modeling of relations between persona and events is the **first challenge** of this problem. Then, we observe that only a small amount of events in a human-written story relate to personas directly and the rest serve for explaining the cause and effect of these events to maintain the coherence of the whole story. Accordingly, the **second challenge** is learning to plan a coherent event sequence (e.g., first "finding the plane shaking", then "checking controls", and finally "landing safely") to embody personas naturally.

In this paper, we propose a generation model named CONPER to deal with *Con*trolling *Per*sona of the protagonist in story generation. Due to the persona-sparsity issue that most events in a story do not embody the persona, directly fine-tuning on real-world stories may mislead the model to focus on persona-unrelated events and regard the persona-related events as noise (Zheng et al., 2020). Therefore, before generating the whole story, CONPER first plans persona-related events through predicting one target sentence, which should be motivated by the given personality following the leading context. To this end, we extract persona-related events that have a high semantic similarity with the persona description in the training stage. Then, CONPER plans the plot as a sequence of keywords to complete the cause and effect of the predicted persona-related events with the guidance of commonsense knowledge. Finally, CONPER generates the whole story conditioned on the planned plot. The stories are shown to have better coherence and persona-consistency than state-of-the-art baselines.

We summarize our contributions as follows:

I. We propose a new task of controlling the personality of the protagonist in story generation.

II. We propose a generation model named CONPER to impose specified persona into story generation by planning persona-related events and a keyword sequence as intermediate representations.

III. We empirically show that CONPER can achieve better controllability of persona and generate more coherent stories than strong baselines.

2 Related Work

Story Generation There have been wide explorations for various story generation tasks, such as story ending generation (Guan et al., 2019), story completion (Wang and Wan, 2019) and story generation from short prompts (Fan et al., 2018), titles (Yao et al., 2019) or beginnings (Guan et al., 2020). To improve the coherence of story generation, prior studies usually first predicted intermediate representations as plans and then generated stories conditioned on the plans. The plans could be a series of keywords (Yao et al., 2019), an action sequence (Fan et al., 2019; Goldfarb-Tarrant et al., 2020) or a keyword distribution (Kang and Hovy, 2020). In terms of character modeling in stories, some studies focused on learning characters' persona as latent variables (Bamman et al., 2013, 2014) or represented characters as learnable embeddings (Ji et al., 2017; Clark et al., 2018; Liu et al., 2020). Chandu et al. (2019) proposed five types of specific personas for visual story generation. Brahman et al. (2021) formulated two new tasks including character description generation and character identification. In contrast, we focus on story generation conditioned on personas in a free form of text to describe one's strengths, weaknesses, abilities, occupations and goals.

Controllable Generation Controllable text generation aims to generate texts with specified attributes. For example, Keskar et al. (2019) pretrained a language model conditioned on control codes of different attributes (e.g., domains, links). Dathathri et al. (2020) proposed to combine a pretrained language model with trainable attribute classifiers to increase the likelihood of the target attributes. Recent studies in dialogue models focused on controlling through sentence functions (Ke et al., 2018), politeness (Niu and Bansal, 2018) and conversation targets (Tang et al., 2019). For storytelling, Brahman et al. (2020) incorporated additional phrases to guide the story generation. Brahman and Chaturvedi (2020) proposed to control the emotional trajectory in a story by regularizing the generation process with reinforcement learning. Rashkin et al. (2020) generated stories from outlines of characters and events by tracking the dynamic plot states with a memory network.

A similar research to ours is Zhang et al. (2018), which introduced the PersonaChat dataset for endowing the chit-chat dialogue agents with a consis-

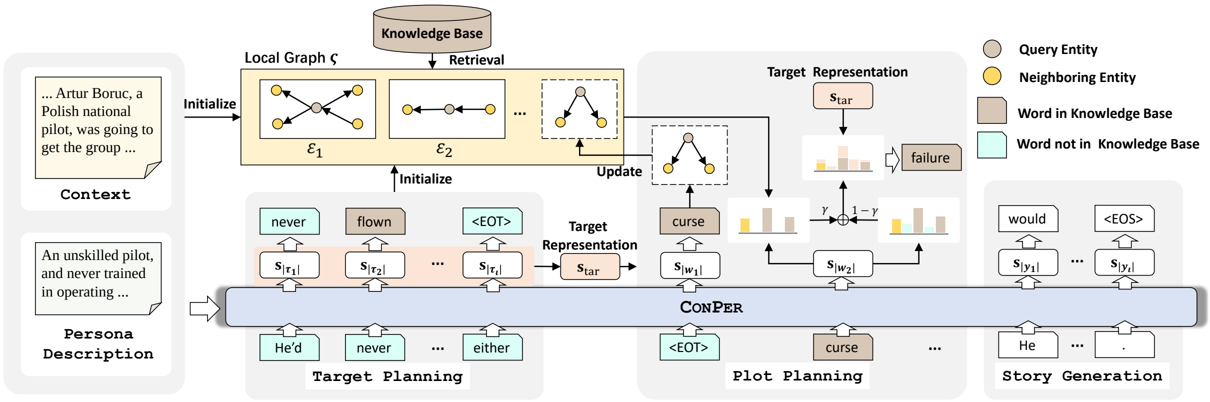

Figure 1: Model overview of ConPer. The training process is divided into the following three stages: (a) Target Planning: planning persona-related events (called "target" for short); (b) Plot Planning: planning a keyword sequence as an intermediate representation of the story with the guidance of the target and a dynamically growing local knowledge graph; And (c) Story Generation: generating the whole story conditioned on the input and plans.

tent persona. However, dialogues in PersonaChat tend to exhibit the given personas explicitly (e.g., the agent says "I am terrified of dogs" for the persona "I am afraid of dogs"). For quantitative analysis, we compute the ROUGE score (Lin, 2004) between the persona description and the dialogue or story. We find that the rouge-2 score is 0.1584 for PersonaChat and 0.018 for our dataset (i.e., STORIUM). The results indicate that exhibiting personas in stories requires a stronger ability to associate the action of a character and his implicit traits compared with exhibiting personas in dialogues.

Commonsense Knowledge Recent studies have demonstrated that incorporating external commonsense knowledge significantly improved the coherence and informativeness for dialog generation (Zhou et al., 2018a; Zhong et al., 2020), story ending generation (Guan et al., 2019), essay generation (Yang et al., 2019), story generation (Guan et al., 2020; Xu et al., 2020; Mao et al., 2019) and story completion (Ammanabrolu et al., 2021). These studies usually retrieved a static local knowledge graph which contains entities mentioned in the input, and their related entities. We propose to incorporate the knowledge dynamically during generation to better model the keyword transition in a long-from story.

3 Methodology

We define our task as follows: given a context $X = (x_1, x_2, \cdots, x_{|X|})$ with $|X|$ tokens, and a persona description for the protagonist $P = (p_1, p_2, \cdots, p_l)$ of length l, the model should generate a coherent story $Y = (y_1, y_2, \cdots, y_{|Y|})$ of length $|Y|$ to exhibit the persona. To tackle the problem, the popular generation model such as GPT2 commonly employ a left-to-right decoder to minimize the negative log-likelihood $\mathcal{L}_{ST}$ of human-written stories:

$$\mathcal{L}_{ST} = -\sum_{t=1}^{|Y|} \log P(y_t|y_{<t}, S), \quad (1)$$

$$P(y_t|y_{<t}, S) = \text{softmax}(\mathbf{s}_t \boldsymbol{W} + \boldsymbol{b}), \quad (2)$$

$$\mathbf{s}_t = \texttt{Decoder}(y_{<t}, S), \quad (3)$$

where S is the concatenation of X and P, $\mathbf{s}_t$ is the decoder's hidden state at the t-th position of the story, $\boldsymbol{W}$ and $\boldsymbol{b}$ are trainable parameters. Based on this framework, we divide the training process of ConPer into three stages as shown in Figure 1.

3.1 Target Planning

We observe that most sentences in a human-written story do not aim to exhibit any personas, but serve to maintain the coherence of the story. Fine-tuning on these stories directly may mislead the model to regard input personas as noise and focus on modeling the persona-unrelated events which are in the majority. Therefore, we propose to first predict persona-related events (i.e., the target) before generating the whole story.

We use an automatic approach to extract the target from a story since there is no available manual annotation. Specifically, we regard the sentence as the target which has the highest semantic similarity with the persona description. We consider only one sentence as the target in this work due to the persona-sparsity issue, and we also present the result of experimenting with two sentences as the target in the appendix B.1. More explorations of using multiple target sentences are left as future work. We adopt NLTK (Bird et al., 2009) for sentence tokenization. And we measure the similarity between sentences using BERTScore$_{\text{Recall}}$ (Zhang et al., 2019) with RoBERTa$_{\text{Large}}$ (Liu et al., 2019) as the backbone model. Let $T = (\tau_1, \tau_2, \cdots, \tau_\iota)$ denote the target sentence of length ι, which should be a sub-sequence of Y. Formally, the loss function $\mathcal{L}_{TP}$ for this stage can be derived as follows:

$$\mathcal{L}_{TP} = -\sum_{t=1}^{\iota} \log P(\tau_t|\tau_{<t}, S). \tag{4}$$

In this way, we exert explicit supervision to encourage the model to condition on the input personas.

3.2 Plot Planning

At this stage, ConPer learns to plan a keyword sequence for subsequent story generation (Yao et al., 2019). Plot planning requires a strong ability to model the causal and temporal relationship in the context for expanding a reasonable story plot (e.g., associating *"unskilled"* with *"failure"* for the example in Table 1), which is extremely challenging without any external guidance, for instance, commonsense knowledge. In order to plan a coherent event sequence, we introduce a dynamically growing local knowledge graph, a subset of the external commonsense knowledge base ConceptNet (Speer et al., 2017), which is initialized to contain triples related to the keywords mentioned in the input and target. When planning the next keyword, ConPer combines the knowledge information from the local graph and the contextualized features captured by the language model with learnable weights. Then ConPer grows the local graph by adding the knowledge triples neighboring the predicted keyword. Formally, we denote the keyword sequence as $W = (w_1, w_2, \cdots, w_k)$ of length k and the local graph as $\mathcal{G}_t$ for predicting the keyword w_t. The loss function $\mathcal{L}_{KW}$ for generating the keyword sequence is as follows:

$$\mathcal{L}_{KW} = -\sum_{t=1}^{k} \log P(w_t|w_{<t}, S, T, \mathcal{G}_t). \tag{5}$$

Keyword Extraction We extract words that relate to emotions and events from each sentence of a story as keywords for training, since they are important for modeling characters' evolving psychological states and their behavior. We measure the emotional tendency of each word using the sentiment analyzer in NLTK, which predicts a distribution over four basic emotions, i.e., *negative*, *neutral*, *positive*, and *compound*. We regard those words as related to emotions whose scores for *negative* or *positive* are larger than 0.5. Secondly, we extract and lemmatize the nouns and verbs (excluding stopwords) from a story as event-related keywords with NLTK for POS-tagging and lemmatization. Then we combine the two types of keywords in the original order as the keyword sequence for planning. We limit the number of keywords extracted from each sentence in stories up to 5, and we ensure that there is at least one keyword for a sentence by randomly choosing one word if no keywords are extracted. We don't keep this limitation when extracting keywords from the leading context and the persona description, since these keywords are only used to initialize the local knowledge graph.

Incorporating Knowledge We introduce a dynamically growing local knowledge graph for plot planning. For each example, we initialize the graph $\mathcal{G}_1$ as a set of knowledge triples where the keywords in S and T are the head or tail entities, and then update $\mathcal{G}_t$ to $\mathcal{G}_{t+1}$ by adding triples related with the generated keyword w_t at t-th step. Then, the key problem at this stage is representing and utilizing the local graph for next keyword prediction.

The local graph consists of multiple sub-graphs, each of which contains all the triples related with a keyword denoted as $\varepsilon_i = \{(h_n^i, r_n^i, t_n^i)|h_n^i \in \mathcal{V}, r_n^i \in \mathcal{R}, t_n^i \in \mathcal{V}\}\}|_{n=1}^{N}$, where $\mathcal{R}$ and $\mathcal{V}$ are the relation set and entity set of ConceptNet, respectively. We derive the representation $\mathbf{g}_i$ for ε_i using graph attention (Zhou et al., 2018b) as follows:

$$\mathbf{g}_i = \sum_{n=1}^{N} \alpha_n [\mathbf{h}_n^i; \mathbf{t}_n^i] \tag{6}$$

$$\alpha_n = \frac{\exp(\beta_n)}{\sum_{j=1}^{N} \exp(\beta_j)}, \tag{7}$$

$$\beta_n = (\boldsymbol{W}_r \mathbf{r}_n^i)^T \tanh(\boldsymbol{W}_h \mathbf{h}_n^i + \boldsymbol{W}_t \mathbf{t}_n^i), \tag{8}$$

where $\boldsymbol{W}_h$, $\boldsymbol{W}_r$ and $\boldsymbol{W}_t$ are trainable parameters, $\mathbf{h}_n^i$, $\mathbf{r}_n^i$ and $\mathbf{t}_n^i$ are learnable embedding representations for h_n^i, r_n^i and t_n^i, respectively. We use the same BPE tokenizer (Radford et al., 2019) with the language model to tokenize the head and tail entities, which may lead to multiple sub-words for an entity.

Therefore, we derive $\mathbf{h}_n^i$ and $\mathbf{t}_n^i$ by adding the embeddings of all the sub-words. And we initialize the relation embeddings randomly.

After obtaining the graph representation, we predict the distribution of the next keyword by dynamically deciding whether to select the keyword from the local graph as follows:

$$P(w_t|w_{<t},S,T,\mathcal{G}_t)=\gamma_t P_k^t+(1-\gamma_t)P_l^t, \tag{9}$$

where $\gamma_t \in \{0,1\}$ is a binary learnable weight, and P_l^t is a distribution over the whole vocabulary while P_k^t is a distribution over the entities in $\mathcal{G}_t$. We incorporate the knowledge information implicitly for computing both distributions:

$$P_k^t = \text{softmax}(\boldsymbol{W}_k[\mathbf{s}_t;\mathbf{c}_t]+\boldsymbol{b}_k), \tag{10}$$
$$P_l^t = \text{softmax}(\boldsymbol{W}_l[\mathbf{s}_t;\mathbf{c}_t]+\boldsymbol{b}_l), \tag{11}$$

where $\boldsymbol{W}_k, \boldsymbol{b}_k, \boldsymbol{W}_p$ and $\boldsymbol{b}_p$ are trainable parameters, and $\mathbf{c}_t$ is a summary vector of the knowledge information by attending on the representations of all the sub-graphs in $\mathcal{G}_t$, formally as follows:

$$\mathbf{c}_t = \sum_{n=1}^{N}\alpha_n \mathbf{g}_n, \tag{12}$$
$$\alpha_n = \text{softmax}(\mathbf{s}_t^T \boldsymbol{W}_g \mathbf{g}_n). \tag{13}$$

where $\boldsymbol{W}_g$ is a trainable parameter. During training process, we set γ_t to the ground-truth label $\hat{\gamma}_t$. During generation process, we decide γ_t by deriving the probability p_t of selecting an entity from the local graph as the next keyword. And we set γ_t to 1 if $p_t < 0.5$ otherwise 0. We compute p_t as follows:

$$p_t = \text{sigmoid}(\boldsymbol{W}_p[\mathbf{s}_t;\mathbf{c}_t]+\boldsymbol{b}_p), \tag{14}$$

where $\boldsymbol{W}_p$ and $\boldsymbol{b}_p$ are trainable parameters. We train the classifier with the standard cross entropy loss $\mathcal{L}_C$ derived as follows:

$$\mathcal{L}_C = -\big(\hat{\gamma}_t \text{log} p_t + (1-\hat{\gamma}_t)\text{log}(1-p_t)\big), \tag{15}$$

where $\hat{\gamma}_t$ is the ground-truth label. In summary, the overall loss function $\mathcal{L}_{PP}$ for the plot planning stage is computed as follows:

$$\mathcal{L}_{PP} = \mathcal{L}_{KW} + \mathcal{L}_C. \tag{16}$$

By incorporating commonsense knowledge for planning, and dynamically updating the local graph, ConPer can better model the causal and temporal relationship between events in the context.

Target Guidance In order to further improve the coherence and the persona-consistency, we propose to exert explicit guidance of the predicted target on plot planning. Specifically, we expect ConPer to predict keywords close to the target in semantics. Therefore, we add a bias term $\mathbf{d}_k^t$ and $\mathbf{d}_l^t$ into Equation 10 and 11, respectively, formally as follows:

$$P_k^t = \text{softmax}(\boldsymbol{W}_k[\mathbf{s}_t;\mathbf{c}_t]+\boldsymbol{b}_k+\mathbf{d}_k^t), \tag{17}$$
$$\mathbf{d}_k^t = [\mathbf{s}_{\text{tar}};\mathbf{c}_t]^T \boldsymbol{W}_d \mathbf{E}_k + \boldsymbol{b}_d, \tag{18}$$
$$\mathbf{s}_{\text{tar}} = \frac{1}{\iota}\sum_{t=1}^{\iota}\mathbf{s}_{|\tau_t|}, \tag{19}$$

where $\boldsymbol{W}_d$ and $\boldsymbol{b}_d$ are trainable parameters, $\mathbf{s}_{\text{tar}}$ is the target representation computed by averaging the hidden states at each position of the predicted target, and $\mathbf{E}_k$ is an embedding matrix, each row of which is the embedding for an entity in $\mathcal{G}_t$. The modification for Equation 11 is similar except that we compute the bias term $\mathbf{d}_l^t$ with an embedding matrix $\mathbf{E}_l$ for the whole vocabulary.

3.3 Story Generation

After planning the target T and the keyword sequence W, we train ConPer to generate the whole story conditioned on the input and plans with the standard language model loss $\mathcal{L}_{ST}$. Since we extract one sentence from a story as the target, we do not train ConPer to regenerate the sentence in the story generation stage. And we insert a special token `Target` in the story to specify the position of the target during training. In the inference time, ConPer first plans the target and plot, then generates the whole story, and finally places the target into the position of `Target`.

4 Experiments

4.1 Dataset

We conduct the experiments on the STORIUM dataset (Akoury et al., 2020). STORIUM contains nearly 6k long-form stories and each story unfolds through a series of scenes with several shared characters. A scene consists of multiple short scene entries, each of which is written to either portray one character with annotation for his personality (i.e., the *"card"* in STORIUM), or introduce new story settings (e.g., problems, locations) from the perspective of the narrator. In this paper, we concatenate all entries from the same scene since a scene can be seen as an independent story. And we regard a scene entry written for a certain character as the target output, the personality of the character as the persona description, and the previous entries written for this character or from the perspective of the narrator in the same scene as the leading context. We split the processed examples for training, validation and testing based on the official split of STORIUM. We retain about 1,000 words (with the correct sentence boundary) for each example due to the length limit of the pretrained language model.

At the plot planning stage, we retrieve a set of triples from ConceptNet (Speer et al., 2017) for each keyword extracted from the input or generated by the model. We only retain those triples of which both the head and tail entity contain one word and occur in our dataset, and the confidence score of the relation (annotated by ConceptNet) is more than 1.0. The average number of triples for each keyword is 33. We show more statistics in Table 2.

	Train	**Valid**	**Test**
# Examples	47,910	6,477	6,063
Avg. Context Length	332.7	324.8	325.7
Avg. Description Length	23.8	22.7	24.6
Avg. Story Length	230.5	225.7	234.3
Avg. Target Length	21.8	21.7	22.2
Avg. # Keywords (Input)	101.1	99.2	99.6
Avg. # Keywords (Story)	31.2	30.5	31.5

Table 2: Dataset statistics. We compute the length by counting tokens using the BPE tokenizer of GPT2. Keywords are extracted either from the input to initialize the local graph, or from the story to train the model for plot planning.

4.2 Baselines

We compare CONPER with following baselines. **(1) ConvS2S:** It directly uses a convolutional seq2seq model to generate a story conditioned on the input (Gehring et al., 2017). **(2) Fusion:** It generates a story by first training a convolutional seq2seq model, and then fixing the model and initializing another trainable convolutional seq2seq model with its parameters. Then the two models are trained together by a fusion mechanism. (Fan et al., 2018). **(3) Plan&Write:** It first plans a keyword sequence conditioned on the input, and then generates a story based on the keywords (Yao et al., 2019). **(4) GPT2$_{\text{Scr}}$:** It has the same network architecture with GPT2 but is trained on our dataset from scratch without any pretrained parameters. **(5) GPT2$_{\text{Ft}}$:** It is initialized using pretrained parameters, and then fine-tuned on our dataset with the standard language modeling objective. **(6) PlanAhead:** It first predicts a keyword distribution conditioned upon the input, and then generates a story by combining the language model prediction and the keyword distribution with a gate mechanism (Kang and Hovy, 2020). We remove the sentence position embedding and the auxiliary training objective (next sentence prediction) used in the original paper for fair comparison.

Furthermore, we evaluate the following ablated models to investigate the influence of each component: **(1) CONPER w/o KG:** removing the guidance of the commonsense knowledge in the plot planning stage. **(2) CONPER w/o TG:** removing target guidance in the plot planning stage. **(3) CONPER w/o PP:** removing the plot planning stage, which means the model first plans a target sentence and then directly generates the whole story. **(4) CONPER w/o TP:** removing the target planning stage, which also leads to the removal of target guidance in the plot planning stage.

4.3 Experiment Settings

We build CONPER based on GPT2 (Radford et al., 2019), which is widely used for story generation (Guan et al., 2020). We concatenate the context and the persona description with a special token as input for each example. For fair comparison, we also add special tokens at both ends of the target sentence in a training example for all baselines. We implement the non-pretrained models based on the scripts provided by the original papers, and the pretrained models based on the public checkpoints and codes of HuggingFace's Transformers[*]. And we set all the pretrained models to the base version due to limited computational resources. We set the batch size to 8, the initial learning rate of the AdamW optimizer to 5e-5, and the maximum training epoch to 5 with an early stopping mechanism. And we generate stories using top-p sampling with $p = 0.9$ (Holtzman et al., 2019). We apply these settings to all the GPT-based models, including GPT$_{\text{Scr}}$, GPT$_{\text{Ft}}$, PlanAhead, CONPER and its ablated models. As for ConvS2S, Fusion and Plan&Write, we used the settings from their respective papers and codebases.

4.4 Automatic Evaluation

Metrics We adopt the following automatic metrics for evaluation on the test set. **(1) BLEU (B-n):** We use $n = 1, 2$ to evaluate n-gram overlap

---

[*] `https://github.com/huggingface/transformers`

Models	Coherence				Persona consistency			
	Win(%)	Lose(%)	Tie(%)	κ	Win(%)	Lose(%)	Tie(%)	κ
ConPer vs. ConvS2S	89.0*	5.0	6.0	0.625	82.0*	8.0	10.0	0.564
ConPer vs. Fusion	71.0*	23.0	6.0	0.213	61.0*	22.0	17.0	0.279
ConPer vs. GPT2_{Ft}	54.0*	18.0	28.0	0.275	53.0*	11.0	36.0	0.215
ConPer vs. PlanAhead	53.0*	25.0	22.0	0.311	59.0*	28.0	13.0	0.280

Table 3: Manual evaluation results. The scores indicate the percentage of *win*, *lose* or *tie* when comparing our model with a baseline. κ denotes Randolph's kappa to measure the inter-annotator agreement. * means ConPer outperforms the baseline model significantly with p-value< 0.01 (Wilcoxon signed-rank test).

Models	B-1	B-2	BS-t	BS-m	PC
ConvS2S	12.5	4.7	22.2	32.8	17.1
Fusion	13.3	5.0	22.7	33.3	30.8
Plan&Write	7.2	2.8	6.2	29.7	23.6
GPT2_{Scr}	13.3	4.8	24.7	38.0	26.6
GPT2_{Ft}	13.5	4.7	26.7	37.8	39.5
PlanAhead	15.4	5.3	26.1	37.8	50.2
ConPer	**19.1**	**6.9**	**32.1**	**41.4**	**59.7**
w/o KG	17.4	6.3	31.6	39.7	53.4
w/o TG	17.7	6.3	31.9	40.2	56.3
w/o PP	14.9	5.3	32.0	40.0	46.9
w/o TP	16.4	5.8	27.8	37.7	44.9
Grouth Truth	*N/A*	*N/A*	*42.6*	*42.6*	*75.2*

Table 4: Automatic evaluation results. The best performance is highlighted in **bold**, and the second best is underlined. All results are multiplied by 100.

between generated and ground-truth stories (Papineni et al., 2002). **(2) BERTScore-target (BS-t):** We use $\text{BERTScore}_{\text{Recall}}$ (Zhang et al., 2019) to measure the semantic similarity between the generated target sentence and the persona description. A higher result indicates the target embodies the persona better. **(3) BERTScore-max (BS-m)**: It computes the maximum value of BERTScore between each sentence in the generated story and the persona description. **(4) Persona-Consistency (PC):** It is a learnable automatic metric (Guan and Huang, 2020). We fine-tune $\text{RoBERTa}_{\text{BASE}}$ on the training set as a classifier to distinguish whether a story exhibits a consistent persona with a persona description. We regard the ground-truth stories as positive examples where the stories and the descriptions are consistent, and construct negative examples by replacing the story with a randomly sampled one. After fine-tuning, the classifier achieves an 83.63% accuracy on the auto-constructed test set. Then we calculate the consistency score as the average classifier score of all the generated texts regarding the corresponding input.

Result Table 4 shows the automatic evaluation results. ConPer can generate more word overlaps with ground-truth stories as shown by higher BLEU scores. And ConPer can better embody the specified persona in the target sentence and the whole story as shown by the higher BS-t and BS-m score. The higher PC score of ConPer also further demonstrate the better exhibition of given personas in the generated stories. As for ablation tests, all the ablated models have lower scores in terms of all metrics than ConPer, indicating the effectiveness of each component. Both ConPer w/o PP and ConPer w/o TP drop significantly in BLEU scores, suggesting that planning is important for generating long-form stories. ConPer w/o TP also performs substantially worse in all metrics than ConPer w/o TG, indicating the necessity of explicitly modeling the relations between persona descriptions and story plots. We also show analysis of target guidance in Appendix C.

4.5 Manual Evaluation

We conduct a pairwise comparison between our model and four strong baselines including PlanAhead, GPT2_{Ft}, Fusion and ConvS2S. We randomly sample 100 stories from the test set, and obtain 500 stories generated by ConPer and four baseline models. For each pair of stories (one by ConPer, and the other by a baseline, along with the input), we hire three annotators to give a preference (*win*, *lose* or *tie*) in terms of *coherence* (inter-sentence relatedness, causal and temporal dependencies) and *persona-consistency* with the input (exhibiting consistent personas). We adopt majority voting to make the final decisions among three annotators. Note that the two aspects are independently evaluated. We resort to Amazon Mechanical Turk (AMT) for the annotation. As shown in Table 3, ConPer outperforms baselines significantly in coherence and persona consistency.

Furthermore, we used human annotation to eval-

Policies	Yes (%)	No (%)	κ
Random	22.0	78.0	0.25
Ours	75.0	25.0	0.36

Table 5: Percentages of examples labeled with "Yes" or "No" for whether the identified sentence reflects the given persona. κ denotes Randolph's kappa to measure the inter-annotator agreement.

uate whether the identified target sentence embodies the given persona. We randomly sampled 100 examples from the test set, and identified the target for each example as the sentence with the maximum BERTScore with the persona description. And we used a random policy as a baseline which randomly samples a sentence from the original story as the target. We hired three annotators on AMT to annotate each example ("Yes" if the sentence embodies the given persona, and "No" otherwise). We adopted majority voting to make the final decision among three annotators. Table 5 shows our method significantly outperforms the random policy in identifying the persona-related sentences.

4.6 Controllability Analysis

To further investigate whether the models can be generalized to generate specific stories to exhibit different personas conditioned on the same context, we perform a quantitative study to observe how many generated stories are successfully controlled as the input persona descriptions change.

Automatic Evaluation For each example in the test set, we use a model to generate ten stories conditioned on the context of this example and ten persona descriptions randomly sampled from other examples, respectively. We regard a generated story as successfully controlled if the pair of the story and its corresponding persona description (along with the context) has the maximum persona-consistency score among all the ten descriptions. We regard the average percentages of the stories which are successfully controlled in all the ten generated stories for each example in the whole test set as the controllability score of the model. We show the results for CONPER and strong baselines in Table 6. Furthermore, we also compute the superiority (denoted as Δ) of the persona-consistency score computed between a generated story and its corresponding description compared to that computed between the story and one of the other nine descriptions (Sinha et al., 2020). A larger Δ means the model can generate more specific stories adhering to the personas.

Models	Controllability Score	Δ
Plan&Write	10.6	0.01
GPT2$_{\text{Ft}}$	24.2	11.2
PlanAhead	23.1	11.2
CONPER	**29.5**	**15.1**

Table 6: Automatic evaluation results for the controllability. All results are mulitplied by 100.

Models	Acco (%)	Oppo (%)	Irre (%)
GPT2$_{\text{Ft}}$	21	10	69
PlanAhead	44	12	44
CONPER	**66**	9	25

Table 7: Manual evaluation results for the controllability. Acco/Oppo/Irre means the example exhibits an accordant/opposite/irrelevant persona with the input.

As shown in Table 6, there are more stories successfully controlled for CONPER than baselines. And the larger Δ of CONPER suggests that it can generate more specific stories to the input personas. The results show the better generalization ability of CONPER to generate persona-controllable stories.

Manual Evaluation For manual evaluation, we randomly sampled 50 examples from the test set, and manually revised the persona descriptions to exhibit an opposite persona (e.g., from "skilled pilot" to "unskilled pilot"). We required a model to generate two stories conditioned on the original and its opposite persona description, respectively. Finally we obtained 300 stories from three models including GPT2$_{\text{Ft}}$, PlanAhead and CONPER. Then, we hired three graduates to judge whether each story accords with the input persona. All annotators have good English language proficiency and are well trained for this evaluation task. Table 7 shows the evaluation results. We can see that 66% of the stories generated by CONPER are accordant with the input persona, suggesting the better controllability of CONPER.

4.7 Case Study

We present some cases in Table 8. We can see that the story generated by CONPER exhibits the specified persona with a coherent event sequence. The planned keywords by CONPER provide an effective discourse-level guidance for the subsequent story generation, such as `tablet`, which has a commonsense connection with `computer skills` and

Context: ··· the group has gathered on the rooftop garden of Miyamoto Mansion ··· the TV set out near the long table on the patio is talking about some spree of thefts at low volume ··· the issue of Chloe's disappearance and the missing statue still hang over their heads.

Persona Description: [Aito] You are above average in your computer skills. If information is power, then your ability to use the internet makes you one of the most powerful people on the planet.

GPT2$_{\text{Ft}}$: *Aito looked at the others, still trying to help find a way out of the hotel. He wasn't sure what the rest of the group wanted to see if they were going to survive and all knew if he needed to be needed ···*

PlanAhead: Miyamoto Mansion ··· perhaps it's just a bit farther away. The music sounds bright enough but the line of visitors does not. *Aito was once a pretty girl, he had always been quite witty when talking to people but she always found it annoying that a group of tourists looked like trash just to her ···*

CONPER: ··· "Oh, wait ··· wait ··· people are talking about Chloe?" ··· "**I have a feeling the internet is probably our best chance to get through this**" ··· Aito looked around the table a moment before pulling out her tablet and starting typing furiously into her computer. She looked up at the tablet that had appeared, and she could see that it was working on a number of things···

Planned keywords: ··· people → look → around → tablet → see ···

Table 8: Generated stories by different models. *Italic* words indicate the improper entities or events in terms of the consistency with the input. The **bold** sentence indicate the generated target by CONPER. Red words denote the consistent events adhering to the input. And the extracted keywords are underlined.

`Internet` in the input. In contrast, the baselines tend to not generate any persona-related events. For example, the given persona description emphasizes the strong computer skills of the protagonist while the stories generated by PlanAhead and GPT2 have nothing to do with the computer skills. We further analyze some error cases generated by our model in Appendix G.

5 Conclusion

We present CONPER, a planning-based model for a new task aiming at controlling the protagonist's persona in story generation. We propose target planning to explicitly model the relations between persona-related events and input personas, and plot planning to learn the keyword transition in a story with the guidance of predicted persona-related events and external commonsense knowledge. Extensive experiments show that CONPER can generate more coherent stories with better consistency with the input personas than strong baselines. Further analysis also indicates the better persona-controllability of CONPER.

Ethics Statements

We conduct the experiments by adapting a public story generation dataset STORIUM to our task. Automatic and manual evaluation results show that our model CONPER outperforms existing state-of-the-art models in terms of coherence, consistency and controllability, suggesting the generalization ability of CONPER to different input personas. And our approach can be easily extended to different syntactic levels (e.g., phrase-level and paragraph-level events), different model architectures (e.g., BART (Lewis et al., 2020)) and different generation tasks (e.g., stylized long text generation).

In both STORIUM and ConceptNet, we find some potentially offensive words. Therefore, our model may suffer from risks of generating offensive content, although we have not observed such content in the generated results. Furthermore, ConceptNet consists of commonsense triples of concepts, which may not be enough for modeling inter-event relations in long-form stories. We resort to Amazon Mechanical Turk (AMT) for manual evaluation. We do not ask about personal privacy or collect personal information of annotators in the annotation process. We hire three annotators and pay each annotator $0.1 for comparing each pair of stories. The payment is reasonable considering that it would cost average one minute for an annotator to finish a comparison.

A Implementation Details

We train our model on one Quadro RTX 6000 GPU. It costs about 25 hours to train our model, and 4 hours to generate stories using our model.

Models	**B-1**	**B-2**	**BS-t**	**BS-m**	**PC**
CONPER	**19.1**	**6.9**	32.1	**41.4**	**59.7**
CONPER (Rand)	17.4	6.2	26.0	38.9	52.1
CONPER (Multi)	17.9	6.6	**32.6**	40.0	55.1
CONPER (Sparse)	18.0	6.6	31.6	40.2	57.0
Grouth Truth	*N/A*	*N/A*	*42.6*	*42.6*	*75.2*

Table 9: Automatic evaluation results for several variants of CONPER. The best performance is highlighted in **bold**. All results are multiplied by 100.

B Analysis of Extraction Strategy

B.1 Target Extraction

We regard one sentence which has the maximum BERTScore with the persona description as the target in our model. We conducted two experiments to further investigate the influence of target extraction strategy: **(1) CONPER (Rand):** It regards a sentence randomly sampled from the story as the target for training in the target planning stage. **(2) CONPER (Multi)**: It regards two sentences which have the maximum BERTScore with the persona description as the target.

As shown in Table 9, when using a random sentence as the target, all the metrics drop significantly. And Table 5 in the main paper shows that it is hard for the random policy to select persona-related sentences. The results indicate the benefit of our methods for modeling relations between personas and events. Moreover, using multiple sentences as the target is inferior to using only one in terms of most metrics. It is possibly because stories in STORIUM tend to embody personas sparsely, and modeling the relations between personas and multiple persona-unrelated events directly may hurt the performance. The BS-t score is higher when using multiple sentences because more words can easily lead to a higher recall score.

B.2 Keyword Extraction

We extracted at most 5 keywords from each sentence for the plot planning stage. We also experimented with a more sparse plan by extracting only one keyword from each sentence (called **CONPER (Sparse)**). Table 9 shows that using a more sparse plan performs worse in all metrics. It is possibly because the limited planning keywords could not make the best of the external knowledge to form coherent and persona-related plots.

C Analysis of Target Guidance

We visualize how target guidance affects word prediction in the plot planning stage in Figure 2. The original word distribution is weighted to those words irrelevant to the target sentence, while the bias term (Equation 18) is weighted to those words related to the target sentence in semantics such as *bar*. After combining the original word distribution with the bias term, the final distribution can balance the trade-off between target guidance and language model prediction. This validates our hypothesis that target guidance can draw the planned plots closer to the target, which helps improve the story coherence and persona-consistency.

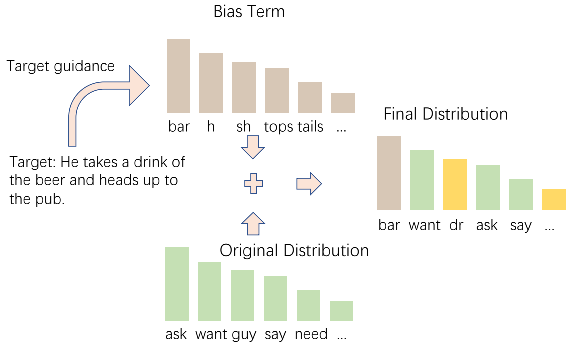

Figure 2: A case showing the effect of target guidance. The planning keywords are brought closer to the target in semantics under the target guidance.

D Diversity

We compare the diversity of CONPER with baselines using distinct-n (D-n) (Li et al., 2016), the ratio of distinct n-grams to all n-grams in generated stories. The results in Table 10 show that CONPER has better coherence and persona consistency without sacrificing the diversity.

Models	D-1	D-2	D-3	D-4
GPT2$_{\text{Scr}}$	0.021	0.134	0.381	0.653
GPT2$_{\text{Ft}}$	0.022	0.184	0.501	0.777
PlanAhead	0.032	0.256	0.618	0.863
CONPER	0.016	0.148	0.439	0.730
Grouth Truth	*0.062*	*0.368*	*0.739*	*0.927*

Table 10: Automatic evaluation results. CONPER is comparable with fine-tuned GPT2 in diversity performance.

Models	Number of Parameters
ConvS2S	135M
Fusion	255M
GPT2	124M
PlanAhead	201M
CONPER	247M

Table 11: Number of Parameters of different models.

E Manual Evaluation

We conduct manual evaluation on Amazon Mechanical Turk. To improve the annotation quality, we provide a detailed instruction for annotators, which contains: (1) a summary of our task; (2) a formal definition for coherence and persona consistency; and (3) good and bad examples for coherence and persona consistency. The detailed evaluation guideline is shown in Figure 3.

F Model Parameters

We compute the number of parameters for some models used in our experiments. The result is shown in Table 11.

G Error Analysis

Although the proposed model outperforms the strong baselines, Table 7 in the main paper shows that there are still many generated stories that exhibit opposite or irrelevant with the given persona. Therefore, we presented some typical error cases generated by our model for each error type in Figure 4. These cases show our model still does not completely control personas in story generation. When there is a slight conflict between the generated target sentence and the given persona (e.g., `you're here for fun` is slightly conflict with `slow to action`), the generated plan would further deviate from the input under the guidance of the target sentence (e.g., `excit`, `like`), and finally the generated story exhibits an opposite persona. Similarly, when the generated target sentence is irrelevant with the given persona (e.g., `That was the hardest thing too see`), the final generated story doesn't have any persona-related event. These errors also indicate the target sentence plays an important role in controlling the protagonist's persona in story generation.

Persona	**Generated Stories**	**PC**	**Rouge-2**
You have a loose grasp on your emotion and are quick to lash out. Often hurting the ones you care about most.	...**She had started to try to get her emotions under control, she had tried to keep herself calm during all of this, and she had only gotten worse.** She stood, just standing, and was staring at the class like an idiot, her head down...	0.90	0.0
<u>In command of</u> some measure of magical power	...Wilhelm is <u>in command of</u> all forces in the north. After the war ended, his mind was full of food and drink, and he was ready for a quick trip to the bar. He had been to the bar on many occasions. Only in there that he could fully relax and forget about all those mess things...	0.16	0.14

Table 12: Typical cases by PC (Persona-Consistency) score. **Bold** words denote the consistent events adhering to the given persona. The overlapping words are <u>underlined</u>.

H Discussion of the Persona-Consistency Metric

To measure whether the generated story is consistent with the given persona, we propose the Persona-Consistency(PC) metric. In our experiments, we replace the ground-truth story with a randomly sampled one to construct a inconsistent story-persona pair as a negative sample. The fine-tuned classifier achieves an 83.63% accuracy on the auto-constructed test set. However, it is possible that the PC metric depends on the word overlap to make predictions because of the simple random sampling of the negative samples (Lin et al., 2020). We thus conduct a case study to investigate whether our PC metric depends on word overlap to make judgments. As shown in Table 12, the first example gets a high PC score since the story embodies a consistent persona with the given persona description, in spite of a low rouge score. In contrast, the second example has an overlapped phrase “in command of” with the persona description but does not embody the corresponding persona description, and thus gets a high rouge score and low PC score. The results show that PC may not depend on shallow features like word overlap to make judgments.

What’s more, we have taken into account the shortcomings of the automatic metrics for NLG and thus additionally added the human evaluation to further prove the effectiveness of our method.

<table>
<tr><th colspan="2">Human Evaluation Guideline</th></tr>
<tr><td colspan="2">This study aims to evaluate automatic story generation systems. Specifically, for each story, we will put the context and the persona description into a generative system, and the following sentences will be generated by the system. In the process of evaluation, you will be given two generated stories by two difference systems, denoted as A, B. You need to compare A with B in terms of the coherence and persona consistency.
Notes:
◆ Please annotate the stories carefully based on comprehensive comparison and technically following the instruction.
◆ Please make a more fine-grained comparison when annotating persona consistency, as it is very common that neither of the two systems can clearly reflect the given persona. Be extra careful when you choose tie.</td></tr>
<tr><td colspan="2">➢ **Coherence**: context relatedness and inter-sentence causal and temporal dependencies.</td></tr>
<tr><td>Options</td><td>1. System A is better 2. System B is better 3. System A and System B are good or bad equally.</td></tr>
<tr><td>e.g.</td><td>Persona: [Pintoos] Go where you’ve never been before and share your experiences through song and story.
Context: You wake up from an uneasy rest in the Inn. The rain batters the window and occasional lightning briefly illuminates the tops of low-rising huts and hovels outside. As your level of consciousness increases you become vaguely aware of a commotion of some sort coming from outside your door...
Generated Story 1: Pintoos descends the wooden stairway from his shabby inn-room confident that this day will be the beginning of his journey to new lands, interesting characters, and forgotten knowledge. Approaching the innkeeper he sits and surveys the room. There is a steady dripping of rainwater falling from a leak in the inn's roof, a few inches from his head... "Say, what brings you here all the way from... well where you from stranger?" Pintoos nods, "Yes, my name is Pintoos I've just come here from the Southern rains. D'welsee is what we call our homeland. There once a boy is of age he is given leave of the land to explore the world and learn... well anything. **(Good coherence, some premise related parts are underlined)**
Generated Story 2: Something about this commotion is... unsettling, and it leaves his mind racing. Well, I should probably stop talking to that commotion, it seems to have been bothering him for a while. He looks around, and a loud clatter, then shakes his head, clearly confused. "Hey, no... I've been out of town, so I don't see much of this, but I think we could get there. You should see if anyone's coming over there, I don't know if I've seen anyone lately... but I think it's best if you go talk to that commotion and see if there's anyone out there. **(Bad coherence, some conflicting parts are underlined)**</td></tr>
<tr><td colspan="2">➢ **Persona Consistency**: Consistency between the generated sentences and the given persona. Specifically, a persona consistent story should reflect the desired persona of the character implicitly by plots or his/her actions.</td></tr>
<tr><td>Options</td><td>1. System A is better 2. System B is better 3. System A and System B are good or bad equally.</td></tr>
<tr><td>e.g.</td><td>Persona: [Anthony] The ghosts scare you. The moaning houses terrify you. The darkness... well, who knows what could be in it?
Context: The InSpectres made their way into the woods, only the vaguest hint of a trail in front of them. The further they went in, the more the trail disappeared. Despite going in midday, a fog seemed to cover the forest. The fact that there was any light at all was the only sign that it was still day beyond the trees. Before them, broken branches and footprints seemed to be the only signs that the creature had gone in front of them. They had to follow the path to find its home. Hopefully it would be easy...But a job like this is never easy. Even as they stepped forward, they could see and hear movement beyond the fog... Something dangerous was out there. It would definitely hamper their search if it wasn't dealt with properly...
Generated Story 1: …There! Something moved, he was sure of it! "Were cat! Were cat! It's here!" "Actually, no," Ronnie observed once it hopped out of the fog… "it'll change then kill us!" .. **(Good persona consistency, personalized sentence is underlined)**
Generated Story 2: His eyes narrowed as he could see through the mist, and his hands danced like a pair of marionettes in the moon. Slowly he started to climb, until he felt his hands begin to brush against the dark fog. It was like the sun was setting. He noticed a light shining outwards, and something...something was there. God he was glad he didn't fall into the same pit. **(Bad persona consistency: reflect no persona)**
Generated Story 3: "A wolf?" Aiden yelled. He felt the urge to make himself sound faster and faster at the end of his body. "It's ok." "No." The wolf said. The other thing began shouting through the forest. "It's not like this. You're not a bad man." **(Bad persona consistency: reflect calm persona, personalized sentence is underlined)**</td></tr>
</table>

Figure 3: The guideline of story quality evaluation.

Error Type	Cases
Opposite	**Context:** The students have a surprisingly restful night of sleep. No weird dreams, no monsters, no strangers in tuxedos. The students head out to school. They run into each other as they enter the building and decide to have a chat about yesterdays events over breakfast…The students grab what the want to eat and sit at a table near the back of the cafeteria. They agree to try to keep calm in order to not raise the suspicion of other students and faculty.
	Persona: [Vivian] You are frequently lost in thought making you slow to action.
	Story: …It's a big space, so that's **a great opportunity to get excited, to get to know some of the new people.** **You may not be the most social person around, but you're here for fun**…"
	Plan keywords: excit→student→like→come→…
Irrelevant	**Context:** The lights are bright above you, you lay in a bed with metal bars on either side. At first you think you are in a hospital but it did not smell like one, in fact you could smell nothing at all. When you lift your head you see that there are seven other people in the room with you and you are all wearing white clothing that looks a lot like scrubs but made of much better fabric...There is a doorway that leads into a hall, there is no door just an open doorway and the hall looks to be the same as the room.
	Persona: [Shay Lorence] You are not anxious and it is easy for you to believe someone else
	Story: *What's going on here? ... Looking up the hall, the room had black or gray light. The dark looked like that from the darkest rooms in the world, or maybe it could be dark, darker. I could see it from the window, the darkness in the room, even the bed, but that couldn't be the case. There was nothing here. There was just a room with no light. ... I had to take the other side to the hall, to the other side of the hall. The hallway was endless. That was the hardest thing to see...*
	Plan keywords:room→bed→nightmare→wall→hallway→wake…

Figure 4: Typical errors by our model. **Bold** words indicate the events exhibiting the opposite persona. *Italic* words indicate the events that are irrelevant with the given persona. And the red sentence indicate the generated target by ConPer.

CHEF: A Pilot Chinese Dataset for Evidence-Based Fact-Checking

Abstract

The explosion of misinformation spreading in the media ecosystem urges for automated fact-checking. While misinformation spans both geographic and linguistic boundaries, most work in the field has focused on English. Datasets and tools available in other languages, such as Chinese, are limited. In order to bridge this gap, we construct CHEF, the first CHinese Evidence-based Fact-checking dataset of 10K real-world claims. The dataset covers multiple domains, ranging from politics to public health, and provides annotated evidence retrieved from the Internet. Further, we develop established baselines and a novel approach that is able to model the evidence retrieval as a latent variable, allowing jointly training with the veracity prediction model in an end-to-end fashion. Extensive experiments show that CHEF will provide a challenging testbed for the development of fact-checking systems designed to retrieve and reason over non-English claims. Source code and data are available[1].

Claim: 2019年, 共有12.08万人参加成都中考，但招生计划只有4.3万。*In 2019, a total of 120,800 students participated in the high school entrance examination in Chengdu, but schools only enrolled 43,000 students.*

Document: 今年共有12.08万人参加中考，这个是成都全市, 包括了20个区，高新区和天府新区的总参考人数。月前，教育局公布了2019年的普高招生计划。招生计划数进一步增加，上普高的机会更大了... 中心城区（13个区）招生计划为43015人。*This year, 120,800 people participated in the high school entrance examination. This number is for the entire city of Chengdu, including 20 districts, high-tech zone and Tianfu new district. A month ago, the Education Bureau announced the 2019 high school enrollment plan. The number of enrollment will be increased, indicating that there is a greater chance of going to high school... The plan of the central area (including 13 districts) is 43,015.*

Verdict: Refuted; **Domain**: Society

Challenges: Evidence Collection; Numerical Reasoning

Table 1: An example from CHEF (Chinese is translated into English). The claim is refuted by the evidence, which are sentences retrieved (highlighted) from the document. For brevity, only the relevant snippet of the document is shown.

1 Introduction

Misinformation is being spread online at increasing rates, posing a challenge to media platforms from newswire to social media. In order to combat the proliferation of misinformation, fact-checking is an essential task that assesses the veracity of a given claim based on evidence (Vlachos and Riedel, 2014). Fact-checking is commonly conducted by journalists. However, fact-checking is a time-consuming task, which can take journalists several hours or days (Adair et al., 2017). Thus, there is a need for automating the process.

Although misinformation spans both geographic and linguistic boundaries, most existing works focused on English (Wang, 2017; Thorne et al., 2018; Augenstein et al., 2019; Hanselowski et al., 2019; Chen et al., 2020). There only exists a handful of non-English datasets for verifying real-world claims. However, these datasets are either small in size (Baly et al., 2018), or designed for multilingual systems (Gupta and Srikumar, 2021). On the other hand, Khouja (2020) and Nørregaard and Derczynski (2021) created claims by paraphrasing sentences from non-English articles, but synthetic claims cannot replace real-world claims for training generally applicable fact-checking systems.

To bridge this gap, we introduce a CHinese dataset for Evidence-based Fact-checking (CHEF). CHEF includes claims that are not only relevant to the Chinese world, but also originally made in Chinese. It consists of 10,000 real-world claims, collected from 6 Chinese fact-checking websites covered multiple domains and paired with annotated evidence. To ensure annotation consistency,

Table 2: Comparisons of fact-checking datasets. Type in the header means the type of evidence used, which can be text, metadata or both. Source means where the evidence are collected from, such as Wikipedia (Wiki), fact-checking websites (FC). Retrieved denotes if the evidence is given or retrieved from the source. Annotated means whether the evidence is manually annotated. Verify, FakeCovid, XFact contain claims in multiple languages, but Chinese claims are not included.

we developed suitable guidelines and performed data validation[2]. We shared some of the insights obtained during the annotation process that we hope will be beneficial to other non-English annotation efforts. Table 1 shows an instance from CHEF. In order to verify the claim, one needs to first retrieve the evidence sentences from related documents (e.g. government reports), then predict the veracity based on the evidence. After comparing the statistics of the entire city and central area, we can reach the verdict that the claim is refuted by evidence. To characterize the challenge of the dataset presented, we perform a thorough analysis and demonstrate the utility of the dataset by developing two types of baselines, including pipeline and joint systems. Our key contributions are summarized as follows:

1. We provide the first sizable multi-domain Chinese dataset for automated fact-checking. It consists of 10K real-world claims with manually annotated evidence sentences.
2. We further propose an approach that is able to model the evidence selection as a latent variable, which can be jointly trained with the veracity prediction module.
3. We develop several established baselines and conduct a detailed analysis of the systems evaluated on the dataset, identifying challenges that need to be addressed in future research.

2 Background: Dataset Comparisons

In this section, we reviewed the existing fact-checking dataset as summarized in Table 2. Following Guo et al. (2022), we grouped the datasets into two categories: natural and synthetic. Natural datasets consist of real-world claims, while synthetic datasets contain claims created artificially by mutating sentences from Wikipedia articles.

2.1 Non-English Dataset

Existing efforts in the construction of non-English datasets are limited, both in scope and in size. Verify (Baly et al., 2018) contains 422 claims in Arabic and FakeCovid (Shahi and Nandini, 2020) has 3,306 non-English claims about COVID-19. Though XFact (Gupta et al., 2020) includes 31,189 claims in 25 languages, it mainly focuses on the multilingual setting, where the average number of instances per language is 1,248. More importantly, these datasets do not include annotated evidence. For example, XFact used search summaries returned by Google as evidence. On the other hand, Khouja (2020) and Nørregaard and Derczynski (2021) constructed synthetic datasets by mutating sentences from Arabic news and Danish

---

[2] The annotation guideline is provided in the appendix.

Wikipedia articles, respectively. Unlike previous efforts, CHEF consists of 10K real-world claims paired with annotated evidence.

There exist Chinese datasets focused on rumor detection (Ma et al., 2016; Zhang et al., 2021), which is classified into claim detection (Kotonya and Toni, 2020a; Guo et al., 2022), as it is based on language subjectivity and growth of readership (Qazvinian et al., 2011). A claim can be factual regardless of whether it is a rumour (Zubiaga et al., 2018). Unlike existing rumor detection datasets, CHEF focuses on factuality of the claim.

2.2 Evidence-Based Fact-Checking

Early efforts predicted the veracity solely based on the claims or with metadata (Rashkin et al., 2017; Wang, 2017), but relying on surface patterns of claims without considering the state of the world fails to identify well-presented misinformation (Schuster et al., 2020). Therefore, synthetic datasets (Thorne et al., 2018; Jiang et al., 2020; Aly et al., 2021) considered Wikipedia as the source of evidence and annotated the sentences supporting or refuting each claim. However, these efforts restricted world knowledge to a single source (i.e. Wikipedia), ignoring the challenge of retrieving evidence from heterogeneous sources on the Internet.

To address this, recent natural datasets (Augenstein et al., 2019; Gupta and Srikumar, 2021) used the summary snippets returned by Google as evidence. One key limitation of this approach is that summary snippets do not provide sufficient information to verify the claim. Gupta and Srikumar (2021) showed that only 45% of snippets provide sufficient information, while 83% of the full text from web pages provides sufficient evidence to determine veracity of the claim. To construct a better evidence-based dataset, we retrieve documents from web pages and manually select relevant evidence sentences from documents as evidence. Such a design makes CHEF suitable to train fact-checking systems that can extract evidence from web-sources and validate real-world claims based on evidence found on the Internet.

3 Dataset Construction

CHEF is constructed in four stages: data collection, claim labeling, evidence retrieval and data validation. Data collection selects sources, crawls claims and associated metadata. Claim labeling identifies claims from fact-checking articles and assigns the veracity labels of claims based on the article. Evidence retrieval collects documents from the Internet and selects the most relevant sentences as evidence. Data validation controls the annotation quality. The annotation team has 25 members, 5 of them are only involved in data validation. All annotators are native Chinese speakers. To ensure the annotation quality, they were trained by the authors and went through several pilot annotations.

Website	Domain	URL	Total
Piyao	Multiple	`www.piyao.org.cn`	3,741
TFC	Multiple	`tfc-taiwan.org.tw`	1,759
Mygopen	Multiple	`www.mygopen.com`	1,654
Jiaozhen	Multiple	`vp.fact.qq.com`	157
Cnews	Multiple	`m.chinanews.com`	2,689
Total	Multiple	-	10,000

Table 3: Statistics of data sources. Piyao, TFC, MyGoPen and Jiaozhen are fact-checking websites. Cnews is a news website.

3.1 Data Collection

We crawled all active Chinese fact-checking websites listed by Duke Reporters[3]. However, most claims fact-checked by the fact-checkers are non-factual, solely relying on such claims will lead to an imbalance dataset. Therefore, we followed Kotonya and Toni (2020b) by crawling articles from the news review site. As shown in Table 3, this resulted in 5 websites in total. From each website, we crawled the full text of the article and corresponding metadata (e.g. author, domain, URL publication date). Totally, we crawled 14,770 fact-checking and news articles. There exists a number of crawling issues, such as the article could not be retrieved, or the content is not textual. We removed such instances. Next, we checked the dataset for duplications. Upon manual inspections, this was mainly due to them appearing on different websites. All duplications would be in the training split of the dataset, so that the model would not have an unfair advantage. As shown in Figure 5, claims cover multiple domains, including politics, public health, science, society and culture. More than 36% of claims belong to public health domain, as many fact-checking articles focused on countering misinformation related to COVID-19. The society domain has second most claims, which involves social events that are closely related to people's daily lives.

---

[3] `www.reporterslab.org/fact-checking/`

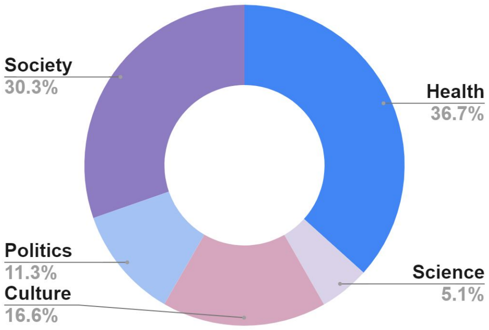

Figure 1: Distributions of domains. Each instance is categorized into five different domains.

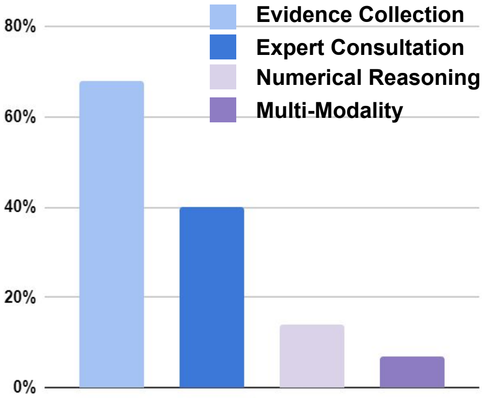

Figure 2: Distributions of challenges. Each instance can have multiple challenges. Evidence collection means finding relevant textual information from web-sources. Expert consultation collects information directly from relevant people. Numerical reasoning requires inference over numbers and multi-modality requires collect and infer over multi-modal evidence.

3.2 Claim Labeling

The major challenge of constructing a non-English dataset is extracting a claim and its veracity from a fact-checking article usually requires human efforts. Unlike fact-checking articles in English, many non-English articles (e.g. Chinese, Hindi, Filipino) do not explicitly give the claim and assign the veracity. Therefore, extracting the claim, which can appear in the title, or anywhere in the article, requires manual efforts. Before labeling the claim, we need to extract them from the fact-checking articles. When performing claim extraction, annotators need to read the fact-checking article first, then identify the claim. They are encouraged to select sentences directly from the article. However, resulted sentences may not be complete, which means they do not provide enough context for fact-checking. One common case is that the sentence describing a fact often lacks the time stamp, or the location. For example, the claim "Price of pork increases dramatically due to the African swine fever." is factual in 2020 but non-factual in 2021. Therefore, annotators are asked to complete the claim by adding missing content to ensure the claim to be standalone for later verification[4]. Another issue is that Chinese fact-checkers tend to use rhetorical questions to express non-factual claims. To alleviate the bias that the factuality of a claim can be decided by its surface form, annotators are required to paraphrase the questions into declarative statements.

Next, annotators are required to label the extracted claims. English fact-checking articles often provide different truth-rating scales, such as false, mostly false and mixture, while many non-English counterparts do not have such taxonomies. Therefore, annotators need to label the extracted claim based on the understanding of the fact-checking article. Journalism researchers showed that fine-grained labels are often assigned inconsistently due to subjectivity (Uscinski and Butler, 2013; Lim, 2018). Therefore, we chose to follow previous efforts (Thorne et al., 2018; Hanselowski et al., 2019) by adopting three types of labels: supported (SUP), refuted (REF) and not enough information (NEI), given the evidence. The distribution of labels in CHEF is shown in Table 4. CHEF consists of a majority of refuted claims, as the majority of fact-checking articles aim to debunk non-factual claims.

3.3 Evidence Retrieval

When verifying a claim, journalists first find information relating to the fact and evaluate it given the collected evidence. As shown in Figure 1, the biggest challenge of verifying a claim is to collect relevant evidence. In order to validate real-world claims, we chose to manually extract evidence from web-sources. We have two measures to ensure the reliability of the evidence. Firstly, we maintained a list of misinformation and disinformation websites, all search results from these websites will be filtered out. Secondly, we required the annotators to manually select evidence sentences from the search results. In order to collect evidence from the web-sources, we first submitted each claim as a query to the Google Search API by following Augenstein et al. (2019) and Gupta and Srikumar (2021). The ten most highly ranked search results are retrieved. For each result, we saved the search rank, URL, time stamp and document. Then we filtered out results from fact-checking websites to prevent the

Test	333	333	333	999
Avg #Words in the Claim				28
Avg #Words in the Google Snippets				68
Avg #Words in the Evidence Sentences				126
Avg #Words in the Source Documents				3,691

Table 4: Dataset split sizes and statistics for CHEF.

answer from being trivially found. Next, annotators were asked to select sentences from the resulted documents. To maintain a balance between keeping relevant and removing irrelevant information, we followed Thorne et al. (2018) and Hanselowski et al. (2019) that up to five sentences were selected as evidence. Before deciding which sentences should be selected, annotators were required to answer auxiliary questions, such as "Whether selected sentences provide sufficient information for factual verification?" They were encouraged to select the five most relevant sentences, but they were allowed to pick less when relevant sentences are not available. A small fraction (5.6%) of instances do not have any relevant evidence, and we chose to discard them.

3.4 Data Validation

To ensure the annotation consistency, we conducted an additional 5-way inter-annotator agreement and manual validation. For inter-annotator agreement, we randomly selected 3% (n = 310) of claims to be annotated by 5 annotators. We calculated the Fleiss K score (Fleiss, 1971) to be 0.74, which is comparable with 0.68 reported in Thorne et al. (2018) and 0.70 in Hanselowski et al. (2019). In order to verify if evidence sentences provide sufficient information, we chose another 310 instances. The second group of annotators were required to assign the labels based on the evidence sentences. We found that 88.7% of the instances were labeled correctly and 83.6% of them provided sufficient information to determine the veracity. Finally, as shown in Table 4, we partitioned the dataset CHEF into training, development and test sets. Our development and test sets have balanced class distributions. Each claim is paired with Google snippets, evidence sentences and source documents.

4 Baseline Systems

Unlike previous natural datasets, CHEF requires the system to first retrieve the evidence sentences from the documents, then predict the veracity based on the evidence. Therefore, we design two types of baselines: pipeline and joint systems.

4.1 Pipeline System

The pipeline system treats evidence retrieval and veracity prediction as two independent steps.

4.1.1 Evidence Retrieval

Given the claim and documents, this step aims to select the most relevant sentences from documents as evidence, which can be viewed as a ranking problem. Thus, we adopt the following models:

Surface Ranker Following retrieval models designed for synthetic datasets (Thorne et al., 2018; Jiang et al., 2020; Aly et al., 2021), We use TF-IDF to sort the most similar sentences first and tune a cut-off using validation accuracy on the dev set.

Semantic Ranker Inspired by Nie et al. (2019) and Liu et al. (2020), we choose semantic matching based on BERT (Devlin et al., 2019) pre-trained on Chinese corpus (Wolf et al., 2020). The cosine similarity scores between the embedding of the claim and the embeddings of other sentences in the document are used for ranking.

Hybrid Ranker Since semantic encoding is complementary to surface form matching, they can be combined for better ranking. Following Shaar et al. (2020), we use the rankSVM, based on the feature sets of rankings returned by TF-IDF and the similarity scores computed with BERT.

Google Snippets As discussed in Section 2, existing natural datasets (Augenstein et al., 2019; Gupta and Srikumar, 2021) do not require the system to retrieve the evidence sentences from the documents. Instead, they used summary snippets returned by the Google Search Engine as evidence. We also include this type of evidence for comparisons.

4.1.2 Veracity Prediction

After retrieving the evidence sentences, veracity prediction aims to predict the label of the given claim. We implement the following classifiers:

BERT-Based Model Following Jiang et al. (2020) and Schuster et al. (2021), we use a multilayer perceptron with embeddings from BERT as the classifier. The embeddings of claim and retrieved evidence are concatenated as the input. The model performs the classification based on the output representation of the `CLS` token.

Attention-Based Model Following Gupta and Srikumar (2021), we first extract the output embedding of the `CLS` token of each selected evidence and calculate relevance weights with the claim through dot product attention. Then we feed the concatenated claim and weighted evidence into the BERT-based classifier.

Graph-Based Model Recent efforts (Zhou et al., 2019; Zhong et al., 2020; Liu et al., 2020) showed that graphs help to capture richer interactions among multiple evidence for fact-checking. We adopt the Kernel Graph Attention Network (Liu et al., 2020) for veracity prediction. The evidence graph is constructed based on the claim and evidence sentences, then node and edge kernels are used to conduct fine-grained evidence propagation. The updated node representations are used to calculate the claim label probability.

4.2 Joint System

Evidence retrieval in the pipeline system could not solicit optimization feedback obtained from veracity prediction. In order to optimize two steps jointly, we proposed to model the evidence retrieval as a latent variable. The joint system contains two modules: a latent retriever and a classifier. For the classifier, we used the same models described in Section 4.1. Latent retriever labels each sentence in the documents with a binary mask. Sentences labeled with 1 are selected as the evidence, while sentences labeled with 0 will be neglected.

4.2.1 Latent Retriever

We built the latent retriever based on the Hard Kumaraswamy distribution (Bastings et al., 2019), which gives support to binary outcomes and allows for reparameterized gradient estimates[5]. We first stretch the Kumaraswamy distribution (Kumaraswamy, 1980) to include 0 and 1 by the support of open interval (l, r) where $l < 0$ and $r > 1$, defined as $K^{'} \sim \mathrm{Kuma}(a, b, l, r)$ with CDF:

$$F_{K'}(k^{'}; a, b, l, r) = F_{K'}((k^{'} - l)/(r - l); a, b) \tag{1}$$

A sigmoid function $k^{''}$=$\min(1, \max(0, k^{'}))$ is used to rectify random variables into the closed interval $[0, 1]$, denoted by $K^{''} \sim \mathrm{HardKuma}(a, b, l, r)$ and $k^{''}$=$s(u; a, b, l, r)$ for short. Note that we map all negative values $k^{'} \in (l, 0]$ into $k^{''}$=0 and $k^{'} \in [1, r)$ into $k^{''}$=1 deterministically, so the sets whose masses under $\mathrm{Kuma}(k^{'}|a, b, l, r)$ are available in the closed form:

$$\begin{aligned}\mathbb{P}(K^{''} = 0) &= F_K(\frac{-l}{r-l}; a, b)\\ \mathbb{P}(K^{''} = 1) &= 1 - F_K(\frac{1-l}{r-l}; a, b)\end{aligned} \tag{2}$$

Given source documents D, the latent retriever selects relevant sentences as evidence that can be used to predict the veracity for the claim c. For the i-th sentence $x_i \in D$, we obtain the sentence-level embedding $\mathbf{h}_i$ based on a BERT encoder by using the `CLS` token. Then we can calculate the latent selector $k_i^{''}$ by:

$$\begin{gathered}k_i^{''} = s(u_i; a_i, b_i, l, r),\\ a_i = f_a(\mathbf{h}_i; \phi_a) \quad b_i = f_b(\mathbf{h}_i; \phi_b) \quad u_i \sim \mathcal{U}(0, 1)\end{gathered} \tag{3}$$

where $f_a(\cdot; \phi_a)$ and $f_b(\cdot; \phi_b)$ are feed-forward networks with softplus outputs a_i and b_i. $s(\cdot)$ turns the uniform sample u_i into the latent selector $k_i^{''}$. Next, we use the sampled $k_i^{''}$ to modulate inputs to the classifier for veracity prediction:

$$f_F\left(k_i^{''} \cdot \mathbf{h}_i, \mathbf{c}; \theta_F\right) \tag{4}$$

where $\mathbf{c}$=$f_{\theta'}(c)$ denotes the embedding for the given claim c obtained by using the `CLS` token through a BERT encoder. $f_F(\cdot; \theta_F)$ represents the classifier (e.g. graph-based model). The joint system can be optimized by gradient estimates of $\mathcal{E}(\phi, \theta)$ via Monte Carlo sampling from:

$$\mathcal{E}(\phi, \theta) = \mathbb{E}_{\mathcal{U}(0,1)}\left[\log P\left(y \mid X, s_\phi(u, X), \theta\right)\right] \tag{5}$$

where y is the label of veracity and $k_i^{''} = s_\phi(u, X)$ abbreviate the transformation from uniform samples to $\mathrm{HardKuma}$ samples.

4.2.2 More Baselines

Apart from the proposed system, we include following baselines for comprehensive comparisons:

Reinforce Instead of using gradient-based training, we follow Lei et al. (2016) by assigning a binary Bernoulli variable to each evidence sentence.

---

[5] Please refer to the detailed derivations in Bastings et al. (2019).

Because gradients do not flow through discrete samples, the evidence retriever is optimized using REINFORCE (Williams, 1992). A L_0 regularizer is used to impose sparsity-inducing penalties.

Multi-task We also adopt the multi-task learning method proposed by Yin and Roth (2018), which is the state-of-the-art joint model on FEVER dataset (Thorne et al., 2018). The model predicts a binary vector that indicates the subset of sentences as evidence, and a one-hot vector indicates the veracity of the claim. The overall training loss is the sum of these two prediction losses.

5 Experiments and Analyses

5.1 Experimental Setup

Following Augenstein et al. (2019), we computed the Micro F1 and Macro F1 as the evaluation metric. We further reported the mean F1 score and standard deviation by using 5 models from independent runs. For the pipeline system, we used 6 different evidence settings, including evidence sentences retrieved by surface ranker, semantic ranker and hybrid ranker, Google snippets, gold evidence and without using any evidence. For the joint system, we used 2 types of evidence: Google snippets and source documents, where the latent retriever can select sentences from. We used three classifiers for both systems, BERT-based (Schuster et al., 2021), attention-based (Gupta and Srikumar, 2021) and graph-based models (Liu et al., 2020).

The hyper-parameters are chosen based on the development set. In the evidence retrieval step of the pipeline system, we set the retrieved evidence obtained from TF-IDF to be more than 5 words for surface ranker. We use the BERT default tokenizer with max-length as 256 to preprocess data for semantic ranker. We use the default parameters in sklearn.svm.LinearSVC with RBF kernel for hybrid ranker.

In the veracity predication step of the pipeline system, we use the BERT default tokenizer with max-length as 256 and pretrained BERT-base-Chinese as the initial parameter to encode claim and evidence[6]. For BERT-based model, the fully connected network for classification is defined with layer dimensions of h_R-$h_R/2$-verification_labels, where $h_R = 768$. We use BertAdam (Devlin et al., 2019) with $5e{-}6$ learning rate, warmup with 0.1 to optimize the cross entropy loss and set the batch size as 16. For attention-based model, we use BertAdam with $2e{-}5$ learning rate, warmup with 0.1 to optimize the cross entropy loss and set the batch size as 8. For graph-based model, we use BertAdam with $5e{-}5$ learning rate, warmup with 0.1, batch size with 16, dropout with 0.6 and kernel size with 21.

For the joint system, we use Adam (Kingma and Ba, 2015) with $5e{-}5$ learning rate, learning rate decay with 0.5 to optimize the cross entropy loss. We set the batch size as 32. The fully-connected networks $f_a(\cdot;\phi_a)$ and $f_b(\cdot;\phi_b)$ for two parameters a_i and b_i are defined with layer dimensions of $h_R = 768$. We set the dropout rate as 0.5.

5.2 Main Results

Pipeline System: According to Table 5, pipeline systems with evidence including Google snippets, sentences returned by rankers and gold evidence consistently outperform systems without using evidence. These results confirm that evidence plays an important role in verifying real-world claims. On the other hand, systems with retrieved sentences achieve higher scores than systems with Google snippets. Specifically, systems with gold evidence significantly outperform the ones with Google snippets, indicating information that is necessary for verification is missing in the snippets. Moreover, systems with retrieved evidence are more robust in terms of standard deviation. We hypothesize the reason is that irrelevant information is presented in the snippets. When comparing with different rankers, we observed that using contextualized representations to measure the similarity (Semantic Ranker) is generally better than exact string match (Surface Ranker). However, there still exists a large performance gap between the pipeline system with semantic ranker and the system with gold evidence. One potential solution is to develop better retrieval models based on the supervision signal of gold evidence provided by CHEF. Given the evidence sentences, graph-based models tend to have higher scores than BERT-based and attention-based models, which shows the effectiveness of leveraging graph structure to synthesize multiple evidence.

Joint System: Similar to the pipeline systems, joint systems that retrieve evidence sentences from documents achieve better F1 scores than directly use the summary snippets. In order to verify real-world claims, it is necessary to train fact-checking systems that learn how to effectively retrieve evi-

Schuster et al. (2021)[1], Gupta and Srikumar (2021)[2], Liu et al. (2020)[3], Lei et al. (2016)[4], Yin and Roth (2018)[5]

Table 5: Results of pipeline and joint systems on CHEF.

dence sentences from full documents on web pages. In addition, joint system outperforms pipeline system consistently with both Google snippets and source documents as inputs. For example, latent retriever with Google snippets are able to achieve an average 2.74% and 1.77% Micro/Macro F1 boost compared with the pipeline systems with the same type of evidence. We attribute the consistent improvement of joint system to the explicit feedback to the evidence retrieval via gradient estimation on veracity prediction. Another advantage of the joint system is that the latent evidence retriever is able to dynamically select relevant sentences from documents for each instance, while rankers return a fixed number of evidence.

Compared with the reinforce and multi-task methods, the proposed latent retriever achieves 1.41% and 1.98% higher F1 on average with Google snippets and source documents as inputs across various classifiers. When considering standard deviation, reinforce is less robust. We believe the main reason is that latent retriever facilitate training through differentiable binary variables, which leads to robust and generalized model that exhibits small variance over multiple runs.

5.3 Analysis and Discussion

In this section, we further provide fine-grained analyses for baseline systems on CHEF. For brevity, we abbreviate pipeline systems with Google Snippets, Surface Ranker, Semantic Ranker, Hybrid Ranker as **GS**, **Sur**, **Sem**, **Hyb**, while joint systems with Google snippets and source documents as inputs as **JG** and **JS**, respectively. All results are reported based on the BERT-based model. We further provide case study and error analysis on CHEF. Due to limited spaces, we attach them in the appendix.

#E	GS	Sur	Sem	Hyb	JG	JS
1	55.24	55.67	56.04	56.72	56.98	57.54
3	58.69	59.24	59.52	59.18	59.89	61.45
5	**60.61**	**61.47**	**61.94**	**61.80**	**62.12**	64.65
10	59.12	60.20	60.37	61.24	61.86	**64.73**

Table 6: Effects of evidence: Macro F1 scores on the test set are reported. #E indicates the number of evidence.

Effect of Evidence: In Table 6, we varied the numbers of evidence retrieved and reported the Macro F1 on the test set. The fluctuation results indicate that both quantity and quality of retrieved evidence affect the performance. Using fewer evidence will lead to incomplete coverage, which may not provide sufficient information to verify the claims. On the other hand, incorporating more evidence may introduce irrelevant sentences thus propagate errors to veracity prediction. In general, systems with 5 evidence sentences achieves the best performance except the joint system with source documents as inputs. We believe the reason is that the latent retriever maintains a better balance between keeping relevant and removing irrelevant sentences, which helps to achieve higher scores with more evidence sentences.

Performance against Claim Length: We partitioned the test set into 4 classes (<10, 10-19, 20-29, ≥30) based on lengths of the claims and reported

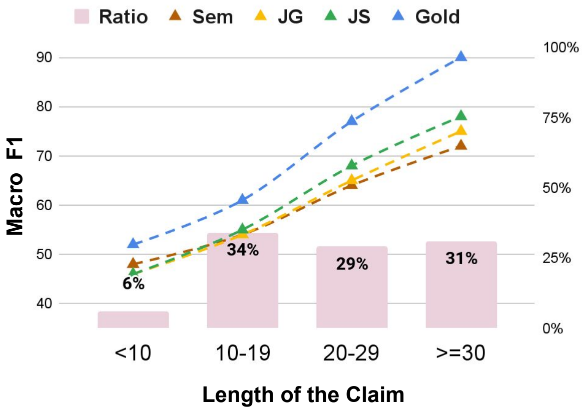

Figure 3: Comparisons against claim lengths.

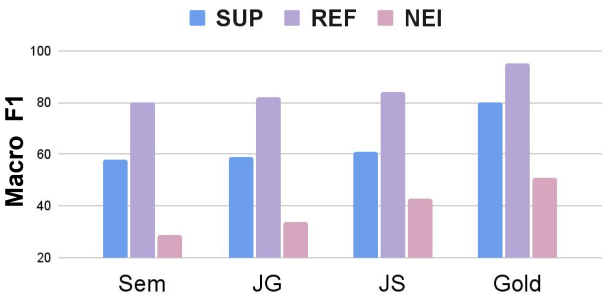

Figure 4: Per-class results.

the Macro F1 score. For clarity, we choose the best reported pipeline system with semantic ranker to compare with joint systems. As shown in Figure 3, most claims are longer than 10 words. Performance of the systems on short claims (e.g. <10) is lower than other. One reason is that such claims do not contain sufficient information to retrieve evidence and to be verified, based on the observation that the performance of all the systems improve as the length of the claim increase. In general, the joint system outperforms the pipeline system against various claim lengths.

Performance against Classes and Domains: As CHEF is constructed based on real-world claims, most of them are non-factual claims verified by fact-checking websites. Such an imbalance issue poses a challenge to the fact-checking system. Figure 4 shows the performance of models for different veracity labels. The scores of minor classes are much lower than the majority class. This reflects the difficulty of judging SUP and NEI. Informative evidence helps to alleviate this issue. For example, the pipeline system with gold evidence achieves significant improvement on predicting NEI labels when comparing with the system with semantic ranker. Figure 5 shows the performance of different domains. Claims from science, politics and culture domains have fewer training instances as most claims in the dataset focus on the society and public health topics. Again, retrieving informative evidence sentences (JS and Gold) from full documents is beneficial to this data sparsity issue.

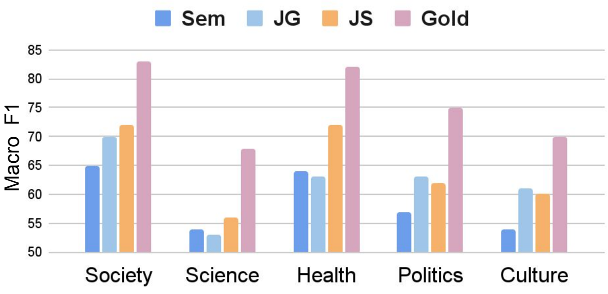

Figure 5: Per-domain results.

6 Conclusion

We constructed the first Chinese dataset for evidence-based fact-checking. Further, we have discussed the annotation methods and shared some of the insights obtained that will be useful to other non-English annotation efforts. To evaluate the challenge CHEF presents, we have developed established baselines and conducted extensive experiments. We show that the task is challenging yet feasible. We believe that CHEF will provide a stimulating challenge for automatic fact-checking.

7 Acknowledgement

We thank the reviewers for their valuable comments. The work was supported by the National Key Research and Development Program of China (No. 2019YFB1704003), the National Nature Science Foundation of China (No. 62021002 and No. 71690231), NSF under grants III-1763325, III-1909323, III-2106758, SaTC-1930941, Tsinghua BNRist and Beijing Key Laboratory of Industrial Bigdata System and Application.

8 Ethical Consideration

Datasets have been collected in a manner that is consistent with the terms of use of any sources and the intellectual property. For each annotator, we compensate based on the number and quality of annotated sentences. More details of our datasets are depicted in Section 3.

A Supplement Materials

A.1 CHEF annotation guidelines

A.1.1 声明抽取和规范化的指引 Guidelines for claim extraction and normalization:

标注者首先需要认真阅读事实验证的文章，然后使用一到两句话来概括这篇文章描述的事件作为声明。请标注者直接使用文章中的句子作为声明，比如文章的标题，或者首段的前几句话都可能是这篇文章需要验证的事实。如果没法抽取出相应的句子，可以使用自己的语言总结文章来撰写声明。在撰写声明的时候，有以下注意事项：

- 每个声明必须完整。
- 每个声明不应该存在事实验证偏差。
- 每个声明不应该存在信息泄露。

请仔细阅读以下详细指引和相应的规范化例子：

- 声明中描述的事件缺乏必要的细节，比如：时间和地点。标注者需要加上这些细节让声明完整，才能被验证。比如：今年共有12.08万人参加中考，但招生计划只有4.3万。需要改写声明为：2019年，共有12.08万人参加成都中考，但招生计划只有4.3万。
- 声明中存在特殊符号，需要去除特设符号避免声明中存在偏差。比如：“纯天然”喷雾一喷“秒睡”。需要去除句子中的“”，因为这些特殊符号隐晦地表达了这个声明其实是不实的。模型可以通过特殊符号直接判断一个声明的真实性。这个句子需要改写为：纯天然喷雾一喷秒睡。，这可以避免由于声明中的特殊符号“”带来事实验证偏差。
- 声明中存在信息泄露，需要去除直接指出声明真实性的相关词语。比如：谣言！纯天然喷雾一喷秒睡。句子中使用的“谣言！”已经直接指出该声明是不实的，造成了信息泄露。需要改写声明为：纯天然喷雾一喷秒睡。不能在声明中出现诸如：“谣言”、“错误”，“骗局”等信息泄露词。
- 声明中的反问句需要被改写为陈述句，由于采用反问句形式的声明大部分都是不实的，反问句的形式会造成数据集偏差。比如：别人打了新冠疫苗，我们就可以不打新冠疫苗吗？需要被改写为：别人打了新冠疫苗，我们就可以不打新冠疫苗。
- 不陈述事实的声明需要被丢弃。有两大类的声明是无法进行事实验证的。第一大类为表示推测的声明，比如：明年深圳房价会上涨。第二大类为表示个人意见的声明，比如：我认为特朗普应该连任。
- 声明中如果包含多个声明，需要拆分为多个声明逐一验证。比如：关于新冠疫苗接种的两个事实：第一，别人打了新冠疫苗，自己就可以不打新冠疫苗。其次，新冠疫苗只需要打一针就能具备新冠病毒防护能力。这个声明包括了两个子声明，需要被拆分为：别人打了新冠疫苗，我就可以不打新冠疫苗。第二个声明为：新冠疫苗只需要打一针就能具备新冠病毒防护能力。

The annotator first needs to read the fact-checking article carefully, and then use one or two sentences to summarize the event described in this article as a claim. The annotator is encouraged to directly extract the sentences in the article as the claim, such as the title of the article, or the first few sentences in the first paragraph. If the annotator cannot find the sentence that can serve as a claim, you can use your own language to write the claim. When extracting the claim, there are the following considerations:

- Each claim must be complete.
- For each claim, explicit bias should be removed.
- Each claim should not have information leakage.

Please read the following detailed guidelines and corresponding normalized examples carefully:

- If the event described in the claim lacks important details, such as time and location, annotator need to add these necessary metadata to make the claim complete before it can be verified. For example, a total of 120,800 people took the entrance examination this year, but the enrollment plan is only 43,000. The claim needs to be rewritten as follows: In 2019, a total of 120,800 people participated in the Chengdu high school entrance examination, but the enrollment plan was only 43,000.
- If there exist special symbols in the claim, such symbols that may lead to bias for claim verification should be removed. For example: "Natural spray" helps you "sleep instantly".

Quotation marks should be removed in the sentence, as these special symbols implicitly indicates such a claim is non-factual. The model can predict the veracity simply based on the special symbols in the claim. This claim needs to be rewritten as: Natural spray helps you sleep instantly.

- Claims contains words that will lead to information leakage should be removed. For example: Rumors! Natural spray helps you sleep instantly. The word "Rumor!" in the claim directly pointed out that the claim is nonfactual, causing information leakage. The word "Rumor!" should be removed. Do not include information leaking words such as "rumors", "errors", "scams", etc. in the claim.

- Claims used rhetorical questions need to be rewritten into declarative sentences. Since most of the claims in the form of rhetorical question are nonfactual, the form of the rhetorical question exhibits a bias in the dataset. For example: if someone else gets the COVID-19 vaccine, can we not get the vaccine? It needs to be rewritten as: if someone else gets a COVID-19 vaccine, we do not need to get the vaccine..

- Claims that do not related to factuality should be discarded. There are two major types of claims that cannot be verified. The first category is speculative claims, such as: Shenzhen housing prices will rise next year. The second category is claims expressing personal opinions, such as: I think Donald Trump should be the president.

- A claim contains multiple statements should be split into multiple claims to be verified one by one. For example, a claim stated that: First, if someone else gets the COVID-19 vaccine, you do not need to get one. Also, the COVID-19 vaccine only needs one shot to protect against the virus. This claim includes two sub-claims. It needs to be split into two claims.

A.1.2 声明标注的指引 Guidelines for claim labeling

标注者在抽取出和规范化声明之后，需要根据事实验证的文章给出的结论，给每个声明打上标签。我们提供了以下三种标签，请选择其中的一种。注意的是，对于大部分为真，部分为真，大部分为为假，部分为假和半真半假的情况，我们统一归类为信息不足：

- 支持，有充分证据表明这个声明是被证据所支持的。

- 反对，有充分证据表明这个声明是被证据所反对的。

- 信息不足，没有足够的证据表明这个声明是被支持还是反对。

After extracting and normalizing the claim, annotators needs to label each claim based on the conclusions of the fact-checking article. We provide the following three labels, please choose one of them. Note that for conclusions such as mostly true, partially true, mostly false, partial false and mixture, we consider them as not enough information:

- Supported, there is sufficient evidence to show that this claim is supported by the evidence.

- Refuted, there is sufficient evidence to show that this claim is refuted by the evidence.

- Not enough information, there is not enough evidence to show whether this claim is supported or refuted.

A.1.3 证据标注的指引 Guidelines for evidence labelling

标注者需要阅读规范化过后的声明，事实验证的文章还有搜集到的源文档。标注者首先需要理解文章的验证思路，再从源文档当中直接选择能够作为证据的句子。针对每个声明，标注者最少选择1个，最多选择5个相关的句子作为证据。在选择句子作为证据的时候有以下注意事项：

- 请标注者选择完整的句子，以句号为结束标志。

- 选择句子作为证据的条件是，在仅仅基于当前选中的句子作为证据的前提下，能够验证给定的声明。也就是说，选中的句子必须要提供给足够的信息来帮助判断声明的事实性。

- 如果出现多于5个句子能够作为证据的情况，选择你认为最相关的5个句子；或者能够形成推理逻辑链的句子；或者和事实验证文章推理过程最相似的句子。

- 如果出现源文档互相矛盾的情况，优先选择支持事实验证文章结论的文档，从中选择相关的句子作为证据。
- 如果提供的源文档并没有提供足够的证据来验证声明，请报告这条声明。
- 如果提供的源文档只包含和事实验证文章结论矛盾的证据，请报告这条声明。

The annotator needs to read the normalized claim, the fact-checking article and the collected documents. Annotators first need to understand the verification process in the fact-checking article, and then directly select sentences from the sources documents. These selected sentence are used as evidence to verify the claim. For each claim, annotators should select at least 1 and at most 5 relevant sentences as evidence. There are the following considerations when choosing sentences as evidence:

- Please select a complete sentence which ends with a period.
- When selecting sentences as evidence, the annotator should consider given the selected sentences if the given claim can be verified. In other words, the selected sentences must provide sufficient information to predict the factuality of the given claim.
- If there are more than 5 sentences that can be used as evidence, choose the 5 sentences that you think are the most relevant; or the sentences that can form a reasoning chain for verification; or the sentence that is most similar to the reasoning process of the fact-checking article.
- If there are conflicting source documents, the documents that support the conclusion of the fact-checking article should be considered, and the most relevant sentences in these documents are selected as evidence.
- If the source documents do not provide sufficient evidence to verify the statement, please report the claim.
- If the source documents only contains evidence that contradicts the conclusion of the fact-checking article, please report this claim.

A.1.4 数据验证的指引 Guidelines for data validation

给定一个声明和搜集到的证据句子，标注者需要根据证据去判断这个声明的真实性。如果标注者认为提供的声明缺失重要信息，或者是不可读的，请报告该条声明。我们提供了以下三种标签，请选择其中的一种：

- 支持，有充分证据表明这个声明是被证据所支持的。
- 反对，有充分证据表明这个声明是被证据所反对的。
- 信息不足，没有足够的证据表明这个声明是被支持还是反对。

Given a claim and the evidence sentences, the annotator needs to label the factuality of the claim based on the evidence. If the annotator believes that the given claim lacks important information or is unreadable, please report the claim. We provide three kinds of labels, please choose one of them:

- Supported, there is sufficient evidence to show that this claim is supported by the evidence.
- Refuted, there is sufficient evidence to show that this claim is refuted by the evidence.
- Not enough information, there is not enough evidence to show whether this claim is supported or refuted.

A.1.5 判断声明领域的指引 Guidelines for determining claim domain

标注者需要阅读声明，根据给出的五个领域判断声明属于哪个领域：

- 政治：主要是关于国际与国内政治等方面的声明。
- 公卫：主要是关于公共卫生方面的声明，比如有关新冠病毒，人体健康，食品安全等方面。
- 科学：主要是关于自然科学和工程技术等方面的声明。
- 文化：主要是关于历史，人文，娱乐，体育等方面的声明。
- 社会：主要是除了上述四类，社会生活方面的声明。

The annotator needs to read the claim and determine which domain the claim belongs to based on the five domains given:

- Politics: Claims mainly focus on international and domestic politics.
- Health: Claims mainly focus on public health, including topic related to COVID-19, health care, food safety, etc.
- Science: Claims mainly focus on natural science and technology.
- Culture: Claims mainly focus on history, humanities, entertainment, sports, etc.
- Society: Claims not related on the above four categories, and related to daily social life.

A.1.6 验证声明的挑战（多选） Claim verification challenges (Multiple choice)

对声明进行事实验证往往会遇到许多挑战，挑战可以分为以下四类，标注者需要阅读事实验证的文章，判断验证声明时会遇到哪些挑战：

- 证据搜集：通过搜集证据，比如找相关的新闻，论文，法律法规等来验证声明。
- 专家咨询：通过咨询专家或者相关人士，比如外交部发言人陈述，部委回复，记者采访等来验证声明。
- 数值推理：通过数值的比较，趋势的分析来验证声明。
- 多模态：通过除了文本外的其他证据，比如图片，视频，音频来验证声明。

Factual verification of a claim often encounters many challenges. The challenges are summarized into the following four categories. The annotator needs to read the fact-checking article to determine which challenges will be encountered in verifying the claim:

- Evidence Collection: Verify the claim by collecting evidence, such as finding relevant news, papers, laws and regulations, etc.
- Expert Consultation: Verify the claim by consulting experts or related people, such as statements by the spokesperson of the Ministry of Foreign Affairs, replies from ministries and commissions, interviews with reporters, etc.
- Numerical Reasoning: Verify the claim by numerical comparison, trend analysis, etc.
- Multi-Modality: Verify the claim with other evidence besides articles, such as pictures, videos, and audio.

VGNMN: Video-grounded Neural Module Networks for Video-Grounded Dialogue Systems

Abstract

Neural module networks (NMN) have achieved success in image-grounded tasks such as Visual Question Answering (VQA) on synthetic images. However, very limited work on NMN has been studied in the video-grounded dialogue tasks. These tasks extend the complexity of traditional visual tasks with the additional visual temporal variance and language cross-turn dependencies. Motivated by recent NMN approaches on image-grounded tasks, we introduce Video-grounded Neural Module Network (VGNMN) to model the information retrieval process in video-grounded language tasks as a pipeline of neural modules. VGNMN first decomposes all language components in dialogues to explicitly resolve any entity references and detect corresponding action-based inputs from the question. The detected entities and actions are used as parameters to instantiate neural module networks and extract visual cues from the video. Our experiments show that VGNMN can achieve promising performance on a challenging video-grounded dialogue benchmark as well as a video QA benchmark.

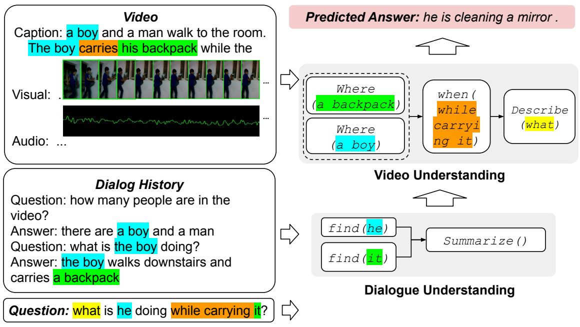

Figure 1: A sample video-grounded dialogue with a demonstration of a reasoning process

1 Introduction

Vision-language tasks have been studied to build intelligent systems that can perceive information from multiple modalities, such as images, videos, and text. Extended from image-grounded tasks, e.g. (Antol et al., 2015), recently Jang et al. (2017); Lei et al. (2018) propose to use video as the grounding features. This modification poses a significant challenge to previous image-based models with the additional temporal variance through video frames. Recently Alamri et al. (2019) further develop video-grounded language research into the dialogue domain. In the proposed task, *video-grounded dialogues*, the dialogue agent is required to answer questions about a video over multiple dialogue turns. Using Figure 1 as an example, to answer questions correctly, a dialogue agent has to resolve references in dialogue context, e.g. “he” and “it”, and identify the original entity, e.g. “a boy" and “a backpack". Besides, the agent also needs to identify the actions of these entities, e.g. “carrying a backpack” to retrieve information from the video.

Current state-of-the-art approaches to video-grounded dialogue tasks, e.g. (Le et al., 2019b; Fan et al., 2019) have achieved remarkable performance through the use of deep neural networks to retrieve grounding video signals based on language inputs. However, these approaches often assume the reasoning structure, including resolving references of entities and detecting the corresponding actions to retrieve visual cues, is implicitly learned. An explicit reasoning structure becomes more beneficial as the tasks complicate in two scenarios: video with complex spatial and temporal dynamics, and language inputs with sophisticated semantic dependencies, e.g. questions positioned in a dialogue context. These scenarios often challenge researchers to interpret model hidden layers, identify errors, and assess model reasoning capability.

Similar challenges have been observed in image-grounded tasks in which deep neural networks exhibit shallow understanding capability as they exploit superficial visual cues (Agrawal et al., 2016; Goyal et al., 2017; Feng et al., 2018; Serrano and

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3377 - 3393
July 10-15, 2022 ©2022 Association for Computational Linguistics

Smith, 2019). Andreas et al. (2016b) propose neural module networks (NMNs) by decomposing a question into sub-sequences called *program* and assembling a network of neural operations. Motivated by this line of research, we propose a new approach, VGNMN, to video-grounded language tasks. Our approach benefits from integrating neural networks with a compositional reasoning structure to exploit low-level information signals in video. An example of the reasoning structure can be seen on the right side of Figure 1.

Video-grounded Neural Module Network (VGNMN) tackles video understanding through action and entity-paramterized NMNs to retrieve video features. We first decompose question into a set of entities and extract video features related to these entities. VGNMN then extracts the temporal steps by focusing on relevant actions that are associated with these entities. VGNMN is analogous to how human processes information by gradually retrieving signals from input modalities using a set of discrete subjects and their actions.

To tackle dialogue understanding, VGNMN is trained to resolve any co-reference in language inputs, e.g. questions in a dialogue context, to identify the unique entities in each dialogue. Previous approaches to video-grounded dialogues often obtain question global representations in relation to dialogue context. These approaches might be suitable to represent general semantics in open-domain dialogues (Serban et al., 2016). However, they are not ideal to detect fine-grained information in a video-grounded dialogue which frequently entails dependencies between questions and past dialogue turns in the form of entity references.

In summary, our contributions include:

- VGNMN, a neural module network-based approach for video-grounded dialogues.
- The approach includes a modularized system that creates a reasoning pipeline parameterized by entity and action-based representations from both dialogue and video contexts.
- Our experiments are conducted on the challenging benchmark for video-grounded dialogues, Audio-visual Scene-Aware Dialogues (AVSD) (Alamri et al., 2019) as well as TGIF-QA (Jang et al., 2017) for video QA task.
- Our results indicate strong performance of VGNMN as well as improved model interpretability and robustness to difficult scenarios of dialogues, videos, and question structures.

2 Related Work

2.1 Video-Language Understanding

The research of video-language understanding aims to develop a model's joint understanding capability of language, video, and their interactions. Jang et al. (2017); Gao et al. (2018); Jiang et al. (2020) propose to learn attention guided by question global representation to retrieve spatial-level and temporal-level visual features. Li et al. (2019); Fan et al. (2019); Jiang and Han (2020) model interaction between all pairs of question token-level representations and temporal-level features of the input video through similarity matrix, memory networks, and graph networks respectively. Gao et al. (2019); Le et al. (2019c, 2020b); Lei et al. (2020); Huang et al. (2020) extends the previous approach by dividing a video into equal segments, sub-sampling video frames, or considering object-level representations of input video. We propose to replace token-level and global question representations with question representations composed of specific entities and actions.

Recently, we have witnessed emerging techniques in video-language systems that exploit deep transformer-based architectures such as BERT (Devlin et al., 2019) for pretraining multimodal representations (Li et al., 2020a; Yang et al., 2020; Kim et al., 2021; Tang et al., 2021; Lei et al., 2021; Zellers et al., 2021) in very large-scale video-language datasets. While these systems can achieve impressive performance, they are not straightforward to apply in domains with limited data such as video-grounded dialogues. Moreover, as we shown in our qualitative examples, our approach facilitates better interpretability through the output of decoded functional programs.

2.2 Video-grounded Dialogues

Extended from video QA, video-grounded dialogue is an emerging task that combines dialogue response generation and video-language understanding research. This task entails a novel requirement for models to learn dialogue semantics and decode entity co-references in questions. Nguyen et al. (2018); Hori et al. (2019); Hori et al. (2019); Sanabria et al. (2019); Le et al. (2019a,b) extend traditional QA models by adding dialogue history neural encoders. Kumar et al. (2019) enhances dialogue features with topic-level representations to express the general topic in each dialogue. Schwartz et al. (2019) treats each dialogue turn as an independent sequence and allows interaction between questions and each dialogue turn. Le et al. (2019b) encodes dialogue history as a sequence with embedding and positional representations. Different from prior work, we dissect the question sequence and explicitly detect and decode any entities and their references. Our approach also enables insights on how models extract deductive bias from dialogues to extract video information.

2.3 Neural Module Network

Neural Module Network (NMN) (Andreas et al., 2016b,a) is introduced to address visual QA by decomposing questions into linguistic sub-structures, known as programs, to instantiate a network of neural modules. NMN models have achieved success in synthetic image domains where a multi-step reasoning process is required (Johnson et al., 2017b; Hu et al., 2018; Han et al., 2019). Yi et al. (2018); Han et al. (2019); Mao et al. (2019) improve NMN models by decoupling visual-language understanding and visual concept learning. Our work is related to the recent work (Kottur et al., 2018; Jiang and Bansal, 2019; Gupta et al., 2020) that extended NMNs to image reasoning in dialogues and reading comprehension reasoning. Our approach follows the previous approaches that learn to generate program structure and require no parser at evaluation time. Compared to prior work, we use NMN to learn dependencies between the composition in language inputs and the spatio-temporal dynamics in videos. Specifically, we propose to construct a reasoning structure from text, from which detected entities are used to extract visual information in the spatial space and detected actions are used to find visual information in the temporal space.

3 Method

In this section, we present the design of our model. An overview of the model can be seen in Figure 2.

3.1 Task Definition

The input to the model consists of a dialogue $\mathcal{D}$ which is grounded on a video $\mathcal{V}$. The input components include the question of current dialogue turn $\mathcal{Q}$, dialogue history $\mathcal{H}$, and the features of the input video, including visual and audio input. The output is a dialogue response, denoted as $\mathcal{R}$.

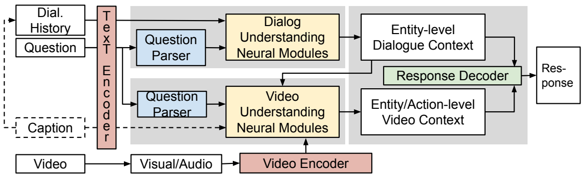

Figure 2: An overview of the VGNMN approach. Colorful boxes are network components and the rest are input/output. Dotted lines are for optional components.

Each text input component is a sequence of words $w_1, ..., w_m \in \mathbb{V}^{in}$, the input vocabulary. Similarly, the output response $\mathcal{R}$ is a sequence of tokens $w_1, ..., w_n \in \mathbb{V}^{out}$, the output vocabulary. The objective of the task is the generation objective that output answers of the current dialogue turn t:

$$\hat{\mathcal{R}}_t = \arg\max_{\mathcal{R}_t} P(\mathcal{R}_t|\mathcal{V}, \mathcal{H}_t, \mathcal{Q}_t; \theta)$$
$$= \arg\max_{\mathcal{R}_t} \prod_{n=1}^{L_{\mathcal{R}}} P_m(w_n|\mathcal{R}_{t,1:n-1}, \mathcal{V}, \mathcal{H}_t, \mathcal{Q}_t; \theta)$$

where $L_{\mathcal{R}}$ is the length of the sequence $\mathcal{R}$. In a Video-QA task, the dialogue history $\mathcal{H}$ is simply absent and the output response is typically collapsed to a single-token response.

3.2 Encoders

Text Encoder. A text encoder is shared to encode text inputs, including dialogue history, questions, and captions. The text encoder converts each text sequence $\mathcal{X} = w_1, ..., w_m$ into a sequence of embeddings $X \in \mathbb{R}^{m \times d}$. We use a trainable embedding matrix to map token indices to vector representations of d dimensions through a mapping function ϕ. These vectors are then integrated with ordering information of tokens through a positional encoding function with layer normalization (Ba et al., 2016; Vaswani et al., 2017). The embedding and positional representations are combined through element-wise summation. The encoded dialogue history and question of the current turn are defined as $H = \text{Norm}(\phi(\mathcal{H}) + \text{PE}(\mathcal{H})) \in \mathbb{R}^{L_{\text{H}} \times d}$ and $Q = \text{Norm}(\phi(\mathcal{Q}) + \text{PE}(\mathcal{Q})) \in \mathbb{R}^{L_{\text{Q}} \times d}$.

Video Encoder. To encode video, we use pretrained models to extract visual and audio features. We denote F as the sampled video frames or video clips. For object-level visual features, we denote O as the maximum number of objects considered in each frame. The resulting output from a pretrained object detection model is $Z_{\text{obj}} \in \mathbb{R}^{F \times O \times d_{\text{vis}}}$. We concatenate each object representation with the

Module	Input	Output	Description
`find`	P, H	$\mathrm{H}_{\mathrm{ent}}$	For related entities in question, select the relevant tokens from dialogue history
`summarize`	$\mathrm{H}_{\mathrm{ent}}$, Q	$\mathrm{Q}_{\mathrm{ctx}}$	Based on contextual entity representations, summarise the question semantics
`where`	P, V	$\mathrm{V}_{\mathrm{ent}}$	Select the relevant spatial position corresponding to original (resolved) entities
`when`	P, $\mathrm{V}_{\mathrm{ent}}$	$\mathrm{V}_{\mathrm{ent+act}}$	Select the relevant entity-aware temporal steps corresponding to the action parameter
`describe`	P, $\mathrm{V}_{\mathrm{ent+act}}$	$\mathrm{V}_{\mathrm{ctx}}$	Select visual entity-action features based on non-binary question types
`exist`	Q, $\mathrm{V}_{\mathrm{ent+act}}$	$\mathrm{V}_{\mathrm{ctx}}$	Select visual entity-action features based on binary (yes/no) question types

Table 1: Description of the modules and their functionalities. We denote P as the parameter to instantiate each module, H as the dialogue history, Q as the question of the current dialogue turn, and V as video input.

corresponding coordinates projected to d_{vis} dimensions. We also make use of a CNN-based pretrained model to obtain features of temporal dimension $Z_{\text{cnn}} \in \mathbb{R}^{F \times d_{\text{vis}}}$. The audio feature is obtained through a pretrained audio model, $Z_{\text{aud}} \in \mathbb{R}^{F \times d_{\text{aud}}}$. We passed all video features through a linear transformation layer with ReLU activation to the same embedding dimension d.

3.3 Neural Modules

We introduce neural modules that are used to assemble an executable program constructed by the generated sequence from question parsers. We provide an overview of neural modules in Table 1 and demonstrate dialogue understanding and video understanding modules in Figure 3 and 4 respectively. Each module parameter, e.g. "a backpack", is extracted from the parsed program (See Section 3.4). For each parameter, we denote $P \in \mathbb{R}^d$ as the average pooling of component token embeddings.

`find(P,H)`$\to$$\mathbf{H}_{\text{ent}}$. This module handles entity tracing by obtaining a distribution over tokens in the dialogue history. We use an entity-to-dialogue-history attention mechanism applied from an entity P_i to all tokens in the dialogue history. Any neural network that learn to generate attention between two tensors is applicable .e.g. (Bahdanau et al., 2015; Vaswani et al., 2017). The attention matrix normalized by softmax, $A_{\text{find,i}} \in \mathbb{R}^{L_{\text{H}}}$, is used to compute the weighted sum of dialogue history token representations. The output is combined with entity embedding P_i to obtain contextual entity representation $H_{\text{ent,i}} \in \mathbb{R}^d$.

`summarize(`$\mathbf{H}_{\text{ent}}$`,Q)`$\to$$\mathbf{Q}_{\text{ctx}}$. For each contextual entity representation $H_{\text{ent,i}}$, $i = 1, ..., N_{\text{ent}}$, it is projected to L_{Q} dimensions and is combined with question token embeddings through element-wise summation to obtain entity-aware question representation $Q_{\text{ent,i}} \in \mathbb{R}^{L_{\text{Q}} \times d}$. It is fed to a one-dimensional CNN with max-pooling layer (Kim, 2014) to obtain a contextual entity-aware question representation. We denote the final output as $Q_{\text{ctx}} \in \mathbb{R}^{N_{\text{ent}} \times d}$.

While previous models usually focus on global or token-level dependencies (Hori et al., 2019; Le et al., 2019b) to encode question features, our modules compress fine-grained question representations at the entity level. Specifically, `find` and `summarize` modules can generate entity-dependent local and global representations of question semantics. We show that our modularized approach can achieve better performance and transparency than traditional approaches to encode dialogue context (Serban et al., 2016; Vaswani et al., 2017) (Section 4).

`where(P,V)`$\to$$\mathbf{V}_{\text{ent}}$. Similar to the `find` module, this module handles entity-based attention to the video input. However, the entity representation P, in this case, is parameterized by the original entity in dialogue rather than in question (See Section 3.4 for more description). Each entity P_i is stacked to match the number of sampled video frames/clips F. An attention network is used to obtain entity-to-object attention matrix $A_{\text{where,i}} \in \mathbb{R}^{F \times O}$. The attended feature are compressed through weighted sum pooling along the spatial dimension, resulting in $V_{\text{ent,i}} \in \mathbb{R}^{F \times d}$, $i = 1, ..., N_{\text{ent}}$.

`when(P,`$\mathbf{V}_{\text{ent}}$`)`$\to$$\mathbf{V}_{\text{ent+act}}$. This module follows a similar architecture as the `where` module. However, the action parameter P_i is stacked to match N_{ent} dimensions. The attention matrix $A_{\text{when,i}} \in \mathbb{R}^F$ is then used to compute the visual entity-action representations through weighted sum along the temporal dimension. We denote the output for all actions P_i as $V_{\text{ent+act}} \in \mathbb{R}^{N_{\text{ent}} \times N_{\text{act}} \times d}$

`describe(P,`$\mathbf{V}_{\text{ent+act}}$`)`$\to$$\mathbf{V}_{\text{ctx}}$. This module is a linear transformation to compute $V_{\text{ctx}} = {W_{\text{desc}}}^T [V_{\text{ent+act}}; P_{\text{stack}}] \in \mathbb{R}^{N_{\text{ent}} \times N_{\text{act}} \times d}$ where $W_{\text{desc}} \in \mathrm{R}^{2d \times d}$, P_{stack} is the stacked representations of parameter embedding P to $N_{\text{ent}} \times N_{\text{act}}$ dimensions, and $[;]$ is the concatenation operation. Note that the parameter P here is extracted from questions, often as the type of questions e.g. "what"

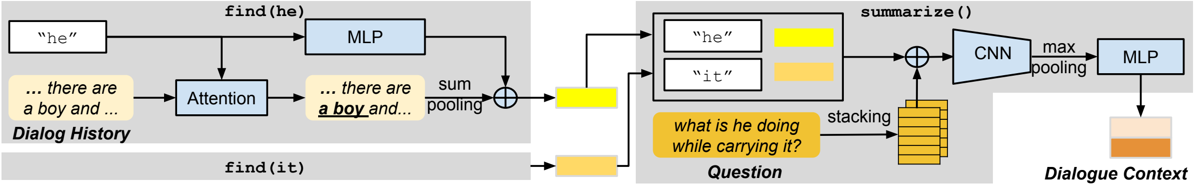

Figure 3: `find` and `summarize` neural modules for dialogue understanding

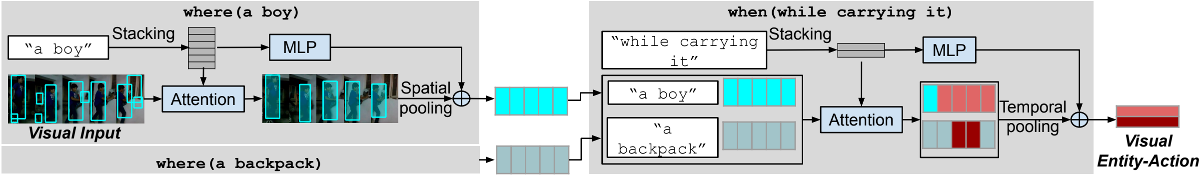

Figure 4: `where` and `when` neural modules for video understanding

and "how". This eliminates the need to have different modules for different question types. However, we noted the current design may be challenged in rare cases in which an utterance contain numerous questions (refer to Figure 5).

The `exist` module is used when the questions are "yes/no" questions. This module is a special case of `describe` module where the parameter P is simply the average pooled question embeddings. The above `where` module is applied to object-level features. For temporal-based features such as CNN-based and audio features, the same neural operation is applied along the temporal dimension. Each resulting entity-aware output is then incorporated to frame-level features through element-wise summation.

An advantage of our architecture is that it separates dialogue and video understanding. We adopt a transparent approach to solve linguistic entity references during the dialogue understanding phase. The resolved entities are fed to the video understanding phase to learn entity-action dynamics in the video. We show that our approach is robust when dialogue evolves to many turns and video extends over time (Please refer to Section 4).

3.4 Question Parsers

To learn compositional programs, we follow (Johnson et al., 2017a; Hu et al., 2017) and consider program generation as a sequence-to-sequence task. We adopt a simple template "$\langle \text{param}_1 \rangle \langle \text{module}_1 \rangle \langle \text{param}_2 \rangle \langle \text{module}_2 \rangle$..." as the target sequence. The resulting target sequences for dialogue and video understanding programs are sequences $\mathcal{P}_{\text{dial}}$ and $\mathcal{P}_{\text{vid}}$ respectively.

The parsers decompose questions into sub-sequences to construct compositional reasoning programs for dialogue and video understanding. Each parser is a vanilla Transformer decoder, including multi-head attention layers on questions and past dialogue turns (Please refer to Appendix A.1 for more technical details).

3.5 Response Decoder

System response is decoded by incorporating the dialogue context and video context outputs from the corresponding reasoning programs to target token representations. We follows a vanilla Transformer decoder architecture (Le et al., 2019b), which consists of 3 attention layers: self-attention to attend on existing tokens, attention to Q_{ctx} from dialogue understanding program execution, and attention to V_{ctx} from video understanding program execution.

$$A^{(1)}_{\text{res}} = \text{Attention}(R|_0^{j-1}, R|_0^{j-1}, R|_0^{j-1}) \in \mathbb{R}^{j \times d}$$
$$A^{(2)}_{\text{res}} = \text{Attention}(A^{(1)}_{\text{res}}, Q_{\text{ctx}}, Q_{\text{ctx}}) \in \mathbb{R}^{j \times d}$$
$$A^{(3)}_{\text{res}} = \text{Attention}(A^{(2)}_{\text{res}}, V_{\text{ctx}}, V_{\text{ctx}}) \in \mathbb{R}^{j \times d}$$

Multimodal Fusion. For video features come from multiple modalities, visual and audio, the contextual features, denoted V_{ctx}, is obtained through a weighted sum of component modalities, e.g. contextual visual features $V^{\text{vis}}_{\text{ctx}}$ and contextual audio features $V^{\text{aud}}_{\text{ctx}}$. The scores S_{fusion} to compute the weighted sum is defined as:

$$S_{\text{fusion}} = \text{Softmax}(W^T_{\text{fusion}}[Q_{\text{stack}}; V^{\text{vis}}_{\text{ctx}}; V^{\text{aud}}_{\text{ctx}}])$$

where Q_{stack} is the mean pooling output of question embeddings Q which is then stacked to $N_{\text{ent}} + N_{\text{act}}$ dimensions, and $W_{\text{fusion}} \in \mathbb{R}^{3d \times 2}$ are trainable model parameters. The resulting S_{fusion} has a dimension of $\in \mathbb{R}^{(N_{\text{ent}}+N_{\text{act}}) \times 2}$.

Response Generation. To generate response sequences, a special token "*_sos*" is concatenated as the first token w_0. The decoded token w_1 is then appended to w_0 as input to decode w_2 and so on. Similarly to input source sequences, at decoding time step j, the input target sequence is encoded to obtain representations of system response $R|_0^{j-1}$. We combine vocabulary of input and output sequences and share the embedding matrix $E \in \mathbb{R}^{|\mathbb{V}|\times d}$ where $\mathbb{V} = \mathbb{V}^{in} \cap \mathbb{V}^{out}$. During training time, we directly use the ground-truth responses as input to the decoder and optimize VGNMN with a cross-entropy loss to decode the next ground-truth tokens. During test time, responses are generated auto-regressively through beam search with beam size 5. Note that we apply the same procedure to generate reasoning programs from question parsers.

4 Experiments

Datasets. We use the AVSD benchmark from the Dialogue System Technology Challenge 7 (DSTC7) (Hori et al., 2019). The benchmark consists of dialogues grounded on the Charades videos (Sigurdsson et al., 2016). Each dialogue contains up to 10 dialogue turns, each turn consists of a question and expected response about a given video. For visual features, we use the 3D CNN-based features from a pretrained I3D model (Carreira and Zisserman, 2017) and object-level features from a pretrained FasterRNN model (Ren et al., 2015b). The audio features are obtained from a pretrained VGGish model (Hershey et al., 2017). In the experiments with AVSD, we consider two settings: one with video summary and one without video summary as input. In the setting with video summary, the summary is concatenated to the dialogue history before the first dialogue turn. We also adapt VGNMN to the video QA benchmark TGIF-QA (Jang et al., 2017). Different from AVSD, TGIF-QA contains a diverse set of QA tasks:

- *Count*: an open-ended task which counts the number of repetitions of an action
- *Action*: a multiple-choice (MC) task which asks about a certain action occurring for a fixed number of times
- *Transition*: an MC task which emphasizes temporal transition in video
- *Frame*: an open-ended QA about visual contents of one of the video frames

	#	Train	Val.	Test
AVSD	Dialogs	7,659	1,787	1,710
	Turns	153,180	35,740	13,490
	Words	1,450,754	339,006	110,252
TGIFQA	Count QA	24,159	2,684	3,554
	Action QA	18,428	2,047	2,274
	Trans. QA	47,434	5,270	6,232
	Frame QA	35,453	3,939	13,691

Table 2: Summary of DSTC7 AVSD and TGIF-QA benchmark

For the TGIF-QA benchmark, we use the extracted features from a pretrained ResNet model (He et al., 2016). Table 2 shows a summary of the AVSD and TGIF-QA benchmarks.

Training Details. We follow prior approaches (Hu et al., 2017, 2018; Kottur et al., 2018) by obtaining the annotations of the programs through a language parser (Hu et al., 2016) and a reference resolution model (Clark and Manning, 2016). During training, we directly use these as ground-truth labels of programs to train our models. The ground-truth responses are augmented with label smoothing technique (Szegedy et al., 2016). During inference time, we generate all programs and responses from given dialogues and videos. We run beam search to enumerate programs for dialogue and video understanding and dialogue responses.

We use a training batch size of 32 and embedding dimension $d = 128$ in all experiments. Where Transformer attention is used, we fix the number of attention heads to 8 in all attention layers. In neural modules with MLP layers, the MLP network is fixed to 2 linear layers with a ReLU activation in between. In neural modules with CNN, we adopt a vanilla CNN architecture for text classification (without the last MLP layer) where the number of input channels is 1, the kernel sizes are $\{3, 4, 5\}$, and the number of output channels is d. We initialize models with uniform distribution (Glorot and Bengio, 2010). During training, we adopt the Adam optimizer (Kingma and Ba, 2015) and a decaying learning rate (Vaswani et al., 2017) where we fix the warm-up steps to 15K training steps. We employ dropout (Srivastava et al., 2014) of 0.2 at all networks except the last linear layers of question parsers and response decoder. We train models up to 50 epochs and select the best models based on the average loss per epoch in the validation set.

All models are trained in a V100 GPU with a capacity of 16GB. We approximated each training epoch took about 20 minutes to run. For each model experiment with VGNMN, we obtained at least 2 runs and reported the average results. We implemented models in Pytorch and released the code and model checkpoints [1].

Optimization. We optimize models by joint training to minimize the cross-entropy losses to generate responses and functional programs.

$$\begin{aligned}\mathcal{L} &= \alpha\mathcal{L}_{\text{dial}} + \beta\mathcal{L}_{\text{vid}} + \mathcal{L}_{\text{res}} \\ &= \alpha\sum_{j} -\log(\mathbf{P}_{\text{dial}}(\mathcal{P}_{\text{dial,j}})) \\ &+ \beta\sum_{l} -\log(\mathbf{P}_{\text{video}}(\mathcal{P}_{\text{video,l}})) \\ &+ \sum_{n} -\log(\mathbf{P}_{\text{res}}(\mathcal{R}_{\text{n}}))\end{aligned}$$

where $\mathbf{P}$ is the probability distribution of an output token. The probability is computed by passing output representations from the parsers and decoder to a linear layer $W \in \mathbb{R}^{d\times V}$ with softmax activation. We share the parameters between W and embedding matrix E.

AVSD Results. We evaluate model performance by the objective metrics, including BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), ROUGE-L (Lin, 2004), and CIDEr (Vedantam et al., 2015), between each generated response and 6 reference gold responses. As seen in Table 3, our models outperform most of existing approaches. We observed that our approach did not outperform the GPT-based baselines (Li et al., 2020b; Le and Hoi, 2020) in the setting that allows video summary/caption input. However, the performance of our model in the setting without video summary/caption input is on par with the GPT-based baseline (Li et al., 2020b), even though our model did not rely on deep pretrained representations on large-scale text data. These observations imply that GPT-based models can better capture video context from video caption/summary through rich pretrained representations. However, without access to video caption/summary, these models may fail to understand video from visual-only representations. In this setting, GPT-based models may be inferior to VGNMN, which explicitly exploits the compositional structures from textual inputs to integrate visual features. We also found that VGNMN applied to object-level features is competitive to the model applied to CNN-based features. The flexibility of VGNMN neural programs show when we treat the caption as an input equally to visual or audio inputs and execute entity-action level neural operations on the encoded caption sequence.

Table 3: AVSD test results: Metrics are: BLEU-4 (B-4), METEOR (M), ROUGE-L (R), and CIDEr (C). The visual features are: I3D (I), ResNeXt-101 (RX), Faster-RCNN (FR), caption as a video input (C). The audio features are: VGGish (V), AclNet (A). ✓on PT denotes models using pretrained weights and/or additional finetuning. The best/second-best results are bold/underlined respectively.

Robustness. To evaluate model robustness, we report BLEU4 and CIDEr of model variants in various experimental settings. Specifically, we compare against performance of output responses in the first dialogue turn position (i.e. 2^{nd}-10^{th} turn vs. the 1^{st} turn), or responses grounded on the shortest video length range (video ranges are intervals of 0-10^{th}, 10-20^{th} percentile and so on). We report results of the following model variants: (1) *w/o video NMN*: VGNMN without using video-based modules, e.g. `when` and `where`. Video features are retrieved through a token-level representation of questions (Le et al., 2019b). (2) *no NMN*: (1) + without dialogue-based modules, e.g. `find` and `summarize`. Dialogue history is encoded by a hierarchical LSTM encoder (Hori et al., 2019).

Robustness to video length: In Table 4a, we noted that the performance gap between VGNMN and (1) is quite distinct, with 7/10 cases of video ranges in which VGNMN outperforms. However, in lower ranges (i.e. 1-23 seconds) and higher ranges (37-75 seconds), VGNMN performs not

(c) Performance by utterance structures between VGNMN and variant (2) (*no NMN*): Single-question utterances (Top) vs. Multi-part utterances (Bottom).

Table 4: VGNMN and model variants by configurations of dialogues, videos, and question structures

as well as model (1). We observed that related factors might affect the discrepancy, such as the complexity of the questions for these short and long-range videos. Potentially, our question parser for the video understanding program needs to be improved (e.g. for tree-based programs) to retrieve information in these ranges.

Robustness to dialogue turn: In Table 4b, we observed that model (1) performs better than model (2) overall, especially in higher turn positions, i.e. from the 4^{th} turn to 8^{th} turn. Interestingly, we noted some mixed results in very low turn position, i.e. the 2^{nd} and 3^{rd} turn, and very high turn position, i.e. the 10^{th} turn. Potentially, with a large dialogue turn position, the neural-based approach such as hierarchical RNN can better capture the global dependencies within dialogue context than the entity-based compositional NMN method.

Robustness to question structure: Finally, we compared performance of VGNMN with the no-NMN variant (1) in different cases of question structures: single-question vs. multiple-part structure. In single-question structures, we examined by the question types (e.g. yes/no, wh-questions). In multi-part structures, we further classified whether there are sentences preceding the question (e.g. "1Sent+Que") or there are smaller (sub-)questions (e.g. "2SubQue") within the question. In Table 4c, we observed that VGNMN has clearer performance gains in multi-part structures than single-question structures. In multi-part structures, we observed higher gaps between VGNMN and model (1) in highly complex cases e.g. "2Sent+Que" vs. "1Sent+Que". These observations indicate the robustness of VGNMN and the underlying compositionality principle to deal with complex question structures. We also noted that VGNMN is still susceptible to extremely long questions (">2Sent+Que") and future work is needed to address these scenarios.

Figure 5: Interpretability of model outputs on AVSD: Example A (Top) and Example B (Bottom).

Interpretability. In Figure 5, we show both success and failure cases of generated responses and corresponding generated functional programs. In each example, we marked predicted outputs as incorrect if they do not match the ground-truth completely (even though the outputs might be partially correct). From Figure 5, we observe that in cases where generated dialogue programs and video programs match or are close to the gold labels, the model can generate generally correct responses. For cases where some module parameters do not exactly match but are closed to the gold labels, the model can still generate responses with the correct visual information (e.g. the 4^{th} turn in example B). In cases of wrong predicted responses, we can further look at how the model understands the questions based on predicted programs. In the 3^{rd} turn of example A, the output response is missing a minor detail as compared to the label response because the video program fails to capture “rooftop” as a `where` parameter. These subtle yet important details can determine whether output responses can fully address user queries. In the 3^{rd} turn of example B, the model wrongly identifies “what room” as a `where` parameter and subsequently generates a wrong response that it is “a living room”.

TGIF-QA Results. We report the result using the L2 loss in *Count* task and accuracy in other tasks. From Table 5, VGNMN outperforms the majority of the baseline models in all tasks by a large margin. Compared to AVSD experiments, the TGIF-QA experiments emphasize the video understanding ability of the models, removing the requirement for dialogue understanding and natural language generation. Since TGIF-QA questions follow a very specific question type distribution (count, action, transition, and frameQA), the question structures are simpler and easier to learn than AVSD. Using exact-match accuracy of parsed programs vs. label programs as a metric, our question parser can achieve a performance 81% to 94% accuracy in TGIF-QA vs. 41-45% in AVSD. The higher accuracy in decoding a reasoning structure translates to better adaptation between training and test time, resulting in higher performance gains.

Table 5: Experiment results on the TGIF-QA benchmark. The visual features are: ResNet-152 (R), C3D (C), Flow CNN from two-stream model (F), VGG (V), ResNeXt-101 (RX).

Cascading Errors. Compared to prior approaches, we noted that VGNMN is a modularized system which may result in cascading errors to downstream modules. One major error is the error of generated programs which is used as parameters in neural modules. To gauge this error, we compare the performance of VGNMN between 2 cases: with generated programs and with ground-truth programs. From Table 6, we noticed some performance gaps between these cases. These observations imply that: (1) program generations and response generations are positively correlated and more accurate programs can lead to better responses; and (2) current question parsers are not perfect, resulting in wrong parameters to instantiate neural modules. Future work may focus on learning better question parsers or directly deploying a better off-the-shelf parser tool.

5 Conclusion

In this work, we introduce Video-grounded Neural Module Network (VGNMN). VGNMN consists of dialogue and video understanding neural modules, each of which performs entity and action-level operations on language and video components. Our comprehensive experiments on AVSD and TGIF-QA benchmarks show that our models can achieve competitive performance while promoting a compositional and interpretable learning approach.

6 Broader Impacts

During the duration of this work, there have been no ethical concerns regarding the model implementation, training, and testing. The data used in this work has been carefully reviewed and accordingly to the description from the original authors, we did not find any concerns on any significant biases. For any potential application or extension of this work, we would like to highlight some specific concerns. First, as the work is developed to build an intelligent dialogue agents, models should not be used with the intention to create fake human profiles for any harmful purposes (e.g. fishing or spreading fake news). For wider use of dialogue systems, the application of work might result in certain impacts to some stakeholders whose jobs may be affected by this application (e.g. customer service call agents). We hope any application should be carefully considered against these potential risks.

A Additional Model Details

A.1 Question Parsers

To learn compositional programs, we follow (Johnson et al., 2017a; Hu et al., 2017) and consider program generation as a sequence-to-sequence task. We adopt a simple template "$\langle \mathrm{param}_1 \rangle \langle \mathrm{module}_1 \rangle \langle \mathrm{param}_2 \rangle \langle \mathrm{module}_2 \rangle$..." as the target sequence. The resulting target sequences for dialogue and video understanding programs are sequences $\mathcal{P}_{\mathrm{dial}}$ and $\mathcal{P}_{\mathrm{vid}}$ respectively.

The parsers decompose questions into subsequences to construct compositional reasoning programs for dialogue and video understanding. Each parser is an attention-based Transformer decoder. The Transformer attention is a multi-head attention on query q, key k, and value v tensors, denoted as $\mathrm{Attention}(\mathrm{q}, \mathrm{k}, \mathrm{v})$. For each token in the q sequence , the distribution over tokens in the k sequence is used to obtain the weighted sum of the corresponding representations in the v sequence.

$$\mathrm{Attention}(q, k, v) = \mathrm{softmax}(\frac{qk^T}{\sqrt{d_k}})v \in \mathbb{R}^{L_{\mathrm{q}} \times d_{\mathrm{q}}}$$

Each attention is followed by a feed-forward network applied to each position identically. We exploit the multi-head and feed-forward architecture, which show good performance in NLP tasks such as NMT and QA (Vaswani et al., 2017; Dehghani et al., 2019), to efficiently incorporate contextual cues from dialogue components to parse question into reasoning programs. At decoding step 0, we simply use a special token *_sos* as the input to the parser. In each subsequent decoding step, we concatenate the prior input sequence with the generated token to decode in an auto-regressive manner. We share the vocabulary sets of input and output components and thus, use the same embedding matrix. Given the encoded question Q, to decode the program for dialogue understanding, the contextual signals are integrated through 2 attention layers: one attention on previously generated tokens, and the other on question tokens. At time step j, we denote the output from an attention layer as $A_{\mathrm{dial,j}}$.

$$A_{\mathrm{dial}}^{(1)} = \mathrm{Attention}(P_{\mathrm{dial}}|_0^{j-1}, P_{\mathrm{dial}}|_0^{j-1}, P_{\mathrm{dial}}|_0^{j-1})$$
$$A_{\mathrm{dial}}^{(2)} = \mathrm{Attention}(A_{\mathrm{dial}}^{(1)}, Q, Q) \in \mathbb{R}^{j \times d}$$

To generate programs for video understanding, the contextual signals are learned and incorporated in a similar manner. However, to exploit dialogue contextual cues, the execution output of dialogue understanding neural modules Q_{ctx} is incorporated to each vector in P_{dial} through an additional attention layer. This layer integrates the resolved entity information to decode the original entities for video understanding. It is equivalent to a reasoning process that converts the question from its original multi-turn semantics to single-turn semantics.

$$A_{\mathrm{vid}}^{(1)} = \mathrm{Attention}(P_{\mathrm{vid}}|_0^{j-1}, P_{\mathrm{vid}}|_0^{j-1}, P_{\mathrm{vid}}|_0^{j-1})$$
$$A_{\mathrm{vid}}^{(2)} = \mathrm{Attention}(A_{\mathrm{vid}}^{(1)}, Q, Q) \in \mathbb{R}^{j \times d}$$
$$A_{\mathrm{vid}}^{(3)} = \mathrm{Attention}(A_{\mathrm{vid}}^{(2)}, Q_{\mathrm{ctx}}, Q_{\mathrm{ctx}}) \in \mathbb{R}^{j \times d}$$

A.2 How to locate entities?

Noted that in the neural modules described in Section 3.3, during training, we simply feed the ground-truth programs to optimize these modules. For instance, the neural module `where` received the ground truth entities P which is then used to instantiate the neural network and retrieve from video V. During test time, we decode the programs token by token through the question parsers, and feed the predicted entities $\hat{P}$ to neural modules. Note that we do not assume, and hence not train model to retrieve ground-truth locations of visual entities in videos. This strategy enables the applicability of VGNMN as we consider these entity annotations mostly unavailable in real-world systems.

B Additional Experimental Results

B.1 Non-NMN Models

We experiment with several Non-NMN based variants of our models. As can be seen in Table 7, our approach to video and dialogue understanding through compositional reasoning programs exhibits better performance than non-compositional approaches. Compared to the approaches that directly process frame-level features in videos (Row B) or token-level features in dialogues (Row C, D), our full VGNMN (Row A) considers entity-level and action-level information extraction and thus, avoids unnecessary and possibly noisy extraction. Compared to the approaches that obtain dialogue contextual cues through a hierarchical encoding architecture (Row E, F) such as (Serban et al., 2016; Hori et al., 2019), VGNMN directly addresses the challenge of entity references in dialogues. As mentioned, we hypothesize that the hierarchical encoding architecture is more appropriate for less entity-sensitive dialogues such as chit-chat and open-domain dialogues.

B.2 Dialogue context integration

Experimenting with different ways to integrate dialogue context representations, we observe that adding an attention layer attending to question during response decoding (Row G) is not necessary. This can be explained as the representation Q_{ctx} obtained from dialogue understanding program already contains contextual information of both dialogue history and question and question input is no longer needed in the decoding phase. Furthermore, we investigate the model sensitivity to natural language generation through its ability to construct linguistically correct programs and responses. To generate responses that are linguistically appropriate, VGNMN needs dialogue context representation Q_{ctx} as input to the response decoder (Row H). The model also needs encoded question Q as input to the video understanding program parser to be able to decompose this sequence to entity and action module parameters (Row I).

Table 7: Ablation analysis of VGNMN with different model variants on the test split of the AVSD benchmark

C Interpretability

We extract the predicted programs and responses for some example dialogues in Figure 6, 7, 8, and 9 and report our observations:

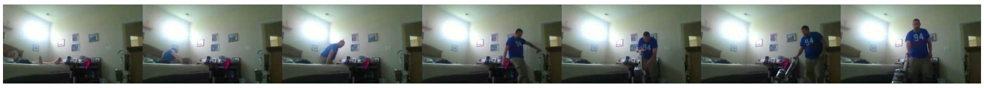
- We observe that when the predicted programs are correct, the output responses generally match the ground-truth (See the 1^{st} and 2^{nd} turn in Figure 6, and the 1^{st} and 4^{th} turn in Figure 8) or close to the ground-truth responses (1^{st} turn in Figure 7).

- When the output responses do not match the ground truth, we can understand the model mistakes by interpreting the predicted programs. For example, in the 3^{rd} turn in Figure 6, the output response describes a room because the predicted video program focuses on the entity "what room" instead of the entity "an object" in the question. Another example is the 3^{rd} turn in Figure 8 where the entity "rooftop" is missing in the video program. These mismatches can deviate the information retrieved from the video during video program execution, leading to wrong output responses with wrong visual contents.

- We also note that in some cases, one or both of the predicted programs are incorrect, but the predicted responses still match the ground-truth responses. This might be explained as the predicted module parameters are still close enough to the "gold" labels (e.g. 4^{th} turn in Figure 6). Sometimes, our model predicted programs that are more appropriate than the ground truth. For example, in the 2^{nd} turn in Figure 7, the program is added with a `where` module parameterized by the entity "the shopping bag" which was solved from the reference "them" mentioned in the question.

- We observe that for complex questions that involve more than one queries (e.g. the 3^{rd} turn in Figure 8), it becomes more challenging to decode an appropriate video understanding program and generate responses that can address all queries.

- In Figure 9, we demonstrate some output examples of VGNMN and compare with two baselines: Baseline (Hori et al., 2019) and MTN (Le et al., 2019b). We noted that VGNMN can include important entities relevant to the current dialogue turn to construct output responses while other models might miss some entity details, e.g. "them/dishes" in example A and "the magazine" in example B. These small yet important details can determine the correctness of dialogue responses.



Turn	Question	Dialogue Understanding Program	Video Understanding Program	Response
1	how many people are in the video ?	**Predicted**: `summarize()` ✓ **Gold**: `summarize()`	**Predicted**: `describe(how many people)` ✓ **Gold**: `describe(how many people)`	**Predicted**: there is only one person in the video. ✓ **Gold**: there is one person in the video.
2	does this person ever leave the field of view ?	**Predicted**: `find(this person)→summarize()` ✓ **Gold**: `find(this person)→ summarize()`	**Predicted**: `where(one person in the video)→when(leave the field of view)→exist()` ✓ **Gold**: `where(one person in the video)→when(leave the field of view)→exist()`	**Predicted**: no, he does not leave the view. ✓ **Gold**: no, he is in the video the whole time.
3	in the door way to the next room, there is an object. what is that?	**Predicted**: `find(the room), find(the door)→summarize()` ✘ **Gold**: `summarize()`	**Predicted**: `where(what room)→when(what is that)→exist()` ✘ **Gold**: `describe(what)`	**Predicted**: it looks like he is in a living room. ✘ **Gold**: he went to the doorway for a vacuum.

Abstract

Designed for tracking user goals in dialogues, a dialogue state tracker is an essential component in a dialogue system. However, the research of dialogue state tracking has largely been limited to unimodality, in which slots and slot values are limited by knowledge domains (e.g. restaurant domain with slots of restaurant name and price range) and are defined by specific database schema. In this paper, we propose to extend the definition of dialogue state tracking to multimodality. Specifically, we introduce a novel dialogue state tracking task to track the information of visual objects that are mentioned in video-grounded dialogues. Each new dialogue utterance may introduce a new video segment, new visual objects, or new object attributes and a state tracker is required to update these information slots accordingly. We created a new synthetic benchmark and designed a novel baseline, Video-Dialogue Transformer Network (VDTN), for this task. VDTN combines both object-level features and segment-level features and learns contextual dependencies between videos and dialogues to generate multimodal dialogue states. We optimized VDTN for a state generation task as well as a self-supervised video understanding task which recovers video segment or object representations. Finally, we trained VDTN to use the decoded states in a response prediction task. Together with comprehensive ablation and qualitative analysis, we discovered interesting insights towards building more capable multimodal dialogue systems.

1 Introduction

The main goal of dialogue research is to develop intelligent agents that can assist humans through conversations. For example, a dialogue agent can be tasked to help users to find a restaurant based on their preferences of price ranges and food choices. A crucial part of a dialogue system is Dialogue State Tracking (DST), which is responsible for tracking and updating user goals in the form of dialogue states, including a set of *(slot, value)* pairs such as *(price, "moderate")* and *(food, "japanese")*. Numerous machine learning approaches have been proposed to tackle DST, including fixed-vocabulary models (Ramadan et al., 2018; Lee et al., 2019) and open-vocabulary models (Lei et al., 2018b; Wu et al., 2019; Le et al., 2020c), for either single-domain (Wen et al., 2017) or multi-domain dialogues (Eric et al., 2017; Budzianowski et al., 2018).

However, the research of DST has largely limited the scope of dialogue agents to unimodality. In this setting, the slots and slot values are defined by the knowledge domains (e.g. restaurant domain) and database schema (e.g. data tables for restaurant entities). The ultimate goal of dialogue research towards building artificial intelligent assistants necessitates DST going beyond unimodal systems. In this paper, we propose Multimodal Dialogue State Tracking (MM-DST) that extends the DST task in a multimodal world. Specifically, MM-DST extends the scope of dialogue states by defining slots and slot values for *visual objects* that are mentioned in visually-grounded dialogues. For research purposes, following (Alamri et al., 2019), we limited visually-grounded dialogues as ones with a grounding video input and the dialogues contain multiple turns of (question, answer) pairs about this video. Each new utterance in such dialogues may focus on a new video segment, new visual objects, or new object attributes, and the tracker is required to update the dialogue state accordingly at each turn. An example of MM-DST can be seen in Figure 1.

Toward MM-DST, we developed a synthetic benchmark based on the CATER universe (Girdhar and Ramanan, 2020). We also introduced Video-Dialogue Transformer Network (VDTN), a neural network architecture that combines both object-level features and segment-level features in video and learns contextual dependencies between videos

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3394 - 3415
July 10-15, 2022

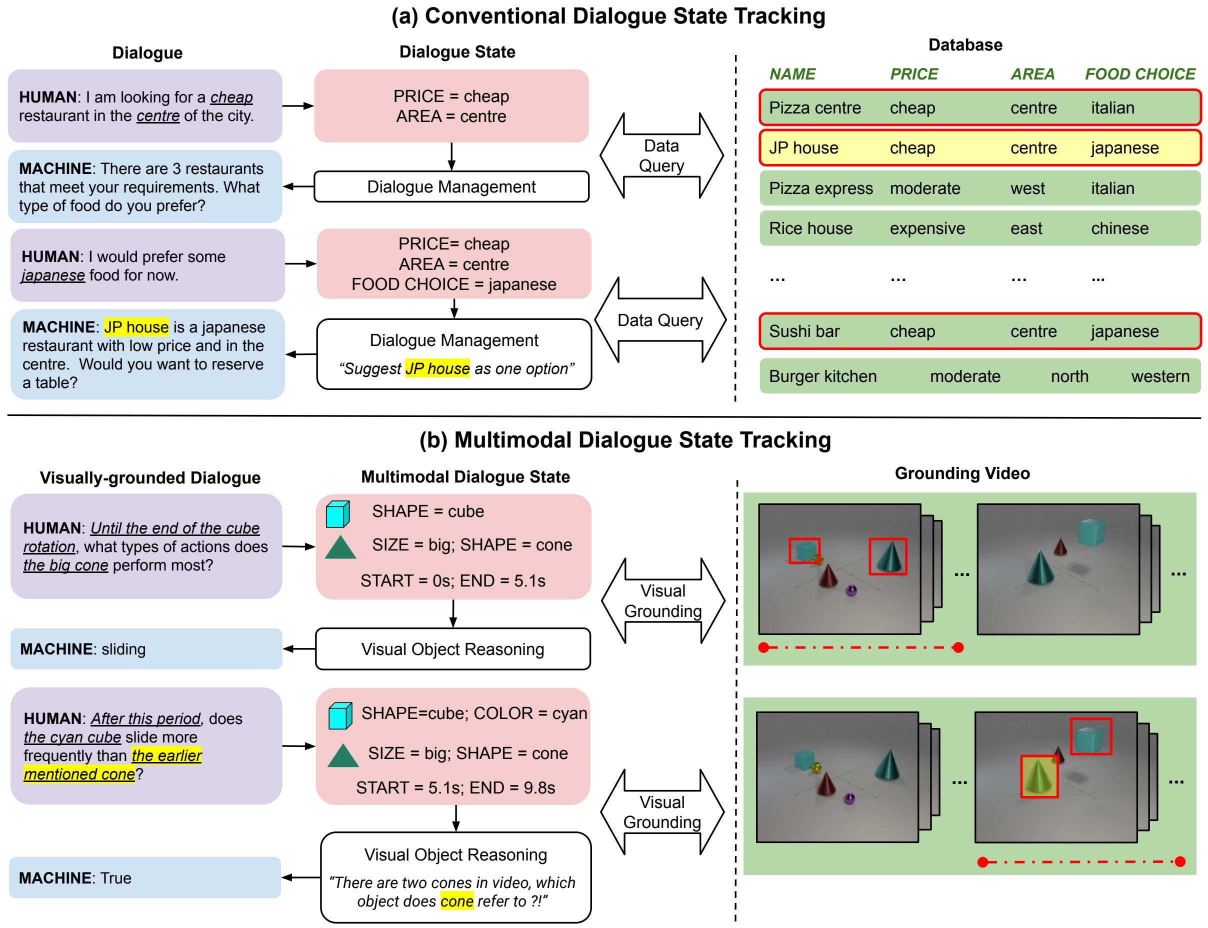

Figure 1: **Multimodal Dialogue State Tracking (MM-DST):** We proposed to extend the traditional DST from unimodality to multimodality. Compared to traditional DST (a), MM-DST (b) define dialogue states, consisting of slots and slots values for visual objects that are mentioned in dialogues.

and dialogues. Specifically, we maintained the information granularity of visual objects, embedded by object classes and their bounding boxes and injected with segment-level visual context. VDTN enables interactions between each visual object representation and word-level representation in dialogues to decode dialogue states. To decode multimodal dialogue states, we adopted a decoding strategy inspired by the Markov decision process in traditional DST (Young et al., 2010). In this strategy, a model learns to decode the state at a dialogue turn based on the predicted/ observed dialogue state available from the last dialogue turn.

Compared to the conventional DST, MM-DST involves the new modality from visual inputs. Our experiments show that simply combining visual and language representations in traditional DST models results in poor performance. Towards this challenge, we enhanced VDTN with self-supervised video understanding tasks which recovers object-based or segment-based representations. Benchmarked against strong unimodal DST models, we observed significant performance gains from VDTN. We provided comprehensive ablation analysis to study the efficacy of VDTN models. Interestingly, we also showed that using decoded states brought performance gains in a dialogue response prediction task, supporting our motivation for introducing multimodality into DST research.

2 Multimodal Dialogue State Tracking

Traditional DST. As defined by (Mrkšić et al., 2017), the traditional DST includes an input of dialogue $\mathcal{D}$ and a set of slots $\mathcal{S}$ to be tracked from turn to turn. At each dialogue turn t, we denote the dialogue context as $\mathcal{D}_t$, containing all utterances up to the current turn. The objective of DST is for each turn t, predict a value v_i^t of each slot s_i from a predefined set $\mathcal{S}$, conditioned by the dialogue context $\mathcal{D}_t$. We denote the dialogue state at turn t as $\mathcal{B}_t = \{(s_i, v_i^t)\}|_{i=1}^{i=|\mathcal{S}|}$. Note that a majority of traditional DST models assume slots are conditionally independent, given the dialogue context (Zhong et al., 2018; Budzianowski et al., 2018; Wu et al., 2019; Lee et al., 2019; Gao et al., 2019). The learning objective is defined as:

$$\hat{\mathcal{B}}_t = \arg\max_{\mathcal{B}_t} P(\mathcal{B}_t|\mathcal{D}_t, \theta)$$
$$= \arg\max_{\mathcal{B}_t} \prod_{i}^{|\mathcal{S}|} P(v_i^t|s_i, \mathcal{D}_t, \theta) \qquad (1)$$

Motivation to Multimodality. Yet, the above definition of DST are still limited to unimodality and our ultimate goal of building intelligent dialogue agents, ideally with similar level of intelligence as humans, inspires us to explore mulitmodality. In neuroscience literature, several studies have analyzed how humans can perceive the world in visual context. (Bar, 2004; Xu and Chun, 2009) found that humans can recognize multiple visual objects and how their contexts, often embedded with other related objects, facilitate this capacity.

Our work is more related to the recent study (Fischer et al., 2020) which focuses on human capacity to create temporal stability across multiple objects. The multimodal DST task is designed to develop multimodal dialogue systems that are capable of maintaining discriminative representations of visual objects over a period of time, segmented by dialogue turns. While computer science literature has focused on related human capacities in intelligent systems, they are mostly limited to vision-only tasks e.g. (He et al., 2016; Ren et al., 2015) or QA tasks e.g. (Antol et al., 2015; Jang et al., 2017) but not in a dialogue task.

Most related work in the dialogue domain is (Pang and Wang, 2020) and almost concurrent to our work is (Kottur et al., 2021). However, (Kottur et al., 2021) is limited to a single object per dialogue, and (Pang and Wang, 2020) extends to multiple objects but does not require to maintain an information state with component slots for each object. Our work aims to complement these directions and address their limitations with a novel definition of multimodal dialogue state.

Multimodal DST (MM-DST). To this end, we proposed to extend conventional dialogue states. First, we use visual object identities themselves as a component of the dialogue state to enable the perception of multiple objects. A dialogue state might have one or more objects and a dialogue system needs to update the object set as the dialogue carries on. Secondly, for each object, we define slots that represent the information state of objects in dialogues (as denoted by (Fischer et al., 2020) as "content" features of objects memorized by humans). The value of each slot is subject-specific and updated based on the dialogue context of the corresponding object. This definition of DST is closely based on the above well-studied human capacities while complementing the conventional dialogue research (Young et al., 2010; Mrkšić et al., 2017), and more lately multimodal dialogue research (Pang and Wang, 2020; Kottur et al., 2021).

We denote a grounding visual input in the form of a video $\mathcal{V}$ with one or more visual objects o_j. We assume these objects are semantically different enough (by appearance, by characters, etc.) such that each object can be uniquely identified (e.g. by an object detection module ω). The objective of MM-DST is for each dialogue turn t, predict a value v_i^t of each slot $s_i \in \mathcal{S}$ for each object $o_j \in \mathcal{O}$. We denote the dialogue state at turn t as $\mathcal{B}_t = |\{(o_j, s_i, v_{i,j}^t)\}|_{i=1,j=1}^{i=|\mathcal{S}|,j=|\mathcal{O}|}$. Assuming all slots are conditionally independent given dialogue and video context, the learning objective is extended from Eq. (1):

$$\hat{\mathcal{B}}_t = \arg\max_{\mathcal{B}_t} P(\mathcal{B}_t|\mathcal{D}_t, \mathcal{V}, \theta)$$
$$= \arg\max_{\mathcal{B}_t} \prod_{j}^{|\mathcal{O}|} \prod_{i}^{|\mathcal{S}|} P(v_{i,j}^t|s_i, o_j, \mathcal{D}_t, \mathcal{V}, \theta) P(o_j|\mathcal{V}, \omega)$$

One limitation of the current representation is the absence of temporal placement of objects in time. Naturally humans are able to associate objects and their temporal occurrence over a certain period. Therefore, we defined two temporal-based slots: s_{start} and s_{end}, denoting the start time and end time of the video segment that an object can be located by each dialogue turn. In this work, we assume that a dialogue turn is limited to a single continuous time span, and hence, s_{start} and s_{end} can be defined turn-wise, identically for all objects. While this is a strong assumption, we believe it covers a large portion of natural conversational interactions. An example of multimodal dialogue state can be seen in Figure 1.

3 Video-Dialogue Transformer Network

A naive adaptation of conventional DST to MM-DST is to directly combine visual features extracted by a pretrained 3D-CNN model. However, as

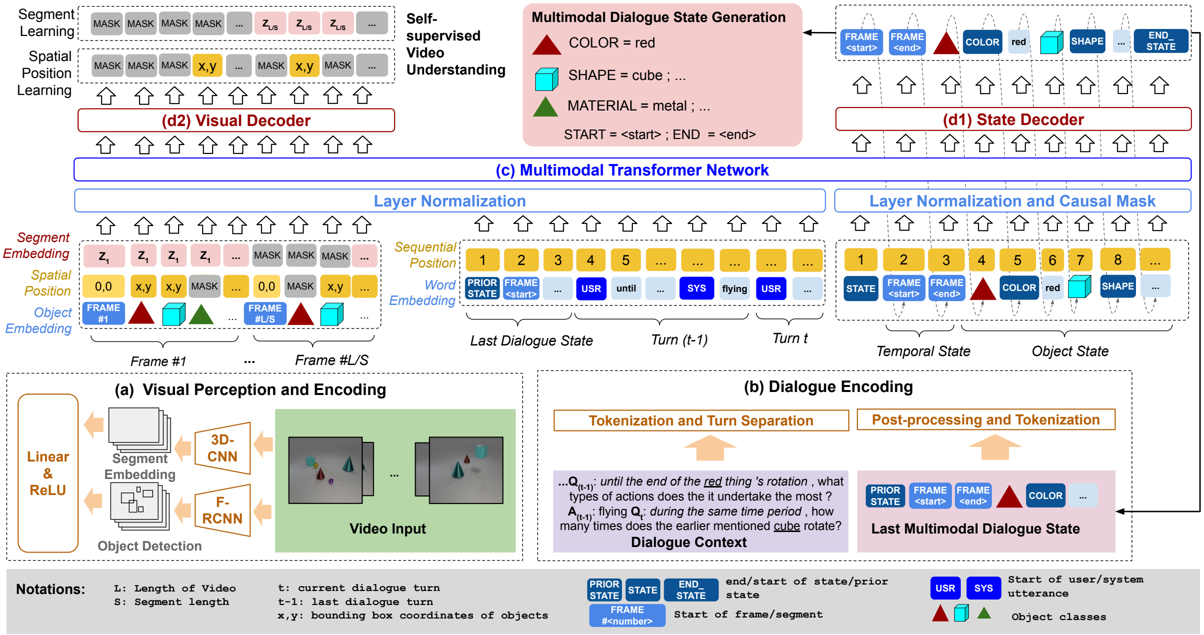

Figure 2: **Video-Dialogue Transformer Network(VDTN)** has 4 key components: (a) *Visual Perception and Encoder* (Section 3.1) (b) *Dialogue Encoder* (Section 3.2) (c) *Transformer Network* (Section 3.3) (d1) *State Decoder* (Section 3.4) and (d2) *Visual Decoder* (Section 3.4)

shown in our experiments, this extension of conventional DST results in poor performance and does not address the challenge of MM-DST. In this paper, we established a new baseline, denoted as Video-Dialogue Transformer Network (VDTN) (Refer to Fig. 2 for an overview):

3.1 Visual Perception and Encoder

Visual Perception. This module encodes videos at both frame-level and segment-level representations. Specifically, we used a pretrained Faster R-CNN model (Ren et al., 2015) to extract object representations. We used this model to output the bounding boxes and object identifiers (object classes) in each video frame of the video. For an object o_j, we denoted the four values of its bounding boxes as $bb_j = (x_j^1, y_j^1, x_j^2, y_j^2)$ and o_j as the object class itself. We standardized the video features by extracting features of up to $N_{obj} = 10$ objects per frame and normalizing all bounding box coordinates by the frame size. Secondly, we used a pretrained ResNeXt model (Xie et al., 2017) to extract the segment-level representations of videos, denoted as $z_m \in \mathbb{R}^{2048}$ for a segment m. Practically, we followed the best practice in computer vision by using a temporal sliding window with strides to sample video segments and passed segments to ResNeXt model to extract features. To standardize visual features, we use the same striding configuration N_{stride} to sub-sample segments for ResNeXt and frames for Faster R-CNN models.

Visual Representation. Note that we do not finetune the visual feature extractors in VDTN and keep the extracted features fixed. To transform these features into VDTN embedding space, we first concatenated all object identity tokens *OBJ<class>* of all frames. An object identity token *OBJ<class>* is the code name of the object class (e.g. a class of small blue metal cones) that a visual object can be unique identified (See Figure 2). Frames are separated by a special token *FRAME<number>*, where *<number>* is the temporal order of the frame. This results in a sequence of tokens X_{obj} of length $L_{obj} = (N_{obj} + 1) \times (|\mathcal{V}|/N_{stride})$ where $|\mathcal{V}|$ is the number of video frames. Correspondingly, we concatenated bounding boxes of all objects, and used a zero vector in positions of *FRAME<number>* tokens. We denoted this sequence as $X_{bb} \in \mathbb{R}^{L_{obj} \times 4}$ where the dimension of 4 is for the bounding box coordinates (x^1, y^1, x^2, y^2). Similarly, we stacked each ResNeXt feature vector by $(N_{obj} + 1)$ for each segment, and obtained a sequence $X_{cnn} \in \mathbb{R}^{L_{obj} \times 2048}$.

Visual Encoding. We passed each of X_{bb} and X_{cnn} to a linear layer with ReLU activation to map their feature dimension to a uniform dimension d.

We used a learnable embedding matrix to embed each object identity in X_{obj}, resulting in embedding features of dimensions d. The final video input representation is the summation of above vectors, denoted as $Z_V = Z_{obj} + Z_{bb} + Z_{cnn} \in \mathbb{R}^{L_{obj} \times d}$.

3.2 Dialogue and State Encoder

Dialogue Encoding. Another encoder encodes dialogue into continuous representations. Given a dialogue context $\mathcal{D}_t$, we tokenized all dialogue utterances into sequences of words, separated by special tokens *USR* for human utterance and *SYS* for system utterance. We used a trainable embedding matrix and sinusoidal positional embeddings to embed this sequence into d-dimensional vectors.

Flattening State into Sequence. Similar to the recent work in traditional DST (Lei et al., 2018b; Le et al., 2020b; Zhang et al., 2020), we are motivated by the DST decoding strategy following a Markov principle and used the dialogue state of the last dialogue turn $\mathcal{B}_{t-1}$ as an input to generate the current state $\mathcal{B}_t$. Using the same notations from Section 2, we can represent B_t into a sequence of o_j, s_i, and $v_{i,j}^t$ tokens, such as "*OBJ4 shape cube OBJ24 size small color red*". This sequence is then concatenated with utterances from $\mathcal{D}_t$, separated by a special token *PRIOR_STATE*. We denoted the resulting sequence as X_{ctx} which is passed to the embedding matrix and positional encoding as described above. As we showed in our experiments, to encode dialogue context, this strategy needs only a few dialogue utterances (that are closer to the current turn t) and $\mathcal{B}_{t-1}$, rather than the full dialogue history from turn 1. Therefore, dialogue representations Z_{ctx} have more compressed dimensions of $|X_{ctx}| \times d$ where $|X_{ctx}| < |\mathcal{D}_t|$.

3.3 Multimodal Transformer Network

We concatenated both video and dialogue representations, denoted as $Z_{VD} = [Z_V; Z_D]$. Z_{VD} has a length of $L_{obj} + L_{ctx}$ and embedding dimension d. We pased Z_{VD} to a vanilla Transformer network (Vaswani et al., 2017) through multiple multi-head attention layers with normalization (Ba et al., 2016) and residual connections (He et al., 2016). Each layer allows multimodal interactions between object-level representations from videos and word-level representations from dialogues.

3.4 Dialogue State Decoder and Self-supervised Video Denoising Decoder

State Decoding. This module decodes dialogue state sequence auto-regressively, i.e. each token is conditioned on all dialogue and video representations as well as all tokens previously decoded. At the first decoding position, a special token *STATE* is embedded into dimension d (by a learned embedding layer and sinusoidal positional encoding) and concatenated to Z_{VD}. The resulting sequence is passed to the Transformer network and the output representations of *STATE* are passed to a linear network layer that transforms representations to state vocabulary embedding space. The decoder applies the same procedure for the subsequent positions to decode dialogue states auto-regressively. Denoting $b_{k,t}$ as the k^{th} token in $\mathcal{B}_t$, i.e. token of slot, object identity, or slot value, we defined the DST loss function as the negative log-likelihood:

$$\mathcal{L}_{dst} = -\sum \log P(b_{k,t} | b_{<k,t}, X_{ctx}, X_{obj})$$

Note that this decoder design partially avoids the assumption of conditionally independent slots. During test time, we applied beam search to decode states with the maximum length of 25 tokens in all models and a beam size 5. An *END_STATE* token is used to mark the end of each sequence.

Visual Denoising Decoding. Finally, moving away from conventional unimodal DST, we proposed to enhance our DST model with a *Visual Decoder* that learns to recover visual representations in a self-supervised learning task to improve video representation learning. Specifically, during training time, we randomly sampled visual representations and masked each of them with a zero vector. At the object level, in the m^{th} video frame, we randomly masked a row from $X_{bb}(m) \in \mathbb{R}^{N_{obj} \times 4}$. Since each row represents an object, we selected a row to mask by a random object index $j \in [1, N_{obj}]$ such that the same object has not been masked in the preceding frame or following frame. We denote the Transformer output representations from video inputs as $Z'_V \in \mathbb{R}^{L_{obj} \times d}$. This vector is passed to a linear mapping f_{bb} to bounding box features $\mathbb{R}^4$. We defined the learning objective as:

$$\mathcal{L}_{obj} = \sum_o \mathbf{1}_{\text{masked}} \times l(f_{bb}(Z'_{V,o}), X_{bb,o})$$

where l is a loss function and $\mathbf{1}_{\text{masked}} = \{0, 1\}$ is a masking indicator. We experimented with both

L1 and L2 loss and reported the results. Similarly, at the segment level, we randomly selected a segment to mask such that the preceding or following segments have not been chosen for masking:

$$\mathcal{L}_{seg} = \sum_{s} \mathbf{1}_{\text{masked}} \times l(f_{cnn}(Z'_{V,s}), X_{cnn,s})$$

4 Experiments

4.1 Experimental Setup

Dataset. In existing benchmarks of multimodal dialogues such as VisDial (Das et al., 2017a) and AVSD (Alamri et al., 2019), we observed that a large number of data samples contain strong distribution bias in dialogue context, in which dialogue agents can simply ignore the whole dialogue and rely on image-only features (Kim et al., 2020). Another observed bias is the annotator bias that makes a causal link between dialogue context and output response actually harmful (Qi et al., 2020) (as annotator's preferences are treated as a confounding factor). The above biases would obviate the need for a DST task.

To address the above biases, Le et al. (2021b) developed a Diagnostic Benchmark for Video-grounded Dialogues ("DVD"), by synthetically creating dialogues that are grounded on videos from CATER videos (Shamsian et al., 2020). The videos contain visually simple yet highly varied objects. The dialogues are synthetically designed with both short-term and long-term object references. These specifications remove the annotation bias in terms of object appearances in visual context and cross-turn dependencies in dialogue context.

Extension from DVD (Le et al., 2021b) . We generated new dialogues following Le et al. (2021b)'s procedures but based on an extended CATER video split (Shamsian et al., 2020) rather than the original CATER video data (Girdhar and Ramanan, 2020). We chose the extended CATER split (Shamsian et al., 2020) as it includes additional annotations of ground-truth bounding box boundaries of visual objects in video frames. This annotation facilitates experiments with Faster-RCNN finetuned on CATER objects and experiments with models of perfect visual perception, i.e. $P(o_j|\mathcal{V}, \omega) \approx 1$. As shown in (Le et al., 2021b), objects can be uniquely referred in utterances based on their appearance by one or more following aspects: "size", "color", "material", and "shape". We directly reuse these and define them as slots in our dialogue states, in addition to 2 temporal slots for s_{start} and s_{end}. We denote the new benchmark as DVD-DST and summarize the dataset in Table 1 (for more detail, please refer to Appendix B).

Split	# Videos	# Dialogues	# Turns
DVD-DST-Train	9300	9295	92950
DVD-DST-Val	3327	3326	33260
DVD-DST-Test	1371	1371	13710
DVD-DST-All	13998	13992	139920

Table 1: Summary of the DVD-DST dataset

Baselines. To benchmark VDTN, we compared the model with following baseline models, including both rule-based models and trainable models:

- *Q-retrieval (tf-idf)*, for each test sample, directly retrieves the training sample with the most similar question utterance and use its state as the predicted state;
- *State prior* selects the most common tuple of (object, slot, value) in training split and uses it as predicted states;
- *Object (random)*, for each test sample, randomly selects one object predicted by the visual perception model and a random (slot, value) tuple (with slots and values inferred from object classes) as the predicted state;
- *Object (all)* is similar to the prior baseline but selects all possible objects and all possible (slot, value) tuples as the predicted state;
- *RNN(+Att)* uses RNN as encoder and an MLP network as decoder. Another variant of the model is enhanced with a vanilla dot-product attention at each decoding step;
- We adapted and experimented with strong unimodal DST baselines, including: *TRADE* (Wu et al., 2019), *UniConv* (Le et al., 2020b) and *NADST* (Le et al., 2020c).

We implemented these baselines and tested them on dialogues with or without videos. When video inputs are applied, we embedded both object and segment-level features (See Section 3.1). The video context features are integrated into baselines in the same techniques in which the original models treat dialogue context features.

Training. We trained VDTN by jointly minimizing $\mathcal{L}_{dst}$ and $\mathcal{L}_{bb/seg}$. We trained all models using the Adam optimizer (Kingma and Ba, 2015) with a warm-up learning rate period of 1 epoch and the learning rate decays up to 160 epochs. Models are selected based on the average $\mathcal{L}_{dst}$ on the validation set. To standardize model sizes, we selected embedding dimension $d = 128$ for all models, and experimented with both shallow ($N = 1$) and deep networks ($N = 3$) (by stacking attention or RNN blocks), and 8 attention heads in Transformer backbones. We implemented models in Pytorch and released the code and model checkpoints [1]. Refer to Appendix C for more training details.

Evaluation. We followed the unimodal DST task (Budzianowski et al., 2018; Henderson et al., 2014a) and used the state accuracy metric. The prediction is counted as correct only when all the component values exactly match the oracle values. In multimodal states, there are both discrete slots (object attributes) as well as continuous slots (temporal start and end time). For continuous slots, we followed (Hu et al., 2016; Gao et al., 2017) by using Intersection-over-Union (IoU) between predicted temporal segment and ground-truth segment. The predicted segment is counted as correct if its IoU with the oracle is more than p, where we chose $p = \{0.5, 0.7\}$. We reported the joint state accuracy of discrete slots only ("Joint Acc") as well as all slot values ("Joint Acc IoU@p"). We also reported the performance of component state predictions, including predictions of object identities o_j, object slot tuples $(o_j, s_i, v_{i,j})$, and object state tuples $(o_j, s_i, v_{i,j}) \forall s_i \in \mathcal{S}$. Since a model may simply output all possible object identities and slot values and achieve 100% component accuracies, we reported the F1 metric for each of these component predictions.

4.2 Results

Overall results. From Table 2, we have the following observations:

- we noted that simply using naive retrieval models such as *Q-retrieval* achieved zero joint state accuracy only. *State prior* achieved only about 15% and 8% F1 on object identities and object slots, showing that a model cannot simply rely on distribution bias of dialogue states.

Model	Dial.	Vid.	Obj Ident. F1	Obj Slot F1	Obj State F1	Joint Acc	Acc IoU @.5	Acc IoU @.7

Table 2: Performance (in %) of VDTN vs. baselines on the test split of DVD-DST. ✓on "Dial" or "Vid" column indicates whether we use dialogue context or video context respectively.

- The results of *Object (random/all)* show that in DVD-DST, dialogues often focus on a subset of visual objects and an object perception model alone cannot perform well.
- The performance gains of *RNN* models show the benefits of neural network models compared to retrieval models. The higher results of *RNN(D)* against *RNN(V)* showed the dialogue context is essential and reinforced the above observation.
- Comparing TRADE and UniConv, we noted that TRADE performed slightly better in component predictions, but was outperformed in joint state prediction metrics. This showed the benefits of UniConv which avoids the assumptions of conditionally independent slots and learns to extract the dependencies between slot values.
- Results of TRADE, UniConv, and NADST all displayed minor improvement when adding video inputs to dialogue inputs, displaying their weakness when exposed to cross-modality learning.
- VDTN achieves significant performance gains and achieves the SOTA results in all component or joint prediction metrics.

We also experimented with a version of VDTN in which the transformer network (Section 3.3) was

$\mathcal{L}_{seg}$	L2	27.4	14.7	12.7
$\mathcal{L}_{obj} + \mathcal{L}_{seg}$	L1	23.7	13.0	11.2
$\mathcal{L}_{obj} + \mathcal{L}_{seg}$	L2	24.3	13.4	11.6

Table 3: Accuracy (in %) by self-supervised objectives. $\mathcal{L}_{obj}$ (tracking) assumes access to oracle bounding box labels and treats the self-supervised learning task as an object tracking task.

initialized from a GPT2-base model (Radford et al., 2019) with a pretrained checkpoint released by HuggingFace[2]. Aside from using BPE to encode text sequences to match GPT2 embedding indices, we keep other components of the model the same. VDTN+GPT2 is about 36× bigger than our default VDTN model. As shown in Table 2, the performance gains of VDTN+GPT2 indicates the benefits of large-scale language models (LMs). Another benefit of using pretrained GPT2 is faster training time as we observed the VDTN+GPT2 converged much earlier than training it from scratch. From these observations, we are excited to see more future extension of SOTA unimodal DST models (Lin et al., 2021; Dai et al., 2021) and large pretrained LMs (Brown et al., 2020; Raffel et al., 2020), especially ones with multimodal learning such as (Lu et al., 2019; Zhou et al., 2020), to MM-DST task.

Impacts of self-supervised video representation learning. From Table 3, we noted that compared to a model trained only with the DST objective $\mathcal{L}_{dst}$, models enhanced with self-supervised video understanding objectives can improve the results. However, we observe that L1 loss works more consistently than L2 loss in most cases. Since L2 loss minimizes the squared differences between predicted and ground-truth values, it may be susceptible to outliers (of segment features or bounding boxes) in the dataset. Since we could not control these outliers, an L1 loss is more suitable.

We also tested with $\mathcal{L}_{obj}$ (tracking), in which we used oracle bounding box labels during training, and simply passed the features of all objects to VDTN. This modification treats the self-supervised learning task as an object tracking task in which all output representations are used to predict the ground-truth bounding box coordinates of all objects. Interestingly, we found $\mathcal{L}_{obj}$ (tracking) only improves the results insignificantly, as compared to the self-supervised learning objective $\mathcal{L}_{obj}$. This indicates that our self-supervised learning tasks do not strongly depend on the availability of object boundary labels.

Video Features	Dialogue State	Video loss	Acc	IoU @0.5	IoU @0.7
X_{bb}	$\mathcal{B}\backslash$time	-	17.9	N/A	N/A
$X_{bb} + X_{cnn}$	$\mathcal{B}\backslash$time	-	22.4	N/A	N/A
X_{bb}	$\mathcal{B}$	-	19.3	11.0	9.5
$X_{bb} + X_{cnn}$	$\mathcal{B}$	-	24.8	13.8	11.8
X_{bb}	$\mathcal{B}$	$\mathcal{L}_{obj}$	24.0	12.9	11.0
$X_{bb} + X_{cnn}$	$\mathcal{B}$	$\mathcal{L}_{obj}$	26.0	14.4	12.4
$X_{bb} + X_{cnn}$	$\mathcal{B}$	$\mathcal{L}_{seg}$	**28.0**	**15.3**	**13.1**

Table 4: Accuracy (in %) by video features and state formulations

Finally, we found combining both segment-level and object-level self-supervision is not useful. This is possibly due to our current masking strategy that masks object and segment features independently. Therefore, the resulting context features might not be sufficient for recovering masked representations. Future work can be extended by studying a code-pendent masking technique to combine segment-based and object-based representation learning.

Impacts of video features and time-based slots. Table 4 shows the results of different variants of VDTN models. We observed that:

- Segment-based learning is marginally more powerful than object-based learning.
- By considering the temporal placement of objects and defining time-based slots, we noted the performance gains by "Joint Obj State Acc" ($\mathcal{B}$ vs. $\mathcal{B}\backslash time$). The performance gains show the interesting relationships between temporal slots and discrete-only slots and the benefits of modelling both in dialogue states.
- Finally, even with only object-level features X_{bb}, we still observed performance gains from using self-supervised loss $\mathcal{L}_{obj}$, confirming the benefits of better visual representation learning.

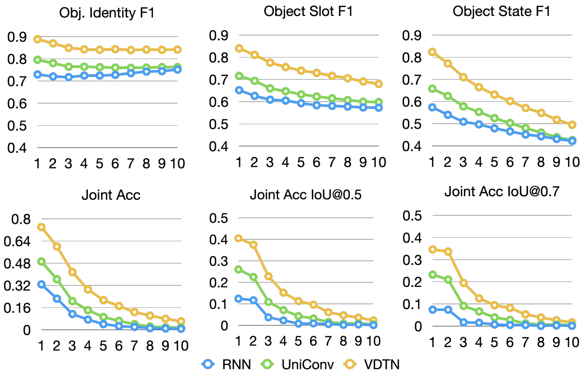

Figure 3: Ablation results of VDTN and baselines by dialogue turn positions (x axis)

Ablation analysis by turn positions. Figure 3 reported the results of VDTN predictions of states that are separated by the corresponding dialogue positions. The results are from the VDTN model trained with both $\mathcal{L}_{dst}$ and $\mathcal{L}_{seg}$. As expected, we observed a downward trend of results as the turn position increases. We noted that state accuracy reduces more dramatically (as shown by "Joint Acc") than the F1 metrics of component predictions. For instance, "Object Identity F1" shows almost stable performance lines through dialogue turns. Interestingly, we noted that the prediction performance of dialogue states with temporal slots only deteriorates dramatically after turn 2 onward. We expected that VDTN is able to learn short-term dependencies (1-turn distance) between temporal slots, but failed to deal with long-term dependencies ($>$ 1-turn distance) between temporal slots. In all metrics, we observed VDTN outperforms both RNN baseline and UniConv (Le et al., 2020b), across all turn positions. However, future work is needed to close the performance gaps between lower and higher turn positions.

Impacts on downstream response prediction task. Finally, we tested the benefits of studying multimodal DST for a response prediction task. Specifically, we used the best VDTN model to predict dialogue states across all samples in DVD-DST. We then used the predicted slots, including object identities and temporal slots, to select the video features. The features are the visual objects and segments that are parts of the predicted dialogue states. We then used these selected features as input to train new Transformer decoder models which are added with an MLP as the response prediction layer. Note that these models are trained only with a cross-entropy loss to predict answer candidates.

Dialogue State	Response Accuracy
No state	43.0
$\mathcal{B}\backslash$time	46.8/47.1
$\mathcal{B}$	48.7/48.9

Table 5: Accuracy (in %) of response predictions (by greedy/beam search states)

From Table 5, we observed the benefits of filtering visual inputs by predicted states, with up to 5.9% accuracy score improvement [3]. Note that there are more sophisticated approaches such as neural module networks (Hu et al., 2018) and symbolic reasoning (Chen et al., 2020) to fully exploit the decoded dialogue states. We leave these extensions for future research.

For more experiment results, analysis, and qualitative examples, please refer to Appendix D.

5 Discussion and Conclusion

Compared to conventional DST (Mrkšić et al., 2017; Lei et al., 2018b; Gao et al., 2019; Le et al., 2020c), we show that the scope of DST can be further extended to a multimodal world. Compared to prior work in multimodal dialogues (Das et al., 2017a; Hori et al., 2019; Thomason et al., 2019) which focuses more on vision-language interactions, our work was inspired from a dialogue-based strategy with a formulation of a dialogue state tracking task. For more comparison to related work, please refer to Appendix A.

We noted the current work are limited to a synthetic benchmark with a limited video domain (3D objects). However, we expect that MM-DST task is still applicable and can be extended to other video domains (e.g. videos of humans). We expect that MM-DST is useful in dialogues centered around a "focus group" of objects. For further discussion of limitations, please refer to Appendix E.

In summary, in this work, we introduced a novel MM-DST task that tracks visual objects and their attributes mentioned in dialogues. For this task, we experimented on a synthetic benchmark with videos simulated in a 3D environment and dialogues grounded on these objects. Finally we proposed VDTN, a Transformer-based model with self-supervised learning objectives on object and segment-level visual representations.

---

[3] The response prediction performance is lower than the results reported by DVD (Le et al., 2021b) as the training splits are not the same; DVD-DST has about 10x smaller training data than (Le et al., 2021b).

6 Broader Impacts

During the research of this work, there is no human subject involved and hence, no ethical concerns regarding the experimental procedures and results. The data is used from a synthetically developed dataset, in which all videos are simulated in a 3D environment with synthetic non-human visual objects. We intentionally chose this dataset to minimize any distribution bias and make fair comparisons between all baseline models.

However, we wanted to emphasize on ethical usage of any potential adaptation of our methods in real applications. Considering the development of AI in various industries, the technology introduced in this paper may be used in practical applications, such as dialogue agents with human users. In these cases, the adoption of the MM-DST task or VDTN should be strictly used to improve the model performance and only for legitimate and authorized purposes. It is crucial that any plan to apply or extend MM-DST in real systems should consider carefully all potential stakeholders as well as the risk profiles of application domains. For instance, in case a dialogue state is extended to human subjects, any information used as slots should be clearly informed and approved by the human subjects before the slots are tracked.

A Details of Related Work

Our work is related to the following domains:

A.1 Dialogue State Tracking

Dialogue State Tracking (DST) research aims to develop models that can track essential information conveyed in dialogues between a dialogue agent and human (defined as hidden information state by (Young et al., 2010) or belief state by (Mrkšić et al., 2017)). DST research has evolved largely within the domain of task-oriented dialogue systems. DST is conventionally designed in a modular dialogue system (Wen et al., 2017; Budzianowski et al., 2018; Le et al., 2020b) and preceded by a Natural Language Understanding (NLU) component. NLU learns to label sequences of dialogue utterances and provides a tag for each word token (often in the form of In-Out-Begin representations) (Kurata et al., 2016; Shi et al., 2016; Rastogi et al., 2017). To avoid credit assignment problems and streamline the modular designs, NLU and DST have been integrated into a single module (Mrkšić et al., 2017; Xu and Hu, 2018; Zhong et al., 2018). These DST approaches can be roughly categorized into two types: fixed-vocabulary or open-vocabulary. Fixed-vocabulary approaches are designed for classification tasks which assume a fixed set of *(slot, value)* candidates and directly retrieve items from this set to form dialogue states during test time (Henderson et al., 2014b; Ramadan et al., 2018; Lee et al., 2019). More recently, we saw more approaches toward open-vocabulary strategies which learn to generate candidates based on input dialogue context (Lei et al., 2018b; Gao et al., 2019; Wu et al., 2019; Le et al., 2020c). Our work is more related to open-vocabulary DST, but we essentially redefined the DST task with multimodality. Based on our literature review, we are the first to formally extend DST and bridge the gap between traditional task-oriented dialogues and multimodal dialogues.

A.2 Visually-grounded Dialogues

A novel challenge to machine intelligence, the intersection of vision and language research has expanded considerably in the past few years. Earlier benchmarks test machines to perceive visual inputs, and learn to generate captions (Farhadi et al., 2010; Lin et al., 2014; Rohrbach et al., 2015), ground text phrases and objects (Kazemzadeh et al., 2014; Plummer et al., 2015), and answer questions about the visual contents (Antol et al., 2015; Zhu et al., 2016; Jang et al., 2017; Lei et al., 2018a). As an orthogonal development from Visual Question Answering problems, we noted recent work that targets vision-language in dialogue context, in which an image or video is given and the dialogue utterances are centered around its visual contents (De Vries et al., 2017; Das et al., 2017a; Chattopadhyay et al., 2017; Hori et al., 2019; Thomason et al., 2019; Le et al., 2021b). Recent work has addressed different challenges in visually-grounded dialogues, including multimodal integration (Hori et al., 2019; Le et al., 2019; Li et al., 2021), cross-turn dependencies (Das et al., 2017b; Schwartz et al., 2019; Le et al., 2021a), visual understanding (Le et al., 2020a), and data distribution bias (Qi et al., 2020). Our work is more related to the challenge of visual object reasoning (Seo et al., 2017; Kottur et al., 2018), but focused on a multi-turn tracking task over multiple turns of dialogue context. The prior approaches are not well designed to track objects and maintain a recurring memory or state of these objects from turn to turn. This challenge becomes more obvious when a dialogue involves multiple objects of similar characters or appearance. We directly tackles this challenge as we formulated a novel multimodal state tracking task and leveraged the research development from DST in task-oriented dialogue systems. As shown in our experiments, baseline models that use attention strategies similar to (Seo et al., 2017; Kottur et al., 2018) did not perform well in MM-DST.

A.3 Multimodal DST

We noted a few studies have attempted to integrate some forms of state tracking in multimodal dialogues. In (Mou et al., 2020), however, we are not convinced that a dialogue state tracking task is a major focus, or correctly defined. In (Pang and Wang, 2020), we noted that some form of object tracking is introduced throughout dialogue turns. The tracking module is used to decide which object

Figure 4: Synthetic visual objects in the CATER universe

the dialogue centers around. This method extends to multi-object tracking but the objects are only limited within static images, and there is no recurring information state (object attributes) maintained at each turn. Compared to our work, their tracking module only requires object identity as a single-slot state from turn to turn. Almost concurrent to our work, we noted (Kottur et al., 2021) which formally, though very briefly, focuses on multimodal DST. However, the work is limited to the task-oriented domain, and each dialogue is only limited to a single goal-driven object in a synthetic image. While this definition is useful in the task-oriented dialogue domain, it does not account for the DST of multiple visual objects as defined in our work.

B DVD-DST Dataset Details

For each of CATER videos from the extended split (Shamsian et al., 2020), we generated up to 10 turns for each CATER video. In total, DVD-DST contains more than $13k$ dialogues, resulting in more $130k$ (human, system) utterance pairs and corresponding dialogue states. A comparison of statistics of DVD-DST and prior DST benchmarks can be seen in Table 6. We observed that DVD-DST contains a larger scale data than the related DST benchmark. Even though the number of slots in DVD-DST is only 6, lower than prior state tracking datasets, our experiments indicate that most current conventional DST models perform poorly on DVD-DST.

CATER universe. Figure 4 displays the configuration of visual objects in the CATER universe. In total, there are 3 object sizes, 9 colors, 2 materials, and 5 shapes. These attributes are combined randomly to synthesize objects in each CATER video. We directly adopted these attributes as slots in dialogue states, and each dialogue utterance frequently refers to these objects by one or more attributes. In total, there are 193 (size, color, material, shape) valid combinations, each of which corresponds to an object class in our models.

Sample dialogues. Please refer to Figure 5, Table 14 and Table 15.

Usage. We want to highlight that the DVD-DST dataset should only be used for its intended purpose, i.e. to diagnose dialogue systems on their tracking abilities. Any derivatives of the data should be limited within the research contexts of MM-DST.

C Additional Training Details

In practice, we applied label smoothing (Szegedy et al., 2016) on state sequence labels to regularize the training. As the segment-level representations are stacked by the number of objects, we randomly selected only one vector per masked segment to apply $\mathcal{L}_{seg}$. We tested both L1 and L2 losses on $\mathcal{L}_{bb/seg}$. All model parameters, except pretrained visual perception models, are initialized by a uniform distribution (Glorot and Bengio, 2010).

Video Features	Dialogue State	Video loss	Greedy			Beam Search		
			Joint Obj State Acc	Joint State IoU@0.5	Joint State IoU@0.7	Joint Obj State Acc	Joint State IoU@0.5	Joint State IoU@0.7

Table 8: Ablation results by component predictions of object identities, slots, and object states

For fair comparison among baselines, all models use both object-level and segment-level feature representations, encoded by the same method as Describe in Section 3.1. In *TRADE*, the video representations are passed to an RNN encoder, and the output hidden states are concatenated to the dialogue hidden states. Both are passed to the original pointer-based decoder. In *UniConv* and *NADAST*, we stacked another Transformer attention layer to attend on video representations before the original state-to-dialogue attention layer. We all baseline models, we replaced the original (domain, slot) embeddings as (object class, slot) embeddings and kept the original model designs.

Note that in our visual perception model, we adopted the finetuned Faster R-CNN model used by (Shamsian et al., 2020). The model was finetuned to predict object bounding boxes and object classes. The object classes are derived based on object appearance, based on the four attributes of size, color, material, and shape. In total, there are 193 object classes. For segment embeddings, we adopted the ResNeXt-101 model (Xie et al., 2017) finetuned on Kinetics dataset (Kay et al., 2017). For all models (except for VDTN ablation analysis), we standardized $N_{obj} = 10$ and $N_{stride} = 12$ to sub-sample object and segment-level embeddings.

Resources. Note that all experiments did not require particularly large computing resources as we limited all model training to a single GPU, specifically on a Tesla V100 GPU of 16G configuration.

D Additional Results

Greedy vs. Beam Search Decoding. Table 7 shows the results of different variants of VDTN models. We observed that compared to greedy decoding, beam search decoding improves the performance in all models. As beam search decoding selects the best decoded state by the joint probabilities of tokens, this observation indicates the benefits of considering slot values to be co-dependent and their relationships should be modelled. This is consistent with similar observations in later work of unimodal DST (Lei et al., 2018b; Le et al., 2020c).

Ablation analysis by component predictions. From Table 8, we have the following observations: (1) In ablation results by component predictions, we noted that models can generally detect object identities well with F1 about 80%. However, when considering object and slot tuples, F1 reduces to $48 - 60\%$, indicating the gaps are caused by slot value predictions. (2) By individual slots, we noted "color" and "shape" slots are easier to track than

Table 10: Ablation results by individual slot type

"size" and "material" slots. We noted that in the CATER universe, the latter two slots have lower visual variances (less possible values) than the others. As a result, objects are more likely to share the same size or material and hence, discerning objects by those slots and tracking them in dialogues become more challenging.

Table 9 and 10 display the ablation results by component predictions, using precision and recall metrics. We still noted consistent observations as described in Section 4. Notably, we found that current VDTN models are better in tuning the correct predictions (as shown by high precision metrics) but still fail to select all components as a set (as shown by low recall metrics). This might be caused by the upstream errors coming from the visual perception models, which may fail to visually perceive all objects and their attributes.

Results by turn positions. Table 11 reported the results of VDTN predictions of states that are separated by the corresponding dialogue positions. The results are from the VDTN model trained with both $\mathcal{L}_{dst}$ and $\mathcal{L}_{seg}$. As expected, we observed a downward trend of results as the turn position increases.

Impacts of dialogue context encoder. In Table 12a, we observed the benefits of using the Markov process to decode dialogue states based on the dialogue states of the last turn $\mathcal{B}_{t-1}$. This strategy allow us to discard parts of dialogue history that is already represented by the state. We noted that the optimal design is to use at least 1 last dialogue turn as the dialogue history. In a hypothetical scenario, we applied the oracle $\mathcal{B}_{t-1}$ during test time, and noted the performance is improved significantly. This observation indicates the sensitivity of VDTN to a turn-wise auto-regressive decoding process.

Impacts of frame-level and segment-level sampling. As expected, Table 12b displays higher performance with higher object limits N_{obj}, which increases the chance of detecting the right visual objects in videos. We noted performance gains when sampling strides increase up to 24 frames. However, in the extreme case, when sampling stride is 300 frames, the performance on temporal slots reduce (as shown by "Joint State IoU@p"). This raises the issue to sample data more efficiently by balancing between temporal sparsity in videos and state prediction performance. We also observed that in a hypothetical scenario with a perfect object perception model, the performance improves significantly, especially on the predictions of discrete slots, although less effect on temporal slots.

Impacts of object-level representation. Table 13 reported the results when only segment-level features are used. We observed that both VDTN and *RNN(V+D)* are affected significantly, specifically by 24% and 3.1% "Joint Obj State Acc" score respectively. Interestingly, we noted that *RNN(V)*, using only video inputs, are not affected by the removal of object-level features. These observations

Table 12: Ablation results by encoding strategies: All models are trained only with $\mathcal{L}_{dst}$.

indicate that current MM-DST requires object-level information. We expected that existing 3DCNN models such as ResNeXt still fail to capture such level of granularity.

Qualitative analysis. Table 14 and 15 display 2 sample dialogues and state predictions. We displayed the corresponding video screenshots for these dialogues in Figure 5. To cross-reference between videos and dialogues, we displayed the bounding boxes and their object classes in video screenshots. These object classes are indicated in ground-truth and decoded dialogue states in dialogues. Overall, we noted that VDTN generated temporal slots of start and end time such that the resulting periods better match the ground-truth temporal segments. VDTN also showed to maintain the dialogue states better from turn to turn.

E Further Discussion

Synthetic datasets result in overestimation of real performance and don't translate to real-world usability. We agree that the current state accuracy seems to be quite low at about 28%. However, we want to highlight that state accuracy used in this paper is a very strict metric, which only considers a prediction as correct if it completely matches the ground truth. In DVD, assuming the average 10 objects per video with the set of attributes as in Figure 4 (+ 'none' value in each slot), we can roughly equate the multimodal DST as a 7200-class classification task, each class is a distinct set of objects, each with all possible attribute combinations. Combined with the cascading error from object perception models, we think the current reported results are reasonable.

Moreover, we want to highlight that the reported performance of baselines reasonably matches their own capacities in unimodal DST. We can consider Object State F1 as the performance on single-object state and it can closely correlate with the joint state accuracy in unimodal DST (remember that unimodal DST such as MultiWOZ (Budzianowski et al., 2018) is only limited to a single object/entity per dialogue). As seen in Table 2, the Object State F1 results of TRADE (Wu et al., 2019), UniConv (Le et al., 2020b), and NADST (Le et al., 2020c) are between 46-50%. This performance range is indeed not very far off from the performance of these baseline models in unimodal DST in the MultiWOZ benchmark (Budzianowski et al., 2018).

Finally, we also want to highlight that like other synthetic benchmarks such as CLEVR (Johnson

Model	$X_{bb} + X_{cnn}$			X_{cnn} only

RNN(V)	1.0%	0.1%	0.1%	1.5%	0.4%	0.4%
RNN(V+D)	6.8%	2.6%	2.3%	3.7%	1.8%	1.6%

Table 13: Results with and without object representations

et al., 2017), we want to use DVD in this work as a test bed to study and design better multimodal dialogue systems. However, we do not intend to use it as a training data for practical systems. The DVD-DST benchmark should be used to supplement real-world video-grounded dialogue datasets.

MM-DST in practical applications e.g. with videos of humans. While we introduced MM-DST task and VDTN as a new baseline, we noted that the existing results are limited to the synthetic benchmark. For instance, in the real world, there would be many identical objects with the same (size, color, material, shape) tuples, which would make the current formulation of dialogue states difficult. In such object-driven conversations, we would recommend a dialogue agent not focus on all possible objects in each video frame, but only on a "focus group" of objects. These objects, required to be semantically different, are topical subjects of the conversations.

Say we want to scale to a new domain e.g. videos of humans, the first challenge from the current study is the recognition of human objects, which often have higher visual complexity than moving objects as in DVD. We also noted that it is impossible to define all human object classes as in CATER object classes, each of which is unique by its own appearance. To overcome this limitation, we would want to explore multimodal DST with the research of human object tracking, e.g. (Fernando et al., 2018), and consider human object identities uniquely defined per video. Another limitation is the definition of slots to track in each human object. While this requires careful considerations, for both practical and ethical reasons, we noted several potential papers that investigate human attributes in dialogues such as human emotions (Wang et al., 2021). Along these lines, we are excited to see interesting adaptations of multimodal dialogue states grounded on videos of humans.

Abstract

In recent years, pre-trained models have become dominant in most natural language processing (NLP) tasks. However, in the area of Automated Essay Scoring (AES), pre-trained models such as BERT have not been properly used to outperform other deep learning models such as LSTM. In this paper, we introduce a novel multi-scale essay representation for BERT that can be jointly learned. We also employ multiple losses and transfer learning from out-of-domain essays to further improve the performance. Experiment results show that our approach derives much benefit from joint learning of multi-scale essay representation and obtains almost the state-of-the-art result among all deep learning models in the ASAP[1] task. Our multi-scale essay representation also generalizes well to CommonLit Readability Prize (CRP[2]) data set, which suggests that the novel text representation proposed in this paper may be a new and effective choice for long-text tasks.

1 Introduction

AES is a valuable task, which can promote the development of automated assessment and help teachers reduce the heavy burden of assessment. With the rise of online education in recent years, more and more researchers begin to pay attention to this field.

AES systems typically consist of two modules, which are essay representation and essay scoring modules. The essay representation module extracts features to represent an essay and the essay scoring module rates the essay with the extracted features.

When a teacher rates an essay, the scores are often affected by multiple signals from different granularity levels, such as token level, sentence level, paragraph level and etc. For example, the features may include the numbers of words, the essay structure, the master degree of vocabulary and syntactic complexity, etc. These features come from different scales of the essay. This inspires us to extract multi-scale features from the essays which represent multi-level characteristics of the essays.

Most of the deep neural networks AES systems use LSTM or CNN. Some researchers (Uto et al., 2020; Rodriguez et al., 2019; Mayfield and Black, 2020) attempt to use BERT (Devlin et al., 2019) in their AES systems but fail to outperform other deep neural networks methods (Dong et al., 2017; Tay et al., 2018). We believe previous approaches using BERT for AES suffer from at least three limitations. First, the pre-trained models are usually trained on sentence-level, but fail to learn enough knowledge of essays. Second, the AES training data is usually quite limited for direct fine-tuning of the pre-trained models in order to learn better representation of essays. Last but not least, mean squared error (MSE) is commonly used in the AES task as the loss function. However, the distribution of the sample population and the sorting properties between samples are also important issues to be considered when designing the loss functions as they imitate the psychological process of teachers rating essays. Different optimizations can also bring diversity to the final overall score distribution and contribute to the effectiveness of ensemble learning.

To address the aforementioned issues and limitations, we introduce joint learning of multi-scale essay representation into the AES task with BERT, which outperforms the state-of-the-art deep learning models based on LSTM (Dong et al., 2017; Tay et al., 2018). We propose to explicitly model more effective representations by extracting multi-scale features as well as leveraging the knowledge learned from numerous sentence data. As the training data is limited, we also employ transfer learn-

Proceedings of the 2022 Conference of the North American Chapter of the Association for Computational Linguistics: Human Language Technologies, pages 3416 - 3425
July 10-15, 2022 ©2022 Association for Computational Linguistics

ing from out-of-domain essays which is inspired by (Song et al., 2020). To introduce the diversity of essay scoring distribution, we combine two other loss functions with MSE. When training our model with multiple losses and transfer learning using R-Drop (Liang et al., 2021), we almost achieve the state-of-the-art result among all deep learning models. The source code of prediction module with a trained model for ASAP's prompt 8 is publicly available[3].

In summary, the contribution of this work is as follows:

- We propose a novel essay scoring approach to jointly learn multi-scale essay representation with BERT, which significantly improve the result compared to traditionally using pre-trained language models.
- Our method shows significant advantages in long text tasks and obtains almost the state-of-the-art result among all deep learning models in the ASAP task.
- We introduce two new loss functions which are inspired by the mental process of teacher rating essays, and employ transfer learning from out-of-domain essays with R-Drop (Liang et al., 2021), which further improves the performance for rating essays.

2 Related Work

The dominant approaches in AES can be grouped into three categories: traditional AES, deep neural networks AES and pre-training AES.

- **Traditional AES** usually uses regression or ranking systems with complicated handcrafted features to rate an essay (Larkey, 1998; Rudner and Liang, 2002; Attali and Burstein, 2006; Yannakoudakis et al., 2011; Chen and He, 2013; Phandi et al., 2015; Cozma et al., 2018). These handcrafted features are based on the prior knowledge of linguists. Therefore they can achieve good performance even with small amounts of data.
- **Deep Neural Networks AES** has made great progress and achieved comparable results with traditional AES recently (Taghipour and Ng, 2016; Dong and Zhang, 2016; Dong et al., 2017; Alikaniotis et al., 2016; Wang et al., 2018; Tay et al., 2018; Farag et al., 2018; Song et al., 2020; Ridley et al., 2021; Muangkammuen and Fukumoto, 2020; Mathias et al., 2020). While the handcrafted features are complicated to implement and careful manual design makes these features less portable, deep neural networks such as LSTM or CNN can automatically discover and learn complex features of essays, which makes AES an end-to-end task. Saving much time to design features, deep neural networks can transfer well among different AES tasks. By combining traditional and deep neural network approaches, AES can even obtain a better result, which benefits from both representations (Jin et al., 2018; Dasgupta et al., 2018; Uto et al., 2020). However, ensemble way still needs handcrafted features which cost numerous energy of researchers.
- **Pre-training AES** uses the pre-trained language model as the initial essay representation module and fine-tune the model on the essay training set. Though the pre-trained methods have achieved the state-of-the-art performance in most NLP tasks, most of them (Uto et al., 2020; Rodriguez et al., 2019; Mayfield and Black, 2020) fail to show an advantage over other deep learning methods (Dong et al., 2017; Tay et al., 2018) in AES task. As far as we know, the work from Cao et al. (2020) and Yang et al. (2020) are the only two pre-training approaches which surpass the other deep learning methods. Their improvement mainly comes from the training optimization. Cao et al. (2020) employ two self-supervised tasks and domain adversarial training, while Yang et al. (2020) combine regression and ranking to train their model.

3 Approach

3.1 Task Formulation

The AES task is defined as following:

Given an essay with n words $X = \{x_i\}_{i=1}^{n}$, we need to output one score y as a result of measuring the level of this essay.

Quadratic weighted Kappa (QWK) (Cohen, 1968) metric is commonly used to evaluate AES systems by researchers, which measures the agreement between the scoring results of two raters.

---

3.2 Multi-scale Essay Representation

We obtain the multi-scale essay representation from three scales: token-scale, segment-scale and document-scale.

Token-scale and Document-scale Input We apply one pre-trained BERT (Devlin et al., 2019) model for token-scale and document-scale essay representations. The BERT tokenizer is used to split the essay into a token sequence $T_1 = [t_1, t_2, ...t_n]$, where t_i is the ith token and n is the number of the tokens in the essay. The **token** we mentioned in this paper all refer to WordPiece, which is obtained by the subword tokenization algorithm used for BERT. We construct a new sequence T_2 from T_1 as following. L is set to 510, which is the max sequence length supported by BERT except the token $[CLS]$ and $[SEP]$.

$$T_2 = \begin{cases} \text{[CLS]+}[t_1, t_2, .., t_L]\text{+[SEP]} & n > L \\ \text{[CLS]+}T_1\text{+[SEP]} & n = L \\ \text{[CLS]+}T_1\text{+[PAD]}*(L-n)\text{+[SEP]} & n < L \end{cases}$$

The final input representation are the sum of the token embeddings, the segmentation embeddings and the position embeddings. A detailed description can be found in the work of BERT (Devlin et al., 2019).

Document-scale The document-scale representation is obtained by the $[CLS]$ output of the BERT model. As the $[CLS]$ output aggregates the whole sequence representation, it attempts to extract the essay information from the most global granularity.

Token-scale As the BERT model is pre-trained by Masked Language Modeling (Devlin et al., 2019), the sequence outputs can capture the context information to represent each token. An essay often consists of hundreds of tokens, thus RNN is not the proper choice to combine all the token information due to the gradients vanishing problem. Instead, we utilize a max-pooling operation to all the sequence outputs and obtain the combined token-scale essay representation. Specifically, the max-pooling layer generates a d-dimensional vector $W = [w_1, w_2, ..., w_j, ..., w_d]$ and the element w_j is computed as below:

$$w_j = max\{h_{1,j}, h_{2,j}, ..., h_{n,j}\}$$

where d is the hidden size of the BERT model. As we use the pre-trained BERT model **bert-base-uncased**[4], the hidden size d is 768. All the n sequence outputs of the BERT model are annotated as $[h_1, h_2, ..., h_i, ..., h_n]$, where h_i is a d-dimensional vector $[h_{i,1}, h_{i,2}, ..., h_{i,d}]$ representing the ith sequence output, and $h_{i,j}$ is the jth element in h_i.

Segment-scale Assuming the segment-scale value set is $K = [k_1, k_2, ...k_i, ..., k_S]$, where S is the number of segment scales we want to explore, and k_i is the ith segment-scale in K. Given a token sequence $T_1 = [t_1, t_2, ...t_n]$ for an essay, we obtain the segment-scale essay representation corresponding to scale k_i as follows:

1. We define n_p as the maximum number of tokens corresponding to each essay prompt p. We truncate the token sequence to n_p tokens if the essay length is longer than n_p, otherwise we pad $[PAD]$ to the sequence to reach the length n_p.

2. Divide the token sequence into $m = \lceil n_p/k_i \rceil$ segments and each segment is of length k_i except for the last segment, which is similar to the work of (Mulyar et al., 2019).

3. Input each of the m segment tokens into the BERT model, and get m segment representation vectors from the $[CLS]$ output.

4. Use an LSTM model to process the sequence of m segment representations, followed by attention pooling operation on the hidden states of the LSTM output to obtain the segment-scale essay representation corresponding to scale k_i.

The LSTM cell units process the sequence of segment representations and generate the hidden states as follows:

$$\begin{gathered} i_t = \sigma(Q_i \cdot s_t + U_i \cdot h_{t-1} + b_i) \\ f_t = \sigma(Q_f \cdot s_t + U_f \cdot h_{t-1} + b_f) \\ \hat{c}_t = tanh(Q_c \cdot s_t + U_c \cdot h_{t-1} + b_c) \\ c_t = i_t \circ \hat{c}_t + f_t \circ c_{t-1} \\ o_t = \sigma(Q_o \cdot s_t + U_o \cdot h_{t-1} + b_o) \\ h_t = o_t \circ tanh(c_t) \end{gathered}$$

where s_t is the tth segment representation from BERT $[CLS]$ output and h_t is the tth hidden state generated from LSTM. Q_i, Q_f, Q_c, Q_o, U_i, U_f, U_c and U_o are weight matrices, and b_i, b_f, b_c, and b_o are bias vectors.

The attention pooling operation we use is similar to the work of (Dong et al., 2017), which is defined as follows:

$$\begin{gathered} \hat{\alpha}_t = tanh(Q_a \cdot h_t + b_a) \\ \alpha_t = \frac{e^{q_a \cdot \hat{\alpha}_t}}{\sum_j e^{q_a \cdot \hat{\alpha}_j}} \\ o = \sum_t \alpha_t \cdot h_t \end{gathered}$$

---

[4] `https://huggingface.co/bert-base-uncased`

o is the segment-scale essay representation corresponding to the scale k_i. α_t is the attention weight for hidden state h_t. Q_a, b_a, q_a are the weight matrix, bias and weight vector respectively.

3.3 Model Architecture

The model architecture is depicted in Figure 1.

We apply one BERT model to obtain the document-scale and token-scale essay representation. The concatenation of them is input into a dense regression layer which predicts the score corresponding to the document-scale and token-scale. For each segment-scale k with number of segments m, we apply another BERT model to get m CLS outputs, and apply an $LSTM$ model followed by an attention layer to get the segment-scale representation. We input the segment-scale representation into another dense regression layer to get the score corresponding to segment-scale k. The final score is obtained by adding the scores of all S segment-scales and the score of the document-scale and token-scale, which is illustrated as below:

$$\begin{gathered} y = \sum_k y_k + y_{doc,tok} \\ y_k = \hat{W}_{seg} \cdot o_k + b_{seg} \\ y_{doc,tok} = \hat{W}_{doc,tok} \cdot H_{doc,tok} + b_{doc,tok} \\ H_{doc,tok} = w_{doc} \bigoplus W \end{gathered}$$

y_k is the predicted score corresponding to segment-scale k. $y_{doc,tok}$ is the predicted score corresponding to the document-scale and token-scale. $\hat{W}_{seg}$ and b_{seg} are weight matrix and bias for segment-scale respectively. $W_{doc,tok}$ and $b_{doc,tok}$ are weight matrix and bias for document and token-scales, o_k is the segment-scale essay representation with the scale k. w_{doc} is the document-scale essay representation. W is the token-scale essay representation. $H_{doc,tok}$ is the concatenation of document-scale and token-scale essay representations.

3.4 Loss Function

We use three loss functions to train the model.

MSE measures the average value of square errors between predicted scores and labels, which is defined as below:

$$MSE(y, \hat{y}) = \frac{1}{N} \sum_i (y_i - \hat{y}_i)^2$$

where y_i and $\hat{y}_i$ are the predicted score and the label for the ith essay respectively, N is the number of the essays.

Similarity (SIM) measures whether two vectors are similar or dissimilar by using cosine function. A teacher takes into account the overall level distribution of all the students when rating an essay. Following such intuition, we introduce the SIM loss to the AES task. In each training step, we take the predicted scores of the essays in the batch as the predicted vector y, and the labels as the label vector $\hat{y}$. The SIM loss awards the similar vector pairs to make the model think more about the correlation among the batch of essays. The SIM loss is defined as below:

$$\begin{gathered} SIM(y, \hat{y}) = 1 - cos(y, \hat{y}) \\ y = [y_1, y_2, ..., y_N] \\ \hat{y} = [\hat{y}_1, \hat{y}_2, ..., \hat{y}_N] \end{gathered}$$

where y_i and $\hat{y}_i$ are the predicted score and label for the ith essay respectively, N is the number of the essays.

Margin Ranking (MR) measures the ranking orders for each essay pair in the batch. We intuitively introduce MR loss because the sorting property between essays is a key factor to scoring. For each batch of essays, we first enumerate all the essay pairs, and then compute the MR loss as follows. The MR loss attempts to make the model penalize wrong order.

$$MR(y, \hat{y}) = \frac{1}{\hat{N}} \sum_{i,j} max(0, -r_{i,j}(y_i - y_j) + b)$$

$$r_{i,j} = \begin{cases} 1 & \hat{y}_i > \hat{y}_j \\ \text{-1} & \hat{y}_i < \hat{y}_j \\ \text{-}sgn(y_i - y_j) & \hat{y}_i = \hat{y}_j \end{cases}$$

y_i and $\hat{y}_i$ are the predicted score and label for the ith essay respectively. $\hat{N}$ is the number of the essay pairs. b is a hyper parameter, which is set to 0 in our experiment. For each sample pair (i, j), when the label $\hat{y}_i$ is larger than $\hat{y}_j$, the predicted result y_i should be larger than y_j, otherwise, the pair contributes $y_j - y_i$ to the loss. When $\hat{y}_i$ is equal to $\hat{y}_j$, the loss is actually $|y_i - y_j|$.

The combined loss is described as below:

$Loss_{total}(y, \hat{y}) = \alpha MSE(y, \hat{y}) + \beta MR(y, \hat{y}) + \gamma SIM(y, \hat{y})$.

α, β, γ are weight parameters which are tuned according to the performance on develop set.

4 Experiment

4.1 Data and Evaluation

ASAP data set is widely used in the AES task, which contains eight different prompts. A detailed description can be seen in Table 1. For each prompt, the WordPiece length indicates the smallest number which is bigger than the length of 90% of the

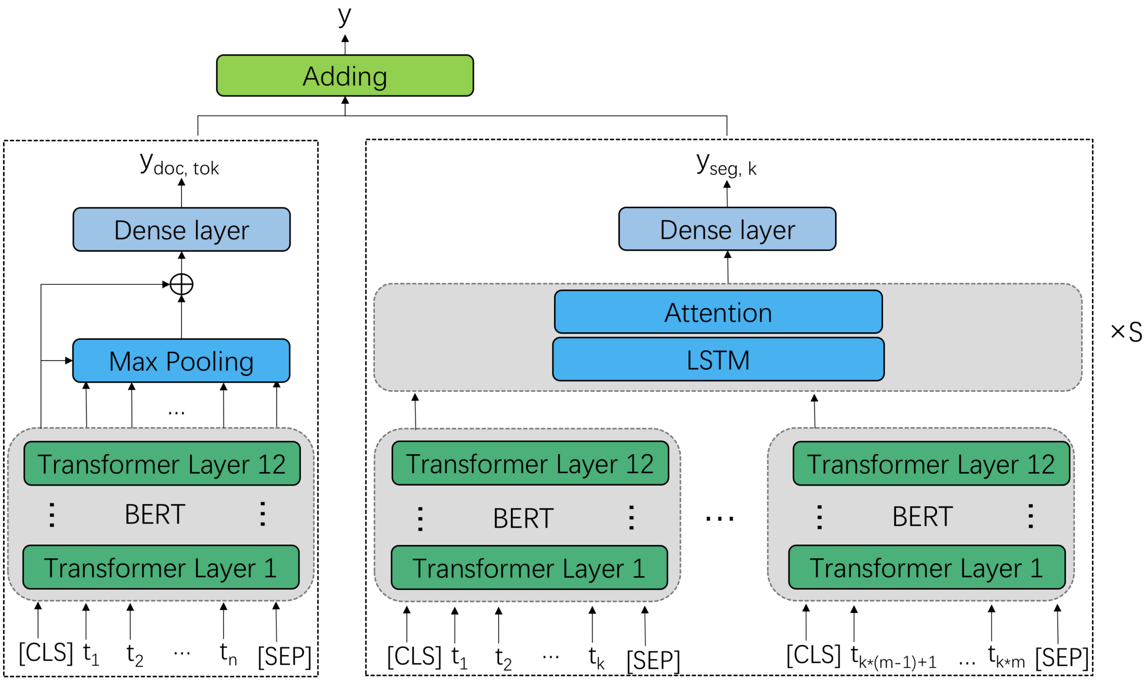

Figure 1: The proposed automated essay scoring architecture based on multi-scale essay representation. The left part illustrates the document-scale and token-scale essay representation and scoring module, and the right part illustrates S segment-scale essay representations and scoring modules.

essays in terms of WordPiece number. We evaluate the scoring performance using QWK on ASAP data set, which is the official metric in the ASAP competition. Following previous work, we adopt 5-fold cross validation with 60/20/20 split for train, develop and test sets.

CRP data set provides 2834 excerpts from several time periods and reading ease scores which range from -3.68 to 1.72. The average length of the excerpts is 175 and the WordPiece length is 252. We also use 5-fold cross validation with 60/20/20 split for train, develop and test sets on CRP data set. As the RMSE metric is used in the CRP competition, we also use it to evaluate our system in ease score prediction task.

Prompt	Essays	Avg length	Score Range	WordPiece length
1	1783	350	2-12	649
2	1800	350	1-6	704
3	1726	150	0-3	219
4	1772	150	0-3	203
5	1805	150	0-4	258
6	1800	150	0-4	289
7	1569	250	0-30	371
8	723	650	0-60	1077

Table 1: Statistics of ASAP data set.

4.2 Baseline

The baseline models for comparison are described as follows.

EASE [5] is the best open-source system that participated in the ASAP competition and ranked the third place among 154 participants. EASE uses regression techniques with handcrafted features. Results of EASE with the settings of Support Vector Regression (SVR) and Bayesian Linear Ridge Regression (BLRR) are reported in (Phandi et al., 2015).

CNN+RNN Various deep neural networks based on CNN and RNN for AES are studied by (Taghipour and Ng, 2016). They combine CNN ensembles and LSTM ensembles over 10 runs and get the best result in their experiment.

Hierarchical LSTM-CNN-Attention (Dong et al., 2017) builds a hierarchical sentence-document model, which uses CNN to encode sentences and LSTM to encode texts. The attention mechanism is used to automatically determine the relative weights of words and sentences in generating sentence representations and text representations respectively. They obtain the state-of-the-art result among all neural models without pre-training.

---

[5] `http://github.com/edx/ease`

SKIPFLOW (Tay et al., 2018) proposes to use SKIPFLOW mechanism to model the relationships between snapshots of the hidden representations of an LSTM. The work of (Tay et al., 2018) also obtains the state-of-the-art result among all neural models without pre-training.

Dilated LSTM with Reinforcement Learning (Wang et al., 2018) proposes a method using a dilated LSTM network in a reinforcement learning framework. They attempt to directly optimize the model using the QWK metric which considers the rating schema.

HA-LSTM+SST+DAT and BERT+SST+DAT (Cao et al., 2020) propose to use two self-supervised tasks and a domain adversarial training technique to optimize their training, which is the first work to use pre-trained language model to outperform LSTM based methods. They experiment with both hierarchical LSTM model and BERT in their work, which are $HA{-}LSTM{+}SST{+}DAT$ and $BERT + SST + DAT$ respectively.

BERT^2 (Yang et al., 2020) combines regression and ranking to fine-tune BERT model which also outperforms LSTM based methods and even obtains the new state-of-the-art.

4.3 Settings

To compare with the baseline models and further study the effectiveness of multi-scale essay representations, losses and transfer learning, we conduct the following experiments.

Multi-scale Models. These models are optimized with MSE loss, and **BERT-DOC** represents essays with document-scale features based on BERT. **BERT-TOK** represents essays with token-scale features based on BERT. **BERT-DOC-TOK** represents essays with both document-scale and token-scale features based on BERT. **BERT-DOC-TOK-SEG** represents essays with document-scale, token-scale, and multiple segment-scale features based on BERT. Longformer (Beltagy et al., 2020) is an extension for transformers with an attention mechanism that scales linearly with sequence length, making it easy to process long documents. We conduct experiments to show that our multi-scale features also works with Longformer and can further improve the performance in long text tasks. **Longformer-DOC-TOK-SEG** uses document-scale, token-scale, and multiple segment-scale features to represent essays, but based on Longformer instead of BERT. **Longformer-DOC** represents essays with document-scale features based on Longformer.

Models with Transfer Learning. To transfer learn from the out-of-domain essays [6], we additionally employ a pre-training stage, which is similar to the work of (Song et al., 2020). In this stage, we scale all the labels of essays from out-of-domain data into range 0-1 and pre-train the model on them with MSE loss. After the pre-training stage, we continue to fine-tune the model on in-domain essays. **Tran-BERT-MS** has the same modules as **BERT-DOC-TOK-SEG** with pre-training on out-of-domain data. **MS** means multiple scale features.

Models with Multiple Losses. Based on **Tran-BERT-MS** model, we explore the performance of adding multiple loss functions. **Tran-BERT-MS-ML** additionally employs MR loss and SIM loss. **ML** means multiple losses. **Tran-BERT-MS-ML-R** incorporates R-Drop strategy (Liang et al., 2021) in training based on **Tran-BERT-MS-ML** model.

For the proposed model architecture which is depicted in Figure 1, the BERT model in the left part are shared by the document-scale and token-scale essay representations, and the other BERT model in the right part are shared by all segment-scale essay representations. We use the "bert-base-uncased" which includes 12 transformer layers and the hidden size is 768. In the training stage, we freeze all the layers in the BERT models except the last layer, which is more task related than other layers. The Longformer model used in our work is "longformer-base-4096". For the MR loss, we set b to 0. The weights α, β and γ are tuned according to the performance on develop set. We use Adam optimizer (Kingma and Ba, 2015) to fine-tune model parameters in an end-to-end fashion with learning rate of 6e-5, $\beta 1$=0.9, $\beta 2$=0.999, $L2$ weight decay of 0.005. The coefficient weight α in R-Drop is 9. We set the batch size to 32. We use dropout in the training stage and the drop rate is set to 0.1. We train all the models for 80 epochs, and select the best model according the performance on the develop set. We use a greedy search method to find the best combination of segment scales, which is shown in detail in Appendix A. Following (Cao et al., 2020), we perform the significance test for our models.

---

[6] For each prompt, we use all the essays from other prompts in ASAP data set.

Table 3: Experiment results of our model and the state-of-the-art models on ASAP long essays (WordPiece length are longer than 510). The name of our implemented model is in bold.

4.4 Results

Table 2 shows the performance of baseline models and our proposed models with joint learning of multi-scale essay representation. Table 3 shows the results of our model and the state-of-the-art models on essays in prompt 1, 2 and 8, whose WordPiece length are longer than 510. We summarize some findings from the experiment results.

- Our model 12 almost obtains the published state-of-the-art for neural approaches. For the prompts 1,2 and 8, whose WordPiece length are longer than 510, we improve the result from 0.761 to 0.772. As Longformer is good at encoding long text, we also use it to encode essays of prompt 1, 2 and 8 directly but the performance is poor compared to the methods in Table 3. The results demonstrate the effectiveness of the proposed framework for encoding and scoring essays. We further re-implement BERT^2 proposed by (Yang et al., 2020), and our implementation of BERT^2 is not as well-performing as the published result. Though (Uto et al., 2020) obtain a much better result(QWK 0.801), our method performs much better than their system with only neural features(QWK 0.730), which demonstrates the strong essay encoding ability of our neural approach.
- Compared to the models 4 and 6, our model 11 uses multi-scale features to encode essays instead of LSTM based models, and we use the same regression loss to optimize the model. Our model simply changes the representation way and significantly improves the result from 0.764 to 0.782, which demonstrates the strong encoding ability armed by multi-scale representation for long text. Before that, the conventional way of using BERT can not surpass the performance of models 4 and 6.

4.5 Further analysis

Multi-scale Representation We further analyze the effectiveness of employing each scale essay representation to the joint learning process.

Models	Average QWK
BERT-DOC	0.760
BERT-TOK	0.764
BERT-DOC-TOK	0.768
BERT-DOC-TOK-SEG	0.782

Table 4: Performance of different feature scale models on ASAP data set.

Models	RMSE
BERT-DOC	0.742
BERT-TOK	0.760
BERT-DOC-TOK	0.691
BERT-DOC-TOK-SEG	0.607

Table 5: Performance of different feature scale models on CRP data set. The evaluation metric is RMSE. Lower numbers are better.

Table 4 and Table 5 show the performance of our models to represent essays on different feature scales, which are trained with MSE loss and without transfer learning. Table 4 shows the performance on ASAP data set while Table 5 shows the performance on CRP data set. The improvement of

BERT-DOC-TOK-SEG over BERT-DOC, BERT-TOK, BERT-DOC-TOK are significant (p<0.0001) on CRP data set, and are significant (p<0.0001) in most cases on ASAP data set. Results on both table indicate the similar findings.

- Combining the features from document-scale and token-scale, BERT-DOC-TOK outperforms the models BERT-DOC and BERT-TOK, which only use one scale features. This demonstrates that our proposed framework can benefit from multi-scale essay representation even with only two scales.
- By additionally incorporating multiple segment-scale features, BERT-DOC-TOK-SEG performs much better than BERT-DOC-TOK. This demonstrates the effectiveness and generalization ability of our multi-scale essay representation on multiple tasks.

Models	Average QWK
Longformer-DOC	0.746
Longformer-DOC-TOK-SEG	0.771

Table 6: Performance of multi-scale Longformer models on ASAP data set.

Reasons for Effectiveness of Multi-scale Representation Though the experiment shows the effectiveness of multi-scale representation, we further explore the reason. We could doubt that the effectiveness comes from supporting long sequences, not the multi-scale itself. As Longformer is good at dealing with long texts, we compare the results between Longformer-DOC and Longformer-DOC-TOK-SEG. The results of the significance test show that the improvement of Longformer-DOC-TOK-SEG over Longformer-DOC are significant (p<0.0001) in most cases. Performance of the two models are shown in Table 6, and we get the following findings.

- Though Longformer-DOC supports long sequences encoding, it performs poor, which indicates us that supporting long sequence ability is not enough for a good essay scoring system.
- Longformer-DOC-TOK-SEG outperforms Longformer-DOC significantly, which indicates the effectiveness of our model comes from encoding essays by multi-scale features, not only comes from the ability to deal with long texts.

These results are consistent with our intuition that our approach takes into account different level features of essays and predict the scores more accurately. We consider it caused by that multi-scale features are not effectively constructed in the representation layer of pre-trained model due to the lack of data for fine-tuning in the AES task. Therefore, we need to explicitly model the multi-scale information of the essay data and combine it with the powerful linguistic knowledge of pre-trained model.

Models	Average
BERT-DOC-TOK-SEG	0.782
Tran-BERT-MS	0.788
Tran-BERT-MS-ML	0.790
Tran-BERT-MS-ML-R	0.791

Table 7: Experiment results for transfer learning with multiple loss functions and R-Drop .

Transfer Learning with Multiple Losses and R-Drop We further explore the effectiveness of pre-training with adding multiple loss functions and employing R-Drop. As is shown in table 7, by incorporating the pre-training stage which learns the knowledge from out-of-domain data, Tran-BERT-MS model improves the result from 0.782 to 0.788 compared to BERT-DOC-TOK-SEG model. The model Tran-BERT-MS-ML which jointly learns with multiple loss functions further improves the performance from 0.788 to 0.790. We consider it due to the reason that MR brings ranking information and SIM takes into account the overall score distribution information. Diverse losses bring different but positive influence on the optimization direction and act as an ensembler. By employing R-Drop, Tran-BERT-MS-ML-R improves the QWK slightly, which comes from the fact that R-Drop plays a regularization role.

5 Conclusion and Future Work

In this paper, we propose a novel multi-scale essay representation approach based on pre-trained language model, and employ multiple losses and transfer learning for AES task. We almost obtain the state-of-the-art result among deep learning models. In addition, we show multi-scale representation has a significant advantage when dealing with long texts.

One of the future directions could be exploring soft multi-scale representation. Introducing linguistic knowledge to segment at a more reasonable scale may bring further improvement.

A Appendix

All the segment-scales we explore range from 10 to 190. The interval between two neighbor scales is 20. As the combination number of all segment-scales is exponential, we use a greedy search method to find the best combination.

1. Initialize the segment-scale value set R as the document-scale and token-scale.

2. Experiment the combination of each segment-scale with the token-scale and document-scale essay representation, and compute the average QWK on develop set for all segment-scales, which is denoted as QWK_{ave}. The scale with higher QWK compared to QWK_{ave} is added to the candidate scale list L and the scales in L are sorted according to their QWK values from large to small.

3. For each i from 1 to $|L|$, we perform experiments on the combination of the first i segment-scales in L with the token-scale and document-scale. The combination segment-scales with the best performance on develop set are added to the segment-scale value set R

Recognition of They/Them as Singular Personal Pronouns in Coreference Resolution

Connor Baumler
University of Maryland, College Park
`baumler@umd.edu`

Rachel Rudinger
University of Maryland, College Park
`rudinger@umd.edu`

Abstract

As using they/them as personal pronouns becomes increasingly common in English, it is important that coreference resolution systems work as well for individuals who use personal "they" as they do for those who use gendered personal pronouns. We introduce a new benchmark for coreference resolution systems which evaluates singular personal "they" recognition. Using these *WinoNB schemas*, we evaluate a number of publicly available coreference resolution systems and confirm their bias toward resolving "they" pronouns as plural.

(1a) **The paramedic** performed CPR on the passenger even though *they* knew it was too late.
(1b) The paramedic performed CPR on **the passenger** even though *they* were already dead.
(2a) **The paramedics** tried to help Riley even though *they* knew it was too late.
(2b) The paramedics tried to help **Riley** even though *they* were already dead.

Figure 1: A (1) "Winogender" and corresponding (2) "WinoNB schema". The correct answers are bolded.

1 Introduction

While singular "they" has been widely used in the English-speaking world as a personal pronoun among nonbinary and other members of the LGBTQIA+ community for many years, it has taken time for this usage to be accepted by cisnormative society at large. In particular, professional institutions' acceptance of singular personal "they" has been much slower, but seen some uptake in recent years. The American Psychological Association began accepting singular "they" as a "self-identified pronoun" in 2019,[1] the same year Merriam-Webster added "nonbinary they" to their dictionary and made it their word of the year. [2]

As a result, English language models trained exclusively on sources such as old newspaper articles are likely not exposed to examples of singular "they" usage, in either the personal or generic setting. Even models trained on more recent data may miss this usage entirely if they rely on text that was subjected to conservative style guides. This means even state-of-the-art coreference resolution systems may not have recognition of singular "they."

In this work, we examine whether existing coreference resolutions systems are able to correctly resolve cases of singular personal "they". We find that when given a choice between resolving "they" correctly to a singular, named entity or to a group, current systems overwhelmingly choose to resolve "they" as plural or even choose not to resolve the pronoun at all. We also investigate these systems' recognition of singular generic "they" and find that this is a much more easily recognized use-case for some models. Overall, we find that models which have been trained on more contemporary or stylistically varied text that may contain examples of singular "they" to have the best performance in both the personal and generic case.

While failing to correctly resolve uses of singular personal "they" may feel like a trivial case to those who do not use it as their personal pronoun, this can cause a number of allocational and representational harms (Barocas et al., 2017; Blodgett et al., 2020; Cao and Daumé III, 2020; Dev et al., 2021). For example, a difference in coreference resolutions system performance between nonbinary people who use they/them pronouns and their peers who use binary personal pronouns would constitute a representational harm. This difference in performance can lead to allocational harms when coreference resolution is used in down-stream tasks

such as ranking authors based on citation counts in the bodies of texts (Dev et al., 2021).

2 Relevant Datasets

To evaluate coreference resolution systems' understanding of singular personal "they", we follow existing work (Rudinger et al., 2018; Zhao et al., 2018) that uses Winograd schemas to test for gender bias in such systems. The Winograd Schema Challenge (**WSC**) dataset consists of pairs of sentences in which there are two possible referents for a pronoun (Levesque et al., 2012). Based on a small edit, the pronoun in each sentence in a pair resolves to the opposite referent. These schemas' resolutions are designed to be obvious to a human reader but require deeper knowledge of the given situation for a model to understand them. Beyond the original WSC schemas, Rahman and Ng (2012) provide a set of definite pronoun resolution schemas (**DPR**) that focus on complex cases of definite pronouns that require world knowledge.

Multiple Winograd-style datasets exist to benchmark gender bias in coreference resolution systems.

Winogender schemas (Rudinger et al., 2018) use an occupation and a participant as their two possible referents. The correct resolution is clear from commonsense knowledge about what the person with the given occupation should be doing in the scenario. For example, in Figure 1, we know it doesn't make sense for the occupation referent "the paramedic" to be dead. We can see in the pair of paramedic examples how, by editing the circumstance (i.e., someone is already dead vs someone knows it is too late), we can change the correct resolution. These schemas are used to confirm that coreference resolution systems are more likely to choose interpretations that match with occupational gender stereotypes instead of the scenario.

WinoBias schemas (Zhao et al., 2018) are constructed similarly, though both possible referents are an occupation. These schemas are also split between cases in which the correct resolution can be found using purely syntactic information and cases that contain no syntactic clues, instead requiring deeper knowledge about the circumstance. Zhao et al. (2018) used these schemas to show that resolution systems will continue to make interpretations based on gender stereotypes, even when the correct answer can be chosen using only syntactic information.

Beyond the Winograd-style datasets we use in this work, there are a number of other coreference resolution datasets that focus on gender bias. GAP (Webster et al., 2018) consists of naturally-occurring ambiguous pronouns. It is balanced between male and female referents, but does not include instances of gender-neutral usage.

Cao and Daumé III (2020) investigate coreference resolution systems' ability to resolve gender neutral pronouns. Their work introduces two datasets: MAP and GICoref. MAP removes social gender cues such as gendered pronouns and semantically gendered nouns from the GAP dataset. They find that these changes dramatically decrease the accuracy of coreference systems. The GICoref dataset consists of naturally occurring text with examples of pronoun usage that are less common in prior datasets such as personal singular "they", neopronouns, and switching pronouns throughout a document. They find that coreference systems still have opportunity for improvement on this dataset, especially in the case of neopronouns. While their datasets contain ambiguous cases of singular personal "they", they do not explicitly test for coreferece resolution systems' understanding of the singular vs plural personal case. Our work is complementary to Cao and Daumé III (2020) as we focus on controlled experiments with constructed schemas (§3) rather than uncontrolled but naturally occurring text.

3 WinoNB Schemas

Winogender and Winobias schemas do not consider understanding of singular personal vs plural "they". While Winogender schemas do include sentences using singular "they", their two possible resolutions were both to individual referents. This means the tested systems had no choice to resolve "they" as a plural pronoun. Additionally, neither the occupation nor the participant referent in Winogender schemas is a specific, named person.

We would like to consider understanding of singular "they" when used as a personal pronoun. To do this, we modify appropriate schemas by hand from the Winogender, Winobias, WSC, and DPR datasets to create "WinoNB schemas".

To modify Winogender schemas into WinoNB schemas, we begin by changing the occupation referent to be a *group of people* and the participant to be a *named individual*. We will not use occupations to test for gender bias as Rudinger et al. (2018) did, but instead use them to make the scenario and the correct resolution more clear. In example 2a of Figure 1, it is sensible for the people with medical training to "know it was too late", but this could be more ambiguous if neither Riley nor the group explained to have medical training.

We further edit the schemas as necessary to ensure that the resulting sentences make sense. For instance, in Figure 1, we can see that it wouldn't have made sense for multiple paramedics to "perform CPR". Instead, we have the paramedics "try to help" the individual.

We also had many cases in which using "The [Occupation]s" was confusing as it sounded as though a group of people with the occupation were acting (or being acted upon) together. For instance, in "The physicians warned Riley that they needed to get more rest," it sounds as though a group of physicians are all giving Riley advice at once. In these cases, we change "The physicians" out for "Several physicians" so the sentence can be interpreted as Riley getting the advice from different physicians on multiple occasions.

We apply this same methodology to the WinoBias, WSC, and DPR datasets. We exclude examples with non-human referents (such as "The dog chased the cat, which ran up a tree. It waited at the {bottom/top}") and examples in which the scenario will not make sense with a singular and plural referent. This left 4077 templates that can be filled with individuals' names. The split between cases in which the pronoun should be interpreted as singular or plural was not perfectly even (with one more plural case than singular) as some datasets provided more than two possible predicates for a handful of scenarios. As our analysis will consider accuracy on the set of plural and singular cases individually, this slight imbalance will not affect the result.

The authors performed the edits to turn the existing Winogender, WinoBias, WSC, and DPR schemas into WinoNB schemas manually. A random subset of 100 of the templates (25 from each source) were verified by a fluent English speaker who resolved the pronouns with 96% accuracy.

3.1 Choice of Names

Since we are examining singular "they" as a personal pronoun, we will need to use the names of people in our examples. Due to biases in training data, pre-trained language models may not treat all names equally on downstream tasks (Shwartz et al., 2020).

To help account for this, we used 15 names to fill the individual's slot in each template. 10 of these were common AMAB (assigned male at birth) and AFAB (assigned female at birth) baby names, and 5 were baby names that were not strongly assigned to either (See Appendix A.1).

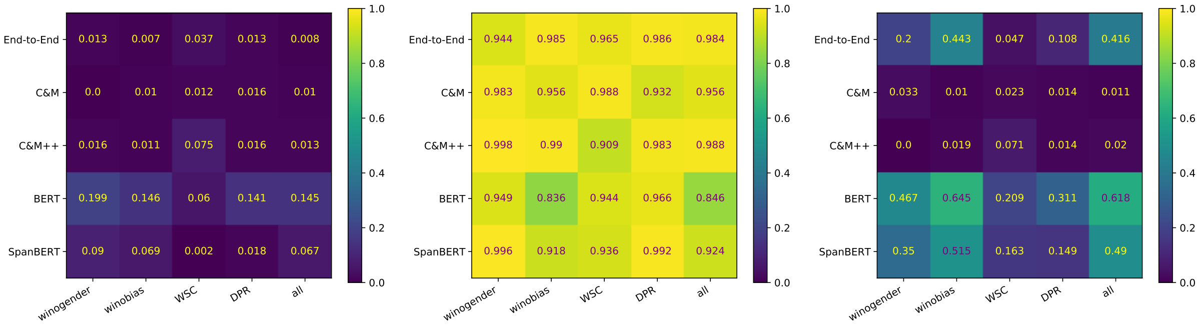
3.2 Using Singular Generic "They"

While some people find cases of singular personal "they" to be hard to resolve, singular generic "they" [is accepted by more people]. As Foertsch and Gernsbacher (1997) found, while singular "they" is less cognitively efficient than a binary pronoun when the gender of the referent is presumably known, generic singular "they" can be equally if not more cognitively efficient than a binary gendered pronoun.

To test if coreference resolution systems are more able to handle singular generic "they" than singular personal, we created an additional set of WinoNB schemas which use the generic "someone" instead of a named person for the singular referent. For instance, Example 2b in Figure 1 would be changed to "The paramedics tried to help **someone** even though *they* were already dead."

4 Results and Discussion

We evaluate a representative but not exhaustive set of five coreference resolution systems on our WinoNB schemas. First, we use Clark and Manning (2016)'s deep reinforcement learning system, which we will refer to as **C&M**. We call Lee et al. (2018)'s model with attention-based span representation refinement **End-to-End**. Both of these models were trained on the CoNLL-2012 dataset (Pradhan et al., 2012) which consists of coreference resolution problems in OntoNotes 5.0 (Weischedel et al., 2012). OntoNotes contains text from sources such as Newswire and magazines. We will also evaluate Hugging Face's model, which we call **C&M++**, which builds on C&M (Wolf, 2017). C&M++ was also trained on OntoNotes. Finally, we will evaluate **BERT** (Joshi et al., 2019) and **Span-BERT** (Joshi et al., 2020), whose original pre-training was done on the BooksCorpus (Zhu et al., 2015) and English Wikipedia with fine-tuning on OntoNotes.



(a) Singular Personal (b) Plural (c) Singular Generic

Figure 2: Model accuracies on WinoNB schemas containing different usages of "they". These results are also shown as a table in Appendix A.2

4.1 Singular Personal "They" vs Plural "They"

First, we consider how well each of our models performs on the examples using singular personal vs plural "they". As we can see in Figures 2a and 2b, the difference in performance is stark. On average, the models are 94.8% less likely to correctly resolve a WinoNB schema that uses singular personal "they" than one that uses plural "they".

The different datasets did not exhibit a consistent ordering of difficulty across models. Using a Friedman Test (Friedman, 1937, 1940), we find that the ranking of the accuracies of each model over all datasets are not significantly different at the $p < .05$ level. However, using paired t-tests, we find that some models have significantly different performances ($p < .05$) on individual schema sources.

We find that BERT-base (which achieved about 3× the average accuracy on the singular personal case) has significantly better performance on three of the datasets, and its results are not significantly different from the other models on the dataset in which it underperforms. The three non-BERT-based models were all trained on OntoNotes 5.0, a dataset that is unlikely to contain instances of singular personal "they". Sampling 100 sentences from OntoNotes 5.0 that contain a they/them pronoun, we found no cases of singular personal "they".[3] While the BERT models were fine-tuned on OntoNotes, their pre-training on the BooksCorpus and Wikipedia may have contained singular personal "they" with Wikipedia officially allowing and encouraging the use of singular "they" since at least 2017.[4] From this, we may speculate that the BERT models' relative success in handling singular personal "they" comes from exposure to the concept during pre-training.

While Span-BERT would have received similar exposure during pre-training, Span-BERT-base achieved a significantly lower accuracy than BERT-base on most WinoNB datasets. Since Joshi et al. (2020) reported that Span-BERT outperforms BERT on OntoNotes, we speculate that Span-BERT's lower WinoNB accuracy comes from optimizing for OntoNotes, which may require a deprioritization of any knowledge of singular personal "they" gleaned from pre-training.

BERT's increased accuracy may also have its drawbacks. While Figure 2a focuses solely on how many pronouns were correctly resolved as singular, many of the mistaken examples were either resolved to an unrelated entity or received no resolution at all. BERT-base failed to resolve 5.15% of singular personal "they" examples to the group or the individual. This rate is more than double the average rate of such failures over all models.

4.2 Singular Personal "They" vs Singular Generic "They"

Beyond cases of singular personal "they", we also considered examples of singular generic "they" in which the individual referent is "someone", not a named person. As we can see in Figure 2c, the

---

[3] We did find cases where of singular "they" referring to an instiution such as "Kraft Foods". In many cases, the number of the pronoun was ambiguous given without larger context of the full document. As the OntoNotes entries from web data consist only of single sentences (Weischedel et al., 2012), some of these examples' number could not be determined, but there was no evidence to suggest that any were intended to be singular, let alone singular personal.

[4] Via English Wikipedia's gender-neutral language policy

models overall are much more able to handle singular generic "they", reaching an average 31.2% accuracy on these cases. The models were, on average, 6.4× more likely to correctly resolve a case of singular generic "they" versus singular personal.

4.3 Effects of Gendered Name Associations

By using a variety of names traditionally given to AFAB or AMAB babies or neither, we can investigate the effect of gender association of the individual's name on the models' willingness to choose the singular personal reading of "they". We do see some subtle differences in the results on these differently gendered names. For instance, BERT-base was about 7.5% more likely to incorrectly resolve Winogender-sourced schemas with traditionally AMAB names than AFAB or neutral names. These differences in performance were significant at the $p < .05$ level.

Overall, we find that in cases with significant difference in performance across differently gendered names, the models generally incorrectly resolve cases of singular personal "they" that ought to refer to masculine names. This could mean that these models more strongly associate common AMAB names with he/him pronouns than they do common AFAB names with she/her.

5 Conclusion

We have introduced "WinoNB schemas", a set of pronoun resolution pairs that test recognition of singular personal, singular generic, and plural "they" in English coreference resolution. These schemas are adapted from four existing sets of Winograd schemas. Testing on five publicly available off-the-shelf coreference models, we demonstrated that current models largely do not interpret "they" as a singular personal pronoun, though they are more likely to accept singular generic "they". We infer that this is due to popular training datasets largely containing text from times and settings in which singular personal "they" is unlikely to have been used. We find that BERT models, which may have seen cases of singular personal "they" during pretraining, are most able to solve WinoNB schemas.

WinoNB schemas can only demonstrate the existence of bias against nonbinary people, not its absence. Our methodology relies on "they" having both singular and plural usages, so it cannot be used to test for understanding of neopronouns such as xe/xem/xyr. A coreference resolution system can handle WinoNB schemas well and still perform poorly for members of the nonbinary community who use neopronouns or switch between multiple sets of pronouns. Still, these schemas can serve as a jumping-off point for creating and evaluating future models that better serve the nonbinary community.

A Appendix

A.1 Names

We use name popularity data from 2013 that was collected from the Social Security Administration (SSA) and Five Thirty Eight, who also use this SSA data. Neutral names were chosen such that the gender ratio was not more than 7:3 in favor of either binary gender. Note that having a weak gender association as a baby name is neither a necessary nor sufficient condition for a name to be popular among nonbinary people. For our purposes, SSA data was the most readily available.

Gender Association	Name	% AFAB
fem	Sophia	99.88%
fem	Emma	99.91%
fem	Olivia	99.87%
fem	Isabella	99.90%
fem	Ava	99.89%
masc	Noah	0.44%
masc	Jacob	0.13%
masc	Liam	0.12%
masc	Mason	0.41%
masc	William	0.08%
neutral	Casey	41.57%
neutral	Riley	49.23%
neutral	Jessie	52.21%
neutral	Jackie	57.86%
neutral	Avery	66.47%
